Family Medicine: Current Concepts and Future Practice

Robert B. Taylor*
Oregon Health & Science University, Portland, OR, USA

A young person entering an American medical school today might think that family medicine (FM) has always existed, with courses and clerkships in the predoctoral curriculum, hundreds of postgraduate programs across the country, and the presence of residency trained, board-certified family physicians in the community serving as role models. But that assumption would be wrong.

In its early years, the specialty of family practice had originated within the lifetimes of all its practitioners. Today, that specialty, now called family medicine, is in its fifth decade, and many of today's family physicians (FPs) were born following the pioneering efforts in the late 1960s and early 1970s to establish the discipline we know today. Some currently practicing FPs were in grade school and high school while family physicians struggled to attain clinical credibility, hospital privileges, and curriculum time in medical schools. Some were in practice during those times. All have benefitted from the specialty's success since its beginning in 1969. Not all know the remarkable and inspiring story of the family practice/family medicine movement, and for this reason, we begin this book with an overview of the specialty's origin, evolution, and current status.

One important function of reference books is to serve as historical records of significant milestones for a specialty and the thinking in a discipline during the time of each edition's life. Sometimes, this record shows how much things have changed: In Osler's *Modern Medicine*, published in 1907, Sir William Osler (1849–1919) tells how to treat diabetes mellitus with opium and arsenic, although adding "the writer rarely resorts to them" [1]. Nor do we do so today. And sometimes, a review of past writings reveals beliefs and values that have not changed over the years. Near the end of his career, Osler also wrote: "It is more important to know what patient has a disease, than what disease the patient has" [2]. In fact, in many ways, Osler's thinking about patient care and teaching seems today to have helped set the stage for what would follow a half century later. After all, family medicine is the specialty that emphasizes caring for the patient, not simply making the diagnosis and treating the disease.

A Very Short History of the Specialty

Family practice in the United States of America evolved from general practice, which was the dominant force in health care until the mid-twentieth century. Here is how it happened.

Introducing the Family Practice Approach

Medical care in the United States has been described as characterized by aggressive action, a mechanistic approach, problem orientation, and an emphasis on victory over disease [3]. This connotes that the good physician will record a comprehensive history, perform exhaustive testing, identify and fix the affected organ, and cure the disease. Into this setting came family practice. In contrast to an aggressive assault on disease, family physicians championed *longitudinal health care*, which allowed both patient and physician to understand the natural history of illness and to share decisions over time. A *relationship-based*, *biopsychosocial approach* integrated with the evolving new technology was advocated. The emphasis of

*Email: taylorr@ohsu.edu

DOI 10.1007/978-1-4939-0779-3_1-1

family practice was on the *broad-based care of the person and family*, rather than a narrow focus on the disease problem. Finally, family physicians advocated *improving the quality of life*, particularly important when patients suffer chronic or terminal illness, and victory over disease is not really possible. These principles, more often intuitively shared than explicitly articulated during the early years, guided subsequent historical events.

The Early Years

Family practice arose as a specialty during the 1960s – the time of the Vietnam War, the civil rights movement, and widespread social unrest – a time when the wisdom of experts was challenged. These events coincided with a decline in access to broad-based health care in the United States, which occurred for a number of reasons: too few medical graduates to serve America's growing population, a trend toward specialization that began following World War II, and generalist training that was inadequate for an increasingly complex health-care system. In response, the American public and far-sighted health-care planners decried the fragmentation of American medicine and called for the creation of a physician who specialized in personal health care – the family physician [4, 5].

With the support of the American Academy of General Practice (AAGP) and US general practitioners, in 1969 family practice became the 20th American medical specialty.

Four early decisions helped shape the future of the new specialty. A *specialty certifying board* – the American Board of Family Practice (ABFP) – was created in 1969; until 1979, a physician could qualify to sit for the certifying examination based on practice eligibility, but since then all candidates for specialty certification must be graduates of approved 3-year family medicine residency programs. *Three-year residency training programs* were established, in contrast to the prior norm for general practitioners of a single year of internship perhaps supplemented by a 2-year general practice residency. *Mandatory recertification* was pioneered by the ABFP, and all US board-certified family physicians must take a periodic recertification examination; most other specialties have since followed this lead in various iterations. Finally, *mandatory continuing medical education* was required by both the American Academy of Family Physicians (AAFP) and the American Board of Family Practice. The latter organization, now the American Board of Family Medicine (ABFM), requires 300 h of approved continuing medical education every 6 years as one component of the recertification process.

The new specialty began with 15 residency training programs, most converted from previous 2-year general practice training programs. Federal grant programs supported new departments of family practice in medical schools, and clinical departments of family practice were formed in community hospitals across America. From 1969 until today, the family practice/family medicine movement has continued to gain momentum, with solid gains in student interest, more residents in training, increased numbers of board-certified FPs in practice, and family physicians in leadership positions in clinical medicine and academia.

Family Medicine in the United States

There are more than 800,000 practicing physicians in the United States; less than one third of these are primary care physicians. Of this number, 90,000 are family physicians, and 12,000 are general practitioners [6]. Today, there are 461 US family medicine residency training programs in community hospitals and academic medical centers. In the early years, a few medical schools created departments of family medicine, often prompted by state legislative mandate or the prospect of federal grants; today, almost all US medical schools have departments of family medicine or other academic family medicine units.

In the beginning, family practice entered the academic setting as both a new specialty and a social movement, aiming to refocus health care on the patient and family; this perceived intrusion was not always welcomed. A patient seen by a family physician was sometimes perceived as a loss to some other

DOI 10.1007/978-1-4939-0779-3_1-1

specialist. Today, medical education and health-care delivery are profoundly influenced by family medicine values, both through the impact of our presence throughout the health-care system and through the power of our core mission of caring for the patient.

There are family medicine courses and clerkships in the curricula of almost all US medical schools, teaching students family medicine's core values and approach to health care. The clinical clerkships with community-based family physicians are demonstrating the importance of medical education outside the academic setting. Students who a generation ago would have never seen a multigenerational family of patients or cared for a patient with problems in multiple body systems are now learning to provide truly comprehensive health care and are doing so in the offices of practicing family physicians.

In 1987, Pellegrino [7] commented: "The birth of Family Practice two decades ago, and its development as a genuine specialty within the bodies of both medical practice and academia is surely one of the most remarkable stories in contemporary medical history. The present success of family practice is a tribute to the intellectual foresight, astute social perceptions, and political acumen of a small group of dedicated general practitioners." Family conferences, shared decision-making with patients, home care, and community-based research are now respected components of twenty-first-century health care. Family physicians are the only physicians who are distributed across America in the same geographic proportions as the American people. Last year, family physicians enjoyed a five percent gain in income, outstripping inflation [8]. Today, we see the continuation of this story as family physicians assume leadership in national medical organizations, such as the American Medical Association (AMA), hold important roles in determining health policy, and become deans of medical schools in the United States. For further information about the history of family medicine, see chapter "▶ Chronology of the Evolution of Family Medicine as a Specialty in the United States," which provides a chronology of the evolution of family medicine as a specialty in the United States.

Family Medicine and General Practice Around the World

Family medicine has a long history in Canada, as well as in the United States. In countries outside North America, family and general practice has evolved in various ways. In Spain, for example, the Royal Decree of 1978 officially endorsed the specialty of family practice: "The family physician shall constitute the fundamental figure of the health system" [9]. In England, the general practitioner (GP) is the key provider in the National Health Service, and the countries of the European Economic Community (EEC) have agreed that postgraduate training in general practice should be a minimum of two full years, of which 6 months should be in an approved practice. There is a European Academy of Teachers in General Practice and Family Medicine (EURACT) founded in 1992.

Family medicine residency programs exist in a number of Latin American countries. There have been family medicine training programs in Chile since 1982. In Cuba, the family physician is the chief provider in a comprehensive health plan for Cuban citizens. Family practice has played a role in the health care of Mexico since the 1970s.

In 14 Asian Pacific countries, there is a core curriculum in family medicine. Family medicine is well established in South Korea, Malaysia, Singapore, Hong Kong, Taiwan, and the Philippines, as well as in Australia and New Zealand. Japan, Russia, India, and China now have family medicine training programs. In Ukraine, pediatricians and internists have been retrained as family doctors to serve as the lead physicians in their health-care system. The government of Vietnam has declared a commitment to deploy trained family physicians in the 10,000 health centers serving the country's population of 88 million people.

There is family medicine training in South Africa, Egypt, Nigeria, and Lesotho. An Arab Board of Family and Community Medicine includes members from 15 Arab countries.

DOI 10.1007/978-1-4939-0779-3_1-1

The nature of day-by-day practice varies from country to country, and in some areas, such as the United States and Canada, family physicians often have an active role in hospital care. In other settings, such as in the United Kingdom and Latin America, family medicine is chiefly office based, often supplemented by home care.

The international group uniting family medicine and general practice is the World Organization of Family Doctors (WONCA), comprised of 126 member organizations in 102 member countries, with membership of some 300,000 family doctors worldwide. In 2015, Istanbul, Turkey, hosted the 20th WONCA Europe Conference. The WONCA World Conference will be held in Rio de Janeiro, Brazil, in 2016.

Philosophical Tenets and Their Impact on the Practice of Medicine

Key values regarding care of the patient and an innovative approach to medical thinking and health-care delivery are important to family physicians in the early twenty-first century and have influenced the global practice of medicine.

Enduring Values

Family physicians are bonded by shared beliefs. They advocate *continuing care* of the individual and family as crucial to the patient-physician relationship and as an effective process of providing care. This continuity allows FPs to increase their knowledge of the patient at each office visit, reducing the need to have the patient recite past medical history, social history, and so forth over and over at each clinical encounter. *Comprehensive care* is an important tenet of family medicine and involves full-service health care of both sexes and all ages. Because FPs emphasize that the patient should receive appropriate care at the right place and at the right time, they place a high premium on *coordinated care*. This emphasis on coordinated care has made family physicians the ideal primary care clinicians in capitated care settings, sometimes metaphorically serving as "conductor" of an orchestra of limited specialists. Finally, a *family-centered approach* has been a cornerstone of family medicine, with increasing recognition that our concept of family includes such diverse units as single-parent families, collective living groups, and same-sex couples. In a family medicine office, a four-generation family of patients is not uncommon.

Relationship-based health care is the philosophical foundation of the specialty, and understanding personal accountability is the key to understanding family medicine. McWhinney [10] writes: "In general (family) practice, we form relationships with patients often before we know what illnesses the patient will have. The commitment, therefore, is to a person whatever may befall them." The family physician will also often ask about the patient's children, parents, job, vacation, dog or cat; many physicians tell their patients about their own hobbies, travels, children, and pets, becoming, in a sense, "a member of the family."

Family physicians have a community-based health-care orientation. As individual practitioners, family physicians can profoundly influence the health of a community and can also share their knowledge by serving on the boards of local agencies, such as a volunteer health clinic or adult day care center. In addition, many FPs are leading efforts in population-based health care, extending from care of the illness of the individual to addressing community health problems such as smoking use or teen pregnancy.

Formal recognition of the specialty's values resulted in a name change following a vote of the AAFP Congress of Delegates in 2003. The official ABFM definition of family medicine now is:

> Family medicine is the medical specialty which provides continuing, comprehensive health care for the individual and family. It is a specialty in breadth that integrates the biological, clinical and behavioral sciences. The scope of family medicine encompasses all ages, both sexes, each organ system and every disease entity.

Advances in Medical Understanding

Over the past three decades, family medicine has advanced medical thought in important ways, answering early skeptics who held that FPs had nothing to bring to the table of medical knowledge. One of these is the use of *comprehensive clinical reasoning*, to include consideration of life events, the family's contribution to disease, and the impact of illness on the family. For example, as FPs, we have all seen how juvenile diabetes can affect a family's dynamics in regard to interpersonal relationships, family decision-making, and the allocation of family resources. When a child with diabetes is sick, everything else in the household is of secondary importance, and eventually, relationships can be severely strained; early intervention by the family physician may avert family problems.

Also, FPs have recognized *how problems of living can influence health*. Patients with stressful lives seldom present stress as a chief complaint. Instead, they tell of fatigue, headache, abdominal pain, or weight change – chief complaints that often represent a "ticket of admission" to health care. Recognition of the underlying cause of symptoms is important because, for example, a patient who has surgery to treat chronic back pain may develop severe headaches as a substitute stress manifestation if underlying life problems have not been identified and addressed.

A third area in which family medicine has advanced medical thinking is by teaching residents the *systems approach to health care*. In general systems theory, there is a hierarchy of natural systems that includes molecules, cells, organs, body systems, person, family, community, nation, world, and so forth. To apply systems theory to medicine, if a person's pancreatic islet cells begin to make insufficient insulin, or if a farmer in Africa contracts acquired immunodeficiency syndrome (AIDS), or if a community suffers an earthquake, all systems in the hierarchy are affected. Although family physicians have special expertise in "person" and "family," they need to consider the impact of disease on all systems, from small particles of matter to the planet we all share [11].

The Development of Family Medicine's Literature Heritage

Family medicine is developing a rich literature heritage. The reports describing our clinical research, practice methods, and advances in medical understanding are being published in a growing number of publications and online. Although I will not attempt to list them all (in fear of offending by omission), there are currently at least six family medicine journals worldwide, two major clinical reference books, four student textbooks, several defining and examining the discipline, and at least four review books for board examinations.

These publications not only are important in presenting the family medicine approach to health care, but also allow the intergenerational transfer of values, methods, and reasoning – the "storytelling" of a specialty.

The Clinical Encounter as the Definable Unit of Family Medicine

When future medical historians ask what was the major contribution of family medicine during its first half century, the answer might be the advances made in the traditional clinical encounter, adapting it to the twenty-first century practice. The family physician's clinical encounter is analogous to the surgeon's surgical procedure, the gastroenterologist's endoscopy, or the radiologist's imaging in that *the clinical encounter is what we do*. Its scope includes the FP's approach to undifferentiated problems, communication techniques, physician behavior, presentation of information to the patient and family, involvement of the patient and family in decisions, and ongoing care in the context of family and community.

The office-based clinical encounter typically includes multiple problems [12]. In fact, a patient with six or eight intersecting health problems is not uncommon. In billing, an encounter may be categorized as ranging from minimal to high complexity. However long or short, the encounter is distinguished by a broad-based and longitudinal approach that is often not seen in care provided in other specialties.

DOI 10.1007/978-1-4939-0779-3_1-1

Over the years, the family physician's clinical encounter has become more streamlined, cost-effective, and (we hope) clinically astute. The improvements have been achieved by the use of enhanced communication techniques, the use of "high-payoff questions," modern diagnostic and therapeutic instruments such as the fiberoptic nasopharyngoscope, advances in decision analysis, and the use of handheld devices and electronic medical records.

In the current millennium, the clinical encounter is rapidly evolving to reflect the current advances in technology, with contact via the World Wide Web and telecommunications expanding our patient care capabilities, as described below.

Challenges to Family Medicine

At this time, the specialty faces several challenges. These include the increasing complexity of primary care practice today, telemedicine and the health-care technology imperative, the growing tendency to consider health care a commodity rather than a professional service, and the need to maintain the pipeline of medical students choosing family medicine as a career.

Coping with the Increasing Complexity of Clinical Practice

Over the past few years, the scope of care provided by all primary care physicians has increased, chiefly because of pressures to provide care for more patients during the working day [13]. Three or four decades ago, the family physician often saw 40 patients a day. At that time, most patients had bronchitis, sprained ankles, earaches, lacerations, vaginitis, back pain, skin rashes, and so forth – problems usually requiring only short office visits. Of course, there would be some complex cases, such the woman with systemic lupus erythematosus and the middle-aged man with amyotrophic lateral sclerosis, who required longer visits, but those were the exceptions. This is no longer the case in the current fee-for-service family medicine model.

Today's office patient, especially if elderly, may have a long list of health problems. The patient is also more likely to be *sick* and to require more time than would be needed to treat an ear infection. Why the change? Today, physicians have learned that health care is most cost-effective when the physician sees only those patients who really need face-to-face care. Many instances of back strain, flu, cystitis, vaginitis, and so forth receive advice through the nurse triage line, and only those who cannot be managed by telephone are given appointments. Also, many persons delay coming to the physician because of work or financial pressures. This, therefore, means that there are very few "easy" visits that allow the physician to catch up if behind on the schedule. Clearly, as reported by Okie, the pressure on physicians in all specialties to work faster and accomplish more has intensified [14].

The complexity of current practice has also been augmented by patients having increased emotional problems and mental diseases, such as hoarding disorder, now included in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), published in 2013. Many of these patient concerns are a direct result of lack of family support and work stress. Physicians are being sought for advice and counseling that used to be offered by family members and/or clergy. Patient expectations for a solution to their problems by the physician are higher than in the past and sometimes are unrealistic. New drugs are approved almost weekly, and disease coding has become even more complex with the implementation of the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). Medical practice, in any specialty, is not as simple as it once was.

DOI 10.1007/978-1-4939-0779-3_1-1

Mastering Telemedicine and the Health-Care Technology Imperative

Over the past few decades, we have been dazzled by the technologic advances in medicine and science: bariatric surgery as therapy for diabetes mellitus, individual genomic sequencing, and colorectal cancer screening using a swallowed capsule, and now we have wristwatches that include heart rate monitors and devices that can transmit a patient's electrocardiogram to a smartphone. Portable ultrasound devices threaten to make the stethoscope obsolete.

There are "virtual doctor visits" available online. Although the program is designed "to feel like a real physician visit," it is a computer program and not a live doctor [15]. In 2013, the US Food and Drug Administration approved the use of a telemedicine robot to make hospital bedside visits. This means that a patient in a hospital bed, instead of seeing the physician at the bedside, may encounter a robot with a television screen chug-chugging into the room to inquire how symptoms are today. While the technology may be astounding, and admitting that these innovations may save time and allow remote consultations, they also serve to put machines between patient and physician.

A current challenge arises in the "seduction of the screen." In far too many office visits the physician spends more time looking at the computer screen than at the patient, thus losing important visual cues as the patient describes symptoms and feelings. It seems that the physician's fingers are more likely to tap a keyboard than to palpate or percuss. The physical examination is often short changed as physicians rely too much on the laboratory and on imaging [16].

Resisting the Commercialization of Medicine

Family physicians can take the lead in preventing medicine from being converted to a commodity. Health care is not a hamburger or a toaster oven, although insurance companies, health maintenance organizations (HMOs), and government often seem to act as though it were.

In 1969, one of family practice's initial objectives was to combat the fragmentation of health care [4]. At that time, there were too many specialists and not enough generalists, and the patient with hypertension, joint pain, and a skin rash often needed to see three physicians. With the current presence of family medicine in America, this is no longer the case in most communities. Family physicians provide care for most common entities without consultation or referral. And yet, the clinical encounter is changing.

Today, the family physician's new role is to be the patient's advocate in a system that appears to treat health care as a commodity, often one to be rationed – using tight schedules, relative value units, incentive payments if the physician orders few tests and lowers cost drugs, and financial penalties for minor coding errors. Even the term *provider* reinforces the "commodity" mentality.

What are family physicians to do? We *must* put the patient first, insist on affording the patient enough time so that we can do a good job, work to eliminate incentive payments that create ethical dilemmas for physicians, fight government efforts to criminalize administrative disagreements, and refuse to accept the demeaning epithet *provider*. We must also look for new models that allow more personalized care and that allow us to be paid for the time spent in fulfilling our advocacy and care coordination roles.

Sustaining Family Medicine as a Desirable Specialty Choice

For the past 5 years for which data are available – 2010 through 2014 – there has been a yearly increase in the number of accredited family medicine residency programs, the number of approved first year residency positions, and the number of total residents in family medicine training programs. In 2014, the fill rate of family medicine residency programs through the National Resident Matching Program (NRMP) was 96 %, with 3,000 students choosing family medicine careers [17]. Is this a trend that will continue over time? Perhaps. The year over year increases are small, but they are increases, nevertheless.

DOI 10.1007/978-1-4939-0779-3_1-1

The recent increase in the number of medical students choosing careers in family medicine will still not be enough to end America's shortage of family physicians. In order to have enough family physicians for every American to be served, America would need an additional 65 family medicine training positions each year over the next 10 years, according to a 2014 report of the AAFP [18].

Current Trends and Future Practice

Tomorrow's health care will be shaped by today's events. In selecting what I believe to be the most significant influences on future practice, I chose from a long list that included the current focus on evidence-based health care, the medical and societal impact of our changing demographics, and some events that are occurring as this page is written. The following are the trends I believe most likely to influence family medicine in the decade to come.

Human Relationships in the Age of Telemedicine

Here, we return to the evolving clinical encounter and information technology. Future practice will include more than lasers, fiber-optics, and diagnostic ultrasound. It also will include patient contact via e-mail or voicemail, health data recorded and sent by cellphone, online decision support systems, cloud storage of clinical information, and online consultation with specialists. Just as the automobile spelled the end of "horse and buggy" travel and the telephone allowed direct communication with the physician and the development of scheduled office practice, the Internet is profoundly changing the practice of medicine.

Today, using asynchronous communication, family physicians communicate with patients by e-mail about their health problems. Sometimes the patient sends an e-mail message at 2 a.m., knowing it will not be answered until the next day; this has saved physicians many early morning telephone calls that were not emergencies. Sometimes the e-mail message is a prelude to an office visit. FPs have the potential to speak with patients by telephone as they simultaneously search the World Wide Web for clinical answers. The Internet, with programs such as Skype, is making the "digital house call" a reality. Personal office visits are needed less often and, when they occur, are longer in duration and offer more value for time spent than in years past. With the Internet as part of comprehensive health care, FPs move one step further in actualizing their role as health advisor and consultant.

All the technology mentioned here is being used by FPs somewhere, and within a decade, these functions will be the state of the art everywhere.

The Aging Population

The growing number of older people in the population is the reward for our success in battling infant diarrhea, accidental injuries, treatable infectious diseases, uncontrolled hypertension, and other causes of early death. According to the once-in-a-decade US Bureau of the Census report in 2010, there are 40.3 million Americans age 65 and older, up from 35 million in the 2000 census. The fastest growing segment of our population is the group aged 85 and older. Of course, these are the people with multiple problems involving various organs and whose health-care costs are the highest of any adult age group.

What is the likely impact on family medicine? Family physicians need to prepare to serve an increasingly older patient panel and must be positioned to compete with others who would claim greater expertise. We must insist upon a family medicine approach, emphasizing continuity of care (there is no reason to change doctors when one turns 65), comprehensive care (the FP can care for a wider range of problems than any other physician), and family-oriented care (why fragment the care of the elderly and make it separate from the rest of the family?).

DOI 10.1007/978-1-4939-0779-3_1-1

Globalization and Global Health Disparities

We see the effect of globalization in the economic marketplace: price and wage differences between countries become a little narrower each year. Goods and jobs are increasingly moving freely across borders, as is information about lifestyle and economic opportunities.

The world has yet to experience the full effect of globalization in health care. We in the United States spend billions of dollars annually for antianxiety medication, while in other countries, children die of infectious diseases for want of a vaccine or an inexpensive antibiotic. At the same time, the acquired immunodeficiency syndrome (AIDS), antibiotic-resistant tuberculosis and gonorrhea, and now the Ebola virus are increasingly problems shared by the global community.

The global disparities in health-care spending are striking. According to the *UC Atlas of Health Care* [19], "Health care spending per head for the top 5 % of world population is nearly 4,500 times spending in the lowest 20 %." The 2014 Ebola epidemic in sub-Saharan West Africa highlighted the meager health-care resources of developing nations in many parts of the world.

Former US surgeon General David Satcher, M.D., Ph.D., a family physician himself, proposes three "prescriptions" to improve health worldwide: supporting public health initiatives; enlisting allies such as computer specialists, economists, and patients; and challenging public health leaders to advocate for all health-care consumers [20].

What about family medicine and family physicians in advantaged countries? Our roles may include controlling unnecessary health-care expenditures in America and other developed countries, serving as physicians in developing countries, and advocating for sick persons whatever their nationality. We should also prepare to live and practice in a world where the so-called third-world diseases may be seen in the office next week.

Economic Policies and Health Care

Health policy is the "wild card" in health-care delivery in any country. How national and state governments dictate eligibility for programs and methods of making health-care payments has a strong influence on how health care is provided. Witness what happens in those countries in which the government controls health-care payments, allows unrestricted access to any physician, and mandates relatively low fees. The result is many office visits for minor problems, long waits, very short visits, and frequent (and often medically unnecessary, at least by US standards) follow-up visits for routine problems. In such a setting, patients report, "Three-hour wait, three-minute visit." It is, curiously, the opposite of the model that has resulted from free-market care in the United States – with increasingly complex problems seen in relatively longer office visits by primary care physicians.

On a national basis, the United States is experiencing the implementation of the Patient Protection and Affordable Care Act of 2010 (the "ACA"), the most impactful overhaul of America's health-care system since the initiation of Medicare and Medicaid in the 1960s. As with any governmental mandate affecting a major segment of the economy, the ACA will profoundly affect how health care is delivered in America, depending on a state's decisions regarding funding, how access is controlled, and how clinicians are paid. One clue that common sense and fairness might prevail is the federal policy edict that, beginning January 2015, physicians who manage care for patients with two or more chronic conditions – such as diabetes, heart disease, or depression – will be paid monthly fees for chronic care management services. Such a policy innovation can only be good news for family physicians.

Specific Initiatives and Events Likely to Shape the Future

Sometimes tomorrow is shaped by carefully laid plans; sometimes what happens occurs because "its time has come." The following are two planned initiatives and one apparent groundswell sure to influence how family physicians practice tomorrow.

DOI 10.1007/978-1-4939-0779-3_1-1

- ***Family Medicine for America's Health***. In 2001, the seven major national family medicine organizations launched the *Future of Family Medicine* (FFM) project to prepare the specialty to cope with a rapidly changing health-care environment. One result of the FFM 2004 report was the eventual change of the specialty's name from "family practice" to "family medicine." The report also called for a new, innovative model of health-care delivery: the patient-centered medical home (PCMH). Now, *Family Medicine for America's Health*, initiated in 2013 by the leading family medicine organizations, aims to find ways to improve health outcomes, enhance the patient experience, reduce health disparities, and lower health-care costs, while spreading the message using an ambitious communication strategy titled *Health is Primary* [21].
- ***Four-year family medicine training programs***. Since 1969, the model for family medicine training has been the 3-year residency program. But educators and residents alike have often remarked that the curriculum is tightly packed and 3 years does not seem long enough to master the full scope of practice. Following approval by the Accreditation Council for Graduate Medical Education (ACGME), 2013 saw the initiation of the *Family Medicine Length of Training Pilot* initiative, to be concluded in June 2019. Of the residency programs that applied, 12 were selected and were matched with an equal number of programs to serve as a control group. The extra year of residency training will allow the use of innovative teaching methods, perhaps leadership training, and certainly increased skills in implementing the PCMH [22].
- ***Direct primary care (DPC)***. At the 2014 National Conference of Family Medicine Residents held in Kansas City, Missouri, resident delegates called on the AAFP to "explore the establishment of curricular experiences in the direct primary care practice setting for residents and medical students." They also called for the Academy "to investigate the establishment of residency programs sponsored by DPC practices that would be self-funded, thus providing an option to increase available residency positions that would not require federal legislation." Sponsors of the resolution pointed out the differences between concierge medicine and DPC, explaining that the latter is less costly to patients and "often helps people who are uninsured" [23].

According to the AAFP web site [24], DPC "gives family physicians a meaningful alternative to fee-for-service insurance billing, typically by charging patients a monthly, quarterly, or annual fee (i.e., a *retainer*) that covers all or most primary care services including clinical, laboratory, and consultative services, and care coordination and comprehensive care management." In contrast, in concierge care "the patient typically pays a high retainer fee in addition to insurance premiums and other plan obligations (e.g., copays, out-of-pocket expenditures), and the practice continues to bill the patient's insurance carrier. [24]" Direct primary care offers an option for the family physician to practice medicine as it used to be, free of involvement with insurance companies and the government. DPC physicians tell of small patient panels and 45-min patient care visits, allowing same-day urgent visits, and supplemented by online or telephone contact to address issues that do not need "face time" with the physician. It may well prove to be the preferred model of family medicine health-care delivery in the future and may remove one of the obstacles to students choosing careers as family physicians.

Caring for America and the World

Family medicine has been such a positive influence on health care worldwide that we would have had to invent it for the new millennium, if it did not already exist. Despite past predictions to the contrary, family medicine has survived into the twenty-first century. In 2010, there were more than one billion visits to non-federally employed, office-based physicians in the United States [25]. During that year, more than

DOI 10.1007/978-1-4939-0779-3_1-1

212 million or 21.2 % of all office visits to US physicians occurred in the offices of family and general physicians [26].

Family medicine has done much more than survive; it has prospered and has had a powerful impact on health-care delivery and medical education worldwide. It is a rapidly evolving discipline that brings a much-needed social conscience to medicine and is continuingly reinventing itself as it uses innovative methods to expand its service role. The values of the specialty put people first – first before profit, first when there are ethical conflicts, first before third party payers, and first before a single-minded emphasis on disease. In the twenty-first century, family physicians continue to care for the world. And all physicians should honor family medicine's remarkable history of achievements and recognize its unlimited potential for future contributions to humankind.

Human Development and Aging

Robin Maier*
Department of Family Medicine, University of Pittsburgh, UPMC Family Medicine, Squirrel Hill, Pittsburgh, PA, USA

General Principles

In committing to caring for the entire family and community, physicians need to have a solid understanding of the range of what is considered normal for each stage of life. Physical, psychological, and social characteristics vary in moderately predictable ways throughout the life span. Understanding what is normal for each life stage enables the physician to identify and treat disease in individual patients, as well as enabling the physician to reassure and counsel patients as they struggle to adapt to normal changes in each stage of life.

The birth of a baby, the death of a parent, or the process of retirement can all precipitate a wide range of physical symptoms. The physician who can put these symptoms into context and recognize the developmental stress which is driving their physical issues can bring much peace and clarity to the patient and their family. In fact, "anticipatory guidance" regarding upcoming stages of development is a central task of "well visits" at every stage of life. This chapter focuses on stages of human development and how they impact upon primary care of the patient.

Stages of Life

While individual human beings vary greatly in their physical, psychological, and social development, there are similarities of direction and timing of development in all three areas. In 1950, Eric Erikson, a student of Marie Freud, developed a theory of the stages of development [1]. Since that time, it has become common understanding to approach human development as a continuum across an entire life span, rather than a process which is complete with the attainment of adulthood.

Prenatal: Embryonic Stage

The earliest stage of human development begins with conception and concludes with the formation of a recognizable human anatomy around 8 weeks after conception. This stage, although only about 2 months long, is responsible for the most dramatic changes visible at any stage of human development. Starting with a single cell, and progressing through multiple cell divisions, differentiation, and development, during this time the heart, brain, spinal cord, limbs, eyes, and ears are all formed. The central task of the embryonic stage is the formation of anatomical structures within the developing human [2].

Physician's Role

Nutrient availability and toxin exposure at the embryonic stage can have dramatic and lifelong consequences. Although many spontaneous abortions are caused by chromosomal errors, early toxin exposure can cause both miscarriage and birth defects. The physician can help to minimize these risks by discussing

Table 1 Supporting early development

Prenatal	
Maintain	Avoid
Prenatal vitamins/folic acid	Tobacco, drugs, alcohol
Balanced nutrition	Medication exposures
Oxygen levels	X-rays/radiation
	TORCH illness exposures (Toxoplasma, Syphilis, Varicella, Parvovirus B19, Rubella, CMV, HSV)
Infancy and toddlerhood	
Support and troubleshoot breastfeeding	
Track normal and identify abnormal growth patterns	
Educate parents regarding: safe sleep, transportation, toys, baby bottle mouth	
Ensure appropriate supplementation of vitamin D and fluoride	
Identify and refer for developmental delays	
Counsel parents on age-appropriate behavior, discipline and expectations	
Childhood	
Track normal and identify abnormal growth patterns	
Educate parents regarding: home safety, importance of language and reading, nutrition	
Identify and refer suspected developmental delays, learning disabilities, psychiatric issues	
Counsel regarding obesity risk factors	
Support appropriate dental care	
Adolescence	
Educate adolescent and parents regarding puberty and physical changes	
Negotiate and maintain confidentiality	
Identify and treat obesity and eating disorders	
Counsel against drugs, tobacco, alcohol	
Counsel regarding STI's, birth control and pregnancy	
Identify and address depression and other psychiatric issues	

them with prospective mothers during preconception or early prenatal visits. Especially important topics to cover include the importance of avoiding alcohol, drugs, medications with risks for teratogenicity, X-ray or other radiation, and exposure to teratogenic illnesses such as rubella, toxoplasmosis, CMV, and others.

Folic acid is especially important in the normal formation and closure of the brain and spinal cord. For optimal development, the mother needs to consume adequate folic acid for at least the 3 months immediately prior to conception, through the first 3 months of pregnancy. The physician will advise a daily intake of at least 400 IU of folic acid for all women of childbearing age and in particular those who express a desire for pregnancy in the near future. This intervention can significantly decrease the developing embryo's risk for neural tube defects including spina bifida and anencephaly (Table 1).

Prenatal: Fetal Stage

The Fetal Stage begins where the Embryonic Stage left off, with the basic anatomy formed and the fetus approximately 3 cm in size. During the remainder of the pregnancy, the tissues and organs

DOI 10.1007/978-1-4939-0779-3_2-1

continue to differentiate and develop, while growth accelerates. The adequacy of the oxygen and nutrients supplied to the fetus through the placenta will affect fetal growth and development throughout this period.

Toward the end of the Fetal Stage, the fetal anatomy becomes increasingly prepared for the transition to life outside the uterus. Lung development matures toward a point after which breathing air will be possible, and tissues in the vasculature ready themselves to recognize and react to the changes which come with birth, most especially the transition to the lungs (instead of the umbilical cord) as the new source of oxygenation for the body. The central task of the fetal stage is growth and organ maturation toward the goal of function outside the uterus [2].

Physician's Role

In order to support fetal growth and maturation, the delivery of adequate oxygen and nutrients is essential. The physician can best support the developing fetus by helping the mother to address problems which can interfere with the delivery of oxygen and nutrients through the placenta. The physician will screen for and treat hypertension, support the mother's efforts at tobacco cessation, and warn against use of cocaine or other vasoconstrictors, all of which can impair placental function. The physician will also keep an eye on fetal growth through ultrasound and fundal height measurements, in order to identify unexpected problems with growth.

Adequate nutrition will include daily prenatal vitamins, as well as intake of adequate and healthy carbohydrates, proteins, and fats to support fetal growth. During the stress of pregnancy, some women will develop gestational diabetes, causing high rates of fetal growth. The physician will screen for maternal development of gestational diabetes and facilitate careful glucose management to minimize the dangers of birth trauma related to macrosomia.

Finally, the physician will help to manage risks resulting from the coming transition from intrauterine life to birth. Medications such as NSAIDs which can inappropriately hasten the closure of the ductus arteriosus should be absolutely avoided during the third trimester. Medications to which the fetus has exposure in utero will dictate particular withdrawal risks to watch for in the immediate postpartum period, including antidepressants, narcotics, and other drugs (Table 1).

Infancy and Toddler Stages

Infancy begins with birth and transitions to toddlerhood at around 12 months of age. While the mother's anatomy has changed most dramatically with the pregnancy, it is important to remember that birth itself begins an even more dramatic and challenging set of changes for the new family. Parents can become bewildered at finding their way through breastfeeding challenges, sleep cycles, car seat, crib and stroller choices, safety and management. During this period, infants learn to trust that food and care will be available when needed.

Breastfeeding is the earliest developmental challenge for the newborn infant and new mother, and successful breastfeeding is correlated with an impressive number of health benefits for both baby and mother [3].

Sleep is a challenge for both infants and their families: when parents suffer from sleep deprivation related to nighttime parenting of infants, the whole family suffers. The fear of SIDS (sudden infant death syndrome) may further disturb parents' sleep. Putting infants to sleep in the supine position, breastfeeding, and eliminating tobacco smoke from the home can all help to minimize SIDS risk [4]. Some authors advocate a systematic program to train infants (usually older than 6 months) to self-soothe and to regulate sleep on their own [5]. Other authors advocate cosleeping and the family bed [6],

DOI 10.1007/978-1-4939-0779-3_2-1

which is controversial in the literature and correlated with an increased risk in infant deaths. Parents can find this literature confusing and challenging to navigate.

Infants double their birth weight by 4–5 months and triple it by 12 months. They develop the ability to sit and to roll by 6 months; by 12 months, toddlers can pull up to a standing position, and they walk by 18 months. Babies begin to smile and follow faces as early as 2 months. Language skills begin with cooing at 2 months; by 9 months, infants understand the word "No," and by 12 months, they begin to have a few words of their own. Over the next year, toddlers build vocabulary, eventually speaking in 2–4-word sentences. "Stranger anxiety" often sets in around 9 months. By 12 months, infants can find hidden things easily and can follow simple directions. Over the next year, toddlers are increasingly independent, sometimes developing temper tantrums and defiance [7].

Physician's Role

Since successful breastfeeding can have a huge impact on an infant's lifelong health, the physician should begin to educate and encourage expectant mothers to breastfeed long before birth. Encouraging new mothers to learn about breastfeeding through classes, reading, and support from experienced breastfeeding mothers is crucial. The physician should be ready to troubleshoot breastfeeding problems, treat both mother and baby for infections (like thrush or mastitis), and be comfortable choosing lactation-safe medications when the mother requires treatment [3].

Physicians should be comfortable advising new parents on safe sleep practices and identifying potential dangers to the infant: soft bedding, tobacco smoke in the home, bottle-feeding in bed, bed-sharing, especially with parents under the influence of alcohol or drugs [4].

Because deviation from a standard developmental pattern can often be the first clue that the infant has some kind of pathology, the physician needs to understand the range of normal development and to be ready to identify infants who fall outside the realm of normal. It is important to have a clear plan for referral for infants and toddlers who are at risk for developmental concerns, so that parents can easily and appropriately arrange for evaluation, ideally within the home environment. When identified early, and treated with early interventions, developmental disorders can have much improved long-term outcomes [7].

Parents will ask their physician for advice on how to manage difficult family situations such as temper tantrums and defiance. Physicians should be ready to advise parents on the importance of finding a balance between the child's need for independence and the family's need for civilized behavior. Parents should strive to define a few clear rules and be very consistent in their enforcement. It is essential that all parents and caregivers be in agreement and consistent about discipline (Table 1).

Childhood Stage

Throughout childhood, children progressively grow physically, as well as developing skills in the motor, language, social, and cognitive domains.

When supplied with optimal nutrients and a well-balanced diet, children will grow progressively along the expected growth curves for their family and genetic makeup.

Children progressively refine gross and fine motor coordination over the years. They progress from walking to running, throwing, catching, and kicking balls. Athletic participation encourages healthy exercise, maintenance of healthy weight, and development of gross motor coordination. Even the littlest children are able to pick up small objects, and over the years, they develop facility in fine motor coordination: turning pages, printing and handwriting, coloring, manipulating scissors, etc. [7]. In general (although there are, of course, many exceptions), boys develop gross motor skills more quickly while girls

DOI 10.1007/978-1-4939-0779-3_2-1

excel at fine motor skills at younger ages. Academic success often depends heavily on fine motor skills, giving girls an advantage at younger ages.

Language development progresses throughout childhood, building vocabulary and then developing reading and writing skills as well. This language development depends heavily on the language environment of the child from the very earliest ages. Studies show that young children's exposure to spoken words from caregivers varies greatly, and future IQ and educational attainment is highly correlated with the number of words to which a child is exposed [8].

Social skills develop throughout childhood as children learn to manage their own emotions, interact with peers and authorities, and participate in the community. Parents can be very helpful to their children as they learn to navigate social situations gracefully. Often behavioral and developmental disorders such as attention deficit hyperactivity disorder (ADHD) and autism spectrum disorders are most evident in their impacts on the social domain [7].

Cognitively, children are supported in their development both at school and at home. Data concerning the effectiveness of early childhood education programs in improving lifelong cognitive achievement are convincing enough that federal, state, and local governments work to support these programs and make them available, especially to disadvantaged children [8].

Physician's Role

The physician will track a child's growth and work to identify health problems which may be interfering with this growth. Screening for developmental disabilities as well as learning disabilities is a crucial role for the primary care provider. It is important to have reliable connections with developmental screening services and educational and psychological evaluators, in order to connect parents with the appropriate agency when a child is showing signs of needing help. Often the school system will offer the best resources for learning disability testing and treatment. When ADHD is diagnosed, the physician will support the family in developing behavioral learning techniques, as well as by prescribing and monitoring appropriate medications.

Physicians can also support children's language and cognitive development by educating parents about the importance of talking with their children, reading to their children, and maintaining a rich linguistic environment for them (Table 1).

Adolescence Stage

Adolescence is a variable period of human development which begins with puberty and ends with the beginning of adulthood. This is a period of dramatic change and upheaval, both physical and emotional. During this period, the individual begins to separate from the family, depending more on peers and developing self-identity as well as a sexual identity.

Over the past 150 years, there have been major changes in the timing of the onset of puberty, resulting in increasingly younger sexual development. While the average age of menarche in the mid-nineteenth century was near 18, now it is between 12 and 13, and breast development is starting earlier and earlier as well [9]. Reasons for these changes in the onset of puberty are matters of controversy: differences in nutrition and exposures to environmental chemicals are common explanations. The physical developments of puberty include growth in height, increase in hair and body odor, and sexual development: breast development and menarche in girls, genital development in boys.

Often as adolescents experience the hormonal shifts of puberty and struggle to define themselves as separate from their family and parents, teens may exhibit more oppositional behavior [10]. It is important

DOI 10.1007/978-1-4939-0779-3_2-1

for parents to understand and expect these changes, while continuing to build on a shared history of trust and affection throughout these years.

Adolescence is the period during which most substance use patterns begin. More than 90 % of all adult smokers started smoking before age 20 [11]. People who start drinking alcohol before the age of 15 are four times more likely to have alcohol dependence at some point in their lives [12]. The teen years are the highest-risk years for initiation of drug use. During adolescence, alcohol and drug use are correlated with criminal activity, motor vehicle accidents, and suicide.

Sexual identity and development is central to the adolescent experience. In the United States, more than half of all adolescents have initiated sexual activity by the time they graduate from high school [13]. Teens who initiate sexual activity earlier are more likely to have multiple partners and thus are at higher risk for sexually transmitted infections (STIs). Other teens struggle with questions of sexual orientation, and find the adolescent years especially difficult, especially when family pressures or bullying are experienced as a result of individual sexual orientation.

Driving is an important rite of passage in most communities in the United States and represents both an adolescent's increased personal independence and increased risks since motor vehicle accidents are the leading cause of death in this age-group [14].

Physician's Role

As with every other stage, the physician will track growth and weight in order to identify emerging problems. Adolescent obesity and eating disorders are important issues for the primary care physician to identify and to advise the adolescent and family in management.

The physician will often support a conversation between the parents and developing adolescent on the process of puberty, the importance of avoiding tobacco, alcohol, and drugs, and the dangers of sexually transmitted infections and pregnancy. It is important to speak to teens with parents, and alone as well, offering confidential advice to adolescents who may be uncomfortable with disclosing substance use or sexual habits to parents.

Physicians are often asked to fill out medical forms to support an application for driver's permits. This is an opportunity to discuss the dangers inherent in driving and the grave dangers of driving while under the influence of drugs or alcohol.

Teens will come to their family doctor for treatment for STIs, as well as for birth control options. Some teens are in communication with their parents regarding these issues. Others are quite anxious that parents not be informed about this. It is important for the physician to be familiar with their state's laws regarding teen's rights to confidential health care without parental consent (Table 1).

Young Adulthood Stage

Eric Erikson saw Young Adulthood as the stage at which the primary focus was on moving away from self-absorption through the development of intimacy [1, 10]. Roughly, this stage corresponds to the 20s and 30s.

During this stage, many young adults initiate life partnerships, get married, have babies, buy homes, and start careers. As culture changes, the nature and length of these life partnerships look different, and career patterns look different as well. Couples are cohabiting and delaying marriage to later ages, while same-sex couples are beginning to take advantage of marriage opportunities. Careers are much less likely to involve lifelong commitment to a single company and much more often will involve a succession of

DOI 10.1007/978-1-4939-0779-3_2-1

different career experiences. The average age at which women give birth to their first child is younger than the average age of first marriage, and in the United States, 40 % of infants are born to unmarried mothers [15].

Young adults' sexual health concerns range from STIs and the avoidance of pregnancy to preconception counseling and infertility.

As young adults settle down into a long-term relationship, they often begin to plan their careers, their relationships, and their health around an upcoming pregnancy. For many couples, the pregnancy and subsequent parenting is a hugely challenging and maturing time, and for others, the experience of infertility can be even more challenging. Because couples blame both themselves and the partner for infertility, relationships can become strained and fragile, while others can become strengthened by the shared pain.

Physical strength and endurance peaks during young adulthood, yet the structured athletics which are available throughout grade school and high school are no longer a part of the young adult's culture. Young adults who successfully make the transition from team sports to individual athletic activity can maintain high levels of fitness throughout the young adult period. Others who have a hard time persevering in workouts outside of the team atmosphere will find themselves gaining weight and losing fitness during this stage.

Physician's Role

Young adults will look to the physician for STI treatment, birth control counseling and methods [16], preconception counseling, preadoption physicals, and infertility counseling. Many family physicians offer prenatal care, and this is a very important opportunity for the care of young adults. In addition, the family physician has a unique ability to support young mothers in the breastfeeding experience and to counsel young parents regarding their children.

Young adult athletes primarily seek care for athletic injuries, and physicians with sports medicine experience can be of great help. Former athletes and others who struggle with obesity will come to the physician for weight loss advice and sometimes a new diagnosis of hypertension (Table 2).

Middle Age

Middle age is somewhat variably defined as the years between 40 and 65. Erikson saw this as a period in which the central developmental focus is on making the world a better place for the younger generations coming after. His terms for the tension inherent in this focus are "generativity vs. stagnation" [1, 10].

Most cognitive attributes peak during the period of middle age [17], while physical strength begins to wane. In most intellectual and managerial professions, the leadership is primarily made of people in their middle ages. Most people expect their careers to peak during these years.

It is also during the years of middle age that people's reports of personal happiness reach their lifelong lows [18]. There is a culturally powerful myth which prescribes a "crisis" to the experience of midlife. Although this is a possible experience of midlife, many more people merely experience a period of relatively lower mood than at other times.

From the point of view of family experiences, the middle years are often a time of stresses, as the person feels pressure to help both their children who are getting started in life, as well as their parents whose health is failing. Colloquially known as "the sandwich generation", this period can be a source of significant distress during the middle years [19, 20].

Physically, there are a number of changes during the middle years. Physical strength and endurance have peaked and are now declining. BMI peaks during the middle years [21]. During the late 40s and early

DOI 10.1007/978-1-4939-0779-3_2-1

50s, most women experience perimenopause and menopause. Their cycles become more disorganized and eventually stop, accompanied by hot flashes and other symptoms. While menopause is a predictable biological change within the entirety of the life cycle, many emotional meanings have come to be attached to these hormonal and physical changes. Some women see these changes as being a sign that their youth, health, and usefulness is over. Others see menopause as an invigorating time when they are set free from vaginal bleeding and contraceptive concerns.

Yet another experience of midlife, "the empty nest" can be experienced as either mournful or invigorating, depending on whether parents have maintained their own relationships, interests, and career aspirations throughout their child-rearing years [19, 20].

Finally, the middle years are the years in which the most prominent chronic illnesses tend to appear in great numbers in the population. Hypertension, diabetes, obesity, and depression are all present in higher numbers in the middle years than in younger age-groups.

Physician's Role

During the middle years, the physician will need to be vigilant in order to identify and treat illnesses as they appear. Ideally, the physician will find ways of motivating their middle-aged patients to commit to lifestyle habits which will minimize their risks for hypertension, diabetes, obesity, and depression, but inevitably some patients will develop these common conditions and will need appropriate and comprehensive care as they develop.

The physician should be ready to talk with women about perimenopausal and menopausal changes and can care for the majority of gynecological, physiological, and psychological issues at this life transition.

Physicians can be of special assistance to middle-aged patients who are struggling to care for both elderly parents and troubled teens. The relationship of trust that the physician has can extend to trusting relationships with other family members. Family physicians can have unique insights into the many pressures on the family and can encourage caregivers to care for themselves as well as their needy relatives (Table 2).

Retirement

Retirement is a relatively new experience in the human life cycle, beginning in the late nineteenth and early twentieth centuries. When Social Security was established in the 1930s, the average life expectancy in the United States was 58 for men and 62 for women [22], while in 2010, overall life expectancy was just under 79 [23]. Since Social Security was originally made for people over 65 in an age when the majority of the population would never reach that age, retirement was originally envisioned as a relatively rare experience. In current times, when life expectancy is most of two decades longer, retirement has become the expectation of the majority of the population.

The retirement years are experienced very differently depending on the health, finances, and life situation of the person [24]. Some people plan ahead financially, retire immediately upon reaching the designated age of Social Security, move to a retirement community, and proceed to participate in the leisure activities available there: golf, crafts, music, etc. Others will continue to play a part in the community in which they spent their working lives: volunteering, serving on boards, helping with grandchildren. Some continue to work part time for an extended period, using the continuing income to add to their financial security or to finance travel or other goals.

Some people find themselves retiring related to their own illness or that of a loved one. For these people, retirement often is a time of heightened involvement in the medical community, and for

DOI 10.1007/978-1-4939-0779-3_2-1

Table 2 Supporting later development

Young adulthood
Contraceptive management
Screening for and treatment of STI's
Pre-conception counseling
Infertility concerns
Sportsmedicine injuries
Prenatal care
Weight management
Middle age
Counseling behavior change regarding diet, exercise, smoking cessation
Identification and treatment of common chronic illnesses: hypertension, diabetes, depression
Counseling and care for menopause and perimenopause
Older adulthood
Screen for common problems: falls, urinary incontinence, osteoporosis
Screen for vision and hearing impairments
Encourage physical exercise
Encourage intellectual activities, screen for dementia
Identify support services as appropriate
Screen for and treat depression
Encourage conversations on advanced directives
Encourage patients to define goals of care, and refer to Hospice when appropriate

caregivers, retirement to care for a spouse or other family member can involve much harder and heavier work than they ever did during their so-called working years.

Because of the structure of health insurance availability in the United States, retirement tends to be a period of relatively better access to health care, due to the Medicare program. Because they have both time and health insurance, sometimes people can be more involved in their own health during these years.

The process of retirement, itself, can be a stressful one, just like any other major life change. It can be difficult for people to develop new activities, friendships, and ways of relating to their spouses after so many years of building habits around their work [25].

Physician's Role

The physician may find that newly retired patients may leave their practice in order to move to a retirement community, or conversely, that established patients may bring in their newly retired parents who have recently moved closer to their children. These new patients will often come with established diagnoses, requiring ongoing care. The physician will need to support the ongoing care needs of these patients, while encouraging them to use their time and resources to pursue healthy exercise and dietary habits.

If new travel destinations are part of the retired person's life goals, the physician will help to make sure that travel immunizations and prophylaxis are followed. Although these vaccines are important for all, it is especially vital to keep up with regular vaccinations against flu and pneumonia for grandparents who are regularly providing care for young children (Table 2).

DOI 10.1007/978-1-4939-0779-3_2-1

Old Age

According to Erikson, the primary tension of the stage of life beginning around 65 and progressing into old age is the tension between ego identity and despair [1, 10]. Many people during this stage in life take stock and become comfortable with who they are and the life they have led. In fact, although depression is certainly an issue for many older adults, reported happiness levels peak during this stage compared with the rest of the life span [18]. During their entire lives, people have been making choices and having experiences, in every case making them more unique and more differentiated from their peers. The older population is considered the most diverse and least homogeneous group of all life stages [25, 26].

During these years, more of the person's friends and family have passed away, and the person becomes more likely to live alone. Because the life expectancy of men is about 7 years less than that of women, and women are likely to be married to men who are older than they, a large part of the elderly population is made up of women, and specifically nonmarried women. Women are more likely to have financial challenges since their lifetime earnings were lower, on average, than were men's [25]. Most people in this age-group have lost family and friends to death, if not a spouse, and will be finding their way through the stages of grief associated with these losses [27].

A number of crucial issues for the quality of life for seniors center around their ability to relate to others and function in the world. Sensory deficits – most especially visual and hearing deficits – can make it very difficult for older people to communicate with others, relate to the world, and stay oriented. Older people who are able to maintain hearing and vision tend to be much more successful in navigating life activities [26].

Physical strength and stamina continue to decrease during these years, as does cognitive function, but for both of these issues, the continued exercise of the skill results in much slower decreases in function. For both physical and mental ability, "use it or lose it" is an important concept, and older people who engage in frequent physical and mental exercise function better overall than peers who do not [17, 26]. Dementias become increasingly common over the older ages and become very frequent over the age of 85. While dementia is considered pathological rather than normal aging, physical and mental activity has been shown to be protective against dementia [17].

Physician's Role

The physician will focus on maximizing function for the aging adult. Screening for difficulty with vision or hearing will allow early detection and treatment of problems which interfere with sensation. Exercise and intellectual activity should be encouraged. Screening for common health problems such as osteoporosis, falls, and urinary incontinence can make a real impact on the lives of seniors. The physician can help the patient and family talk about when is the right time to move to safer housing or to give up driving. Ideally, the physician will have a close working relationship with a social worker who can help to connect seniors with services that are appropriate and specific to their current needs. Overall, the goal will be to maximize function and to minimize pathology over the duration of the older age span.

In addition, the physician will help families to have clear conversations about end-of-life care preferences. Advanced directives allow for patients to designate ahead of time what kinds of care they do and do not desire. When cure is no longer possible, hospice referral and care will allow the patient to continue receiving medical care aimed at quality of life and symptom control. The physician who takes these conversations and referrals seriously can significantly improve their patients' experience of the end of life (Table 2).

DOI 10.1007/978-1-4939-0779-3_2-1

Conclusion

Throughout the span of the human life cycle, from the embryonic stage through the end of old age, the human continues to develop and change. The physician who can keep these developmental stages in mind will be best suited to advise patients as they make the transitions of their lives.

Culture, Race, and Ethnicity Issues in Healthcare

The need for cultural awareness and cultural sensitivity has never been greater for family physicians. As access to transportation broadens to more and more corners of the United States and the globe – and as information traverses even more quickly than people – the influence of culture grows and becomes more complex with every passing year. Areas of the United States that saw relatively little change in population for decades have experienced unprecedented change in recent decades.

Although cultural differences are not new, today's family physician has a unique opportunity – and responsibility – to care for the whole person during this period of rapid cultural change. Because cultural groups and their members each have the potential to interpret their world differently, a solid understanding of the underpinnings of culture is necessary to providing safe and effective primary care in today's society.

The Context of Race, Ethnicity, and Culture

The concepts of race, ethnicity, and culture are frequently used interchangeably in clinical settings. Racial distinctions are perhaps mentioned most often, conventionally as a means of introducing a patient in a clinical presentation. Yet, racial distinctions often have limited clinical utility and, worse, can perpetuate misleading and potentially inaccurate patient stereotypes. Ethnic

and cultural factors, by contrast, are less often mentioned in clinical settings even though they can facilitate clinical decision-making to a greater degree.

Race

Physical characteristics (e.g., skin color, facial features, hair type) that are shared by a group of people generally define racial classifications. From these classifications, many make an assumption of a shared genetic heritage that may be intended as useful historic information in clinical settings. Unfortunately such assumptions are neither useful nor accurate and add little to medical decision-making [1].

Ethnicity

Ethnicity is more useful than the term race in clinical settings. The word *ethnic* is defined in the *Oxford Dictionary* as "the fact or state of belonging to a social group that has a common national or cultural tradition." The word *ethnicity* is derived from the Greek terms *ethnos*, which refers to the people of a nation or tribe, and *nikos*, which means national or nationality. Ethnicity commonly refers to dimensions of race and nationality, as well as concepts included within culture.

Culture

Culture can be described as the knowledge, skills, and attitudes learned and passed from one generation to the next. One's identity is ever-changing, shaped by personal experience throughout a person's life. Conclusive statements about culture, therefore, are rarely possible. Cultural norms, on the other hand, are often defined by members of that culture and can be modified over time. One's affinity to his or her culture and its norms can be highly variable, determined in part by the amount of time since his or her family migrated from one society to another, level of education, and socioeconomic status. In fact, there may be more similarities between two individuals of the same socioeconomic status who are from different cultures than between two individuals of the same culture but different socioeconomic status.

Population Demographic Shifts

Demographic shifts in the US population continue at a rapid pace. As a consequence, the Western biomedical model is challenged more than ever before to meet the needs of minority populations who have differing – and sometimes conflicting – views of health and illness.

Census data project an increasingly diverse US population. Between 2010 and 2050, the Hispanic population is expected to grow from 49.7 million to 132.8 million, an increase of 83 million or 167 %. The group's share of the nation's population will almost double, from 16 % in 2010 to 30 % in 2050. The Asian population will grow 213 % or from 14.4 million to 34.4 million. Asians' share of the population will double, from 4.7 % to 7.8 %. The black population will grow from 39.9 million to 56.9 million, an increase of 17 million or 46 %. The black share of the population will remain relatively the same at around 13 %. By contrast, the non-Hispanic white population will increase by only 1 %, from 200.9 million to 203.3 million, a gain of 2.5 million. The non-Hispanic white share of the population will decline from 64.7 % in 2010 to 46.3 % in 2050 [2].

The US population is generally older than it was in generations past. The estimated population median age in 2009 was 36.8, up from 35.3 in 2000 – a natural consequence of 77 million baby boomers who are living longer than previous generations. Altogether, the elderly segment of the population is expected to increase dramatically. A Congressional Research Service report released in 2015 projected that people 65 and older – currently constituting 13 % of the population – would make up 20.2 % of the US population by 2050 [3]. At the same time, the birthrate has remained relatively flat since the 1970s and in 2009 posted the largest 2-year drop in over

30 years, according to the Centers for Disease Control and Prevention [4].

Health Disparities

The United States has experienced great improvements in health, due in large part to advances in medical technology and our healthcare system. Life expectancy increased from just less than 70 years in 1960 to approximately 79 years in 2011, and in general, people live longer, healthier, and more productive lives than before. However, this upward trend is neither as rapid as it should be nor is it uniform across all people in the United States [5].

Life expectancy and other key health outcomes vary greatly by race, sex, socioeconomic status, and geographic location. In the United States, whites have a longer healthy life expectancy than blacks, and women live longer than men. There are also marked regional differences, with much lower life expectancy among both white and black Americans who live in the Southeast [6]. Dr. Martin Luther King summarized this best when he proclaimed at the 1966 Second National Convention of the Medical Committee for Human Rights that "Of all the forms of inequality, injustice in health care is the most shocking and inhumane."

Health Status of African Americans

Health disparities between African Americans and other racial and ethnic populations are striking and apparent in life expectancy, death rates, infant mortality, and other measures of health status and risk conditions and behaviors. Cardiovascular disease is the leading cause of death in the United States, and it is disproportionately more common among African Americans. Non-Hispanic black adults are at least 50 % more likely to die of heart disease or stroke prematurely (i.e., before age 75 years) than their non-Hispanic white counterparts [7]. The infant mortality rate for non-Hispanic blacks is more than double the rate for non-Hispanic whites. Rates also vary geographically, with higher rates in the South and Midwest than in other parts of the country [8]. In 2010, the prevalence of diabetes among African American adults was nearly twice as large as the prevalence among white adults [5].

Health Status of Hispanics

Health disparities impacting Hispanics are projected to increase as the proportion of Hispanics in the United States grows. The US Census defines "Hispanic or Latino" as a person of Cuban, Mexican, Puerto Rican, South or Central American, or other Spanish culture or origin regardless of race. The prevalence of obesity among female Mexican American adults during 2007–2010 was larger than the prevalence among female white, non-Hispanic adults during the same period. The prevalence of adult diabetes is higher among Hispanics, non-Hispanic blacks, and those of other or mixed races than among Asians and non-Hispanic whites. Prevalence is also higher among adults without college degrees and those with lower household incomes [9].

Health Status of Native Americans

Health disparities within American Indian/Alaska Native (AI/AN) populations remain among the most underappreciated health disparities in the United States. Further, AI/AN populations are historically marginalized by our healthcare system. Though the Indian Health Service is charged with serving the health needs of these populations, more than half of AI/ANs do not permanently reside on a reservation and therefore have limited or no access to IHS. As a result, AI/AN disparities persist. AI/AN adults aged 50–75 years who reported being up to date with colorectal cancer screening were 11 percentage points less than the percentage screened among white adults [10]. In 2010, AI/AN and Hispanic adults had the highest age-adjusted mean number of physically unhealthy days in the past 30 days compared with other racial/ethnic populations. During 1999–2010, drug-induced death rates in the 30–39 year age group were highest among

AI/AN compared to other racial/ethnic populations [10].

Health Status of Asian-Pacific Americans

Asian and Pacific Islanders (APIs) make up less than 5 % of the total population in the United States. This, combined with the fact that as a whole APIs have lower overall death rates for cancer, heart disease, stroke, unintentional injuries (accidents), and diabetes than other racial/ethnic populations, may contribute to the misperception that APIs are somehow immune to the disparities that impact other groups. Closer analysis reveals, however, that disparities also exist among APIs and in many cases to a much greater degree than other subgroups. APIs account for more than 50 % of Americans living with chronic hepatitis B. Despite these high rates, many APIs are not tested for hepatitis B. They are frequently unaware of their infection, and many recent immigrants do not have access to medical services that can help save lives [11]. As a result, chronic hepatitis B associated with liver cancer in APIs is one of the most serious health disparities in the United States.

Special Populations

Health Status of LGBT People

Lesbian, gay, bisexual, and transgender (LGBT) individuals encompass all races, ethnicities, religions, and social classes. The "LGBT" acronym is a general term to refer to a group of people that are diverse with regard to their sexual orientation and gender identity [12]. "Sexual orientation" refers to an individual's erotic, physical, and emotional attraction to the same or opposite sex. "Gender identity" refers to personal association to female, male, or other genders (e.g., transgender) and may be compatible or incompatible with sexual assignment determined at birth. Sexual orientation and gender identity questions are not asked on most national or state surveys, making it difficult to estimate the number of LGBT individuals and their health needs. Research suggests that LGBT individuals face health and social disparities linked to social stigma, discrimination, and denial of their civil and human rights. A long-standing history of discrimination against LGBT individuals has contributed to their distrust of the healthcare system. Compared with their heterosexual counterparts, LGBT individuals have been associated with higher rates of psychiatric disorders [13], substance abuse [14, 15], suicide [16], sexually transmitted diseases (STDs) including HIV, and increase incidence of some cancers [12, 17].

Creating a Welcoming Environment

Studies have demonstrated that LGBT individuals and their families survey their surroundings to determine if they are in an accepting environment [12]. In the primary care outpatient setting, modifying patient intake questionnaires to include a range of sexual orientations and gender identities is one example of creating an inclusive environment for LGBT individuals. Other examples include posting nondiscrimination policies in high-traffic areas and providing LGBT-relevant brochures and reading material, asking questions during sexual history taking in a nonjudgmental open-ended manner, and mirroring the terms LGBT individuals use to describe themselves [12]. Care should be taken to ensure confidentiality and to be mindful of assumptions made about gender identity and sexual orientation. Additionally, physicians should have awareness of specific issues involving LGBT youth and elderly to ensure that appropriate referrals, community resources, and supports are available to the patient.

LGBT Youth

LGBT youth may face unique challenges including rejection from family and friends, bullying at school from classmates and authoritative figures, harassment, and violence [18].

LGBT Elderly

Compared to their younger counterparts, elderly LGBT individuals grew up in an era of

discrimination and less social acceptance. In the medical world prior to 1973, homosexuality was listed in the Diagnostic and Statistical Manual of Mental Disorders with treatment modalities including electroconvulsive therapy and castration. LGBT elderly are less likely to have children compared to their heterosexual counterparts and thus have less family supports. Prior to the June 2015 nationwide ruling for legalization of same-sex marriages in the United States, LGBT individuals did not have access to spousal benefits through Social Security and thus may have been impoverished by the death of a partner [12]. LGBT elderly who lose their ability to live independently and are subsequently institutionalized may tend to conceal their sexual orientation [12, 19].

Health Maintenance and Screening

Care should be taken to ensure that routine health maintenance is offered to LGBT patients such as pap smears, mammograms, cancer screening tests, and immunizations. Sexual behaviors such as anal-receptive intercourse and oral intercourse may predispose LGBT individuals to STDs including HIV/AIDS [20]. STD screening should be offered annually and at shorter intervals for high-risk individuals (e.g., multiple partners, drug use in conjunction with intercourse).

Health Status of Deaf People

Hearing loss is the second most common disability in the United States, accounting for approximately 10 % of Americans [21]. Out of the 8.8 million North Americans who are deaf, it is estimated that between 100,000 and 1 million belong to the Deaf community [22, 23]. Of note, "Deaf" (uppercase "D") refers to the culture and community of Deaf people, whereas "deaf" (lowercase "d") refers to the lack of hearing [23]. The US Deaf community is a linguistic and sociocultural minority group that is often overlooked as such. It is distinguished by its preferred use of American Sign Language (ASL) and distinct culture [22]. Members of this community were typically deafened during childhood, around age 3, before the acquisition of English language skills [23]. Individuals who were deafened during adulthood are less likely to be members of the Deaf community as they are more likely to have English language proficiency and communicate orally or through speech-reading [23]. Similar to other linguistic and cultural minority groups, studies have shown health disparities in Deaf individuals related to lower socioeconomic status and literacy levels, altered healthcare utilization, communication issues with their physicians, and misinterpretation of medical treatment [21–24]. In an effort to provide culturally competent care, primary care physicians should be mindful of language barriers and differences in sociocultural norms among Deaf people.

Sociocultural Norms

Similar to other cultural minority groups, Deaf individuals tend to socialize among themselves and have differing social norms compared to the majority population. These differences may result in cross-cultural misunderstanding with hearing individuals during social encounters [25]. For instance, communication heavily depends on visual and tactile cues. It is culturally appropriate etiquette for Deaf individuals to describe and distinguish others based on physical features such as weight, nose shape, and hairline. To seek attention, Deaf individuals may touch one another, bang on tables, and wave in someone's visual field. Although these are all acceptable ways to communicate among the Deaf, it may be misunderstood in hearing culture [25]. Another area of cross-cultural misunderstanding is the difference in conversation structure between the Deaf and hearing individuals. English conversations build up to a main point and then conclude, whereas Deaf conversations immediately address the main point and then take a longer time to conclude the conversation [21]. For example, a physician may initiate a conversation by taking time to build a rapport with the patient before eventually discussing the medical issue and treatment plan and then concluding the visit [25]. In Deaf culture, it would be more appropriate for the physician to first discuss the main medical issue followed by clarifying the treatment plan and moving to

rapport building toward the end [21, 25]. During conversation, a hearing physician should be mindful to not exclude a Deaf individual from conversation as it is considered offensive. Additionally any environmental sounds, such as a knock on the door, should be communicated [21]. For example, if two hearing individuals in the room are having a side conversation, the conversation should be communicated to the Deaf individual.

Language Barriers

In the United States, the preferred language of the Deaf community is ASL; however, unlike other language minority groups, Deaf people are assumed to have fluency in written English and are often expected to communicate via speech-reading and note writing [23, 24]. This can put a Deaf patient at high risk for miscommunication for several reasons. Written and spoken English are often a second language for those who communicate in ASL. Speech-reading is a difficult skill as most English words appear visually ambiguous on the lips. In the context of lower literacy levels among the Deaf, they may not understand specific written words [25]. Furthermore, Deaf people are less likely to repeat themselves than non-English-speaking immigrants [23]. Physicians who are not fluent in ASL should communicate in simple terms, ensure that patients understand medical recommendations, and work with an ASL interpreter to facilitate communication whenever possible [21, 23, 25].

Health Status of Refugee Populations

Family physicians are likely to encounter refugees in the context of a continuity primary care relationship as well as during medical screening examinations conducted as part of the naturalization process into the United States. In either case, an awareness of – and sensitivity to – the unique needs and experiences of refugees can be extremely helpful.

Since 2000, at least 600,000 refugees have resettled in the United States from over 80 different countries, with almost 70,000 refugees in 2014 alone [26]. Unlike immigrants who generally *choose* to relocate, refugees are forced to relocate and experience emotional trauma, physical trauma, or both when war, famine, or persecution *force* them to flee their countries of origin. Refugees seldom have time to plan, and frequently the move is unplanned and incomplete. Although refugees differ greatly in their cultures and countries of origin, patterns of experiences shared among refugees can be observed and may offer some understanding for family physicians seeking to offer care to the refugees and their families.

Common Presenting Problems

Many refugees seek attention for a variety of health problems, most commonly musculoskeletal and pain, mental and social health problems, infectious diseases, and chronic medical conditions. Evaluation of musculoskeletal problems and chronic pain should assess history of physical trauma or physical labor and prior living conditions that may be contributing factors. When presenting with ill-defined pain symptoms, thorough workups rarely yield an organic cause but should nonetheless include assessment for *Helicobacter pylori*, intestinal parasites, vitamin D deficiency, and imaging when appropriate. Not surprisingly, the mental and social health concerns common among refugees can be highly complex and unfamiliar to many family physicians. Depression, anxiety, and posttraumatic stress are more common in refugees than in the general population, as are social isolation, financial problems, and disability, among other concerns [27].

Medical Screening Examinations

Before being permitted to resettle in the United States, refugees must pass the overseas medical screening exam performed by physicians under the oversight of the Department of State (DOS) and the US Citizenship and Immigration Services (USCIS). The goal of these evaluations is to detect conditions that render a person ineligible for admission (e.g., active tuberculosis or untreated communicable infections) or significant health problems that greatly impair caring for oneself or that might require extensive treatment or possible institutionalization (e.g., pregnancy, inactive

tuberculosis, or other sexually transmitted infections). The initial evaluation should include a full medical history and physical examination. Mental status should be assessed, with particular attention to intelligence, thought, judgment, affect, and behavior. Laboratory evaluation should exclude syphilis and tuberculosis, and appropriate immunizations should be administered [28].

Healthcare Issues of Spiritual and Religious Culture

Over the last 20 years, there has been increasing attention to the role of spirituality in multiple areas of healthcare [29–31]. In 2014, a Gallup poll revealed that 86 % of Americans believe in God or a universal spirit [32]. Transcending culture, race, and ethnicity, research studies have demonstrated that many seriously ill patients turn to their spiritual beliefs to cope with their illnesses and make important medical decisions [31, 33]. Though studies suggest that most patients would desire integration of spirituality in their medical care, less than 20 % of physicians discuss spiritual issues with their patients [31]. In that regard, equally emphasizing the physical, psychosocial, and spiritual facets of humanity is important in the family medicine approach to healing the patient as a whole.

Understanding the difference between "religion" and "spirituality" is essential to having a meaningful conversation with patients about their spirituality [31]. Religion is typically defined as an organized system of beliefs and observances to worship a God or a group of gods, usually embodied within an institution or organization. Spirituality is defined more broadly to describe the search for an ultimate meaning, a deeper sense of values, and relationship with a higher being and may be expressed through religious or nonreligious frameworks. Religious and spiritual practices in particular have been associated with positive health benefits in numerous research studies [33–35]. Regular spiritual practices have been associated with longer lifespan in some observational studies [35–37]. Over 850 studies have examined the relationship between religious involvement and mental health. Close to 75 % of these studies have demonstrated that religious involvement is associated with the experience of better mental health and coping skills [33]. Though spirituality generally leads to positive coping, in some instances it can also lead to negative coping, for instance, when an illness or medical crisis is viewed as a punishment from God or when devout prayer does not result in a miraculous cure [35].

As our nation's population grows exponentially so does the mosaic of religious communities, spiritual beliefs, and practices. Physician demographics across the United States similarly mirror our nation's cultural and religious pluralism. Secular physicians must be mindful to not undermine the spiritual belief system of their patients. Likewise, religious physicians must be mindful to not impose their own belief system onto patients [34]. Though familiarity with diverse spiritual communities and beliefs would be an asset to the clinical encounter, keeping abreast of the wide-ranging nuances is not expected of physicians. It is however important for the beneficent physician to listen, respect these differences, and understand the impact of spirituality on medical decision-making and coping skills in the setting of illness.

Approach to Religion and Spirituality in the Clinical Encounter

In the outpatient encounter, an informal spiritual history can be incorporated as part of a social history during an annual physical exam or follow-up visit for new or established patients. Obtaining a formal spiritual assessment can be essential for older patients, hospitalized patients, patients with chronic medical conditions, and those with terminal illnesses to reveal their coping skills, to elucidate their support systems, and to refer to chaplain services [35, 38, 39].

Several formal spiritual assessment tools are available to assess a patient's beliefs [31]. One spiritual screening tool suggested by a consensus panel of the American College of Physicians [33, 34] uses four simple questions:

Table 1 FICA spiritual history tool

F	**F**aith and belief	"Do you consider yourself spiritual or religious?" or "Do you have spiritual beliefs that help you cope with stress?" If the patient responds "No," the healthcare provider might ask, "What gives your life meaning?"
I	**I**mportance	"What importance does your faith or belief have in our life? Have your beliefs influenced how you take care of yourself in this illness? What role do your beliefs play in regaining your health?"
C	**C**ommunity	"Are you part of a spiritual or religious community? Is this of support to you and how? Is there a group of people you really love or who are important to you?"
A	**A**ddress in care	"How would you like me, your healthcare provider, to address these issues in your healthcare?"

Table 2 HOPE questions for spiritual assessment

H	Sources of **H**ope	"What are your sources of hope, strength, comfort, and peace?"
O	**O**rganized religion	"Are you a part of a religious or spiritual community?"
		"Do you consider your religious or spiritual community supportive?"
P	**P**ersonal spirituality and **p**ractices	"Do you consider yourself spiritual? What are your spiritual beliefs?"
		"Do you observe any spiritual practices? Do you find these practices helpful?"
E	**E**ffects on medical care and **e**nd-of-life issues	"How is your current health affecting your ability to observe your spiritual practices?"
		"Are there any specific observances, rituals, or restrictions that your medical team should be aware of?"

1. "Is faith (religion, spirituality) important to you in this illness?"
2. "Has faith been important to you at other times in your life?"
3. "Do you have someone to talk to about religious matters?"
4. "Would you like to explore religious matters with someone?"

The FICA spiritual assessment tool (Table 1) [40] and HOPE spiritual assessment questions (Table 2) [31, 38] use a more comprehensive series of questions to elicit open-ended discussions on spiritual beliefs with patients.

Integrating the Spiritual Assessment with Medical Management

After evaluating a patient's spiritual needs and observances, physicians should document their assessment for future reference or for guiding current treatment. Anandarajah and Hight suggest four outcomes following the spiritual assessment [31]:

1. No further action other than offering support, acceptance, and compassion.
2. Incorporate spiritual resources into preventive healthcare. Some examples include meditation, yoga, and listening to music.
3. Integrate spirituality as an adjuvant to medical treatment. For example, a patient may request for scriptures to be read prior to a surgical procedure.
4. Modify the treatment plan. For example, a patient with a terminal illness may decide to forego medical treatment and opt for hospice care.

When the spiritual needs of a patient are beyond a physician's competence or there is a request for in-depth spiritual counseling and prayer, physicians should be attentive to their

professional boundaries, and a referral should be made to chaplain services [35]. Most chaplains are expertly trained in listening and communication skills and have specialized knowledge on how various spiritual paradigms view healthcare [39]. They may provide or arrange for special rituals and rites directly or act as a liaison with a patient's religious leader. If a patient explicitly requests that a physician prays with them, Post and colleagues suggest that it would be acceptable for a physician to listen respectfully however discourage physician-led prayer unless pastoral care is not readily available [34].

Approach to the Cross-Cultural Clinical Encounter

Several general guidelines have been developed to guide clinicians during cross-cultural clinical encounters. The LEARN model developed by Berlin and Fowkes [41] can identify and resolve issues arising from cultural differences and facilitate communication. The LEARN acronym offers a five-step approach to the cross-cultural interview:

1. *Listen*. The first step of the interview is listening and gaining insight into a patient's perception of illness and treatment. This part of the interview creates a milieu for the physician to "join" with the patient. Questions may include "What is your understanding of your illness?," "What is your understanding of the treatment?," "What are your fears?," and "What is your treatment preference?"
2. *Explain*. After gaining an understanding of the patient's concept of the illness, it is the physician's turn to explain his or her perception of the medical condition. It is important that the physician uses a "Western medicine" or biomedical model for his or her explanation of the illness.
3. *Acknowledge*. After the patient and physician have explained their perceptions of the medical condition, the next step is to acknowledge the patient's explanatory model and highlight areas of agreement and resolve areas of conflict.
4. *Recommend*. During this part of the cross-culture interview, it is important for the physician to incorporate the patient's explanatory model and cultural parameters into the biomedical recommendations. This approach is conducive to acceptance of a treatment plan.
5. *Negotiate*. The last stage of negotiation between patient and physician is a key step to the LEARN model. In this stage, the patient and physician work in partnership to negotiate and develop a treatment plan that fits within a culturally competent framework of healing and health.

Special Considerations

Language and Working with Medical Interpreters

More than 60 million Americans speak a language other than English at home, and of those more than 25 million reported proficiency with English as less than "very well" [42]. As a result, this population is less likely to receive preventive care, have regular care, or be satisfied with their care [43], and they are more likely to have complications from medications, have limited understanding of their medical concerns, and have a greater chance of being misunderstood by their care providers [44, 45].

Professional medical interpreters are trained to interpret the spoken word, in contrast to translators who work with written words. Every effort should be made to utilize trained medical interpreters. Using untrained interpreters is more likely to result in errors, violate confidentiality, and increase the risk of poor outcomes [46]. When working with an interpreter, clinicians should view him or her as a collaborator in providing care for the patient. In addition, to work effectively with the interpreter, the clinician should:

1. Allow extra time for the encounter.
2. Meet with the interpreter first to discuss background, build rapport, and set goals.

3. Look at the patient when speaking; address the patient and not the interpreter.
4. Pay additional attention to body language, as it will precede the interpretation of spoken words.
5. Keep sentence structure simple.
6. Be wary of interpretation provided by family members, and remember that in some cultures, it may be taboo for them to discuss certain topics with their loved ones.
7. Test for understanding, especially when nonprofessional interpreters are used.
8. Consider a post-encounter discussion with the interpreter to obtain feedback and make corrections if necessary.

Health Literacy

Conveying patient education and medical instructions to patients with limited English proficiency is challenging. For literate patients, printed patient instructions and educational material should be provided in their preferred language. An effective approach to gauging effective communication and health literacy is to actively involve patients in treatment planning and assessing their understanding through "teach-back." This technique has a prospect of better understanding and adherence to a treatment plan [47].

Time

Different cultures frequently perceive the concept of time in different ways. If allowed to go unrecognized, this difference may present a challenge in the cross-cultural encounter. For some patients, being on time may mean arriving within 15 min or within half a day. For some patients, the concept of an appointment may be foreign or unfamiliar. The concept of future time may also vary. Some patients in rural cultures may have difficulty conceptualizing advice to undertake preventive measures or illnesses that may not exist later or may only exist in an abstract way.

Medical Decision-Maker

In Western culture the decision-maker is typically the patient or next of kin (e.g., spouse, children). However, physicians should be mindful that decision-makers may vary across cultures. For example, a patient may rely on their community or a designated family leader for making important medical decisions. Spiritual and cultural beliefs may influence decisions that result in refusal or delay in medical care. For instance, believers in faith healing may rely on prayer for a miracle and therefore delay medical intervention [35]. Patients of Jehovah's Witness faith tend to refuse both donor and autologous blood transfusions, and if this wish is known, it should be respected whenever possible, even in the setting of a life-threatening emergency. For some patients of Islamic faith, genetic defects are considered God's will [48]; therefore, physicians should facilitate referrals to supportive resources for families that decline genetic screening during prenatal counseling.

Models of Illness and Treatment

Physicians and patients in a cross-cultural encounter may have differing views on what conditions are regarded as "illness" and "treatment." Coining is a practice common in some Southeast Asian cultures that is intended to release unhealthy elements from injured areas and stimulates blood flow and healing. Because this practice results in physical marks on the skin, practitioners may incorrectly conclude that this is a sign of physical abuse.

Staff Gender

Medical care from same-sex health professionals is preferred for some patients. It would be advisable for healthcare providers to announce arrival before entering a room, for example, to give enough time for a Muslim woman to cover her hair and body with a hijab [48]. Some patients may decline sensitive and sometimes even general examinations by opposite-sex physicians for cultural and religious reasons, and care must be taken to respect their wishes. When same-sex providers are unavailable, the patient should be notified and offered alternate suggestions such as having a

female chaperone while a male provider examines a female patient.

Diet

Physicians should keep in mind strict dietary observances such as vegetarian, Kosher and Halal laws, when counseling on nutrition. Some faiths practice fasting, which may affect health status in the chronic or acute setting. For example, in Muslim patients with type 1 or type 2 diabetes who are fasting during Ramadan, care must be taken to counsel on diet, glucose control, and medication management [49].

Human Sexuality

Sexuality outside of marriage, homosexuality, abortion, and birth control may be condemned in several cultures and may result in social ridiculing and shame. Sexual issues may be considered extremely private for some. Discussion of sexually transmitted diseases might be perceived as offensive as it may imply deviation from monogamy [48]. Ensuring privacy for culturally sensitive discussions, counseling and assuring patient confidentiality is of utmost importance.

Mental Illness

Mental illness might be considered taboo in some cultures and religious beliefs. Patients may not acknowledge their mental illness and legitimacy of antidepressants, and therefore a physician should be sensitive to tactful depression screening, building trust, and providing appropriate support.

Death and Grief

Understanding views on death and grief may help navigate the clinician on delivering culturally sensitive end-of-life care and bereavement support. For example, some patients may find comfort in end-of-life prayers and completion of religious rites before death.

Caring for families remains one of the defining characteristics of family medicine. From the change in our discipline's name from general practice to family practice in the 1960s, family-centered care has been central to clinical practice in family medicine. Over the past decade, the role of the family in health care has evolved with the patient's natural support system becoming increasingly important in the era of health-care reform.

Despite rapid societal changes in its structure and function, the family remains the most important relational unit as it tends to individuals' most basic needs for physical and emotional safety, health, and well-being. As such, family members, not health professionals, provide most of the health care for patients. Outside the hospital, health-care professionals give advice and suggestions for the acute and chronic illness, but the actual care is usually provided by the patient (self-care) and family members. Chronic illness requires families to adapt and change roles to provide needed care. The aging of the population and increasing medical technology have led to a significant increase in the prevalence of chronic illness and disability and a rise in family caregiving.

In this chapter, the term "family" refers to the patient's natural support system – any person defined by the patient as significant to their well-being and their health care and "any group of people related either biologically, emotionally, or legally" [1]. This includes all forms of traditional

and nontraditional families, such as unmarried couples, blended families, and LGBT couples. The relevant family context may include family members who live a distance from the patient or all the residents of a community home for the developmentally delayed persons. In daily practice, family physicians are most often involved with family members who live in the same household.

Role of the Family in Health and Illness

Over one-third of all deaths in the United States can be directly attributable to unhealthy behaviors, particularly smoking, lack of exercise, poor nutrition, and alcohol abuse, and are potentially preventable. These unhealthy behaviors account for much of morbidity or suffering from chronic illnesses, such as heart disease, cancer, diabetes, and stroke. Health habits usually develop, are maintained, and are changed within the context of the family. Unhealthy behaviors or risk factors tend to cluster within families, since family members tend to share similar diets, physical activities, and use or abuse of unhealthy substances, such as smoking. The World Health Organization [2] characterized the family as "the primary social agent in the promotion of health and well-being."

Despite societal changes, families still tend to eat together, share the same diets, and consume similar amounts of salt, calories, cholesterol, and saturated fats [3]. If one family member changes his or her diet, other family members tend to make similar changes. However, most dietary interventions are directed at individuals with little or no attention to the rest of the family. Over 30 % of the population is considered obese (more than 20 % over ideal body weight), which contributes to numerous chronic illnesses, including diabetes, hypertension, coronary heart disease, and arthritis. Obesity is a major public health problem. Overeating and obesity can play important homeostatic roles in families. The parents of obese children are less likely to encourage exercise and more likely to encourage their children to eat than other parents. Obesity programs that involve the patient's spouse or partner have better outcomes, especially with long-term follow-up [4]. The family plays an important role in both the development and the treatment of eating disorders such as anorexia nervosa and bulimia [5].

Smoking causes over 350,000 deaths per year, mostly from heart disease and cancer, and remains the number one public health problem in the United States. Smoking is strongly influenced by the family. Adolescents are five times more likely to start smoking if a parent or older sibling smokes. Smokers tend to marry other smokers, to smoke the same number of cigarettes as their spouse, and to quit at the same time. Smokers married to non- or ex-smokers are more likely to quit and remain abstinent. Support from the smoker's partner or spouse is highly predictive of successful smoking cessation. Specific supportive behaviors such as providing encouragement and positive reinforcement predict successful quitting, while negative behaviors such as nagging or criticism predict failure to quit or relapse. The Agency for Healthcare Research and Quality (AHRQ) recommends family and social support interventions as components of effective smoking cessation [6].

Challenges to Family-Centered Care

In the 1990s, there was a surge of interest in the role of the family in family medicine. Several major textbooks and numerous articles on family-centered and family-oriented medical care [1, 7, 8] were published and used in medical schools and family medicine residencies across the country. The Society of Teachers of Family Medicine sponsored a popular Family in Family Medicine Conference where the latest approaches to working with families in primary care and teaching family-centered care were presented and discussed. Interest in the family in family medicine seemed to decline in the early 2000s with the end of the Family in Family Medicine Conference and a decline in publications on the family in family medicine. There are many possible reasons for this decline in interest and focus.

Over the past two decades, there has been pressure on family physicians and other primary

care physicians to see more patients under the current fee-for-service reimbursement system. Many primary care physicians complain that they have less time with patients and feel like they are on a "hamster wheel" having to work faster and faster. Having less time for individual patients has meant little time for families, whether it is meeting with family members during a routine office visit or a family conference.

The widespread adoption of electronic medical records has impacted family-centered care. Gone are family folders in which the charts of family members are included in one folder and can be consulted during an office visit. None of the major EMRs have methods for linking the electronic charts of family members, and many don't have ways to easily identify other members of the family or household. Clinicians must often rely primarily on household address to determine family members.

The genogram or family tree has always been a hallmark of family-centered care and a valuable tool but is being used less often. There are no easy methods available for documenting the genogram within most current EMRs. While genogram programs do exist, they are difficult to integrate into the major EHR systems. Instead, family histories are usually recorded linearly in the EMR, rather than graphically, with a list of family members and what diseases they have. Genograms can be created on paper and scanned into the medical record but become difficult to access or modify over time.

Over the past few decades, the scope of practice of family physicians has been narrowing. The percentage of family physicians who deliver babies has been steadily declining and currently is around 15 %. Furthermore, according to data from the American Board of Family Medicine [9], the number of family physicians who care for children has declined from 77 % in 2000 to 67 % in 2009. Some of this decline is due to the aging of the family medicine workforce and subsequent aging of the patients in their practices, as well as the rising number of pediatricians at a time when the birth rate is flat. As family physicians deliver fewer babies and take care of fewer children, the goal of caring for the entire family recedes.

The Role of the Family in Health-Care Reform

Despite these challenges, there has been a resurgence of interest in family-centered care, in part due to heath care reform. We are in the midst of an enormous change in health care as we transition from a fee-for-service system of reimbursement to a value-based model. With a value-based system of reimbursement, clinicians and health-care systems are paid for the outcomes that they achieve, rather than the procedures that they perform. With these changes, there are new incentives to prevent illness and keep patients and families healthy and out of the hospital. Clinicians can get paid for spending extra time with families and family caregivers to prevent hospitalization and other expensive interventions.

As CEO of the Institute for Healthcare Improvement, Don Berwick, MD, first proposed the concept of the Triple Aim: better care, better health, and lower costs. The Triple Aim has become the primary goal of health care in the United States. Better care refers to the experience that patients and families have with our health-care system. Patient and family-centered care has become a major focus of most health-care institutions. Medicare now bases a portion of its reimbursement on the scores that were received on patient and family satisfaction. More hospitals and practices are starting patient and family advisory councils to help guide health-care policies. As our health-care system moves from fee-for-service to value-based care where outcomes matter, family involvement and family satisfaction will play an increasingly important role.

Family-Centered Care

Since family physicians meet with individual patients more often than with family members, having a family-centered approach to all patients is an important skill. This approach complements

a patient-centered approach in which the physician explores the patient's experience of illness, an experience that occurs in a family or relational context. The patient's presenting complaint can be thought of as an entrance or window into understanding the patient in the context of the family. By exploring the patient's symptoms and illness, the physician can learn more about the patient's family, its relationship to the presenting complaint, and how the family can be used as resource in treatment. A key to being family centered is choosing appropriate questions to learn about the psychosocial and family-related issues without the patient feeling that the physician is intruding or suggesting that the problem is "all in your head."

In a qualitative study of exemplar family physicians, Cole-Kelly and colleagues examined the core components of a family-centered approach with individual patients [10]. These family physicians used both global family questions, "how's everyone doing at home?" and focused family-oriented questions, "how is your wife doing with that new treatment?" The exemplars frequently inquired about other family members and were able to keep a storehouse of family details in their minds that they frequently interspersed in the visits. A common time to bring up family details was in the closing of the visit where the physician would punctuate the end of the visit with a greeting to another family member: "be sure to tell John I say hello."

A risk of being family centered with an individual patient is getting triangulated between family members – having a patient speak to the physician about another family member in a conspiratorial way. In Cole-Kelly's study, the exemplar physicians were sensitive to the dangers of inappropriately colluding in a triangulated relationship with the patient and were facile at avoiding those traps. The exemplars seemed to have an appreciation for the importance of understanding the concept of developing a "multi-partial alliance" with all family members, rather than triangulating it. The exemplars often explored family-oriented material during physical exams or while doing procedures, thus not using extra time for these areas of inquiry. Visits with high family-oriented content occurred 19 % of the time, while family-oriented talk was low or absent in 52 % of the visits. The visits that had the highest degree of family-oriented content were chronic illness visits and well baby and child visits.

Asking some family-centered questions can metaphorically bring the family into the exam room and provide a family context to the presenting problem [11]. Examples of family questions include:

Has anyone else in your family had this problem? This question is often part of obtaining a genogram. It not only reveals whether there is a family history of the problem but how the family has responded to the problem in the past. The treatment used with one member of the family or in a previous generation may be a guide for the patient's approach to his/her illness or may describe how a patient does not want to proceed.

What do your family members believe caused, or could treat, the problem? Family members often have explanatory models that strongly influence the patient's beliefs and behaviors regarding the health problem and how it should be treated. If the physician's treatment plan conflicts with what important family members believe or have recommended, it is unlikely the patient will comply.

Who in your family is most concerned about the problem? Sometimes, another family member may be the one most concerned about the health problem and may be the actual "customer," the one who really wants the patient to receive care. When the patient does seem concerned about the health problem or motivated to follow treatment recommendations, finding out who is most concerned may be helpful in creating an effective treatment plan.

Along with your illness (or symptoms), have there been any other recent changes in your family? This question is a useful way to screen for other additional stressors, health problems, and changes in the patient's family and how it is affecting the patient.

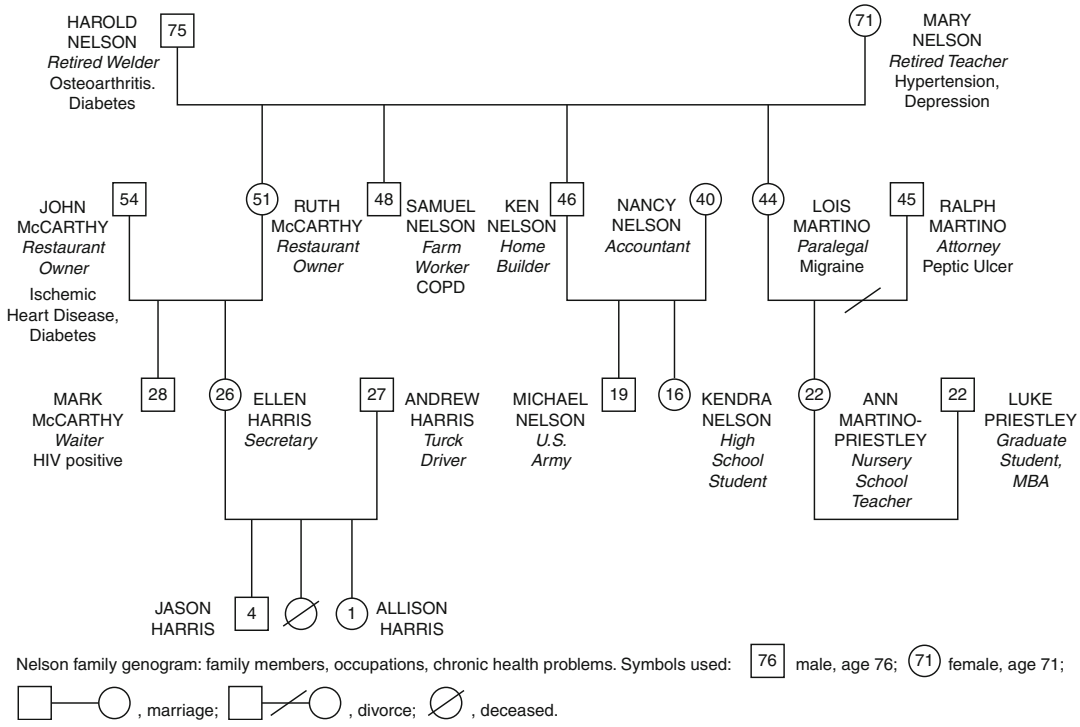

Fig. 1 Genogram

How can your family be helpful to you in dealing with this problem? Discovering how family members can be a resource to the patient should be a key element of all treatment planning.

These questions can be integrated into a routine office visit with an individual patient and provide valuable family information relevant to the problem.

Genograms

Genograms or family trees are one key to family-centered care. They are the simplest and most efficient method for understanding the family context of a patient encounter [11] (see Fig. 1) and provide a "psychosocial snapshot" of the patient. Genograms provide crucial information about genetic risks and any family history of serious illnesses. With advances in genetic research, detailed genogram should be an essential component of every patient's medical evaluation and database [12, 13]. Ideally a genogram should integrate genetic and psychosocial information.

The genogram can be started at an initial visit and added to during subsequent encounters. It may be quite simple and only include the current household and family history of serious diseases or provide more detailed information about family events and relationships. When possible, the genogram should include family members' names, ages, marital status, significant illnesses, and dates of traumatic events, such as deaths.

Obtaining a genogram can be a particularly effective way to understand the family context and obtain psychosocial information from a somatically focused or somatizing patient. These patients often present with multiple somatic complaints and try to keep the focus of the encounter on their physical symptoms and distress. They are challenging patients, and it is often difficult to obtain family or psychosocial information from them. Since obtaining a family history is

Table 1 Dos and Don'ts of family interviewing

Dos
Greet and shake hands with each family member
Affirm the importance of each person's contribution
Recognize and acknowledge any emotions expressed
Encourage family members to be specific
Maintain an empathic and noncritical stance with each person
Emphasize individual and family strengths
Block persistent interruptions
Don'ts
Don't let any one person monopolize the conversation
Don't allow family members to speak for each other
Don't offer advice or interpretations early in a family interview
Don't breach patient confidentiality
Don't take sides in a family conflict, unless someone's safety is involved

Source: Adapted from McDaniel et al. [5]

considered a routine part of a medical evaluation, it can often provide access to more relevant psychosocial illnesses. It provides a way to step back from the presenting complaints to obtain a broader view of the patient and his/her symptoms in a manner that is acceptable to the patient.

While there are efforts to create digital genograms and integrate them into the electronic medical records, this is not widely available for most EMRs. Currently, the best option is to create the genogram on paper and scan it into the EMR and use a bookmark or similar system to easily identify its location.

Meeting with Family Members

Routine visits, in which one or more family members are present, are common and may be initiated by the patient, family members, or clinician. These visits allow clinicians to obtain the family member's perspective on a problem or treatment plan and answer the family member's questions. Family members accompany the patient to office visits in approximately one-third of all visits, and these visits last just a few minutes longer than other visits [14]. In some situations, they may be more efficient and cost effective than a visit with an individual patient since a family member can provide important information about the health problem or the visit may prevent later questions. Family members may serve various roles for the patients, including helping to communicate patient concerns to the doctor, helping patients to remember clinician recommendations, expressing concerns regarding the patient, and assisting patients in making decisions. Physicians report that the accompanying family members improve their understanding of the patient's problem and the patient's understanding of the diagnosis and treatment.

There are many situations when a family physician may want to invite another family member to the next office visit. Partners and spouses are routinely invited to prenatal visits. Fathers and co-parents should be invited to well-child visits, especially when the child has a health or behavior problem. Whenever there is a diagnosis of a serious medical illness or concerns about adherence to medical treatments, it is helpful to invite the patient's spouse or other important family members to come for the next visit. Elderly couples are usually highly dependent on each other. It can be particularly effective and efficient to see them together for their routine visits. Each can provide information on how the other one is doing and help with implementation of treatment recommendations. Consulting with family members during a routine visit is advised whenever the health problem is likely to have a significant impact on other family members or when family members can be a resource in the treatment plan.

Principles of Family Interviewing

The principles of interviewing an individual patient also apply to interviewing families, but there are additional complexities (see Table 1). One must engage and talk with at least one additional person, and there is opportunity for interaction between the patient and family members. In general, the physician must be more active and establish clear leadership in a family interview. This may be as simple as being certain that each participant's voice is heard: "Mrs. Jones, we haven't heard from you about your concerns about your husband's illness.

Can you share those?" to acting as a traffic cop with a large and vocal family, "Jim, I know that you have some ideas about your mother's care, but I'd like to let your sister finish talking and then we'll hear from you."

When interviewing families, establishing rapport and an initial relationship with each family member is particularly important. In a family systems approach, this is known as joining. An essential component of joining is making some positive contact with each person present so that each feels valued and connected enough to the physician to participate in the interview. Family members have often been excluded from health-care discussions and decisions, even when they are present. They may not expect to be included in the interview or to be asked to participate in decision making. By making contact with each person, the physician is making clear that everyone is encouraged to participate in the interview.

There are several other important reasons for joining with family members at the beginning of the interview. The physician often has an established relationship with the patient, but may not with other family members. The family member may either feel left out or that his or her role is merely as an observer. One example of this occurs commonly during hospital rounds when there is a family member by the bedside. The usual approach is to either ask family members to leave during the interview or to ignore them. This is disrespectful to families and fails to use family members as a resource. It is recommended that the physician greet and shake hands with each family member and find out something about each person. At a minimum, this may be the family member's relationship with the patient and involvement in the patient's health problems. It may also involve thanking them for their presence and help.

All the principles of good medical interviewing can be extended to family interviewing. It is helpful to encourage each family member to participate and to be as specific as possible, when discussing problems. Individual and family strengths should be emphasized. Emotions that are present in any family member during the interview should be recognized and acknowledged. ("Mr. Canapary, you look upset. Is there anything about your wife's health or her medical care that you are concerned about?") In addition, the physician must take an active role in blocking persistent interruptions and preventing one person from monopolizing the conversation.

Establishing a positive relationship with family members is particularly important and more challenging when there is conflict in the family. In these cases, a family member may assume that the physician has taken the side of the patient in the conflict. The physician must take extra steps to join with family members in conflict and establish one's neutrality. The goal in these situations is to develop an alliance with each family member and the patient without taking sides in the conflict. An exception to this goal is when family violence threatens and then safety must be the first priority.

In addition to establishing rapport and building a relationship through verbal communication, the physician can also make use of nonverbal strategies to enhance the relationship with the patient and family members. Just as it is important to be sure that the physician and an individual patient are in a comfortable sitting position and at eye level with one another, so is it important that other family members are sitting near enough that they can hear what's being said and be easily seen by the physician. This proximity will help the physician make eye contact with each person in the room.

Upon entering the room and seeing that one family member is sitting very far from the physician or isolated from other family members, the physician can gently motion the person to come closer to enhance the sense of everyone being included in the patient visit and being an important part of the encounter. Similarly, one family member might dominate both the verbal and nonverbal space in the encounter, making it difficult for the other family members to have as much involvement with the patient or physician. For these cases, the physician must "direct traffic," so all voices can be heard.

A physician who meets with multiple family members needs to learn how to avoid taking sides with one family member or the exclusion of another. It is very easy for the physician to unwittingly be pulled into unresolved conflicts between

family members. In the case of an ill child, one parent may try to form a relationship with the physician that excludes the other parent. Or, a wife can try to get the physician to side with her, hoping that the physician's alliance will bolster her position against her husband. To avoid getting caught in the middle of a triangle, the physician needs to be facile at reassuring each member of the family that he/she is there to hear each person's story but will remain neutral. Furthermore, the physician can assert that it won't be helpful to the family if he/she takes sides with one member against another. The physician can emphasize the importance of everyone working together as the most beneficial way to enhance the health care of the patient.

Confidentiality

When working with family members, the family physician must maintain confidentiality with the patient. Prior to speaking with a family member, it is important that the physician is clear about what the patient feels can be shared and what, if anything cannot be. A family member may bring up difficult or awkward concerns, but the physician may only disclose information the patient has approved (unless that patient is incompetent). In most cases, patients will agree that their care plan can be fully discussed with the family members. However, in family meetings involving adolescents or divorced parents, the "rules" for the meeting need to be clearly spelled out. The physician may remind families at the beginning: "John has agreed that I can talk with you about the options for his diabetes treatment. He, of course, will be the one who will make the final decisions, but we both think it will be helpful to have all of your thoughts about what may be best." Such discussions value both the doctor-patient relationship and the patient-family relationships. The positive support of these relationships is only one of the positive outcomes of well-crafted family meetings.

Conclusion

Health-care reform, the aging of the population, and advances in medical research will continue to have a dramatic impact on family issues in health care. There are increasing demands on families to provide care for aged and chronically ill patients, often without adequate services or insurance reimbursements. Family caregiving has led to increasing burden on family members and poor physical and mental health for many caregivers. The role of the family in end-of-life decision making is only beginning to be addressed. Health-care proxy laws allow patients to identify an individual, usually a close family member, to make medical decisions if the patient is unable to, but little research has been done on how patients make these choices, what they discuss with their designated health-care agent, and whether family members follow the wishes of the patient. Because of the genetic revolution, we will soon have the ability to screen or test for hundreds of genetic disorders, but the impact of this technology on families is just beginning to be examined. Genetic counseling not only needs to address the genetic risks of the individual but the implications for other family members. More family research is needed in each of these areas.

One of the unique and distinguishing characteristics of family medicine is its emphasis on the family. No other medical specialty has a family focus or uses a family-oriented approach. Under our changing health-care system, there is increasing recognition of the importance and cost-effectiveness of involving the family in all aspects of medical care. New models of care are being developed that emphasize teamwork, prevention, and collaboration with patients and their families. A family-oriented approach will become an increasingly valued and effective model in the twenty-first century.

Evidence-Based Family Medicine

Susan Pohl* and Katherine Hastings
Department of Family and Preventive Medicine, University of Utah, Salt Lake City, UT, USA

Medicine is built on a foundation of scientific breakthrough, with constant change; a physician practicing for even a few years can appreciate this change. Incorporating the knowledge gained from research into clinical practice, however, is inherently difficult. Historically, it can take many years for medicine to adopt change [1]. This fact is not surprising, as research must be replicated and validated. Yet even validated clinical guidelines can take many years to be widely adopted. The number of clinical trials, clinical summaries, and clinical guidelines produced each year continues to increase [2], and physicians in any specialty can feel overwhelmed with the volume of information. Family physicians who care for the undifferentiated patient can feel that the task of analyzing information in the primary care literature and also multiple specialty areas is insurmountable.

Fortunately, the practice of evidence-based medicine (EBM) does not require physicians to incorporate *all* of the latest research into practice. EBM is defined as the integration of only the best clinical research evidence with clinical expertise and patient values into medical decision making [3]. Physicians who demonstrate knowledge and skills in EBM practice have been shown to have higher quality indicators in clinical practice [4].

The goal of this chapter is to provide practical methods and resources to help family physicians who wish to incorporate EBM into their practice of clinical medicine. The steps to achieve this can be summarized as follows: Ask a precise clinical question, search for the best evidence, appraise the evidence, and then apply the evidence ("Ask, Acquire, Appraise, and Apply").

The first section of this chapter contains foundational information on EBM, including developing a meaningful question, efficiently acquiring evidence, and analyzing the quality of that evidence. The next section outlines the principles of information mastery and synthesized data. The final section reviews application of the evidence through shared decision making.

Foundational Principles of Evidence-Based Medicine

Asking an EBM Question

The methodologies used to apply EBM to clinical practice in a systematic way were not clearly defined until the 1980s. One of the first developments was the crafting of a clear clinical question. A question that seeks to incorporate EBM into practice will contain the following information: a specific population, an intervention or exposure, a comparison intervention, and patient-relevant outcomes [5]. This strategy has been simplified to the mnemonic "PICO" (see Table 1).

Acquiring and Analyzing Evidence

Asking a precise clinical question helps to identify exactly what evidence needs to be acquired. For example, when a healthy teenage patient admits to frequently drinking highly caffeinated energy drinks and wants to know the risks of this practice, the appropriate clinical question is "in healthy teenage patients, do those who drink highly caffeinated energy drinks experience increased health risks compared

Table 1 Creating a searchable question

	P	I	C	O
Description	**Patient** or **population**	**Interventions** including diagnostic evaluation, treatment, or screening	**Comparison** group	Patient-oriented **outcome**
Example	Healthy adult with upper respiratory infection	Nasal saline irrigation	Usual care	Improvement of symptom scores
Example	Adult female with obesity	Treatment of subclinical hypothyroidism	Monitoring subclinical hypothyroidism	Improvement in weight loss or symptom scores
Example	Adult patient with type 2 diabetes mellitus	Control of systolic blood pressure to <130 mmHg	Control of systolic blood pressure to <140 mmHg	Decrease in stroke rate

to those who do not ?" Then, the necessary information or evidence can be searched for and acquired. Evidence that leads to an answer may exist in the form of individual clinical trials or synthesized data. Because clinical trials are the foundation of research, a review of methods to acquire and analyze individual trials is needed.

Family physicians may find individual trials using an online search engine such as PubMed (http://www.ncbi.nlm.nih.gov/pubmed). PubMed is a database that houses online references to and abstracts for individual trials and synthesized data. It is run by the National Center for Biotechnology Information (NCBI), a division of the National Library of Medicine (NLM) at the National Institutes of Health (NIH). Because PubMed contains multiple databases and links to basic science research, clinicians can find that using the general search function at this resource is cumbersome. Using tools to limit searches to human subjects or the English language may make the process more relevant to the user. The clinical studies search engine will also narrow a search (http://www.ncbi.nlm.nih.gov/pubmed/clinical).

Once a study reference or abstract has been located, it must be evaluated: "Is this piece of evidence helpful?" All types of evidence should be evaluated for relevance, validity, and clinical importance, in that order [6]. If evidence passes all three requirements, then it should be determined whether this evidence supports a possible change to current clinical practice.

Relevance

The first step in evaluating evidence is determining if the question being addressed is relevant to clinical practice. Evidence is most relevant if it describes at least one patient-oriented outcome, is a common issue within clinical practice, and will change clinical practice [7]. Determining relevance can often be achieved by reading the abstract alone.

The majority of evidence published in medical journals is disease-oriented evidence (DOE) [7]. DOE refers to outcomes such as blood pressure, hemoglobin A1C, or DEXA scan results. Although this evidence is vital for understanding disease processes, it may or may not be relevant to clinical practice. In other words, intermediate results that may or may not lead to an improvement in patients' lives should not be studied in depth. Evidence related to changes in patients' lives is patient-oriented evidence (POE) [7]. Results such as morbidity, mortality, symptoms, quality of life, and cost are POE. This differentiation matters, because promising DOE does not always lead to the expected POE; for example, in patients with high cardiovascular risk but no history of MI, supplementation with *n*-3 fatty acids significantly reduces triglyceride levels, but does not decrease cardiac deaths or hospital admissions [8].

In addition to reporting patient-oriented outcomes, relevant evidence should address a common problem within family medicine [6]. Relevant information may differ from physician to physician. Family

DOI 10.1007/978-1-4939-0779-3_5-1

physicians who provide obstetrical care will find a study addressing new developments in managing postpartum hemorrhage relevant, whereas family physicians that do not provide obstetrical care may not.

Lastly, relevant evidence should have the potential to lead to a change in clinical practice [6]. Whether it is a screening test, a diagnostic test, or a treatment option, the intervention must be accessible, affordable, feasible, and sufficiently different than the current standard of care to make a change in practice. Such evidence is referred to as "patient-oriented evidence that matters" (POEM) [7]. Evidence that matters may differ from physician to physician. For example, evidence for the effectiveness of lung cancer screening using CT scans in smokers may not seem relevant to a family physician caring for poorly insured or uninsured patients who cannot afford expensive tests; however, given the scans' ability to identify early and treatable lung cancer, it may be more relevant to physicians who care for populations who can afford this test [9].

Validity and Types of Evidence

Once evidence is found to be relevant to a clinical practice, then the evidence must be evaluated for validity. Validity can be evaluated both internally and externally. For family physicians, external validity usually means that the study population is comparable to a primary care population. Results from studies that include only patients who were referred to a specialty clinic may or may not be similar to results from clinical trials in the primary care population. Studies that exclude patients of certain ages, races, genders, or socioeconomic classifications may also limit external validity.

External validity also includes considering the effect of comorbidities on the evidence. For instance, a study comparing a new pharmacologic treatment of obesity to usual care that excludes diabetic patients will be difficult to apply to the general population because the efficacy and risks of the medication in diabetics are unknown. Even small changes in age or comorbidities can lead to differences in outcomes.

Once evidence passes evaluation for external validity, then internal validity of the study can be explored. Internal validity refers to the level or robustness of the evidence being presented in the study. A good first step is identifying the type of study and the focus of the study. This information should be available in the abstract and often is clearly stated in the title.

All clinical evidence is not equally strong, as illustrated in Fig. 1. Guidelines, systematic reviews, and meta-analyses involve the review and analysis of multiple studies and are often assigned a higher level of evidence than individual trials. Randomized controlled trials (RCTs) examining treatment, prevention, or screening are considered the highest level of evidence for individual trials. This is followed by cohort

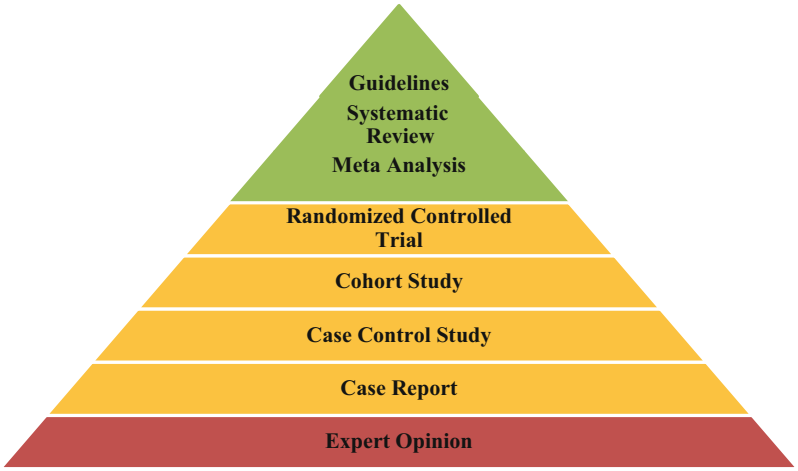

Fig. 1 EBM evidence pyramid

DOI 10.1007/978-1-4939-0779-3_5-1

studies examining diagnosis or prognosis and finally case studies and expert opinion. It is important to note that it is not common for a single scientific trial, no matter how well designed, to change clinical practice on its own; more often, it is the replicability of the results that changes practice over time.

In addition to clinical trials, the medical literature also includes qualitative research. Qualitative research is a tool that physicians use to understand the social, emotional, and experiential phenomena that their patients experience. Understanding and appreciating these forces can help in the implementation of evidence-based care. The goal of qualitative research is to explore complex phenomena that may not be amenable to quantitative research.

Qualitative research is being increasingly valued in the medical literature. Each qualitative study should be evaluated for internal and external validity in the same way that it is done for quantitative studies [10]. Do the people in the study adequately represent the population of patients that the physician is trying to understand? Is the quantity and quality of the information reasonable? Several qualitative studies can also be synthesized, in much the same way that quantitative studies are synthesized [10]. Qualitative information published in the medical literature should not be viewed as competing with quantitative evidence; rather, it should be viewed as a complementary tool for understanding the patient's or medical team's experience. It is also a tool that can help the practicing physician bridge the gap between the quality of care described in quantitative research and the care that is actually delivered in diverse practice communities.

Clinical Applicability

The final step in assessing evidence that is both relevant and valid is determining whether the outcome is clinically important [6]. RCTs aim at altering outcomes, whether it be increasing a benefit or decreasing harm. This change in rate of an outcome is often reported as the "relative risk reduction" (RRR). In general, the RRR can magnify the significance of an intervention by reporting the change as a percent change [6]. For instance, if intervention A drops the rate of Cesarean sections from 10 % to 5 %, the RRR is 50 %. Generally, a more accurate reporting measure is the "absolute risk reduction" (ARR) [6], which reports the change as an absolute change. (For intervention A, the ARR is 5 %, which may not be as clinically important as the 50 % RRR would suggest.)

In practical terms, an even more helpful measure is the number needed to treat (NNT). The NNT is the number of patients who must receive an intervention in order for one positive change to occur. The calculation for NNT is simply 1/ARR. In the example above, the NNT for intervention A is 20. Clinically, this means that for every 20 patients who receive the intervention, one patient will avoid a Cesarean section. The lower the NNT, the more clinically important the intervention.

While evaluating individual clinical trials can be complex, developing a systematic approach makes it easier. Becoming familiar with a few basic study designs and statistical tests provides access directly to the foundational evidence. Physicians should have skill in the evaluation of individual studies, but may find that using synthesized data, which pools the results of individual clinical trials into systematic reviews and clinical guidelines, improves their efficiency.

Information Mastery

The foundational principles of EBM are defining the clinical question and reviewing the evidence in the literature to answer that question. The volume of individual clinical trials published, however, makes evaluation of all clinical trials by busy physicians impractical. The principles of "information mastery" were developed and popularized by Drs. Shaughnessy and Slawson as a means of making the practice of EBM more practical. These principles refine and limit the scope of the EBM information search by

DOI 10.1007/978-1-4939-0779-3_5-1

encouraging physicians to begin their search for information by first focusing on synthesized information when it exists [11].

Information mastery places a high value on synthesized information when it is available. Using synthesized information in the form of evidence-based texts, guidelines, and systematic reviews will reduce the work of searching. Answering clinical questions by searching for relevant and valid information using synthesized information from online resources such as online textbooks, guidelines, and systematic reviews is the key to efficiency.

Data Systems

Physicians frequently access data systems to answer clinical questions. Physicians may use a reference textbook for answering basic questions or clinical questions that are beyond the scope of their usual practice; however, the information published in hardbound textbooks is not easily updated. Frequently updated online clinical resources are easier to access than published hardbound reference textbooks [12]. These resources have Web-based and mobile platforms that can be accessed without a computer; by their nature, they may contain less outdated material. These subscription services can be purchased by individuals or by hospital systems. An evidence-based online resource will include the date of initial publication and the date each topic has been updated; it will also give references to individual clinical trials, clinical guidelines, and systematic reviews. Physicians can answer many clinical questions from an online text or delve further into the reference materials to evaluate those source materials for validity and application. Accessing a systematically updated online text is frequently the most efficient way to quickly answer a clinical question [11].

Clinical Guidelines

If a clinical question is not answered in an accessible online text, then literature review is necessary. Clinical guidelines and systematic reviews are the next sources to search when efficiency is key. Clinical guidelines can be accessed via the Internet at the National Guideline Clearinghouse (http://www.guideline.gov/). Like individual trials, however, each clinical practice guideline (CPG) should be analyzed for relevance, validity, and clinical applicability. Each guideline is only as valid as the process used to develop it. The Institute of Medicine published criteria for analyzing the reliability of CPGs. According to their criteria, each guideline should (1) be based on a systematic review of the existing evidence; (2) be developed by a multidisciplinary panel; (3) consider important patient subgroups; (4) describe transparently the development process to help minimize distortions, biases, and conflicts of interest; (5) provide alternative care options; (6) provide ratings of both the quality of evidence and the strength of the recommendations; and (7) be reconsidered and revised as appropriate [13].

Understanding the level of evidence and the strength of recommendation in a guideline is an important step in analyzing the validity of that guideline. Table 2 lists the commonly used strength of recommendation taxonomy (SORT) that was developed specifically for family medicine [14]. Table 3 lists the level of evidence that is referenced in the SORT criteria. Physicians should be aware that guidelines created

Table 2 Strength of recommendation taxonomy (SORT)

Strength of recommendation	Description
A	Recommendation based on consistent and good-quality patient-oriented evidence
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence
C	Recommendation based on consensus, usual practice, disease-oriented evidence, case series for studies of treatment or screening, and/or opinion

DOI 10.1007/978-1-4939-0779-3_5-1

Table 3 Level of evidence (LOE)

Study quality	Type of evidence		
	Diagnosis	Treatment	Prognosis
Level 1 Good-quality patient-oriented evidence	Validated clinical decision rule Systematic review or meta-analysis of high-quality studies	Systematic review or meta-analysis of randomized controlled trials (RCTs) with consistent findings High-quality individual RCTs	Systematic review or meta-analysis of cohort studies Prospective cohort studies with good follow-up
Level 2 Limited-quality patient-oriented evidence	Decision rules SR of low-quality studies	Systematic review or meta-analysis of low-quality studies Low-quality clinical trials Cohort studies Case–control studies	Systematic review or meta-analysis of lower-quality cohort studies or inconsistent results Retrospective cohort studies Case–control studies Case series
Level 3 Other evidence	Consensus guideline, usual practice, opinion, disease-oriented evidence, extrapolation from bench research		

Summarized from Ref. [15]

from the US Preventive Services Task Force (USPSTF) and other entities use different labeling systems for strength of recommendation and level of evidence.

Systematic Reviews

Disease and clinical summaries are another form of synthesized information that physicians can access when reviewing the medical literature. Clinical reviews can be accessed via the PubMed search engine by limiting search criteria to review articles; however, just like CPGs, not all clinical summaries are equally relevant or valid. Summary articles may be based only on clinical opinion or personal experience. Systematic reviews are a subset of clinical reviews that are based on a review of the medical literature. Many systematic reviews will contain a meta-analysis, which is the use of statistical methods to summarize the results of individual clinical trials [16].

There are several resources that can be used to access systematic reviews. PubMed Health is a search engine that limits searches to systematic reviews; it can be accessed at www.ncbi.nlm.nih.gov/pubmedhealth. Cochrane database is an additional resource for accessing evidence-based systematic reviews; it can be accessed at www.cochrane.org. The Cochrane Library is a complete listing of the systematic reviews of individual topics produced by the Cochrane organization.

Once a systematic review has been located, it must be reviewed for applicability and relevance. Drs. Swanson and Reed listed the following criteria for family physicians to use when evaluating a systematic review: Systematic reviews should be based on a comprehensive literature search including EBM resources such as the Cochrane databases that describe their method of determining which trials to include, have a transparent system for grading evidence, prioritize patient-oriented evidence over disease-oriented evidence, and make an effort to include unpublished or negative data if possible [17].

The concepts of information mastery as described above make the steps involved in answering clinical questions more efficient. Physicians focus on synthesized data that is relevant, valid, and clinically applicable. Once a clinical question has been answered by a review of the evidence, the physician applies this information to clinical care.

DOI 10.1007/978-1-4939-0779-3_5-1

Applying the Evidence: Shared Decision Making

As previously stated, EBM is more than providing evidence-based answers to clinical questions. The final component of EBM is incorporating patient values into evidence-based clinical care. A practical description of implementing EBM in the clinical setting is sharing the best research information with patients and supporting their decision-making processes as they make choices about the care they receive, a process known as shared decision making (SDM).

SDM is more than patient education. It is a process that can be simple or quite complex, but it always involves participation by at least two people – the physician and the patient (or his or her advocate). The process includes communicating information by both parties, building a consensus about the preferred treatment, and agreeing on the care plan to implement [18]. The physician shares prognostic, diagnostic, or treatment information based on the best evidence available. Likewise, the patient shares information about his or her own goals and values. Finally, a plan for care is negotiated and implemented.

For many clinical scenarios, the process of SDM is relatively straightforward. For example, a patient seen in clinic with a urinary tract infection requests and expects treatment to relieve symptoms and prevent complications. A patient wanting to prevent illness might request an influenza vaccination. In each of these cases, both the patient expectation and evidence are clear. The necessary communication includes a review of the risks, benefits, and alternatives of treatment options. This process can be accomplished verbally or with appropriate printed educational materials.

More complex scenarios often occur, requiring more information and support. For example, a patient requesting treatment for an anxiety disorder may want to consider pharmacologic and nonpharmacologic treatment options. A patient with persistent radicular back pain may want to consider surgical, nonsurgical, or complimentary treatment options (such as acupuncture). A patient also may want to have further discussions with family members, caregivers, or friends prior to making a decision on a treatment plan. A recent systematic review of medical decision making showed that physicians typically are open to shared decision making and that patients frequently desire more involvement in this process [19].

Studying the clinical outcomes related to SDM is complex. Physician–patient relationships and communication methods are not amenable to isolated interventions; they vary in location, duration, and complexity. SDM is currently being advocated by the USPSTF based on ethical, interpersonal, and educational considerations [20]. SDM promotes individual autonomy in complex medical systems, enhances communication, and helps promote patient education. A systematic review of SDM demonstrated that a patient report of SDM correlates well with improved patient satisfaction regarding medical treatment with less associated decisional conflict over care decisions [21].

Models for SDM

Several models describe the individual steps involved in shared decision making [22]; a complete description of these models is beyond the scope of this text. It is helpful, however, to approach this interaction systematically. Physicians will need to continually assess patient desire for information and control during this process. A patient's current understanding of a specific medical scenario should be assessed. Information about clinical options should be clearly stated. Risks and benefits of the various care options should be reviewed. Decision support in the form of written material, videos, pamphlets, or online resources may help the patient through the decision-making process. Decision making may progress quickly, or it may take several interactions and include negotiation to reach a decision.

DOI 10.1007/978-1-4939-0779-3_5-1

Barriers to SDM

Physicians and other members of the medical system encounter barriers to adoption of SDM in clinical practice. Currently, there is little financial incentive to promote discussions about healthcare goals. Many physicians have not been educated on techniques to promote SDM. In addition, physicians may feel the time needed to adequately engage in these conversations makes this process unproductive. Finally, studies have shown that both low health literacy and numeracy limit a patient's ability to understand or engage effectively in the decision-making process [23].

Overcoming Barriers to SDM

Physicians can engage members of the healthcare team to facilitate SDM; for example, a clinical pharmacist, nurse, or health educator can help educate patients on many options for clinical care. Hospitals and healthcare systems may also offer classes that promote chronic disease management. When difficult or complex decisions need to be made, physicians can provide patients with decision aids. These tools aid in communication and may help physicians understand what role the patients want to play in the process.

Decision Aids

Decision aids are particularly helpful when there is more than one reasonable option for clinical care. Aids exist in multiple formats: paper tools, videos, and Web-based resources. A valuable decision aid will include disease information and also help patients reflect upon and explore their own values and healthcare goals. Decision aids describe the benefits and potential risks of various treatment options. Some tools have graphic elements that explain difficult concepts such as risk reduction and NNT. These elements help patients consider care options from a personal point of view. Ultimately, decision aids are tools that promote communication, but they do not replace the role of the physician–patient relationship or meaningful conversation during SDM.

A standard grading system for decision aids has been developed. The International Patient Decision Aids Standards (IPDAS) collaboration has developed a system to grade the components and development process of decision aids; the tool grades decision aids in areas of content, development, and effectiveness [24]. A library of decision aids and their IPDAS grade can be accessed at http://decisionaid.ohri.ca/index.html. A systematic review of the use of decision aids in medical practice showed that patients using a decision aid were more knowledgeable about their condition and had a greater understanding of risks involved in care [25]. It is clear that these tools have an effect on clinical care, and there is a need for further study as their use increases.

Family and Community Issues

Clinical decision making is often a complicated process. Physicians may be tempted to predict patient preferences using a framework that is "rational" or "logical." However, patients may value certain emotional, ethical, and community values over a simple rational approach to decision making. *Individuals* interact with the healthcare system, but each individual is also part of a larger community. Each community can be defined by geographic, racial, economic, and educational influences. Within a community, individuals also may strongly associate with a particular subset defined by vocation, avocation, gender, familial status, or sexual preference. Complex social dynamics play a role in the medical decision-making process. Family physicians can be thoughtful about these issues, but may not have insight into the exact definitions or forces involved. Qualitative research is a tool that physicians can

DOI 10.1007/978-1-4939-0779-3_5-1

use to understand the social, emotional, and experiential phenomenon that their patients experience. Understanding and appreciating these forces can help in the implementation of evidence-based care.

Conclusion

The concepts of EBM have evolved over time, and significant work has been done to simplify the process of incorporating the best evidence into care. Our understanding of healthcare delivery will change as EBM becomes more incorporated into daily patient care. Screening tools, diagnostic methods, and treatment options will be refined. Physicians who use the tools within the EBM process can efficiently incorporate meaningful changes into their practice. Family physicians who embrace these tools in their daily practice should be comfortable knowing that they are providing the best possible care for their patients.

Population Health: Who Are Our Patients?

Richard Bikowski[a]* and Christine Matson[b]
[a]EVMS Family Medicine – Portsmouth Family Medicine, EVMS Medical Group, Portsmouth, VA, USA
[b]Ghent Family Medicine, EVMS Medical Group, Norfolk, VA, USA

Introduction

The US health care is currently undergoing a fundamental transformation. "Population health" is emerging as an important component in a changing system that has traditionally focused on individual patients and encounters.

The Institute of Medicine (IOM) formed the Committee on Quality of Health Care in America in 1996. Two pivotal committee reports identified significant problems with safety and quality in the US health care [1, 2]. Unsafe and fragmented care, under-adoption of health information technology, inadequate application of scientific evidence, and growing complexity of chronic disease in an aging population, were all identified as significant challenges for a delivery model that was "overly devoted to dealing with acute, episodic care. . ." and would "require a fundamental, sweeping redesign of the entire health system" [2]. Two key drivers of this transformation are disappointing performance on measures of health care quality and rapidly escalating health care costs. The USA has consistently demonstrated low rankings in both when compared to many "like" countries with similar economic, social, and political environments [3].

Quality: Evidence consistently shows that the USA lags behind other countries in health measures such as infant mortality, life expectancy, and mortality from causes considered amenable to medical care [4]. Americans only get 54.9 % of evidence-based "recommended care" [5]. More discouraging is a decade of minimal improvement in a majority of the quality measures reported by the National Committee for Quality Assurance (NCQA) for insured patients. Only 52–74 % of women get a mammogram according to evidence-based guidelines, and 45.6 % of diabetics in the Medicaid program have poorly controlled diabetes (A1C $>$ 9 %) [6]. Hospital readmission rates within 30 days of discharge (many avoidable) exceed 20 % for Medicare patients with chronic diseases such as CHF, COPD, and chronic renal failure [7]. The current system does a poor job of identifying patients with gaps in care, ensuring automatic reminders for providers and patients, and providing support and motivation for patients to adopt healthy behaviors and manage chronic illness.

Cost: Health care costs of $2.9 trillion a year account for 17.4 % of the US GDP (up from 7.2 % in 1970) [8]. $9,255 per American is twice the spending of many countries reporting better health outcomes and performance on measures of quality and access [3]. From 2000 to 2010, premiums for health insurance paid by workers have increased at four times the rate of their earnings, with greater increases in recent years, as employers shift more costs to patients. Rising costs are in part related to waste and duplication of services, overtreatment, poor coordination of care, and failure of care delivery in areas of prevention and patient safety. The IOM recently estimated the extent of this waste and ineffective treatment at 30 cents of every health care dollar spent [9]. The dramatic increase in chronic disease accounts for more than 80 % of health care costs. Utilization is highly concentrated, with 5 % of patients accounting for 50 % of health care spending [10].

DOI 10.1007/978-1-4939-0779-3_6-1

Rising costs, waste, gaps in care, and care coordination are poorly addressed by a delivery model that has traditionally focused on one patient, one episode, and one disease, and is encounter-driven and "acute care"-oriented. Patient care is tied to face-to-face encounters with a provider, yet encounters may not occur due to poor access, lack of insurance, or inadequate reminders. If encounters do occur, overburdened primary care providers, who are often solely responsible for the prevention and treatment of acute and chronic illness, do not have the time, the information, or the team support to address all care gaps and patient needs.

Recently, the "Institute for Healthcare Improvement" (IHI) proposed the "Triple Aim," suggesting that improving the US health care system requires the "simultaneous pursuit of three aims: improving the experience of care, improving the health of populations, and reducing the per capita costs of health care" [11]. Evolving models of care such as the "Patient-Centered Medical Home" (PCMH) and "Accountable Care Organization" (ACO) recognize that understanding the patient population served can improve care quality and identify opportunities for cost savings. This emphasis on population health also has the potential to identify high-risk and vulnerable patients and to impact social, behavioral, and economic determinants of health not adequately addressed in our current system.

Defining Population Health

Defining "population health" is not simple and may be viewed differently from a health care delivery versus a public health perspective. The term "population" commonly refers to "the whole number of people or inhabitants in a country or region" where a group is defined in geopolitical terms. Another definition is "a body of people or individuals having a quality or characteristic in common" [12]. Different views and definitions of patient populations have resulted in various approaches to improving population health. Patients with poorly controlled diabetes in a family medicine practice and the women age 50–74 in an Accountable Care Organization who have not had a mammogram are both very useful examples of populations amenable to improvement efforts. Population in this context is best described by the terms "population medicine" and "population management," concepts very useful to a medical system or physician practice in identifying patients who need reminders or outreach for recommended medical interventions. Concern exists that this concept of "population health" may not be broad enough to identify upstream and perhaps more important social, economic, and behavioral determinants of health. Does that poorly controlled diabetic live in a healthy community that fosters good nutrition and exercise? Does the woman needing a mammogram lack insurance or transportation?

The "World Health Organization" (WHO) defines health as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity" [13]. To achieve health defined in this way will require a broader, more community-based view of the population being served. Kindig has described "the health outcomes of a group of individuals, including the distribution of such outcomes within the group" and has proposed a model with mortality and life quality as outcomes where disparities in achieving good outcomes exist and where determinants affecting these outcomes include not just the quality of health care but also individual behaviors, social and environmental factors, and genetics [14]. This more comprehensive definition of population health has been called "Total Population Health" by Jacobson and Teutsch [15] and considers the health of all people in a geopolitical area. Targeted performance improvement activity by physicians and health systems will be helpful in clinically defined "subpopulations," but improving the health outcomes of the total population in a comprehensive way will require collaboration from multiple stakeholders including public health, government, medical providers, employers, and community leaders. The IOM recently initiated a Roundtable Discussion on Population Health with this goal in mind [16].

DOI 10.1007/978-1-4939-0779-3_6-1

Populations in Primary Care (Who Are Our Patients?)

The IOM call for health care transformation has resulted in new and evolving models of care delivery that are the blueprints for building an advanced system of integrated and patient-centered medical homes and neighborhoods with a focus both on the populations and individual patients. The "American Recovery and Reinvestment Act of 2009" (ARRA) has encouraged electronic health record (EHR) vendors to develop helpful tools, and EHR certification mandates functionality that supports practice-based population management. Incentives provided through the "Meaningful Use" (MU) program have markedly increased EHR adoption by providers. The "Patient Protection and Affordable Care Act" (PPACA) advances population health by expanding insurance coverage for uninsured patients, promoting "Accountable Care Organizations" (ACO) and establishing new value and population-based reimbursement programs such as the Medicare Shared Savings and the Value-Based Modifier programs. The ACA has several provisions that encourage research and innovations around quality and value that will help to achieve the Triple Aim. These blueprints, tools, and financial incentives will help family physicians build advanced medical homes with population health capabilities. Populations and "subpopulations" relevant to family physicians include patients in the medical home, neighborhood, and in the community.

Patients in Our Medical Home (Practice Population)

Registry function: Identifying the patients in a practice (usually defined by encounters) is critical for a successful population management. A patient "registry" allows for queries that search, filter, and group patients and identify important clinical information. Registry function is possible in a paper practice but is limited by manual entry and effort to keep data current. Accurate, complete, and automatically updated patient data is a major benefit of EHR adoption and recent MU standards. The first stage of MU required EHR entry of structured, searchable data including patient demographics like age, race and ethnicity, active problems, medication lists, allergies, vital signs and BMI, smoking status, office encounters, and results such as lab testing and immunization administration. Information such as the number of patients with chronic illness in a practice and age and gender distribution allows for "practice-based learning" and provides physicians valuable insight into the care they need to provide.

A registry enables a practice to group patients by chronic disease and health maintenance needs and to identify gaps in care. The number of diabetics in a practice and those overdue for a yearly eye exam, patients prescribed a recalled medication, or children overdue for vaccinations are all examples of "patient lists" easily generated from a practice registry. Registries can help to stratify risks for a practice population and identify patients who would benefit from additional support. Risk categories are useful for grouping patients with similar needs [17]. Higher risk groups account for disproportionate health care spending and utilization of resources and include patients with multiple or poorly controlled chronic diseases, terminal illness, chronic pain or substance abuse, depression, and cognitive impairment. Frequent office visits or hospitalizations and polypharmacy are additional markers of risk that are searchable with a registry. Physicians can review identified patients and determine the need for *care management*. Other at-risk or vulnerable patients include those with multiple emergency room visits, the uninsured or underinsured, and those with social or economic challenges such as poverty, unemployment, or unsafe living situations. These factors are not easily identified by an electronic health record or practice registry nor easily addressed in the traditional practice model.

Meaningful Use stage 2 certified EHRs do provide some registry functionality, including the ability to generate such *patient lists*. Physicians value the ability to update and customize patient queries and reports, not always possible with some EHR reporting. Additional registry software that can analyze the

DOI 10.1007/978-1-4939-0779-3_6-1

data present in an EHR and generate provider-friendly custom lists and reports can add significantly to population management.

A *health risk assessment* is another valuable practice tool, also used by insurance companies, to risk stratify patients. Dartmouth College has developed *howsyourhealth.org* and *healthconfidence.org*. These no-cost, patient-administered tools can identify patient risk factors and functional limitations and provide patient feedback on quality of care and confidence in self-care. Physicians and patients who develop care plans as a result of the health assessment have shown improvements in care. High health confidence and patient engagement in their own care correlate with better health outcomes, better patient experiences, and less costly care [18]. Practices can positively influence patient health confidence by providing quality health information and good access to care [19].

Patient and provider reminders: Registry and EHR technology can automatically generate provider, care team, and patient reminders based on scientific evidence. This "Clinical Decision Support" (CDS) functionality is an MU requirement. Care team members can address reminder alerts at the point of patient care. Registry searches produce "lists" of patients who have not been seen and need care such as screening and lab testing, immunizations, or office follow-up. Reminders can be sent via mail, personal or TeleVox calls, or preferably secure patient portal messaging.

High functioning care teams: In the traditional encounter-driven "Acute Care Model" (ACM), the physician is responsible for all patient care tasks. A typical primary care panel of patients requires 7.4 h a day to meet preventive care needs and 10.6 h to manage all chronic conditions [20]. It is not surprising that many patients do not receive recommended care or that primary care physicians are at high risk of burnout [21]. An aging population and a relatively smaller primary care workforce will increase the problem. Recent advanced practice models emphasize team care with each member of the care team performing duties at the top of their license. Shared responsibility ensures all patients in a practice population get what they need. Practice teams require clearly defined roles for clinical and nonclinical members. Pre-visit planning and communication via daily *huddles* help foster quality and efficiency. Medical assistants and nurses use rooming protocols that include medication reconciliation, registry reminders to close gaps in care, and ordering protocols for immunizations, screening, and lab testing. *Panel management* by clinical staff includes outreach via phone or patient portal to ensure all care gaps are addressed in the population. Medical assistants can take on the role of health coaches, providing education on lifestyle and chronic disease management. Front desk personnel can help coordinate referrals to ensure proper transitions of care and help with patient outreach, reminder, and follow-up. Medical records personnel can satisfy alerts and reset reminders when test results are received and can track to completion ordered tests and referrals that have not been received.

Advanced primary care practices are utilizing RNs for complex "Patient Care Management" (PCM). These care coordinators support patients with poorly controlled chronic disease, encourage self-management, and coordinate care transitions such as hospital emergency room follow-up. Embedded care managers promote shared decision making and care planning involving patient and physician. Team care has led to outcomes such as lower readmission rates, better control of chronic disease, better medication adherence, and lower costs [22].

Recently, many commercial insurers have provided care management fees to practices with these capabilities. Centers for Medicare and Medicaid Services (CMS) payment reforms reimburse practices for team care with new transition of care, annual wellness visits, and, more recently, "Chronic Care Management" (CCM) codes that pay for care coordination performed by nonphysician care team members. Reports that have examined these high-functioning primary care practices show better patient, physician, and staff satisfaction, increased patient access, and increased revenue to support transformation [22].

DOI 10.1007/978-1-4939-0779-3_6-1

Measurement and reporting: Practice-based learning and continuous improvement is an important competency for a primary care practice. It requires measuring performance around process and outcomes of patient care. EHR and registry technology provide a practice with the tools to develop practice scorecards based on nationally recognized quality measures. CMS provides incentives for measuring quality and aligned metrics in the "Physician Quality Reporting System" (PQRS) and the MU program. Rewards or penalties based on performance are part of the "Value-Based Modifier" (VBM) program. These value initiatives are population based and include measures of practice performance on quality, cost, and patient experience. Sharing how the practice is doing with team members and patients, along with organized efforts to continuously improve performance, is an important standard incorporated into advanced care models such as PCMH.

Patients in Our Neighborhood (ACOs and Integrated Networks)

New care delivery models such as PCMH can improve quality and decrease waste and fragmentation of care [23]. Achieving significant progress toward the Triple Aim, however, will require family physicians to embrace a broader view of population and to coordinate effectively with the specialists and hospital systems that provide care for their patients. Such coordination has been recently described in the position paper, "The Patient-Centered Medical Home Neighbor (PCMH-N): The Interface of the Patient-Centered Medical Home with Specialty/Subspecialty Practices" and standardized by the "Patient-Centered Specialty Practice" (PCSP) NCQA recognition program [24]. The ACA promotes population care at the network level with the concept of ACO's and other value and population-based initiatives. Commercial payers are also experimenting with new reimbursement models around quality and care management as they develop agreements with "Clinically Integrated Networks" (CINs), a term now used interchangeably with ACO in describing a collaboration of primary care providers, specialists, and other providers to improve care. Early evidence indicates that integration at this level can improve quality measures and the patient experience and lower the cost of care [25]. Primary care and the PCMH are at the core of these networks, and the patient populations served are defined by a relationship with a primary care provider. Physician leadership and direction with a goal of improving quality is a Federal Trade Commission requirement of clinical integration and likely critical to achieve the Triple Aim. Primary care providers must take on leadership roles and understand the key principles in managing the health of this larger patient population.

Patients in the neighborhood *(patient attribution*): Medicare attributes patients to an ACO using a two-step attribution process. Most patients are assigned having received a majority of "primary care services" from a primary care physician (step 1). Patients not seeing a primary care provider are attributed based on a majority of ambulatory visits with a specialty provider (step 2). Commercial payers frequently follow similar PCP assignment models based on plurality of visits. Importantly, these methods of PCP/patient attribution may not always align with the perception of the patient or the provider.

Contracts with private CINs often involve populations defined by larger self-insured employer groups, and network collaboration with the employer is important. Quality performance and care coordination of the entire population served by an ACO is the responsibility of all network providers. This global population view is critical for network success but will require a change in thinking for physicians who have been trained and practiced in an encounter-driven, fee-for-service system.

"Network Registry" (Big Data): A network can bring family physicians population management resources not available to smaller independent practices. Data is more complete, as these registries can aggregate data from multiple sources including labs, EHR feeds, hospitals, pharmacies, state immunization registries, insurer claims, and physician member billing claims. Physician encounters and payer

DOI 10.1007/978-1-4939-0779-3_6-1

attribution define the network population. Combining this encounter data with comprehensive clinical information allows for accuracy of quality measures and reporting functionality not available to physician practices. Payer partners provide total costs of care information and the ability to identify cost saving opportunities not available from other sources. Risk analysis and *predictive modeling* tools can group patients by risk groups for effective care management and identify areas of inappropriate utilization. Information on ER use, avoidable hospital admissions and readmissions, medication prescribing and adherence, and unnecessary diagnostic testing is very helpful in planning interventions to improve outcomes and decrease cost of care. For practices unable to support care managers internally, provision by ACOs is highly effective. Commercial payer contracts provide a care management fee to networks for care coordination done in partnership with physicians who have an established relationship with the patient, an important advantage not available in traditional payer disease management programs.

Collaboration: Physician networks provide an infrastructure that facilitates working relationships among the primary care, specialists, hospital system, and other providers. Coordination of improvement efforts based on data and evidence-based guidelines, transparent reporting of performance on quality metrics, identification of opportunities to reduce cost as outlined in the "Choosing Wisely" initiative [26], and commitment to best practice and success for all network providers are key elements for network success. Active physician engagement, leadership in governance, and decisions on quality initiatives, contracts, and incentive distribution differentiate ACOs from the managed care "gatekeeper models" of the 1980s.

Payment reform: Fee-for-service has been the predominant payment model in the US health care and rewards volume and utilization. "Value-Based Payment" (VBP) rewards good outcomes, supports primary care and care management, and reduces unnecessary spending. Current value/population payment models include care management fees, incentive for quality performance, and sharing in network-generated savings. Shared savings programs have been criticized for putting networks and providers at risk, even in "no risk" models, because significant up-front investments are required that may not be recouped. Additionally, year-to-year savings are not likely to be sustainable in the long term. Alternative payment models have been suggested: "fee-for-service" (FFS) for desired care such as immunizations or unavoidable events such as accidental injuries, "episode-of-care payment" and "bundling" for an entire episode of care such as labor and delivery or major joint replacement, and "comprehensive care payment" for care of chronic illnesses like diabetes and CHF, with risk adjustment based on patient population complexity [27]. All have advantages and disadvantages. Networks provide the framework where trusting relationships can develop and communication can occur among all providers and stakeholders so that Value-Based Payment models can be tested and continue to evolve.

Total Population Health

As previously discussed, addressing practice populations with the use of data tools such as patient registries provides the opportunity to examine specific intermediate outcomes based on patient characteristics, provider interventions, or other parameters. This approach, or "population medicine," is characterized by a relationship (physician to multiple unique patients registered in the practice). A wider focus on the health of all those individuals in our geopolitical area (Kindig's "Total Population Health") [14] compels providers to consider a broader range of behavioral, community/environmental, social, and physical factors that influence health outcomes, beyond the quality of clinical practice or even population-based medicine. Family medicine has a rich history of connection with our communities, as the discipline was born out of the 1960s, with its focus on social justice and expanding access to primary care [28]. As many new academic departments of family medicine were founded, they found expression in the "Community-

DOI 10.1007/978-1-4939-0779-3_6-1

Oriented Primary Care" (COPC) model developed in South Africa by Kark and Cassel and interpreted in this country by Nutting [29] and others. This movement included their mission for the underserved and uninsured in their title as departments of family and community medicine. Also developing in the 1960s was the concept of the community health center [30, 31] serving not only those in the center's panel but also the community in which the center was located, often with leadership from the community. The *multidisciplinary teams* assembled by community health centers, including physicians and nurses, educators, social workers, lay health workers, and sometimes dental practitioners, could begin to address the multifactorial "social determinants of health" (SDH) in communities, in addition to providing needed medical care. This model of varying professionals bringing their respective lenses for a sharper focus on patient-centered care within the context of their families and community is the one that has broad application today (the assemblage of professionals now called "interprofessional teams").

Fast forward now to the previously cited fact that the USA spends almost twice as much for per-person health care than any other country yet with very poor outcomes in measures of the health of the population. Could this be a widespread poor quality of health care that is being provided, or are there other explanations for this *health gap* between the USA and other developed countries? Certainly, waste within the system accounting for one-third of total health care expenditures is a huge reason for relatively costly care in the USA, with the startling irony that this waste diverts dollars in the federal budget away from other areas that play a substantial role in health outcomes, such as education and employment opportunities [32].

Camara Jones describes the range of factors affecting "health outcomes" using concentric circles [33] with "health behaviors" at the center of determinants (explaining ~80 % of outcomes) and "social determinants of health" as the next level (e.g., education and health literacy; socioeconomic status affecting opportunities and resources). But Jones describes yet another concentric circle in this diagram: "social determinants of equity." For example, "zip code matters" in determining rates of infant mortality or differential spending per student among school districts affecting whether or not a child has access to early childhood programs: an intervention highly correlated with health outcomes later in life. Jones' metaphor of "red flowers and pink flowers" also illustrates how institutionalized, interpersonal, and internalized racism lead skin color to be mistaken for "hardwired" risk for disease (and therefore beyond our control, opportunity, or responsibility for addressing disparities in health outcomes).

Medical training has been filled with examples of ways that we learn to "blame the patient" for poor *outcomes*, including the label of "noncompliance" with treatment plan when cost of pharmaceuticals, even generics, makes their purchase beyond reach for some, provider attitudes toward obese patients regardless of underlying predisposing national policies and environmental influences [34], and office policies that a patient will be dismissed for the third "no show." However, when motivated by PCMH principles to drill down on suboptimal outcomes such as the "Did Not Keep Appointment" (DNKA) list, many practices find that transportation (e.g., "my Medicaid ride didn't come") leads the reasons for "DNKA," and practices that track *High Emergency Department Utilizers* find thoughtful reasons for going to the ED instead of the primary care office (e.g., not risking losing a day of work without being seen or having all tests/consultations done at once) [35].

All these and other barriers to access to care illustrate the "social determinants of health" (e.g., higher poverty, obesity, and stress levels) that partly explain the USA's relatively poor *health rankings*. They must be addressed to improve overall health in the population. Within the medical home, building *interprofessional teams (*nurses as care managers, pharmacists, social workers, community health workers, legal aid) to help address these barriers have been reported to be highly effective in reducing readmissions and unnecessary emergency department use [36]. The Camden Coalition of Healthcare Providers identified "super-utilizers" of emergency department services through a city-wide database of ED use and organized a system that improves coordination and quality of care and at the same time reduces cost [37].

DOI 10.1007/978-1-4939-0779-3_6-1

This perspective represents a major shift from the more limited approach of seeing patients who come to us and attempting to provide the best possible care, often dismissing those who do not keep their appointments with us or labeling those unable to follow the treatment plans we prescribe as "noncompliant." In a population-based system in which the goal is to facilitate improved *health status* among individuals in the community served, providers must measure the effect of interventions or services in populations receiving them; seek to improve outcomes of care, i.e., quality improvement; search for those factors (social determinants of health) that prevent our population from reaching a state of *optimal health and function*; and identify and work toward potential solutions for those factors that lead to unequal and unjust health outcomes within our community (*social determinants of equity or disparities*).

Who Is Accountable for Individuals in Our Community?

So how can family physicians act within their practices, or practice group, or delivery system, or as motivated citizens to bridge the gap between focus on health outcomes for their patient panel and improving health at the level of their community? One familiar intervention that spans care of individuals and community health is preventing by counseling and screening for and treating sexually transmitted illness (STI) that in turn reduces the spread of the STI within the community. Active engagement in identifying and modifying when possible the common risk behaviors that together account for a substantial proportion of mortality (tobacco use, poor nutrition, physical inactivity, and unhealthy alcohol use) is imperative to offer to patients within one's practice. This focus on prevention can also extend to the community by offering options such as smoking cessation workshops, advocating for removal of unhealthy food choices in school vending machines, and supporting community resources offering alcohol and substance abuse prevention and treatment. Sponsoring "Walk with my Doc" Saturdays, promoting national initiatives such as the "Million Hearts Campaign," and serving on one's local or state Academy's Health of the Public committee can have ripple effects in the community and beyond. At another level, the difference between clinical practice with focus on individual behaviors *relative risk* versus *attributable risk* in populations (as defined, e.g., by census tract, average income level, or prevalence of crime) highlights a strength of the population-based approach. Physicians can examine the distributions of health outcomes within their practices and potentially identify the factors behind disparities thus identified. Electronic health records now commonly can produce reports of distributions of physiologic outcomes (e.g., blood pressure or A1C) by a provider or practice and in some cases by the age of the patient, or self-identified race, or comorbid disease state. The next level identifying not only the community or census track where the patient/family lives but also identifying the *community vital signs* known to convey attributable risk (or protection) to those who reside in that area could be of considerable importance in recognizing factors associated with poor treatment response or *disparities in outcomes*.

Collaborating with the multi-sectoral health system in *coalitions* of organizations whose core mission is addressing *upstream factors* for health may be beyond the motivation or ability of an individual physician. But physician organizations can through representatives participate in such *coalition*, not necessarily as leaders but by bringing their perspective as health care providers to clinical/community partnerships, with members of the community defining the issues most important to the health of the community. Physicians' influence with *change agents* from the community, including those in business, government, and other policy-makers can be instrumental in shifting toward alignment of incentives for improved health across the spectrum of stakeholders. Family physicians can build on a foundation of primary care-based patient-centered medical homes, integrating with the patient-centered neighborhood of specialty care all embedded within accountable care communities. These structures will increase possibilities and incentives for addressing upstream determinants of health and equity and give us the opportunity to achieve the higher level of total population health that we seek.

Clinical Prevention

Roger J. Zoorob*, Maria C. Mejia de Grubb and Robert Levine
Department of Family and Community Medicine, Baylor College of Medicine, Houston, TX, USA

Traditionally, there are three tiers of clinical prevention: (a) primary, before disease onset; (b) secondary, after disease onset but before clinical signs or symptoms; and (c) tertiary, after clinical signs and/or symptoms. Examples include immunization (primary), screening (secondary), and post-diagnostic patient education (tertiary – e.g., teaching patients with pedal peripheral neuropathy to check bathwater temperatures with their arms).

Healthy People 2020 Leading Health Indicators

The Healthy People program, led by the US Centers for Disease Control and Prevention (CDC), provides a national blueprint for health that identifies 26 issues of high-priority objectives, four of which apply directly to clinical prevention. Improvement has been recorded in three of these areas: colorectal cancer screening, increasing from 52 % in 2008 to 59 % in 2010, with a target of 71 % by 2020; the percentage of adults with hypertension whose blood pressure is under control, increasing from 44 % in 2005–2008 to 49 % in 2009–2012, with a target of 61 % by 2020; and childhood immunization, with the percentage of children receiving recommended doses of DTaP, polio, MMR, Hib, hepatitis, varicella, and PCV vaccines by ages 19–35 months increasing from 44 % in 2009 to 69 % in 2011 with a target of 80 % by 2020. In contrast, there was little or no detectable change for diabetes control, which only increased from 18 % in 2005–2008 to 21 % in 2008–2012 [1]. Additional data has shown that only 28 % of smokers received recommended preventive care, 37 % of adults aged 50 and older received a flu vaccination, and only 40 % of sexually active young women received annual screening for chlamydial infection [2].

Key Recommendations from the US Preventive Services Task Force (USPSTF) and Advisory Committee on Immunization Practices (ACIP)

Three key recommendations from the USPSTF – tobacco cessation screening and assistance, discussing daily aspirin use, and alcohol counseling with brief counseling – were cited as examples of services that could contribute significantly to net additional yearly medical savings if delivery were increased [3]. Along with colorectal cancer screening, an increase to 90 % delivery would have contributed 100,000 years of life to the US population in 2006. Recommendations concerning aspirin [4] were tempered in May 2014 when the Federal Drug Administration (FDA) cautioned that the totality of evidence for primary prevention is not yet sufficient to make general guidelines for aspirin prescription [5]. The FDA advised that individual clinical judgment by providers is required [5]. Additionally, it was noted [3] that childhood immunizations as recommended by ACIP could save 1,233.1 life years per 10,000 people per year of intervention at an annual net savings of $267 per person per year in medical costs.

DOI 10.1007/978-1-4939-0779-3_7-1

Screening Evidence in Clinical Prevention

Screening is the most prominent example of secondary prevention. In general, screening is appropriate when the following conditions are met: (a) the disease must affect a sizable portion of the population and/or have a high level of severity; (b) the detectable preclinical phase of the disease cannot be so short as to require rapid rescreening since this can become overwhelming in terms of logistics and/or cost; (c) early detection must lead to either a better outcome for the individual being screened or to effective prevention of the spread of the disease to others, and these benefits must be more likely when the disease is detected before signs or symptoms appear; and (d) the screening test itself must be safe, acceptable to those targeted for screening, and valid (i.e., sufficiently capable of truly distinguishing between those with and without the disease) [6]. Further, when evaluating a screening program, several types of bias must be avoided. These include lead time bias (e.g., crediting early detection with improved survival when all that has happened is earlier detection); prognostic selection bias (people who choose to be screened may be more likely to take care of themselves and therefore to have a better clinical course than those who do not choose to be screened); and length bias (deaths due to more aggressive disease may occur during the inter-screening interval, meaning that disease detected at screening is less severe) [7]. Randomized, controlled trials are ways to overcome such bias [7].

A number of measurements are available for assessing screening tests. An example is shown in Fig. 1: a = screening test positive and disease present (true positives) = 300, b = screening test positive and disease absent (false positives) = 100, c = screening test negative and disease present (false negatives) = 50, and d = screening test negative and disease absent (true negatives) = 550. In this case, sensitivity or positivity in disease is 300/350 or 86 %. Tests with high sensitivity have relatively few false-negative results. Specificity or negativity in health is 550/650 or 85 %. Tests with high specificity have relatively few false-positive results.

While some screening test results are dichotomous ("yes" or "no," as for tuberculin skin tests), many others, such as fasting plasma glucose, are continuous. When screening results are continuous, a cutoff value is often chosen to distinguish a positive test from a negative test. This produces a trade-off between sensitivity and specificity. Specifically, as the cutoff criterion decreases, the number of false negatives decreases while the number of false positives increases, thereby increasing sensitivity and decreasing

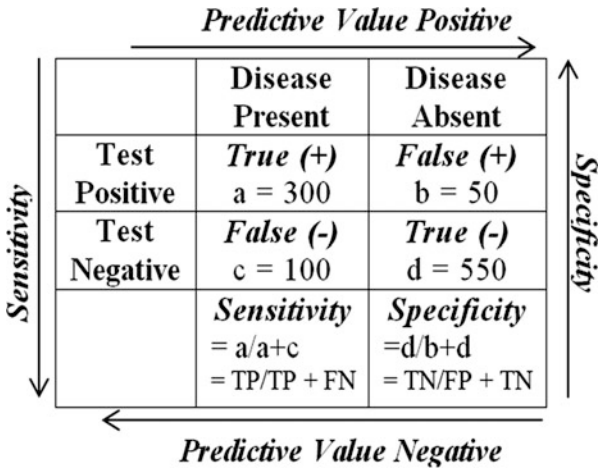

Fig. 1 Sensitivity and specificity of screening tests (As the cutoff criterion decreases, the number of false (−) decreases, while the number of false (+) increases, thereby increasing sensitivity and decreasing specificity. In contrast, as the cutoff criterion increases, the number of false positives decreases, and the number of false negatives increases, thereby increasing specificity and decreasing sensitivity)

DOI 10.1007/978-1-4939-0779-3_7-1

specificity. In contrast, as the cutoff criterion increases, the number of false positives decreases and the number of false negatives increases, thereby increasing specificity and decreasing sensitivity. Also, the specificity of a test may be improved (and sensitivity reduced) by requiring a positive result from two tests, while the reverse occurs if a positive result on either of the two tests is required. Receiver Operating Characteristic (ROC) curves – graphs in which sensitivity (y-axis) is plotted against 1-specificity (x-axis) – are also used to estimate the best cut point.

Several other types of information may be obtained. These include:

- Prevalence = (a+c)/(a+b+c+d) = 350/1,000 = 35 % = proportion of persons being tested who have the disease.
- Accuracy = (a+d)/(a+b+c+d) = 850/1,000 = 85 %. If the prevalence of the disease being tested differs in two populations undergoing screening, the accuracy of the test could be different even if the sensitivity and specificity were the same.
- Predictive value of a positive test (PV+) = a/a+b = 300/400 = 75 % = proportion of persons with a positive screening test who have the disease. As the prevalence of disease among those being screened decreases, the PV+ decreases.
- Predictive value of a negative test (PV−) = d/c+d = 550/600 = 92 % = proportion of persons with a negative screening test who do not have the disease. As the prevalence of the disease among those being screened decreases, the PV- increases.

PV+ and PV− are both influenced by prevalence. For example, screening for a hematologic disease in a hematologist's office would be expected to produce a higher predictive value than screening with the same test in a primary care clinic. Positive and negative likelihood ratios, in contrast, address similar questions but do not depend on prevalence:

- Positive likelihood ratio = sensitivity/(1-specificity) = 0.86/0.15 = 5.73 = a positive screening test is 5.73 times more likely to occur among those with the disease than among those without the disease.
- Negative likelihood ratio = (1-sensitivity)/specificity = 0.14/0.85 = 0.16 = a negative screening test is 0.16 times more likely among persons with the disease than among persons without the disease.

In all cases, the discomforts and risks associated with screening, including the stress of waiting for diagnostic results and possible adverse effects associated with testing, need to be considered when ordering a screening test. Also the evidence base for clinical prevention is rapidly evolving. Therefore, while we have endeavored to provide current information in this chapter, providers should keep track of evidence and recommendations as they appear and treat patients accordingly.

Health Maintenance

All clinical encounters are opportunities for health promotion and disease prevention, including early identification of risk behaviors and disease, updating immunizations, and providing health guidance. Family medicine encounters, in turn, act in conjunction with preventive interventions provided through schools and other community resources. The US Preventive Services Task Force (USPSTF) is a leader in providing evidence-based guidance for clinical prevention in primary care. The Task Force is an independent volunteer panel made up of experts from preventive and primary care medicine and nursing. Convened by the Agency for Healthcare Research and Quality (AHRQ), the Task Force gives a letter grade based on the strength of evidence pertaining to the benefits and harms of services that may be

DOI 10.1007/978-1-4939-0779-3_7-1

offered to people being in the primary care setting and who do not have signs or symptoms of a specific disease or condition. "A" and "B" grades are given to those services for which the Task Force has found good or fair evidence of benefit. All such services are mandated for coverage as part of the Affordable Care Act (ACA). As Task Force recommendations are regularly updated, the ePSS (Electronic Preventive Services Selector) is a convenient tool to identify recommended services based on the patient's sex, age, pregnancy status, tobacco use, and sexual activity. It is available at http://epss.ahrq.gov/PDA/widget.jsp. The Task Force does not review all types of preventive services, however. In particular, it defers to the Advisory Committee on Immunization Practices (ACIP) for annual reviews and updates of the recommended immunization schedule. Primary care physicians should refer to the CDC Vaccines and Immunizations website (http://www.cdc.gov/vaccines/recs/default.htm) for updates and the most current schedules. In the following sections, primary and secondary preventive services as recommended by the Task Force and other organizations according to patient age are described. Additional reviews of prevention for infectious diseases (e.g., postexposure, travel and occupational prophylaxis, screening for tuberculosis, etc.) may be found in other chapters in this volume.

Prevention for Infants, Children, and Adolescents (Birth to 18 Years)

Immunization

***Birth to eighteen years*:** The immunization program is one of the most successful examples of effective preventive care in the United States. Through immunization, infants and children can be protected from 14 vaccine-preventable diseases before age two. Low prevalence of most vaccine-preventable diseases has been the result of high coverage (90 % and above) for many childhood vaccinations in the last two decades. Yet, while more than 90 % of children aged 19–35 months are getting the recommended vaccines, booster shots and second doses lag for 2-year-olds [8]. Additional efforts by parents and healthcare providers are warranted to maintain and improve the rate of administration of recommended immunizations.

The ACIP recommends the administration of all age-appropriate vaccines during a single visit. If a dose is not administered at the recommended age, however, it should be administered at a subsequent visit. The CDC Vaccines and Immunizations website provides the catch-up schedule. An Instant Childhood Immunization Scheduler is also available at http://www2a.cdc.gov/nip/kidstuff/newscheduler_le/. Through this link, providers can generate a personal, customized patient immunization schedule.

In addition to *childhood immunizations*, ACIP recommends that *immunizations for adolescents* include one dose of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine; two doses of meningococcal conjugate (MenACWY) vaccine; and three doses of human papillomavirus (HPV) vaccine [9]. Annual influenza vaccinations for all persons aged ≥6 months and "catch-up" vaccinations such as measles, mumps, and rubella (MMR), hepatitis B, and varicella vaccinations are also recommended [9]. See Fig. 2.

Federal law mandates that healthcare staff provide a Vaccine Information Statement (VIS) containing both the benefits and risks of a vaccine to a patient, parent, or legal representative prior to the administration of a vaccine. Adverse events associated with vaccines should be reported to the DHHS using the Vaccine Adverse Event Reporting System (VAERS, http://vaers.hhs.gov/index).

Prophylaxis

***Newborn*:** *Ocular Prophylaxis for Gonococcal Ophthalmia Neonatorum* should be provided within 24 h of birth. At present, 0.5 % erythromycin ophthalmic ointment is the only approved drug approved for this purpose by the US Food and Drug Administration.

DOI 10.1007/978-1-4939-0779-3_7-1

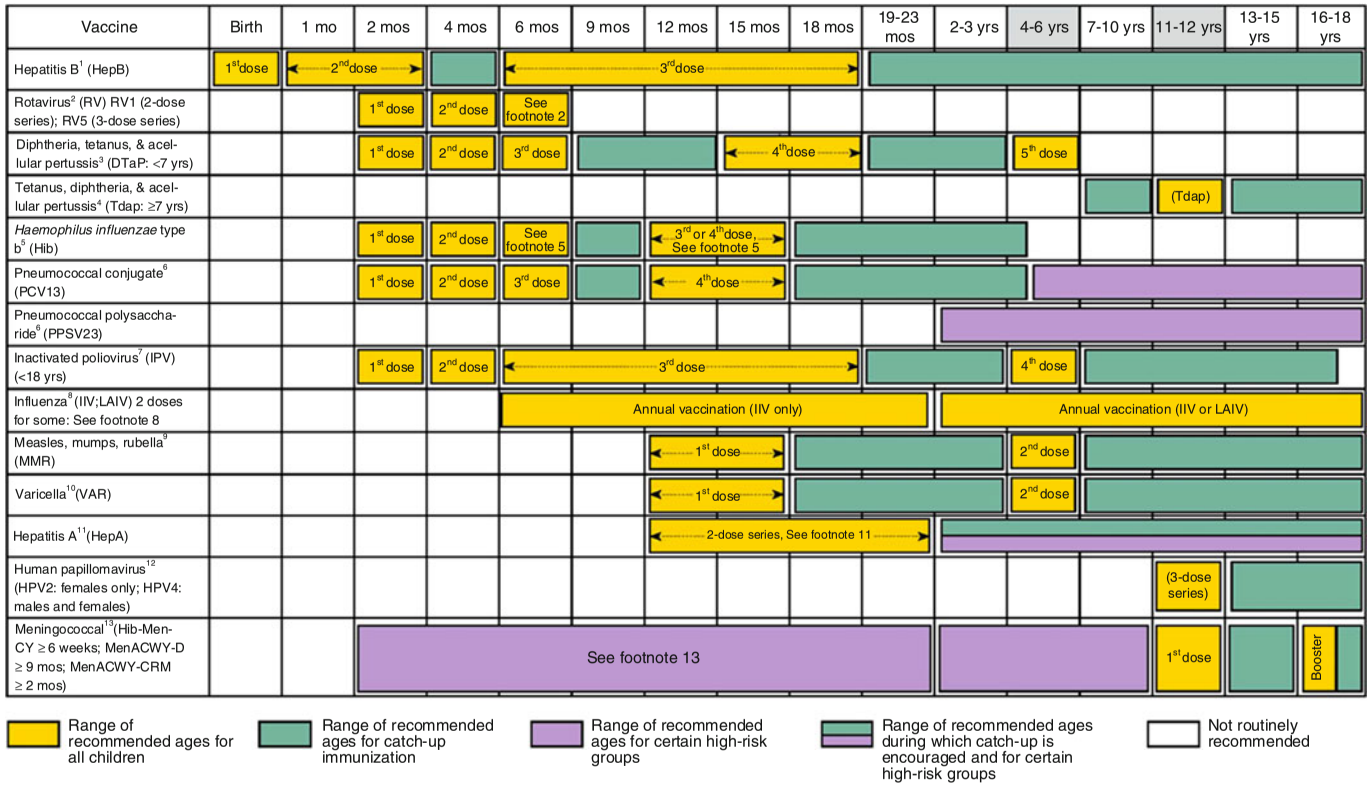

Fig. 2 Recommended immunization schedule for persons aged 0–18 years – United States, 2014 (Note: The above recommendations must be read along with the footnotes of this schedule. See: http://www.cdc.gov/vaccines/schedules/downloads/child/0-18yrs-child-combined-schedule.pdf. This schedule includes recommendations in effect as of January 1, 2014. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant ACIP statement for detailed recommendations, available online at http://www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/index.html. Clinically significant adverse events that follow vaccination should be reported to the VAERS online (http://www.vaers.hhs.gov).). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm)

DOI 10.1007/978-1-4939-0779-3_7-1

***Six months to 17 years*:** For oral health, the USPSTF recommends applying *fluoride* varnish to the primary teeth of all infants and children starting at the age of primary tooth eruption and prescribing oral fluoride supplementation starting at age 6 months for children whose water supply is deficient in fluoride (<0.6 mg fluoride ion/L [ppm of fluoride]). The USPSTF recommends routine supplements with iron for asymptomatic infants aged 6–12 months who are at increased risk for IDA. *Folic acid* prophylaxis (400 micrograms per day) is recommended for females beginning at age 15 years in order to prevent spina bifida and anencephaly, in part because more than half of pregnancies are unplanned and because these birth defects occur during the first three to four weeks of conception, when many women are unaware they are pregnant.

Counseling and Anticipatory Guidance

***Birth to two years*:** Counseling and anticipatory guidance during the first 2 years of life may decrease hospitalizations among children irrespective of race and health status, especially among the socioeconomically vulnerable [10]. This part of the visit allows the family physician to provide culturally and developmentally appropriate information about the patient and is an effective tool to educate parents about maintaining children's health. It is also important to document all counseling efforts. Particular attention should be given to parental concerns such as those related to newborn care, breastfeeding decisions, potential health/environmental risks, and safety. *Breastfeeding* should be encouraged. The benefits of breastfeeding include lower risk of ear infections, respiratory tract infections, and incidence of gastrointestinal infections. Furthermore, studies also show that breastfed children are less likely to present with asthma, type 2 diabetes, and obesity [11]. The AAP recommends exclusive breastfeeding and/or human milk for infants for the first 6 months of life and continuing at least through the first year in addition to complementary foods, except in rare circumstances such as HIV infection or galactosemia. The USPSTF found adequate evidence to indicate that formal breastfeeding education increases rates of initiation, duration, and exclusivity of breastfeeding. Although the USPSTF has not made a recommendation about infant *safe sleep*, sudden infant death syndrome (SIDS) incidence has decreased since the AAP's 1992 recommendation that infants be placed for sleep in a non-prone position. However, recent data shows an increase of other causes of sleep-related deaths including suffocation, asphyxia, and entrapment. To address this new evidence, the guidelines have been updated to include recommendations for a safe sleep environment for all infants such as firm sleep surface, breastfeeding, room-sharing without bed-sharing, and avoidance of overheating and exposure to tobacco smoke, alcohol, and illicit drugs [12]. Children are particularly vulnerable to the effects of *secondhand smoke*. It increases the risk for SIDS, asthma, otitis media, and lower respiratory tract infections [13]. The American Academy of Family Physicians (AAFP) strongly recommends that physicians counsel smoking parents with children in the house regarding the harmful effects of smoking and children's health.

Primary prevention with provider counseling to include environmental assessments is recommended by the CDC prior to screening for elevated *blood lead* levels in asymptomatic children who are at increased risk. Children who are on Medicaid, living in poverty, and living in older housing are considered to be at especially high risk (USPSTF Grade: I). The physician should inquire about in-home exposures, unsafe renovation practices (houses built before 1978), and potential lead exposures associated with parental occupations and hobbies. Until recently, the CDC used a *blood lead* level result of 10 or more micrograms per deciliter (μg/dL) as a "level of concern" with respect to screening for lead exposures. In 2012, the term "reference value" $\geq$ 5 μg/dL was introduced to identify children who have been exposed to lead and who require case management. Confirmatory testing, ongoing monitoring of blood lead level, and assessment of iron deficiency and general nutrition (e.g., calcium and vitamin C levels) are also required. The recommendation for medical treatment (tertiary prevention) is chelation for lead levels $\geq$ 45 μg/dL.

DOI 10.1007/978-1-4939-0779-3_7-1

The American Academy of Pediatrics issues extensive policy statements on the prevention of *drowning*, including the use of direct counseling, handouts, websites, and other educational materials as well as specific targeted messages to children with special risks. Community efforts should also be supported [14].

***Three to ten years*:** Anticipatory guidance and counseling for *lead exposure* should continue through at least 5 years of age. Anticipatory guidance is also warranted during well-child visits in such areas as nutrition, healthy lifestyle practices, and injury prevention. Recommendations for counseling for *lifestyle risk factors* include encouraging a diet high in fruits and vegetables and low in fats; eating a healthy breakfast daily; regularly eating meals as a family; limiting the consumption of sweetened beverages, fast foods, and high-fat snacks; and limiting television and other screen time to no more than 2 h/day [15]. The US Department of Health and Human Services (DHHS) recommends that children participate in at least 60 min of physical activity daily. Parents should be encouraged to motivate their children to play and to lead by example by participating in an active lifestyle.

Drowning is the main cause of death due to injury among children aged 3–4 years, and anticipatory guidance is important throughout childhood and adolescence [14]. Most deaths of children aged 5–10 years are due to *traffic injuries* as occupants, pedestrians, bicyclists, or motorcyclists. The USPSTF refers clinicians to the CDC's Community Guide recommendations for actions that they could support within the community, such as laws mandating the use of children's car seats, safety belts, and helmets along with education programs, community-wide information, and enhanced enforcement campaigns (http://www.thecommunityguide.org). The use of child safety seats and safety belts are among the most important preventive measures to reduce motor vehicle-related injuries and deaths [16]. The AAP recommends that infants and toddlers should ride in a rear-facing car seat until they are at least 2 years old.

***Eleven to eighteen years*:** *Unintentional injuries* (from traffic injuries and other causes as stated above) continue to be major causes of death, and counseling/anticipatory guidance should continue as well. Counseling and interventions to reduce *cardiovascular risk* (e.g., healthy weight, smoking cessation) and reduce involvement in health-risk behaviors (e.g., alcohol and drug use, unsafe sexual practices) are also a priority. Anticipatory guidance should be provided about the benefits of regular physical activity (at least 60 min per day) to reduce the risk of developing obesity and chronic diseases, decrease the risk of depression and anxiety, and promote psychological well-being. Children aged 10 years and above who have fair skin should be advised about minimizing their exposure to ultraviolet radiation to reduce risk for skin cancer and especially to avoid excess/midday sun exposure, to wear protective clothing, and to use sunscreen as directed [4].

An evidence-based statement from the American Dietetic Association recommends using *family-based lifestyle interventions* for children and adolescents. Parents should be encouraged to lead by example by providing a healthful food environment and by discouraging the consumption of unhealthy foods outside the home [4]. Cyberbullying is associated with *mental health and substance use* problems in adolescents. In addition to counseling about avoiding online behaviors that can have negative consequences, such as "sexting" and sharing of personal information and pictures with strangers, the clinician should confer about strategies to deal with bullying and resources available through recognized organizations such as Bright Futures (http://www.brightfutures.org/mentalhealth/pdf/families/mc/bullying.pdf).

All sexually active adolescents are at risk of *sexually transmitted infections*. In 2013, 34 % of 9th through 12th grade American students reported having sexual intercourse within the last 3 months, and only 59 % used a condom during the last episode [14]. Family physicians should provide high-intensity behavioral counseling to prevent STIs including HIV infection and unintended pregnancy. *Tobacco* use is the main cause of preventable illness and death in the United States, accounting for more than 480,000 deaths per year or 1,300 per day [17]. Most smoking and smokeless tobacco use begins in youth and young adulthood. In 2012, 23.3 % of high school students and 6.7 % of middle school students reported current use of any tobacco product [18]. Education and counseling reduces the chances children and teens

DOI 10.1007/978-1-4939-0779-3_7-1

will start smoking. Interventions include direct counseling with teens individually or with families, videos, apps, print materials, activity guides, workbooks, and preprinted prescriptions. While there is insufficient evidence that routine counseling by an individual practitioner to reduce *alcohol and illicit drug misuse* in children and adolescents is effective, the AAFP recognizes the importance of counseling aimed at alcohol avoidance by adolescents aged 12–17 years and strict prohibition of driving under the influence of alcohol or impairing agents at any age.

Screening

Comparisons between the USPSTF and the American Academy of Pediatrics (AAP) screening recommendations are summarized in Tables 1 and 2.

Table 1 Comparison of USPSTF A and B recommendations with corresponding recommendations from the American Academy of Pediatrics

Recommendation	USPSTF[a]	American Academy of Pediatrics[b]
Height and weight BMI	Screen children aged 6 years and older; offer or refer for intensive counseling and behavioral interventions	BMI calculated and plotted at least annually
Hypertension	Insufficient evidence to make a recommendation (before 18 years)	Annually beginning at 3 years of age
Newborn blood screening	Congenital hypothyroidism, phenylketonuria, and sickle cell disease	Universal newborn screening (31 conditions)
Critical congenital heart disease	No recommendation	Newborns using pulse oximetry
Hearing loss	Newborn screening but no recommendation beyond the newborn period	Newborn screening. Confirm positive newborn screen by 3 months with comprehensive evaluation. Continue regular assessments throughout childhood
Vision screen	Screen children aged 3–5 years at least once	Assess at 3, 4, 5, 6, 8, and 10 years, and once during each period of early, middle, and late adolescence
Eye prophylaxis	Newborns	Newborns
Iron deficiency anemia	Insufficient evidence to make a recommendation	Hemoglobin at 1 year of age. Risk assessment at 4-, 15-, 18-, 24-, and 30-month visits and annually thereafter
Dyslipidemia	Insufficient evidence to make a recommendation (up to age 20 years)	Assess risk at 2, 4, 6, and 8 years of age. Universal screen between 9 and 11 years of age
Dental caries Prevention, birth to age 5 years	Apply fluoride varnish to the primary teeth of all infants and children starting at the age of primary tooth eruption	Oral health assessment for all children by age 6 months and a first dental visit by age 1 year
Immunization	Refer to Advisory Committee on Immunization Practices (ACIP) http://www.cdc.gov/vaccines/recs/schedules/default.htm	
Speech and language delay in preschool children	Insufficient evidence to make a recommendation (children $\leq$ 5 years of age)	Periodic screening for developmental delays. Administer screening tests at the 9, 18, and 30 month visits
Autism spectrum disorder (ASD)	Topic review in progress	If no concerns have been raised during the course of the preventive visit and the child is not the sibling of a child who has already been diagnosed with an ASD, screening with an autism-specific tool is indicated at 18 or 24–30 months

(*continued*)

DOI 10.1007/978-1-4939-0779-3_7-1

Table 1 (continued)

Recommendation	USPSTF[a]	American Academy of Pediatrics[b]
Major depressive disorder (MDD)	Adolescents (aged 12–18) when systems are in place to ensure accurate diagnosis, psychotherapy, and follow-up. Use Patient Health Questionnaire for Adolescents [PHQ-A] and the Beck Depression Inventory-Primary Care Version [BDI-PC]	
Tobacco use in children and adolescents	Provide interventions to prevent initiation of tobacco use in school-aged children and adolescents: face-to-face or phone interaction with a healthcare provider, print materials, and computer applications	Counseling starting at 5 years against initiating tobacco use and provide counseling on tobacco cessation. Also advise all families to make their homes and cars smoke-free
Alcohol misuse, adolescents	Insufficient evidence to make a recommendation Note: The AAFP recognizes the avoidance of alcohol products by adolescents aged 12–17 years is desirable. However, the effectiveness of the physician's advice and counseling in this area is uncertain	Annually beginning at 11 years of age. Use the CRAFFT to screen for high-risk alcohol use and other drug use disorders simultaneously C – Have you ever ridden in a CAR driven by someone (including yourself) who was "high" or had been using alcohol or drugs? R – Do you ever use alcohol or drugs to RELAX, feel better about yourself, or fit in? A – Do you ever use alcohol/drugs while you are by yourself, ALONE? F – Do you ever FORGET things you did while using alcohol or drugs? F – Do your family or FRIENDS ever tell you that you should cut down on your drinking or drug use? T – Have you gotten into TROUBLE while you were using alcohol or drugs?
Illicit drug use	Insufficient evidence to make a recommendation	

[a]USPSTF A and B Recommendations. US Preventive Services Task Force. December 2014. With permission from the Agency for Healthcare Research and Quality

[b]Note that AAP Bright Futures recommendations are more comprehensive than those of the USPSTF. Complete AAP recommendations may be found at http://www.aap.org/en-us/professional-resources/practice-support/periodicity/periodicity%20schedule_FINAL.pdf

***Newborn*:** Certain *genetic*, *endocrine*, *and metabolic disorders*, as well as *hearing loss* and critical *congenital heart disease* (CCHD), can adversely affect an infant's survival, or inhibit a child from achieving full potential. It has been 50 years since the US newborn screening program was first implemented. Universal newborn blood screening *for phenylketonuria* (*PKU*), *congenital hypothyroidism* (*CH*), *and sickle cell disease* is now mandated in all 50 states. Although state law determines which disorders are included in the screening, the Secretary's Advisory Committee on Heritable Disorders in Newborns and Children (SACHDNC) recommends that states test for a *core panel of 31 congenital disorders*, including severe combined immunodeficiencies (SCID) [19]. The USPSTF recommends that infants who are tested for *PKU* within the first 24 h after birth should receive a repeat screening test by two weeks of age [4]. Screening for *CH* should be done between 2 and 4 days of age or immediately before discharge if this occurs earlier. Confirmatory testing for *sickle cell disease* should occur no later than 2 months of age. Because 50 % of children with permanent *congenital hearing loss* have no identifiable risk factors, the USPSTF recommends that universal (as opposed to targeted) screening for hearing loss be completed before 1 month of age. Early detection improves language outcomes. Additional audiologic and medical evaluation before 3 months of age for confirmatory testing is warranted for those who do not pass the newborn screening, and infants with risk indicators should undergo periodic monitoring for 3 years. Although the USPSTF has not made a recommendation for *CCHD screening*, the SACHDNC

DOI 10.1007/978-1-4939-0779-3_7-1

Table 2 Comparison of USPSTF A and B recommendations with corresponding recommendations from the American Academy of Pediatrics for high-risk populations

Hyperbilirubinemia: infants of at least 35 weeks' gestation	Insufficient evidence to make a recommendation	Risk evaluation by using predischarge levels individually or in combination with clinical risk-factor assessment
Developmental dysplasia of the hip (DDH)	Insufficient evidence to make a recommendation	Hip imaging for female infants born in the breech position and optional hip imaging for boys born in the breech position or girls with a positive family history of DDH
Iron supplementation	Routine iron supplementation for asymptomatic children aged 6–12 months who are at increased risk: premature and low birth weight infants; adult females; recent immigrants and, among adolescent females, fad dieters; and those who are obese	Breastfed infants should be supplemented with 1 mg/kg per day of oral iron beginning at 4 months of age until they can be fed with appropriate iron-containing complementary foods
Lead poisoning	Insufficient evidence to make a recommendation in children 1–5 years of age	Blood lead level at 12 and 24 months for patients with Medicaid or in high-prevalence areas
Sexually transmitted infections (STI), counseling	High-intensity behavioral counseling for all sexually active adolescents: provided basic information about STIs and transmission, assess the individual's risk for transmission, and provide training in pertinent skills such as condom use, communication about safe sex, problem solving, and goal setting	Annually beginning at 11 years of age. Counseling for adolescents regarding abstinence and the importance of barrier contraceptives is recommended
Chlamydia/gonorrhea screening	Sexually active women aged $\leq$ 24 years	Sexually active women aged $\leq$25 years at least annually
Hepatitis B virus infection, screening adolescents	Persons at high risk for infection including all foreign-born in countries with a high rate of infection, regardless of vaccination history, mainly Asia, sub-Saharan Africa, the Pacific Islands, the Middle East, and Eastern Europe. Also injection drug users; men who have sex with men; household contacts and sexual partners of HBsAg-positive persons; patients receiving hemodialysis; and immunosuppressed and HIV-positive persons	
HIV infection, screening	All adolescents and adults aged 15–65 years and others who are at increased risk for HIV infection and all pregnant women Note: The AAFP endorses the CDC recommendation to initiate routine screening at age 13 years	Once between the ages of 16 and 18, making every effort to preserve confidentiality of the adolescent. Those at increased risk of HIV infection, including those who are sexually active, participate in injection drug use, or are being tested for other STIs, should be tested for HIV and reassessed annually
Tuberculosis	Refer to the CDC website at http://www.cdcnpin.org/scripts/tb/cdc.asp	Annual tuberculin skin test in children infected with HIV, incarcerated adolescents, those with a family member or contact with TB disease, and those born in or who had recent travel to a high-risk country
Dental caries prevention, birth to age 5 years	Oral fluoride supplementation starting at age 6 months for children whose water supply is deficient in fluoride (<0.6 ppm F)	Oral fluoride supplementation and application of fluoride varnish in children at risk for dental caries
Skin cancer, counseling	Aged 10–24 years who have fair skin High risk: fair skin, freckles, atypical nevi, >50 mol, increased lifetime or intense sun exposure	Sun safety advice during health maintenance visits at least once per year

(*continued*)

DOI 10.1007/978-1-4939-0779-3_7-1

Table 2 (continued)

Suicide risk in adolescents, adults, and older adults	Insufficient evidence to make a recommendation	Recommends to ask questions about mood disorders, sexual orientation, suicidal thoughts, and other risk factors associated with suicide during routine healthcare visits
Child maltreatment	Insufficient evidence to make a recommendation	Use the parent-screening tool to screen for risk factors: a Safe Environment for Every Kid (SEEK) (http://brightfutures.aap.org/pdfs/Other%203/PSQ_screen.pdf)
Counseling about proper use of seatbelts and avoidance of alcohol use to prevent injury	Refers clinicians to the CDC's Community Guide recommendations: laws mandating use, distribution and education programs, community-wide information, and enhanced enforcement campaigns (http://www.thecommunityguide.org)	Counseling and demonstrating the use of child safety seats. Insufficient evidence about counseling for other restraints and to discourage driving under the influence of the alcohol.

recommends pulse oximetry after 24 h of age but before discharge for early detection of serious heart defects that could require specialized care within the first year of life.

***Birth to two years*:** Infants should have a follow-up visit within 3–5 days of birth and within 48–72 h after hospital discharge to prevent problems related to *feeding*, *jaundice*, *and weight loss* [20]. Well-infant and child visits for developmental screening and monitoring should occur at ages 1, 2, 4, 6, 9, 12, 15, 18, and 24 months. The CDC recommends using WHO growth standards (http://www.cdc.gov/growthcharts/who_charts.htm). Screening should encompass length, weight, and head circumference. Dental referral is recommended by the first birthday. The USPSTF found insufficient or inconsistent evidence to recommend for or against the routine use of brief, formal screening instruments in primary care to detect *speech and language delay* in children up to 5 years of age. In contrast, the AAP recommends developmental surveillance to identify infants at risk for developmental delays at every well-child preventive care visit through the age of 5 years. Surveillance consists of asking about parents' concerns, obtaining a developmental history, identifying risk and protective factors, and interacting and making observations of the child. Per AAP recommendations, children with Medicaid are mandated to periodically receive a standardized developmental screening test (e.g., Ages & Stages Questionnaires (ASQ), Infant Development Inventory). *Autism-specific screening* for all children at 18 and either 24 or 30 months is also recommended. Additional screening might be needed by children at high risk for developmental problems due to preterm birth or intrauterine growth restriction.

The USPSTF found insufficient evidence to recommend universal screening for *iron deficiency anemia* (*IDA*) in asymptomatic children aged 6–12 months. In contrast, the AAP recommends universal screening for anemia via hemoglobin concentration at approximately 1 year of age.

***Two to ten years*:** *Well-child visits* should occur at 24 and 30 months and once every year thereafter. The family physician should ask questions about injury/illness, visits to other healthcare providers, and changes in the family or home and should also address any parental concerns. During these well-child visits, the child's growth and development should be measured, and testing for vision and hearing starting at age 3 years should be performed. A dental home in addition to a medical home should be established, and a preventive visit to the dentist should occur twice per year [18]. During this period, parents often have questions about their child's behavior and social functioning. *Developmental milestones* and observation of parent and child interaction should also be included at every preventive care visit. If needed, intervention by age 3 years can greatly improve a child's development and learning ability. Developmental surveillance in school-aged children can be monitored by asking about school performance to identify the need to test for learning disabilities.

DOI 10.1007/978-1-4939-0779-3_7-1

The CDC has recommended growth charts for *monitoring growth* from ages 2 years and older (http://www.cdc.gov/growthcharts/clinical_charts.htm) and *body mass index* (*BMI*) should be calculated at least annually. Overweight and obesity are defined as an age-gender-specific BMI between the 85th and 95th percentiles and ≥95th percentile, respectively. In the last three decades, obesity rates have more than doubled in US children, and recent statistics show that 8.4 % of 2–5-year-olds had obesity compared with 17.7 % of 6–11-year-olds [21]. Screening for obesity in children aged 6 years and older and referral for intensive counseling are recommended by the USPSTF, including interventions for diet and physical activity (Table 1). Interventions that focus on younger children should also incorporate parental involvement as a component.

The USPSTF has given a Grade: I recommendation (insufficient evidence) to screening for *primary hypertension* in asymptomatic children and adolescents (before 18 years of age). Furthermore, although there is good evidence that *dyslipidemia* during childhood increases risks in adulthood, the clinical health benefits shown in adults identified and treated for dyslipidemia have not been studied in children, making the role of screening children uncertain (USPSTF Grade: I). In contrast, the National Heart, Lung, and Blood Institute (NHLBI) recommends that children aged 3 years and older have blood pressure measurement at least once at every "healthcare episode." The NHLBI also recommends universal lipid screening between 9 and 11 years of age and selective screening in children and adolescents with a family history of premature coronary heart disease (CHD), a parent with dyslipidemia, or high-risk conditions such as diabetes, obesity, or hypertension [22].

***Eleven to eighteen years*:** Preventable conditions remain the leading causes of morbidity and mortality among adolescents. *Health-risk behaviors* (e.g., alcohol and drug use, unsafe sexual practices, etc.) are major contributors to unintentional injuries such as motor vehicle collisions, intentional injuries such as homicide and suicide, and sexual risk behaviors leading to sexually transmitted infections (STIs) and unintended pregnancy. Obesity has become a major cause of adolescent morbidity, is a contributor to a dramatic increase in the number of youth with type 2 diabetes mellitus, and is the strongest risk factor for primary hypertension in children and adolescents. BMI measurement should be standard during health maintenance visits, and patients with excess weight should be referred for counseling and comprehensive weight-management programs that include dietary, physical activity, and behavioral counseling [4].

Sexually active teens should be screened for *STIs including chlamydia and gonorrhea*. The risk for chlamydial infection is higher among sexually active women 24 years of age or younger. Because adolescents are a vulnerable population at increased risk of *HIV infection*, assessment for high-risk behaviors and screening for HIV should be standard. The USPSTF advises one-time screening beginning at age 15 years to identify persons who are already HIV positive, with repeated screening of those who are known to be at risk for HIV infection, those who are actively engaged in risky behaviors, and those who live or receive medical care in a high-prevalence setting (Table 2). The CDC recommends opt-out HIV testing (i.e., testing is done after notifying the patient that the test is normally performed but that the patient may elect to decline or defer testing) for all patients seen in healthcare settings beginning at age 13 years [23]. Although such testing is generally performed without a separate written informed consent or pretest counseling, providers must anticipate that some patients are poorly equipped to deal with a positive HIV test result.

Major depressive disorder (*MDD*) among adolescents, often undiagnosed and untreated, is a disabling condition that is associated with increased risk of suicide, decreased school performance, poor social functioning, early pregnancy, increased physical illness, and substance abuse. Important risk factors that can be assessed relatively accurately and reliably include parental depression, the presence of comorbid mental health or chronic medical conditions, and a major negative life event in the patient's life. Some instruments developed for primary care (Patient Health Questionnaire for Adolescents [PHQ-A] and the Beck Depression Inventory-Primary Care Version [BDI-PC]) have been used successfully in adolescents to screen for MDD.

DOI 10.1007/978-1-4939-0779-3_7-1

The AAP, however, recommends screening annually beginning at 11 years of age using the CRAFFT six-item tool (Car, Relax, Alone, Forget, Friends, Trouble) to screen adolescents for high-risk alcohol use and other drug use disorders simultaneously (Table 1).

Prevention at Ages Over 18 Years

Immunization

Adult vaccination coverage remains low for most recommended vaccines. The 2010 National Health Interview Survey reported that only 18.5 % of adults aged 18–64 years at risk of pneumococcal disease have received the vaccine. Furthermore only 40 % of those at risk for influenza were immunized against influenza during the 2012–2013 influenza season. Limited awareness among the public about vaccine schedules for adults and missing opportunities to incorporate age-appropriate immunizations into routine visits are some of the factors. A recommendation by a patient's healthcare provider for needed vaccines is a strong predictor of patients receiving recommended vaccines [24]. The Community Guide describes additional interventions that could help to increase vaccination rates like routine screening and offering of vaccines and implementation of reminder systems (http://www.thecommunityguide.org/vaccines/index.html). The ACIP annually reviews and updates the "Recommended Immunization Schedule for Adults Aged 19 Years or Older" (Fig. 3). With the exception of the yearly *influenza* vaccination, which is recommended for all adults, recommendations for adults target different populations based on age, health conditions, behavioral risk factors (e.g., injection drug use), occupation, travel, and other indications.

The ACIP recommends beginning *zoster* vaccination at age 60 years. For *pneumococcus bacteria*, all adults 65 years of age or older receive a dose of PCV13 followed by a dose of PPSV23 6–12 months later. If a dose of PPSV23 cannot be given during this time window, it should be administered later, during the next doctor's visit. PCV13 protects against 13 strains of pneumococcus bacteria, and PPSV23 protects against 23 strains of pneumococcus bacteria. Both vaccines provide protection against illnesses like meningitis and bacteremia. PCV13 also provides protection against pneumonia. *Hepatitis B vaccine* is recommended for all unvaccinated adults at high risk for HBV infection and diabetic adults <60 years of age. For patients with diabetes ≥ 60 years of age, vaccination may be warranted based on likelihood of acquiring hepatitis B and immune response. A single dose of *Tdap* is recommended for all adults aged 19 years and older who have not received Tdap previously regardless of the interval since the last dose of Td. Adults should also receive a Td booster every 10 years. Tdap should be administered to pregnant women during each pregnancy (preferred during 27–36 weeks' gestation) regardless of interval since prior Td or Tdap vaccination. All adults without evidence of immunity to *varicella* should be vaccinated against it. Pregnant women who do not have evidence of immunity should receive the first dose of varicella vaccine upon completion or termination of pregnancy and before discharge from the healthcare facility. Vaccination for *varicella*, *zoster*, *and MMR* is contraindicated in pregnancy and immune-compromising conditions (safe in patients with HIV who have CD4 ≥ 200 cells/μL).

Prophylaxis

Folic acid prophylaxis (400 micrograms per day) is recommended through age 45 years to prevent spina bifida and anencephaly. The USPSTF considers *low-dose aspirin* (81 mg/day) to be of substantial benefit for pregnant women at high risk for preeclampsia (grade B recommendation). Risk factors for preeclampsia include autoimmune disease, hypertension, multiple gestation pregnancy, renal disease, diabetes, and history of preeclampsia (Table 4). Low-dose aspirin therapy can also be considered for those with multiple moderate risk factors [4]. The USPSTF also recommends that clinicians engage in shared, informed decision making with women who are at increased risk for breast cancer about medications to reduce their

DOI 10.1007/978-1-4939-0779-3_7-1

Recommended adult immunization schedule, by vaccine and age group

VACCINE ▼ AGE GROUP ▶	19-21 years	22-26 years	27-49 years	50-59 years	60-64 years	≥ 65 years
Influenza [2,*]	1 dose annually					
Tetanus, diphtheria, pertussis (Td/Tdap)[3,*]	Substitute 1-time dose of Tdap for Td booster; then boost with Td every 10 yrs					
Varicella[4,*]	2 doses					
Human papillomavirus (HPV) Female[5,*]	3 doses					
Human papillomavirus (HPV) Male[5,*]	3 doses					
Zoster[6]	1 dose					
Measles, mumps, rubella (MMR)[7,*]	1 or 2 doses					
Pneumococcal 13-valent conjugate (PCV13)[8,*]	1 dose					
Pneumococcal polysaccharide (PPSV23)[9,10]	1 or 2 doses					1 dose
Meningococcal[11,*]	1 or more doses					
Hepatitis A[12,*]	2 doses					
Hepatitis B[13,*]	3 doses					
Haemophilus influenzae type b (Hib)[14,*]	1 or 3 doses					

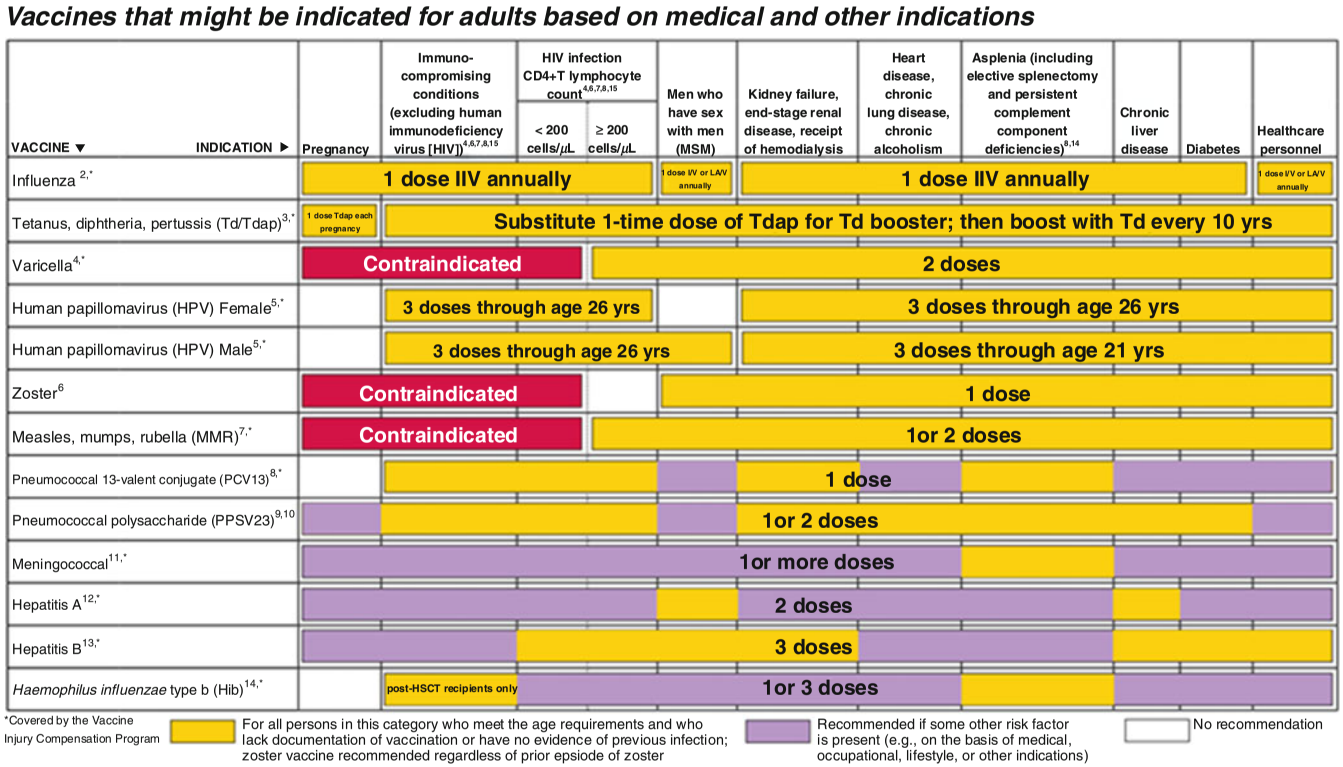

Fig. 3 Recommended Adult Immunization Schedule – United States, 2014 (Note: The above recommendations must be read along with the footnotes of this schedule. See: http://www.cdc.gov/vaccines/schedules/downloads/adult/adult-schedule.pdf. The recommendations in this schedule in effect as of January 1, 2014, were approved by the Centers for Disease Control and Prevention's (CDC) Advisory Committee on Immunization Practices (ACIP), the American Academy of Family Physicians (AAFP), the American College of Physicians (ACP), the American College of Obstetricians and Gynecologists (ACOG), and the American College of Nurse-Midwives (ACNM). Additional information about the vaccines in this schedule, extent of available data, and contraindications for vaccination is also available at www.cdc.gov/vaccines)

DOI 10.1007/978-1-4939-0779-3_7-1

risk. For women who are at increased risk for breast cancer and at low risk for adverse medication effects, clinicians should offer to prescribe risk-reducing medications, such as *tamoxifen or raloxifene*. Increasing bone strength includes *calcium and vitamin D supplementation*.

Counseling and Anticipatory Guidance

Preventive counseling and services are an important component of the health maintenance visit. The family physician should emphasize a shared decision-making approach including unique goals of prevention, life expectancy, comorbidities, potential for harms, and patient values and preferences. Preventive services are more likely to be discussed when patients have an established relationship with an identified clinician [25]. The five leading causes of death – comprising almost two-thirds of all US deaths – are *heart disease*, *cancer*, *stroke*, *lung disease* (*emphysema*, *chronic bronchitis*), and *unintentional injuries* (especially motor vehicle collisions, medication overdoses). Up to 40 % of deaths from leading causes could be prevented by making healthy lifestyle choices.

Counseling comprises recommendations for healthy lifestyle and intensive behavioral counseling for adults known risk factors for *coronary heart disease* and *diet-related chronic disease* and also advise on the importance of regular physical activity including aerobic, strength, and flexibility training in the prevention of disease and nontraumatic weight-bearing exercise (e.g., walking) for osteoporosis prevention. All patients should be asked about *tobacco* use and provided tobacco cessation interventions. Brief counseling within primary care for smoking cessation increases quit rates and decreases cardiovascular risk. Clinicians have many resources to help patients stop smoking. The CDC has developed a website with many such resources, including information on tobacco quit lines, available in several languages (www.cdc.gov/tobacco/campaign/tips). It is also recommended to assess any history of *alcohol*/*drug* use. Brief questionnaires (e.g., CAGE, AUDIT) may help clinicians assess the likelihood of problems or hazardous drinking. Patients should receive behavioral counseling about the effects of alcohol and substance use, including prescription and over-the-counter drugs. Brief interventions in primary care, including feedback, goal setting, and follow-up with short contacts, are effective in reducing alcohol consumption. High-intensity behavioral counseling to prevent *STIs* for adults who are at increased risk of STIs is also recommended. Older adults continue to be sexually active in their later years. In fact, the rate of STIs has more than doubled among middle-aged adults and the elderly over the last decade for reasons that are still not clear. The lack of awareness about STIs and their prevention may be contributing to the increasing reported rates. It is important to provide counseling and offer STI testing to those at risk.

Because women may not be aware of *pregnancy* in its earliest stages, patients should be counseled about the adverse effects of obesity, alcohol, illicit drugs, tobacco, and other environmental exposures. If a patient has a BMI >30, recommend weight loss before becoming pregnant. Advise women that there is no known safe level of alcohol consumption during pregnancy and stress the harmful effects of alcohol and illicit drug use on fetal development. Counsel that smoking during pregnancy can cause infant death and is associated with increased risk for premature birth and intrauterine growth retardation. Provide smoking cessation counseling sessions, augmented with messages and self-help materials tailored for pregnant smokers if appropriate.

Screening

The USPSTF recommends screening for four cancer sites – *cervix*, *female breast*, *colorectal*, and *lung*. It does not favor *prostate* cancer screening. Most patients with *cervical cancer* are women younger than 50 years, and most invasive cervical cancers occur in women lacking appropriate screening during the 5 years immediately preceding diagnosis. Cervical cancer screening is not recommended before age 21 regardless of when sexual activity begins. Screening should usually be stopped at age 65 if adequate screening was carried out in the preceding 10 years. Also, if the patient had a total hysterectomy (with

DOI 10.1007/978-1-4939-0779-3_7-1

complete cervical removal) for benign disease, screening is not necessary [4]. For *breast cancer*, family history and age are key risk factors. The USPSTF recommends biennial mammography for women aged 50–74 years, while the American Cancer Society (ACS) recommends that annual mammography begin at age 40 and continue so long as the woman is in good health. Women with a family history suggestive of breast and ovarian cancer syndrome should receive counseling for options which may include genetic testing for BRCA1 and BRCA2 and more intensive screening for breast cancer. The harms resulting from screening for breast cancer include psychological distress, unnecessary imaging tests and biopsies in women without cancer, and inconvenience due to false-positive screening results. Partly because such problems may be accentuated by annual mammography, the USPSTF recommends against annual testing even though models used by the Task Force suggest that annual testing brings a survival advantage. The ACA requires insurers to cover screening mammograms every 1–2 years for women aged 40+ years. Teaching breast self-examination is not recommended by the USPSTF, based in part on data showing that it takes time, increases the rate of breast biopsy for benign disease, and does not result in lower breast cancer mortality [26].

Colorectal cancer (CRC) is the second leading cause of cancer-related deaths and the third most common cancer among American men and women. Early detection and removal of precancerous polyps before CRC develops reduces mortality. Screening is recommended for all adults aged 50–75 years. Despite compelling evidence of cost-effectiveness, screening rates remain far below what would be necessary to decrease incidence and mortality. Behavioral Risk Factor Surveillance Survey (BRFSS) data from 2012 showed that only 65.1 % of adults in that age group met CRC screening guidelines, and 27.7 % had never been screened. Strategies to increase screening rates besides clinician recommendation include patient and clinician reminders, decision aids, and organization of office staff to support a program of patient education, monitoring, outreach, and follow-up (e.g., patient navigator, fecal occult blood test (FOBT) cards). *Lung cancer* is the leading cause of cancer-related death and the second most common in the USA. Prevention of tobacco use, which accounts for nearly 85 % of all US lung cancer cases, is the most important intervention to prevent the disease. Although lung cancer screening is not an alternative to smoking cessation, screening high-risk patients aged 55–80 years with low-dose computer tomography (LDCT) is recommended by the USPSTF. Current smokers should be informed of their continuing risk for lung cancer and offered cessation treatments. Screening with LDCT should be viewed only as an adjunct to tobacco cessation interventions. Screening for *prostate cancer* is not recommended. The Task Force guideline applies to men in the general US population. Most cases of prostate cancer have a good prognosis, even without treatment, and the lifetime risk of dying from the disease is 2.8 %. In addition, the mortality benefits of prostate-specific antigen (PSA)-based prostate cancer screening are, at best, small and potentially none, and the harms are moderate to substantial potentially due to harms associated with overdiagnosis and overtreatment (need for biopsy, and impotence or incontinence occurring in at least 50 % of men who undergo treatment for a disease that may be indolent).

Overweight, *obesity*, *and lack of physical activity* are associated with hypertension, diabetes, increased cardiovascular events, and increased all-cause mortality. The USPSTF recommends that clinicians screen their adult patients for obesity and offer or refer them if appropriate to intensive, multicomponent behavioral programs promoting healthy eating, increasing physical activity, or both. In nutrient-sufficient adults, evidence is insufficient to support multivitamin supplementation to prevent cancer and cardiovascular disease. *Hypertension* affects approximately 25–30 % of adult Americans, and it is a major risk factor for ischemic heart disease, left ventricular hypertrophy, renal failure, stroke, and dementia. Screening for hypertension in adults aged 18 and over is recommended by the USPSTF. In addition, the Task Force recommends screening for *type 2 diabetes mellitus* in asymptomatic adults with treated or untreated sustained BP >135/80 mmHg. The USPSTF strongly recommends screening for *lipid disorders* among men 35 years of age and older and for men aged 25–35 years if they are at increased risk for heart

DOI 10.1007/978-1-4939-0779-3_7-1

disease. Comparable recommendations are made for women aged 45 years and older and 25–45 years. The optimal interval for screening is uncertain, although every 2 years for hypertension and every 5 years for dyslipidemia are generally considered reasonable.

Chlamydia and gonorrhea are the most commonly reported STIs in the USA with chlamydial infections being ten times more prevalent than gonococcal infections (4.7 % vs. 0.4 %) in women aged 18–26 years [27]. The USPSTF recommends screening in sexually active women aged 24 and younger and in older women at increased risk for infection (history of chlamydial or other STIs, new or multiple sexual partners, inconsistent condom use, and exchanging sex for money or drugs). Recommendations for *HIV* differ regarding age for screening. The USPSTF recommends one-time screening through age 65 years, while the suggested CDC cutoff is 64 years. The American College of Physicians suggests expanding the age range to 75 years due to the growing number of older adults with HIV infection. Screening for *hepatitis B*, *hepatitis C*, *and syphilis* should be offered to all persons at high risk for infection (Table 3). The USPSTF recommends screening all adults for *depression* when staff-assisted depression care supports are in place to assure accurate diagnosis, effective treatment, and follow-up. "Staff-assisted depression care supports" refers to clinical staff (e.g., nurse specialists) that assist the primary care clinician by providing some direct depression care including coordination, case management, or mental health treatment. Several screening tools are available; however, asking two simple questions about mood and anhedonia (Table 4) may be as effective as using more formal instruments [28]. *Intimate partner violence* (*IPV*) and *abuse of elderly and vulnerable adults* often remain undetected. Nearly 25 % of women and 14 % of men have experienced the most severe types of IPV in their lifetime [29]. Victims of IPV, which refers to physical, sexual, or psychological harm by a current or former partner or spouse, often develop chronic mental health conditions, such as depression, posttraumatic stress disorder, anxiety disorders, substance abuse, and suicidal behavior. Risk factors for IPV include young age, substance abuse, marital difficulties, and economic hardships. Available screening instruments can identify current and past abuse or increased risk for IPV, but for vulnerable adults, the USPSTF found inadequate evidence on the accuracy of screening instruments. Interventions for women of childbearing age include counseling, home visits, information cards, referrals to community services, and mentoring support. Most *abdominal aortic aneurysms* (*AAA*) ($\geq$3 cm) are asymptomatic until they rupture, and they are also most prevalent in men who have ever smoked. Although the risk for rupture varies greatly by aneurysm size, the associated risk for death is as high as 75–90 %. Therefore, considering an effective method for screening and treating appropriate patients before rupture is important. One-time ultrasound screening for AAA in men aged 65–75 years who are current or former smokers is recommended. Selective screening in this age group who have never smoked should be considered if risk factors for AAA are present (e.g., first-degree relative with an AAA, history of other vascular aneurysms, cardiovascular disease, cerebrovascular disease, atherosclerosis, hypercholesterolemia, obesity, or hypertension).

Effectively reducing *bone fractures* among older people involves both preventing falls and increasing bone and muscle strength. Older adults should be asked about recent falls. Fall prevention includes minimizing psychotropic medications and encouraging weight-bearing physical activity and muscle strengthening. The USPSTF recommends routine osteoporosis screening in women aged 65 and older and those at increased risk most commonly with dual-energy X-ray absorptiometry (DXA) and quantitative ultrasonography. Routine screening for *osteoporosis* is not recommended for young postmenopausal women who do not meet risk-factor-based criteria. *Depression in older adults* is often misdiagnosed and undertreated having a significant adverse impact on quality of life, health outcomes, healthcare utilization, morbidity, and mortality. Medicare beneficiaries with chronic diseases and associated depression have significantly higher healthcare costs than those with chronic diseases alone. Also, suicide rates are almost twice as high in the older adults as the general population, with the rate highest for white men over 85 years of age.

DOI 10.1007/978-1-4939-0779-3_7-1

Adhering to Prevention Guidance: Barriers to Care

Barriers to conducting preventive care services may be due to the medical care providers or patients. This section summarizes those barriers and addresses a few techniques to implement in practice to improve patient and provider compliance with preventive care.

Barriers to Provider Adherence

Provider adherence is related, in part, to the challenges of a busy practice, system barriers, or simple human error. In a large systematic review, the common reasons for provider gaps in preventive care were classified as lack of awareness of guidelines, lack of familiarity with guidelines, lack of agreement, lack of

Table 3 USPSTF A and B recommendations for adults

Recommendations	USPSTF[a]	Other recommendations[b]
Cancer		
Breast cancer, mammography	Biennial screening for women 50–74 years of age. Before age 50 should be individualized and take into account patient's risks and values regarding specific benefits (Grade: C)	ACA: every 1–2 years for women >40 ACS, AMA: annually beginning at 40 ACOG: annually for women ≥40
Breast self-examination (BSE)	Recommends against teaching BSE	ACOG: "breast self-awareness" for women ≥ 20 and can include BSE
Breast cancer, clinical examination	Insufficient evidence	ACOG: annually for women ≥ 40 and every 1–3 years for women aged 20–39
Breast cancer, digital mammography or MRI	Insufficient evidence	ACS, NCCN: annually in addition to mammography for women with a strong family history or genetic predisposition
Breast cancer, prevention medication	Risk-reducing medications, such as tamoxifen or raloxifene, for women who are at increased risk for breast cancer and at low risk for adverse medication effects[c]	ASCO: tamoxifen for ER-positive breast cancer in women ≥35 years who are at increased risk. Raloxifene and exemestane for postmenopausal women
Breast and ovarian cancer/ BRCA risk assessment and genetic counseling/testing	Screen women who have family members with breast, ovarian, tubal, or peritoneal cancer that may be associated with an increased risk for BRCA1 or BRCA2. If screening is positive, provide genetic counseling and BRCA testing	ACOG recommends genetic risk assessment for women who have more than a 20–25 % risk for an inherited predisposition to breast and ovarian cancer
Cervical cancer	Women aged 21–65 years with cytology every 3 years or for women aged 30–65 years with cytology plus HPV testing every 5 years	ACS, ACOG same
Colorectal cancer (CRC)	Screening beginning at age 50–75 years: (1) annual high-sensitivity FOBT, (2) sigmoidoscopy every 5 years combined with high-sensitivity FOBT every 3 years, or (3) screening colonoscopy at intervals of 10 years	US Multi-Society Task Force on CRC: beginning at 50 years: (1) annual high-sensitivity FOBT; every 5 years (2) flexible sigmoidoscopy or (3) double-contrast barium enema or (4) virtual colonoscopy; (5) colonoscopy every 10 years; or (6) fecal DNA
Colorectal cancer, genomic testing	No recommendation	The AAFP recommends offering genetic testing for Lynch syndrome to patients newly diagnosed with CRC and to first-degree

(*continued*)

DOI 10.1007/978-1-4939-0779-3_7-1

Table 3 (continued)

Recommendations	USPSTF[a]	Other recommendations[b]
		relatives of those found to have Lynch syndrome (2012)
Lung cancer: screening	Annually with LDCT in adults aged 55–80 years who have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years	AAFP: insufficient evidence ACS, National Comprehensive Cancer Network (NCCN): adults aged 55–74 years
Prostate cancer	Do not use prostate-specific antigen (PSA)-based screening for prostate cancer	The American Urological Association (AUA) recommends against screening men < 40, average-risk men 40–54, men >70, or men with a life expectancy of less than 10–15 years
Counseling to prevent skin cancer	Children and young adults aged 10–24 years who have fair skin. Limit sun exposure (10 a.m. and 4 p.m.); wear protective clothing and sunscreen (SPF 15 or greater)	
Cardiovascular disorders		
Abdominal aortic aneurysm (AAA), men	One-time screening by ultrasonography in men aged 65–75 years who have ever smoked (≥100 cigarettes) Selectively offer screening for AAA in men aged 65–75 years who have never smoked	The AHA: one-time screening in men aged 65–75 years who have ever smoked and in men ≥ 60 years who are the sibling or offspring of a person with AAA. Does not recommend screening for AAA in men who have never smoked
Aspirin for primary prevention of cardiovascular disease	For men aged 45–79 years when myocardial infarction prevention and for women aged 55–79 years when reduction in ischemic stroke outweighs potential harm of GI hemorrhage	ADA/AHA: aspirin therapy (75–162 mg/d) for persons with diabetes >40 years or who have additional risk factors for CVD and no contraindications
Blood pressure (BP) hypertension	Screening for high blood pressure in adults aged 18 and over	The JNC7[d] recommends every 2 years for adults with BP <120/80 and every year for BP 120–139/80–89 mmHg
Diabetes mellitus type 2: screening	Asymptomatic adults with sustained BP >135/80 mmHg (either treated or untreated)	The ADA recommends a 3-year interval. The AAFP recommends screening in adults with HTN and hyperlipidemia.
Lipid disorders: screening	Men aged 35 and older Men aged 20–35 and women aged 20 and older if they are at increased risk for CHD	ATP III recommends a fasting lipid panel (total cholesterol, LDL, HDL, and TG) in all adults >20 y/o every 5 years
Healthy diet and physical activity: counseling adults with high risk of CVD	Recommends offering or referring adults who are overweight or obese and have additional CVD risk factors to intensive behavioral counseling interventions to promote a healthful diet and physical activity for CVD prevention	The AHA recommends counseling interventions to promote a healthful diet and physical activity (≥2 strategies): setting specific, proximal goals; providing feedback on progress; strategies for self-monitoring; planning for frequency and duration of follow-up; motivational interviews; and building self-efficacy
Obesity in adults: screening and management	Screen all adults for obesity Clinicians should offer or refer patients with a BMI of ≥ 30 kg/m^2 to intensive, multicomponent behavioral interventions	The NIH suggests considering the use of weight-loss medications as part of a multicomponent program if BMI >27 kg/m^2 and if with comorbid medical conditions
Infectious diseases		
Chlamydia and gonorrhea: screening	Sexually active women aged ≤ 25 years and in older women who are at increased risk for infection (prior STIs, HIV, new or multiple sex	The CDC recommends annual screening in all sexually active women ≤ 25 years and in older

(*continued*)

DOI 10.1007/978-1-4939-0779-3_7-1

Table 3 (continued)

Recommendations	USPSTF[a]	Other recommendations[b]
	partners, exchanging sex for money or drugs) Insufficient evidence for screening in men	women who are at increased risk and in MSM, based on exposure history
Hepatitis B virus infection: screening	Persons at high risk for infection including all foreign born in countries with a high rate of infection, regardless of vaccination history, mainly Asia, sub-Saharan Africa, the Pacific Islands, the Middle East, and Eastern Europe. Also injection drug users, MSM, household contacts and sexual partners of HBsAg-positive persons, patients receiving hemodialysis, and immunosuppressed and HIV-positive persons	
Hepatitis C: screening	Persons at high risk for infection (past or current injection drug use, blood transfusion before 1992) and one-time screening for adults born between 1945 and 1965	
HIV infection: screening	Persons aged 15–65 years, all pregnant women, and persons who are at increased risk (MSM, IDU, having sex partners who are HIV-infected, unprotected vaginal/anal intercourse, bisexual, exchanging sex for drugs or money)	The AAFP's recommendation differs from the USPSTF only on the age to initiate routine screening for HIV beginning at age 13 years as recommended by CDC
Immunizations	Refer to the National Immunization Program http://www.cdc.gov/vaccines/schedules/index.html	
Sexually transmitted infections: behavioral counseling	Intensive behavioral counseling for all sexually active adolescents and for adults who are at increased risk for STIs	The CDC recommends routinely obtain a sexual history from their patients and encourage risk reduction
Syphilis infection: screening	Persons at increased risk for syphilis infection including MSM and those engaged in high-risk sexual behavior, commercial sex workers, persons who exchange sex for drugs, and those in adult correctional facilities	The CDC recommends universal screening for persons in correctional facilities
TB screening	Recommendation in progress	CDC recommends targeted testing for latent tuberculosis infection (LTBI) in high-risk populations (shelters, migrant farm camps, prisons)

[b]In most cases the AAFP agrees with the USPSTF. Circumstances where there are differences have been noted. Summary of Recommendations for Clinical Preventive Services. November 2014. AAFP, with permission. http://www.aafp.org/dam/AAFP/documents/patient_care/clinical_recommendations/cps-recommendations.pdf

[c]Breast Cancer Risk Assessment Tool (available at www.cancer.gov/bcrisktool) is based on the Gail model and estimates the 5-year incidence of invasive breast cancer in women on the basis of characteristics entered into a risk calculator. This tool helps identify women who may be at increased risk for the disease

[d]JNC7: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. http://www.nhlbi.nih.gov/files/docs/guidelines/express.pdf

outcome expectancy, inertia based on previous practice, and external barriers such as patient and environmental factors [30]. The following sections consider these barriers more fully.

Time constraint: Time constraints affect even the most prevention-oriented providers. Patients presenting for annual well exams offer the best opportunity to perform indicated preventive services, as patients are then most receptive to prevention, provider time constraints are addressed, and payment is likely to be covered. In contrast, when patients present with complaints that use up the allotted visit time to assess, diagnose, and treat, it is likely to limit the capacity of the family physician to provide preventive care. Furthermore, some services may require time-consuming patient education or counseling. Often it is necessary for practices to reevaluate the delegation of duties, shifting some responsibilities to nursing and

DOI 10.1007/978-1-4939-0779-3_7-1

Table 4 Continuation of USPSTF A and B recommendations for adults

Mental health conditions and substance abuse		
Alcohol misuse: screening and behavioral counseling	Screen adults aged 18 years or older for alcohol misuse and provide persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce alcohol misuse. "How many times in the past year have you had 5 [for men] or 4 [for women and all adults older than 65 years] or more drinks in a day?" **Audit-C alcohol screening**: 1. How often did you have a drink containing alcohol in the past year? 2. How many drinks did you have on a typical day when you were drinking in the past year? 3. How often did you have 6 or more drinks on one occasion in the past year?	
Cognitive impairment in older adults (≥65 y/o): screening	Insufficient evidence	Included in Medicare's Annual Wellness Visit benefit (2011). The Alzheimer's Association recommends an algorithm involving a health risk assessment, patient observation, and unstructured questioning (Mini-Cog Test, the General Practitioner Assessment of Cognition)
Counseling and interventions to prevent tobacco use and tobacco-caused disease	Ask all adults about tobacco use and provide tobacco cessation interventions for those who use tobacco products. *The "5-A" framework*: 1. Ask about tobacco use 2. Advise to quit through clear personalized messages 3. Assess willingness to quit 4. Assist to quit 5. Arrange follow-up and support	
Depression in adults: screening	Adults aged 18 and over when staff-assisted depression care supports are in place to assure accurate diagnosis, effective treatment, and follow-up ("Over the past 2 weeks, have you felt down, depressed, or hopeless?" and "Over the past 2 weeks, have you felt little interest or pleasure in doing things?")	
Miscellaneous		
Fall prevention in older adults: counseling and preventive medication	Exercise or physical therapy and vitamin D supplementation to prevent falls in community-dwelling adults aged ≥65 years who are at increased risk for falls	The CDC recommends exercise, home modification for hazard reduction, and multifaceted (including medical screening for visual impairment and medication review)
Osteoporosis: screening, women	DXA in women aged ≥65 years and in younger whose fracture risk is ≥ than 65-year-old white women who have no additional risk factors http://www.shef.ac.uk/FRAX/	
Intimate partner violence screening, women	Screen women of childbearing (18–46) age and provide or refer women who screen positive to intervention services. *HITS*: *Hurt*, *Insult*, *Threaten*, *Scream* Insufficient evidence to recommend screening all elderly or vulnerable adults (physically or mentally dysfunctional) for abuse and neglect	
Recommendations for pregnant women		
Asymptomatic bacteriuria	Urine culture for pregnant women at 12–16 weeks' gestation or at their first prenatal visit, if later	
Breastfeeding: counseling	Interventions during pregnancy and after birth to promote and support breastfeeding	
Chlamydial infection: screening	Pregnant women aged 24 and younger or pregnant women aged 25 and older at increased risk	
Folic acid to prevent neural tube defects	All women planning or capable of pregnancy take a daily supplement containing 0.4–0.8 mg (400–800 μg) of folic acid	
Gestational diabetes mellitus, screening	Asymptomatic pregnant women after 24 weeks of gestation	ACOG: all pregnant women with a patient history or the 50-g OGCT
Hepatitis B (HBV): screening	Pregnant women at their first prenatal visit	
Iron deficiency anemia: screening	Routine screening in asymptomatic pregnant women	

(*continued*)

DOI 10.1007/978-1-4939-0779-3_7-1

Table 4 (continued)

Preeclampsia: low-dose aspirin	Low-dose aspirin (81 mg/day) as preventive medication after 12 weeks of gestation in women who are at high risk for preeclampsia
Rh (D) incompatibility: screening	Rh (D) blood typing and antibody testing at the first visit for pregnancy-related care. Repeated Rh (D) antibody testing for all unsensitized Rh (D)-negative women at 24–28 weeks' gestation, unless the biological father is known to be Rh (D)-negative.
Syphilis infection in pregnancy	Screen all pregnant women for syphilis infection
Tobacco use in pregnant women	Recommends that clinicians ask all pregnant women about tobacco use and provide augmented, pregnancy-tailored counseling for those who smoke

other staff in order to allow providers to cover the preventive service needs of most patients.[31] It has been estimated that full adherence to USPSTF recommendations could require 7.3 physician hours out of each working day [32].

Training needs: Training is a key component of overall practice compliance with the provision of preventive services. It is essential to ensure that the staff is skilled at providing the services required, such as standing orders for vaccination and screenings. In addition, they should be knowledgeable about brief intervention for alcohol and drug use, depression, and lifestyle changes. Barriers include the knowledge base and practice patterns of providers (awareness, familiarity, and agreement with guidelines). Awareness and familiarity with guidelines could be partially addressed through continuing medical education. Other factors may require more extensive training and possibly systematic practice change. As is evident from the above review, confusion may also stem from updates to guidelines and/or conflicting recommendations from different organizations.

Coding and billing difficulties: Though electronic medical records (EMR) systems with billing systems are quickly becoming standard tools with important potential benefits, they are not uniform in their interfaces, features, or data entry requirements. In some instances, EMR may even introduce new challenges into daily practice. It is often difficult to receive reimbursement for preventive services. While many insurers have long recognized the value of a set of covered preventive items, other indemnity insurance plans and Medicare have traditionally been reluctant to cover common preventive services. It was not until 2005 that most insurers began to recognize the "preventive care visit." It is encouraging to note that the list of covered preventive services grows more comprehensive annually, particularly in light of the Accountable Care Act (ACA). A similar barrier stems from the disparate coverage provided by states in response to federal mandates. For example, Medicaid coverage of preventive services varies between states, and even as the ACA has included the coverage of key preventive services, many states have not expanded their Medicaid programs. This failure to expand Medicaid means that those states' residents may continue to lack access to preventive coverage [33].

Practice culture: Some providers or practices may be resistant to focusing on preventive services. This resistance can be due to personal prejudices held toward patients (e.g., patients with poor self-care habits or combative attitudes). More importantly, the entire practice may be averse to systematic approaches to implementing preventive services for many reasons, including an orientation toward providing only acute care. In this scenario, the practice-wide goal may be to see as many patients as possible in the most efficient way, addressing presenting complaints, with less emphasis on delivering preventive services. This type of practice alignment may even discourage individual attempts to follow prevention guidelines.

Barriers to Patient Adherence

Much like provider compliance, patients may face various barriers that undermine prevention.

DOI 10.1007/978-1-4939-0779-3_7-1

Access and socioeconomic barriers: The greatest barrier to patient adherence is a lack of access to preventive services and primary care in general. A lack of access may stem from patient choice. Cost barriers to regular primary care visits are important, but sociodemographically vulnerable groups are also more likely to face other barriers that include transportation, competing time demands, fear, perceptions of risk, provider time pressures, and fragmented care [34]. These dynamics may result in visits to emergency departments when the situation has become acute. In this scenario, most often the presenting complaint is remedied on a short-term basis, and other preventive services are not likely to be rendered. Even in the primary care office setting, patients may refuse or delay preventive services because of the additional associated costs.

Health literacy: Health literacy is an important factor impacting patient adherence to preventive care across cultural and socioeconomic groups [35]. Low health literacy, low incomes, and low education are often correlated. Lifestyle and behavioral health are key components in many of the leading causes of mortality and morbidity in the USA. Obesity and type 2 diabetes are examples of preventable yet highly prevalent and increasingly common conditions in primary care populations that indicate a lack of patient knowledge or control over basic lifestyle behaviors. Even when patients are generally knowledgeable about healthy living, they may lack specific knowledge about vaccination, cancer screening, and other preventive services.

Cultural and demographic factors: Reviews of women's preventive service utilization have identified cultural and racial differences, even among physicians receiving care [36, 37]. In some cases, fear, myths, or anecdotes may inhibit a patient from participating in preventive care. Some patients may resist preventive services because they expect a procedure to be uncomfortable. Some may even wish to remain ignorant of any potentially negative test result. Age, lifestyle, previous preventive service or other medical experiences, obesity, and location may all contribute to the likelihood of patient compliance as well [37–39]. More research is needed to understand the best ways to address these complex factors.

Strategies to Improve Adherence to Prevention Guidance

Addressing *all* patient barriers to preventive care is beyond the scope of this discussion. However, public education, insurance coverage, and a variety of public health campaigns are key features of improving rates of screening and intervention. Preventive services have proven to be cost-effective, cost saving, and lifesaving in the longer term [40]. Unfortunately, in many cases, the implementation of such services requires a financial investment by providers on the front end and faces the reimbursement challenges previously discussed.

***Training and time*:** Improvement strategies can produce significant results by targeting a key barrier identified by providers within a particular practice. Readiness-to-change surveys may be helpful in this regard since there is consensus that a systems approach is needed [41]. If, for example, providers report that they lack training about a new guideline or screening tool, then training targeting that particular item may be sufficient. This scenario requires functional communication between providers and administrators and the will of all parties to solve the problem. Administrators and providers may also proactively collaborate to assess the uptake of new or existing evidence-based guidelines in practice and design improvement programs to facilitate providing the needed education and infrastructure to meet goals. However, time constraints can also be addressed in several other ways. Standing orders utilizing nursing staff can effectively shift routine recurring tasks to nursing personnel, such as immunizations and behavioral screenings [42]. Nursing staff effort can be utilized to not only deliver primary preventive services but also secondary and tertiary prevention counseling, case management, care coordination, and even practice management. When well executed, this workflow can improve quality and efficiency [43].

***Practice improvement and facilitation*:** Most practices are highly dynamic workplaces, and many experience varying caseloads over time. Even a medium-sized practice may require addressing each of the

DOI 10.1007/978-1-4939-0779-3_7-1

aforementioned barriers in order to be successful. Practice facilitation, which is in essence the act of employing or tasking an identified person with the role of "helping to get evidence-based guidelines into practice," has been shown effective, and a range of methods are available to initiate this facilitation [41]. The interest of practices to adhere to guidelines and pursue high standards of care while maintaining the capacity to meet individual patient needs has generated a demand for and a range of practice improvement models.

***Patient-centered medical home*:** Perhaps the most widely recognized and comprehensive model for primary care practice improvement is the patient-centered medical home (PCMH) model. The PCMH principles were developed by the American Academy of Family Physicians, the American College of Physicians, the American Academy of Pediatrics, and the American Osteopathic Association and include: a personal physician for each patient; whole-person care, including preventive services; integrated and coordinated care including mental and behavioral health; quality and safety standards including compliance with evidence-based guidelines; and improved patient access [44]. Ideally, transforming a practice into a PCMH involves addressing many of the provider barriers presented herein, while also aiming to support patient compliance. Making the transition to a PCMH can require significant inputs of human and material resources, depending on the starting point of the particular practice. These inputs include staffing changes and hiring, quality improvement assessment processes, regular planning and evaluation meetings, case management and care coordination system development or improvement, practice culture change, health information technology (HIT) utilization, integration of mental and behavioral health, and outreach and dialogue with patients to enhance awareness and feedback.

Special Considerations in Underserved Populations

Practices addressing underserved populations, whether in low-income status urban or rural areas, tend to serve populations with a higher incidence of preventable disease, less access to treatment, and lower health literacy. These patient-level determinants of health demand higher inputs of resources and time to address long-standing patient needs ranging from counseling to numerous tests or procedures in a given visit. Higher needs combined with lower resources result in larger demands on practices, but at the same time, this offers an opportunity for the practice to achieve greater impact and to identify potential areas for further improvement.

Special Considerations in Teaching Practices

Teaching practices require special training and cultural considerations. Resident physicians are often well equipped with knowledge of the most recent prevention guidelines, but may lack the experience to effectively recognize opportunities or counsel patients. Moreover, residency practices have higher turnover of physicians due to the nature of training duration, impacting the practices' ability to create effective long-term patient-provider relationships. Continuity clinics, in which family medicine physicians track the same patient group through the entire training period, as well as specific training in behavior change modalities and integrative medicine may be helpful in addressing these issues.

Health Promotion and Wellness

Naomi Parrella[a]* and Kara Vormittag[b]
[a]Department of Family & Preventive Medicine, Rosalind Franklin University of Medicine and Science, North Chicago, IL, USA
[b]Department of Family Medicine, Advocate Lutheran General Hospital, Park Ridge, IL, USA

The evidence shows that health and well-being are affected and created by a combination of physical activity, nutrition, and rest. Family physicians can directly impact all of these components by educating and guiding patients regarding healthy lifestyle choices. With appropriate nutrition, physical activity, and rest, bodily function is optimized, and health and well-being of patients and communities are improved. In addition, tobacco cessation has been shown repeatedly to directly improve morbidity and mortality. While we know that health outcomes are also heavily affected by socio-demographic factors, this chapter is focused on patient lifestyle choices.

Lifestyle Choices and Risk of Disease

Individual and familial risk of disease throughout the lifespan can be modified positively or negatively by lifestyle choices and behavior patterns. Preventable diseases account for 60 % of all non-communicable disease deaths. The main causes of preventable disease and death are related to poor lifestyle choices, especially physical inactivity, unhealthy diet, and tobacco and alcohol abuse [1]. This chapter will focus on tobacco cessation, activity, and nutrition to promote health and well-being in the United States and reduce the burden of preventable disease.

Physical Activity

Regular physical activity (PA) is associated with enhanced health and reduced risk of all-cause mortality [2]. Research shows that a low level of physical activity exposes an individual to a greater risk of dying than does smoking, obesity, hypertension, or high cholesterol. Regular physical activity can [3]:

- Reduce mortality and risk of recurrent breast cancer by approximately 50 %
- Lower the risk of colon cancer by over 60 %
- Reduce the risk of developing Alzheimer's disease by 40 %
- Reduce the incidence of heart disease and high blood pressure by 40 %
- Lower the risk of stroke by 27 %
- Lower the risk of developing type 2 diabetes by 58 %
- Be twice as effective in treating type 2 diabetes than the standard insulin prescription
- Can decrease depression as effectively as Prozac or behavioral therapy
- In an elementary school setting, regular physical activity can decrease discipline incidents involving violence by 59 % and decrease out of school suspensions by 67 %

Physical Activity Guidelines for Pregnancy

Most studies show the overwhelming benefits of physical activity to the maternal-fetal unit. Physical activity has a role in chronic disease prevention for both mother and offspring [4]. Obesity is the most common chronic disease of pregnancy and affects mother and child negatively [5]. Maternal BMI increases in pregnancy correlate with the odds of an overweight child. Excessive gestational weight is associated with higher likelihood of the child becoming overweight. Exercise during pregnancy reduces the likelihood of excessive weight gain. A vast majority of women who exercise during pregnancy continue to exercise after birth, and parental physical activity correlates positively with the physical activity of their offspring [5].

ACOG recommends that, in the absence of either medical or obstetric complications, pregnant women should exercise at a moderate level for 30 min or more per day on most, if not all, days of the week [4]. Weight-bearing and non-weight-bearing exercises are likely to be safe during pregnancy. However, physically active women with a history of or risk for preterm labor or fetal growth restriction should be advised to reduce her activity in the second and third trimesters [6]. Physical Activity Readiness Medical Examination (PARmed-X) for pregnancy can assist in evaluations of medical problems that may require special considerations in pregnant patients. For a full list of absolute and relative contraindications, see the ACOG statement or the ACSM Exercise Prescription and Testing guidelines [6].

Physical Activity Guidelines for Children and Adolescents

Physical activity declines with age, while time spent in sedentary activities steadily increases [5]. Childrens' physical activity is closely linked to time spent in front of a screen (e.g., television, computer, cellphone). As screen time increases, vigorous activity declines and BMI increases. The American Academy of Pediatrics (AAP) recommends that children have 60 min of vigorous activity per day, which may be accumulated over the course of a day in smaller increments [5]. Activity should be of moderate intensity and include a wide variety of activities – sports, recreation, transportation, chores, work, planned exercise, and school-based physical education classes. These activities should preferably be unstructured and fun.

Age-specific physical activity considerations [5]:

- Infants and Toddlers – Provide opportunities for safe play activity and movement.
- Preschool (4–6 years) – Focus on fun, playful, and safe activities and movement. Encourage activities that emphasize exploration and experimentation, and begin motor learning such as running, kicking, catching, and throwing a ball. Preschoolers can tolerate walking longer distances. Establish walking as a habit and option for transportation.
- Elementary School-Aged Children (6–9 years) – Encourage play to develop motor skills, visual tracking, and balance. Consider organized sports with the focus on enjoyment.
- Middle School-Aged Children (10–12 years) – Encourage play, movement, and sports. Supervised weight training, emphasizing proper technique with small weights and high repetitions may begin. Avoid heavy weights and max lifts. Additionally, certain types of Olympic-style weightlifts should be avoided, including squat lifts, clean and jerk or dead lifts.
- Adolescents – This is a critical age for promotion of lifetime physical activity. Encourage organized sports, other traditional forms of exercise, or exercise with friends and peer group.

Physical Activity Guidelines for Adults

A brief summary of American College of Sports Medicine (ACSM) PA recommendations and Physical Activity Guidelines for Americans is included here: [1, 7].

DOI 10.1007/978-1-4939-0779-3_8-2

Cardiorespiratory Exercise

- Adults should get at least 150 min of moderate-intensity exercise per week.
- Exercise recommendations can be met through 30–60 min of moderate-intensity exercise (5 days per week) or 20–60 min of vigorous-intensity exercise (3 days per week).
- One continuous session and multiple shorter sessions (of at least 10 min) are both acceptable to accumulate desired amounts of daily exercise.
- Gradual progression of exercise time, frequency, and intensity is recommended for best adherence and least injury risk.
- People unable to meet these minimums can still benefit from some activity.

Resistance Exercise

- Adults should train each major muscle group 2 or 3 days each week using a variety of exercises and equipment.

Flexibility Exercise

- Adults should do flexibility exercises at least 2 or 3 days each week to improve range of motion.

Neuromotor Exercise

- Neuromotor exercise (sometimes called "functional fitness training") is recommended for 2 or 3 days per week. Neuromotor exercises develop motor skills. They work a precise group of muscles that are used to perform a learnt act and improve balance, coordination, gait, and agility. Examples of activities that incorporate neuromotor exercises are yoga and thai chi.

Physical Activity Guidelines for Older Adults

The structural and functional decline, overall decrease in physical activity, and increase in chronic disease that accompanies human aging can all be limited by physical activity [8]. Older adults are defined as those older than 65 years or adults between 50 and 64 years who have chronic conditions or functional limitations. Recommendations for older adults are similar to those for adults, with a few special considerations [8]:

- Patients who are deconditioned, functionally limited or with chronic conditions that may affect their ability to be active, should start with low intensity and duration.
- Activities that do not impose excessive orthopedic stress like walking, stationary bike, or aquatic exercise should be considered.
- For flexibility, static stretches are encouraged versus multiple options for others.
- Neuromotor exercises should focus is on progressive balance improvement.

Physical Activity Assessment and Counseling Tools

Many resources are available to family physicians to help incorporate regular counseling into patient visits. These resources and tools should be used in conjunction with behavior change counseling,

DOI 10.1007/978-1-4939-0779-3_8-2

motivational interviewing, and the five A's (Ask, Advise, Assess, Assist, Arrange). The "Five A's" is a convenient approach to physical activity counseling in clinical practice and reviewed in depth later in this chapter.

Physical Activity Assessment and Counseling for Children and Adolescents

Assess what the child AND parents do for physical activity. There is no clinically validated office tool to assess physical activity in children**.** The physical activity vital sign (PAVS) may be used starting at age 13. PACE+ is a validated tool that may be used in adolescents [9].

PAVS for adolescents:

1. How many days in the past week have you participated in physical activity where your heart was beating faster and your breathing was harder than normal?
2. How many days in a typical week do you participate in activity like this?

Other questions used to assess physical activity in younger children:

- How many days of physical education do you participate in at school in a week?
- How many days in a week do you run, bike, swim, or play a sport for 1 h?
- On average, how many hours each day to you spend in front of a screen, either TV or computer, outside of school?

Counsel parents to be role models for their children and involve the whole family in physical activity. Also, parents should limit screen time to 2 h daily.

Physical Activity Assessment and Counseling for Adults

The adult PAVS consists of two questions:

1. On average, how many days per week do you engage in moderate to strenuous exercise like a brisk walk?
2. On average, how many minutes do you engage in exercise at this level?

These two screening questions will provide you with a snapshot of whether your patients are meeting the current PA guidelines of 150 min of moderate intensity physical activity each week. By repeating the assessment of PAVS at every clinic visit, you will be able to track changes in their physical activity levels over time.

In addition to PAVS, there are several validated tools that are designed to facilitate physical activity assessment in adults [3, 10]. These tools evaluate readiness to change, self efficacy, medical contraindications, and other aspects of physical activity. They are available online and include the PAAT, PARmed-X, PAR-Q, and RAPA [10]. They vary greatly in length and content and can be utilized based on physician and patient needs. The most comprehensive guide for PA risk assessment is ACSM's Guidelines for Exercise Testing and Prescription [11]. A useful algorithm based on ACSM guidelines is available for free online as part of the Exercise is Medicine – Healthcare Providers' Action Guide [3].

Sedentary Behavior

Sedentary behavior – sitting for long periods of time – as distinct from simple inactivity has been shown to be a health risk in itself. Meeting the guidelines for exercise does not make up for a sedentary lifestyle [8]. High non-exercise physical activity (NEPA) defined as physical activity that is engaged in to

DOI 10.1007/978-1-4939-0779-3_8-2

accomplish daily activities, such as gardening or cleaning, is associated with a number of positive health markers, including more preferable waist circumference, HDL cholesterol, and triglycerides. Additionally the prevalence of metabolic syndrome is lower in those with higher NEPA in non-exercising AND regularly exercising individuals. Lastly, high NEPA has been associated with a lower risk of CVD events and all-cause mortality [12]. It is important to discuss sedentary behavior and encourage more non-exercise physical activity. For example, substituting walking or biking for short car rides, or using a push mower instead of a riding mower can be very helpful. Additionally, these lifestyle activities are more likely to be sustained than structured activities such as exercising in a gym [10].

Exercise Prescription

For most healthy adults, the simplest prescription is to recommend an increase in activity in daily routines to prevent a sedentary lifestyle and to provide a goal of achieving 150 min of moderate intensity physical activity each week. It is important that a written physical activity prescription be provided. Written prescriptions are an effective means of motivating patients to be more physically active [3].

Consider a physical activity referral to a fitness professional if it is felt that additional instruction or structure is needed. Identifying other community programs may help to personalize recommendations. Numerous mobile technologies exist for promoting, tracking, and advancing physical activity. These include apps, websites, and individual devices.

Nutrition

Nutrition is the intake, digestion, and absorption of nutrients that provide energy and determine the structure and metabolic functions of the human body. With proper nutrition, the body and mind are more resilient and able to develop, respond, and adapt to the environment. The challenge for family physicians has been to determine which of the various nutrition recommendations are appropriate to guide patients to promote health and well-being. This section is focused on evidence-based nutrition counseling for the general population with the goals of promoting health and well-being.

Low fat diets have failed a large portion of the US population. By decreasing the high density caloric intake of fats in the American diet, it was assumed that daily caloric intake would decrease. However, since the initiation of the “low fat” dietary recommendations, the explosion of overweight and obesity, metabolic syndrome, Type II diabetes, sleep apnea, and other weight-related health issues have sky-rocketed to levels never seen before. Individual caloric intake was not decreased by cutting fat, instead the *proportion* of calories changed to a diet with higher intake of calories from sugar [13] and other refined carbohydrates.

Unlike fat, which is satiating, consuming excessive sugar stimulates appetite, triggers cravings for more sugar, and promotes the development of central obesity and insulin resistance. With excessive circulating insulin, the body continues to produce and enlarge ever more adipose cells, mainly around the waist. To maintain this metabolically active excess adipose tissue, once again, the appetite is stimulated to support energy needs. This vicious cycle accelerates as insulin resistance develops further.

One promising approach to improving health with nutrition is the Mediterranean style diet, which is similar to diets found in the areas of the world where more people experience longevity and healthy aging [14]. These diets are not exactly defined but consist of mainly plant-based foods including vegetables, fruit and nuts, whole grains and legumes, moderate poultry and fish, olive oil in place of butter, margarine or cream, reduced simple carbohydrates, and minimal red meat and processed foods [15].

Greater adherence to Mediterranean style diets have been shown to reduce cardiovascular mortality [16]; decrease risk of cancer incidence and mortality [17]; decrease risk of cerebrovascular disease [18]

DOI 10.1007/978-1-4939-0779-3_8-2

and the metabolic syndrome [19]; and reduce cognitive decline and dementia [20] with aging. In fact, greater adherence to the Mediterranean style diet has been found to result in longer leukocyte telomere lengths which have been linked to healthy aging and longevity [21, 22].

Some tools to assess dietary quality include food frequency questionnaires (these are fast, inexpensive, and easy to use), 1–7 day food logs (these are more accurate, but require patients prepare ahead of appointment. This may be easier with smartphone apps like MyFitnessPal), and 24 h dietary recall (quick interview during office visit). There is a validated 14 point screening tool to assess adherence to Mediterranean style diet [15]. Also, the simple act of requesting a food log improves eating behavior(s) by developing a greater awareness of what is consumed. Logging food and drink intake can be done easily with smartphone apps and online resources. These can also be used to log physical activity and sleep.

Using a nutrition assessment tool, family physicians or staff can counsel patients appropriately towards a Mediterranean style diet by offering one or two dietary recommendations at a time.

1. Limit sugar: Work towards limiting or eliminating sweetened food and drink in the diet. Recommend avoidance of sugar sweetened beverages. Educate patients that 100 % fruit juice is NOT equivalent to a serving of fruit.
2. Fluids: Most liquids should consist of water, unsweetened tea, coffee, dairy or dairy alternative with calcium. Wine (up to one glass for women and up to two glasses for men) may be included as appropriate.
3. Vegetables: Work towards daily consumption of leafy greens and increased quantity and variety of colors of vegetables to ensure adequate supply of the various nutrients and phytochemicals necessary for disease prevention and health promotion [23].
4. Grains: Suggest replacement of processed grains with whole grains. Grain may be replaced entirely with more vegetables. This strategy improves insulin resistance, blood sugar control, and triglyceride levels [24, 25].
5. Protein: Include plant-based protein sources (nuts and legumes) and animal protein sources such as eggs, seafood, poultry, and wild game. Limit commercially raised red meat.
6. Fats: Recommend avoiding trans-fatty acids and switching to naturally occurring fats and olive oil.
7. Probiotics can be recommended for health promoting benefits [26].
8. Non-nutritive sweeteners: Despite much controversy, there are no clear evidence that these FDA-approved sweeteners are harmful. There are acceptable daily intake (ADI) levels for each of the seven FDA-approved non-nutritive sweeteners (acesulfame K, aspartame, neotame, saccharin, sucralose; and food products such as luo han guo fruit extract, stevia) [27].
9. Individual patients have different needs. Referral to a registered dietician is recommended for patients with complicated medical issues or needs. For example, the Dietary Approach to Stop Hypertension (DASH) diet may benefit those with hypertension and lower carbohydrate diets may benefit those with metabolic syndrome or type II diabetes. This diet has been found to be more effective than low fat diets in reducing cardiovascular risk factors [28].
10. Recommend sitting down to eat meals and connecting with others. Regular relaxing breaks spaced throughout the day improve well-being [29].

Evidence and Common Areas of Concern

Fats

Trans-fats are primarily found in artificially hydrogenated fats such as margarine and shortening and should be avoided due to adverse effects on lipid panels and cardiovascular health. Rather than decreasing

DOI 10.1007/978-1-4939-0779-3_8-2

saturated fat in the diet, modification of dietary fat leads to cardiovascular benefit [30]. Recommend switching fats from red meats and sugar-laden foods to fats from fish, avocado, nuts, and nut oils (i.e., coconut or olive oil).

Fiber

Dietary fiber is found in whole grains, vegetables, legumes, and fruit. Dietary fiber from grains, vegetables, and legumes is inversely related to deaths from cardiovascular disease, cancer, infectious and respiratory disease in both men and women. This is not true for fruit fiber however. Encouraging high fiber food choices may reduce the risk of premature death [31]. There is no upper limit of recommended fiber intake, although as a practical matter, excess intestinal gas may be experienced by those who increase their fiber intake quickly. The recommended total daily fiber intake is 14 g fiber per 1000 kcal ingested [32].

Sodium

According to the Institute of Medicine, evidence supporting the recommendations for strictly limiting dietary sodium seems to be weak or nonexistent for many medical issues [33]. While there is some evidence that salt restriction may lead to increased insulin resistance and cardiovascular mortality [34], the data are conflicting. There are also data that suggest that the risk of death and cardiovascular events are lower when sodium consumption is maintained between 3–6 g daily [35].

Calcium and Vitamin D

There exists an inverse association between 25-hydroxyvitamin D levels and all cause mortality in primary prevention cohort studies. Vitamin D3 supplementation (but not Vitamin D2) reduced all cause mortality by 11 % [36]. There is inconsistent evidence to support vitamin D and calcium supplementation for improved health outcomes related to pregnancy, bone or cardiovascular health, incidence of cancer, immune function, all-cause mortality or vitamin D status in the general population [37].

Multivitamins

Links between vitamin supplementation and cardiovascular disease are also complex. Multivitamins alone have not consistently been shown to improve cardiovascular outcomes or to reduce mortality risk. The United States Preventive Services Task Force (USPSTF) recommends against the use of beta carotene or Vitamin E supplementation for primary prevention of cardiovascular disease or cancer [38, 39].

Fish Oil

No trials examining fish oil with endpoints of vascular events or mortality were identified. Clinically significant lower triglyceride levels and VLDL were noted in trials with mean omega-3 poly-unsaturated fatty acid (PUFA) doses of 3.5 g/day. No significant changes in total or HDL cholesterol, HbA1c, fasting glucose, fasting insulin, or body weight were observed. No adverse effects of the intervention were reported [40].

Iron

Iron deficiency is the most common nutritional deficiency and leading cause of anemia in the USA and the world. People at high risk for iron deficiency anemia include infants and children after 6 months old, unless they are breast feeding or drinking iron fortified formula, people who restrict some food groups from their diets, women with heavy menstrual periods, and pregnant or breastfeeding women. Among children with iron deficiency, decreased motor and brain development as well as poor health and even death can be prevented with appropriate iron supplementation and education to avoid overconsumption of cow's milk, which limits iron absorption.

DOI 10.1007/978-1-4939-0779-3_8-2

Nutrition Recommendations for Special Populations

Vegan

Vegans do not consume any animal products and are at risk of developing Vitamin B12 deficiency. Counseling about Vitamin B12 supplements or fortified cereals or beverages is needed. Consultation with a registered dietician should be considered.

Vegetarian

When planned well, vegetarian diets may provide complete nutrition for individuals of all ages. Vegetarian patients may want to ensure adequate calcium, iron, zinc, and vitamins D and B12 with the guidance of a registered dietician. Vegetarian meal planning assistance is also available through the American Dietetic Association at http://www.eatright.org/.

Pediatrics

Water and dairy or dairy equivalent containing calcium and vitamin D are the only beverages children need. For children under 2 years old, dietary fat should not be restricted. Recommend introducing and re-introducing a variety of colorful vegetables, proteins, whole grains, and whole fruit to picky eaters as their tastes are constantly developing. Minimizing or eliminating sugar sweetened beverages and foods will help prevent obesity.

Geriatrics

Older adults require adequate protein combined with physical activity to limit sarcopenia which can **increase** frailty and contribute to the development of metabolic disorders [41].

Mind-Body Connection and Resiliency

The mind-body connection to health and healthcare costs is well established. Stress, poor lifestyle choices, and disease symptoms often coexist and if not managed, exacerbate each other. Mind-body therapies act through the common factor of increasing nitric oxide which elicits the relaxation response (RR) and stimulates the body's endogenous stress management responses. These include adaptive changes to gene expression and neurobiological signaling that seem to promote health and resiliency [29]. The RR effectively treats stress and reduces symptom severity in chronic disease, increases positive lifestyle behaviors, and improves many mental health symptoms [42]. The RR has been described as a hypo-metabolic state with decreased sympathetic tone, [29] resulting in lower heart rate, blood pressure, respiratory rate, and oxygen consumption and increased heart rate variability. At the cellular level, the RR positively affects gene expression related to mitochondrial metabolism, insulin secretion, telomere maintenance, and inflammatory pathways [43]. Of the multiple mind-body techniques that elicit the RR, meditation, yoga, and tai chi are reviewed below.

Meditation, tai chi, yoga, and sleep are some of the ways to obtain the health benefits of stress reduction by inducing the relaxation response. Meditation has repeatedly been shown to be effective in decreasing stress in otherwise healthy individuals [44–46]. Mindfulness meditation has been shown to result in positive changes in the brain and immune function [47]. There is evidence that mindfulness meditation programs may alleviate anxiety, depression, and pain, and they may reduce stress, distress, and improve quality of life in those patients with chronic disease or mental health diseases [29, 45,

DOI 10.1007/978-1-4939-0779-3_8-2

46]. Also, in the pediatric population, among children 6–18 years old, sitting meditation was effective in improving physiologic (improved systolic blood pressure, cardiac output, urinary sodium excretion, and endothelial vasodilation function) parameters, as well as psychosocial and behavioral conditions [48].

Mind-body movement programs such as tai chi and yoga appear to have physiological and psychosocial benefits [49, 50]. Tai chi has been shown to promote balance control, flexibility, and cardiovascular fitness in older patients with chronic conditions [50]. In addition, adequate sleep is essential to rest and resiliency. Inadequate sleep leads to a range of health problems and is addressed elsewhere in this text.

Identifying Disease Risks: Weight, Waist Circumference and Body Mass Index (BMI) Screening

Regular physical activity levels, weight, waist circumference, and BMI can be objective measures of overall health risk over time. In addition to physical activity assessment, patients of all ages can be screened for overall health risk assessment with simple measures of height, weight, and waist circumference. Using height and weight, BMI can be calculated to screen for underweight, overweight, and obesity which are linked with increased risks for adverse health outcomes in all ages [51].

Body mass index (BMI) is calculated as weight (kg)/height^2 (m^2). Abnormal BMI, excessive weight loss, or weight gain at any age can be associated with negative health outcomes at all ages. Excess weight is a risk factor for many types of cancer.

Definitions of underweight, overweight, and obesity depend on BMI and differ in pediatrics and adults. In children, BMI *percentiles* are used for assessment from 2 years old and older: these are based on the age and sex of the child. Underweight is defined as those with a BMI $<$5th percentile, overweight, as having a BMI between the 85–95 percentiles, and obesity as a BMI $>$95th percentile for age and sex [52]. In adults, the definitions are based on weight and height. Underweight is considered to be a BMI $<$18.5, the BMI classified as overweight is between 25 and 29.9 and obesity is a BMI greater than 30, with morbid obesity defined as a BMI $\geq$40. In postmenopausal women and older adults, being overweight is less strongly correlated with mortality than it is in younger age groups [53].

An equally important risk factor assessment in adults is the waist circumference. Although the traditional measurements were defined as men $>$40 in. (102 cm) or women $>$35 in. (88 cm), it is now recognized that different ethnic groups have different waist circumference measurements at which elevated cardiometabolic risk occurs. The waist circumference is measured using a tape at the level of the top of the iliac crest.

Monitoring a patient's weight, BMI, and waist circumference is a relatively simple way of monitoring for increased disease risks in the outpatient office. In the pediatric population, the child's weight and BMI percentile is expected to follow a similar curve if he/she is getting adequate nutrition and growing appropriately. Appropriate weight assessment and management at all ages is important in optimizing health.

In pediatrics, the height and weight should be measured and monitored for unhealthy trends during every routine pediatric wellness visit with specific screening for risk of overweight and obesity beginning at 2 years old [52]. Though specific screening frequency guidelines do not exist for adults, it is recommended to obtain a waist circumference and BMI at routine chronic disease follow up visits and/or during annual exams in order to recognize unhealthy weight trends and to provide earlier interventions that may be more effective in promoting health.

DOI 10.1007/978-1-4939-0779-3_8-2

Tobacco Cessation

Tobacco use is a modifiable risk factor responsible for disease and deaths from cancer and cardiovascular and pulmonary diseases. There is no evidence that any form of tobacco use is safe. Cessation should be addressed with all patients who use tobacco in any form [54]. The "Five A's" framework was developed to allow physicians to incorporate smoking cessation counseling into practice [54]. It is described below.

There are medication and non-medication options to assist patients with smoking cessation. Medication options include nicotine replacement, varenicline, and buproprion [54]. Nicotine replacements (gum, inhaler, lozenge, patch, nasal spray) increase the chances of quitting successfully by 50–70 %. They usually need to be titrated based on the amount the patient smokes. Varenicline is a nicotine receptor agonist. It reduces cravings and withdrawal symptoms while blocking the binding of smoked nicotine. It increases the chances of quitting by two- to threefold. Buproprion doubles the odds of smoking cessation when compared to placebo.

Non-medication options include complementary and alternative therapies including acupuncture and hypnotherapy which are not supported by evidence. Exercise is useful and literature supports the use of internet-based interventions and telephone quit lines [54].

E-cigarettes were introduced in the United States in 2007. These operate with a small heating element that creates a water vapor that can be inhaled. There are still many concerns regarding their use and at this time, their safety is unknown [55].

Promoting Adoption of Healthy Behaviors

In order to have a successful intervention in a busy office practice, it is important to be aware of evidence-based treatment options and then to have an effective and practical method to facilitate behavior change, improve treatment compliance, and support successful adoption of healthy lifestyle choices.

Understanding that many patients already have ideas about what they "should be doing" for health, and that patients will only respond to information and suggestions for which they are ready, physicians will be more effective in promoting healthy behavior changes using the "Stages of Change (SOC)," model and appreciate that the patient must progress through each stage *in sequence* to be successful. Two tools that family physicians can use to facilitate this progress include motivational interviewing (MI) [56] and the 5 A's [57] (see Table 1).

5 A's

The Five A's construct – Assess, Advise, Agree, Assist, and Arrange, adapted from tobacco cessation interventions in clinical care – provides a structured strategy for many different types of behavioral counseling intervention [57].

Ask – Address the behavior change agenda
Advise – Provide personalized information on benefits of change
Assess – Address previous attempts, and identify barriers and readiness for change
Assist – Strategize to overcome barriers, and match advice to stage of change
Arrange – Arrange follow-up, and inquire about behavior and readiness for change
Agree* – Shared decision making with a plan that physician and patient mutually agree upon

DOI 10.1007/978-1-4939-0779-3_8-2

Table 1 Counseling for behavior change incorporating Stages of Change and Motivational Interviewing (Adapted from [56, 59])

Stages of change	Patient status	Physician action: motivational interviewing
Precontemplation	No interest, unaware	Assess awareness, help develop awareness, plant the seed, offer hope
Contemplation	Longest stage Aware of risk. Ambivalent: wants to change "but" may not believe it is possible or may not know how	**Identify ambivalence** ("I should start exercising *but* I have no time.") **Listen for change talk**: **Desire** ("I wish I ate healthier," "I want to start exercising.") **Ability** ("I could eat healthier if. . .," "I might be able to start exercising if. . .") **Reasons** ("I would probably feel better if I started eating healthier," "I want to be able to run around with my grandkids.") **Need** ("I should plan ahead and make my lunches," "I have to find a place to walk during lunch.") **Commitment** ("I am going to take a 10 min walk three times a week," "I plan to bring my lunch to work every day.") **Taking steps** ("Last week, I brought my own lunch 4 days, and I started walking with a coworker during lunch on those days.") **Help patient progress in his/her discussion** **Ask permission** ("Would you like to talk about quitting smoking?) **Offer choices** ("We can discuss some of the ways to quit smoking: "cold turkey," nicotine patches, nicotine gum, or medications.") **Share others' success stories** that the patient will be able to identify with and visualize for him/herself
Preparation	Change planned within next 6 months Patient hopeful and inspired	Continue to encourage change talk ("I could eat a salad for lunch most days") Focus on eliciting patient's positive consequences after change ("I could go on a cruise with the money I save if I quit smoking.")
Action	Change made within past 6 months Resisting return to old habits	Elicit patient's sense of satisfaction and pride ("My clothes fit better and my friends are asking me what I am doing!") Provide recognition and positive support ("You must feel so proud of your success.")
Maintenance	Avoid triggers	Positive reinforcement. Enthusiasm. Watch for signs of relapse

*Some models omit "Ask" and incorporate that information in "Assess." Agree is then added as the fifth "A."

A successful visit means moving forward through the SOC in the appropriate sequence, not necessarily immediately adopting the new lifestyle habit. The physician can use brief moments through multiple visits to help the patients' progress through predictable stages and toward the ultimate desired behavior change [57, 58, 59] (see Table 1).

DOI 10.1007/978-1-4939-0779-3_8-2

Patient health and well-being are strongly impacted by healthy lifestyle choices, including avoidance of tobacco, increased physical activity, improved nutrition, and adequate rest. By counseling and encouraging patients and their families and advocating for tobacco control and other measures to improve health, physicians can have large-scale impacts on populations and improve both individual and public health outcomes.

Health Care of the International Traveler

Ann Tseng[a]* and Timothy Herrick[b]
[a]Oregon Health & Science University, Portland, OR, USA
[b]Oregon Health and Science University, Department of Family Medicine, Portland, OR, USA

Introduction

The number of travelers crossing borders each year continues to rise. According to the World Tourism Organization, the number of travelers crossing international borders is set to exceed 1.1 billion by the end of 2014 [1]. Currently, fewer than half of all international travelers seek a travel consultation prior to departure [2]. A basic understanding of traveler's health is necessary to provide travel advice to patients, as family physicians often bridge the gap between knowledge of a patient's health history and travel medicine. In a recent study, primary care providers were second only to the Internet in patient-identified sources of travel health advice [2].

Pretrip Consultation

A pretrip consultation is recommended at least 4–6 weeks prior to departure. The components of the consultation are history intake, review of routine vaccinations, travel-related vaccinations, traveler's diarrhea treatment and prophylaxis, malaria prophylaxis, review of personal protective measures, altitude illness prophylaxis, and safety and accident prevention.

History Intake

This includes the traveler's pertinent medical history, current medications, and allergies, which may affect choices for both travel-related medications and vaccinations. Anticipatory guidance for chronic conditions such as diabetes and heart disease may also need to be addressed. Vaccination history is also relevant, as live vaccines must be given either simultaneously or 28 days apart. Several important travel-related questions are also pertinent, including purpose of travel, specific locations that will be visited in the destination country or countries, accommodations, and traveler habits.

Routine Vaccinations

The travel visit also presents an opportunity to catch up on routine vaccinations. These may include pneumococcal vaccination, Tdap, herpes zoster vaccine, and flu shots. Especially important to verify are MMR and varicella immunity, as immunity is pertinent for travel to parts of the world where disease burden for these illnesses is relatively high.

Travel-Related Vaccinations

Hepatitis A

Hepatitis A is transmitted through fecal-oral contamination. Its prevalence in developing countries is often high, and vaccination is recommended for all destinations in these areas. The illness rarely causes

*Email: tsenga@ohsu.edu

DOI 10.1007/978-1-4939-0779-3_9-1

death but morbidity is significant. Severity of illness is variable between age groups; the illness tends to be more severe in adults.

Hepatitis A is a two-dose vaccine series, with each dose separated by at least 6 months. It is licensed for use in patients 1 year and older and is safe for use in pregnant women. The first hepatitis A shot imparts >90 % immunity and, in healthy travelers <40 years old, can be given at any time prior to departure [3]. In older or immunocompromised travelers, it is recommended that at least one hepatitis A dose is given at least 2 weeks prior to departure to generate adequate immunity [3]. Once both doses are given, immunity is considered lifelong for hepatitis A and no further boosters are needed.

Hepatitis A vaccine also exists in a three-dose series called Twinrix, in which it is combined with a hepatitis B vaccine. Only persons aged 18 and older are eligible to receive the Twinrix vaccine. The vaccine is administered at 0, 1, and 6 months. It is important to note that immunity imparted with each Twinrix shot is less than the individual hepatitis vaccines administered separately. For adequate immunity (>95 %), two doses of Twinrix are recommended prior to travel [7].

In children <1 year old, hepatitis A immunoglobulin (Ig) is available; however, this age group tends to have controlled diets which may reduce hepatitis A risk. There are also conflicting recommendations for hepatitis A Ig use for pretravel prophylaxis [3, 7]. The availability and cost of hepatitis A Ig can also be a challenge; therefore, these considerations should be taken into account.

Hepatitis B

Hepatitis B is transmitted through contact with infected blood or bodily fluid products. Several factors increase the risk of hepatitis B. These include volunteer work in which contact with blood or bodily fluids might be encountered (e.g., medical volunteer projects) and potential for sexual contact. An injury or illness while abroad which leads to local medical care may also increase risk of exposure to hepatitis B. Traveler risk factors should be assessed prior to administration of hepatitis B vaccination.

Hepatitis B vaccine exists in a three-shot series spaced at least 0, 1, and 6 months apart. It is licensed for use starting at birth and is safe for use in pregnancy. One dose of hepatitis B imparts approximately 30–55 % immunity, two doses 75 % immunity, and three doses >95 % immunity in adults [4]. At least two doses of hepatitis B are recommended prior to travel. It is important to note that the immune response to hepatitis B decreases with age; after age 40, protective immunity from full hepatitis B vaccination decreases to below 90 % and to 75 % by age 60 [4]. Immune suppression can also decrease the response to hepatitis B vaccination. Therefore, for some at risk travelers, there may be a benefit in checking hepatitis B antibody titers prior to travel.

Typhoid

Typhoid fever indicates an infection by *Salmonella typhi*, which is spread by fecal-oral transmission. *S. paratyphi* can also cause illness.

There are currently two licensed vaccines in the United States. Typhim Vi is a polysaccharide subunit vaccine, with an effectiveness of 55–75 %. A booster for ongoing exposure is needed after 2 years. Oral typhoid vaccine consists of a live attenuated strain, Ty21a, which confers similar protection. Unlike the polysaccharide vaccine, however, studies have shown that the oral vaccine does confer some protection against paratyphoid [5]. The manufacturer's instructions are for one capsule to be taken an hour before eating every 48 h for four doses. The capsules require refrigeration, and revaccination is recommended every 5 years. It can be administered concurrently or at any time in relationship with other live viral vaccines (i.e., yellow fever). However, as antibiotics can impact the vaccine's immunogenicity, it is recommended that no antibiotics be given with, or 3 days before or after, the vaccine. In the case of proguanil, which is one of the active components of the antimalarial atovaquone/proguanil (Malarone ®), a 10-day interval should be maintained between completing the oral typhoid vaccine and starting

DOI 10.1007/978-1-4939-0779-3_9-1

proguanil. Coadministration with mefloquine is not problematic. As no vaccine confers complete protection, attention to hygiene and eating practices should be emphasized in all travelers.

Yellow Fever

Yellow fever has a widespread distribution in Africa, Panama, and parts of South America. Though classified a hemorrhagic fever, liver and kidney injury is responsible for its morbidity and mortality.

There is a safe and effective vaccine based on an attenuated strain, 17D. Many countries mandate vaccination of travelers. Some countries may even require vaccination of travelers who will transit in airports. Vaccination is restricted to certified vaccination centers. Vaccinees should be provided the International Certificate of Vaccination (yellow card) correctly filled out. Travelers should be told to keep this card with their passport as generally it must be displayed before passport control.

The WHO has recently stated that a single yellow fever immunization confers lifelong immunity, but many countries still require a booster every 10 years [6]. While yellow fever vaccine is generally safe, as a live vaccine, it is contraindicated for the immunosuppressed and generally is avoided in pregnant and lactating women. In addition, there are visceral and neurological reactions which occur more frequently at the extremes of age. Therefore, yellow fever is relatively contraindicated less than 9 months of age and absolutely contraindicated below 6 months of age. There is a relative contraindication over age 60 as well, as adverse reactions, though still rare, are increasingly common above this age [7].

Those travelers who have a contraindication to yellow fever vaccination should be provided an exemption card certifying the medical reason for not receiving the vaccine. The exemption section is included in the International Certificate of Vaccination (yellow card).

Polio

The eradication of polio worldwide has proven to be an elusive goal. At present there are ten countries in the world that are considered either polio infected or polio exporting. This list evolves rapidly, but those countries affected and recommendations for polio vaccination are listed and maintained on the CDC website (www.cdc.gov). All travelers to countries with polio should have completed the standard series. In addition to this, adults whose polio vaccinations took place in the remote past should have a single, lifetime polio booster. Long-term travelers to such countries should verify requirements for entry and exit with the CDC's regularly updated recommendations [8].

Meningococcus

Infections due to *Neisseria meningitidis* occur worldwide. In the United States, quadrivalent meningococcal vaccine (MCV4) is part of the routine vaccination program. There are two destinations for which vaccination is required or recommended: the *Hajj*, the pilgrimage to Mecca in Saudi Arabia, and the meningitis belt of sub-Saharan Africa. In the meningitis belt in Africa, meningitis can occur at any time but is more frequent during the dry season, from December to June. The serotype of greatest concern is group A.

Our practice is to consider vaccination for all travelers to any country which contains part of the meningitis belt if their travel will extend within a month of the December-June window. Quadrivalent vaccines are recommended. Conjugated vaccine (MCV4) has greater longevity and efficacy so this should be chosen if possible, although only the polysaccharide vaccine (MPSV4) is licensed for use in those over 55. Boosters are required every 5 years should the traveler remain at risk. For those traveling with children under 2 years of age, current vaccination schedules should be reviewed, as they vary by product. Adolescents and preadolescents already vaccinated will not need additional boosters for travel.

DOI 10.1007/978-1-4939-0779-3_9-1

Japanese Encephalitis

Japanese encephalitis (JE) is a mosquito-borne illness prevalent in areas of Asia. Its overall prevalence is one case per one million travelers [9]. The risk of contracting the illness includes travel lasting 1 month or greater in rural areas or itineraries in at risk destinations which include prolonged and extensive outdoor activities. Symptoms of the disease include change in mental status, fever, and seizures. The fatality rate is 20–30 % [9]. Long-term neurological and psychiatric sequelae are seen in 30–50 % of survivors [9].

Several brands of Japanese encephalitis vaccine exist in different parts of the world. The current vaccination in use in the United States is IXIARO. IXIARO is a two-dose vaccination, with doses separated by 28 days with the second dose recommended at least 1 week prior to travel. The first dose imparts approximately 41 % immunity, while the second dose leads to 97 % immunity [10]. In addition to use in adults, the IXIARO vaccine has now been approved in use for children aged 2 months to 16 years as of May 2013.

Boosters for JE vaccination are recommended in 1 year for adults, if repeat travel to affected areas is planned. Booster dosing in the pediatric population is still being actively studied.

Rabies

Rabies unfortunately is almost always a fatal illness. The most common transmission occurs through a bite with an infected animal. Worldwide, the most common source of rabies is infected dogs [11]. Children are particularly prone to rabies exposure while traveling as they are less likely than adults to exercise caution when coming into contact with animals.

Pretravel vaccination against rabies is recommended for travelers who are visiting locations with high animal rates of rabies and inadequate access to rabies treatment [12]. In many locations in developing countries, access to rabies immunoglobulin (Ig) might not be readily available. Pretravel rabies vaccination would preclude the need for rabies Ig postexposure in these locales. Vaccination can also be considered for travelers who plan on visiting rabies-endemic locations for extended periods of time (>1 month). Vaccination is often quite expensive and consists of a three-dose series at days 0, 7, and 21 (or 28). It is licensed for use in persons of all ages and is safe for use in pregnant women.

Postexposure treatment is three pronged [12], consisting of wound care, administration of the rabies immunoglobulin (if no preexposure vaccination was given), and postexposure vaccination. See Table 1 for postexposure treatment.

Boosters for rabies are generally not recommended for most travelers on subsequent trips where exposure to rabies may be significant [12]. Exceptions to this are travelers who may be working in a veterinary capacity or research capacity with wildlife, where it is recommended that serum antibody titers for rabies be checked prior to revaccination.

Traveler's Diarrhea Prophylaxis

Traveler's diarrhea is a common cause of infectious illness while abroad, affecting an estimated 30–70 % of travelers [13]. It is defined as three or more episodes of diarrhea in 24 h with at least one of the following associated symptoms: fever, nausea, vomiting, abdominal cramps, tenesmus, or bloody stools. Traveler's diarrhea causes significant morbidity, as it leads to significant disruption in traveler activities and

Table 1 Postexposure treatment of rabies [12]

Received preexposure vaccination?	Wound cleansing needed?	Rabies immunoglobulin administration needed?	Postexposure immunization schedule
Yes	Yes	No	Days 0 and 3
No	Yes	Yes	Days 0, 3, 7, 14

DOI 10.1007/978-1-4939-0779-3_9-1

Table 2 Treatment regimens for traveler's diarrhea

	Southeast Asia, including India	Central and South America, Africa, the Middle East
Adults	Azithromycin, 500 mg PO BID × 3 days or 1 g once	Ciprofloxacin, 500 mg PO BID × 3 days
Children <18 years old	Azithromycin, 10 mg/kg once per day × 3 days	Azithromycin, 10 mg/kg once per day × 3 days
Pregnant women (all trimesters)	Azithromycin, 500 mg PO BID × 3 days or 1 g once (category B in pregnancy)	Azithromycin, 500 mg PO BID × 3 days or 1 g once (category B in pregnancy)

itineraries due to symptoms. While adventure travel and avoidance of precautions put a traveler at higher risk, traveler's diarrhea is also reported on luxury travel itineraries as well.

The most common cause of traveler's diarrhea worldwide is enterotoxigenic *Escherichia coli* [13]. On the rise is enteroaggregative *E. coli* as a pathogen. Other pathogens include *Campylobacter*, *Salmonella*, *Shigella*, viral pathogens, and protozoa such as *Giardia*.

Treatment for traveler's diarrhea is guided by pathogen and location (see Table 2). Ciprofloxacin is the most common antibiotic used to treat traveler's diarrhea in adults and is very effective in all locations in developing countries excluding Southeast Asia [14]. Due to emerging ciprofloxacin resistance and increased rates of *Campylobacter* in Southeast Asia and India, azithromycin is the preferred drug for traveler's diarrhea treatment in this region of the world [14]. Azithromycin is the treatment of choice for both pregnant women and children. Many clinicians prescribe treatment doses of antibiotics for traveler's diarrhea for each traveler to fill in advance and take with them on their trips.

Concurrent treatment of traveler's diarrhea with both loperamide and antibiotics has been shown to decrease traveler's diarrhea symptoms more rapidly than either treatment option alone [15]. A recent meta-analysis of traveler's diarrhea in several communities around the world showed increased likelihood of clinical cure at 24 and 48 h if combination loperamide/antibiotic therapy is given [15].

Prophylaxis for traveler's diarrhea is a controversial topic. The first-line measure of "boil it, cook it, peel it, or forget it" should be reviewed with all travelers. Drinking water which is bottled or boiled at a rolling boil for 1 min to kill potential pathogens is advisable in all at risk locations. The CDC currently does not recommend traveler's diarrhea prophylaxis [13] due to the development of possible antibiotic resistance. It should be noted however that prophylaxis is very effective and can be considered for those with risk factors such as inflammatory bowel disease. Options for prophylaxis include quinolones, which can reduce incidence of diarrhea by up to 90 % [13]. Rifaximin is limited by expense but is another option for traveler's diarrhea prophylaxis. Daily bismuth subsalicylate (Pepto-Bismol®), an option which is not available to pregnant women or children due to its aspirin component, reduces incidence of diarrhea around 50 % [13], though the patient should be warned of black stools. Lactobacillus is also a popular prophylactic option though studies regarding its use in traveler's diarrhea prophylaxis are inconclusive [13].

Malaria Prophylaxis

The WHO reported for 2013 an estimated 128 million cases of malaria with 584,000 deaths, most of which are in children in sub-Saharan Africa [16]. Malaria in travelers is potentially lethal, but avoidable. Each year, there are between 1,200 and 2,000 cases reported in the United States [17].

Four species, *Plasmodium falciparum*, *P. ovale*, *P. malariae*, and *P. vivax*, cause human disease. A fifth species, *Plasmodium knowlesi*, a primate species, causes significant human disease in Southeast Asia, with a dozen cases reported in travelers through 2013 [18]. While all species contribute to human morbidity, the burden of mortality is due to *P. falciparum.* While resistance patterns vary, in general,

DOI 10.1007/978-1-4939-0779-3_9-1

prophylaxis and treatment that effectively target *P. falciparum* in a given area will be effective against the other forms of malaria as well.

Individuals exposed to malaria on an ongoing basis often develop a partial immunological protection called premunition. This protection allows a low level of chronic infection but generally does not allow the malaria to develop into clinical illness. Anyone who has been outside a malarious area for over 2 years generally has the same risk as a nonimmune individual, though the precise rate of decay of immunity is unclear.

The best measures against malaria are mosquito avoidance, including application of DEET to the skin, bed nets, and clothing, and taking an approved medication for chemical prophylaxis [19]. There are currently several antimalarials recommended for prophylaxis, discussed below.

Mefloquine

Mefloquine has been widely used for several decades. It is somewhat controversial, with common minor side effects such as vivid dreams and disturbed sleep and rare adverse cardiac and psychiatric effects. Avoidance of this drug in patients with known cardiac problems, especially those who take QT interval prolonging medications, is recommended. Those who have or have had a psychiatric diagnosis, including depression, should use another agent. It is helpful to begin mefloquine prophylaxis 2 weeks prior to travel instead of the traditionally prescribed 1 week prior. This both allows for a period of time to evaluate the development of any side effects and achieves a drug steady state prior to arrival. Mefloquine should continue to be taken 4 weeks after leaving the malarious area. Areas of increasing resistance have made this drug less useful for much of Southeast Asia [20].

Doxycycline

Doxycycline is useful and effective for malaria prophylaxis. It should be started 2 days prior to travel, taken daily and continued daily for 4 weeks after leaving the malarious area. It is contraindicated in children <8 years of age and in pregnant and lactating women. Dairy products should be avoided for a 2–3 h window before and after ingesting doxycycline. Doxycycline is helpful to take with food to reduce nausea. Photosensitivity has been reported but is not as frequent a problem as with tetracycline. Candida infections can be seen, at times even in men. Interference with oral contraceptives does not seem to be the problem it was once thought to be. However, as with other antibiotics, those taking warfarin should have their dose monitored while on doxycycline.

Malarone

Atovaquone/proguanil (Malarone®) is generally regarded as the best tolerated and most effective of available antimalarials for prophylaxis. There are very few side effects. It is taken daily, 2 days prior to, during, and only 7 days after travel in a malarious area, making this the shortest "tail." Its main disadvantage is cost.

Primaquine

Primaquine is not officially indicated for malaria prophylaxis, outside of the practice of presumptive anti-relapse treatment (PART), also known as "terminal prophylaxis." Terminal prophylaxis with primaquine, at a dose of 30 mg [52.6 mg of salt] per day for 14 days [21], is recommended to all who visit areas where *P. vivax* is present. Primaquine is capable of eliminating dormant malarial hypnozoites in the liver, thereby reducing the frequency of relapse. However, it is active against all forms of malaria and easily tolerated as primary prophylaxis, at the same dosage as used for terminal prophylaxis. Like atovaquone/proguanil, it is started just prior to travel and taken daily, but it is only necessary for 5 days after leaving the malarious area. When used as primary prophylaxis, no terminal prophylaxis is necessary. Primaquine triggers a

DOI 10.1007/978-1-4939-0779-3_9-1

hemolysis in those with G6PD deficiency, so the level of the enzyme should be tested prior to prescribing this drug. Primaquine should not be prescribed to pregnant women.

Personal Protective Measures

Insect avoidance is an important component of prevention for travelers to the tropics. Medical prophylaxis for malaria works better in combination with avoidance to lessen the parasite exposure. Other diseases, such as Japanese encephalitis, are preventable by vaccination, but the cost and availability of vaccines may discourage their use, especially in short-term travelers. In addition, diseases such as dengue and chikungunya have no treatment or vaccine yet available, so protective measures are the only prevention.

Permethrin-impregnated bed nets are a major element in malaria prevention. Travelers should take advantage of these when available. Permethrin is also available as a spray-on product for the treatment of clothes [19].

DEET (*N*,*N*-diethyl-meta-toluamide) is a repellent with a long history of safe use. Adverse effects are rare. However, it is best to use clothing that covers much of the body so that DEET can be applied sparingly. The American Academy of Pediatrics recommends 10–30 % strength for children older than 2 months of age. Picaridin is a product that can be used as well.

Trypanosomiasis is a rare disease in travelers, but there have been reported cases from those going on game drives. Long sleeves and pants and permethrin treatment are helpful strategies for avoidance. In addition, given that tsetse fly traps are purposefully made in royal blue and black colors to attract the flies, these are good clothing colors to avoid during such activities.

Schistosomiasis is one of the most common diseases of returned travelers. There are several species of this fluke, which in its larval stage is an infection of freshwater snails. Travelers to the tropics should be counseled against swimming in freshwater. Wading and even dangling a body part in the water can also transmit the fluke, as well as bathing with untreated lake or river water.

Certain preventive strategies are difficult to apply to those at highest risk: children under the age of 1, pregnant women, and the immunocompromised. For such travelers, it is helpful to encourage thoughtful reflection as to the risks and benefits of travel. In some cases, travel plans can be modified in such a way that the risk can be mitigated.

Altitude Illness Prophylaxis

In several destinations in the world, altitude illness and prevention become a concern. Symptoms of altitude illness include headache, insomnia, nausea, fatigue, and dizziness. Severity of altitude illness can range from acute mountain sickness which is mild to more serious complications such as high-altitude cerebral edema (HACE) and high-altitude pulmonary edema (HAPE).

A discussion of altitude prophylaxis is recommended for destinations exceeding 2,500 m [22]. The most widely accepted preventive measure is slow ascent [22]. Several medications are available for altitude prophylaxis, including acetazolamide and dexamethasone. Recommended dosing for acetazolamide is 125 mg by mouth twice per day, to start the day prior to ascent and to continue until the traveler has acclimatized at their maximum altitude (generally 48 h) [22]. Acetazolamide can cause side effects such as diuresis and paresthesias and cannot be used in patients with sulfa allergies. Dexamethasone is a second-line prophylactic option, but as it does not aid in acclimation, it can cause rebound symptoms of acute mountain sickness once stopped. Local herbal remedies are also popular and available in high-altitude destinations worldwide, but efficacy in preventing altitude illness is unproven in studies [22]. The most effective treatment for altitude illness is descent.

DOI 10.1007/978-1-4939-0779-3_9-1

Safety and Accident Prevention

A significant proportion of the pretravel visit is dedicated toward the discussion of pretrip immunizations, malaria, and traveler's diarrhea. However, the primary cause of death among travelers is accidents, such as motor vehicle accidents and falls [23]. For this reason, the topic of safety and accident prevention deserves specific mention during the pretrip consultation. Depending on the destination, standards and safety for driving can vary significantly. There may be political or civil unrest occurring in various destinations that a traveler should be aware of. Registering an international trip with the US State Department and consulting their website may be helpful in trip preparation.

Sexually transmitted diseases are a risk for travelers who might consider having sex while abroad. Assessing for the likelihood of this during the pretrip consultation is important, and these travelers should be reminded of both the incidence of STDs in their destinations and the use of barrier protection. There can be variability in the quality of condoms purchased abroad.

Finally, trip and evacuation insurance should be considered prior to departure. This might be most useful for those travelers abroad for an extended period of time, especially in remote locations or for travelers who have one or more chronic illnesses.

Post-Trip Consultation

The goal of the pretravel consultation is the avoidance of illness during and after travel. There will be times when such measures fail. The likelihood of illness is negatively correlated with preventive measures taken. Pathologies frequently encountered in returned travelers include fever, gastrointestinal disease, skin disease, eosinophilia, and latent tuberculosis.

Fever in Returned Traveler

For purposes of this discussion, fever will be defined as an oral temperature greater than 100.0 F, although given the cyclical nature of many fevers, subjective reports of fever should be taken seriously. Even remotely completed travel can cause illness, but the large proportion of fever cases present within weeks to months of return from travel. One exception is non-*falciparum* malaria, which can incubate for up to a year, and delayed relapse can occur many years later [24].

The most critical subgroup of febrile returned travelers are those with hemorrhagic symptoms. All patients with fever and hemorrhage who have returned within 21 days from travel should be considered to have a viral hemorrhagic fever and placed in isolation until proven otherwise. Not all of these diseases are contagious, but until a specific identification has been made, high transmissibility should be assumed.

The next most important task in the care of returned travelers is to identify potential cases of malaria. In many cases, malaria is the most important cause of fever in a returned traveler [25], and the risk of mortality from this pathogen makes its rapid identification and treatment critical. Malaria can be contracted in any tropical continent and is the most frequent cause of fever in those traveling from Africa. Dengue is the most frequently encountered pathogen from Southeast Asia, and enteric fever is the most frequently encountered fever from the Indian subcontinent [26]. Other important causes of fever include schistosomiasis, leptospirosis, amebic abscess, tuberculosis, and sexually transmissible diseases, including HIV.

Workup for fever should include a careful history, including the itinerary, associated symptoms and a physical exam emphasizing ENT, pulmonary, GI, neurological, and integumentary systems. A lab workup including a CBC with differential, thin, and thick smears for malaria and blood cultures can also

DOI 10.1007/978-1-4939-0779-3_9-1

be helpful. For clinical situations such as dengue or chikungunya, specific viral serologies can also be considered.

In practice settings where results are likely to be delayed, empiric treatment with an antimalarial should be strongly considered. Atovaquone/proguanil is widely available as a prophylactic and is effective as a treatment as well. The same can be said for mefloquine. A more ideal medication artemether-lumefantrine (Coartem) is preferred as a treatment and avoids the theoretical problem of using a medication as treatment which may have failed as a prophylactic agent. Availability of Coartem, however, may be a factor. Parenteral options such as artesunate are effective but should be done in consultation with the CDC. Quinine has a long track record, but its potential for arrhythmias limits its utility.

GI Illness in Returned Traveler

GI illness is one of the most common illnesses in the returned traveler [23]. A history of destination, activities during travel, and onset of symptoms can help distinguish whether or not the illness is travel related. A more in-depth discussion of traveler's diarrhea is reviewed in the pretrip consultation section of this chapter.

Diarrheal symptoms lasting more than 2 weeks should prompt screening for *Giardia* and other parasites. Multiple stool samples for O and P testing may need to be submitted to accurately diagnose parasitic infection. The authors recommend three stool O and P samples on three different days, as one sample can miss potential infection dependent on time of collection. In cases where clinical suspicion persists despite negative microscopic results, stool testing for *Giardia* and *Cryptosporidium* antigen is available and is sensitive.

Extended symptoms of diarrhea can also be seen with post-infectious irritable bowel syndrome (IBS), a diagnosis of exclusion in travelers with prolonged diarrheal symptoms >30 days after travel [27]. The incidence of post-infectious IBS is variable and ranges from 4 % to 31 % across all studies [27]. In one study of North American travelers to Mexico, the incidence was 11 % of all travelers with diarrhea, 10 % of these 11 % being newly diagnosed cases of IBS [28]. There is no widely accepted strategy for treatment, but options are similar to those recommended for noninfectious IBS including probiotics, antispasmodics, and low doses of tricyclic antidepressants [28].

Skin Lesions in the Returned Traveler

Skin lesions and rashes are common after return from travel. They may reflect a discrete condition (i.e., cutaneous larva migrans, swimmers itch, or tungiasis) or a systemic illness (i.e., dengue, chikungunya). History of activities during travel and specific locations visited during travel are important in the diagnoses of these conditions.

Eosinophilia

Perhaps the most common laboratory value in a returned traveler is eosinophilia. A cutoff of 500×10^6 should be used to promote further evaluation. The most common causes of eosinophilia in travelers are schistosomiasis, filariasis, and nematode infections [29], but *Strongyloides stercoralis* is an important consideration and may present decades after a stay in the tropics. Stool for ova and parasites may shed light on certain species of schistosomes and nematodes. Urinalysis should be performed for hematuria and schistosomal ova. Skin exam and a snip test can be helpful with filariasis.

Tuberculosis Screening in the Returned Traveler

In travelers to some destinations, especially developing countries, screening for tuberculosis on return is advised. If the trip itinerary includes a work in health-care settings or frequent face-to-face contact with persons residing in a TB endemic location, a PPD screen is recommended 8 weeks after return [30].

DOI 10.1007/978-1-4939-0779-3_9-1

In some populations, a PPD may not be appropriate. These would include travelers with a history of BCG vaccine, as immunity is variable and a PPD test in these populations may be positive for decades. For these special populations, an interferon gamma release assay (IGRA)-based test such as QuantiFERON®-TB Gold is preferable for screening [31]. In populations in which there are no special indications for IGRA-based testing, there is no superiority of the IGRA-based test over the PPD test for screening [31]. For travelers who convert either their PPD- or IGRA-based screening to positive, a chest x-ray is recommended to assess for active tuberculosis. Persons with active disease are reportable to the local health department. Persons with latent disease should receive a discussion on the risks and benefits of treatment for latent tuberculosis.

Reentry for Long-Term Travelers: Psychological Concerns

For many return travelers who have been abroad long term, reentry into life in the United States can be difficult. A variety of emotions can arise on the return, from happiness to anger and sadness. Long-term expatriates can feel isolated and unable to connect with loved ones from home after their experiences abroad. Reverse culture shock can occur as well. Screening for depression, anxiety, and posttraumatic stress disorder (PTSD) should be considered for all long-term returned travelers when seen by their primary care providers. Counseling is highly recommended for travelers with psychological concerns on reentry.

Preconception and Interconception Care Defined

Preconception care is defined as *a set of interventions that aim to identify and modify biomedical, behavioral, and social risks to a woman's health or pregnancy outcome through prevention and management* [1]. Interconception care is care provided to women beginning with childbirth until the birth of a subsequent child. It is a subset of preconception care that addresses the continuity of risk from one pregnancy to the next [2]. Preconception and interconception care has increasingly been recognized as a crucial component of both women's and infant's health.

Ongoing Problem of Perinatal Morbidity and Mortality

Infant mortality remains a significant problem in the USA. In 2010, the US infant mortality rate was 6.1 per 1000 live births. Despite leading the world in health-care expenditures, the USA ranks 26th among developed nations in infant mortality [3]. Since 2000, after 40 years of improvement, infant mortality rates have stalled and maternal morbidity and mortality are *increasing* [4, 5].

The most important causes linked to infant mortality are preterm birth and birth defects (see Figs. 1 and 2). Birth defects account for 20 % of all infant deaths and affect 1 in 33 infants born in the USA [6]. Approximately 36.5 % of all infant deaths in the USA are attributable to prematurity [7]. After decades of focus on improving prenatal care interventions, the preterm birth rate in the USA remains unacceptably high. Significant racial and ethnic disparities persist. For example, the perinatal infant mortality rate among non-Hispanic black infants is 2.3 times higher than that of white infants [8].

Need to Address Risks Prior to Pregnancy

It is now recognized that many of the modifiable risk factors affecting preterm birth, birth defects, maternal morbidity, and both maternal and infant mortality occur prior to pregnancy. Structural organogenesis of the central nervous system and heart begins as early as 3 weeks post-conception, and development of the heart, limbs, and reproductive organs is nearly completed by 8–9 weeks' gestation. As early as the missed menses and by the time a woman enters prenatal care, it is often too late to affect periconception risks [9]. Unfortunately, approximately 50 % of pregnancies in the USA are unintended, thus limiting the ability to "plan" preconception risk reduction [10]. Unintended pregnancy is an independent risk factor for poor birth outcomes. Additional examples of maternal risk factors which determine birth outcomes are: inter-pregnancy interval, maternal age, exposure to teratogenic

medications, exposure to substances, chronic disease control, and preventable congenital anomalies [11] (Table 1).

CDC Recommendations on Preconception Health

In 2006, the CDC released "Recommendations to Improve Preconception Health and Health Care – United States: A Report of the CDC/ATSDR Preconception Care Work Group and the Select Panel on Preconception Care" [1]. This report included 10 recommendations to improve women's health and address the problem of preterm birth, birth defects, and infant mortality through increased focus on preconception care. Recommendation #3: "As a part of primary care visits, provide risk assessment and educational and health promotion counseling to all women of childbearing age to reduce reproductive risks and improve pregnancy outcomes." The select panel also recommended to: (1) encourage each woman and couple to have a reproductive life plan; (2) deliver preconception interventions as follow up to risk screening, focusing on those interventions with high population impact and sufficient evidence of

effectiveness; and (3) use the interconception period to provide intensive interventions to women who have had a prior adverse pregnancy outcome (e.g., infant death, low birth weight, preterm birth).

As part of its goal to reduce infant mortality and decrease disparities in reproductive outcomes, the CDC incorporated preconception care into *Healthy People 2020* and launched the Preconception Health and Health Care (PCHHC) initiative focusing on five areas of engagement: clinical, consumer, public health, policy/finance, and surveillance/research [12]. In 2008, the clinical working group of the PCHHC published a systematic review of the evidence in support of the clinical content of preconception care.

DOI 10.1007/978-1-4939-0779-3_10-1

More than 30 experts reviewed over 80 topics using the strength of recommendation taxonomy approach consistent with USPSTF. This compendium of evidence has informed the distillation of preconception care into 10 focused content areas of risk reduction and intervention to improve future birth outcomes: family planning, nutrition, infectious disease/immunizations, chronic disease management, medication and environmental exposures, substance use, previous pregnancy outcomes, genetic history, mental health, and interpersonal violence [13].

Barriers

Unfortunately, there remain significant barriers to successful implementation of quality preconception health. Women often do not seek reproductive health care prior to pregnancy and a large proportion of women of reproductive age do not have insurance coverage until they are already pregnant [14]. When there is an opportunity in a clinical setting, there is often insufficient time to address preconception health [15]. Other health issues often take priority and preconception care is usually not the reason for visit. When it comes to interconception care, the focus is more often on the child than on the woman's health [16, 17]. Finally, providers may lack education, guidance, or resources on approaching preconception health issues in the continuum of care [15].

Opportunities in Primary Care

Despite evidence that managing preconception health can help to improve pregnancy outcomes, many women do not receive this care [18]. Family physicians and other primary care providers have many opportunities to interact with women of childbearing age and provide this care during well-woman exams, acute care, and chronic disease management visits, as well as when they accompany their children or partners to their visits. "It is not a question of whether you provide preconception care. Rather, it's a question of what kind of preconception care you are providing" Sanford and Hobbins [19]. Making preconception health a part of routine primary care could significantly impact the health of women and future pregnancies as well as the health of infants and children.

Clinical Content of Preconception Care

History

Past Medical History

A thorough past medical history is the cornerstone of comprehensive primary care and equally so in the provision of preconception care. More than 25 % of women of childbearing age have a chronic condition such as chronic hypertension, asthma, major depression, etc. (Table 1). It is essential that these chronic conditions be recognized and treated in the preconception period. For example, poorly controlled or undiagnosed diabetes resulting in hyperglycemia in the first trimester results in a fourfold increase in congenital heart defects and increased risk of pregnancy loss [20].

Previous Obstetrical History

Women who have had three or more spontaneous abortions should undergo additional testing to rule out thrombophilia, thyroid dysfunction, and other potential genetic syndromes. Women with a history of a

DOI 10.1007/978-1-4939-0779-3_10-1

spontaneous preterm delivery are at increased risk of this outcome in the next pregnancy [21]. Women with a prior history of preeclampsia, gestational diabetes, or other poor birth outcomes should prompt additional evaluation for chronic medical conditions and counseling on the importance of early prenatal care.

Family History

A three-generation family history will identify women who are at increased risk for genetic syndromes such as thrombophilia, coagulopathies, hemoglobinopathies, cystic fibrosis, trisomies, etc. Genetic counselors may be of assistance for patients with positive three-generation family history screening. The carrier frequency for some of these conditions is also increased in selected ethnicities such as African, European, Ashkenazi Jewish, Mediterranean, and Asian descent [22].

Social History

Poverty and the constant stressors associated with housing and food insecurity are the norm in many clinical settings. It is important that women living in poverty are given clear instruction and logistical assistance to access available social service resources. These resources vary from community to community and the clinical team should be actively involved in linking patients to these resources.

Women who are currently experiencing or have a history of intimate partner violence are at marked increase of physical and emotional injury. A national survey in the late 1990s estimated that approximately 4.8 million partner rapes and physical assaults occur in the USA on an annual basis [23]. It is important to screen for exposure to violence routinely in the office setting. The CDC has extensive resources at www.cdc.gov/violenceprevention/pdf/ipv/ipvandsvscreening.pdf.

Smoking exerts deleterious effects on the current and future health of women and future pregnancies. Although smoking rates have been declining in the USA since 1990, an estimated 18.7 % of nonpregnancy reproductive-aged women were smoking in 2009 [11]. Approximately 54 % of nonpregnant women of childbearing age consume alcohol and approximately 15.2 % binge drink [11]. Women with alcoholism are at marked increased risk for adverse future pregnancy outcomes because alcohol is both a teratogen and fetal toxic agent. There is no known safe level of alcohol ingestion in pregnancy.

Illicit drug use/abuse is common in rural and urban settings, often putting women at increased risk of significant morbidity and mortality. Ten percent of women of reproductive age report illicit drug use in the past month [11]. Women using illicit drugs have a higher incidence of medical, psychiatric, psychosocial, and infectious comorbidities.

Medication History

It is important to review all prescribed and over-the-counter medications and to note which ones could exert teratogenic effects on the developing embryo. About 10–15 % of congenital birth defects are thought to be caused by teratogenic exposure [24]. Many anticonvulsant agents, most notably valproic acid and carbamazepine, markedly increase the incidence of neural tube defects. A valuable source for identifying prescriptive and OTC medications that pose risks to the developing embryo can be found at http://otispregnancy.org/otis_fact_sheets.asp.

Environmental History

Women should be assessed for exposure to major environmental agents including mercury, lead, hydrocarbons, bisphenols (organic compounds with estrogenic properties), and nitrates. These exposures may come from the workplace, hobbies, exposure from well water, contact from plastic containers (#7 plastic containers), or dietary sources (ingestion of large game fish). Clinicians and patients both need to be conversant about these common exposures in the environment [25].

DOI 10.1007/978-1-4939-0779-3_10-1

Physical Examination
The physical exam, in combination with a thorough history, offers the best opportunity to diagnose chronic medical conditions that can adversely impact a woman's current or future health.

Nutritional Status
When conducting the preconception physical examination, the clinician should determine the patient's BMI. Underweight women will have a BMI less than 18.5 while obese women will have a BMI greater than 30. Both of these extremes should trigger more extensive nutritional assessments/screening for eating disorders. Obese women have increased risk of developing hypertension, diabetes, cardiovascular disease, infertility, sleep apnea, and breast/uterine/colon cancer. Health risks of women with low BMIs include nutrient deficiencies, cardiac arrhythmias, osteoporosis, amenorrhea, and infertility [26].

It is important to ask patients about their use of dietary and nutritional supplements. It has been estimated that between 18 % and 52 % of women of childbearing age consume some kind of OTC dietary supplements. Excessive amounts of the fat-soluble vitamin A (>10,000 IU/day) may be teratogenic and can result in cranial and neural crest defects [24].

Standard Nutritional Recommendations
Women without a history of a previous pregnancy complicated by a neural tube defect (NTD) should be placed on a multivitamin supplement containing at least 400 mcg of folic acid. This is not only effective in preventing 70 % of future neural tube defects but also results in a decreased incidence of limb, cranial facial, and urogenital congenital birth defects [26]. Women with a previous history of an infant with a NTD require a much higher amount of daily supplementation with folic acid of 4000 mcg [27].

Vaccine Preventable Infections
Women of reproductive age should be counseled about vaccine preventable infections and offered appropriate immunizations according to the CDC ACIP recommendations [28, 29]. Particularly important for preconception health are: hepatitis B, rubella, varicella, annual influenza, and HPV (for those aged 11–26 years).

Sexually Transmitted Infections
Obtain risk-based STI tests for gonorrhea, chlamydia, HIV, and syphilis.

Laboratory Evaluation
Women should be screened for diabetes according to current USPSTF guidelines. Screen for anemia for patients with a history of excessive menstrual blood loss, those whose physical exam is suggestive of anemia, or whose family history is positive for hemoglobinopathy.

Preconception Care for Women with Chronic Medical Conditions

Family physicians are well versed to provide preconception care to women of childbearing age because of their expertise in managing a wide range of primary care conditions. However, they must be prepared to understand how the care of these conditions must be adjusted in the preconception period in preparation for the critical period of embryogenesis during the first trimester of an ensuing pregnancy [20, 30]. Table 2 provides an overview of condition and medication management in anticipation of pregnancy for 10 common chronic conditions. It also addresses family planning considerations. Another key information source to

DOI 10.1007/978-1-4939-0779-3_10-1

Table 2 Preconception care of women with chronic medical conditions [20, 30]

Condition	Epidemiology/natural history	Preconception interventions	Contraception strategies	Medication use
Diabetes mellitus (DM) and relationship to gestational diabetes (GDM)	One percent of pregnancies with DM and 7 % with GDM. Poorly controlled DM in the first trimester associated with fourfold increase in congenital abnormalities. High rate of recurrence of GDM. Fifty percent GDM develop DM within 5 years	Strict glycemic control of DM in the first trimester reduces the risk of congenital malformation. Lifestyle modification decreases risk of developing DM among women with previous history of GDM	Avoid use of estrogen-containing birth control if patient with DM has concurrent hypertension, renal disease, or thrombophilia	Diabetic medications such as sulfonylureas, metformin, and insulin safe to use in pregnancy
Thyroid conditions	Graves (0.2 % prevalence) untreated: poor outcomes Overt hypothyroid (2.5 %) Untreated: decreased IQ and increased spontaneous AB and preterm delivery Subclinical hypothyroidism (2–5 %) associated with adverse perinatal outcomes	Hypothyroid: levothyroxine should be increased 25 % as soon as pregnancy diagnosed Subclinical hypothyroid: RCT evidence for screening and treatment lacking	Overt hypothyroidism and subclinical hypothyroidism are associated with impaired fertility and increased risk of miscarriage	Graves: avoid methimazole in the first trimester; avoid use of propylthiouracil in the second and third trimester Hypothyroid: maintain TSH below 2.5 in the first trimester
Epilepsy	One percent of population; 3–5/1000 births; increased congenital anomalies in women who have seizures and who take antiseizure meds (two to threefold increase)	Discontinue antiseizure meds if seizure-free for 2 years; switch to meds that are less teratogenic before pregnancy such as lamotrigine and levetiracetam	Decreased efficacy of OCs when taking meds that induce liver enzymes, i.e., phenytoin and carbamazepine; use progesterone-only contraceptive methods if using these medications	consider switching to safest alternative medication - experts do not suggest immediate cessation of therapy due to possible increased risk of seizures; use high-dose folic acid (4 mg/day) 4 weeks before and 12 weeks after conception
Chronic kidney disease (CKD)	Patients with mild CKD (Creat 0.9–1.4) have good outcomes. Patients with moderate CKD (1.4–2.5) or severe (>2.5) at risk of developing worsening disease. These patients have increased risk of	Very important to control blood pressure. Try to avoid pregnancy with moderate to severe CKD	Absolute contraindication to use estrogen OCs with CKD if they have cardiovascular disease and history of VTE and are smokers >35 and patients with liver disease. Use	Avoid use of ACEs, ARBs, and spironolactone in pregnancy

(*continued*)

DOI 10.1007/978-1-4939-0779-3_10-1

Table 2 (continued)

Condition	Epidemiology/natural history	Preconception interventions	Contraception strategies	Medication use
	adverse outcomes if they have HTN		progesterone-only or barrier methods	
Cardiovascular disease (CVD)	Three percent of women have CVD with a 1 % incidence in pregnancy. CVD is the cause of 10–25 % of maternal mortality. Conditions that result in NYHA class greater than II or cyanosis at baseline prenatal visit are most predictive of increased risk of perinatal and maternal mortality	Use of warfarin in pregnancy should be avoided; instead, heparin or enoxaparin is used. With prosthetic valves, warfarin may be used in the second and third trimester. Structural heart lesions should be repaired prior to pregnancy. Certain cardiac syndromes have genetic etiology	Important to have thorough cardiac assessment/imaging prior to pregnancy to assist in risk stratification of patients at high risk of morbidity and mortality. Avoid COCs for patients with R to L shunts and ischemic disease and for patients with multiple cardiac risk factors. Progestin use is okay	Do not use warfarin in the first trimester. Avoid use of ACE, ARBs, and spironolactone in pregnancy
Hypertension (HTN)	Ten percent of women of childbearing age; women with chronic HTN at increased risk of worsening CKD, preeclampsia, and eclampsia in pregnancy	Preconception treatment of mild to moderate HTN results in 250 women needing treatment to prevent one fatal or nonfatal cardiovascular event such as a stroke	Combination OCs may be used in women with mild essential hypertension (140–159/90–99); copper IUD listed as preferred contraception for moderate to severe HTN	ACEs and ARBs are teratogenic and fetotoxic; should be stopped prior to conception
Asthma	Eight percent of pregnant women; 30 % of women with asthma have worsening symptoms in pregnancy. Increased maternal and perinatal morbidity and mortality among women with poor control of asthma	Use of systemic steroids in the first trimester associated with threefold increased risk of oral clefts and maternal preeclampsia	Anticholinergic agents are class B and short-acting beta agonists are class C. Budesonide is class B and other inhaled corticosteroids are class C. Maternal smoking cessation is of great importance	Avoid use of systemic steroids in the first trimester. Administer influenza vaccine early in pregnancy
Thrombophilia	Factor V Leiden gene present in 5 % of Caucasians; antiphospholipid antibody syndrome most common acquired condition and is more common in blacks. Thrombophilias are associated with increased risk of VTE, arterial thrombosis, and severe preeclampsia	Diagnostic testing available for high-risk populations: FH of VTE, personal Hx of VTE; Hx of recurrent pregnancy loss, severe preeclampsia, severe IUGR. Consensus expert opinion recommends treatment for many of these conditions in	Genetic counseling and targeted screening indicated for high-risk populations during preconception care. Combined OCs not recommended; progestin-only methods, IUDs, and barrier methods preferred	Use heparin or enoxaparin throughout pregnancy. Avoid use of warfarin, especially in the first trimester

(*continued*)

DOI 10.1007/978-1-4939-0779-3_10-1

Table 2 (continued)

Condition	Epidemiology/natural history	Preconception interventions	Contraception strategies	Medication use
		pregnancy; recommend MFM consultation		
Obesity	More than one third of US women are obese which is associated with increased risk of DM, HTN, CVD, OSA, and cancers (breast, uterine, colon). Associated adverse perinatal outcomes include NTD, GDM, HTN, PTD, VTE, IUFD	Important to achieve weight loss prior to conception. Counseling alone or combined with medication can result in modest and sustained weight loss (USPSTF). Bariatric surgery prior to pregnancy is another effective intervention. This surgery is associated with increased fertility rates [31]	Clinicians need to assess obese women for comorbid conditions such as DM, HTN, and OSA and hx of VTE that markedly increase risk to women. With many of these conditions, use of combined OCs is relatively contraindicated. Increased risk of impaired fertility and early pregnancy loss	Bariatric surgery associated with decrease incidence of DM, GDM, HTN, and OSA but increased risk of preterm delivery, SGA, and NICU admissions. Increased risk of nutritional deficiencies with GI bypass surgery, less so with gastric banding [32]
Major depression/ bipolar	Approximately 12 % of women in both the preconception and interconception periods have major depression [11]. Victims of intimate partner abuse have a fivefold increase in major depression. Major depression in pregnancy associated with increase in PTD and low birth weight. Bipolar disease associated with increased incidence of postpartum psychosis	Optimizing depression care with medication and psychotherapy associated with improved pregnancy outcomes [20]	Victims of intimate partner abuse have higher incidence of unplanned pregnancy and high-risk sexual behavior. Consider use of long-acting reversible contraception (LARC) for patients who find it difficult to use other daily methods	Patients receiving valproic acid and carbamazepine should be placed on 4 mg of folic acid/day for 4 months prior to conception. Valproic acid should not be used in pregnancy. Avoid use of paroxetine and lithium in the first trimester. Lithium can be used in the second/third trimester

assist women is http://www.cdc.gov/reproductivehealth/UnintendedPregnancy/Contraception_Guidance.htm.

Preconception Risk Assessment

At the conclusion of a preconception visit, the clinician summarizes the significant risk factors that were identified in the process of screening for positive family history, prior obstetrical history, psychosocial factors, alcohol, smoking, illicit drug use, medication use, and presence of active medical conditions that

DOI 10.1007/978-1-4939-0779-3_10-1

should be addressed that will have a beneficial effect on the woman's current health and future pregnancy outcome. The clinician will then recommend a specific action plan to address the identified risk factors. In many circumstances the development of the preconception risk assessment and action plan may occur over two visits.

Strategies for the Prevention of Adverse Birth Outcomes

Because the traditional approach of addressing maternal risk factors through a single preconception visit has failed to improve birth outcomes, current recommendations focus on integrating preconception screening, risk reduction, and health promotion into all routine health-care encounters for women with childbearing potential, regardless of pregnancy intention. Visits for preventive and routine gynecologic care provide natural opportunities for risk reduction, health promotion, and family planning. However encounters for pregnancy testing, treatment of sexually transmitted infections, and management of chronic medical conditions provide unique opportunities for the delivery of preconception care and counseling. In each setting, advice should be tailored to the needs of patient based on individual attitudes, beliefs, preferences, and stage in the reproductive life span [1].

The Reproductive Life Plan

A key strategy for preconception health promotion is the development a reproductive life plan. Family physicians should encourage all men and women to explore their intention to conceive in the short and long term, taking into account their personal values and life goals. Once developed, patients should be educated about how their reproductive life plan impacts their contraceptive and medical decision-making. Because planned pregnancies are associated with improved outcomes for mothers and infants, women should be encouraged to make intentional decisions regarding the number and timing of pregnancies. The CDC has developed resources to assist health-care providers and patients with developing a reproductive life plan which can be accessed at http://www.cdc.gov/preconception/rlptool.html.

Novel Approaches to Preconception Care

In response to the lack of improvement in birth outcomes at the state and national level, many novel strategies for delivering preconception education, screening, and intervention have been developed including the following examples:

- *The Grady Memorial Hospital Interpregnancy Care Program (Atlanta, Georgia)* – In this groundbreaking program, low-income African American women with a history of very low-birth-weight delivery received individualized primary care services, intensive case management, and social support from multidisciplinary teams for 24 months following delivery. A significant reduction in rapid repeat pregnancies and adverse subsequent birth outcomes was achieved with an estimated net cost savings of $2397 per participant. The Grady program has been recognized as a successful model for improving birth outcomes by reducing disparities [33].
- *One Key Question® Initiative* (Oregon Foundation for Reproductive Health) – This initiative encourages all primary care providers to routinely ask women ages 18–50 "Would you like to become pregnant in the next year?" This question facilitates a conversation between providers and patients in

DOI 10.1007/978-1-4939-0779-3_10-1

which reproductive needs and preferences are explored. Women are then offered essential preventive services based on identified needs [34] (http://www.onekeyquestion.org).

- *The North Carolina Statewide Multivitamin Distribution Program* – This program provides multivitamins with folic acid to low-income, nonpregnant women of childbearing potential to help prevent birth defects. Reported use doubled over a 10-month period among a sample of women receiving multivitamins through this program [35] (http://everywomannc.com/public-health-programs/north-carolina-programs/statewide-multivitamin-distribution-program).
- *The IMPLICIT Network* – This collaborative of 19 family medicine residency programs has implemented an evidence-based interconception screening and risk-reduction intervention for mothers bringing their infants for well-child visits. Quality improvement techniques are used to improve care delivery and future family physicians are trained in best practices (www.fmec.net/implicitnetwork.htm).
- *Nurse-Family Partnership* – This program partners low-income, first-time mothers with a registered nurse early in pregnancy; women receive ongoing nurse home visits through their child's second birthday. Nurses help mothers access good preventive and prenatal care, provide parenting support, and encourage self-sufficiency by helping mothers plan future pregnancies, continue their education, and find work (www.nursefamilypartnership.org).
- *"Show Your Love" Campaign* – This social marketing campaign launched by the CDC Preconception Health and Health Care Initiative encourages women of childbearing age to maintain good health, reduce health risks, and make intentional decisions about pregnancy (www.cdc.gov/preconception/showyourlove).

Preconception Care and the Family

The health of a woman is interdependent with the health and well-being of her family. A woman's health is influenced by her family's medical history, culture, and view of health and illness. Some maternal risks for poor birth outcomes such as poor nutrition, smoking, and depression are associated with adverse effects for family members, especially children. The birth of a premature or critically ill newborn has a significant impact on family members. Parents experience stress related to uncertainty of the outcome, increased time away from work, financial burdens, and little time to spend with one another. Older children often experience anxiety due to separation from their parents, disruption of the family schedule, and a limited understanding of the newborn's condition. Family physicians should consider family values, beliefs, and influences (both positive and negative) when delivering preconception care emphasizing the goal of improving the health of all family members.

Preconception Issues for Men

Preconception care for men engages them in achieving planned, healthy pregnancies with their partners. Like women, men should be encouraged to develop a reproductive life plan to guide decisions about reproductive health. The CDC recommends that all men have a preventive care visit prior to conception to promote physiologic and emotional wellness, manage chronic health conditions, and educate men about the importance of avoiding sexually transmitted infections, substances, and toxic exposures. Men should be made aware of factors that can lead to decreased fertility and how to avoid them. Family physicians should also counsel men on the importance of supporting their partner in efforts to adopt a healthy

DOI 10.1007/978-1-4939-0779-3_10-1

lifestyle, follow treatment plans for chronic conditions, and take responsible steps to ensure planned, appropriately spaced pregnancies [36].

Key Preconception Care Partnerships and Resources

Family physicians should become familiar with the resources and partnerships in their community that provide preconception services for women. Examples include the local Health Department, Healthy Start Programs, Planned Parenthood, and WIC. State chapters of the March of Dimes also support programs that improve preconception health. Many national organizations have developed extensive preconception resources for clinicians:

- Center for Disease Control and Prevention, Preconception Health and Health Care – Information for Health Professionals – summary of the content of preconception care for women and men, reproductive life planning tools, index of state and local resource, and collection of useful articles (http://www.cdc.gov/preconception/hcp/index.html).
- The National Preconception Curriculum and Resource Guide for Clinicians developed by the Preconception Health and Health Care Initiative – includes the National Preconception/Interconception Care Clinical Toolkit and online continuing education modules (http://beforeandbeyond.org).
- National Healthy Start – HRSA-funded, locally administered programs that connect pregnant women and new mothers in at-risk communities with health-care and support services through the child's first 2 years of life (www.nationalhealthystart.org).
- National March of Dimes, Resources for Professionals – includes prematurity prevention resources, genetic risk assessment tools, birth outcome statistics (PeriStats), and patient education resources (http://www.marchofdimes.org/professionals.aspx).

Normal Pregnancy, Labor, and Delivery

Naureen B. Rafiq

Contents

Pregnancy and childbirth are normal physiological processes for most women. Although an integral part of the fabric of pregnancy and birth is the availability of quality prenatal care to ensure the highest level of safety, modern medicine has sometimes been guilty of using a disease model for the management of pregnancy and childbirth, resulting in higher rates of complications.

The national US cesarean section rate was 4.5 % in 1965[1], when it was first measured, and steadily increased to the current rate of 32.8 % in 2010/2011 [2]. More recent studies reaffirm earlier World Health Organization recommendations about optimal rates of cesarean section. The best outcomes for women and babies appear to occur with cesarean section rates of between 5 % and 10 %. Rates above 15 % seem to do more harm than good [3].

In 1902, J.W. Ballantyne, a Scottish physician, introduced modern prenatal care. In the late nineteenth century, he observed that while much was done for mothers and babies during labor and birth, these activities did little or nothing to reduce the morbidity and mortality of congenital anomalies, multiple births, and fetal diseases. He identified maternal exposures including alcohol, nicotine, and lead and infectious diseases, such as syphilis and tuberculosis, as major fetal hazards and began promoting specific antenatal treatments to reduce their impact on pregnancy outcomes [4].

Beginning in 1907, Dr. Josephine Baker, noting Dr Ballantynes' methods, began applying these principles to slum dwellers in New York

City, among whom infant mortality rates were very high. Services were offered to pregnant women and extended to the postpartum period. Women were seen every 2 weeks in their homes by nurses until 7th month of gestation and then weekly until delivery. At these visits, nurses would inquire about danger signs, check blood pressure, urine, assess fetal heart tones, and provide advice about diet, hygiene, exercise, and preparation for childs' arrival. This focus on good nutrition and screening for problems during pregnancy dramatically improved outcomes, bringing the maternal and infant morbidity and mortality rates to record lows.

Today, approximately 30 % of family physicians provide maternity care. Women living in rural areas and smaller communities often have difficulty accessing maternity care because they reside in places that generally cannot support an obstetrician or a hospital with a labor and delivery suite. Instead they must travel to larger regional medical centers and may delay seeking prenatal care or are seen less frequently during their pregnancies. As a result, the need for family physicians providing maternity care is particularly important in underserved and rural areas. Because the family physician is the physician for the father, mother, and the child makes them ideal to provide family-centered care.

Family-centered care means providing care in the context of the family. This practice considers, includes, and fosters the development of families with the birth of a child, as new relationships are made, family members taking new responsibilities for each other, the baby, and community. A family physician through the family-centered maternity care not only respects the woman's autonomy but also helps guide her into shared decision making in accordance with her goals. This chapter reviews principles and practice of normal pregnancy, labor, and delivery.

Prenatal Care

Ideally, prenatal care starts well before conception. Planning for pregnancy helps to prevent complications and results in optimal maternal and fetal outcomes. Efforts should be made and opportunities utilized with women of childbearing age who present for health maintenance exam to counsel on healthy lifestyle, identifying social, behavioral, environmental, and biomedical risks that can affect fertility or pregnancy outcomes. Although many women will seek prepregnancy counseling before attempting to become pregnant, in the USA about 50 % pregnancies are unintended [5]. A reproductive health plan should be created and revised with each subsequent visit, taking into consideration contraceptive needs and the timing of pregnancy.

It is recommended that prenatal care should begin as soon as possible after conception, since organogenesis occurs at 3–10 weeks of gestation, but about 30 % of women begin prenatal care in second trimester at or around 13 weeks.

Woman's work, home, pets, hobbies, potential toxic exposures, nutrition, hygiene, chronic diseases, teratogenic medications, and substance abuse are some of the examples where early intervention can lead to better outcomes.

Traditional prenatal care involves monthly visits until 28 weeks of gestation, then biweekly until 36 weeks, and weekly until the delivery. This schedule may be modified based on risk factors and may be multidisciplinary as required [6].

The supplementation of folate for the prevention of neural tube defects (NTD) is an important intervention and may reduce the risk of NTDs three- to fourfold. Because at least 50 % of pregnancies are unplanned, and organogenesis is usually well established before many women realize that they are pregnant, all women of childbearing age who are at average risk of bearing a child with an NTD should be counseled to take 0.4 mg of folate daily. Women at high risk should be counseled to take at least 4 mg of folate. Those at high or intermediate risk include those with a history of previous NTD, pregestational diabetes mellitus, those on anticonvulsants, having a BMI of >35 kg/m^2, and certain ethnic groups [7].

First Trimester

The first trimester is from week 1 to the end of week 12. Amenorrhea is the cardinal sign of pregnancy in a woman of childbearing age with regular menstrual cycles and should prompt a pregnancy test to confirm.

Patients may present with morning sickness that may strike any time of the day and can sometimes begin as soon as 3 weeks after conception. It is due to rapidly rising levels of estrogen and progesterone resulting in gastroparesis. Nausea has also been directly related to beta hCG levels and is considered a likely candidate for the emetogenic stimulus arising from the placenta. This nausea may be accompanied by heartburn for the same reason. Eating small frequent meals rather than three large meals and prescribing medications for intractable cases is helpful. It is imperative to ensure that patients have adequate urine output and are not dehydrated.

Patients may have vaginal bleeding or spotting around the time of their usual menstrual cycle likely due to implantation of embryo in the uterine wall that completely resolves on its own. This may result in confusion on pregnancy dating.

Sore, tender, fuller breasts often occur and are caused by hormones preparing milk ducts to produce milk.

Constipation also occurs – the result of progesterone causing reduced GI tract motility. Constipation may also occur as a result of iron in the prenatal vitamins. Regular physical activity, hydration, and increased fiber intake usually helps.

Fatigue is also very common in the first trimester and may go on into the second and third trimester. It is thought that progesterone may have a role in inducing sleep (reference needed). Rest and adequate intake of protein may be helpful.

Urinary frequency occurs due to physical pressure on the urinary bladder by the enlarging uterus. Patients are advised to urinate frequently to avoid incontinence and urinary tract infections.

Pregnancy causes dilation of blood vessels that leads to drops in blood pressure, which may cause postural dizziness and light-headedness. Patients are advised to avoid prolonged standing and to rise slowly after sitting or lying down.

Health Promotion/Counseling

Pregnant women are often more motivated to adapt healthy behaviors during pregnancy. A special effort should be made to counsel and educate women on healthy lifestyles during pregnancy, child birth, and parenting.

Usually, the first prenatal visit is used for a comprehensive care plan but all prenatal visits should be considered potential counseling opportunities.

1. Patients should be counseled on number and frequency of visits.
2. Maternal weight, blood pressure, uterine growth, fetal activity, and heart rate are monitored.
3. Danger signs : Call the physician with danger signs such as vaginal bleeding, rupture of membranes, decreased fetal activity, and uterine contractions.
4. Seat belts and airbags

   Patients should be advised to wear seat belts low across the lap and not to turn off airbags.
5. Nutrition and vitamins

   Continue to take prenatal vitamins containing iron and folic acid. Suggestions to improve nausea and vomiting, constipation, and gastroesophageal reflux should be provided if present. Severe nausea and vomiting, ketonuria, and or electrolyte abnormalities should be investigated to rule out other medical causes of it, and consider ultrasound to rule out twin or molar pregnancy.
6. Obesity

   Obesity is common in pregnant women. They should be counseled on obesity-related complications and may benefit from early screening for gestational diabetes.
7. Gestational weight gain

   For the majority of pregnancies, the average weight gain is 25–35lb (11–16 kg), but a

10–14 lb (4–6 kg) weight gain in an obese female and a 40 lb (18 kg) weight gain in a lean female are considered normal.

8. Alcohol, cigarettes, and substance abuse

   Pregnant women should be strongly advised to quit smoking, alcohol, and any substance abuse to reduce their risk of low birth weight, mental retardation, preterm premature rupture of membranes, preterm labor, and other conditions.

9. Infection precautions: During influenza season, women should receive influenza vaccine regardless of trimester of pregnancy. Tetanus, diphtheria, and acellular pertussis should be administered to the mother in the third trimester of each pregnancy. This helps to prevent maternal pertussis infection and also provides the fetus with some level of immunoglobulin protection against pertussis after birth.

   Advise mothers to avoid cat feces, such as cleaning out litter boxes, or eating raw or undercooked meat due to the risk of toxoplasmosis.

   If pregnant women are found to lack immunity to varicella or rubella, immunization should be administered immediately after delivery or termination of pregnancy.

10. Work

    The effects of physical exertion that include long hours standing, exposure to heat, heavy metals, and hazardous gases should be evaluated and possibly modified on a case by case basis. Daycare and health care workers should be cautioned regarding the risks of exposure to certain infections [8]. Most women should continue to engage in moderate physical activity, keep their heart rate below about 140/min and their body temperature within 1–2° of normal [9].

    Special attention should be paid to oral health. Preventive work or treatments should not be deferred.

    Saunas and hot tubs should be avoided, due to rapid changes in temperature.

    Sexual intercourse to be avoided in undiagnosed vaginal bleeding or ruptured membranes.

Prenatal Screening

Prenatal screening is done for early detection of potential risks to the pregnancy. There are standard screening tests offered to all women, and more specific tests available for women with particular risks. The choice of tests should be evidence based and based also on the genetic history, ethnicity, psychosocial stress, [10, 11] history of domestic abuse, and substance abuse (Table 1).

Prenatal screening is discussed with each patient at the initial prenatal visit, and each prenatal test is evaluated to ensure that benefit outweighs the risks and complications.

Nuchal translucency with maternal serum screening markers is used to detect chromosomal abnormalities. Studies in the 1990s showed that decreased levels of pregnancy-associated plasma protein A and increased levels of free beta hCG combined with nuchal translucency (an echo free area at the back of fetal neck on ultrasound) have a comparable detection rate of Down's syndrome at 10–14 weeks to the second trimester quad screen [12–14].

Chorionic villous sampling (CVS) for chromosomal analysis is also offered at 10–14 weeks to all women 35 years or older. It has the advantage that it can detect Down's syndrome earlier than amniocentesis, but carries a slightly higher risk of miscarriage than amniocentesis.

Second Trimester

The second trimester is from the end of the 12th week to 24th week. There is usually significant improvement in nausea and fatigue.

The extra weight gained in the first 3 months often results in back pain. To ease the pressure, it is advised to practice good posture and use a chair that provides good back support. Sleeping on the side with a pillow tucked between legs and avoiding excessive lifting may be helpful. It is advised to wear low-heeled, comfortable shoes with good arch support.

About half of pregnant women develop swollen, tender gums around this time. Hormone

Table 1 Common screening tests in pregnancy

First trimester
Complete blood count
Blood group and Rh factor
Antibody screen
Urine analysis and culture
RPR
Hepatitis B surface antigen
Rubella IgG
Varicella IgG
Papanicolaou smear
Gonorrhea and Chlamydia culture
"opt out" HIV screening
Sickle cell screening in appropriate ethnic groups or suspicion
Hemoglobin electrophoresis considered in appropriate ethnic groups or suspicion.
Counseling for Tay-Sachs and cystic fibrosis genetic testing
PPD if indicated
Second trimester
Quadruple screen at 14–18 weeks in which levels of alpha-fetoprotein (AFP), estradiol, beta HcG, and inhibin are measured.
Amniocentesis if indicated
Ultrasonography for fetal age and anatomy
Third trimester
1h glucose test to screen for gestational diabetes
Repeat CBC
Repeat antibody screen if appropriate
Group B streptococcal screening at 35–37 weeks
Repeat GC/Chlamydia, RPR, and a check for bacterial vaginosis if indicated

changes send more blood to the gums, making them more sensitive and causing them to bleed more easily. Studies suggest that pregnant women with periodontal disease are prone to a number of adverse outcomes that include preterm labor and low birth weight [15].

Much of the breast tenderness experienced during the first trimester resolves. Often, a thin, milky white vaginal discharge (called leukorrhea) occurs in the second trimester of pregnancy. The use of tampons is discouraged. If the discharge is foul-smelling, green or yellow, bloody, or if there is a lot of clear discharge, then other etiologies may be explored.

Hemorrhoids are common in pregnancy due to increased blood flow and pressure from the gravid uterus.

By the midpoint of pregnancy around 20 weeks women start to feel the first delicate flutters of movement in the abdomen, known as "quickening."

Pregnant women often look as though they are "glowing" because changing hormone levels make the skin on the face appear flushed. An increase in the pigment melanin can also lead to brown marks on the face (chloasma, or the "mask of pregnancy") and a dark line (linea nigra) may be seen down the middle of the abdomen. All of these skin changes typically resolve postpartum.

Thin, reddish-purple lines (striae) may appear on the abdomen, breasts, or thighs. These stretch marks emerge as the skin expands to accommodate the growing belly.

As morning sickness diminishes by the end of the first trimester the appetite returns. Caloric requirements increase by about 300–500 cal a day during the second trimester. Pregnant women should be gaining about 1/2 to 1 pound a week (226–453 g) at this time.

Health Promotion/Counseling

Most women who did not feel so great in the first trimester of pregnancy usually start to feel much better in the second. They gain weight more rapidly this trimester, adding as much as 4 pounds (1.8 kg) a month for the rest of the pregnancy.

Fetal growth, development, and movement accelerate in the second trimester with the development of most of the body organs. Women are advised to wear loose clothing to accommodate the growing belly. A childbirth class is a great way to prepare for labor and birth. Classes range from 1-day intensive workshops to weekly sessions lasting a month or more. The typical class consists of lectures, discussions, and exercises, all led by a trained childbirth instructor and usually covers the signs of labor, the normal progress of labor and birth, techniques for coping with pain, how a partner can help during labor, and when to call the doctor or midwife.

Patients are also counseled and encouraged to breast feed.

Second trimester bleeding should be evaluated carefully. It is not uncommon for women to experience self-limited vaginal bleeding after sexual intercourse. Rh negative patients should receive intramuscular RhoGAM at 28 weeks and after any bleeding or amniocentesis, if done.

Mothers are instructed to report any vaginal bleeding, new onset headaches, blurring of vision, significant edema, right upper quadrant pain, or changes in the frequency or intensity of fetal movement.

Second Trimester Screening

The quad screen – also known as the quadruple marker test is a prenatal test that measures the levels of four substances in a pregnant woman's blood: alpha-fetoprotein (AFP), a protein made by the fetus; human chorionic gonadotropin (HCG), a hormone made by the placenta; estriol, a hormone made by the placenta and the baby's liver; and inhibin A, another hormone made by the placenta. Typically, the quad screen is done between weeks 15 and 20 of pregnancy, in the second trimester, to detect chromosomal abnormalities and NTDs. Cell free fetal nucleic acid testing in maternal blood is becoming available for various genetic conditions, as is noninvasive testing for fetal Rh in women who are Rh negative. The cell free fetal DNA gets fragmented and gets into maternal bloodstream via shedding of placental microparticles. It can be detected as early as 7 weeks of gestation, and its level increases as the pregnancy progresses and quickly drops after the baby is born. Cell free fetal DNA has been used to detect noncompatible RhD factors, X-linked genetic disorders, and single gene disorders. This test although carries no risk of miscarriage has its limitations.

The results of these screens will help the mother make an informed decision whether or not to proceed to invasive testing for a number of genetic conditions. Amniocentesis is the confirmatory test that measures amniotic fluid level as well as the chromosomes. It has slightly lower risk of complications than chorionic villous sampling. Ultrasound dating is less accurate as the pregnancy progresses but uterus grows in a predictable manner in normal pregnancy. A 12-week uterus fills the pelvis and is a size of a cantaloupe. Twenty-week uterus is up to the umbilicus and the fundal height usually corresponds in centimeters with the week of gestation and is measured from the pubic symphysis to the top of uterus. A fetal anatomical survey is done by a detailed ultrasound between 18 and 22 weeks for detection of any developmental abnormalities.

Third Trimester

The third trimester is from 25 weeks onwards. Biweekly visits until 36 weeks and weekly visits until delivery are recommended. The normal duration of pregnancy varies considerably but can be anywhere between 37 and 43 weeks. The fetus really fills out over these next few weeks, storing fat on the body, reaching about 15–17 in. long, and weighing about 4–4 ½ lbs (1.8–2.0 kg) by the 32nd week. The lungs are not fully mature yet, but some rhythmic breathing movements occur. The bones are fully developed but are still soft and pliable. The fetus is storing its own calcium, iron, and phosphorus. The eyelids open after being closed since the end of the first trimester. Around 33–36 weeks, the fetus will descend into the head down position. The fetus is beginning to gain weight more rapidly. The lanugo hair will disappear from the skin, and it is becoming less red and wrinkled. The fetus is now 16–19 in. and weighs anywhere from 5 ¾ lbs to 6 ¾ lbs (2.6–3.0 kg).

At 38 weeks, the fetus is considered full term and will be ready to make its appearance at any time. Mom may notice a different quality of fetal movement, as the fetus is now filling the uterus with little room to move. The fingernails have grown long and small breast buds are present on both sexes. The mother is supplying the fetus with antibodies that will help protect against disease. All organs are developed, with the lungs maturing all the way until the day of delivery. The fetus is

about 19–21 in. in length and weighs anywhere from 6 ¾ lbs to 10 lbs (3.0–4.5 kg).

RhoGAM may be given to Rh negative moms at 28 weeks if the antibody screen is negative.

Health Promotion/Counseling

The mother at this time is not just carrying an added 20–30 pounds (or more) (9.0–13.6 kg), but the expanding uterus rearranges other organs in the body, adding even more strain. To avoid fatigue and increase energy it is often recommended to do small amounts of exercise. A walk, swimming, and prenatal yoga are good options. Taking short breaks at work, putting feet up, eating small, frequent meals and snacks also may help. A constant low level of energy can be a sign of anemia and should be ruled out.

An expanding belly can throw off the posture, and the hormone relaxin, which loosens joints in anticipation of delivery, exacerbates the stress on the body.

Doing pelvic tilts, trying an under-the-belly support garment, supporting the back and abdomen with extra padding underneath the back, and keeping a wedge pillow between legs to create equilibrium for the hips can help. Nearly half of all moms-to-be will suffer from heartburn. Avoiding classic heartburn triggers is helpful. These include highly seasoned or acidic foods; greasy, fried, or fatty foods; and caffeine and carbonated drinks, citrus and some dairy foods, such as milk or ice cream. Switching from three meals daily to six easier-to-digest small ones, eating them sitting upright, and avoid eating too close to bedtime or lying down right after eating also helps.

Over-the-counter remedies like Tums, Rolaids, Mylanta, Maalox, and Zantac are okay to take during pregnancy if lifestyle changes do not help.

Growing uterus puts pressure on the bladder most heavily in the third trimester leading to frequency of urination and sometimes urges incontinence. Trying to urinate on a schedule, such as every hour or two helps prevent this. It is also important to drink eight-ounce glasses of water a day to stay properly hydrated and to eat plenty of high-fiber foods to prevent constipation. Edema is caused by fluid retention in the lower half of the body. Varicose veins occur when valves inside blood vessels in the legs become soft or weak, which allows the blood to flow backward, pool, and form painful bulges. Although the swelling normally subsides, but sometimes varicose veins persist after pregnancy so to ease the discomfort of both edema and varicose veins, it is advised to put feet up often, switch standing and sitting positions frequently, not to cross legs, lie down whenever possible, preferably on the side, and to wear support hose, which may help soothe the aches and diminish the appearance of varicose veins. It is advised to avoid wearing anything that reduces circulation, like knee-high stockings and not to limit fluids to try to minimize puffiness. By 36–38 weeks patients may feel Braxton Hicks ("false") contractions. False contractions tend to be felt in the front of the abdomen only; whereas labor contractions tend to start in the back and come around to the front, sometimes moving from top to bottom of the uterus.

Third Trimester Screening

In women at average risk for gestational diabetes, a 50-g nonfasting 1-hour glucose challenge test between 24 and 28 weeks of gestation is done. In contrast, women at high risk for gestational diabetes should be screened using the 50-g glucose challenge test at their first antepartum visit. Women who are at high risk for gestational diabetes include those with personal history of prediabetes, or diabetes in close family member, age more than 25 years, BMI of 30 or higher at the time of conception, history of gestational diabetes in previous pregnancy, and for reasons unknown in nonwhite races including black, Hispanic, American Indian, and Asians. Screening cutoffs are 130 mg per dL (7.20 mmol per L; 90 % sensitivity) or 140 mg per dL (7.75 mmol per L; 80 % sensitivity). The most recent American Diabetes Association (ADA) and ACOG6 guidelines recommend either cutoff. Random or fasting glucose measurements are not recommended for screening because of poor specificity [16].

For women with a positive screening test, the 100-g 3-hour oral glucose tolerance test is used to diagnose gestational diabetes. Although most organizations recommend a high-carbohydrate diet for up to 3 days before the test, a recent study showed that test results are not affected by modest variations in carbohydrate intake. Gestational diabetes is diagnosed if two or more plasma glucose measurements meet or exceed the following thresholds: fasting level of 95 mg per dL (5.25 mmol per L), 1-hour level of 180 mg per dL (10.00 mmol per L), 2-hour level of 155 mg per dL (8.60 mmol per L), or 3-hour level of 140 mg per dL (7.8 mmol per L).

Vaginal and rectal swabs are taken at 35–37 weeks of pregnancy to detect group B streptococcus (GBS). GBS colonizes the vagina and gastrointestinal tract of up to 30 % of all women and is the leading cause of early onset neonatal group B strep infection. Women who test positive are treated with intrapartum antibiotics to reduce the risk. The lower vagina, perineum, and rectum are cultured between 35 and 37 weeks of gestation and a positive culture is treated intrapartum with intrapartum penicillin G. In women with a high-risk penicillin allergy, clindamycin or erythromycin should only be used if susceptibility testing confirms the organisms' sensitivity. If it is not sensitive, or results are not available, intrapartum vancomycin is recommended [17].

A CBC is also recommended to check anemia at this time due to growing fetal needs.

Gonorrhea, chlamydia, RPR, and bacterial vaginosis are screened again in certain high-risk patient populations in the third trimester, although the cost versus benefit of treating for bacterial vaginosis is unclear. USPSTF recommends against screening for asymptomatic low-risk pregnant women and concluded with moderate certainty that screening has no net benefit. The results of assessing high-risk asymptomatic pregnant women were conflicting, as a result USPSTF concluded that evidence is insufficient to make a recommendation [18].

Fetal Assessment

The previously mentioned "kick counts" that mothers are instructed to perform and the general advice to report decreased fetal movement is the most widely applied method of fetal surveillance. Sensitizing the mother to the importance of detecting a change in fetal movement often provides the first indication of a problem with the pregnancy. Other early indications of a problem include a lack of weight gain and reduced growth velocity as reflected in small fundal height for dates. Assessment of the fetus remote from term is typically intensified as soon as a condition that increases the risk of fetal demise is recognized.

Fetal heart rate monitoring: Electronic fetal heart monitoring (FHM) or intermittent auscultation is almost universally *performed as the first test* during pregnancy, labor, and delivery to identify the distressed and hypoxic fetus. The data to support improved outcomes with FHM are scarce and conflicting, but the long experience with this testing and the relative lack of availability of other methods to assess fetal condition in utero make FHM the most commonly utilized in the clinical setting.

Although there are many methods used to assess the fetus that include other options for noninvasive testing like Doppler velocimetry, umbilical artery Doppler flow assessment, and other ultrasound assessments. However, the most commonly utilized assessments include the nonstress test, amniotic fluid volume, and the biophysical profile as well as the contraction stress test.

Nonstress test is a simple low-risk procedure in which fetal heart rate is monitored along with simultaneous monitoring of uterine contractions through external monitors strapped around the abdomen. It is done every week after 32 weeks in many high-risk pregnancies. The fetal heart responds to uterine contractions with tachycardia. Two accelerations of 15 bpm lasting more than 20 s each within a 15 min period are reassuring and is considered reactive NST. This is recommended for women carrying more than one fetus, has gestational diabetes, or has gestational hypertension.

Contraction stress test is also done in high-risk pregnancies, a fetal monitor measures the baby's heart rate in response to contractions stimulated either by oxytocin (Pitocin) or nipple stimulation. Doctors use the measurements to predict how well the baby will cope with the stress of labor. They are also routinely applied for postdates, IUGR, oligohydramnios, polyhydramnios, decreased fetal movement, gestational diabetes and hypertension, Rh sensitization or previous unexplained stillbirth. The contractions should occur within 30 min and last 40–60 s with a frequency of three in 10 min. A CST is positive if late decelerations are present with 50 % or more of contractions. It is considered inconsistent if decelerations are fewer than 50%, and a negative CST has absent decelerations.

A biophysical profile combines the nonstress test with an assessment of amniotic fluid index, fetal breathing movement, fetal activity, and fetal muscle tone. These parameters are assessed with ultrasound. It gives a reliable indication of fetal acid base balance and academia. A score of 0–2 is given to each parameter.

Score of 8 or more is reassuring and indicates low risk for still birth

Score of 6 warrants further work up and is considered equivocal.

Score of 0–4 correlates well with fetal pH of less than 7.2 and is an indication for immediate delivery.

Labor and Delivery

Three Stages of Labor

Labor is described in three stages, and together these stages complete the delivery and the passage of the placenta.

Stage One

The first stage is the process of reaching full cervical dilatation. This begins with the onset of uterine labor contractions, and it is the longest phase of labor. The first stage is divided into three phases: latent, active, and deceleration.

In the latent phase, the contractions become more frequent, stronger, and gain regularity, and most of the change of the cervix involves thinning, or effacement. The latent phase is the most variable from woman to woman and from labor to labor. It may take a few days or be as short as a few hours. Typically, the latent phase lasts for 10–12 h for a woman who has had children. For first pregnancies, it may last closer to 20 h. For many women, the latent phase of labor can be confused with Braxton Hicks contractions. Membranes may spontaneously rupture in the early- to mid-portion of the first stage of labor. If they rupture, the labor process usually speeds up.

The next portion of the first stage of labor is the active phase, which is the phase of the most rapid cervical dilatation. For most women this is from 3 to 4 cm of dilatation until 8–9 cm of dilatation. The active phase is the most predictable, lasting an average of 5 h in first-time mothers and 2 h in mothers who have birthed before.

Finally, there is the deceleration phase, during which the cervical dilation continues, but at a slower pace, until full dilation. In some women, the deceleration phase is not really noticeable, blending into the active phase. This is also a phase of more rapid descent, when the baby is passing lower into the pelvis and deeper into the birth canal. The deceleration phase is also called transition, and, in mothers with no anesthesia, it is often punctuated by vomiting and uncontrollable shaking. These symptoms can be frightening to watch, but they are a part of normal birth, and they signal that the first stage is almost completed.

Stage Two

The second stage is the delivery of the infant. During the second stage, mom actively pushes out the baby. For first-time mothers, this can take 2–3 h, so it is important to save your energy and pace yourself. For second babies and beyond, the second stage often lasts less than an hour – and sometimes, only a few minutes.

Stage Three

The third stage of labor is the passage of the placenta, which can be immediate or take up to

30 min. The process may be sped up naturally by breastfeeding (which releases oxytocin) or medically by administering pitocin.

Support During Labor

Emotional and physical support significantly shortens labor and decreases the need for cesarean deliveries, forceps and vacuum extraction, oxytocin augmentation, and analgesia. Doula-supported mothers also rate childbirth as less difficult and painful than do women not supported by a doula. Labor support by fathers does not appear to produce similar obstetrical benefits. A number of studies report early or late psychosocial benefits of doula support. Early benefits include reductions in state anxiety scores, positive feelings about the birth experience, and increased rates of breastfeeding initiation. Later postpartum benefits include decreased symptoms of depression, improved self-esteem, exclusive breastfeeding, and increased sensitivity of the mother to her child's needs. A thorough reorganization of current birth practices is in order to ensure that every woman has access to continuous emotional and physical support during labor [19].

Intrapartum Analgesia

Maternal request is a sufficient medical indication for pain relief during labor. Laboring patients are educated about the different available methods of analgesia. Many pharmacological and nonpharmacological methods of labor analgesia have been adopted over the years. Nonpharmacological methods include support from labor attendants, doulas, changes of position, rest, ambulation, or a warm shower. Of the pharmacological methods, regional analgesia has become the most popular method. Short acting narcotics given in the first stage of labor are also commonly used, and may help facilitate dilation of cervix. Possible regional anesthesia techniques include epidural analgesia, spinal analgesia, or a combination of epidural and spinal analgesia. Approximately 60 % of laboring women (2.4 million each year) choose regional analgesia for pain relief during labor [20].

Uterine contractions and cervical dilatation result in visceral pain whereas the descent of fetal head and subsequent pressure on the pelvic floor, vagina, and perineum generates somatic pain. Regional analgesia provides partial or complete loss of pain sensations below the T8 to T10 spinal level and is not just helpful in first and second stages of labor but also facilitates patient cooperation during labor and delivery, and if needed, procedures such as forceps or vacuum extraction.

It also allows extension of anesthesia for cesarean delivery if needed. Opioid induced maternal and fetal respiratory depression can be avoided. It also helps to control blood pressure in women with preeclampsia by alleviating labor pain, and it blunts the hemodynamic effects of uterine contractions and the associated pain response in patients with other medical complications. Possible adverse effects of epidural anesthesia are prolonged first and second stages of labor and the decreased maternal urge and ability to push. However, in spite of these drawbacks epidural anesthesia is extensively and routinely utilized in many hospitals and is requested by many women.

Delivery

Cervical effacement and dilatation is monitored every few hours. Anesthesia options should be reviewed with the patient early so that appropriate plans can be made.

Frequent spontaneous bladder voiding is encouraged. In patients with an epidural, a Foley catheter may be placed. Positioning options for the upcoming second stage of labor should be discussed. Mothers may ambulate and reposition themselves to maximize comfort. They may also eat small amounts of food throughout this stage, unless concern exists for impending difficulty during vaginal delivery and the possible need to convert to a cesarean section.

Delivery is imminent at crowning. Crowning occurs when the fetal head bulges the perineum as the head moves through the birth canal. A feeling

of pressure due to distention of the perineum creates a tremendous urge to push for most women. Episiotomy should be avoided unless it appears that the perineum is obstructing progress or emergency delivery is required. If the mother does not instinctively feel when to push, as can occur with heavy anesthesia, she should be instructed to push with contractions.

Preparations for delivery are made when the fetal station is low. Drapes and gowns protect the clinician from the fluid of delivery; sterile preparation is not required. One hand is used to support and maintain the head in the flexed position as it delivers. The other hand is used to support the perineum. This will help control the pace of the delivery of the head. Maternal pushing is often helpful, but too forceful pushing can cause the head to deliver precipitously and can lead to perineal lacerations.

After the head is delivered, the fetal neck is checked for a nuchal cord. Routine suctioning of the nares is no longer recommended by the American Academy of Pediatrics. However, in infants who are likely to require resuscitation, suctioning may be necessary. With both hands on the head, a gentle posterior traction is applied at an angle of 45° to deliver the anterior shoulder followed by gentle anterior traction of the head to deliver the posterior shoulder. Oxytocin is often started at delivery of the anterior shoulder. Continue to support the head with one hand and use other hand to deliver the body. The cord is clamped at two locations, several centimeters apart and cut between the clamps. There has been increasing data over the past few years suggesting benefits for delayed cord clamping. It has been shown to decrease anemia in term infants. Delayed cord clamping is defined as 2–3 min after delivery [21]. The infant is cleaned or placed directly with the mother, assuming a normal appearance and Apgar evaluation. Encouraging skin to skin contact between mother and newborn as much as possible is recommended.

Placental separation is evidenced by an increase in the length of umbilical cord, a bolus of blood from the uterus, and migration of superior border of the uterus within the abdomen with an increase in uterine firmness.

Placental delivery is facilitated by applying gentle traction on the umbilical cord with one hand and a gentle counter traction with a vertical pressure just superior to the pubic symphysis with the other hand to prevent inversion of the uterus.

Intravenous oxytocin is administered for the prevention of postpartum hemorrhage. The placenta is examined for its completeness and the uterus is manually explored if the placenta is not intact.

Retained placental fragments increase the risk of postpartum hemorrhage. The mother is examined for cervical, vaginal, or perineal tears. First degree tears or hemostatic abrasions usually do not require suturing.

Every family physician providing care to women of childbearing age should have an understanding of the effect that various medical conditions can have on pregnancy. Pregnancy has significant effects on the progression of many medical conditions; medical conditions coexisting with pregnancy can adversely affect pregnancy outcomes if not treated adequately and judiciously. The role of the family physician begins at preconception, advising patients with significant medical conditions, like diabetes and chronic hypertension, to ensure adequate control before planning a pregnancy. This chapter will address many of these medical conditions (see Table 1).

Infectious Diseases

Urinary Tract Infections

Urinary tract infections are the most commonly seen infectious condition in pregnancy (see chapter "► Urinary Tract Infections").

Asymptomatic bacteriuria (ASB) refers to positive urine culture in an asymptomatic patient and occurs in 2–7 % of pregnancies [1]. Up to 40 % progress to pyelonephritis in pregnant women [2]. UTI and pyelonephritis are associated with increased risks of preterm birth, low birth weight, and perinatal mortality.

The Infectious Disease Society of America in its 2005 guidelines recommended screening for and treatment of ASB in pregnancy with short-term (3–7 day) therapy with antimicrobials such as nitrofurantoin, cephalexin, amoxicillin, or fosfomycin. A follow-up culture is recommended to ensure resolution [3].

Acute cystitis is a symptomatic infection of the urinary bladder and can also be complicated by pyelonephritis if left untreated. The treatment regimen and follow-up is similar to that recommended for ASB.

Acute pyelonephritis is characterized by flank pain, nausea, vomiting, fever >38 °C, and costovertebral tenderness with or without cystitis symptoms. E. coli accounts for 70 % of these cases, and Proteus, Klebsiella, and Group B streptococcus comprise most of the remainder. Traditionally, pyelonephritis is treated with IV antibiotics until 24 h after the woman is afebrile. Blood cultures are obtained if there is another underlying comorbidity such as diabetes.

Recurrent pyelonephritis occurs in 6–8 % of cases, therefore low-dose antimicrobial prophylaxis for the remainder of the pregnancy after an episode of pyelonephritis is recommended [4].

Viral Hepatitis

Acute viral hepatitis is the most common cause of jaundice in pregnancy [5] (see chapter "► Diseases of the Liver"). Differential diagnoses include acute fatty liver of pregnancy; hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome; and intrahepatic cholestasis of pregnancy.

Hepatitis B (HBV) during pregnancy may present unique management challenges for the mother as well as the fetus. Acute HBV during

Table 1 Selected medical conditions during pregnancy

Infections	Urinary tract infection, cystitis, and pyelonephritis Viral hepatitis A, B, C HIV, herpes, syphilis, tuberculosis, measles
Cardiovascular diseases	Chronic hypertension
Hematologic disorders	Anemia, iron deficiency
Clotting disorders	Thromboembolic disorders, deep venous thrombosis, pulmonary embolism
Endocrine disorders	Diabetes, thyroid disorders
Respiratory disorders	Asthma
Neurological disorders	Seizure disorders, migraine, Bell's palsy
Muscular skeletal	Carpal tunnel syndrome
Special circumstances	Obesity, bariatric surgery, advanced maternal age, illicit drug use

pregnancy in itself is not associated with increased mortality or teratogenicity [5]. In the absence of advanced liver disease, pregnancy is well tolerated by women with chronic hepatitis B in general. However, liver function tests are monitored in each trimester and until 6 months postpartum to detect the possibility of a hepatitis flare. HBV DNA (viral load) should be obtained in cases when there is transaminase elevation. The perinatal transmission rate is as high as 90 % in HbeAg-positive mothers [6]. However, transplacental transmission is rare. Maternal serum HBV DNA levels also correlate with the risk of vertical transmission, in spite of proper administration of prophylaxis; however, prophylaxis with HBIG and first dose of HBV immediately after delivery reduces transmission rates dramatically. The mode of delivery does not appear to influence transmission rates. In hepatitis B, treatment can be considered during pregnancy in carefully selected women using Telbivudine and Tenofovir (FDA Category B).

Hepatitis C

Women chronically affected with hepatitis C (HCV) can have an uneventful pregnancy without worsening of liver disease or adverse effects to the fetus. Although some studies have recorded low birth weights, low Apgar scores, and neonatal jaundice, additional data are needed to prove a definite correlation to HCV infection.

According to one meta-analysis, the vertical transmission of HCV occurs exclusively in women having detectable levels of HCV RNA in the blood. The risk of transmission is usually about 5 %, but it is almost doubled in patients coinfected with HCV and HIV [7]. Other risk factors are IV drug use and HCV infection of peripheral blood mononuclear cells. Routine prenatal screening for HCV is not recommended; however, women with significant risk factors for HCV infection should be offered anti-HCV antibody screening (ACOG level B recommendation).

Hepatitis A (HAV)

Hepatitis **A** is primarily transmitted by the fecal-oral route. HAV is usually an acute self-limiting disease. Diagnosis is confirmed by a positive serum anti-HAV IgM. Treatment is supportive. Hospitalization for IV hydration may be necessary in cases with severe nausea and vomiting.

Tuberculosis in Pregnancy

Pregnancy is not a risk factor for tuberculosis (TB) and is not known to influence its pathogenesis or progression. Congenital transmission of TB is rare and mostly occurs with maternal coinfection with HIV. However, active TB in the mother can cause congenital or more commonly neonatal infection. Screening for latent TB infection (LTBI) is limited to women at high risk of progression from LTBI to active TB, i.e., women with HIV, recent infection, or those who are otherwise immunocompromised. Treatment for LTBI is restricted to these high-risk groups, and the drug of choice is isoniazid along with pyridoxine supplementation. Active TB (except for monoresistant or multidrug-resistant strains) in pregnancy is treated with isoniazid, rifampicin, and ethambutol for 60 days followed by a 2-day-per-week regimen of rifampicin and isoniazid for 7 months [8]. In pregnancy, the use of pyrazinamide is limited to patients with extensive disease, TB meningitis, drug resistance, or HIV coinfection. Aminoglycosides are not recommended during pregnancy.

HIV in Pregnancy

All pregnant women should receive HIV screening in early pregnancy (see chapter "▶ Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome"). All pregnant HIV-infected women should receive combination antiretroviral therapy (CART) regardless of HIV RNA viral load or CD4 T lymphocyte count. Antepartum, intrapartum, and infant antiretroviral (ARV) prophylaxis is recommended to reduce

perinatal transmission. The patient should receive counseling about the importance of adherence to ARV regimens. The National Perinatal HIV Hotline is available for free consultation on all aspects of perinatal HIV care (by phone:1-888-448-8765, by web http://www.ucsf.edu/hivcntr/Hotlines/Perinatal.html). All ARV exposure during pregnancy should be reported to the Antiretroviral Pregnancy Registry. A protease inhibitor (PI)–based regimen poses a slight increase in the risk of preterm birth. In antiretroviral naïve HIV-infected pregnant women, immediate start of therapy versus its delay until 12 weeks is often determined by CD4 lymphocyte count, HIV RNA levels, and maternal condition [9]. The coordination of services among primary care, HIV specialty care providers, mental health, and public health programs is needed to ensure CART adherence. In 2014 the Department of Health and Human Services published updated guidelines for evaluation and management of HIV-infected pregnant women [10].

Genital Herpes Simplex

Transmission of maternal herpes simplex virus (HSV) to neonate usually occurs during labor and delivery. Treatment with acyclovir is considered safe throughout pregnancy (see chapter "▶ Sexually Transmitted Diseases").

In women with prodromal symptoms or active lesions of HSV, cesarean delivery is recommended to reduce if not eliminate the possibility of neonatal HSV infection [11].

Measles

In late 2014, a significant outbreak of measles occurred in the United States. Pregnant women are among the patients who face particularly high risks for complications from this disease. Postexposure prophylaxis with IVIG is recommended in pregnant women without evidence of measles immunity [12]. MMR vaccine is contraindicated during pregnancy.

Syphilis

The CDC recommends screening of all pregnant women for syphilis at their first prenatal visit and a repeat test in the third trimester in those at high risk (see chapter "▶ Sexually Transmitted Diseases"). Untreated syphilis in pregnant woman can lead to its transplacental transmission resulting in perinatal death or congenital anomalies and congenital syphilis in the neonate with long-term sequelae. Penicillin is the gold standard for the treatment of syphilis and the only acceptable option in pregnancy. In pregnant patients who have a major penicillin allergy, treatment with penicillin after desensitization is recommended [13].

Cardiovascular Disease

Chronic Hypertension in Pregnancy

Chronic hypertension (CH) is defined by ACOG as blood pressure $\geq$140 mmHg systolic and/or $\geq$90 mmHg diastolic before pregnancy or before 20 weeks of gestation, the use of antihypertensive medications before pregnancy, or the persistence of hypertension for more than 12 weeks after delivery [14] (see chapter "▶ Hypertension").

It is important to distinguish chronic hypertension from new-onset hypertensive complications of pregnancy (see Table 2).

Chronic hypertension (CH) is estimated to occur in 3–5 % of all pregnancies [15]. Major risk factors include advanced maternal age and obesity.

In the African-American population, there is a higher prevalence of chronic hypertension, and it tends to occur at younger ages [15]. Despite increasing prevalence, the majority of women with chronic hypertension do well in pregnancy. However, some women develop complications such as superimposed preeclampsia, placental abruption, preterm birth, fetal growth restriction, and an increased likelihood of cesarean delivery [16].

Women with chronic hypertension planning pregnancy should receive preconception

Table 2 Various hypertensive disorders in pregnancy

Chronic hypertension	Gestational hypertension	Preeclampsia	Chronic hypertension with superimposed preeclampsia
Onset before 20 weeks of gestation and persists after 12 weeks post delivery	Onset after 20 weeks of gestation in a previously normotensive woman	Onset after 20 weeks of gestation with proteinuria	New onset of proteinuria in hypertensive woman after 20 weeks of gestation

counseling including evaluation for the presence of end organ damage and choosing an antihypertensive agency that is safe in pregnancy. The effect of lifestyle modifications such as weight management and healthy diet adaptations on pregnancy outcomes needs to be studied.

Management During Pregnancy

The ACOG recommends that blood pressure in women with uncomplicated hypertension be maintained between 120/80 and 160/105 mmHg. Further, it recommends initiating antihypertensive treatments when blood pressures are consistently more than 150 mmHg systolic and/or 100 mmHg diastolic. Tapering of antihypertensives is recommended when blood pressures consistently fall below 130/80 mmHg [16]. Alpha-methyldopa, labetalol, and nifedipine are among commonly used antihypertensive agents for CH in pregnancy. ACEs and ARBs are contraindicated in pregnancy.

There is a consensus in the guidelines that women with CH who are at high risk for preeclampsia should be treated with low-dose aspirin.

Pregnant women with CH are recommended to have more frequent prenatal visits to monitor blood pressures, urine protein, fundal height, maternal symptoms, and surveillance of fetal well-being, although there is no consensus regarding the most appropriate tests or intervals for ultrasound evaluation, NST, and biophysical profiles [14].

Clotting Disorders

Venous Thromboembolism (VTE) in Pregnancy

Venous thromboembolism (VTE) includes deep venous thrombosis (DVT) and pulmonary embolism (PE) (see chapter "▶ Venous Thromboembolism"). VTE complicates 0.1 % of pregnancies, and PE is the seventh leading cause of maternal mortality. Pregnancy in itself is a major risk factor for VTE. Others include thrombophilia, BMI $\geq$30, age $\geq$35 years, diabetes, infection, dehydration, multiparity, prolonged immobility during travel or bed rest, and smoking. Strikingly, in pregnancy DVT is 90 % more common in the left lower extremity than the right due to compression of left iliac vein by the right iliac artery [17].

Inherited thrombophilias include factor IV Leiden mutation, prothrombin G2021OA mutation, antithrombin III, and protein C or S deficiency. Pregnancy is a hypercoagulable state and leads to a decrease in protein S and resistance to activated protein C. A natural rise of D dimer in pregnancy limits its diagnostic value in detection of intravascular clotting.

The Wells score is not validated in pregnancy; however, the LEFt clinical prediction rule (left sided symptoms, edema, first trimester) might be an alternative [18]. The diagnosis of pulmonary embolism (PE) in pregnancy presents a clinical dilemma due to its overlap with normal symptoms in pregnancy like dyspnea.

The American Thoracic Society 2011 recommendations define a chest radiograph (CXR) as the first imaging procedure; lung scintigraphy is the preferred test in when the CXR is negative. CT pulmonary angiogram (CTPA) is used when a VQ scan is nondiagnostic, and clinical suspicion is

still high [19]. Radiation risk of theVQ scan and CTPA are balanced against the 20–30 % risk of maternal mortality from untreated PE. Gadolinium contrast is listed as category C in pregnancy by the US FDA.

Treatment of VTE in pregnancy based on American College of Chest Physician guidelines: subcutaneous low molecular weight heparin (SC LMWH) is preferred due to efficacy, ease of use, and safety profile [17]. Intravenous (IV) unfractionated heparin (UFH) is used in patients with persistent hypotension. SC LMWH treatment is withheld at least 24 h prior to planned delivery by C-section or induction. Patients with a high risk for recurrence of VTE are switched to IV UFH which can be stopped 4–6 h prior to delivery. Temporary IVC filter placement is reserved for patients having limited cardiopulmonary reserve. A heparin regimen can be resumed 6–12 h after delivery and continued for at least 6 weeks postpartum or longer depending on associated risk factors.

Hematologic Disorders

Anemia in Pregnancy

Hematologic changes in pregnancy include physiological anemia, neutrophilia, mild thrombocytopenia, and an increase in procoagulant factors (see chapter "▶ Anemia"). The CDC defines anemia in pregnancy as hemoglobin levels below 11 g/dL in the first and third trimesters and below 10.5 g/dL in the second trimester [20]. Patients with iron deficiency anemia (IDA) may present with fatigue, malaise, and pica. The fetus is usually spared any significant morbidity as a result of maternal IDA because iron is preferentially transmitted to the fetoplacental unit. IUGR is reported in patients with IDA when hemoglobin levels fall below 6.5 g/dL. Oral iron therapy often worsens the bloating and constipation in pregnant women resulting in poor adherence to therapy. Parenteral iron therapy is considered FDA Category C and therefore limited to selected groups.

Endocrine Disorders

Diabetes in Pregnancy

In recent years diabetes management in pregnancy has improved significantly (see chapter "▶ Diabetes Mellitus"). Although nine out of ten diabetics in pregnancy can be classified as gestational diabetes mellitus (GDM), pregestational type I or II diabetes tends to be associated with higher rates of maternal and fetal complications.

The ACOG recommends early pregnancy screening for diabetes with fasting or random blood sugar in women with risk factors such as history of GDM. All other patients should be screened between 24 and 28 weeks of pregnancy (1 h glucose test value of 140 mg/dl or less). Once a diagnosis of diabetes is confirmed, counseling and dietary consultation are imperative. Careful monitoring of plasma glucose to a goal of 105 mg/dl fasting and 140 mg/dl 1 h postprandial is recommended. Fetal ultrasonography is recommended to evaluate the presence of malformations, fetal growth, and biophysical profile. Patients not well controlled on insulin may need be referred to a perinatologist.

Pregestational diabetes was historically classified using the White classification. However, it is believed that presence or absence of vascular complications is a better predictor of pregnancy outcome [21].

Glycated hemoglobin reflects control over prior weeks and is helpful in counseling and assessing the risk of congenital abnormalities. Additional tests obtained to assess comorbidities are renal function tests, 24 h proteinuria quantification, thyroid function, EKG if hypertensive, and dilated eye exam to rule out retinopathy. The patient should be counseled regarding adherence to dietary recommendations as well as exercise and medications, as well as more frequent prenatal visits.

The ACOG recommends antepartum monitoring including fetal movement counting, NST, and biophysical profile as early as 32 weeks. The incidence of preeclampsia in patients with diabetes without vascular complications is 8 % and is

17 % among those with vascular disease [22]. Timing of delivery for women with well-controlled pregestational diabetes and without vascular disease is recommended at ≥39 weeks [23]. Those pregestational diabetics with vascular disease, delivery as early as 34 weeks may be considered among patients with poor glycemic control and patients with other obstetric indications such as preeclampsia, fetal growth restriction, and nonreassuring fetal surveillance. Maternal pregestational diabetes alone is not an indication for cesarean birth in absence of usual obstetric indications. The ACOG recommends prophylactic caesarean birth for those patients with an estimated fetal weight greater than 4500 g to avoid comorbidities associated with shoulder dystocia. Induction of labor is not recommended if there is suspected fetal macrosomia [22].

Thyroid Disease in Pregnancy

Thyroid disease is second only to diabetes among endocrinopathies affecting women in the reproductive age-group [24] (see chapter "▶ Thyroid Disease"). In iodine-sufficient regions the most common causes of hypothyroidism are autoimmune thyroiditis and iatrogenic hypothyroidism after treatment for hyperthyroidism [25]. In addition, hypothyroidism can lead to fetal neurocognitive deficits and preterm birth. Radioiodine uptake scans are contraindicated during pregnancy.

Therefore, current guidelines recommend targeted screenings of women at risk including those with history of thyroid disease or type-1 diabetes. Indications for thyroid testing in pregnancy include current thyroid hormone or other therapy, family history of autoimmune thyroid disease, and goiter. The incidence of overt hypothyroidism (elevated TSH and low free T4) during pregnancy is estimated to be 0.3–0.5 % and that of subclinical hypothyroidism (elevated TSH with normal T4 levels) to be 2–3 %. TSH levels should be checked every 4–6 weeks. The levothyroxine dose should be adjusted to keep TSH levels around 3 mIU/L. Ultrasonography is recommended for fetal growth and surveillance. Hyperthyroidism is less common than hypothyroidism with an approximate incidence during pregnancy of 0.2 %. Graves' disease accounts for 95 % of cases of hyperthyroidism; other less common causes include gestational trophoblastic disease, nodular goiter, and viral thyroiditis. Transient hyperthyroidism can be associated with hyperemesis gravidarum [25]. If left untreated during pregnancy, hyperthyroidism leads to increased risk of miscarriage, placental abruption, hypertension, fetal goiter, and growth restriction.

Appropriate management of thyroid disorders leads to improved pregnancy outcomes. In pregnant women with hypothyroidism levothyroxine is titrated to achieve a goal TSH of less than 2.5 mIU per liter (SORT recommendation level A), whereas patients with hyperthyroidism are treated with antithyroid medications (Methimazole after the first trimester of pregnancy) to keep free thyroxine levels in the upper third of the normal range.

Respiratory Disorders

Asthma in Pregnancy

Asthma is the most common respiratory disorder complicating pregnancy (see chapter "▶ Selected Disorders of the Respiratory System"). The effect of pregnancy on asthma is variable. The goal of effective management of asthma during pregnancy should be prevention of asthma exacerbations. Pharmacological therapy for asthma aims to control symptoms and achieve lung function at the lowest effective dose of medication [26]. Rescue agents (short-acting beta agonists) are used on as needed basis to treat acute symptoms. A recent study suggested that the use of inhaled corticosteroids was unlikely to contribute to adverse effects on fetal growth and development [27]. Studies have also suggested that pregnant women may benefit from asthma self-management education as a part of their obstetric care [28].

Lower Respiratory Infections

Pregnant women, especially smokers, are more prone to the development of bronchitis and pneumonia (see chapter "▶ Selected Disorders of the Respiratory System"). The diagnosis of pneumonia may be delayed, as clinicians often refrain from ordering chest radiographs. *Streptococcus and Mycoplasma pneumoniae* are common organisms causing pneumonia in pregnancy. Decreased tidal volume during later pregnancy due to an enlarging uterus may lead to complications of pneumonia such as empyema and respiratory failure. Chest radiography with appropriate shielding is recommended to confirm a diagnosis of pneumonia. Pneumonia in pregnancy is commonly treated in the inpatient setting, although ambulatory treatment may be reserved for selected cases with close monitoring. Choice of antibiotics is guided by culture results, and epidemiological resistance patterns of the organism involved.

Neurological Disorders

Seizure Disorders in Pregnancy

Seizure disorder is one of the most frequent major neurological conditions in pregnancy (see chapter "▶ Seizure Disorders"). During pregnancy approximately 60 % of patients have no change in frequency of seizures while 30 % report an increase in seizures.

Continuation of antiepileptic drugs (AEDs) is a necessity for most women with epilepsy. AEDs easily cross the placenta to the fetus. This poses a risk of teratogenicity; its extent is dependent on the drug, doses, timing of exposure, and genetic predisposition of mother and fetus. Also, there is increasing evidence to associate prenatal exposure AEDs to negative physical and neurodevelopmental outcomes in childhood [29].

Women with epilepsy should receive preconception counseling regarding the risks and benefits of AEDs (see Table 3). The antiseizure medication should be selected and optimized in consultation with a neurologist and if possible a maternal fetal medicine specialist. High-dose folic acid supplementation is recommended for all patients taking AEDs.

Table 3 AEDs and major fetal risks

AEDs	Major fetal risk
Topiramate, carbamazepine	Craniofacial anomaly
Phenolbarbital, phenytoin	Teratogenesis, coagulopathy
Valproic acid	Spina bifida

Migraine in Pregnancy

Migraines affect one in every five women in their reproductive years (see chapter "▶ Headache"). Therefore, it is imperative that women with migraines are counseled about safe and effective prophylaxis as well as symptomatic treatment. It is noted that two out of three patients with preexisting migraine report improvement of migraine during pregnancy; [30] those whose symptoms persist through the first trimester are likely to continue through the postpartum period [31]. Although there is no direct evidence linking migraine with adverse pregnancy outcomes [32], a number of studies have suggested an increased incidence of preeclampsia especially in obese migraineurs. Migraine is also considered to be a risk factor for pregnancy-related stroke [33].

Indications for imaging are similar to those for nonpregnant migraineurs. Although MRI is considered safe in pregnancy, iodine-containing contrast media should be avoided as it may cause fetal thyroid suppression.

Migraine trigger prevention is achieved by encouraging regular meals, adequate hydration, exercise as tolerated, and sleep hygiene. Acetaminophen is still the drug of choice for mild to moderate migraine, and NSAIDS should be avoided after 30 weeks of gestation. Antiemetics such as metoclopramide and promethazine can be given in pregnancy for symptomatic relief. Sumatriptan may be used in pregnancy if other treatments mentioned previously fail (FDA Category C). Propranolol, amitriptyline, and SSRIs such as escitalopram are used in

pregnancy for migraine prophylaxis (FDA Category C) in the lowest effective doses. Some studies have suggested that nonpharmacological, preventive methods like acupuncture and biofeedback may be beneficial during pregnancy [34].

Bell's Palsy

Bell's palsy (BP) is defined as acute peripheral facial paralysis resulting from inflammation and edema of the seventh cranial nerve as it exits from the stylomastoid foramen (see chapter "▶ Selected Disorders of the Musculoskeletal System"). Its prevalence increases two- to fourfold during pregnancy [35]. The suggested potential etiology is hypercoagulability leading to thrombosis of the vasa nervorum [36].

Other than its association with preeclampsia, no increase in adverse obstetrical outcomes among patients with BP have been noted [37]. The long-term outcome appears slightly worse in pregnant women, which is attributed to the fact that pregnant women are less likely to receive treatment for BP. However, the treatment recommended for pregnant women, except during first 9 weeks of gestation, is the same as for nonpregnant patients [38].

Musculoskeletal Disorders

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) typically presents as paresthesias and pain of the first three fingers, often bilaterally resulting from compression of median nerve in the carpal tunnel (see chapter "▶ Selected Disorders of the Musculoskeletal System"). Pregnancy accounts for 7 % of cases of CTS among women of childbearing age [39]. Symptoms usually occur during the third trimester. Half of patients report persistence of CTS 1 year after delivery, and symptoms may recur in subsequent pregnancies [40]. Patients may receive symptom relief from a wrist splint used in neutral position throughout the day and night. Surgical intervention (release of flexor retinaculum) or local corticosteroid injection are rarely indicated in the absence of motor weakness or atrophy. In a 3 year prospective study of pregnant women with age-matched controls, the pregnancy cohort showed significantly better outcomes than nonpregnant controls [41].

Special Circumstances in Pregnancy

Obesity and Pregnancy

Even modest increases in preconception BMI are associated with increased risk of perinatal morbidity and mortality (see chapter "▶ Care of the Obese Patient"). In addition, these pregnant women may experience greater risks of obstructive sleep apnea, hypertension, diabetes, VTE, and anesthesia complications. Weight management guidelines for women who plan pregnancies should take these findings into consideration to reduce these complications [14].

Pregnancy After Bariatric Surgery

Currently, it is recommended that women delay pregnancy for 12–18 months after bariatric surgery. The starvation phase may be dangerous for both mother and fetus. Although malnutrition may not increase the risk of congenital defects, it can increase risk of "small for gestational age" and preterm-birth infants [42].

Advanced Maternal Age in Pregnancy

In the past half century, changing socioeconomic patterns have led to an increase in the incidence of advanced maternal age. In 2011 alone, 1 in 12 women gave birth to their first child at age greater than or equal to 35 years, and 1 in 7 of all childbirths in the United States were to women in that age-group [43].

The prevalence of medical and surgical morbidities such as obesity, cardiovascular diseases, and cancers increase with advancing maternal age. Diabetes and hypertension, gestational and

pregestational, both occur at higher rates in older women especially among those who are overweight. Women greater than or equal to 35 years of age also should be counseled to expect at least twofold increased rate of cesarean delivery, hospitalization, and medical complications than their younger counterparts. Vigilant monitoring and fetal surveillance when indicated may improve pregnancy outcomes in these patients.

Illicit Drug Use in Pregnancy

In the United States 15.4 % of pregnant women admit to smoking cigarettes, 5.4 % admit to the use of illicit drugs, and 9.4 % reported drinking alcohol in the previous month [44]. The ACOG therefore recommends screening for substance abuse during first prenatal visit. The CRAFFT screening tool is available for use without restriction [45]. In addition to smoking tobacco, opiates, marijuana, cocaine, amphetamines, alcohol, and prescription psychotherapeutics are substances that are commonly abused by pregnant women. Positive tests for illicit drugs also have legal ramifications. There are state requirements for notification; therefore an informed consent is needed from the patient unless she is unable to consent (e.g., due to intoxication). Clinical manifestations can arise from the use, overdose, or withdrawal of these substances. Multiple obstetric complications such as fetal growth restriction, placental abruption, preeclampsia, prematurity, premature rupture of membranes, miscarriage, and fetal death can result from substance abuse during pregnancy especially opiates, alcohol, and cocaine [46]. A multidisciplinary team approach by the family physician, social service provider, addiction medicine, and fetal maternal medicine specialists may be needed for the management of these patients.

There are a wide range of obstetric complications that may occur during pregnancy. This chapter will focus on six of the most common complications including spontaneous abortion, ectopic pregnancy, hypertensive disorders of pregnancy, placenta previa, and preterm labor.

Spontaneous Abortion

Spontaneous abortion is defined as the involuntary loss of pregnancy prior to 20 weeks of gestation.

Vaginal bleeding in the first trimester of pregnancy is common. It may occur as a result of spontaneous abortion, ectopic pregnancy, gestational trophoblastic disease, or cervical causes. Approximately half the pregnancies complicated by first trimester bleeding result in viable pregnancies.

Epidemiology

Spontaneous abortion or miscarriage occurs in about 15 % of clinically identified pregnancies and may occur in up to 50 % of pregnancies prior to clinical identification [1].

Etiology

The cause of spontaneous abortion is rarely identified in the individual patient. Research has demonstrated, however, that approximately half of miscarriages occur as a result of trisomy, triploidy, monosomy, or another significant genetic abnormality [2]. Additionally, several environmental factors have been associated with miscarriage including both internal and external factors. Internal factors include advanced maternal age, uterine anomalies, leiomyomata, incompetent cervix, and luteal phase defects that lead to progesterone deficiency. External factors include substance use such as tobacco, alcohol, and cocaine, radiation exposure, infections, and occupational chemical exposure to substances such as arsenic, benzene, ethylene oxide, formaldehyde, or lead.

Diagnosis

Women experiencing a spontaneous abortion typically present with vaginal bleeding and cramping. They may also report a diminution or reversal of early pregnancy symptoms (fatigue, nausea, breast tenderness).

The first steps in evaluation of a patient with suspected miscarriage are to obtain vital signs and establish an estimated gestational age based on last menstrual period. If the estimated gestational age is greater than 9 weeks, an attempt should be made to auscultate fetal heart tones. Examination should then include abdominal, speculum, and pelvic examinations. If adnexal tenderness is identified, ectopic pregnancy should be considered. Non-uterine causes of bleeding can be identified during the speculum examination as can the presence or absence of cervical dilation. The diagnosis of spontaneous abortion can be assisted by use of transvaginal ultrasound. A completed spontaneous abortion will present with an empty uterus with an echogenic endometrial stripe. In a viable gestation, a gestational sac should be visualized between 4 and 5 weeks gestation and must be present with a beta-HCG greater than 1500–2000 mIU/mL. The yolk sac should be visualized between 5 and 6 weeks gestation and must be present with a gestational sac >10 mm, the embryo should be visualized between 5 and 6 weeks gestation and must be present with a gestational sac >18 mm, and cardiac activity should be visualized between 5 and 6 weeks gestation and must be present if the crown-rump length is greater than 5 mm [3]. The presence of a gestational sac with a diameter greater than 20 mm without an identifiable embryo or presence of an embryo with a crown-rump length greater than 5 mm without a heartbeat are diagnostic of a pregnancy demise [4].

In patients with unclear course, serial quantitative beta-HCGs and ultrasounds may be beneficial. Between the 4th and 8th week of gestation, beta-HCG levels should double every 48–72 h. Likewise, both the diameter of the gestational sac and the crown-rump length should increase by 1 mm/day. Therefore, repeating labs and an ultrasound in 7–10 days should demonstrate a measurable change in both.

Prevention

Several interventions can lower the risk of spontaneous abortion. These include not smoking, drinking alcohol, or using recreational drugs. Additionally, avoiding exposure to certain viral infections such as rubella can lower the risk. Finally, obesity increases the risk of miscarriage, therefore, patients should be encouraged to achieve a healthy weight prior to pregnancy.

Management

Miscarriage can be managed expectantly, medically, or surgically. Frequently, spontaneous abortions complete spontaneously without intervention. In women with significant bleeding, pain, or infection, either medical or surgical intervention should be considered [5]. Misoprostol administered either 600 micrograms orally or 600–800 micrograms vaginally can be utilized for medical management of miscarriage. The initial dose can be repeated in 24–48 h if the initial dose is unsuccessful [6]. Surgical management can be performed using either sharp curettage or vacuum aspiration. While complication rates are comparable between the two, vacuum aspiration is faster and causes less pain and bleeding [7].

Ectopic Pregnancy

Ectopic pregnancy is the implantation of an embryo outside of the uterine cavity. The vast majority are located in the fallopian tubes, however, they may rarely occur in the broad ligament, cervix, ovary, or in the abdominal cavity. Ectopic pregnancy is the second most common cause of maternal mortality.

Epidemiology

Between 2002 and 2007, a study of women enrolled in health plans demonstrated the ectopic pregnancy rate in the United States to be 0.64 % [8]. Previous data, which included patients enrolled in Medicaid, demonstrated a rate of 1.9 % in 1992 [9]. Both data sets demonstrate an increasing rate of ectopic pregnancy with age. Mortality rates have declined from 1.15 deaths in 100,000 live births to 0.50 deaths per 100,000 live births between 1980–1984 and 2003–2007 [10]. This is a result of increased awareness and improvements in early diagnosis.

Etiology

Any factor that interferes with the fallopian tube's function and ciliary motility increases the risk of ectopic pregnancy. Risk factors can be divided into anatomic and functional. Anatomic risk factors include a history of tubal ectopic pregnancy, infection (e.g., pelvic inflammatory disease), ligation, or surgery. Functional risk factors include hormonal stimulation of ovulation, use of progestin containing contraceptives, and tobacco use. Risk factors can also be divided based on the strength of their risk for ectopic pregnancy. Factors strongly associated with ectopic pregnancy include previous ectopic pregnancy, history of tubal surgery, and history of DES exposure. Factors moderately associated with ectopic pregnancy include history of sexually transmitted infection, having more than one sexual partner, and cigarette smoking. Finally, factors slightly associated with ectopic pregnancy include prior abdominal or pelvic surgery, douching, and sexual intercourse prior to age 18 [11].

Diagnosis

Most patients presenting with an ectopic pregnancy will have abdominal pain, typically lower abdominal and unilateral, and bleeding. Physical examination may help identify a tender adnexal mass, as well as signs of shock (hypotension, tachycardia, altered mental state) or hemoperitoneum (distended abdomen with decreased bowel sounds, referred shoulder pain, and a posterior cul-de-sac which bulges into the vaginal fornix). Serum hCG and progesterone can both contribute to making the diagnosis of an

ectopic pregnancy. Serum hCG will typically increase early in pregnancy then plateau and possibly fall. If the initial hCG is <1500 mIU/mL, a rise of at least 53 % over 48 h is indicative of a viable pregnancy [12].

A recent meta-analysis reviewing 26 cohort studies, including over 9400 women in the first trimester of pregnancy, found that in women with abdominal pain and/or bleeding and an inconclusive ultrasound, a single progesterone test (cutoff between 3.2 and 6 ng/mL) predicts a non-viable pregnancy with pooled sensitivity of 74.6 % (95 % confidence interval 50.6–89.4 %) and specificity of 98.4 % (90.9–99.7 %) [13].

The gold standard for diagnosis of ectopic pregnancy is the transvaginal ultrasound. At an hCG level between 1500 and 2000 mIU/mL or higher, a gestational sac should be seen in the uterus using transvaginal ultrasound. Identification of an intrauterine pregnancy essentially rules out ectopic pregnancy (heterotopic pregnancy is exceedingly rare). Ectopic pregnancy is very likely if any adnexal mass or significant free pelvic fluid is identified. Finally, ectopic pregnancy is confirmed if a gestational sac with embryo and heart beat is identified outside of the uterus [14].

Prevention

While there is no specific prevention strategy for ectopic pregnancy, the risk can be minimized by avoiding modifiable risk factors that increase the risk of an ectopic. These include not smoking, avoiding pregnancy before age 18, and taking precautions to prevent sexually transmitted infections.

Management

The management of ectopic pregnancy can be expectant, medical, or surgical.

In reliable patients with an hCG <1000 mIU/mL that is declining, expectant management can be considered if there is minimal pain and bleeding, no evidence of rupture, and if a mass is detected it is <3 cm in diameter and no fetal heart beat is detected [15]. Close follow up is required and hCG levels should be followed until they are <5 mIU/mL.

Medical management of ectopic pregnancy has utilized the folic acid antagonist, methotrexate. Single dose methotrexate is administered at one mg/kg or 50 mg/m^2. It should be considered in patients with stable vital signs, an hCG of <2000 mIU/mL, a mass <= 3.5 cm in diameter without fetal heart beat, and no evidence of rupture. Additionally, patients should not have a contraindication to methotrexate administration such as elevated liver enzymes, immunodeficiency, or blood dyscrasias. Serum hCG levels should be checked at days 4 and 7 and then weekly until it is <5 mIU/mL. If the hCG level does not fall between days 4 and 7, a second dose of methotrexate or surgical intervention should be considered [16, 17].

Surgical management of ectopic pregnancy should be considered when the patient is unreliable for follow up, is unstable, has signs of hemoperitoneum, or has a more advanced ectopic pregnancy. Additionally, surgical intervention should be considered when the diagnosis is unclear or there is a contraindication to either expectant or medical management. Surgical interventions include linear salpingostomy (opening the fallopian tube and removing the ectopic pregnancy) or salpingectomy (removing the fallopian tube) via laparoscopy or laparotomy. Salpingostomy is preferred in patients who wish to maintain fertility [18]. Laparotomy should be limited to patients in whom visualization is compromised or hemostasis cannot be achieved utilizing laparoscopy [19].

Hypertensive Disorders of Pregnancy

Hypertensive disorders of pregnancy can be classified into chronic hypertension, gestational hypertension, preeclampsia, and chronic hypertension with superimposed preeclampsia. The term ‘gestational hypertension’ replaces ‘pregnancy induced hypertension.’ The nomenclature of ‘mild’ and ‘severe’ preeclampsia has been

abandoned, and preeclampsia is now characterized as being with or without severe features [20]. This distinction helps to emphasize that severe features may develop at any time, and that ongoing evaluation is essential in identifying patients with more severe disease.

Epidemiology

Hypertensive disorders of pregnancy affect between 6 % and 8 % of pregnancies in the United States making them the most common medical complication of pregnancy [21]. The majority of women that develop preeclampsia are nulliparous. In multiparous women, those with multiple gestations, age >40, history of preeclampsia in prior pregnancy, chronic disease (hypertension, diabetes, and renal disease), elevated BMI, and the presence of the antiphospholipid syndrome increase the risk of developing preeclampsia [22]. Approximately 20 % of women with chronic hypertension will develop preeclampsia [20]. Additionally, a family history of preeclampsia, African-American and Latina race, lower socioeconomic class, and women who do not seek or do not have access to prenatal care are at increased risk for developing preeclampsia [20].

Etiology

It has been hypothesized that the pathophysiology of preeclampsia may be the result of a genetic predisposition, an immunologic condition, abnormal implantation of the placenta, endothelial injury to the vascular system, activation of platelets, placental growth factor deficiency, or vasoconstriction as a result of maladaptation of the cardiovascular system. Despite these theories, the exact etiology remains unknown [23].

Diagnosis

Hypertension during pregnancy is defined as a blood pressure of >= 140/90 on two separate occasions 4 h apart or >= 160/110 on a single occasion. Chronic hypertension is defined as hypertension that presents before 20 weeks of gestation or that persists after 6 weeks postpartum.

Gestational hypertension is ultimately a provisional diagnosis. It is defined as the presence of hypertension after 20 weeks gestation without the features of preeclampsia defined below. Of those women initially diagnosed with gestational hypertension, approximately 50 % will go on to develop preeclampsia [24]. Another proportion will have persistent hypertension after 6 weeks postpartum and be diagnosed with chronic hypertension.

In preeclampsia, hypertension (blood pressure >= 140.90) develops after 20 weeks of gestation and is accompanied by proteinuria. Proteinuria can be identified through a 24 h protein demonstrating >= 300 mg of protein, a protein/creatinine ratio of >0.3 on a random voided urine, or a dipstick of +1 protein on a random voided urine. It is important to note that the presence of edema is no longer a criterion for preeclampsia [20].

Severe features of preeclampsia include two blood pressures of >= 160/110 obtained 4 h apart while the patient is on bed rest, a platelet count <100,000/mL, doubling of AST or ALT, severe right upper quadrant pain without other etiology, creatinine >1.1 mg/dL, doubling of baseline creatinine without evidence of other renal disease, development of pulmonary edema, cerebral/visual disturbances that did not preexist. Intrauterine growth restriction and proteinuria >5 g in a 24 h urine collection are no longer considered criteria for severe features [20].

Prevention

A Cochrane review of prophylactically treating women with increased risk of developing preeclampsia with low dose aspirin demonstrated that the number needed to treat to prevent one case of preeclampsia and one fetal death were 69 and 227, respectively [25] Among women with the highest risk of developing preeclampsia, the number needed to treat to prevent one case of preeclampsia was 18 [25].

Similarly, a Cochrane review of calcium supplementation demonstrated reduced risk of

preeclampsia among women at high risk for this condition with low calcium intake [26].. However, routine prophylaxis/supplementation with calcium, magnesium, omega 3 fatty acids, vitamin C, and vitamin E in low risk patients has not been demonstrated to be effective in lowering the risk of preeclampsia.

Management

For both gestational hypertension and preeclampsia without severe features, patients should be instructed to do daily kick counts to assess for fetal wellbeing and to self-assess for severe signs or symptoms such as development of a new headache, visual disturbances, chest pain, shortness of breath, persistent nausea and vomiting, or right upper quadrant pain. Patients should be evaluated in the office weekly with blood pressure measurement, platelet count, and liver enzymes. For patients with gestational hypertension, urine should be collected weekly to assess for protein. There is low quality evidence to support weekly antenatal testing. Additionally, serial ultrasounds should be obtained to assess for growth restriction. Bed rest is no longer recommended [20]. In both gestational hypertension and preeclampsia without severe features, delivery is recommended at 37 weeks gestation [20]. Neither magnesium sulfate during labor nor antihypertensives are recommended.

Once a patient develops preeclampsia with severe features >= 34 weeks gestation, the goal is to stabilize the patient and move toward delivery. If the patient is <= 34 weeks gestation, they should be cared for at a facility that has the required resources to provide care to both the mother and premature fetus. For women who develop preeclampsia with severe features before fetal viability is attained (22–24 weeks depending on location and available resources), once the patient is stabilized delivery should be planned. In women with preeclampsia and severe features <= 34 weeks gestation who are stable, expectant management with close monitoring and appropriate hypertensive control is recommended until the patient is >34 weeks gestation and then delivery should be planned. In women with preeclampsia with severe features who have reached viability but are <34 weeks gestation and also present with preterm premature rupture of membranes, labor, platelet count <100,000/mL, AST or ALT elevated > twice the upper limit of normal, growth restriction, severe oligohydramnios, new onset or worsening renal dysfunction, or reversed end-flow umbilical Doppler readings, steroids should be administered to promote fetal lung maturity and an attempt should be made to delay delivery for 48 h to maximize their effectiveness. For patients <34 weeks who present with preeclampsia with severe features and uncontrollable severe hypertension, eclampsia, pulmonary edema, placenta abruption, disseminated intravascular coagulopathy, or Category III fetal heart rate tracing (defined as a sinusoidal pattern OR a tracing with absent variability and recurrent late decelerations, variable decelerations, or bradycardia; replaces "non-reassuring" terminology), steroids should be administered to promote fetal lung maturity but delivery should not be delayed to maximize effectiveness of the steroids. Finally, in women with intrauterine fetal demise steroid administration is unnecessary and delivery should be planned [20].

Magnesium sulfate is recommended for patients who present with either preeclampsia with severe features to prevent a seizure or eclampsia to prevent further seizures. The Magpie trial determined that in women with severe preeclampsia (old nomenclature), 63 women needed to be treated with magnesium sulfate to prevent one seizure [27]. Magnesium sulfate should typically be continued until 24 h postpartum or until the patient has demonstrated significant diuresis indicating resolution of vasoconstriction.

Antihypertensive medications are indicated in patients that have blood pressures >= 160/110, although the optimal blood pressure goal is unclear. In acute management, intravenous medications offer a rapid onset and the ability to titrate therapy. Both labetalol and hydralazine have been commonly used. For chronic management of patients with preeclampsia with severe features being expectantly managed, oral medications are preferred. Both oral nifedipine and labetalol have been used in these patients [21].

Placenta Previa

Normal placental implantation occurs at the uterine fundus. Placenta previa, however, occurs when the site of implantation is the lower uterine segment and the placenta overlies or approaches the cervical os. Marginal previa is defined as placenta located within two centimeters of the os, whereas, complete previa indicates that the placenta covers the os. Morbidity related to placenta previa occurs with maternal hemorrhage, need for cesarean delivery, and risk of abnormal placental implantation (accreta, increta, percreta) which may result in hysterectomy.

Epidemiology

Placenta previa affects approximately 0.4 % of pregnancies at term [28]. It typically presents as painless vaginal bleeding in the second or third trimesters which is often triggered by sexual intercourse. Risk factors include chronic hypertension, history of uterine curettage or cesarean delivery (incidence increases to 2.3 % after just two cesarean deliveries [29]), cocaine or tobacco use, increasing maternal age, multiparity, and male fetuses [28].

Etiology

The exact etiology of placenta previa is unknown. It has been hypothesized that atrophy or scarring of the endometrium related to prior trauma, surgery (uterine curettage or cesarean), or infection may lead to inadequate or abnormal vascularization of the endometrium in the fundus to allow for implantation [30]. Further research is required to evaluate this hypothesis.

Diagnosis

The diagnosis of placenta previa should be suspected in women who present in either the second or third trimester with painless vaginal bleeding. Additionally, persistent breech or malpresentation at term should raise suspicion. Diagnosis is confirmed with ultrasonography to locate the site of placental implantation. Transvaginal ultrasound is more sensitive and specific than transabdominal ultrasound and has been demonstrated to be safe to perform [31]. In patients in whom abnormal insertion is suspected (accreta, increta, percreta), MRI may be useful in differentiating the level of invasion into the uterine wall.

Prevention

While there is no specific prevention strategy for placenta previa, the risk can be minimized by avoiding modifiable risk factors that increase risk for previa. These include not smoking or using cocaine when considering and during pregnancy, and careful consideration of first cesarean in patients who desire additional children.

Management

The management of placenta previa remains somewhat controversial. Most authors recommend expectant management between the time of identification of previa and the first (sentinel) bleed as long as they have ready access to a hospital that provides maternity care services [32]. A similar strategy is reasonable for patients after a sentinel bleed following a period of inpatient hospitalization, stabilization, and observation. Patients should be advised to avoid placing any object in the vagina, including intercourse and tampons. In patients with recurrent bleeding, delivery should be considered at 36 weeks gestational age; and in patients without vaginal bleeding, delivery should be considered at 38 weeks gestational age [32].

In women with marginal previa, the mode of delivery should be determined following ultrasound at 36 weeks. If the placental edge is >= 2 cm from the cervical os, an attempt of vaginal delivery should be made. In cases where the placental edge is 1–2 cm from the cervical os, vaginal delivery can be considered; however, facilities

should be prepared for the need for emergent cesarean delivery [33].

In women with complete previa, cesarean delivery should be planned for between 36 and 38 weeks gestation, as noted above. Because of the increased risk of placenta accreta, increta, or percreta, the delivery team should be prepared to perform a cesarean hysterectomy [32].

In women with recurrent episodes of bleeding prior to delivery, transfusion should be considered for signs or symptoms of symptomatic anemia. Additionally, because of the risk of severe postpartum hemorrhage and disseminated intravascular coagulopathy during or following delivery, patients should be evaluated for transfusion and the blood bank notified of the potential need to activate massive transfusion protocols.

Preterm Labor and Delivery

Preterm labor is defined as the development of regular uterine contractions that result in cervical change, effacement and dilation, occurring before 37 weeks of gestation. The greatest risk of preterm labor is resultant preterm delivery.

Epidemiology

In the United States, 11.39 % of deliveries in 2013 occurred prior to 37 weeks [34], 40–45 % of which are the result of preterm labor without premature rupture of membranes [35]. Between 1990 and 2006, the incidence of preterm delivery increased 20 %, largely as a result of an increase in multiple gestations (resulting from increased use of assistive reproductive technology) and late preterm deliveries. Since that time, with an increased focus on decreasing the number of near term inductions and cesarean deliveries, that rate has fallen to a 15-year low [34, 35]. While efforts persist to decrease the number of preterm deliveries, it will be difficult to eliminate them completely as 30–35 % of preterm deliveries are secondary to medically indicated inductions or cesarean deliveries (preeclampsia with severe features, placental abruption, etc.) [35]

Etiology

Common pathways resulting in preterm labor and delivery include immune mediation, inflammation, stress, over distension of the uterus, uteroplacental hemorrhage, and uteroplacental ischemia [36]. Many risk factors for preterm labor and delivery, which activate these pathways, have been identified and can be divided into preconception, maternal, and fetal factors. These are summarized in Table 1. Unfortunately, nearly 50 % of preterm deliveries occur in women without known risk factors for preterm labor or delivery [37]. Of the known risk factors, history of both spontaneous and medically indicated preterm delivery is the most significant distinguishable risk factor for recurrence, increasing the risk by 2.5 fold [38].

Infection is an important cause of preterm labor and delivery and may be responsible for 25–40 % of all preterm births. Bacterial vaginosis increases the risk of preterm delivery between 1.5 and 3 times. In women with the TNF-alpha allele 2 gene, the presence of bacterial vaginosis doubles the risk of preterm delivery [36]. Asymptomatic bacteriuria and pyelonephritis have both been associated with preterm delivery. Periodontal disease increases the risk by twofold. Sexually transmitted infections including chlamydia, gonorrhea, and syphilis likewise increase the risk of preterm birth. While group B streptococcus, M hominus and U urealyticum are commonly identified in women with preterm labor, they are not felt to be causal of the preterm labor [35].

Diagnosis

Patients presenting with complaint of preterm contractions should be placed on a tocodynamometer to assess for frequency of uterine contractions. Fetal wellbeing should be assessed by continuous Doppler and position determined by ultrasound.

In a patient presenting with preterm contractions, assessment should evaluate for status of amniotic membranes (intact or ruptured), presence of infection, and likelihood that contractions

Table 1 Risk factors for preterm delivery

Preconception	Maternal	Fetal
Body mass index <20 or poor nutrition	Abdominal surgery	Assisted reproductive technology (both singleton and multiple gestations)
History of LEEP or cone biopsy of the cervix	African American race	Congenital anomalies
Interpregnancy interval <6 months	Chronic medical conditions (diabetes, hypertension)	Intrauterine fetal demise
Psychological stress and emotional or physical abuse	History of preterm delivery	Intrauterine growth restriction
Sexually transmitted illnesses	Infection (bacterial vaginosis, chlamydia, trichomonas)	Multiple gestation
Smoking	Lack of prenatal care	
Substance abuse (cocaine, amphetamines)	Oligohydramnios	
Uterine anomaly	Periodontal disease	
	Placenta abruption	
	Placenta previa	
	Polyhydramnios	
	Poor social support	
	Short cervix	
	Smoking	
	Strenuous work	
	Uterine contractions	

will lead to delivery. Evaluation for rupture of membranes is discussed below in the section entitled "Premature Rupture of Membranes." Patients should be evaluated for bacterial vaginosis, gonorrhea and chlamydia, urinary tract infection, and group B streptococcus.

Likelihood of delivery can be assessed via digital cervical examination, terbutaline challenge, fetal fibronectin collection, and measurement of cervical length. Digital cervical examination, while subjective in nature, may be useful if advanced dilation or effacement is noted on examination. A single dose of terbutaline 0.25 mg administered subcutaneously may result in resolution of contractions in patients not in preterm labor. Fetal fibronectin, a placental glycoprotein, is typically absent from vaginal secretions prior to term and its presence between 24 and 34 weeks has been associated with preterm delivery. Presence of fetal fibronectin in vaginal secretions collected in the posterior fornix between 24 and 34 weeks has a positive predictive value of 13–30 % for delivery in the next 7–10 days. Its absence has a negative predictive value of 99 % for delivery in the following 2 weeks [39]. False positive results may occur if the patient has had intercourse, a digital cervical exam, or transvaginal ultrasound in the past 24 h or is having active bleeding from the cervix or vagina. Transvaginal measurement of cervical length can also be useful in stratifying risk for preterm delivery. In symptomatic women, an initial cervical length of >30 mm excludes the diagnosis of preterm labor, whereas, women with a cervical length <15 mm are at high risk for preterm delivery [40].

Prevention

In women with a history of preterm delivery (spontaneous and not medically indicated), 17 alpha-hydroxyprogesterone caproate (17P) has been demonstrated to reduce the recurrence rate of preterm delivery. It is indicated in women between 16 and 36 weeks gestation who have a history of preterm delivery, have not demonstrated signs of preterm labor in the current pregnancy, and who are not allergic to the compound. Beginning at 16 weeks, patients should receive 250 mg intramuscularly weekly through 36 weeks or delivery. Studies have demonstrated a decrease in preterm deliveries in women meeting the above criteria who are treated with 17P versus controls (37 % vice 55 %) as well as an improvement in the health of their infants [41]. Vaginal progesterone has not been shown to be beneficial in this population.

Women with a history of preterm delivery should have their cervical length evaluated by transvaginal ultrasound between 16 and 24 weeks gestation [42]. If the cervical length is found to be <25 mm, cervical cerclage should be offered. Studies have demonstrated a decrease in preterm birth and perinatal morbidity and mortality when cerclage is used in this population [42]. Additionally, in women with history of preterm delivery and a cervical length of <20 mm, vaginal progesterone 100–200 mg administered vaginally on a daily basis has shown to decrease rates of preterm delivery and perinatal morbidity and mortality [43]. Intramuscular progesterone has not been demonstrated to improve outcome in this population.

Although several studies have examined the treatment of asymptomatic bacterial vaginosis in the prevention of preterm labor and delivery, data remains conflicted. The U.S. Preventive Services Task Force recommends against screening in low risk women and states that there is insufficient evidence to recommend for or against screening and treatment of women at high risk for preterm labor [44].

Management

Women diagnosed with preterm labor should, when feasible, be transferred to a facility that has the capability to manage a preterm infant. Antenatal corticosteroids should be administered to women between 24 and 34 weeks gestation who present in preterm labor. Either betamethasone 12 mg administered intramuscularly for two doses 12 h apart, or dexamethasone 6 mg administered intramuscularly for 4 doses 6 h apart have been shown to be effective in decreasing perinatal morbidity and mortality [45]. Magnesium sulfate administered intravenously as a 4–6 g bolus followed by a maintenance dose of 1–2 g/h for 24 h in women with preterm labor has been shown to decrease the rate of cerebral palsy in their infants [46].

Short term tocolysis may be considered in women presenting with preterm labor to allow time to transfer to a facility with a higher level of care, to allow administration of corticosteroids and magnesium sulfate, and provide for group B streptococcus prophylaxis. Nifedipine has been shown to decrease the risk of delivery within 48 h and has the advantage of increased latency till birth, improved neonatal outcomes, and decreased maternal side effects compared to other tocolytics [45]. Beta mimetics, such as terbutaline, may also be used to delay delivery. Magnesium sulfate, on the other hand, has not been shown to prolong pregnancy or to improve perinatal morbidity [47].

Group B streptococcus is the leading cause of death secondary to infection in newborns despite widespread implementation of CDC guidelines for its prevention. In women presenting with preterm labor, either ampicillin 2 g intravenously on admission then 1 g every 4 h through delivery or penicillin G 5 million units intravenously on admission then 2.5–3 million unites every 4 h through delivery should be administered [48]. Dosing may be discontinued if preterm labor is ruled out or if a negative group B streptococcus culture is obtained. Cefazolin should be used in women with a non-anaphylactic allergy to penicillin. In women with a history of anaphylaxis, clindamycin or vancomycin should be utilized.

Problems During Labor and Delivery

Amanda S. Wright[a]* and Aaron Costerisan[b]

[b]University of Illinois College of Medicine at Peoria, Family Medicine Residency Program, Peoria, IL, USA

Introduction

Labor is a process, and difficulties can arise at any point. This chapter will outline antepartum considerations and focus on the complications that can arise as labor progresses. It is important to keep in mind, however, that there is much overlap in the timing of these questions and problems. The clinician must try to anticipate them early.

Trial of Labor and Vaginal Birth After Cesarean Section

Background

It is well known that the cesarean section rate has dramatically increased over several decades. Supported by accumulating evidence of relative safety, increased offering of a trial of labor after cesarean (TOLAC) represented a countertrend from the 1970s to 1990s, with a resultant decrease in the cesarean rate [1]. However, as more reports of complications such as uterine rupture surfaced, this trend reversed. Among other interested parties, the National Institutes of Health (NIH) in 2010 called on organizations to facilitate access to TOLAC, in an effort to improve perinatal outcomes by reducing complications associated with repeat cesarean sections [1].

Uterine Rupture

The most feared complication of TOLAC is uterine rupture, which can result in significant morbidity and mortality both for the mother and fetus. Uterine rupture usually involves the previous hysterotomy scar but may extend in the uterine wall or beyond. Risk factors include excessive oxytocin administration, dysfunctional labor, history of more than one cesarean, multiparity, and history of nonpregnant uterine perforation. Rates of rupture have been estimated at 4–9 % after a classical incision, 0.5–1.5 % after a low transverse incision, and 1–4 % after a low vertical incision [2]. Its presentation most frequently involves fetal heart rate abnormalities. Other symptoms and signs may include abdominal pain, decrease in frequency and/or intensity of contractions, bleeding, or loss of fetal station. Urgent laparotomy may be indicated for any of these findings, as fetal death or adverse neonatal neurologic outcomes may occur in as many as 20–25 % of cases of uterine rupture.

Approach to the Patient

While decreasing the occurrence of repeat cesareans would be an obvious benefit, comparing elective repeat cesarean (ERC) with a trial of labor (TOL) in patients with a history of one prior cesarean is complex. The decision of whether to undergo a TOL involves assessing both the chance of successful vaginal birth after cesarean (VBAC) and the risks associated with TOLAC. A calculator is available on the

Table 1 Indications for cesarean section

Indisputable	Generally accepted[a]	Marginal
Placenta previa	Previous cesarean section	Fear of repeating previous bad outcome
Confirmed fetal compromise or imminent fetal demise (*clear fetal heart rate evidence, umbilical cord prolapse, vasa previa, uterine rupture, severe placenta abruption*)	Breech presentation	Fear of fetal injury
Definite obstruction (*unequivocal cephalopelvic disproportion, soft tissue obstruction, fetal malpresentation*)	Labor dystocia	Fear of maternal pelvic floor injury
	Concern for fetal compromise	
	Maternal medical conditions *(severe preeclampsia, severe cardiovascular disease, super obesity)*	

[a]Within this category, indications may range from relative to absolute

website for the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network (https://mfmu.bsc.gwu.edu), which allows for more individualized counseling of pregnant patients with a prior cesarean. The decision is ultimately patient specific, reached after conversation with her provider beginning early in pregnancy. Although there is no consensus, it has been suggested that patients with at least a 60–70 % predicted chance of successful VBAC do not have an increased likelihood of morbidity when compared to patients undergoing ERC [1, 3].

Management

The most recent ACOG practice bulletin on this issue made a number of recommendations based on "consistent scientific evidence" [1]: most patients with one prior low transverse cesarean section should be offered TOLAC; epidural analgesia may be used in patients undergoing TOLAC; misoprostol should not be used for induction of labor. A number of recommendations were made based on more limited scientific evidence, including that TOLAC is a reasonable option for patients with two prior cesarean deliveries, as well as for patients with an unknown type of uterine scar as long as there is no high clinical suspicion for a classical uterine incision. ACOG recommends a trial of labor even for patients with twins and a history of one low transverse cesarean delivery, as long as the first twin is cephalic [1, 4].

Indications for Cesarean Delivery

Cesarean delivery was once considered the last resort, resulting in maternal death in the majority of cases [5]. It is now generally viewed as safe and increasingly requested and performed without clear indication. It is imperative to understand appropriate indications for cesarean section.

Four indications currently account for up to 90 % of cesarean sections: prior cesarean section (~35–40 %), labor dystocia (~20–35 %), abnormal fetal presentation (~10–20 %), and non-reassuring fetal status (~10–25 %) [5, 6]. See Table 1 for a helpful categorization of cesarean indications, suggested in *Munro Kerr's Operative Obstetrics* [5]. Frequently, a combination of relative indications, rather than one absolute indication, leads to the decision for cesarean.

DOI 10.1007/978-1-4939-0779-3_14-2

Breech Delivery

Background

The Term Breech Trial in 2000 led to a dramatic change in obstetric practice [7]. When compared with planned cesarean delivery, the study demonstrated increased morbidity with planned vaginal breech delivery. Follow-up analyses have not been consistent in suggesting increased long-term risk [8, 9], but hesitance to plan vaginal breech deliveries has persisted. ACOG expresses support for a general policy of cesarean delivery for these patients [10].

General Principles

Breech presentation persists in approximately 3–4 % of singleton pregnancies at term [6]. There are several types of breech presentation, defined by the relationship of the lower extremities to the buttocks. In frank breech presentation, the hips are flexed and the knees extended, so that the feet are close to the head. In complete breech presentation, one or both of the knees are flexed. In incomplete breech presentation (also referred to as footling breech), one or both knees are not flexed and therefore below the buttocks. As a pregnancy approaches term, the larger mass of the buttocks typically finds its place in the more spacious fundus. Multiple factors increase the risk of breech presentation [6]: amniotic fluid volume abnormalities, high parity, hydro-/anencephaly, previous breech delivery, uterine anomalies, placenta previa, fundal placentation, and pelvic tumors. Risks of vaginal breech delivery include maternal cervical and vaginal trauma; uterine rupture; fetal humerus, clavicle, or femur injuries; brachial plexus injuries; skull fractures; and difficulty delivering the aftercoming head.

Management

Because unexpected breech deliveries occur, and because some resource settings make cesarean section impossible, it is important to understand the technique of breech delivery. While multiple sources describe the technique in detail, several points are worth mentioning: episiotomy should be strongly considered; delivery is easier if the fetus is allowed to deliver spontaneously up to the umbilicus, in order to avoid cord compression; delivery must be accomplished promptly once the breech has passed through the introitus [6].

Bleeding Complications During Labor

General Principles

Patients who have placenta abruption, placenta previa, placenta accreta, and vasa previa can present with vaginal bleeding later in pregnancy. It is important to understand the conditions and respond quickly when there is a high index of suspicion. Advances in ultrasonography have improved the early and accurate diagnosis of placenta previa, placenta accreta, and vasa previa allowing the clinician time for preparation.

Placenta Abruption

Placenta abruption occurs when there is premature separation, either partial or total, of the placenta prior to birth. Placenta abruption occurs in 0.4–1 % of pregnancies [11]. Half of women who experience placenta abruption have hypertension. Other risk factors for placenta abruption include abdominal trauma, grand multiparity ($\geq$3), uterine anomalies, folate deficiency, short umbilical cord, cigarette smoking, cocaine usage, history of abruption, and maternal age over 35 [11, 12]. Most women will experience third trimester bleeding (80 %), pain (50 %), or a non-reassuring fetal heart rate tracing.

DOI 10.1007/978-1-4939-0779-3_14-2

Ultrasonography does not always detect a clot underneath the placenta. Therefore, placenta abruption remains a clinical diagnosis and treatment is recommended if there is a high index of suspicion. Close monitoring of mother and baby is necessary. The mother may become hemodynamically unstable and require IV fluids or blood products. When there is a non-reassuring fetal heart rate tracing, an emergency cesarean section may be necessary.

Placenta Previa

Placenta previa occurs when the placenta overlies or is proximate to the cervical os. Placenta previa can be classified as complete if the placenta completely covers the internal os, partial if the placenta partially covers the internal os, marginal if the placenta reaches the internal os but does not cover it, or low-lying placenta if the placenta extends into the lower uterine segment but does not reach the internal os.

Placenta previa is seen in 0.4–0.6 % of all births [12]. Risk factors include multiparity, previous placenta previa, history of cesarean section, history of dilation and curettage, smoking, pregnancy termination, prior evacuation of retained products of conception, advanced maternal age, multifetal gestation, abnormal fetal lie, and previous intrauterine surgery. The condition is a relatively common finding on second trimester ultrasounds. If the placenta previa is marginal, they tend to resolve in 95 % of cases. Placenta previa is usually diagnosed in asymptomatic women during ultrasonography examination (transvaginal ultrasound is superior). Symptomatic women present during their third trimester with painless vaginal bleeding. Placenta previa is associated with antepartum bleeding, the need for hysterectomy, maternal hemorrhage, blood transfusion, septicemia, thrombophlebitis, and an increased risk of preterm birth [12]. Once diagnosed the initial management is usually conservative as long as there is a reassuring fetal heart rate tracing and the mother is hemodynamically stable, in order to allow for the fetus to progress to as close to term as possible. If bleeding occurs between 24 and 34 weeks of gestation, it is also recommended to administer steroids in case preterm delivery is necessary. Cesarean section for complete and partial placenta previas is usually performed at 36–37 weeks of gestation [12].

Placenta Accreta

Placenta accreta refers to a placenta that is abnormally adhered to the uterus, invading the myometrium, serosa, or even adjacent organs. This becomes a problem at the time of delivery when the placenta does not separate and may lead to massive hemorrhage. This hemorrhage can cause further complications such as disseminated intravascular coagulopathy, need for hysterectomy, injury to other maternal tissues, renal failure, or death [12]. The incidence of accreta is rising due to the rise in cesarean delivery rates [12] and is estimated to occur in between one in 533–2510 deliveries. Other uterine surgeries, advanced maternal age, and multiparity can also increase risk of placenta accreta. It is critical to make the diagnosis of placenta accreta prenatally via sonography or MRI so that proper planning and delivery can occur. Management of placenta accreta involves a planned preterm cesarean section followed by total abdominal hysterectomy without an attempt to separate the placenta from the uterus to avoid excessive bleeding. The clinician should be prepared to manage blood loss since women with placenta accreta typically lose 3000–5000 ml of blood at time of delivery [12].

Vasa Previa

Vasa previa is a rare but life-threatening condition that refers to fetal vessels running through the membranes over the cervix and under the fetal presenting part; it is the result of velamentous insertion of the cord into the membranes instead of the safer placenta. Because this can lead to fetal hemorrhage at the time of membrane rupture, it carries a mortality rate greater than 50 % [12]. Vasa previa occurs in 1 in 2500 deliveries [12]. Risk factors include a low-lying placenta, placenta with accessory lobes, multiple

DOI 10.1007/978-1-4939-0779-3_14-2

pregnancies, and pregnancies from in vitro fertilization [12]. Vasa previa can be seen with ultrasonography but is sometimes diagnosed at rupture of membranes when vaginal bleeding is noted along with fetal distress. The diagnosis is confirmed on visual inspection of the placenta after delivery. For vasa previa prenatally diagnosed, administration of corticosteroids is recommended at 30–32 weeks with planned cesarean section between 35 and 36 weeks of gestation. Treatment of vasa previa is immediate cesarean section if found at the time of rupture of membranes.

Premature Rupture of Membranes and Preterm Premature Rupture of Membranes

General Principles

Premature rupture of membranes (PROM) at term is defined as rupture of the chorioamniotic membranes more than an hour prior to the onset of labor at 37 weeks of gestation or later. Preterm premature rupture of membranes (PPROM) is defined as the premature rupture of membranes before 37 weeks of gestation. PROM occurs in 8 % of pregnancies and PPROM occurs in 3 % of all pregnancies [13].

Risk factors for PROM include primiparity, prior PROM, preterm labor, first trimester bleeding, and chlamydia infection. Risk factors for PPROM include prior history of PPROM, infection, second or third trimester bleeding, cerclage, shortened cervical length, uterine overdistention, smoking, low socioeconomic status, BMI <20, maternal pulmonary disease, previous LEEP, and nutritional deficiencies [13]. Group B streptococcus (GBS) status is not a risk factor for PROM or PPROM.

There is an increased risk of chorioamnionitis and endometritis if time from rupture to delivery is >12 h. Neonatal infection is associated with chorioamnionitis and positive maternal GBS status in women with term PROM. Other complications include placental abruption, umbilical cord compression during labor, and umbilical cord prolapse.

Diagnosis

Women will present with a gush of fluid in both PROM and PPROM. It is interesting to note that patient history of a gush of fluid is 90 % sensitive for PPROM [14]. On exam, the clinician should look for pooling of fluid and do a visual assessment of cervical effacement and dilation. The clinician can also perform a nitrazine test, ferning examination, or an AmniSure/AmnioSense to confirm rupture of membranes.

Treatment

Women presenting with PROM should be induced, usually with IV oxytocin, although misoprostol can also be considered. In the setting of PROM, antibiotics may reduce chorioamnionitis and endometritis; however, it has not been shown to improve neonatal outcomes. Thus, the routine use of antibiotics without confirmed maternal infection should be avoided in PROM [15]. GBS prophylaxis should be based on prior culture results if available. The treatment of PPROM is dependent on gestational age and assessment of fetal status.

- PPROM at $\geq$34 weeks of gestation: Delivery is recommended with induction of labor. GBS prophylaxis is based on prior culture results or risk factors.
- PPROM at 24–33 weeks of gestation: Expectant management until 33 weeks if lung maturity is not proven. Treatment with antibiotics, corticosteroids, and intrapartum GBS prophylaxis is recommended. Consider the use of magnesium sulfate for fetal neuroprotection if there is a risk of delivery before 32 weeks of gestation.

DOI 10.1007/978-1-4939-0779-3_14-2

- PPROM at <24 weeks of gestation (previable): Counsel regarding risks and benefits; including likely neonatal morbidity and mortality, compare immediate delivery vs. expectant management. No GBS prophylaxis necessary. Monitor for signs of infection. Corticosteroids are not recommended until fetus has reached viability.

Postterm Pregnancy

General Principles

Postterm pregnancy refers to a pregnancy that is ≥42 $^{0/7}$ weeks of gestation or ≥294 days from first day of the last menstrual period. Early and accurate dating is critical to the diagnosis. In the United States approximately 28 % of pregnancies deliver in the 40th and 41st week and 5–7 % delivers at over 42 weeks [16]. When compared to dating based on LMP, early sonographic dating has been linked to a reduction in prevalence of postterm pregnancy from 6–12 % to 2 % [17].

One risk factor for postterm pregnancy is inaccurate dating. Of the true postterm pregnancies, most have no known etiology. Women at highest risk for postterm pregnancy are those with a previous postterm pregnancy. The risk of a second postterm birth is increased two- to threefold and quadruples after two prior postterm pregnancies [18]. Other risk factors for postterm pregnancy include nulliparity, male fetus, maternal obesity, older maternal age, and Caucasian ethnicity.

Postterm fetuses tend to be larger than term fetuses, further increasing their risk of prolonged labor, shoulder dystocia, meconium-stained amniotic fluid, and cephalopelvic disproportion. These complications increase the risk of birth injury. Beyond 42 weeks of gestation, the perinatal mortality rate is twice the rate at term (4–7 deaths vs. 2–3 deaths per 1000 deliveries) [19]. Other risks to the fetus include low umbilical artery pH, low 5-min Apgars, and an increased probability of death in the first year of life.

Maternal complications of a postterm pregnancy include increase in labor dystocia, fetal macrosomia, failed induction, third or fourth degree lacerations, postpartum hemorrhage, and increased risk of cesarean section. A postterm pregnancy can also be a cause of emotional distress to the mother.

Management

In well-dated postterm pregnancies, it is recommended to induce after 41 $^{0/7}$ weeks of gestation regardless of cervical status in order to reduce perinatal mortality and meconium aspiration syndrome [20]. This approach has not resulted in an increased risk of cesarean delivery compared to expectant management. Cervical ripening agents can be utilized in women with unfavorable cervices. The efficacy of antenatal fetal assessment has not been well studied due to ethical implications of assigning patients to the control group. Based on case-control studies, it is reasonable to perform antenatal fetal assessments twice a week beginning at 41 weeks of gestation and these assessment may include nonstress testing, biophysical profile (BPP), or modified BPP (nonstress test plus amniotic fluid volume).

Labor Dystocia

General Principles

The word dystocia means difficult labor [6]. Numerous maternal and fetal complications can result in increased rates of uterine rupture, intrauterine infection, uterine atony following delivery, pathological retraction rings, fistula formation, pelvic floor injury, maternal lower extremity nerve injury, fetal sepsis, and fetal mechanical injuries. Labor dystocia is likely the most common indication for primary cesarean

DOI 10.1007/978-1-4939-0779-3_14-2

delivery [21, 22], as well as the underlying factor in at least one third of all cesarean deliveries [2, 23], and therefore a significant public health concern. The problem is significantly more common in nulliparas than multiparas. Consequently, decreasing the incidence of dystocia in nulliparous patients would significantly impact the overall cesarean birth rate [2].

Approach to the Patient

Dystocia has multiple causes, though identifying a specific cause is limited by frequent overlap and lack of definitive diagnostic tools. A common helpful framework divides these causes into problems with *power* (or uterine action), *passenger* (or fetal position in relationship to the maternal pelvis), or *passageway* (or shape and size of the maternal pelvis, i.e., cephalopelvic disproportion). Ineffective uterine action is the most common cause [2, 6], of which there can be various mechanisms (e.g., insufficient strength, incoordination, other events in labor such as [arguably] chorioamnionitis). True cephalopelvic disproportion is likely rare [6] and in practice is diagnosed if labor does not progress normally in the setting of adequate uterine contractions and cephalic presentation. Conceptualizing abnormal labor in this way organizes clinical thought processes and guides interventions.

Diagnosis

No universal set of diagnostic criteria for labor dystocia exists. The labor curves put forth by Friedman in the mid-1900s are increasingly questioned [6], with more recent data suggesting that labor may last longer overall, that the latent phase in particular may last longer, and that labor progress may accelerate as it advances. At the very least, experience since Friedman suggests that labor patterns are contingent on multiple patient variables, including parity, use of regional anesthesia, and fetal presentation [24].

Requiring specific periods of time to pass before diagnosis may not be helpful for each individual labor, but certain conditions should be fulfilled in order to prevent premature decisions [6]. First, dystocia should be diagnosed only after a patient has entered the active phase of labor. Second, every effort should be made to ensure that the patient has been given an adequate trial of labor, which includes adequate contractions over an extended period of time (e.g., 200 Montevideo units per 10 min over 2–4 h). Third, amniotomy should be performed prior to diagnosis [2].

Management/Prevention

The management of labor dystocia follows from the above discussion. As a means of prevention, elective induction should be undertaken with caution. When active labor has been diagnosed, steps should be taken to ensure the adequacy of contractions. Especially in the case of nulliparous patients, this will often be accomplished with the use of oxytocin, which is very safe in this group of patients. These steps will also include accurately quantifying the contractions.

Various labor management protocols have arisen since the 1980s, all with the goal of reducing rates of labor dystocia and thereby reducing rates of cesarean delivery. These efforts target nulliparous patients, since rates of dystocia are highest in this group and as oxytocin is comparatively safe. One such program arose in a large maternity center in Dublin in the 1980s, employing an approach that has come to be known as the "active management of labor" [25]. The protocol achieved remarkable success – one highlight being a cesarean delivery rate of 4.8 %. The overarching lesson from this protocol and others is that the clinician must be vigilant in recognizing and addressing abnormal labor, and then effectively intervene to improve uterine action when necessary.

DOI 10.1007/978-1-4939-0779-3_14-2

Infection

Group B *Streptococcal* Disease

Background

The 1970s witnessed the emergence of group B streptococcus (GBS) as the leading cause of neonatal morbidity and mortality, with reported case-fatality rates as high as 50 % [26]. Guidelines issued in 1996 and 1997 recommended intrapartum antibiotic prophylaxis to prevent neonatal GBS disease [26]. This was followed by guidelines in 2002 recommending universal culture-based screening for GBS colonization in pregnant patients at 35–37 weeks of gestation [26]. These efforts have led to an 80 % reduction in the incidence of early-onset neonatal sepsis due to GBS. Despite this significant progress, GBS remains the leading cause of neonatal infectious morbidity and mortality [27].

Management/Prevention

Prevention of perinatal GBS disease focuses on early-onset neonatal disease (within the first week of life), as the above efforts have not changed the incidence of late-onset disease [26]. The recommendations for intrapartum management discussed below come from the Centers for Disease Control and Prevention (CDC) 2010 revised guidelines [26], which were officially endorsed by ACOG in 2011 [27].

Intrapartum GBS prophylaxis is indicated in patients who have had a previous infant with invasive GBS disease, in patients with GBS bacteriuria during the current pregnancy, and in patients with a positive GBS vaginal/rectal culture obtained late in the current pregnancy. In patients whose GBS status is unknown at the time of labor, antibiotic prophylaxis is indicated only in patients with a gestational age less than 37 weeks, rupture of membranes for greater than 18 h, or an intrapartum fever. Of note, antibiotic prophylaxis is not indicated for patients with intact membranes undergoing cesarean delivery before the onset of labor, regardless of GBS colonization status. All patients with preterm labor or preterm premature rupture of membranes (PPROM) should be screened for GBS colonization at the time of diagnosis and then treated with appropriate antibiotics for GBS prevention until labor is either ruled out or completed. Ideally, antibiotics should be initiated at least 4 h prior to delivery, though this goal should never delay medically necessary interventions during labor. Penicillin remains the antibiotic of choice, except in the case of severe penicillin allergy.

Chorioamnionitis

General Principles

Chorioamnionitis, also termed "intra-amniotic infection" (IAI), is acute inflammation of the placenta and chorion [28]. Most commonly, IAI is caused by polymicrobial bacterial infection ascending from the lower genital tract. IAI may account for half of deliveries prior to 30 weeks and up to 40 % of cases of early neonatal sepsis and pneumonia [29].

Risk factors for chorioamnionitis include prolonged labor, nulliparity, meconium-stained amniotic fluid, longer duration of internal uterine monitoring, the presence of genital tract pathogens such as bacterial vaginosis (BV) and GBS, and a greater number of digital vaginal examinations [29]. Potential maternal complications of chorioamnionitis include maternal bacteremia, postpartum endomyometritis, and postpartum hemorrhage. Potential fetal complications include death, asphyxia, sepsis, cerebral palsy, and long-term neurodevelopmental disability [28]. The majority of fetal and neonatal complications are significantly more common with decreasing gestational age.

DOI 10.1007/978-1-4939-0779-3_14-2

Diagnosis

The common diagnostic criteria for chorioamnionitis are maternal fever with two or more of the following: maternal leukocytosis, maternal tachycardia, fetal tachycardia, uterine tenderness, or foul-smelling amniotic fluid [2]. In practice the diagnosis is clinical, confirmed by histopathology only after clinical decisions are made. Amniotic fluid culture is the gold standard for clinical diagnosis, but the utility of fluid culture is limited by the time it takes for results.

Treatment

Management of chorioamnionitis is straightforward. As soon as the diagnosis of chorioamnionitis is made, antibiotics should be initiated, as immediate treatment with antibiotics has been shown to reduce maternal and neonatal complications [28]. The typical antibiotic regimen includes ampicillin and gentamicin, with the addition of clindamycin if a cesarean section is performed. One dose of antibiotics should be administered following delivery [28]. Treating maternal fever with antipyretics is also critical, providing two benefits: avoiding the adverse neonatal outcomes associated with maternal fever and potentially reducing the inclination to perform a cesarean section by resolving the associated fetal tachycardia [28]. Labor should be expedited in the setting of chorioamnionitis, but cesarean delivery is only indicated for usual obstetric indications.

Meconium-Stained Amniotic Fluid

General Principles

Meconium-stained amniotic fluid (MSAF) presents as greenish- to brown-stained amniotic fluid seen at rupture of membranes. It is the result of the passage of fetal colonic material into the amniotic cavity.

Meconium-stained amniotic fluid occurs in approximately 12 % of live births and its incidence increases with gestational age. While MSAF occurs in <5 % of preterm deliveries, it increases to 7–22 % of term deliveries and affects 23–52 % of postterm pregnancies [30].

Both prenatal stressors (fetal hypoxia and acidosis) and head or cord compression can cause vagal stimulation and relaxation of the fetal sphincter, leading to MSAF. Exposure of the meconium to the fetus can occur either in utero or at the time of the infant's first breath.

Risk factors for MSAF include postterm gestation, maternal diabetes, maternal tobacco usage, maternal respiratory or cardiovascular disease, preeclampsia, oligohydramnios, intrauterine growth restriction, low score on biophysical profile, and abnormal fetal heart rate tracing.

Meconium aspiration, chorioamnionitis, and endometritis are all more likely to occur with MSAF [31]. Meconium aspiration syndrome (MAS) is respiratory distress in a newborn that was born through MSAF. MAS develops in 5 % of infants delivered through MSAF; 95 % of infant with inhaled meconium will clear it spontaneously without complication [31]. MAS is the most serious complication associated with MSAF and can lead to intubation and mechanical ventilation, pneumothorax, seizures, and death [32].

Management

It is thought that MSAF may support bacterial growth by acting as a medium for bacteria, inhibiting the bacteriostatic properties of amniotic fluid, or antagonizing typical host defense systems by diminishing the phagocytic response of neutrophils [33]. It was theorized that prophylactic antibiotics would reduce the rate of adverse events. However, no significant reductions in the incidence of neonatal sepsis, endometritis, or NICU admissions were found. And yet, there was a reduction in the incidence of chorioamnionitis [33]. Because the rates of neonatal sepsis were similar regardless of antibiotics, there

DOI 10.1007/978-1-4939-0779-3_14-2

is insufficient evidence at this time to recommend administration of prophylactic antibiotics to laboring mothers with MSAF [33].

Because oligohydramnios can lead to increased cord compression and subsequently the passage of meconium, it has been theorized that amnioinfusion (AI) could be a promising therapy. While AI has been shown to reduce the risk of fetal heart rate deceleration and cesarean section in the presence of oligohydramnios, it has not been shown to reduce the risk of moderate or severe MAS, perinatal death, or other major maternal or neonatal disorders in the setting of standard peripartum surveillance [32]. In settings with limited peripartum surveillance, AI did reduce the risk of MAS. Currently, it is not recommended to use prophylactic amnioinfusion to reduce the risk of MAS.

Shoulder Dystocia

General Principles

Shoulder dystocia is a relatively rare and uncomplicated condition but can become an obstetrical emergency. It occurs at delivery and is characterized by difficulty delivering fetal shoulders, requiring additional maneuvers to facilitate extraction. It is also defined as a head-to-body delivery time of greater than 60 s [34]. Shoulder dystocia affects 0.6–1.4 % of vaginal deliveries of fetuses in the vertex presentation [35]. Shoulder dystocia cannot be predicted or prevented. The goal is to understand the risk factors and signs of shoulder dystocia and then quickly respond when it does present.

Maternal risk factors include diabetes, postterm pregnancy, previous shoulder dystocia (recurs in up to 25 % of subsequent pregnancies), pelvic anatomy, short maternal stature (less than 5 ft tall), maternal obesity (over 200 lb), previous infant over 4000 g, or advanced maternal age. Fetal risk factors include macrosomia (estimated fetal weight over 4000 g), size inconsistent with dating, and male gender. Labor risk factors include operative vaginal delivery and abnormal progression of labor (either prolonged active or second-stage or precipitous delivery).

If the fetal shoulders remain in an anterior-posterior position during descent or descend simultaneously, then the anterior shoulder can become impacted behind the symphysis pubis, or the posterior shoulder may be obstructed by the sacral promontory. If descent of the fetal head continues while the anterior or posterior shoulder remains impacted, then stretching of the nerves in the brachial plexus may occur and may result in nerve injury.

Five percent of shoulder dystocias are complicated by neonatal injury, the most common complications being brachial plexus injury and clavicular fracture. Brachial plexus injury (Erb's palsy) occurs in 2–16 % of shoulder dystocias. Most cases resolve but it can result in permanent neurologic impairment. Clavicular fracture and humerus fractures usually have a benign course and complete recovery. Other more serious complications include pneumothorax, permanent neurological damage due to hypoxia, and death. Maternal complications include postpartum hemorrhage, third or fourth degree perineal lacerations, uterine rupture, bladder rupture, rectovaginal fistula, sacroiliac joint dislocation, pubic symphysis separation, neuropathy, and stool incontinence.

Diagnosis

The diagnosis of shoulder dystocia is a clinical diagnosis based on the inability to deliver shoulders after delivery of the head. The physician should be alerted to the potential of shoulder dystocia if they notice the fetal head remains tightly applied to the vulva or retracts (turtle sign) against the perineum.

DOI 10.1007/978-1-4939-0779-3_14-2

Table 2 Maneuvers for managing shoulder dystocia

	Initial maneuvers
McRobert's	Flex the patient's legs against the abdomen Reduces 42 % of shoulder dystocias
Suprapubic pressure	Apply moderate suprapubic pressure obliquely to the anterior shoulder to adduct the shoulders into the oblique plane When combined with McRoberts – reduces 50 % of shoulder dystocias
Posterior arm	Flex the fetal elbow and sweep the arm across the chest, grasp the hand and extend the arm along the side of the face, deliver the posterior arm Highly effective
Rubin	Place a hand on the posterior surface of posterior (or anterior) shoulder and rotate it anteriorly
Woods corkscrew	Place a hand on the anterior surface of the posterior shoulder and rotate the posterior shoulder 180° May combine with Rubin to increase effectiveness
Gaskin	Place mother in hands and knees and apply downward traction on posterior shoulder or upward traction on anterior shoulder Use in mothers without epidurals that can support their weight
Episiotomy	Perform an episiotomy to allow room for maneuvers, does not itself reduce shoulder dystocia
	Extraordinary maneuvers
Clavicle fracture	Press the anterior clavicle against the ramus of the pubis or pull the anterior clavicle outward to fracture the clavicle
Zavanelli	Return the fetal head to the OA or OP position, flex the fetal head and push it back into the vagina, proceed with cesarean section
Abdominal rescue	If unable to replace the fetal head into the vagina, perform a cesarean section to manually rotate the anterior shoulder into the oblique diameter; proceed with vaginal delivery
Symphysiotomy	Division of anterior fibers of symphyseal ligament – performed by individuals who have knowledge and experience in this procedure

OA occiput anterior, *OP* occiput posterior

Management

As soon as a shoulder dystocia is suspected, the physician should respond by alerting the team for the need for additional assistance and preparing the patient. The mother should be alerted to the situation, discouraged from pushing, and moved toward the edge of the bed to better support the maneuvers required. Refer to Table 2 for list of maneuvers used to reduce a shoulder dystocia. When using a maneuver, the clinician should move on to another maneuver if unsuccessful after 20–30 s. In most cases, the physician has up to 5 min to deliver a previously well-oxygenated term infant before there is an increased risk of asphyxial injury. The pH is estimated to fall between 0.01 and 0.04 pH units per minute in the interval between delivery of the fetal head and trunk. No one maneuver has been shown to be superior over another nor has an established sequence been determined. Knowledge of all the maneuvers is important so that the most appropriate maneuver is applied in each clinical situation.

Prevention

Prophylactic labor induction for the prevention of shoulder dystocia is not routinely recommended in women without diabetes and suspected fetal macrosomia, as it does not prevent shoulder dystocia. Prophylactic cesarean delivery is not routinely recommended unless the estimated fetal weight is >4500 g in women with diabetes or >5000 g in women without diabetes. Both of these are ACOG level C recommendations.

DOI 10.1007/978-1-4939-0779-3_14-2

Assisted Vaginal Delivery

General Principles

Assisted vaginal delivery (or "operative vaginal delivery" when referring specifically to forceps and vacuum) includes forceps delivery, vacuum delivery, and manual rotation of the fetal head. All the maneuvers aim to expedite delivery for maternal or fetal well-being. Performed with good technique and for appropriate indications, these methods are safe and effective. Overall, rates of assisted vaginal delivery have declined over time, concurrent with an increase in the cesarean rate. However, over several decades the rate of vacuum-assisted vaginal delivery has increased while the rate of forceps delivery has dramatically decreased [6]. This shift may owe to the perception that vacuum delivery is less likely to cause maternal pelvic floor injury, which may be true at least in the short term [5].

Approach to the Patient

The indications for forceps and vacuum delivery include conditions that threaten the well-being of the mother or fetus, as well as nonprogressive second-stage labor [5, 6]. Prerequisites for both forceps and vacuum application are largely the same [6]: complete dilation of the cervix, ruptured membranes, engagement of the fetal head, vertex presentation, no suspected cephalopelvic disproportion, adequate anesthesia, and precise knowledge of fetal head position. The last prerequisite is worth highlighting, as knowledge of fetal head position is essential for safe and correct application of the assistive device.

The current classification system for forceps deliveries, endorsed widely by groups including ACOG, also applies to vacuum deliveries. A central purpose of its implementation was to avoid unsafe application of these techniques, as potential for harm is greater with higher fetal head position and more rotation applied to the head [36]. Outlet forceps delivery occurs with the fetal scalp visible at the introitus, the fetal skull on the pelvic floor, and application of no more than 45° of rotation. Low forceps delivery occurs with the fetal skull at or below +2 station, and midforceps delivery occurs between 0 and +2 station. High forceps delivery is no longer viewed as being appropriate in any circumstance.

There remains a lack of consensus regarding the relative risks and benefits of forceps versus vacuum delivery. Potential benefits of forceps are increased likelihood of achieving vaginal delivery [37] and its ability to achieve head rotation. However, forceps have also been associated with a trend toward more cesarean sections, as well as more third and fourth degree tears, vaginal trauma, altered continence, and facial injury [37]. The likely decreased maternal risk is a potential benefit of the vacuum, though cephalohematoma may be more common [37]. In practice, the experience of the operator will often be the primary factor when choosing between forceps and vacuum.

Technique

The technique of forceps and vacuum-assisted delivery is very similar among the numerous specific devices and well described in multiple sources. For occiput anterior presentations, correctly placed forceps travel the occipitomental diameter, with the largest portion of the blades covering the face and the greatest distance between the blades corresponding to the biparietal diameter. Correct placement of the vacuum is also essential, as this allows the fetal head to be flexed to the narrowest diameter in its passage through the pelvis. The center of the vacuum cup should be placed over the flexion point, which is in line with the sagittal suture and approximately 3 cm anterior to the anterior edge of the posterior fontanelle. Assisted delivery should be continued only if clear progress in descent is being achieved. In the case of the vacuum, rotation should not be attempted, pop-offs should be minimized, and traction should occur for the shortest amount of time possible.

DOI 10.1007/978-1-4939-0779-3_14-2

Manual rotation of the fetal head may be beneficial for occiput posterior or occiput transverse presentations. A decreased rate of operative vaginal delivery has been achieved when employing this technique, without increasing risk [38].

Cord Prolapse

General Principles

Umbilical cord prolapse (UCP) is an obstetrical emergency in which the umbilical cord passes through the cervical os in advance of the fetal presenting part (overt) or alongside the fetal presenting part (occult). This can cause cord compression which can lead to fetal hypoxia.

The incidence of UCP has remained stable and affects 1.4–6.2 per 1000 deliveries [39]. In the past UCP carried a high mortality rate; however, with the increased availability of cesarean delivery, the mortality rate has decreased to 10 % or less [39].

There are spontaneous and iatrogenic risk factors for UCP. Spontaneous UCP can occur in uncomplicated pregnancies and are related to conditions that prevent the fetus from properly engaging in the pelvis or abnormalities of the umbilical cord itself including: fetal malpresentation (most common), polyhydramnios, preterm delivery, preterm premature rupture of membranes, multiple gestation, fetal anomalies, grand multiparty, cord abnormalities (higher risk of prolapse with a thin cord), birth weight less than 2500 g (although some authors quote <1500 g) [40], and spontaneous rupture of membranes (57 % of cases occurred within 5 min of rupture) [41]. Iatrogenic causes include artificial rupture of membranes without an engaged presenting part, attempted rotation of the fetal head, amnioinfusion, and external cephalic version in patient with ruptured membranes, placement of an intrauterine pressure catheter or fetal scalp electrode, and placement of a cervical ripening catheter. These risk factors are usually maneuvers performed by the clinician on the labor and delivery floor and do not increase morbidity and mortality due to the availability of a quick response by the clinician.

Diagnosis

UCP is diagnosed clinically by the umbilical cord being palpable or visible in the vagina. The clinician may also notice a severe and sudden drop in the fetal heart tones (FHT) or variable decelerations. It is worth noting that these FHT changes are not always initially seen.

Prevention

As the act of rupturing membranes, whether spontaneous or artificial, is a risk factor for cord prolapse, it is recommended that care be taken when considering rupture of membranes. If the head is well applied to the cervix, amniotomy may be safely performed. When the fetal head is ballotable, amniotomy should be delayed or performed in a controlled manner to avoid sudden decompression.

Management

Umbilical cord prolapse can quickly compromise the fetus which can lead to disability and death. The primary management of UCP is immediate delivery and is usually done via cesarean section. Until delivery can be performed, the goal is to alleviate pressure on the umbilical cord. This is done by:

- Funic decompression – the clinician places two fingers or the palm on the fetus' presenting part and elevates it.
- Trendelenburg or knee-chest position – place the mother in Trendelenburg position or knee-to-chest position to allow gravity to assist in alleviating pressure on the umbilical cord.

DOI 10.1007/978-1-4939-0779-3_14-2

- Foley catheter (first described in 1970 by Vago) – bladder instilled with saline to allow the distended bladder to provide an upward pressure on the fetal presenting part.

Neonatal outcomes in cases of UCP are generally good when delivery can be accomplished within 30 min.

Postpartum Care

Rahmat Na'Allah[a]* and Craig Griebel[b]
[a]Department of Family and Community Medicine, University of Illinois College of Medicine, Peoria, Family Medicine Residency Program, Peoria, IL, USA
[b]Family Medicine Residency at Methodist Medical Center, Peoria, IL, USA

Introduction

Childbirth and the postpartum period constitute an exciting yet challenging time for the mother, newborn, and family members. This includes physiological, physical, and psychosocial changes which many new mothers transition through uneventfully. However, this period can also pose overwhelming challenges with associated health issues. Hence, the importance of effective prenatal, intrapartum, and postpartum anticipatory guidance cannot be overemphasized.

Immediate Postpartum Care

The Golden Hour: Maternal Infant Bonding

The "golden hour" is the immediate 60 min after childbirth. In the past when more babies were born outside the hospital, placing the newborn directly skin to skin on the mother's chest or abdomen was necessary for the infant's survival. It continues to be the practice in many developing countries. However, in industrialized nations, it has become common practice for infants to be immediately whisked away for "transition" which includes a check of vital signs, maintaining temperature by placing on the warmer, medications, immunizations, and sometimes a bath. A Cochrane review of 34 randomized trials involving 2177 mothers and newborns concluded that babies who were immediately exposed to skin-to-skin contact (SSC) cried less, had better cardiorespiratory function, and had better interactions with their mothers. They also were more likely to breastfeed in the first 1–4 months of life and breastfed longer when compared to babies who were not exposed to SSC. There were no negative effects of SSC found in these trials [1].

The concept of maternal-infant bonding was introduced as far back as the 1960s [2, 3] through the work of Rubin and subsequently popularized by Klaus and Kennell in the 1970s [4]. Formation of a strong bond between the mother and infant has been shown in multiple studies to enhance the cognitive and neurobehavioral development of the child while the lack of this bond can have long-term negative effects on the maternal-child relationship. Some of these negative consequences include irritability, hostility, and lack of maternal feelings for the child which can progress to child abuse and neglect [3, 5]. Hospitals began to institute "rooming in" policies after the publication of the book *Maternal-Infant Bonding* by Klaus and Kennell in 1983 [6]. Recommendations from early research on maternal-infant bonding include delaying newborn procedures such as medication application, initiating breastfeeding immediately after birth, rooming in, and encouraging parents to touch, gaze, and talk to their babies [5, 7]. However, it is important to note that unlike animals, humans are able to form bonds with their infants and vice versa if

*Email: rahmat.na'allah@unitypoint.org

DOI 10.1007/978-1-4939-0779-3_15-1

separation is temporary and the infant's basic needs are being met [8]. Caution should be exercised in equating the interruption of maternal-infant bonding with future catastrophe.

Promotion of Breastfeeding

Part of the benefit of early maternal-infant bonding is the initiation and continuation of breastfeeding. Obstetric and pediatric physicians have a significant role to play in helping to ensure the success of breastfeeding. Discussion about breastfeeding should begin in the prenatal period. Emphasizing the immediate and long-term benefits of breastfeeding on the mom and baby early in the prenatal period is optimal. The benefits of breastfeeding on the infant and mother have been demonstrated by scientific evidence, hence all major maternal-child health organizations recommend exclusive breastfeeding in the first 6 months of life and continued through 1–2 years of age [9]. Early anticipation of barriers to breastfeeding will help in providing the necessary support for the new mother and her family. During the first several weeks of breastfeeding, infants should be nursed at least 8–12 times in a 24 h period on demand [10]. The Academy of Breastfeeding Medicine recommends creating a breastfeeding-friendly office; understanding the effect of cultural influence on families and communities; and integrating breastfeeding promotion, education, and support throughout the prenatal period [11]. Current evidence suggests that the Baby Friendly Hospital Initiative and the "Ten steps to Successful Breastfeeding" are proven and effective measures to ensure breastfeeding initiation, duration, and exclusivity [12]. Hospitals that are certified as being "baby friendly" have the highest breastfeeding rates [10, 13].

Postpartum Complications

Postpartum Hemorrhage

Various definitions for postpartum hemorrhage (PPH) have been proposed. The most commonly used definition is the loss of 500 ml of blood after a vaginal delivery or the loss of 1,000 ml after a Cesarean delivery. However, blood loss estimates often underestimate the actual blood loss at a delivery. Another suggested definition is the drop in the hematocrit of 10 % or more, but if blood loss is ongoing, the decline in hematocrit may underestimate the actual blood loss [14].

Postpartum hemorrhage has been reported to occur in up to 18 % of deliveries, with approximately 3 % of births resulting in severe postpartum hemorrhage. PPH is the most common cause of maternal morbidity in developed countries [15]. Complications after PPH include hypotension, difficulty with breastfeeding and caring for the newborn, extreme fatigue, and blood transfusion reactions if a transfusion is required. Hemorrhagic shock after postpartum hemorrhage can lead to Sheehan's syndrome (posterior pituitary necrosis) [15].

There are a number of risk factors for PPH, including a past history of PPH, prolonged labor, augmented labor, overdistended uterus, chorioamnionitis, preeclampsia, and operative delivery [14]. However, many patients who develop PPH have no risk factors, so providers must be alert to this complication at every delivery.

The active management of the third stage of labor (AMTSL) has long been recognized as an effective method for the prevention of PPH. An intravenous infusion of oxytocin (20 units) is widely recommended and is the most important component in the AMTSL. It can be administered as soon as the anterior shoulder is delivered but no later than after placental delivery. Most protocols for the AMTSL have now discontinued immediate cord clamping, since a delay in cord clamping of 1–2 min (assuming the newborn does not require resuscitation) has been shown to improve the hematologic status of newborns. Controlled

DOI 10.1007/978-1-4939-0779-3_15-1

cord traction is often recommended and has been shown to result in a small reduction in blood loss. Routine uterine massage is often performed, but a World Health Organization guideline recommends against this practice, while stipulating that the uterine tone should be routinely assessed [16].

The most common cause of PPH is uterine atony (70 %). Trauma is the second-most common cause, at 20 %. Trauma can include perineal, vaginal wall, and cervical lacerations; vaginal or vulvar hematomas; uterine inversion; and uterine rupture. Retained placental tissue is the next most common cause, at 10 %. The final and least common cause of PPH at a rate of less than 1 % is coagulopathy. The coagulopathy may be due to an inherited coagulopathy that was identified before delivery or due to a coagulopathy that develops as a result of a complication of pregnancy or delivery [15].

The initial management of uterine atony involves bimanual uterine massage. If this is not successful, then uterotonic medications should be administered. Oxytocin may already be infusing if it was started as part of the active management of the third stage of labor. If it has not already been initiated, administration of oxytocin 10 units IM or 20–40 units by intravenous infusion should be initiated. If the atony persists, second-line medications include misoprostol (Cytotec), 800–1,000 microgram PO, SL, or PR; methylergonovine (methergine), 0.2 mg IM every 2–4 h; or carboprost (Hemabate), 0.25 mg IM or imtramyometrially every 15 min up to 8 doses [15].

The clinician can evaluate for trauma as a cause of PPH by inspecting the vulva, vagina, and cervix for lacerations and hematomas. Uterine inversion is diagnosed by visual inspection of the cervix [15].

The placenta usually delivers within 10 min of delivery of the baby. Visual inspection of the delivered placenta can provide evidence that the placenta delivered intact but does not rule out retained placental tissue. Retained placental tissue is usually easily removed by performing a finger sweep of the uterus with gauze. If placenta accreta, increta, or percreta is present, this can result in difficulty in removal of the placenta and significantly increases the risk for severe postpartum hemorrhage [15].

If a patient has been previously diagnosed with a coagulopathy, measures may already be in place to treat the disorder. If no coagulopathy has been diagnosed in a patient experiencing a PPH and other causes excluded, evaluation of the patient with a complete blood count (CBC), prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen level is indicated [15].

If a patient does not respond to basic measures for the management of PPH, more drastic measures may be required. It is recommended that hospitals have an established protocol that can be activated in cases of severe PPH. This involves a multidisciplinary approach between the physician, nursing personnel, blood bank, and laboratory [16]. Specialty consultation may include an obstetrician, intensivist, and interventional radiologist. Fluid resuscitation is initiated, followed by transfusion of packed red blood cells (PRBCs) and, if necessary, fresh frozen plasma and cryoprecipitate. Placement of a Bakri balloon to provide uterine tamponade should be considered. Other drastic measures include uterine artery embolization, recombinant factor VIIa, placement of B-lynch sutures, or hysterectomy [14].

Postpartum Gestational Hypertension, Preeclampsia, and Eclampsia

The onset of gestational hypertension, preeclampsia, and eclampsia usually occurs before delivery but can occur in the postpartum period. Diagnosis, treatment, and management of these conditions are the same as before delivery and are discussed elsewhere. Onset of these conditions can occur up to 4 weeks after delivery [17].

DOI 10.1007/978-1-4939-0779-3_15-1

Postpartum Infection

Postpartum patients are at risk for a number of postpartum infections, including endometritis, wound infection, urinary tract infections, mastitis, and pneumonia [18, 19]. Sepsis is diagnosed when the postpartum patient develops systemic symptoms and may progress to septic shock, which has a high rate of morbidity and can also cause maternal death. The presence of fever (100.4 °F (38.0 °C) or greater) after delivery should prompt an evaluation for infection. Evaluation should include a CBC; a catheterized urine specimen for urinalysis and culture; and a physical exam. Further testing such as a blood culture, chest X-ray, wound culture, and CT scan or ultrasound of the abdomen and pelvis will be dictated by the patient's symptoms and physical exam. The value of a culture from the endometrium is limited and not usually indicated [19]. The white blood cell count can be mildly elevated after a normal delivery, so it must be interpreted with caution. Fever can also be caused by medication, so the patient's medications should be reviewed.

Endometritis is the most common cause of postpartum infection. The incidence of postpartum endometritis is approximately 5 % after vaginal and 10 % after Cesarean delivery [20], although preoperative antibiotic prophylaxis reduces the rate of endometritis [21]. Other risk factors include prolonged labor, prolonged rupture of membranes, intrauterine monitoring, and multiple vaginal examinations. In addition to fever, affected patients often have symptoms of malaise, tachycardia, uterine tenderness, and foul-smelling lochia. Postpartum endometritis is usually polymicrobial, and common causative organisms include Group B *Streptococcus*, *Enterococcus*, gram-positive anaerobes, *Staphylococcus* species, and gram-negative bacilli. Intravenous clindamycin and gentamicin has been shown to have fewer treatment failures than other regimens [22]. Intravenous antibiotics are continued until the patient has been afebrile for 24–48 h, the WBC count has normalized, and the patient is otherwise clinically stable [20]. There has not been shown to be any benefit of continuing oral antibiotic therapy after intravenous antibiotic therapy has been discontinued [22].

Postpartum wound infection is diagnosed by redness, swelling, drainage, and/or pain at the site of the Cesarean section or the episiotomy/perineal tear. Risk factors for post-Cesarean wound infection include prolonged labor/prolonged rupture of membranes, chorioamnionitis, obesity, and prolonged surgery [21]. If an abscess is present, this should be opened and drained. A culture should be obtained from any drainage that is present or if an abscess is opened. Causative organisms typically originate from skin flora or by spread from the amniotic cavity (if the patient delivered by Cesarean section) [21] and include *Staphylococcus aureus*, *Streptococci*, and gram-negative bacilli.

Urinary tract infections are diagnosed as in general medical patients by the presence of pyuria, usually accompanied by positive nitrate testing on the dipstick analysis. Urinary tract infections in the postpartum period are treated as in general medical patients. Similarly, pneumonia is diagnosed as in general medical patients with a clinical exam and confirmatory chest X-ray. Treatment is the same as in a general medical patient, with attention to antibiotic selection if the woman is breastfeeding.

Mastitis is diagnosed by physical exam findings of redness, swelling, and tenderness of one breast, usually occurring in the first 3 months postpartum. No blood work or diagnostic testing is needed in uncomplicated cases. Mothers should be encouraged to continue breastfeeding since uncomplicated mastitis does not pose a risk to the infant and milk removal is an important component of treatment [23]. Mastitis is usually caused by *Staphylococcus* aureus, Group A or B Streptococci, or Hemophilus organisms. An oral antibiotic with coverage for *Staphylococcus aureus* is usually employed, typically dicloxacillin, cephalexin, or amoxicillin/clavulate unless methicillin-resistant *Staphylococcus aureus* is suspected, in which case clindamycin may be used. Breast abscess may arise as a complication of postpartum mastitis. Treatment involves drainage of the abscess and usually antibiotics. In most cases, breastfeeding may continue.

Postpartum Preventive Care

Immunization

According to the advisory committee on immunization practices, all pregnant women should be immunized with Tdap between 27 and 36 weeks, irrespective of the patient's prior immunization history. Since 2010, there has been a resurgence of pertussis with the highest incidence in 2012. Over 2000 cases were infants, 15 of whom died [24]. Vaccination during pregnancy will prevent hospitalization and death from pertussis. However, if the immunization is not received during pregnancy, it should be provided postpartum [24].

Rhogam

The Rh immune globulin (Rhogam) is given to an Rh-negative mother who gives birth to an Rh-positive baby or any Rh-negative patient after a miscarriage. The purpose is to prevent immune response occurring from alloimmunization which can lead to hemolytic disease of the newborn in subsequent pregnancies. Typical dose is one vial of 300 mcg of Rhogam within 72 h if there is no evidence of fetal red cells in maternal blood. Otherwise, the quantity of fetomaternal hemorrhage determines how many vials of Rhogam are given [25]. The risk of rhesus alloimmunization can decrease from 1–2 % to 0.1 % if Rhogam is given at 28 weeks gestation and postpartum [26]. It is still acceptable to give Rhogam up to 28 days postpartum if it is not given within 72 h of delivery [27].

Postpartum Office Visit

The postpartum period begins an hour after delivery of the placenta though the subsequent 6 weeks. The postpartum office visit usually takes place at 6 weeks during which the physician addresses issues like breastfeeding, postpartum depression, complications including urinary incontinence, constipation, sexuality, and also contraception [28]. However, for some women, waiting till 6 weeks might be too late [29]. Selected patients may benefit from postpartum office visits as early as 2 weeks after discharge. The discontinuation rate for breastfeeding at 2 weeks is as high as 25 %, with many women citing lack of confidence, support, and perceptions of insufficient milk production as reasons [30]. Earlier visits and encouragement from the clinician may play a significant role in breastfeeding continuation. Fifty-five percent of women cited individualized encouragement by their clinician as reason for continuing breastfeeding up till 12 weeks postpartum [31]. Women in the adolescent age-group, recent immigrant status, lack of social support, history or predisposition to depression/bipolar/psychosis, and physician judgment are some indications to consider an earlier visit [29].

In the early postpartum period, issues such as abnormal vaginal bleeding, anemia, perineal pain, constipation, breast pain/engorgement, fever, and contraception should be addressed. Prior to discharge, it is important to evaluate patient's mood, support, and readiness for discharge. A detailed anticipatory guidance regarding postpartum blues and risk for depression is very important [29]. It is the family physician's role to provide support and encouragement for the entire family. Patients should have access to a contact that they can call for support and advice as necessary. At the 3–6 week visit, discussion should surround breastfeeding support, anemia, contraception, and libido and sexuality. Health maintenance, lifestyle modification, and immunization are often addressed after 6 weeks [28]. Physicians provide information and guidance about sexuality in pregnancy and childbirth in fewer than 30 % of cases [32]. Sexuality after childbirth can be affected by vaginal dryness, pelvic floor dysfunction, and decreased libido [33]. There is need for education for new parents both before and after childbirth as cultural beliefs and myths continue to play significant roles in sexuality in pregnancy and after childbirth.

DOI 10.1007/978-1-4939-0779-3_15-1

Postpartum Contraception

The choice of contraception should be individualized based on a number of factors including breastfeeding, patient's age, parity, previous contraceptive experience, birth spacing, partner's plan, health status, and accessibility. Birth spacing is not only important to mothers but also to their children and to the society in general. The longer the interval between births (especially between 27 and 32 months), the lower the risk of major maternal complications such as bleeding, anemia, infection, and even death [34]. A 3 year interval between births has been shown to decrease neonatal and post-neonatal mortality for the subsequent child [35].

Breastfeeding is a form of contraception. The lactation amenorrhea method (LAM) is an effective mode of contraception up to 6 months in a woman who exclusively breastfeeds and has not resumed menstruation [36]. Once supplemental feeding is introduced or menstrual bleeding starts, an alternative form of contraception becomes necessary [37]. There is much controversy on the safety of contraceptive agents in breastfeeding women, especially regarding milk volume, and the passage of exogenous hormones into breast milk. Many studies have shown decreased milk supply as a major side effect of using combined oral contraception (COC) prior to 6 weeks. The WHO found a statistically significant reduction in milk volume among COC users when compared to users of progestin-only contraceptive pills [38, 39].

Postpartum Contraceptive Options

The WHO medical eligibility criteria (MEC) for contraception in postpartum women is more conservative than the US MEC (Table 1). The WHO MEC allocates category four level of risk for combined oral contraceptive use to breastfeeding women who are less than 6 weeks postpartum and category three for the same women using progestin-only contraception. Between 6 weeks and 6 months, the categories for combined OCP and progestin-only OCP are 3 and 1 respectively [40]. The WHO MEC is aimed at policymakers in developing countries where the risk of pregnancy far outweighs that of contraceptive use. See Table 2 below.

Postpartum Depression

The incidence of postpartum depression is approximately 13 % of all new mothers [41]. Routine screening for postpartum depression is recommended. The Edinburgh Postnatal Depression Scale [42] has been the most widely used validated screening tool. Risk factors for postpartum depression include previous postpartum depression, previous history of depression, poor social support, and psychosocial stressors [43]. Typical symptoms include depressed mood, anhedonia, decreased energy, feelings of guilt, psychomotor retardation, and suicidal ideation. Physicians should measure thyroid-stimulating hormone levels in women with suspected postpartum depression [43]. Psychosocial and psychological interventions including peer support, nondirective counseling, cognitive behavioral therapy, and interpersonal psychotherapy appear to be effective in reducing symptoms of postpartum depression [41]. Selective serotonin reuptake inhibitors have also been shown to be effective in the treatment of postpartum depression [43].

Postpartum Thyroid Dysfunction

The postpartum period is a common time for the development of thyroid dysfunction. The most common postpartum thyroid condition is thyroiditis, affecting approximately 8 % of postpartum women [44].

There is currently insufficient evidence to recommend universal screening of all women for postpartum thyroiditis; however, it is recommended that all women with postpartum depression be screened for thyroid disease with a TSH, free T4, and thyroperoxidase antibody testing [45].

The typical clinical course for postpartum women who develop thyroiditis is to initially develop transient thyrotoxicosis between 2 and 6 months postpartum. This is usually asymptomatic. This is often followed by hypothyroidism, but they usually return to the euthyroid state by the end of the initial postpartum year. Postpartum women with symptomatic thyrotoxicosis should be treated with beta blockers [44]. Following resolution of the thyrotoxic phase, the TSH should be monitored every 2 months to screen for hypothyroidism. Hypothyroidism may require treatment with levothyroxine. If treatment with levothyroxine is initiated, tapering off of the medication can usually be initiated in 6–12 months, with intermittent monitoring as long as the patient is not trying to get pregnant.

Postpartum Venous Thromboembolism

Increased risk for venous thromboembolism continues after pregnancy and actually increases during the postpartum period [46]. In addition, the risk for pulmonary embolism is higher in the postpartum period than during pregnancy [46]. Risk for venous thromboembolism is greatest in the first 3 weeks postpartum, returning to baseline at 12 weeks postpartum [47]. Older age, obesity, smoking, Black race, Cesarean delivery, preeclampsia, maternal hemorrhage, anemia, and postpartum infection all represent risks for venous thromboembolism. Diagnosis of postpartum lower extremity venous thromboembolism can be made difficult by the common occurrence of lower extremity edema. However, unilateral leg swelling (particularly left sided), redness, and pain should increase the suspicion for venous thromboembolism. Venous compression Doppler ultrasound is the recommended diagnostic test to evaluate for a lower extremity venous thrombus. Treatment with warfarin is recommended and is safe to use in a breastfeeding mother. Low molecular weight heparin can be used as a bridge until the prothrombin time is therapeutic for the requisite period of time. Dyspnea and tachypnea are the most common presenting symptoms of pulmonary embolism. A computed tomographic pulmonary angiogram is recommended for diagnosis in most patients. Postpartum pulmonary embolism has a relatively high mortality rate [48].

Management of Selected Common Postpartum Symptoms

Anemia is a common postpartum problem, and presentations vary by severity. Mothers can present with fatigue, pallor, dizziness, hypotension, and tachycardia. Treatment depends on the clinical scenario and can include blood transfusion or oral or parenteral iron supplementation.

A prior history of hemorrhoids and/or constipation are predisposing factors worsening hemorrhoidal symptoms postpartum. Common solutions are hydration and increased fiber intake, to avoid constipation. Perineal pain is a common complaint after vaginal birth especially in women who had prolonged second stage. Warm sitz baths, ice packs to the perineum, topical lidocaine, and analgesics are all treatment options.

Genetic Disorders

Mylynda Beryl Massart

Contents

Introduction

This chapter will serve as an initial introduction to genomic medicine for the family medicine physician. Historically, family medicine physicians have recognized and managed many common genetic syndromes such as Trisomy 21, Klinefelter's syndrome, Neurofibromatosis, and Huntington's chorea which exist in the population. In the current era of molecular and genomic medicine, there are an ever increasing set of competencies to adequately assess, interpret, and counsel our patients regarding their genetic contributions to the detection, prevention, and management of disease. Family physicians have an increasing responsibility to be able to accurately assess genetic familial risk, provide guidance in a vast array of genetic health care choices including prenatal testing, cancer risk assessment and intervention, medication choices based on genetically determined variations in metabolism and the exponentially increasing numbers of clinical and direct to consumer genetic testing available. The goal is that this genetic data is then integrated into personalized medicine plans for chronic disease prevention.

Despite the existence of Medical Genetics specialists, and genetic counselors, studies have shown that patients prefer genetic risk assessment and counseling be done by their primary care provider [1]. In addition, as molecular medicine expands away from rare highly penetrant single gene disorders to the complex interplay of

Table 1 Seven key roles [5]

1. Evaluate through screening and surveillance: Use family health history for primary prevention of chronic illness and to identify a patient's need for increased surveillance
2. Educate patients and their families: Discuss the importance of screening, early diagnosis, and how genetic tendencies may be present with an acute manifestation of the disease
3. Explain the results: Review and discuss the meaning of screening, test results, and what to expect from genetic consultation and referral
4. Make appropriate referrals: Provide information based on clinical history and ensure adequate follow up for patients
5. Coordinate care with a sub specialist: Initiate a co-management plan, including treatment and diagnostic testing when indicated
6. Council patients and families: Help them understand and adapt to the implications of a genetic diagnosis
7. Provide long-term follow-up and care: Continue to support patients and families and provide primary care through an ongoing relationship within the medical home

multiple genes, environmental, and lifestyle choices there will not be an adequate supply of Medical Geneticists and genetic counselors to meet the ever growing need or geographic distribution of the population. Therefore, much of the management and prevention of heritable disease will be left to the primary care physician, who is ideally suited for this role [2]. In addition, legal precedent has now been set for negligence claims when providers have failed to identify increased risk for heritable disease, specifically cancer [3].

To address these advancements in genetics, the American Academy of Family Physicians (AAFP), has outlined recommended competencies in medical genetics [4]. In addition, The Genetics in Primary Care Institute [5], developed initially with pediatric primary care in mind has narrowed many of these competencies down to seven key roles for the Primary Care Physician (see Table 1). This chapter will provide the basic tools and references for additional resources to begin integrating these genetic competencies into practice.

Basic Science of Genetics

Terminology

Within normal cellular function, genes are the basic physical unit of inheritance which contain the information to encode a protein. The genes are arranged in discrete units on chromosomes which consist of a long double-stranded DNA molecule [6]. There are approximately 26,000 genes arranged over the 22 pairs of autosomes and one pair of sex chromosomes in the nucleus of a human cell. At conception, each parent contributes one copy of each of their autosomes and one sex chromosome to the subsequent offspring [6]. This collection of genes is known as an individuals' genotype. The chromosomes are then packaged into compressed packages called chromatin which allows the DNA material to be condensed into the nucleus. Changes in chromatin structure can affect gene expression and are one mechanism of variation of phenotype without alteration of the genotype, called epigenetic variation. Via the process of gene expression, the cell reads the sequence of DNA three bases at a time and assembles the amino acids together to form proteins. These proteins are then responsible for all cellular functions.

When the normal cellular process is disrupted, mutations or variations in the genetic code develop. These can occur by copying errors during cell division, from exposure to ionizing radiation, chemicals, or viruses. When an error occurs in a germ line cell (sperm or ova), the mutation can be passed on to subsequent offspring. If the mutation occurs in a somatic cell elsewhere in the body, the mutation is not passed on to subsequent generations. Mutations can occur by a single base pair change, or by deletions, duplications, or rearrangements of small or large sequences of DNA. These alterations in genotype (genetic makeup of a cell) can then manifest in several different phenotypes

(observable characteristic or trait). It can result in no effect, called a silent mutation, or in failure to produce a protein, or to produce a modified version of the protein which could impact its function, and even excess production of a protein. Some variations may result in a nonviable fetus, others in a genetic syndrome or increased disease risk or susceptibility. The most common variation seen are known as single nucleotide polymorphisms (SNPs). These are variations of a single base pair and can be tracked for correlation with disease manifestation, drug response variability, and other phenotypes.

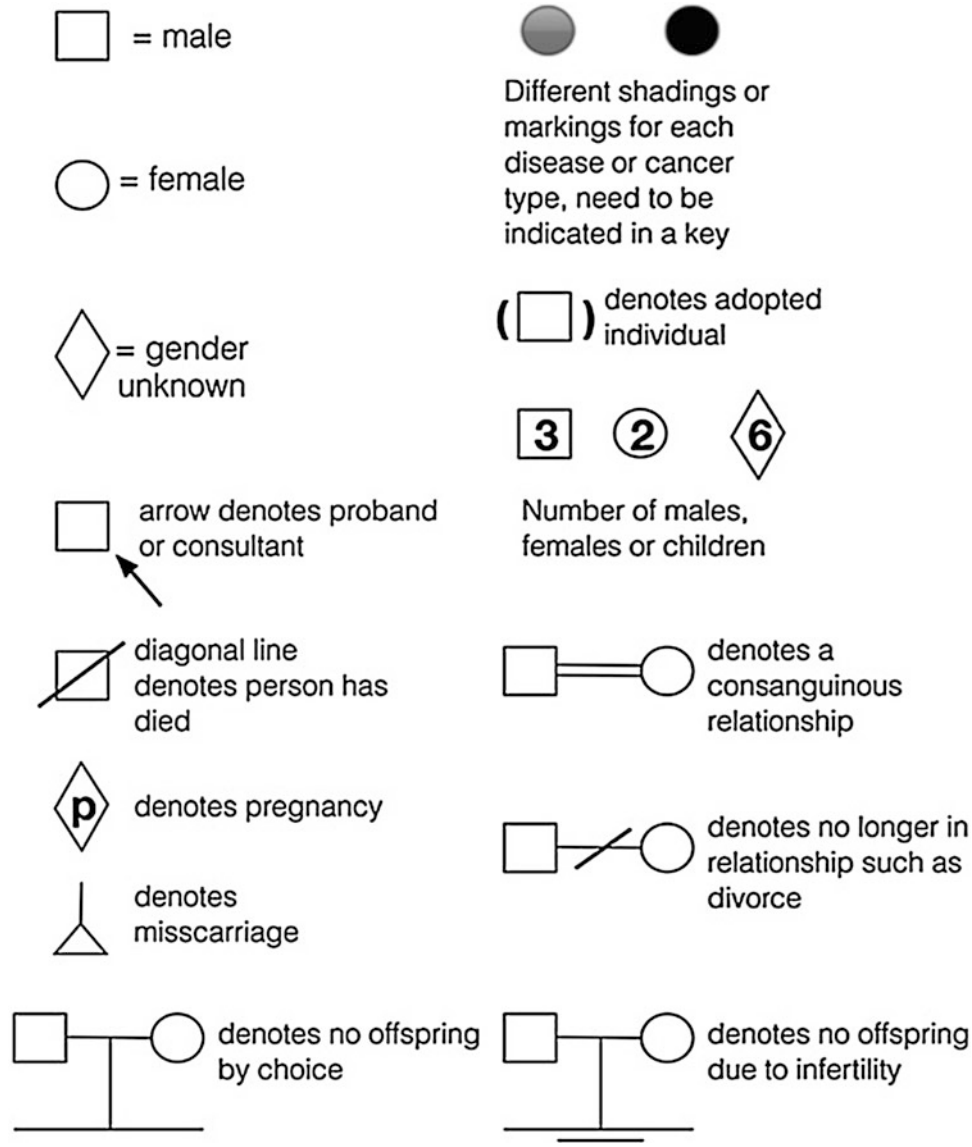
Once genetic variation occurs in the germ line, it can be passed on through several different modes of inheritance. Genetic diseases can be autosomal dominant, meaning that individuals who inherit one mutated copy of a gene will manifest the disease. In this type of inheritance, each affected individual has at least one affected parent and the disease tends to be seen in each generation of an affected family [7]. De novo mutations may also be seen, where the disease appears initially only in the index case. Autosomal recessive disorders affect individuals who inherit two copies of a mutated gene, one from each parent. The parents are carriers of the mutation since they are heterozygous (possess only one copy of the mutated gene) and are unaffected. Mitochondrial disorders are mutations in the mitochondrial genome which are only inherited from the mother. Mitochondrial diseases affect both males and females and appear in every generation of an affected family. X-linked disorders can be dominant or recessive. X-linked dominant mutations affect females more than males since there is no male-to-male transmission. X-linked recessive mutations, however, affect males more then females since males only need to inherit one copy of the mutated gene from their mother. While most syndromes are single gene disorders, the expression of these conditions are often strongly influenced by multiple factors. These may include combinations of mutations in multiple genes, as well as the impact from chromatin compaction and environmental influences. In addition, many genetic syndromes and diseases have incomplete or variable penetrance, where the genetic trait is not expressed or fully expressed in all individuals carrying the mutation [7]. All of these factors may affect the conditions encountered by the family medicine physician in the clinical setting.

Family History Taking/Genogram

In an ideal office situation, each provider would be able to take a detailed family history of each new patient as they establish care and then periodically review and update this information. With respect to genetic risk assessment this is best done by creating a Pedigree or Genogram. The basic pedigree would assess at least three generations, and include any relevant medical problems, age of death, and ethnic origins. The advantage of the Genogram is the additional overlay of the psychosocial information of the family structure and each individual contribution. The result is a visual aid that may help to detect increased risk for diseases and any associated modifiable risk factors [8].

The pedigree should include the current age of each family member and the age of onset of each disease or diagnosis and the age and cause of death for the patient and the first-, second-, and third-degree relatives on both the patients maternal and paternal lineage [3, 8, 9]. The use of standardized symbols and diagrams allows for rapid recognition of patterns of disease transmission (see Table 2, and Fig. 1). The identification of two or more individuals on the same side of the pedigree with the same disease, or earlier onset of disease then expected should raise a red flag for possible genetic pattern of inheritance and increased risk [5]. Identification of consanguinity will also increase the risk due to the higher degree of shared genetic material [8, 9]. Specific ancestral origins are also important to identify due to genetic variation among geographical and ethnic subpopulations. This is especially important in

Table 2 Standard pedigree symbols

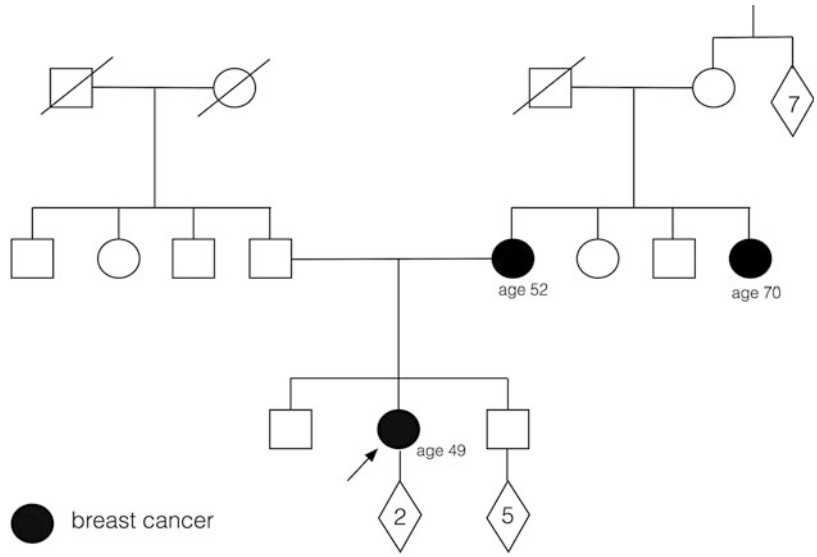


identifying the need for possible prenatal screening. The largest ethnic specific prenatal panel is the Ashkenazi Jewish genetic panel which tests for carrier status for Bloom syndrome, Canavan disease, cystic fibrosis, familial dysautonomia, Fanconi anemia group C, Gaucher disease, glycogen storage disease Type 1a, maple syrup urine disease, mucolipidosis IV, Niemann-Pick disease, and Tay-Sachs disease [10].

Common Chromosomal and Genetic Disorders

Most patients with common chromosomal and genetic disorders will be diagnosed shortly after birth or early in life. However, all family medicine physicians should be able to recognize common dysmorphic features or raise concern in the presence

Fig. 1 Sample pedigree



of multiple physical anomalies or cognitive impairment and coordinate referral to a genetic specialist for diagnosis and management recommendations. There are numerous references available to allow the primary care physician to manage individuals with these known genetic syndromes in the context of their overall health care and the unique medical needs related to their diagnosis. After initial diagnosis, these patients can be effectively managed by the family physician to coordinate any additional interventions, specialty care and therapies through their primary care medical home (see Table 3).

Some syndromes may not present until adulthood, for example, Klinefelter's syndrome may present with a primary infertility evaluation. In these cases, the family medicine physician needs to be prepared to access disease specific information in order to provide education and emotional support to the newly diagnosed patient, or referral to genetic counseling if available.

Types of Genetic Testing

There are five main classes of genetic testing. These include newborn screening, carrier testing, prenatal testing, diagnostic testing and predictive testing.

The most widespread form of genetic testing currently in use is newborn screening. These tests are done by tandem mass spectroscopy on a state level to screen for numerous genetic disorders at birth, which allows for early detection and intervention to prevent or minimize disease onset or severity [11].

Carrier testing is done to identify individuals who may carry mutations for specific recessive disorders. These tests are appropriate for those with a family history of a specific genetic disorder, or those from an ethnic group with an increased carrier frequency. The carrier status of an individual or couple is important for reproductive decision making with regards to their risk of having a child affected with the disorder. In order to pass on the disease, both parents must be carriers of the recessive disorder and then each pregnancy will have a 25 % chance of inheriting both mutations and developing the disorder. One prevalent carrier testing program is for Tay Sachs disease amongst people of Ashkenazi Jewish descent where the carrier frequency is 1/27 [12]. Other examples include cystic fibrosis and sickle cell disease.

Pregnancy related testing includes preconception testing, preimplantation testing, and prenatal testing. Preconception testing is a form of carrier

Table 3 Common genetic disorders in primary care

Disorder	Inheritance
Achondroplasia	Autosomal dominant
Adult polycystic kidney disease	Autosomal dominant and autosomal recessive
Alpha 1 antitrypsin deficiency	Autosomal codominant
Congenital adrenal hyperplasia	Autosomal recessive
Cystic fibrosis	Autosomal recessive
Down syndrome	Spontaneous chromosomal abnormality
Familal hypercholesterolemia	Autosomal dominant
Fragile X	X-linked dominant
Galactosemia	Autosomal recessive
Gaucher	Autosomal Recessive
Hemachromatosis	Autosomal recessive
Hemoglobinopathies	Variable/autosomal recessive/ X-linked
Huntington's chorea	Autosomal dominant
Klinefelter syndrome	Spontaneous chromosomal abnormality
Marfan syndrome	Autosomal dominant
Multiple exostosis	Autosomal dominant
Myotonic dystrophy	Autosomal dominant
Neurofibromatosis	Autosomal dominant
Phenylketonuria	Autosomal recessive
Spinal muscular atrophy	Autosomal recessive
Tay Sachs	Autosomal recessive
Trisomy 18	Spontaneous chromosomal abnormality
Turner syndrome	Spontaneous chromosomal abnormality

testing done prior to conception. Preimplantation genetic testing is done on embryos generated by IVF for selection and implantation to avoid embryos that are homozygous for a specific genetic condition. Prenatal testing is done to identify genetic changes in the developing fetus when there is a higher risk of genetic or chromosomal disorders due to advanced maternal age or strong family history of a particular condition. These tests are typically performed on cells obtained from amniocentesis or by chorionic villus sampling.

Diagnostic genetic testing is used to confirm a suspected genetic diagnosis in an already affected individual. This type of testing provides a yes or no answer and can diagnose or rule out a specific condition as the cause of symptoms. Having a confirmed diagnosis can then help provide anticipatory guidance for the patient in terms of progression and management of their disease.

Predictive testing is used to identify high risk individuals based on family history, prior to the onset of disease. "Presymptomatic testing" identifies individuals who will go on to demonstrate diseases such as Huntington's chorea. "Predispositional testing" shows that an individual is at higher risk for the development of a certain disease but may not ever develop the disease in one's lifetime, such as breast cancer. The ultimate goal of predictive testing is to prevent or minimize the effects of a genetic disease [7].

Clinical Testing

There are three main types of clinical genetic testing: cytogenetic, molecular, and biochemical testing.

Cytogenetic testing is the examination of whole chromosomes for abnormalities. Whole cells are prepared and the chromosomes are fixed and stained on slides for analysis. The distinct banding pattern of each chromosome allows for detection of variation. In addition, fluorescent in situ hybridization (FISH) can be used to paint chromosomes or portions of chromosomes with fluorescent molecules to enhance the identification of abnormalities [7].

Biochemical testing uses techniques to evaluate protein activity to assess gene function. These tests measure protein activity and quantity in the collected cell samples. The most prominent example of this is the use of tandem mass spectroscopy in newborn screening [7].

Molecular testing evaluates for DNA sequence changes. Many screening panels have been developed for the most common mutations associated with specific diseases. For example, the CFTR panel screens for the 30 most common mutations in the cystic fibrosis transmembrane conductance regulator gene (CFTR). To further enhance detection, additional techniques such as comparative

genomic hybridization (CGH), chromosomal microarray analysis (CMA), and DNA chip analysis are utilized to screen and identify small deletions, duplications, or variations in gene expression when compared to a normal-reference DNA [7].

Direct-To-Consumer Testing

In the last several years a new industry has blossomed as a result of genetic testing advances in the form of direct to consumer testing. In this form of testing, test kits are marketed directly to the patient. This type of free-market medical testing is the center of significant debate regarding the appropriateness of medical data being obtained in the absence of physician interpretation, versus the rights of patients to obtain and manage their own private medical data. Although most direct to consumer testing is paid "out of pocket," some are attempting to work with the insurance industry to achieve third party billing for these services. In addition, the FDA is now investigating how direct to consumer (DTC) testing should be monitored and approved, as this form of medical industry sets a new precedent. There are currently over 27 companies offering DTC genetic testing on the market [13–15]. They offer a range of services from ancestral DNA analysis to whole genome chip analysis. It is projected that the global market for this technology will reach $230 million by 2018 [13–15]. The primary concerns at this time are whether the test results oversimplify complex information, mislead patients by not providing complete informed consent, and whether testing meets clinical validity standards [16]. There is further concern as to whether patients can adequately understand the results and the overall implications of the results on their personal health and that of their family. Patients might overestimate their risk of disease which could cause unnecessary stress, or may misinterpret the results resulting in inappropriately increased screening and/or intervention without the context of a knowledgeable physician or other professional directing their care [16]. Nonetheless, DTC testing may provide an excellent opportunity for collaboration between the primary care physician and the patient when it comes to the interpretation of results and integration of the data into personalized medical management.

Result Interpretation

Before ordering any test in medicine it is critical to understand the potential results one might receive and the potential impact of these results on both medical decision making as well as the psychological and social implications for the patient. Testing should generally be reserved for cases in which the result can lead to changes in care that impact clinical outcomes. It is no different when it comes to genetic testing. Genetic testing results can come back as positive, negative, true negative, uninformative negative (see below), false negative, a variant of unknown significance, or a benign polymorphism. The primary care provider must be able to understand the implications of each of these answers and communicate the results with respect to the genetic question at hand.

A positive result means that a mutation or variation was identified. Depending on the context, this can have several different meanings. For simplicity, this will be discussed in the context of carrier testing vs diagnostic testing. If one is testing to determine carrier status, then a positive result confirms that the individual being tested carries an altered form of that gene. If the variation is associated with a recessive disorder, then this person can potentially pass this mutation on to their children, and if the offspring inherits a second mutated copy from the other parent would manifest the recessive disorder. If the alteration is a marker representing an increased risk for disease, then the presence of the variation would confirm that the individual is at an increased risk for developing that disease in the future.

If testing is being done to confirm a diagnosis associated with a specific mutation, then a positive test result confirms the diagnosis of that disease and may influence disease treatment.

A negative test result means that a mutation or variation was not identified. If testing carrier

status in a family with a known mutation, then this result shows that the tested family member did not inherit that specific mutation and is not at higher risk for the disease or syndrome being tested. This is known as a true negative, and it reduces the risk of a specific disease to that of the general population. If the test is being done in the context of a family with a disease or syndrome with no known associated mutation, then a negative genetic screening test result is an uninformative negative. The uninformative negative does not provide clinically useful data, since it does not distinguish between the absence of the mutation or mutations in the individual and the failure to detect the presumed mutation or mutations leading to the condition of interest. A variant of unknown significance (VUS) is a new mutation found in the tested individual that has not been previously proven or linked with a specific disease and uncertainty exists whether or not it is related to the disorder in question. It is hoped that in the future research will reclassify variants of unknown significance as a disease associated mutation, a benign polymorphism, or normal variation within the general population.

Pharmacogenomics

The genetics of drug metabolism has exploded over the last several years. Not all drugs affect each patient the same way and it can be very hard to predict who will respond well, who will not respond at all, and who will have an adverse reaction to a given medication [17]. Clinicians are now able to apply information regarding genetic variation to predict the effectiveness and potential for reactions to some medications on the individual patient level. The most common variation is the single nucleotide polymorphisms (SNPs). There are an estimated 11 million SNPs amongst the human population [18]. Interpretation of a patient's genetic metabolism can potentially provide tailored drug therapy or personalized medicine which ideally would lead to maximizing therapeutic effect in a more timely manner with dosing specific to the patients inherent metabolism [18]. Currently, there exists testing that helps to optimize the treatment of many diseases including cardiovascular disease, Alzheimers, cancer, HIV, asthma, and mental health [17]. In HIV medicine, routine testing is now done for a genetic variant that makes patients more prone to side effects from the drug abacavir (Ziagen) [6]. Oncologists test for tumor expression of the HER2 protein for targeted treatment with trastuzumab (Herceptin) [6]. The FDA now also recommends genetic testing for the chemotherapy drug mercaptopurine (Purinethol) in patients with acute lymphoblastic leukemia since some people possess a genetic variant that interferes with the metabolism of the drug leading to severe side effects [6]. The presence of certain SNPs can also impact the metabolism of warfarin (Coumadin) and clopidogrel (Plavix) which is a class of polymorphisms identified in the cytochrome P450 enzymes that affect drug metabolism. These variations can enhance or diminish metabolism which can result in variable outcomes depending on the active metabolites of the drug [19]. The FDA has now labeled several hundred medications with pharmacogenomic warnings or indications on the labels (see Table 4).

Table 4 Common medications with FDA pharmacogenomic labels

Psychiatry medications: amitriptyline (Elavil), aripiprazole (Abilify), citalopram (Celexa), diazepam (Valium), fluoxetine (Prozac), paroxetine (Paxil), risperidone (Risperdal), venlafaxine (Effexor)
Analgesics: tramadol (Ultram), codeine
Cardiology: carvedilol (Coreg), clopidogrel (Plavix), isosorbide (Imdur), hydralazine, metoprolol (Lopressor, Toprol), propranolol (Inderall), warfarin (Coumadin, Jantoven)
Gastroenterology: dexlansoprozole (Dexilant, Kapidex), pantoprazole (Protonix), omeprazole (Prilosec), esomeprazole (Nexium), lansoprazole (Prevacid)
Infectious disease: nitrofurantoin (Macrobid, Macrodantin,Furadantin), terbinafine (Lamisil), rifampin (Rifadin, Rimactane), sulfamethoxazole (Bactrim)
Neurology: carbamazepine (Tegretol), galantamine (Razadyne), phenytoin (Dilantin), valproic acid (Depakote, Depakene, Depakon, Stavzor)

Cancer Genetics

Cancer Genetic Risk Assessment

In a recessive or simple "two hit" model of cancer development, one must have a cancer causing mutation on each chromosome in specific genes to develop cancer. However, 5–10 % of all cancers are related to an inherited cancer syndrome in which individuals inherit one cancer predisposing mutation in all cells of their body, and thus only need to acquire one additional cancer causing "hit" to develop cancer in their lifetime (such as exposure to a mutagenic chemical or virus). However, individuals without this inherited cancer causing predisposition must acquire both hits in their lifetime to develop cancer. There also exist dominant forms of cancer syndromes in which only a single inherited mutation is adequate for the development of cancer. However, due to variable expression or incomplete penetrance, not all patients with dominant cancer mutations will manifest cancer in their lifetime. More then 50 types of hereditary cancer syndromes have been identified and most are in genes that control cell growth or repair DNA damage. Family physicians should be able to recognize the "red flags" that are suggestive of an inherited cancer syndrome and properly counsel patients regarding their risk and options for genetic testing and subsequent screening or treatment to mitigate the potential development of cancer [20]. Some cancers can appear to have an inherited pattern in a pedigree but are caused by nongenetic factors such as living environment, tobacco, diet, or other carcinogen exposures.

Specific red flags within a pedigree include similar types of cancer appearing in multiple generations of the same side of the pedigree, affected individuals younger than 50, male breast cancer, bilateral breast cancer, and cancer diagnosed at an unusually young age. Other red flags include multiple different cancer types occurring independently in the same person, several close relatives with the same type of cancer, the presence of birth defects that are known to be associated with certain inherited cancer syndromes, or being from an ethnic group with a high frequency of certain cancer syndromes. To date more than 50 hereditary cancer syndromes have been identified (see Table 5).

If a specific syndrome is suspected, genetic testing can be done to confirm the presence of a mutation. Most experts agree that testing should be recommended if there is a personal or strong family history of an inherited cancer condition and it the test can be adequately interpreted and the results provide information that will guide medical decision making. Once this mutation is identified, it can be looked for in relatives of the index case.

Genetic Risk Reduction

Once testing for a potentially deleterious mutation has been confirmed, the patient may be able to take steps to reduce the risk of developing cancer or to begin early or intensive screening for detection. Clinical guidelines include screening at an earlier age for cancer, medication and prophylactic surgery such as a mastectomy, and/or oophorectomy with hereditary breast and ovarian cancer syndrome or colectomy for Lynch syndrome [21]. Other forms of risk reduction might include modifying personal behaviors such as smoking, weight reduction, and abstinence from alcohol.

Epigenetics

Epigenetics is the study of factors that control gene expression, rather than analysis of the DNA code itself [22]. These factors are able to turn gene expression on or off. Epigenetic factors are what help to distinguish cell types in different organs that share all of the same DNA complement, and this is why genetically identical twins are not fully phenotypically identical [22]. This epigenetic modification can be part of normal cellular processes, such as X-inactivation [23].

There are three main methods of epigenetic modulation with interact with each other to modify gene expression, including DNA methylation, histone modification and RNA-associated silencing [23]. Interaction with the environment including naturally occurring and man made compounds

Table 5 Common cancer genetic syndromes

Syndrome	Genes	Related cancer types
Hereditary breast cancer and ovarian cancer syndrome	BRCA1, BRCA2	Female breast, ovarian, and other cancers, including prostate, pancreatic, and male breast cancer
Li-Fraumeni syndrome	TP53	Breast cancer, soft tissue sarcoma, osteosarcoma (bone cancer), leukemia, brain tumors, adrenocortical carcinoma (cancer of the adrenal glands), and other cancers
Cowden syndrome (PTEN hamartoma tumor syndrome)	PTEN	Breast, thyroid, endometrial (uterine lining), and other cancers
Lynch syndrome (hereditary nonpolyposis colorectal cancer)	MSH2, MLH1, MSH6, PMS2, EPCAM	Colorectal, endometrial, ovarian, renal pelvis, pancreatic, small intestine, liver and biliary tract, stomach, brain, and breast cancers
Familial adenomatous polyposis	APC	Colorectal cancer, multiple nonmalignant colon polyps, and both noncancerous (benign) and cancerous tumors in the small intestine, brain, stomach, bone, skin, and other tissues
Retinoblastoma	RB1	Eye cancer (cancer of the retina), pinealoma (cancer of the pineal gland), osteosarcoma, melanoma, and soft tissue sarcoma
Multiple endocrine neoplasia type 1 (Wermer syndrome)	MEN1	Pancreatic endocrine tumors and (usually benign) parathyroid and pituitary gland tumors
Multiple endocrine neoplasia type 2	RET	Medullary thyroid cancer and pheochromocytoma (benign adrenal gland tumor)
Von Hippel-Lindau syndrome	VHL	Kidney cancer and multiple noncancerous tumors, including pheochromocytoma

can modify these epigenetic signals. Therefore epigenetics can be considered the interface between the environment and the genome [6]. Therefore, environmental factors may play a large role in the disruption in gene expression leading to over or under expression of proteins, both of which can result in phenotypic changes, including disease.

Counseling Considerations

Any person considering genetic testing should be counseled by a trained professional. These may include physicians, genetic counselors, or other health care providers with additional training in genetic risk assessment and counseling. The counseling should focus on the process of informed consent including the risks, benefits, and limitations of genetic testing in the context of the disease being tested for. Pretest counseling should include which specific tests are most appropriate, the accuracy of the test, the medical implications of a positive or negative result, or of an uninformative result. In addition, the psychosocial implication of genetic test results on the individual being tested as well as relatives who may be implicated by the result and the potential for future inheritance should be considered [24]. Finally, additional discussions regarding confidentiality and insurance discrimination should be addressed. Written informed consent should then be obtained. Though the process of detailed family history taking, it may be determined that testing is not indicated, or that a different family member is the one who should be considered for testing first. Testing should then be followed up by posttest counseling to review the results and develop a management plan accordingly as well as again assessing the psychosocial impact of these results [25]. If at any point in this process, the family medicine physician feels that they have exceeded their knowledge or comfort level regarding the condition or conditions or if the condition involves multiple complex tests, then referral to a genetic counselor or specialist might be considered [25].

In the specific case of pediatric diagnosis, physicians should be prepared to provide education on the etiology, prognosis, genetic

mechanism, and recurrence risk of the disorder as well as available treatment options. These children can often be successfully managed between the primary care physician and genetic specialist [5, 26, 27].

Ethics and Privacy Laws

As with many aspects of primary care medicine, genetic medicine frequently encounters sensitive and ethical issues including consanguinity, ethnicity, and patient confidentiality. The potential impact for harm if genetic information were shared without regard is enormous. In addition, the information is not unique to the individual being tested but could possibly impact multiple generations of relatives.

While genetic test results are governed under the same HIPPA laws as all other protected health information, they are not always private. For example, health insurance companies will have access to these results. Genetic privacy and nondiscrimination is therefore of utmost importance. Legal protection in the form the Genetic Information Nondiscrimination Act (GINA) was instituted in 2008, in the United States to protect such information and to prevent discrimination based on genetic test results [13, 28, 29]. GINA prohibits genetic information from being used in health insurance eligibility or to establish premiums or to prevent employment. GINA is not all encompassing and currently does not apply to members of the military, and does not apply to other insurance coverage such as life insurance, disability insurance or long-term care insurance. There are additional laws that vary by state, which may cover these gaps.

The Future of Genetics in Primary Care

It is likely that, in the near future, Family physicians will be utilizing genetic tools to identify and prevent many common illnesses such as diabetes, hypertension, Alzheimer's and chronic obstructive pulmonary disease. How soon this technology becomes integrated into every day practice remains to be seen. In the meantime, it is clear that the Family physician will need to continue to advance their understanding of the field of genetics and personalized medicine and participate in developing methods of effectively incorporating the technology into daily practice.

Newborn Resuscitation

Term infants who appear well at delivery and have clear amniotic fluid and good respiratory effort as well as muscle tone may receive routine newborn care. This includes providing warmth, clearing of the airway if needed, drying and stimulating of the infant, and ongoing assessment of the infant's color as they transition to extrauterine life. These babies may remain with their mothers during and after this time [1].

Infants who do not meet the criteria for routine newborn care require more intervention. This may include not only initial stabilization but also ventilation, chest compressions, and emergency medications.

All health-care providers that are involved in the delivery of newborns should be skilled in neonatal resuscitation. In about 10 % of all deliveries, the transition from fetus to newborn will require intervention by a skilled provider or team. One of the most highly respected sources of information available on the training, skills, and procedures needed for delivery room stabilization is the Neonatal Resuscitation Program (NRP). Completion of the NRP program should be considered by all hospital personnel who may be involved in the stabilization and resuscitation of neonates.

The delivery room should be equipped with equipment that is appropriately sized to resuscitate infants of all gestational ages and sizes. This includes a radiant warmer, a source of oxygen

with an oxygen blender, instruments for intubation as well as for establishing intravenous access, a source for regulated suction, trays equipped for emergency procedures such as umbilical line placement, and drugs that may be needed in resuscitation.

Basic resuscitation skills for a depressed newborn include (1) controlling the thermal environment with the use of a radiant warmer and drying of the infant, (2) positioning and clearing the airway and gentle tactile stimulation, and (3) providing positive-pressure ventilation for newborns with apnea and a heart rate of less than 100. More extensive resuscitation for infants not responding to efforts include (1) administration of chest compressions when the heart rate remains below 60 bpm, despite 30 s of effect positive-pressure ventilation; (2) endotracheal intubation for infants not responding or requiring more prolonged positive-pressure ventilation; (3) central circulation access through the umbilical venous catheter; and (4) administration of emergency medications such as epinephrine through the endotracheal tube or preferentially the umbilical vein [1].

Stabilization for Transfer to the Nursery or Transport to Intensive Care

Postresuscitation priorities include assessment for emergent anomalies, maintenance of basic needs, effective communication with and support of the family, and decisions about the level of care required. Pulse oximetry and a cardiorespiratory monitor are used to monitor ongoing success. Oxygen saturations should be kept at 88–92 % for preterm newborns and 9–100 % for term newborns. Baseline tests for unstable newborns include a chest radiograph, complete blood count (CBC), glucose, and blood gases (arterial if possible). A sepsis workup and other laboratory tests may also be considered. Ventilatory support is needed for persistent respiratory distress, apnea, or deteriorating blood gases (especially Pco2>60 with acidosis). Until respiratory status stabilizes, intravenous fluids are started with 10 % dextrose in water (D10W) at 60 ml/kg/day for term infants in the first 24 h of life. Timely transport of unstable or high-risk neonates for tertiary care enhances outcome [1].

Giving Bad New to Parents After Delivery

Family physicians will confront situations where they need to discuss bad news with parents regarding their newborn. These situations can range from a stillbirth to a neonatal death, to a serious anomaly, or an isolated problem such as cleft palate. Studies have surveyed patients and family members to determine how they believe physicians should give bad news. These studies have covered a wide range of patient and family experiences including cancer, birth defects, traumatic injury, death, etc. Four common themes emerge from this work and indicate that patients want (1) a clear, direct statement of the news, (2) time to talk together in private, (3) openness to emotion, and (4) ongoing involvement in decision making [2]. In addition, when physicians are discussing bad news with parents regarding a newborn, parents prefer that the physician talk to both parents together and early. Parents also prefer that the physician, when possible, discuss the news with the baby present and being held by a parent or the physician [1].

Common Problems in the Nursery

Late Preterm Infants

Late preterm infants are born at a gestation age between 34 and 36-6/7 weeks. These infants should not be considered “near term” as developmental and physiologic immaturity leads to a higher morbidity and mortality rate than term infants. These babies are more likely to have issues with respiratory distress, apnea, temperature instability, hypoglycemia, jaundice, and feeding difficulties. Physicians who care for these infants need to be aware that these infants are at increased risk both during their hospital stay and after discharge. Due to higher rates of hospital readmissions than term infants, there are now

recommended criteria for discharge. These include (1) 24 h of successful feeding, (2) weight loss less than 7 %, (3) formal evaluation of breastfeeding, (4) passing a car seat trial, and (5) an established discharge feeding plan [2, 3].

Term infants who are appropriate for gestational age have birth weights between 2500 and 3999 g [4].

Small for Gestational Age

A neonate termed small for gestational age refers to a birth weight below the 10th percentile for gestational age [4]. They may have either symmetric or asymmetric fetal growth restriction; symmetric FGR have reductions in both body and head growth. Symmetric FGR begin early in gestation due to an intrinsic etiology such as congenital infections, chromosomal abnormalities, or decreased nutrient supply early in development. Infants with asymmetric FGR have a relatively normal length and head growth but reduced body weight. This usually begins in the late second and third trimester, and the etiology is often less clear. Possible reasons include reductions in fetal nutrients that limit glycogen and fat storage, yet allow continued brain growth. However, in about 70 % of cases, no cause can be identified. SGA infants should be monitored closely for hypoglycemia, polycythemia, as well as temperature instability [4].

Large for Gestational Age

Large for gestational age babies are defined as a birth weight greater than the 90th percentile for gestational age [4]. Macrosomia refers to excessive intrauterine growth beyond a specific threshold, regardless of the infant's gestational age, and is usually defined as a birth weight greater than 4000 g or 4500 g.

The etiology of this condition may be due to (1) various genetic and intrauterine environmental factors including a familial trait (e.g., mothers who were LGA are more likely to deliver an infant who is LGA) and (2) maternal factors including maternal diabetes and excessive maternal weight gain. These infants are at higher risk for birth injury, respiratory distress, hypoglycemia, and polycythemia [4].

Neonatal Sepsis

Neonatal sepsis is typically classified into "early onset" sepsis (neonates less than 3 days old) and "late onset," occurring beyond 3 days of age.

Sepsis is often accompanied by nonspecific signs and symptoms, making early detection difficult; 2 in 1000 neonates have bacterial sepsis. The risk increases with preterm labor, premature rupture of membranes (greater than 18 h), or intrapartum fever. The etiology of early onset sepsis is transmission from mother to baby during the course of labor and delivery. The organisms commonly causing early onset infection include group B streptococcus (GBS), *Escherichia coli*, and *Listeria monocytogenes*. The implementation of prenatal screening and GBS treatment protocols have resulted in decreasing prevalence of GBS sepsis [5, 6].

The onset of early sepsis is most rapid in infants born prematurely; however, 85 % will present in 24 h, 5 % present in 24–48 h, and an even smaller percentage present in 48–72 h of age [5, 6]. The clinical diagnosis of sepsis in the neonate is difficult because the signs of sepsis are nonspecific and can be observed with other conditions that are not related to infection. Early manifestations include temperature instability, lethargy, and poor feeding. The physician must have a high index of suspicion for sepsis and carefully observe for subtle signs in order to detect this potentially devastating condition as soon as possible.

Diagnosis

Helpful studies include CBC, blood cultures, and C-reactive protein (CRP) values. Urine cultures are not routinely obtained as part of the sepsis workup in a neonate less than a few days old. Lumbar puncture should be performed as part of the sepsis workup for those whose clinical course suggests sepsis or meningitis. Mortality from untreated sepsis can be as high as 50 %, so treatment is initiated while awaiting culture results. Figure 1 demonstrates a suggested protocol for initial diagnosis and management of sepsis in newborns.

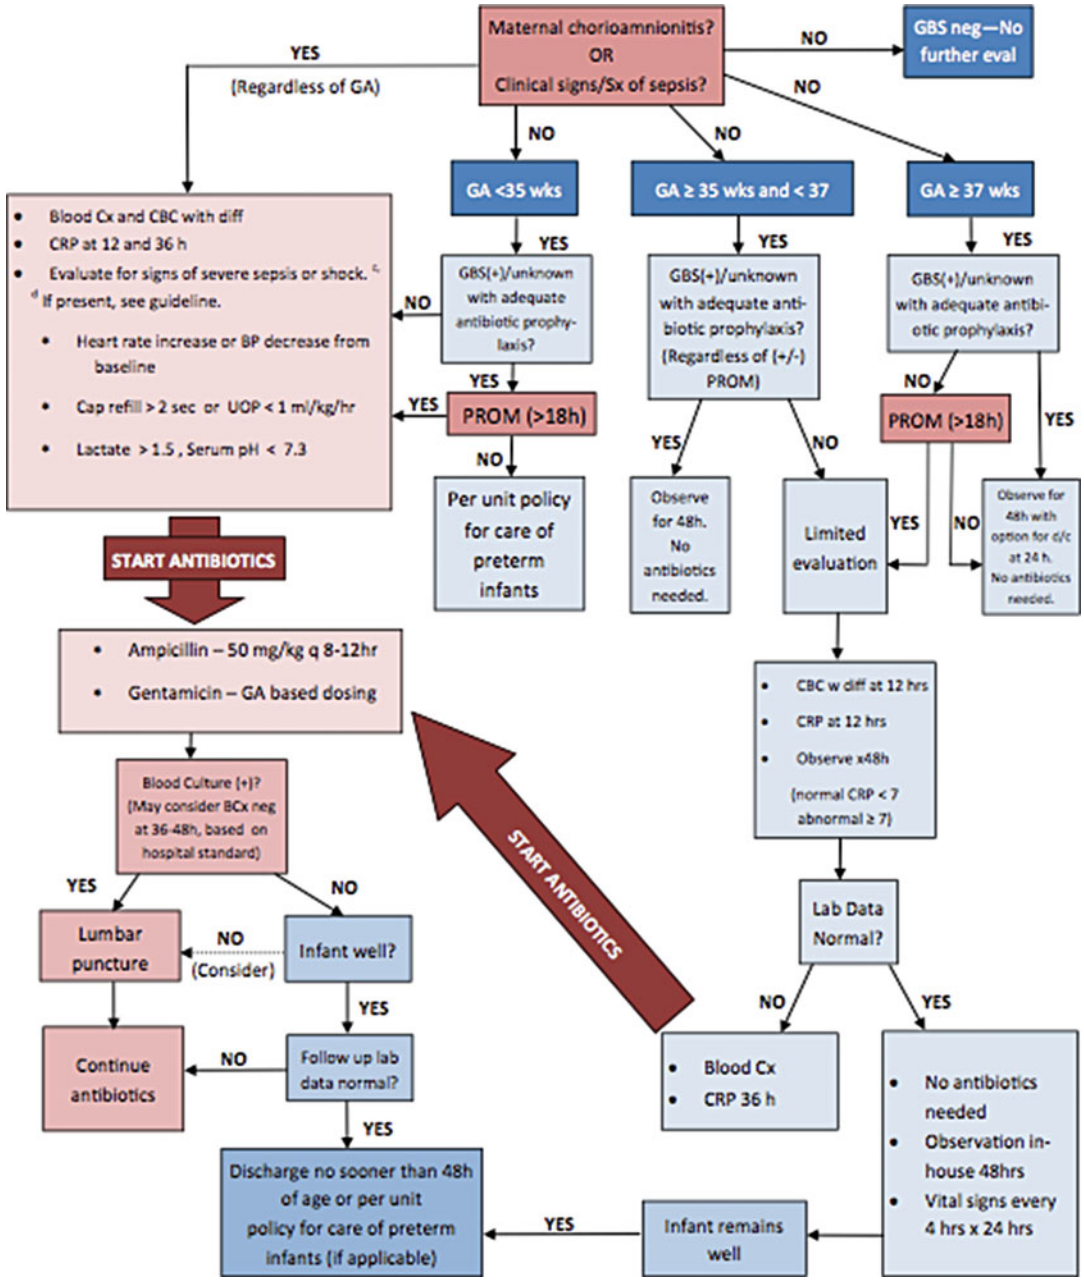

Fig. 1 Suggested protocol for management of suspected sepsis in term and preterm newborns

Treatment

The optimal treatment of infants with suspected early onset sepsis is broad-spectrum antimicrobial agents (ampicillin and an aminoglycoside). Once the pathogen has been identified, antimicrobial therapy should be narrowed, unless synergism of multiple antibiotics is required. Typically, ampicillin is used with dosing of 50 mg/kg/dose given every 8 h and gentamicin with dosing of 4 mg/kg/dose given every 24 h. The results of blood cultures, CRP values, and clinical course will guide the duration of antibiotic therapy; antimicrobial

therapy should be discontinued at 48 h in patients with negative cultures. Bacteremia is treated for 10 days and meningitis requires at least 14 days of therapy depending on the response and causative organism [5, 6].

The addition of acyclovir to the antibiotic regimen should be considered if there is suspicion for herpetic infection.

Respiratory Distress

Tachypnea, grunting, nasal flaring, retractions, and cyanosis are manifestations of respiratory distress. In neonates, this may be transient; however, if these symptoms persist, a diagnostic and therapeutic evaluation should be pursued. In newborns, differential diagnosis includes sepsis, transient tachypnea of the newborn (TTN), respiratory distress syndrome (RDS), persistent pulmonary hypertension (PPHN), pneumonia, pneumothorax, congenital heart disease, and more rare congenital defects including congenital diaphragmatic hernia [7, 8].

Transient tachypnea of the newborn presents within 2 h of birth and frequently resolves within 24 h; not uncommonly, it may persist for up to 72 h. Tachypnea (respiratory rate greater than 60), little hypoxia or hypercarbia, and radiographic findings of perihilar streaking and/or fluid in the fissures are common. Oxygen requirements gradually decrease after the first few hours. If the course is atypical or there is a risk of sepsis, neonatal pneumonia and other causes must be considered [7, 8].

Respiratory distress syndrome (RDS) is caused by a deficiency of surfactant, the phospholipids that reduce alveolar surface tension and maintain alveolar stability. RDS is more common in preterm infants, who can exhibit hypercarbia, hypoxia, and a "ground-glass" appearance on x-ray with air bronchograms.

Persistent pulmonary hypertension usually occurs in term infants and is characterized by tachypnea and cyanosis. A common finding is a significant difference in pre(right hand)- and post-ductal (foot) saturation. Transfer to a tertiary care center for further management is recommended in these infants.

Jaundice

Elevated bilirubin levels are seen in the majority of neonates in the first few days of life, due to increased production and decreased clearance of bilirubin. This condition is known as "physiologic jaundice." Conditions that aggravate this physiologic hyperbilirubinemia include inborn errors of metabolism, ABO incompatibility, hemoglobin variants, and conditions such as sepsis. It is important to distinguish "physiologic" from "exaggerated physiologic" and "pathological" forms of hyperbilirubinemia. "Pathological hyperbilirubinemia" is a medical emergency.

Neonatal hyperbilirubinemia appears to be more common among Asian and Native American newborns than those of Black or Caucasian ethnicity [9].

One of the main goals of screening for and treating pathological hyperbilirubinemia is the prevention of neurologic sequelae. "Acute bilirubin encephalopathy" describes acute manifestations of bilirubin toxicity in the first few weeks of life, including lethargy and hypotonia and progressing to apnea, fever, coma, seizures, and death. "Kernicterus" refers to the chronic and permanent sequelae of bilirubin toxicity for newborns that survive, including cerebral palsy, auditory dysfunction, dental dysplasia, and paralysis of upward gaze [10].

Primary Prevention

Since poor caloric intake and dehydration are associated with hyperbilirubinemia, clinicians should advise breastfeeding mothers to nurse their newborns at least 8–12 times daily during the first week of life. Routine supplementation of liquids other than breast milk should be discouraged in infants who are not dehydrated.

Secondary Prevention

It is advised that all pregnant women be tested for ABO and Rh (D) blood types and undergo serum screening for isoimmune antibodies. For Rh-negative mothers and those without prenatal blood group testing, the infant cord blood should be tested for ABO and Rh (D) typing, and a direct antibody (or Coombs' test) should be performed.

Table 1 Risk factors for development of severe jaundice in term infants

Major risks for development of significant jaundice
ABO or other blood group incompatibility with positive Coombs' test
Gestational age 35–36 weeks
East Asian race
Newborn with sibling who received phototherapy
Cephalhematoma or significant bruising
Minor risks for development of significant jaundice
Predischarge TSB or TcB in the high intermediate risk zone
Gestational age 37–38 weeks
Male gender
Jaundice observed before discharge

Info from Refs. [10, 11, 14]

Screening and Assessment

Maternal-child hospital units should have established protocols to routinely monitor all newborns for the development of jaundice. Clinical assessment for jaundice should occur at least every 8–12 h. Jaundice is usually first seen in the face and progresses to the trunk and extremities, but assessment by physical examination alone may not be sufficiently sensitive or specific, especially for darkly pigmented infants [11].

A total serum bilirubin (TSB) study should be drawn for every newborn with clinical jaundice in the first 24 h of life. A transcutaneous bilirubin (TcB) or TSB should also be performed on all infants in whom there appears to be clinical jaundice that is excessive for the infant's age. The American Academy of Pediatrics recommends that all infants be screened for jaundice before hospital discharge by either assessment of clinical risk factors or a TcB or TSB level [10]. Risk factors for the development of severe hyperbilirubinemia are listed in Table 1. All parents should be given information about jaundice and how to monitor for it after discharge, and all infants should be examined by a health professional within the first few day of discharge. This should include an assessment of weight, intake, and output as well as jaundice [10].

Laboratory Assessment

All bilirubin levels should be interpreted based upon the infant's age in hours, and the need for phototherapy should be based on the zone in which the TSB falls. See Table 2 for recommendations on laboratory studies based upon risk factors. Standard curves for risk stratification have been developed by the American Academy of Pediatrics [10].

Table 2 Laboratory evaluation for jaundice in infants 35 weeks or greater

Clinical finding	Laboratory evaluation
Jaundice in the first 24 h of life	Check TSB
Newborn on phototherapy or with bilirubin rising rapidly (crossing percentiles on curve)	Maternal and infant blood types, Coombs' test, complete blood count with reticulocyte count, and peripheral smear; consider G6PD
	Repeat TSB every 4–24 h, depending on level and likely etiology
TSB level approaching exchange transfusion levels and/or not responsive to phototherapy	Check reticulocyte count, G6PD, albumin
	Check phototherapy unit output; consider increasing intensity with additional overhead phototherapy lights and/or bili blanket
Elevated direct (conjugated) bilirubin	Check urinalysis and culture; consider sepsis evaluation; consider evaluation for congenital viral infection, anatomic abnormalities (biliary atresia, cholodochal cyst) – viral cultures, abdominal ultrasound
Jaundice at or beyond week 3 of life	Check total and direct bilirubin, evaluate for cholestasis if direct elevated, check thyroid and galactosemia screens

Info from Refs. [10, 11, 14]

For any infant requiring phototherapy or for those in whom a suspicion for pathological hyperbilirubinemia exists, appropriate investigations should be carried out. These infants should undergo measurement of total and direct (conjugated) bilirubin to evaluate for cholestasis, as well as a Coombs' test and other testing as appropriate. This may include testing for galactosemia and thyroid problems. If the

direct bilirubin is elevated, further investigation for causes of cholestasis should be undertaken. The glucose-6-phosphate dehydrogenase (G6PD) level should be measured for infants receiving phototherapy whose response to phototherapy is poor or whose family history or ethnic origin suggests risks for G6PD deficiency [10].

Treatment

Decisions to initiate treatment should be made based upon the American Academy of Pediatrics standardized algorithm [10]. If the TSB rises to a level necessitating exchange transfusion or if the TSB is 25 mg/dl or higher, the infant must be immediately admitted to a hospital for exchange transfusion. Exchange transfusions should only be performed by trained personnel in a neonatal intensive care unit. Immediate exchange transfusion should be initiated for any infant with jaundice and signs of intermediate to advanced acute bilirubin encephalopathy: hypertonia, arching, retrocollis, opisthotonos, fever, or high-pitched cry [12].

When initiating phototherapy, precautions include assuring adequate fluid intake, patching eyes, and monitoring temperature. A transient rash, green stools, and irritability may occur. Phototherapy may generally be stopped when the TSB falls by 5 mg/dl or below 14 mg/dl. A rebound rise is uncommon in newborns with initial suboptimal feeding that has improved, but more common in those with blood group incompatibilities. Home phototherapy for uncomplicated jaundice (using a fiber-optic blanket) in carefully selected newborns with reliable parents allows continued breastfeeding and bonding with the family.

Breastfeeding is often associated with higher bilirubin levels than those seen in exclusively formula-fed infants. More frequent feeding usually reduces bilirubin levels. "Breast milk jaundice" is a delayed but common form of jaundice that is usually diagnosed in the second week of life and peaks by the end of the second week, gradually resolving over 1–4 months. If evaluation reveals no pathologic source, breastfeeding can generally be continued, although supplementation may be required to ensure adequate hydration. Temporary discontinuation of breastfeeding for diagnosis or other reasons increases the risk of breastfeeding failure and is usually unnecessary [13]. Assessment of newborns for adequate feeding and hydration is reviewed in Table 3.

Table 3 Assessment of newborn feeding and weight gain

Maternal factors
Has the mother experienced engorgement?
Do the breasts feel softer after feedings?
Are there risk factors for delayed lactogenesis? (Cesarean delivery, maternal obesity, LGA, prolonged second stage labor, flat or inverted nipples)
Does latch occur without difficulty, pain, or pinching?
Are there signs of milk ejection reflex? (Breast tingling, uterine cramping, dry mouth)
Newborn factors
Does the newborn feed at least 8–12 times daily?
Does the newborn complete feedings in 15–45 min?
Does the baby self-detach from breast after most feedings?
Is there an audible swallow with feedings?
Has the baby lost more than 8–10 % of birth weight?
Has the baby returned to birth weight by the 14th day of life?

Information from Refs. [13, 31, 32]

Hypoglycemia

Hypoglycemia can occur with or without risk factors or symptoms and is more common in preterm, small for gestational age, and large for gestational age newborns, as well as those born to mothers with gestational diabetes and/or obesity [14]. The most common signs are "jitteriness," hypothermia, poor feeding, abnormal cry, hypotonia, and seizures [13]. Treatment for the asymptomatic infant is debated, but most sources agree that infants with an initial blood glucose (BG) less that 25 mg/dl within the first 4 h of life should be treated, as well as those who are symptomatic [15–17]. Prolonged or several hypoglycemia may result in long-term neurologic sequelae and childhood metabolic syndrome [18, 19]. A proposed algorithm for treatment can be found in

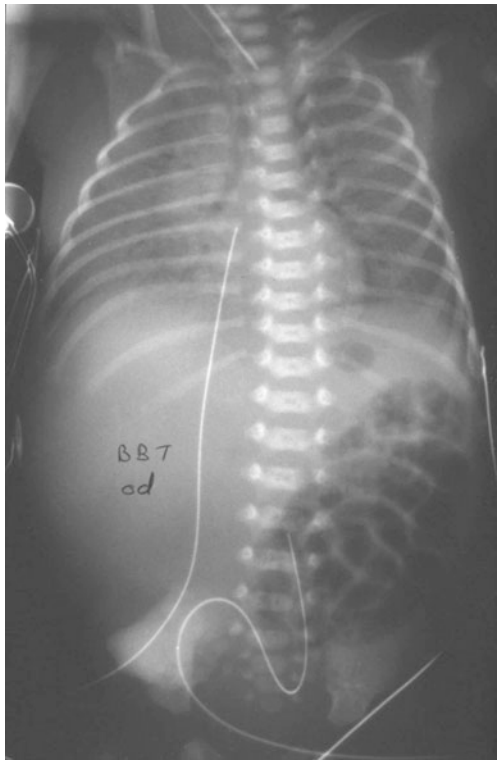

Fig. 2 RDS with sever features. An endotracheal tube is in place

Fig. 2. An initial attempt at feeding should occur (preferably breast or formula if maternal choice) in the first hour of life before a BG is checked [14].

Metabolic Disorders

Unexplained poor feeding, vomiting, lethargy, seizures, or coma in a previously healthy newborn in the first few hours to weeks of life may suggest an inborn error of metabolism. After excluding conditions such as sepsis and hypocalcemia, plasma levels of ammonia, bicarbonate, lactate, and pH should be measured. Early consultation and treatment can avoid severe metabolic and neurologic complications. Each state in the United States has enacted legislation for mandated screening of newborns for certain hereditary metabolic disorders. The exact conditions screened for, however, vary from state to state, and the results of serum screening are often not available for 3–4 weeks.

Anemia

The World Health Organization recommends late clamping of the umbilical cord (1–3 min after birth) to maximize perfusion to the neonate, unless immediate resuscitation is required [20]. This approach can help prevent anemia, with a more substantial benefit for preterm newborns. In newborns delivered after 34 weeks, a central venous hematocrit less than 45 % is often caused by blood loss and less often by hemolysis or congenital anemias. Further evaluation should include review of prenatal history, physical examination, red blood cell indices, and a peripheral smear. A Coombs' test, reticulocyte count, and Kleihauer-Betke stain of maternal blood (to assess for fetomaternal transfusion) may be necessary. If the hematocrit is more than 20 % and the newborn is hemodynamically stable, observation is generally indicated. Severe hemolysis may require exchange transfusion.

Polycythemia

A venous hematocrit of more than 65 % or a capillary hematocrit of more than 70 % may cause plethora, hyperviscosity, and jaundice. Signs and symptoms may include lethargy, respiratory distress, irritability, seizures, feeding difficulties, cyanosis, and hypoglycemia. If the infant is symptomatic and hematocrit elevation is confirmed, a partial exchange transfusion may be considered to lower the hematocrit to 50 %.

Birth Injuries

Caput succedaneum (soft tissue swelling of the scalp that crosses suture lines) usually results from vertex vaginal delivery but may also be seen with cesarean deliveries. It is benign and resolves over the first few weeks of life. *Cephalhematoma* is a slow subperiosteal hemorrhage limited to the surface of one cranial bone and does not suture lines. It is much more common with assisted vaginal birth (incidence with vacuum higher than with forceps) and resolves spontaneously but may be

associated with jaundice as the blood collection dissipates [21]. *Subgaleal hemorrhage* occurs when blood accumulates in the space between the periosteum of the skull and the aponeurosis, with the potential for massive blood loss as blood accumulates in the subgaleal space. Although rare, mortality is high unless rapid volume resuscitation is initiated. Surgical evacuation is rarely needed [22]. *Intracranial hemorrhage* is usually associated with preterm delivery but may occur in term infants. Risk is increased with operative delivery. Close monitoring is required due to risk of extension of the hemorrhage into surrounding tissue and the potential for post-hemorrhagic hydrocephalus [23].

Clavicle fractures are most commonly associated with shoulder dystocia and/or birth weights more than 4 kg. Nondisplaced fractures are often asymptomatic until a palpable callus forms in days to weeks. Displaced fractures are more likely to be accompanied by findings immediately post delivery, including crepitus, edema, crying with passive motion, and lack of movement (pseudoparalysis) in the affected arm. Diagnosis is made by plain radiography and requires investigation for accompanying brachial plexus injury. Most clavicle fractures heal spontaneously with no long-term sequelae. Analgesics may be given for pain. Also for comfort, the arm on the affected side can be place in a long-sleeved garment and the sleeve pinned to the chest, with the elbow flexed at 90°. Callus formation and lack of tenderness on exam are usually sufficient to document healing, but some clinicians advocate for radiography at 2 weeks [24].

Brachial plexus injury generally occurs with shoulder dystocia and clavicle fracture but may be seen in atraumatic deliveries. Upper plexus injury involving C5 and C6 manifests as adduction and internal rotation of the arm and forearm extension, with preserved and wrist movement. When C7 is also involved (Erb palsy), there is also flexion of the wrists and fingers. Total brachial plexus palsy (C5 to T1) presents with arm paralysis and is occasionally accompanied by a Horner syndrome [25].

Management of newborn brachial plexus injury is controversial. Physical therapy and observation for recovery is often sufficient. Surgical evaluation and possibly intervention are usually recommended when functional recovery does not occur in 3–9 months [25].

Human Immunodeficiency Virus (HIV) Infection in Newborns and Infants

In 2010, an estimated 217 children under the age of 13 years were diagnosed with HIV in the United States, and 162 (75 %) of those children were perinatally infected. Despite an overall increase in the number of HIV-infected people giving birth, since the mid-1990s, interventions have resulted in more than a 90 % decline in the number of perinatally acquired HIV infections in the United States. Despite these encouraging results, HIV disproportionately affects black/African American children [26].

In 1994, the AIDS Clinical Trials Group (ACTG) Protocol 076 demonstrated that if previously untreated HIV-infected pregnant women are treated with zidovudine (ZDV), the risk of vertical transmission can be reduced by two thirds. Protocol 076 involved started pregnant women on oral ZDV as early as 14 weeks' gestation and continuing until labor, with conversion to intravenous ZDV infusion during labor. Neonates were then treated with oral ZDV for the first 6 weeks of life [27].

Since 1994, additional research has demonstrated that mother-to-child transmission can be reduced to less than 1 % when HIV infection is diagnosed before or during pregnancy, and appropriate protocols are followed. The CDC continues to recommend intravenous zidovudine during labor and neonatal prophylaxis, but currently recommends that pregnant women be offered highly active antiretroviral therapy (HAART) regimens during pregnancy, starting by 12 weeks' gestation. Universal HIV screening for all pregnant women is thus recommended, as early in pregnancy as possible. Previously untested women who present in labor should undergo rapid HIV testing, with subsequent testing for the newborn [28].

For women with a known prepregnancy HIV-positive serostatus, many HAART regimens

can and should be continued throughout pregnancy, but clinicians should refer to the CDC website for frequently updated guidelines on the use of the multidrug regimens. For HIV-infected pregnant women with HIV viral loads (HIV RNA) greater than 1000 copies/ml3, cesarean delivery is recommended. In the United States and other developed countries, in which the protective effect of breastfeeding does not outweigh the risk of transmission, breastfeeding is not recommended for HIV-infected women; their newborns should receive either donor breast milk from a certified milk bank or formula feedings [28].

Because approximately 18 % of all people with HIV do not know their HIV status, many women who are infected with HIV may not know they are infected. The Centers for Disease Control and Prevention (CDC) recommends routine, opt-out HIV testing for all persons aged 13–64 years in health-care settings, including women during every pregnancy [29].

Infant Diagnosis and Treatment

Newborns and infants with HIV infection must be quickly identified and started on HAART to improve long-term outcomes and prevent opportunistic infections. The physical examination is often normal in newborns. Presenting symptoms may be subtle but can include: failure to thrive, lymphadenopathy, hepatosplenomegaly, recurrent diarrhea, pneumonia, and persistent candidal infections.

Any infant with the above symptoms, other signs of immunocompromise, or born to a known HIV-infected mother should be tested. Initial testing should include a standard HIV screening (Western blot) test as in adult patients as well as an HIV viral load (quantitative HIV RNA), since the Western blot may not be positive with acute infection. For infants born to HIV-infected mothers, if initial newborn testing is negative, follow-up test should occur at 2 weeks, 1–2 months, and 3–6 months [28].

Where possible, treatment of newborns with HIV infection should be initiated in conjunction with a consultant with expertise in neonatal HIV management.

Approaches to Common Neonatal Anomalies

Table 4 provides a brief overview of common anomalies encountered by those caring for newborns.

Guidelines for Early Hospital Discharge of the Newborn

The newborn hospital stay should be long enough to allow identification of early problems and to assure that the family is prepared for the infant's transition to home. Many of the most concerning cardiopulmonary problems become apparent in the first 12 h after birth. Detection of significant jaundice, ductus arteriosus-dependent cardiac anomalies, gastrointestinal obstruction, and certain other issues may require a longer period of observation by skilled health professionals.

A 48-h stay after vaginal delivery and a 96-h stay after cesarean delivery are generally recommended and may help avoid readmissions [30]. Discharge after a shorter length of stay for term infants, especially those born between 39 and 42 weeks gestation, may be considered if a number of criteria are met. These include: a negative prenatal maternal group B streptococcus screen, normal clinical course and physical examination at discharge, stable vital signs for 12 h prior to discharge, regular urination and passage of at least one stool, and successful completion of two consecutive feedings; clinical risk for hyperbilirubinemia has been assessed; maternal laboratory screen results have been reviewed (especially HIV, hepatitis B, blood type, and syphilis screens); hepatitis B vaccine has been administered; metabolic and hearing screens have been completed; home safety and social support has been assessed; and a medical home for follow-up care has been identified.

Newborns discharged at less than 24 h of age will need to have state-mandated newborn metabolic screening repeated. Newborns being discharged less than 48 h after delivery should generally be seen by a health professional (either home or office visit) within 48 h of discharge.

Table 4 Approaches to common neonatal anomalies

Abnormality	Causes	Evaluation/treatment
Head		
Caput succedaneum	Soft tissue swelling of scalp crossing suture lines, occurs with assisted vaginal birth but may occur with spontaneous vaginal or cesarean delivery	Observation
Cephalhematoma	Subperiosteal hemorrhage, does not cross suture lines. More common with assisted vaginal birth	Observation; treat jaundice if develops
Subgaleal hemorrhage/hematoma	Hemorrhage into subgaleal space	Rapid volume resuscitation; monitoring; rare need for surgical evacuation
Macrocephaly (head size >97 %)	May be normal; hydrocephalus; genetic and metabolic disorders	Check for neurologic impairment; consider ultrasonography or head magnetic resonance imaging (MRI)
Microcephaly (head size <3 %)	Cerebral dysgenesis; prenatal insults; other syndromes; familial	MRI, maternal phenylalanine level, viral studies
Large fontanels	Skeletal disorders; chromosomal anomalies; hypothyroidism; high intracranial pressure	Check for neurologic impairments; obtain thyroid function tests
Small fontanels	Hyperthyroidism; microcephaly; craniosynostosis	Check for neurologic impairments; consider head imaging
Craniotabes (softening of cranial bones giving a "ping-pong ball" sensation)	Prematurity; if local, benign bone demineralization; if generalized, syphilis or osteogenesis imperfecta	Should recalcify and harden over 3 months. If persists, screen for syphilis and check for blue sclera and fractures
Eyes		
Abnormal red reflex ("white pupil")	50 % of patients have cataracts, must rule out retinoblastoma	Ophthalmologic evaluation
Nasolacrimal duct obstruction (6 % of newborns; overflow tearing or mucopurulent drainage; erythema)	Incomplete canalization of duct with residual membrane near nasal cavity; 96 % resolve spontaneously by 1 year	Nasolacrimal massage tid; topical antibiotics for mucopurulent drainage; surgery at 9–12 months, earlier if severe
Ears		
Any significant ear anomaly and preauricular pits/fistulas		Check for hearing impairment and possible renal abnormalities
Mouth/palate		
Long philtrum; thin upper lip; small jaw; large tongue	fetal alcohol syndrome; other genetic syndromes	Check for genetic abnormalities; maternal alcohol use
Epstein's pearls (2–3 mm white papules on the gums or palate)	Keratogenous cysts	Spontaneous resolution in weeks; reassurance
Short lingual frenulum ("tongue-tie")	Normal	Clip if feeding impaired; tip of tongue notches when extruded or cannot touch upper gums

(*continued*)

Table 4 (continued)

Abnormality	Causes	Evaluation/treatment
Cleft lip or palate	Isolated variant; some genetic anomalies	Feeding assessment; lip repair usually at 3 months (exact timing varies per patient, surgeon will advise based on individualized plan), palate by 1 year; revision of repair at 4–5 years; speech therapy
Neck		
Fistulas, sinuses, or cysts midline or anterior to the sternocleidomastoid (SCM); may retract with swallow	Branchial cleft anomalies; thyroglossal duct cysts	Nonemergent surgical referral
Cystic hygroma (soft mass of variable size in the neck or axilla)	Dilated lymphatic spaces (failure of drainage into jugular vein)	Semiurgent surgical referral as lesion can expand rapidly; consider karyotype
Congenital torticollis (tilting of the infant's head due to SCM spasm)	Usually an isolated neurologic defect from traumatic delivery; appears at 2 weeks	Early physical therapy usually successful in 2–3 months; orthopedic referral if persists
Skin		
Umbilical cord granuloma	Vascular, red/pink granulation tissue after cord separation	Apply silver nitrate one to three times protecting surrounding skin; excise if persists
Pustular melanosis	Erythematous maculopapulo-pustular rash of face and trunk, unclear etiology	Observation
Café-au-lait spots (flat, light brown macules; usually <2 cm)	Consider neurofibromatosis if more than four spots larger than 5 mm	No treatment if few in number
Hemangiomas (often raised, red, vascular nodules, deeper lesions appear blue; usually <4 cm; onset during first 3–4 weeks, increases over 6–12 months)	Multiple lesions suggest possible dissemination involving internal organs	Most involute and disappear by 2 years of age; observe without treatment unless involving vital structures (may give propranolol in these cases), ulceration, or infection; evaluate further if multiple
Mongolian spots (gray-blue plaques, up to several centimeters, often lumbosacral, may appear elsewhere)	Hyperpigmentation, seen in up to 70 % of nonwhite infants	Benign; most fade over first year; document location since sometimes confused with abuse during infancy
Nevi (variably sized light to dark congenital; brown macules; some others appear later during infancy)	Congenital giant (>20 cm) may undergo malignant degeneration	No treatment needed, although some advise removal of congenital nevi at puberty; refer giant nevi for evaluation
Petechiae (normal only on head or upper body after vaginal births)	Infection or hematologic problem if abnormal	If abnormal, check CBC and look for signs of TORCH syndrome
Port-wine stains (permanent vascular macules)	Possible associated ocular or central nervous system (CNS) abnormalities	Cosmetic problem only, unless other abnormalities found

(*continued*)

Table 4 (continued)

Abnormality	Causes	Evaluation/treatment
Subcutaneous fat necrosis (hard, purplish, defined areas on cheeks, back, buttocks, arms, or thighs, appearing during the first week)	Necrosis of fat from trauma or asphyxia	Spontaneous resolution over several weeks; rare complication of fluctuance or ulceration
Abdomen/gastrointestinal		
Mass	Genitourinary (GU) in 50 % (either kidney or bladder), can be GI origin as well	Emergent ultrasound (US) of urinary tract
Single umbilical artery	2–4 % have other congenital defects, especially cardiac and renal	Careful clinical exam for other defects, consider renal ultrasonography
Delayed passage of meconium (99 % of healthy term neonates pass meconium within 24 h)	Small bowel obstruction with bilious vomiting (atresias, malrotations, meconium ileus) or large bowel obstruction (Hirschsprung's, anorectal atresias, meconium plug syndrome)	Anal inspection and rectal exam; if distended, abdominal x-ray and consider contrast enema, rectal biopsy; vomiting, bilious emesis, or distention requires rapid surgical evaluation
Intestinal atresia (bilious vomiting with variable degrees of distention)	If duodenal, resorption of lumen occurred. If jejunoileal, mesenteric vascular injury	Replogle tube to low intermittent suction, lab, abdominal x-ray; contrast enema; surgery
Meconium ileus (distended at birth, x-ray with distended loops and bubbly picture of air/stool in right lower quadrant; absent air/fluid levels)	Abnormal meconium trapping resulting in small bowel obstruction; often associated with cystic fibrosis; may be associated with small for gestational age/ intrauterine growth restriction	Abdominal x-ray; consider gastrograffin enema (successful in two thirds), otherwise surgery; consider referral to a pediatric pulmonologist, check sweat chloride test at approximately 3 months of age
Meconium plug syndrome (most common distal obstruction)	Inspissated colorectal meconium; diffuse gaseous distention of intestinal loops on x-ray; no air fluid levels	Abdominal x-ray; contrast enema is diagnostic and often therapeutic; search for other causes if symptoms continue
Genitourinary tract		
Ambiguous genitalia (if gonads are palpable, likely to be male)	Virilization of genetic female (esp. congenital 21-hydroxylase deficiency) or undermasculinized male	Obtain blood for chromosomal analysis, may consider buccal smear and 17α-hydroxy- progesterone; withhold diagnosis of sex until karyotype complete
Hypospadias (urethral opening proximal to tip of glans; may be associated chordee: abnormal penile curvature)	Isolated defect unless other GU anomalies present; 10–15 % have first-degree relative with hypospadias	Avoid circumcision; repair 6–12 months of age by experienced surgeon; check for cryptorchidism and hernia; siblings at increased risk

(*continued*)

Table 4 (continued)

Abnormality	Causes	Evaluation/treatment
Cryptorchidism (failure of testicular descent; 20 % bilateral; long-term complications of infertility and cancer if left untreated)	May be normal: seen in 30 % of preterm, 4 % of term; if bilateral, consider ambiguous genitalia; if hypospadias and bilateral, consider urologic or endocrine problems	Observe for descent by 6 months; if not, treatment by 1 year of age; if bilateral, obtain karyotype; if also hypospadias, do full urologic and endocrine evaluation
Hydrocele (scrotal swelling that transilluminates but does not reduce during the exam)	Persistence of processus vaginalis distally without communication to the abdominal cavity	If no hernia, most spontaneously resolve in 3–12 months; prompt surgical referral if hernia or increasing size; persistence beyond 1 year makes hernia likely
Inguinal hernia (inguinal bulge that extends toward or into the scrotum; larger with crying or straining)	Processus vaginalis persists and communicates with abdominal cavity	If reducible, prompt referral for surgery to avoid incarceration; if irreducible, emergent referral
Testicular torsion	Idiopathic	Emergent evaluation with ultasonography and surgery
Musculoskeletal		
Syndactyly (fusion of two or more digits)	Sporadic or autosomal dominant with varying expressivity	Depending on site, surgery between 6 and 18 months of age
Polydactyly (more than five digits)	Sporadic or autosomal dominant	If no cartilage/bone, remove early, otherwise referral to plastic surgery for evaluation and removal
Metatarsus adductus (forefoot supinated and adducted; may be flexible or rigid; ankle range of motion must be normal)	Hereditary "tendency," but often due to uterine crowding; 10 % association with hip dysplasia, requires careful exam	If flexible and overcorrects into abduction, no treatment; if corrects only to neutral, use corrective shoe for 4–6 weeks and reassess; if rigid, needs early casting
Talipes equinovarus (clubfoot; variably rigid foot, calf atrophy, hypoplasia of tibia, fibula, and foot bones)	Multifactorial with autosomal dominant component; 3 % risk in sibs and 20 % to 30 % for offspring of affected parent	Anteroposterior (AP) and stress dorsiflexion lateral x-ray; early serial casting; if persists, surgery by 6–12 months (90 % success rate)
Nervous system		
Spina bifida occulta (spinal defect with cutaneous signs: patch of abnormal hair, dimple, lipoma, hemangioma)	Nonfusion of posterior arches of spine; may be tethering of cord or sinus to spinal space with risk of infection; clinical exam for other defects	Examine for neurologic deficits; US to document defect if cutaneous signs; nonemergent referral to neurosurgeon if dermal sinus or tethering suspected; prompt referral if deficits present

Infant Care

Well-Child Care

Well-infant visits should emphasize anticipatory guidance and answering parental questions about infant health during the period of rapid transitions. Cultural and socioeconomic issues, family expectations and stressors, and an assessment of the infant's physical environment should be addressed – preferably starting with prenatal care. Each visit should include an age-appropriate physical examination and developmental assessment as well as pertinent immunizations and screening tests. After an initial clinician visit within the first 4 days of life as noted above, newborns should be seen again at 1–2 weeks, then 1 month, 2 months, 4 months, and 6 months of life. Additional visit schedules and guidelines for well-infant visits are covered in greater detail in chapter "► Clinical Prevention".

Nutrition and Feeding

Breast Milk

The American Academy of Family Physicians and American Academy of Pediatrics recommend that most infants be exclusively breastfed for the first 6 months of life and continue some breastfeeding for at least 12 months [31, 32]. Infant feeding is a personal and family choice, but in the absence of medical contraindications to breastfeeding, physicians should provide up-to-date information to expectant parents regarding the risks and benefits of feeding choices.

Breastfeeding optimizes newborn immune system development and disease prevention and assists with maternal postpartum weight loss and psychologic well-being. Exclusively or primarily formula-fed newborns are at increased risk for: gastrointestinal, ear, and respiratory infections throughout infancy and childhood, type 1 diabetes, asthma, childhood and adult obesity, and leukemia. Mothers who primarily feed their newborns formula increase their own risks for obesity, diabetes, ovarian and breast cancer, and depression [31, 32].

Evidence-based studies indicate that maternal education regarding the benefits of breastfeeding should begin early in prenatal care and include physician counseling as well as structured breastfeeding classes or prenatal groups. Women with a history of breast surgery or flat or inverted nipples may visit a trained lactation consultant for support during their pregnancy to help prevent or ameliorate breastfeeding difficulties [13].

During intrapartum care, physicians should seek to minimize the use of unnecessary medical interventions, as many medications and interventions utilized during labor can decrease milk supply or otherwise negatively impact breastfeeding. Every effort should be made to support immediate and prolonged maternal-newborn skin to skin contact (provided the newborn is medically stable at birth), latch and breastfeeding within the first hour of life, and "rooming in" during the hospital stay with minimal mother-newborn separation. A pacifier should not be given to breastfeeding infants during the first several weeks of life until breastfeeding is well established. Liquids other than colostrum or breast milk should not be given unless there is a documented medical need, such as weight or feeding difficulty. If the newborn experiences early latch difficulties, supplementation with expressed breast milk is preferable to supplementation with formula. Assistance from a trained lactation consultant is a key element in the support of breastfeeding dyads [13].

There are very few absolute contraindications to breastfeeding. These include maternal HIV infection and a newborn diagnosis of galactosemia. Certain medications pass through breast milk – updated guides to medications can be found at the National Institutes of Health LactMed website [33]. In many cases, if a maternal medication is not compatible with breastfeeding, the family physician could consider substituting an alternate medication that is compatible.

Vitamin D Supplementation

All newborns should consume 400 IU/day of vitamin D to prevent vitamin D deficiency and associated abnormalities of calcium metabolism that may occur, including rickets. Deficiencies of vitamin D have also been linked to a number of conditions, including developmental delay, and

possibly type 1 diabetes or cardiovascular disease later in life [34]. Newborns that are exclusively breastfed and newborns consuming less than 1 l of formula daily should be prescribed an oral vitamin D supplement containing 400 IU daily. In the first month of life, few newborns that are fully formula fed will consume a full liter daily; these newborns should also be prescribed vitamin D for at least 1 month.

Formula

If formula feeding is chosen, the majority of infants tolerate cow's milk-based formulas. For healthy term infants, differences between brands of formula are generally insignificant. True infant intolerance to cow's milk-based formulas is unusual. Soy protein formulas are of value only if lactose intolerance is strongly suspected, such as after prolonged episodes of loose stools. Even then, the intolerance is usually transient and cow's milk-based formula can be tried again in 2–4 weeks.

Because formulas do not contain fluoride, physicians should suggest that parents mix the powdered forms with fluoridated water. Low iron formulas offer no advantage; their use will result in iron deficiency anemia in most infants.

Advancing Infant Diet

Infants should continue breast milk or formula until 12 months of life because introducing cow's milk before this age increases the risk of occult gastrointestinal bleeding and iron deficiency anemia. At 12 months, the child can generally start whole or 2 % milk and switch to skim milk at 2–3 years of age.

Introducing nonmilk foods before 6 months of life is generally not beneficial and may increase risks of food allergies and obesity – although findings in the scientific literature are controversial [32, 35]. Some generally accepted guidelines for introducing nonmilk foods include:

1. Separate the introduction of new foods by 2–3 days to more easily determine the cause of any food intolerance.
2. Start with easily digested fruits and vegetables, such as yellow vegetables, avocados, and sweet potatoes.
3. Postpone potential allergens such as citrus fruits, wheat, and eggs until 9–12 months of age.
4. Minimize the risk of airway obstruction by avoiding spongy foods (e.g., hot dogs and grapes) and foods with kernels (e.g., corn and nuts).

Treatment of Colic

All infants, whether they are described as having colic or not, will cry more in the first 3 months of life than any other time. Colic is broadly defined as crying for no apparent reason that lasts greater than 3 h/day and occurs on more than 3 days a week in an otherwise healthy infant less than 3 months of age [36].

The incidence of colic does not seem to differ between breast- and formula-fed babies, term and preterm, or male and female. Etiology is unknown, although there is probably a combination of factors that contribute to it.

A principal focus is on reassuring parents that the process is a common, self-limited one and providing them with some basic measures to try. These include providing motion as in a mechanical swing, rocker, or front infant carrier or exposure to a steady hum such as in a car or a vacuum cleaner, bundling, and burping well and frequently during and after feeding. Often the physician's most important roles are providing support over time and legitimizing the parents' sense of frustration, and even anger, with the situation. The physician should also encourage parents to help each other with caring for the infant and whenever possible to enlist the help of others so that they have an opportunity to take a break. When all else fails, parents may need permission to periodically shut the door and let the infant "cry it out."

Infants with more prolonged, severe bouts of crying, especially if intermittent throughout the day, may have a remediable organic cause. Constipation should be treated as it would in other infants. Frequent vomiting, especially if accompanied with poor feeding, suggests gastroesophageal reflux. If a trial of medication is not effective, further workup is indicated. With signs of allergy

(eczema, asthma) or a strong family history of allergies, milk allergy should be considered. Finally, although anticholinergic agents have been advocated in the past, their efficacy probably has more to do with their sedating effect than any specific effect on the gastrointestinal muscles. Because they have a potential for severe side effects, they are now considered contraindicated.

Failure to Thrive

The diagnosis of failure to thrive (FTT) is based on growth parameters that (1) fall over 2 or more percentiles (2) are persistently below the 3rd percentile or (3) are less than the 80th percentile of median weight for height measurement. A thorough history and physical examination detect most organic, behavioral, family, and environmental problems that contribute to FTT. This initial assessment should include (1) prior records including growth charts and prenatal history (prematurity, growth restriction), (2) nutrition (diet, behavior), (3) development (cognitive, motor, behavioral, emotional), (4) social context (parental knowledge, family dysfunction, drug abuse, isolation), and (5) environment (poverty, shelter, toxic exposures to lead or pesticides). Diagnostic studies can follow in a stepwise manner, with step 2 studies chosen based on history, physical exam, and severity:

Step 1: complete blood count, electrolytes, urinalysis, and lead level
Step 2: thyroid, stool (culture, ova and parasites, fat), sweat chloride, tuberculosis, HIV screening, skeletal survey, and renal studies

Patients with severe malnourishment who have had no prior workup or for whom outpatient care has failed may require inpatient care. Collaborative, interdisciplinary treatment involves the parents, physician, social worker, nutritionist, and psychologist. It implements one or more of the following strategies: (1) treating organic factors first, (2) implementing a written nutritional plan for meals and snacks with caloric intake 1.5–2.0 times normal, (3) beginning a vitamin supplement, (4) supporting parents with mealtime observation and coaching, (5) treating specific family problems that interfere with the family's ability to care for the infant (misunderstanding, depression, drug abuse), (5) enlisting social support (family, friends, church), (6) mobilizing community and economic resources for the family, (7) establishing continuity of care and access to the treatment team, and (8) promoting parental competence.

Fever

In children under 3 years of age, if a source for the fever cannot be found, or if otitis media is found, 3–11 % have occult bacteremia. The risk is even higher in infants under the age of 3 months who have an 8.6 % risk of having a serious bacterial infection (27, 28). Although most neonates (younger than 28 days of age) and young infants (29–90 days of age) with fever have a viral illness, the goal of the provider is to identify those children who are at high risk for serious bacterial infection (SBI), requiring empiric antimicrobial therapy and possible hospitalization.

Neonates (0–28 Days)

Available guidelines for fever in young infants do not perform well in newborns less than 28 days of age, and therefore most experts agree that all neonates, regardless of clinical appearance, with a rectal temperature greater than 38 °C or 100.4 °F, have blood, urine, and CSF cultures obtained. Infants should be admitted to the hospital and treated with empiric intravenous antibiotics until cultures are found to be negative, or a full course of treatment is completed.

Ill-Appearing Infants (29–90 Days)

Up to 45 % of ill-appearing young infants may have an SBI and should have blood, urine, and CSF evaluation and empiric antibiotic therapy with admission to the hospital [37, 38].

Well-Appearing Infants (29–60 Days)

Laboratory testing is necessary to help determine which patients are at high risk for a serious bacterial infection. Lab evaluation includes CBC, blood and

urine culture, and CSF cultures in most patients. Some clinicians may elect to perform less of a laboratory evaluation; there are no guidelines for the minimal evaluation of fever in well-appearing infants ages 29–60 days. Many studies have reported, however, that infants who are at low risk of SBI based on history, physical examination, and laboratory tests can be safely managed as outpatients. Follow-up must be arranged within 24 h, either by phone or return visit to the provider. If 24 h follow-up is problematic, for whatever reason, then the infant should be admitted to the hospital. Infants who are followed as outpatients may be treated presumptively with ceftriaxone (50 mg/kg), pending culture results [37, 38].

However, patients should not receive empiric antibiotics unless a full sepsis workup has been done, including obtaining a CSF culture.

Infants 61–90 Days Old

Data regarding the incidence of SBI among infants 61–90 days with fever on which to base definitive guidelines is limited. Since infants less than 3 months of age have not yet been fully immunized against *Haemophilus influenzae* type b and pneumococcus, most experts recommend laboratory analysis including CBC, urinalysis, and blood and urine cultures. A WBC count outside of the normal range of 5000–15,000/microL or band count greater than 1500/microL necessitates the need for CSF culture and treatment with parenteral antimicrobials. Any ill-appearing infant warrants full laboratory evaluation and admission to the hospital for well-appearing patients with normal CSF and urinalysis, IM ceftriaxone (50 mg/kg) is an option. These infants must have follow-up within 24 h either by phone or by visit [38, 39].

Infants 3–36 Months Old

There is no need to screen for occult bacteremia in infants with temperatures <39 °C (102.2 °F). However, infants with persistent fever for more than 2–3 days, worsening clinical appearance, or temperatures >39 °C without an apparent source of the fever other than otitis media, constitute a higher risk group. They should be evaluated with a WBC count. If the count is >15,000/mm^3 or they have a bandemia, a blood culture is indicated, as well as a parenteral antibiotic (Ceftriaxone 50 mg/kg/dose) while the cultures are pending. In addition, a catheterized urine sample should be considered for all boys less than 6 months of age or girls less than 2 years of age [39].

Fever is a common symptom in this age group of children. The majority of children will have a self-limited viral infection or a recognizable source of infection upon physical examination. The introduction of vaccines to prevent *Haemophilus influenzae* type b and pneumococcal disease has been very successful in lowering the incidence of occult bacteremia, and therefore the approach to the child who has a fever without a source is greatly determined by immunization status. Fever of 39 °C or higher is the threshold above which evaluations for a source of occult infection, including UTI, may be warranted [40].

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is the leading cause of infant mortality between 1 month and 1 year of age in the United States. It is defined as the sudden death of an infant younger than 1 year of age, which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and comprehensive review of the clinical history. The risk of SIDS in the United States is <1 per 1000 live births and the rate of SIDS peaks between 2 and 4 months of age. The incidence of SIDS had declined dramatically since the initiation of the "Back to Sleep" campaign, which encourages caregivers to place infants in a supine position for sleep.

Numerous risk factors for SIDS have been identified including maternal factors such as (1) young maternal age, (2) maternal smoking during pregnancy, and (3) late or no prenatal care. Infant or environmental factors include (1) preterm birth and/or low birth weight, (2) prone sleeping position, (3) sleeping on a soft surface and/or with bedding accessories such as loose blankets and pillow, (4) bed-sharing (sleeping in parents' bed), and (5) overheating.

More than 95 % of SIDS cases are associated with one or more risk factors, and in many cases, the risk factors are modifiable. The prone sleeping position is the strongest modifiable risk factor for SIDS. A theory that has been proposed in terms of etiology involves a triple-risk model. This suggests that SIDS occurs in infants at a vulnerable developmental stage of the central nervous system. These infants may have an underlying vulnerability, such as a brainstem abnormality and then experience a triggering event, such as airflow obstruction or being exposed to an environment with smoke. To minimize the risk for SIDS, parents should be educated on the risk factors, prenatally as well as at each well-infant visit. The use of home monitors has not been proven to reduce the incidence of SIDS and is not recommended [41,42].

Other Common Problems of the Infant

Table 5 provides short summaries of common problems of infancy and their management.

Family and Community Issues

Child Care

More than 50 % of infants under 1 year of age have parents who work outside the home. A quality child care setting supports normal infant development while protecting health and safety. Children in day care are 2–18 times more likely to contract certain infectious conditions including enteric, respiratory, and herpesvirus infections [43]. The optimal adult-to-child ratio for children under 1 year old in day care is 1:3. Staff should be trained in child development, be paid sufficiently to minimize turnover, and engage in recommended sanitation practices, such as washing their hands after diapering and before food preparation.

Risks and Resources

Normal infant development is promoted by fostering a family's strengths and resources while attempting to mitigate risk factors. Infant risk factors include: chronic illness, physical disability, lower birth weight, delayed growth, and developmental delay. Family risk factors include: physical abuse, family violence, neglect, parental depression, chemical dependence, and chronic illness. Environmental factors include poverty and toxins such as lead. Screening for risk factors should begin during prenatal care. Early intervention programs promote healthy development when families face these types of obstacles. Effective early intervention includes five elements:

1. Crisis intervention – addressing immediate threats to safety such as violence, abuse, or severe neglect.
2. Family-centered care – collaboration with parents to avoid labeling a child or parent. Challenges as well as strengths and resources should be identified.
3. Social support – assisting families to identify sources of support, such as family members, friends, and religious or community groups.
4. Community resources – linking families to existing programs that can help meet specific needs (e.g., specialized day care or parenting classes).
5. Ecologic model of intervention – assessing the individual infant, family, and physical environment to customize interventions that build on family strengths. Intervention should be culturally sensitive and nonstigmatizing.

Table 6 lists recommended screening questions to family risks and resources.

Partner Violence

One in five pregnant women experience intimate partner violence during their pregnancy, with higher rates among adolescent pregnant women [44] (see also chapter "▶ Domestic Violence"). Partner violence exerts well-documented negative impacts on maternal and infant health. Pregnant women who are experiencing abuse are more likely to delay seeking prenatal care and demonstrate higher rates of depression, anxiety, suicide attempts, alcohol and drug abuse, and smoking. Intentional injury, often the result of intimate partner violence, is one of the leading causes of death

Table 5 Approaches to common problems of the infant

HEENT (head, ears, eyes, nose, and throat)
Thrush (pearly white pseudomembranes on the oral mucosa). Causes: transmission from vaginal mucosa during delivery; contaminated fomites (nipples – both breast and bottle, toys, teething rings). Rx: clean fomites (boil bottle nipples, toys); oral nystatin, 200,000–500,000 U q4–6h until clear X48 hours
Nasolacrimal duct obstruction (see Table 1). Symptoms usually delayed until days to weeks after birth. Rx: nasolacrimal massage tid and cleansing of eyelids with warm water; topical antibiotics (sulfacetamide or gentamicin drops) for secondary conjunctivitis
Strabismus (misalignment of eyes). Screen with corneal light reflex and cover test. Rx: ophthalmology referral for persistent deviation > several weeks or any deviation >4 months of age
Hearing loss. Screening recommending after delivery by American Academy of Pediatrics: family history; congenital infection; craniofacial abnormalities; birth weight <1500 g; hyperbilirubinemia requiring exchange transfusion; severe depression at birth; bacterial meningitis. Screening: otoacoustic emissions testing or auditory brainstem response. Treatment by 6 months can greatly improve future language development. Infants not passing should have an audio logic evaluation by 3 months (or by 6 weeks if CMV is the potential etiology)
Teething (painful gums secondary to eruption of teeth with irritability, drooling). Fever and other systemic effects not caused by teething. Rx: chewing on soft cloth, teething ring, dry toast hastens eruption; topical and systemic analgesia
Skin problems
Circumcision. Elective procedure performed only on healthy, stable newborns using a penile block. Contraindicated if any genital abnormalities. Advantages: decreased incidence of phimosis and urinary tract infection. Risks (small): hemorrhage; sepsis; amputation; urethral injury; removal of excessive foreskin with painful scarring
Diaper dermatitis (erythematous, scaly eruptions that may advance to papulovesicular lesions or erosions; may be patchy or confluent; genitocrural folds often spared). Due to reaction to overhydration of skin, friction, and/or prolonged contact with urine, feces, chemicals such as in diapers, and soaps. Rx: frequent changing of diapers; exposure to air; bland, protective topical ointment (petrolatum, zinc oxide) after each diaper change; advanced cases may require 1 % hydrocortisone ointment
Candidal superinfection (pronounced erythema with sharp margins, satellite lesions, involvement of genitocrural folds). Rx: topical antifungal; treat associated thrush
Milia (superficial 1–2 mm inclusion cysts). Common on face and gingiva. Requires no Rx
Miliaria (clear or erythematous papulovesicles in response to heat or overdressing; especially in flexural areas). Resolves with cooling
Seborrheic dermatitis (most commonly greasy yellow scaling of scalp or dry white scaling of inguinal regions; may be more extensive). Rx: generally clears spontaneously; may require 1 % hydrocortisone cream; mild antiseborrheic shampoos for scalp lesions; mineral oil with gentle brushing after 10 min for thick scalp crusts
Atopic dermatitis (intensely pruritic, dry, scaly, erythematous patches). Acute lesions may weep. Typically involves face, neck, hands, abdomen, and extensor surfaces of extremities. Genetic propensity with frequent subsequent development of allergic rhinitis and asthma. Consider evaluation for food and other allergens. Rx: mainstay is avoidance of irritants (temperature and humidity extremes, foods, chemicals) and drying of the skin (frequent bathing, soaps) with frequent application of lubricants (apply to damp skin after bathing); severe disease usually requires topical steroids; acute lesions may require 1:20 Burrow's solution and antihistamines (diphenhydramine, hydroxyzine)
Heart murmur
Innocent or functional (typically diminished with decreased cardiac output)
Newborn murmur. Onset within first few days of life that resolves by 2–3 weeks of age. Typically soft, short, vibratory, grade I–II/VI early systolic murmur located at lower left sternal border that subsides with mild abdominal pressure
Still's murmur. Most common murmur of early childhood. May start in infancy. Typically loudest midway between apex and left sternal border. Musical or vibratory, grade I–III early systolic murmur
Pulmonary outflow ejection murmur. May be heard throughout childhood. Typically soft, short, systolic ejection murmur, grade I–II and localized to upper left sternal border
Hemic murmur. Heard with increased cardiac output (fever, anemia, stress). Typically grade I–II high-pitched systolic ejection murmur heard best in aortic/pulmonic areas
Pathologic or organic murmurs. Any diastolic murmur. Consider when a systolic murmur has one or more of the following: grade III or louder, persistent through much of systole, presence of a thrill, single second heart sound (most important finding), abnormal quality of second heart sounds (loud, "click"), or a gallop. Other ominous signs: congestive heart failure, cyanosis, tachycardia. Evaluation: chest x-ray (CXR), electrocardiogram (ECG), consider arterial blood gas, and if persistent or any distress then cardiology consult

(*continued*)

Table 5 (continued)

Gastrointestinal
Constipation (intestinal dysfunction in which the bowels are difficult or painful to evacuate). Associated failure to thrive, vomiting, moderate to tense abdominal distention, or blood without anal fissures requires ruling out organic disease (Hirschsprung's, celiac disease, hypothyroidism, structural defects, lead toxicity). Common causes are anal fissures, undernutrition, dehydration, excessive milk intake, and lack of bulk. Less common with breast feeding. Rarely caused by iron- fortified cereals. Rx: in early infancy increase amount of fluid or add sugars (Maltsupex); later add juices (prune, apple) and other fruits, cereals, and vegetables; may add further artificial fiber (Citrocel); severe disease may require brief use of milk of magnesia (1–2 tsp), docusate sodium, and glycerin suppositories and when persistent requires ruling out of organic disease
Gastroesophageal reflux (GERD). Vomiting noted in 95 % of infants within the first 6 weeks, resolving in 60 % by age 2. Important to distinguish "spitting up" from true GERD. Spitting up is not associated with significant weight loss, breast milk or formula intolerance, or other warning signs. GERD may be associated with growth delay, esophagitis, hemoccult positive stool, chronic cough, and wheezing. Consider cow's milk allergy. Dx: mild cases confirmed by history and therapeutic trial. If more severe, esophageal pH probe and barium fluoroscopic esophagography. Endoscopy if esophagitis is suspected. Rx: position prone for neonates; elevate head of bed for older infants. Thickened feedings with cereal; acid suppression if esophagitis. If more severe, consider metoclopramide (side effects are common); surgery if medical therapy fails
Pyloric stenosis (nonbilious vomiting immediately after feeding becoming progressively more projectile). 4:1 male: female preponderance. Onset 1 week to 5 months after birth (typically 3 weeks). More common in males. May be intermittent. Dx: palpation of pyloric mass (typically 2 cm in length, olive shaped) that may be easier to palpate after vomiting; ultrasound is preferred method to confirm difficult cases (90 % sensitivity). Rx: surgery after rehydration
Anemia
Improved nutrition has reduced incidence but infants remain at significant risk. Additional risk factors: low socioeconomic status, significant maternal anemia, consumption of cow's milk prior to age 6 months, use of formula not iron fortified, low birth weight, prematurity. Effects: fatigue, apathy, impairment of growth, and decreased resistance to infection. Causes: iron deficiency most common (usually sufficient birth stores to prevent occurrence prior to age 4 months), sickle cell disease, thalassemia, lead toxicity. Screening: hemoglobin (Hgb) or hematocrit (Hct) between ages 6 and 9 months (some recommend only for infants with risk factors). Rx: if microcytic give trial of iron (elemental iron, Feosol, 3–6 mg/kg/day); if not microcytic or unresponsive to iron consider other causes (family history, environment)
Sleep disturbances
Seventy percent of infants can sleep 5 or more hours of the night by age 3 months. Most 6-month-olds no longer require nighttime feeding. Screening: a sudden change in sleeping pattern should prompt a search for new stresses, physical (infection, esophageal reflux, etc.) or emotional (new surroundings or household members, etc.). Rx: establish realistic parental expectations (consider the natural sleeping patterns of the infant); allow the infant awakening at night to learn how to fall asleep by himself (keep bedtime rituals simple and put the infant in his bed awake; do not respond to infant's first cry; keep interactions during the night short and simple; provide a security object for older infants); slowly change undesirable sleeping patterns (move bedtime hour up and awaken infant earlier in the morning; decrease daytime napping)

among pregnant women. Current research demonstrates that infants born to abused women are more likely to experience preterm birth and be born at low birth weight. Family physicians can play a valuable role by screening all pregnant women for intimate partner violence at multiple points during prenatal care [44].

Infants of Substance-Abusing Mothers

Tobacco exposure during pregnancy is associated with miscarriage, placental abruption, late pregnancy bleeding and placental abruption, preeclampsia, and intrauterine growth restriction. Fetal alcohol syndrome includes the well-described triad of growth restriction, nervous system abnormalities, and midfacial hypoplasia, with possible involvement of cardiac and renal systems. The full syndrome involves heavy drinking throughout pregnancy, but lower levels of exposure also affect fetal development. Cocaine use during pregnancy is associated with preeclampsia, placental abruption, intrauterine growth restriction, and withdrawal symptoms in the neonate [43].

Exposure to one substance is often confounded by the abuse of other drugs and social and

Table 6 Assessing resources and risks for early family development

Concept	Interview questions
Social support	Do you have at least one friend or relative you can turn to for support and advice?
	Do you work, attend school, or participate in a religious community?
Housing	Do you have any concerns about housing?
Child care	Do you have any concerns about child care?
Transportation	Do you have any concerns about transportation?
Finances	Will you have any problems paying for food and clothing? Vitamins and medications? Health care?
Safety	During the past year, has anyone you know:
	Made you afraid for your safety?
	Pushed, kicked, slapped, hit, or otherwise hurt you?
	Forced sexual or physical contact?
	Tried to control your activities, your friends, or other parts of your life?
	Do you have any guns in your house?
	Do you have any concerns about safety or violence in your neighborhood?
	Do you use a seat belt when you ride in a car?
	Do you use an infant or car seat for each infant and toddler in your family?
	Do your children always use a seat belt?
Personal health	In general, how healthy do you consider yourself? (Excellent, good, fair, or poor)
STI and HIV risk	Have you ever had herpes, gonorrhea, chlamydia, trichomonas, genital warts, or a pelvic infection?
	Have you had two or more sexual partners in the past year?
Emotions	During the last 30 days, how much of the time have you felt downhearted and blue? (Very little, sometimes, often, most of the time)
Alcohol and drugs	Have your parents had any problems with alcohol or drugs?
	Does your partner have any problems with alcohol or drugs?
	Have you had any problems in the past with alcohol or drugs?
	During the past 30 days, on how many days did you have at least one drink of alcohol?
	During the past 30 days, on how many days did you have five or more drinks of alcohol in a row, that is, within a couple of hours?
Tobacco or electronic cigarettes	Does anyone in your home smoke tobacco or use electronic cigarettes?
	Do you currently smoke or use tobacco or electronic cigarettes?

environmental factors that correlate with chemical dependence and are known to affect infant outcome. Parents should be encouraged to seek treatment for substance abuse or chemical dependence at any point during pregnancy or after birth, as intervention at any point can improve outcomes.

Adolescent Parents

Adolescent women with access to appropriate pre- and postnatal resources can give birth to healthy children with normal developmental outcomes. Many adolescent pregnant women, however, experience other risk factors such as poverty, lack of access to health care, family violence, and substance abuse. When working with adolescent parents, the family physician should:

1. Expect a positive outcome while offering respect and dignity.
2. Encourage family support, if appropriate, including support of the father of birth and his family.
3. Encourage use of community resources such as child care, parenting classes, education, and early intervention programs.
4. Initiate family planning early during the pregnancy.
5. Encourage continued education and delay of the birth of another child.

Public Policy

Federal law PL99-457 encourages states to develop programs that identify and provide services to at-risk children from birth to 3 years of age. These early intervention programs are to be individualized, are family centered, and involve the primary health-care provider. Implementation varies from state to state, making it important for family physicians to familiarize themselves with local programs and resources.

Introduction

Infections are the most common cause of acute illness in children. Most commonly these are respiratory infections which peak when the child starts to go to school or out-of-home day care. Although the majority of these diseases have benign course, they cause significant discomfort, anxiety, missed work, and stress to many families caring for children. Frequent office visits, and unnecessarily prescribed medications, and sometimes dubious home remedies can be reduced by following best evidence-based practice and having a good doctor-patient (and parent) relationship.

In developed countries, morbidity and mortality from infections have declined dramatically, and deaths from infectious diseases are uncommon. However, serious infections still occur, e.g., meningococcal septicemia, meningitis, and multidrug-resistant pathogens, and some have reemerged, for example, tuberculosis and PVL-toxin-secreting *Staphylococcus aureus*, which requires early recognition and treatment. With an increase of global air travel, tropical diseases are encountered in all countries. In addition, epidemics may spread widely, e.g., SARS and H1N1 influenza, with children (and the elderly) being the most vulnerable.

Family physicians spend about 10 % of their time caring for children. About two-thirds of practicing family physicians report that they provide care for children [1]. Thus, the family physician's role in early proper management of infections is of paramount importance. Office visits must concentrate on clinical evaluation and diagnosis, appropriate management and advice, and prevention and early detection of complications. In this chapter, the clinical presentations, differential diagnosis, and management of common acute infectious diseases in children will be discussed.

Acute Upper Respiratory Tract Infections (URTIs)

The common cold or URTI is the third most common primary diagnosis in outpatient practice.

Patients seek care for URTIs throughout the year, especially in winter, with young children commonly experiencing five to eight colds a year [2, 3]. Day-care attendance is a major risk factor for URTI in young children. Other risk factors include smoking in the home, poor nutrition, and crowded living conditions [4–6]. Colds are most commonly caused by rhinovirus although other viruses have been isolated from children presenting with typical cold symptoms such as adenoviruses, coronaviruses, enteroviruses, influenza virus, parainfluenza virus, and respiratory syncytial virus (RSV) [7]. Direct inoculation has been the main mode of transmission; rhinoviruses are detectable on the hands of 40–90 % of cold sufferers; viruses also can be transmitted through coughing, sneezing, and nose blowing [8, 9].

Signs and symptoms of the common cold include some combination of nasal congestion and discharge, sore throat, cough, fever, hoarseness, mild fussiness or irritability, decrease in appetite, sleep disturbance, and mild eye redness or drainage. Although most of viral URTIs are self-limited, the family doctor must

Table 1 Differential diagnosis of a child presenting with cold symptoms

Diagnosis	Signs and symptoms	Diagnostic test	Management
Viral URI	Some combination of the following: Nasal congestion and discharge, fever, sore throat, cough, hoarseness, mild fussiness or irritability, decrease in appetite, sleep disturbance, mild eye redness, or drainage [3]	Clinical picture Usually no testing is needed	Symptomatic treatment: Complementary therapy such as vapor rub, zinc sulfate syrup, buckwheat honey (avoid in children <1 year old – risk of botulism), nasal irrigation with saline, high-dose inhaled corticosteroids (for children who are wheezing) Prophylaxis: Complementary therapies such as probiotics, Vitamin C, Chizukit herbal preparation, nasal saline irrigation [8]
Acute bacterial rhinosinusitis (ABRS)	Any of the following presentations: Persistent illness [nasal discharge (of any quality) *or* daytime cough *or* both lasting more than 10 days without improvement] A worsening course (worsening or new onset of nasal discharge, daytime cough, or fever after initial improvement) Severe onset (concurrent fever/temperature ≥39 °C and purulent nasal discharge for at least 3 consecutive days) [10, 11]	NO routine imaging studies are needed CT or MRI for sinuses ONLY when a child is suspected of having orbital or central nervous system complications of ABRS [10, 11]	Antibiotic Rx for severe onset or worsening course (signs, symptoms, or both) Prescribe antibiotic therapy *or* offer additional outpatient observation for 3 days to children with persistent illness Amoxicillin with or without clavulanate is first-line treatment In penicillin-allergic patients, second of third-generation cephalosporins or levofloxacin or clindamycin plus a third-generation oral cephalosporin (cefixime or cefpodoxime) Reassess if there is either a caregiver report of worsening (progression of initial signs/symptoms or appearance of new signs/symptoms) or failure to improve within 72 h of initial management: *consider modification of antibiotic for the child initially managed with antibiotic if worsening symptoms or failure to improve **or* initiate antibiotic treatment for the child initially managed with observation [10, 11]
Group A streptococcal pharyngitis (GAS)	Sudden onset of sore throat in a child aged 5–15 years Systemic symptoms (fever, headache, occasional nausea, vomiting, abdominal pain) Tonsillopharyngeal erythema, patchy tonsillopharyngeal exudates, palatal petechiae	Throat swab for rapid antigen detection test (RADT) and/or culture Negative RADT should be backed by throat culture Not indicated for children <3 years old [12]	Antibiotic for 10 days (except azithromycin for 5 days) as follows: for non-penicillin-allergic patients, penicillin or amoxicillin (drugs of choice); *for penicillin-allergic individuals (not anaphylaxis), first-generation cephalosporin Clindamycin, clarithromycin, or

(*continued*)

DOI 10.1007/978-1-4939-0779-3_18-1

Table 1 (continued)

Diagnosis	Signs and symptoms	Diagnostic test	Management
	Anterior cervical adenitis (tender nodes), scarlatiniform rash Winter and early spring presentation. History of exposure to strep pharyngitis [12]		azithromycin Adjunctive therapy to manage symptoms: acetaminophen or NSAIDS;*DO NOT use aspirin; *use of corticosteroids is NOT recommended [12]
Acute otitis media (AOM)	Moderate to severe bulging of the tympanic membrane (TM) *or* new onset of otorrhea not due to acute otitis externa *or* mild bulging of the TM *and* recent (less than 48 h) onset of ear pain or intense erythema of the TM [13]	AOM should not be diagnosed in children who do not have middle ear effusion (MEE) (based on pneumatic otoscopy and/or tympanometry) [13]	Analgesics if pain is present Antibiotics should be prescribed for all children less than 6 months old, children ≥6 months old with bilateral or unilateral AOM with severe signs or symptoms, and 6–23-month-old children with bilateral AOM without severe signs or symptoms Antibiotic therapy or observation offered with close follow-up for 6–23-month-old children with nonsevere unilateral AOM and ≥24-month-old children with nonsevere AOM (either unilateral or bilateral) [13]
Whooping cough (pertussis)	Coughing illness lasting 2 weeks with one classic sign of pertussis (paroxysmal cough, post-tussive emesis, or inspiratory whoop), without another apparent cause [14]	Culture and polymerase chain reaction (PCR) testing recommended by CDC [14]	Antibiotics: azithromycin, clarithromycin, or erythromycin base;*TMP/SMX for patients who cannot tolerate macrolides; clindamycin as third line Prophylaxis: same antibiotics in same doses for contacts of case within 21 days onset of symptoms in index case Prevention: vaccination [14]
Community-acquired pneumonia (CAP)	Fever, cough, dyspnea and tachypnea, pleuritic chest pain, abdominal pain, rhonchi [3, 15]	CXR, antigenic testing for RSV and influenza A and B [15]	Hospitalization vs outpatient treatment clinical decision Empiric antibiotic treatment for 7–10 days if the clinical diagnosis favors CAP: oral amoxicillin is the drug of choice for mild CAP; macrolides (azithromycin or clarithromycin) are good alternative for penicillin-allergic patients and are the drug of choice for children 6–18 years old Symptomatic treatment: analgesics antipyretics for fever and pain (acetaminophen or ibuprofen) [15]

(*continued*)

Table 1 (continued)

Diagnosis	Signs and symptoms	Diagnostic test	Management
Acute bronchitis/ bronchiolitis	For bronchitis: Cough (lasting more than 7–10 days up to 3 weeks in older children) and or wheezing; no fever; no nasal congestion or rhinorrhea; no respiratory distress For bronchiolitis: Cough, fever, rhinorrhea, wheezing, labored respirations, occasional hypoxia [16, 17]	For bronchitis: Clinical diagnosis; no tests are necessary For bronchiolitis: No laboratory or imaging needed for diagnosis; selected severe cases need admission to hospital with work-up as clinically appropriate [16, 17]	For bronchitis: No antibiotics as routine empiric treatment Symptomatic treatment: NO antitussives or expectorants, may use corticosteroid inhalers for wheezing Alternative therapies (*see treatment of cold symptoms in this table*) For bronchiolitis: Clinical decision: hospitalization according to risk factors and severity, fluid hydration, oxygen as needed, palivizumab only used according to strict guidelines, NO albuterol, NO epinephrine, NO systemic corticosteroids, NO antibiotic Rx unless there is evidence of concomitant bacterial infection [16–18]
Epiglottitis	Toxic appearance, alteration in voice, severe sore throat and dysphagia, stridor, drooling [3]	Clinical diagnosis Occasionally lateral neck X-ray and WBC count if clinical diagnosis is unclear [3, 17]	Needs immediate evaluation at appropriate site and ENT consultation [3]
Croup	Hoarseness, barking cough, low-grade fever, different degrees of respiratory distress (e.g.,, nasal flaring, respiratory retraction, inspiratory stridor) [3, 19]	Clinical diagnosis Only selected severe or atypical cases need work-up to rule out other causes [19]	General care: keep child calm, comfortable positioning; AVOID croup tent; oxygen if hypoxia; systemic corticosteroids (dexamethasone); nebulized epinephrine for severe cases [19]

recognize the signs of a serious illness early (respiratory distress, low level of responsiveness and activity, dehydration and vomiting, meningeal signs, and the presence of petechiae or purpuric rash) [3]. A diagnosis of viral URI also must be differentiated from a group of diagnoses that require specific management (Table 1 summarizes these diagnoses, their clinical presentation, diagnostic methods, and principles of their management).

The most important strategy in management of the common cold is education of patients, parents, and caregivers; they should be educated on prevention, comfort measures, and treatment recommendations. Handwashing or the use of hand sanitizers has been recommended as the best method to prevent the spread of viral upper respiratory infection; in addition encouraging breastfeeding and evaluation of day-care conditions for children have shown reduction in duration and severity of ARTIs. Comfort measures commonly used by parents, including some of complementary therapies listed in Table 1, are good choices that may help to control the symptoms and avoid the unnecessary use of antibiotics which are not indicated in the treatment of viral URTIs. Parents should be advised against the use of OTC cold and cough medicines for children younger than 6 years of age both because of the lack of benefit and also the potential harm that these preparations can result in. In addition parents should be educated about the

DOI 10.1007/978-1-4939-0779-3_18-1

office call-back instructions (If fever lasts 3 days or more, symptoms worsen after 3–5 days or if new symptoms appear, or if symptoms have not improved or resolved after 7–10 days) [3, 8].

Acute Bacterial Rhinosinusitis (ABRS)

Though most viral ARTIs involve the paranasal sinuses, only a small minority are complicated by bacterial sinusitis (6–8 %), and the majority of ABRS follow viral URTIs. Diagnosis of ABRS is made based on the clinical picture. The color of nasal discharge cannot be relied on to differentiate between a viral or bacterial etiology. ABRS is usually caused by *Haemophilus influenzae*, and *Moraxella catarrhalis*, or *Streptococcus pneumoniae*. Antibiotic use remains the mainstay of treatment in the latest Infectious Diseases Society of America (IDSA) guidelines. Neither antihistamines nor decongestants are recommended because they are unlikely to be of benefit and may have adverse effects [10, 20].

Group A Streptococcal Pharyngitis (GAS)

GAS is the most common bacterial cause of acute pharyngitis, responsible for 20–30 % of pharyngitis in children. Accurate diagnosis of streptococcal pharyngitis followed by appropriate antimicrobial therapy is important for the prevention of acute rheumatic fever and for the prevention of suppurative complications (e.g., peritonsillar abscess, cervical lymphadenitis, mastoiditis, and, possibly, other invasive infections). The signs and symptoms of GAS and nonstreptococcal pharyngitis overlap so broadly that accurate diagnosis on the basis of clinical grounds alone is unreliable. Therefore, it is advisable for family physicians to follow the ISDA clinical practice guidelines for proper diagnostic test use and antibiotic prescription for all children with GAS where possible (Table 1) . In addition to viral pharyngitis, other less common or rare causes of pharyngitis must also be considered when the tests for GAS are negative, or the clinical picture is suggestive. Infectious mononucleosis caused by Epstein-Barr virus and diphtheria caused by *Corynebacterium diphtheriae* are examples [12].

Acute Otitis Media (AOM)

AOM is usually a complication of eustachian tube dysfunction that occurs during a viral upper respiratory tract infection. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* are the most common organisms isolated from middle ear fluid. Accurate diagnosis in the updated American Academy of Pediatrics (AAP) guideline endorses stringent otoscopic criteria for diagnosis. Otitis media with effusion (OME) is defined as middle ear effusion in the absence of acute symptoms. If OME is suspected and the presence of effusion on otoscopy is not evident, pneumatic otoscopy, tympanometry, or both should be used to make the diagnosis. AAP guidelines recommend against antibiotic use in OME and also provide detailed guidelines of appropriate antibiotic use in children diagnosed with AOM [13, 21].

Respiratory Syncytial Virus Infections (RSV)

Respiratory syncytial virus (RSV) causes respiratory tract infections in children. Lower respiratory tract infections (e.g., bronchiolitis, pneumonia) are more common in children younger than 2 years, whereas upper respiratory tract infections tend to affect older children. Since previous infection does not protect children against reinfection, it is common for the family doctor to see patients with repeated RSV infections. Adherence to the American Academy of Pediatrics clinical practice guidelines for the diagnosis and management of bronchiolitis can decrease unnecessary diagnostic testing and intervention. In most previously healthy children, an RSV infection is self-limited and responds to supportive care. Children with unrepaired cardiac disease or chronic lung disease are at increased risk of severe RSV infection. Premature children and the very young (less than 3 months old) tend to be more at risk of having severe symptoms and therefore may require hospitalization.

Table 2 Differential diagnosis of viral exanthems in children

Viral exanthem	Etiology/ infectivity	Clinical manifestations/ incubation period (IP)	Diagnostic methods	Treatment	Prevention	Complications
I macular and maculopapular exanthems						
Measles (rubeola) [22, 23]	RNA measles virus/highly contagious	IP:10–12 days Prodrome: fever, coryza, conjunctivitis, rhinorrhea, sore throat, and a dry cough Enanthem: Koplik' s spots Exanthem: 3–4 days later, begins behind the ears and hairline area, spreads over the rest of the skin over few days, resolves in the same order as its appearance, and will often desquamate	Clinical presentation Serum measles IGM test for confirmation	No specific antiviral therapy for measles Treatment of symptoms	Measles vaccine alone or as part of MMR vaccine	Transient immune suppression Acute postinfectious encephalitis Subacute sclerosing panencephalitis (SSPE)
Rubella (German measles) [22, 24]	RNA rubella virus/highly contagious	IP: 3–4 weeks Prodromal symptoms, which include low-grade fever, headache, sore throat, and myalgias Exanthema stage: appears after 2–5 days and spreads in a cephalocaudal pattern Symmetrical lymphadenopathy in postauricular and occipital areas, arthralgias, and arthritis	Serum rubella IGM titer test	No specific antiviral therapy for rubella Supportive treatment	Rubella vaccine alone or part of MMR vaccine	Congenital rubella syndrome (deafness, cataracts, and cardiac disease)
Erythema infectiosum (fifth disease) [22]	DNA Parvovirus B19	IP: 1–2 weeks First stage: fiery-red facial erythema (slapped cheeks) Second stage: 3–4 days later (rash over proximal extremities) Third stage: exanthem recurs intermittently in response to stimuli (local irritation, high temperatures, and emotional stress)	Clinical Diagnosis ELISA test highly sensitive; however, false positive results may recur PCR test is available	Supportive At-risk patients may require transfusions or intravenous immunoglobulin therapy	No specific preventive measure Handwashing might be helpful during epidemics	Transient aplastic crisis, chronic red cell aplasia, hydrops fetalis, or congenital anemia

		Asymmetric large joint arthropathy (10 % of patients)				
Roseola infantum	Human herpesvirus (HHV) types 6 and 7	IP:5–15 days High fever (3–5 days),followed by the acute onset of a rosy pink, nonpruritic macular rash, predominantly on the neck and trunk; leukopenia	Clinical diagnosis No available standardized lab test	Supportive treatment	No specific preventive measures	Febrile seizures
II vesicular and pustular exanthems						
Varicella (chickenpox) [22, 25]	DNA varicella zoster virus (VZV) Highly contagious during IP and active skin rash	IP: 2–3 weeks Two different clinical presentations: Varicella manifestations: Prodromal stage: fever, malaise, and myalgias Exanthem stage: begins in the hairline and spreads in a cephalocaudal pattern, involving the scalp and mucous membranes, vesicle crust (within 4–5 days of onset of the initial lesion), older lesion crust over as newer lesions form (polymorphous exanthema); lesions may heal with hypopigmentation and scarring Herpes zoster (shingles) manifestation: unilateral vesicular skin eruption involving one to three dermatomes, may be painful or pruritic Usually a benign, mild, self-limiting disease (in immunocompetent individuals)	Clinical Diagnosis Can be confirmed by skin scraping testing for the antigen with immunofluorescence	Oral acyclovir (ACV) is not routinely recommended except for adolescents (for 5 days, starting within 24 h of rash development) Symptomatic treatment for fever (only use acetaminophen) and pruritus (calamine lotion and colloidal oatmeal baths)	Varicella vaccine	Immunocompetent children: bacterial superinfection, due to group A *Streptococcus* or *Staphylococcus aureus* Immunocompromised patients are at risk for severe and protracted varicella, multiorgan involvement, and hemorrhagic varicella
Hand, foot, and mouth disease	Coxsackie A16 virus, other Coxsackie,	IP: 3–7 days Prodrome: fever, lymphadenopathy Exanthem: 1–2 days later	Is a clinical diagnosis Can be confirmed by	No specific treatment Symptomatic	No specific measures Handwashing, surface	Rare: neurological or cardiopulmonary complication

(*continued*)

DOI 10.1007/978-1-4939-0779-3_18-1

Table 2 (continued)

Viral exanthem	Etiology/ infectivity	Clinical manifestations/ incubation period (IP)	Diagnostic methods	Treatment	Prevention	Complications
(HFMD) [22]	and enteroviruses	painful vesicles on the palmar and plantar skin, buccal mucosa, and tongue Resolves in 5–7 days	isolating the virus from vesicles		cleaning, and disinfection	(meningoencephalitis or myocarditis)
III Papular exanthem, e.g., papular acrodermatitis of childhood (PAC) [22]						
IV Other viral exanthems, e.g., pityriasis rosea, erythema multiforme, nonspecific viral exanthems [22]						

DOI 10.1007/978-1-4939-0779-3_18-1

Supportive treatment, including hydration, good airway management, and oxygenation, is the mainstay of RSV management [17, 18].

Croup/Epiglottitis

Croup is a syndrome that includes spasmodic croup (recurrent croup), laryngotracheitis (viral croup), laryngotracheobronchitis, and laryngotracheobronchopneumonitis, with recurrent and viral croup being the most commonly encountered. The incidence of croup often peaks during the fall season, although sporadic cases may occur throughout the year. Croup is usually caused by viruses, with parainfluenza virus (type 1) being the most common. Other viruses that cause croup are enterovirus, human bocavirus, influenza A and B viruses, respiratory syncytial virus, rhinovirus, and adenovirus.

Both recurrent croup and viral croup have the same clinical presentation, with the exception that recurrent croup tends to recur and typically lacks associated symptoms of respiratory tract infection. Although croup tends to have a benign course, a differential diagnosis of more serious but less common conditions must be entertained. Bacterial tracheitis may result from a secondary infection, most often due to *Staphylococcus aureus* or *Streptococcus pneumoniae*, and usually leads to a more toxic appearance, with higher fever and severe respiratory symptoms. Bacterial tracheitis does not respond to usual croup treatment. Intravenous antibiotics are needed, and intubation may become necessary. Epiglottitis (supraglottitis) is a life-threatening bacterial infection of the upper airway almost always caused by *Haemophilus influenzae* type b (Hib). The incidence has declined dramatically as a result of the use of Hib vaccine. Other diagnoses to consider include foreign body aspiration, peritonsillar abscess, retropharyngeal abscess, and angioedema [19]. Principles of management of croup and epiglottitis are summarized in Table 1.

Viral Exanthems

An exanthem is a widespread erythematous rash that is accompanied by systemic symptoms such as fever, headache, and malaise. In children, exanthems are usually associated with infections, and viral infections are the most common. Determining the cause of an exanthem is based on the characteristic morphology, distribution and time course of the eruption, and a careful assessment of infectious contacts, immunization status, and aspects of the physical examination. Table 2 shows the common skin rash morphologies associated with viral infections, their causative agents, clinical presentation, diagnostic tests needed, treatment and prevention methods, and complications. Although uncommon, serious acute illnesses with skin rash must be identified immediately; for example, a skin rash in a child with meningeal signs is an indicator of life-threatening condition (meningococcemia) that warrants immediate hospital referral and treatment. Kawasaki disease also is a childhood illness with rash that must be diagnosed and treated early to ensure better prognosis. The classic viral exanthems have been discussed; other important skin rashes related to viral infections and bacterial infections (e.g., scarlet fever), in addition to other noninfectious causes such as drug eruptions, must be considered in the differential diagnosis. New viral-associated exanthems have been identified; papular acrodermatitis of childhood (PAC) is now recognized to be a manifestation of a number of infectious agents, including viruses. The ability to detect parvovirus B19 virus in seronegative patients using PCR has been useful in linking the virus to erythema infectiosum, as well as other viral exanthems. The viral role in another group of exanthematous disease is yet to be fully identified (e.g., Kawasaki disease, pityriasis rosea, and erythema multiforme) [22, 26].

DOI 10.1007/978-1-4939-0779-3_18-1

Kawasaki Disease (KD)

KD is an acute vasculitis of childhood that predominantly affects the coronary arteries. An infectious etiology is suspected based on epidemiological and clinical data; however as of today, the cause of KD remains unknown. In the United States, KD is more common during the winter and early spring months, in boys more than girls, in children younger than 5 years old, and in children of Asian ethnicity [27]. The classic clinical presentation of KD includes at least 5 days of fever plus four or more of the five major clinical features (conjunctival injection, erythema of the lips and oral mucosa, polymorphous skin rash, cervical lymphadenopathy (with one of the nodes being at least 1.5 cm in diameter),and swelling or redness of the extremities). The classic peeling of the fingers and toes (starting in the periungual region) usually does not occur until 2–3 weeks after onset of symptoms. In addition, classic KD can be diagnosed with three of the above clinical features if coronary artery abnormalities are observed on echocardiography. "Incomplete KD" refers to patients who do not fulfill the classic criteria and is more common in children younger than 1 year. In this group, the rate of coronary artery aneurysms is paradoxically higher if not treated. Some children with KD develop coronary artery aneurysms or ectasia, ischemic heart disease, and sudden death. Therefore early clinical suspicion and diagnosis are important [28]. Nonspecific lab tests such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may suggest the diagnosis of Kawasaki disease because they are often unusually highly elevated. In patients with compatible features, and elevated CRP levels or ESR, supplemental laboratory test results are often seen (these include leukocytosis with shift to the left, mild anemia, thrombocytosis, proteinuria and sterile pyuria on urine analysis, hypoalbuminemia, and elevated serum transaminases). Cardiac manifestations for any suspected case of KD might be detected earlier by performing echocardiography. Initial treatment with a single dose (2 g per kg) of intravenous immunoglobulins (IVIG) and high-dose aspirin (80–100 mg per kg per day, divided into four doses) is recommended. Treatment is preferably started as soon as possible, optimally within the first 10 days of fever; however, treatment is still recommended if patients present after 10 days and still have fever and manifestations of inflammation. Low-dose aspirin (3–5 mg per kg per day, given as a single dose) has an antiplatelet effect and should be continued for 6–8 weeks after disease onset if there are no coronary artery abnormalities or indefinitely if abnormalities are present. Children on long-term aspirin therapy should receive an annual influenza vaccination. Also, parents should be told to contact their physician if symptoms of influenza or varicella arise, because alternative agents to aspirin might be considered. Children who have Kawasaki disease without evidence of abnormalities on echocardiography appear to return to their usual state of health without any cardiac sequelae. The current American Heart Association guidelines provide a stratification system to categorize patients by their risk of myocardial infarction and provide guidelines for management [27, 28].

Gastrointestinal Infections

Acute Gastroenteritis

Although often considered a benign disease, acute gastroenteritis remains one of the major causes of morbidity and mortality in children around the world, accounting for 10.5 % of deaths among children younger than 5 years of age [29].

Etiology

By far, viruses remain the most common cause of acute gastroenteritis in children, both in the developed and developing world. Rotavirus represents the most important viral pathogen worldwide; it is responsible for 20–60 deaths per year in the United States and up to 500,000 deaths from diarrhea worldwide [30].

DOI 10.1007/978-1-4939-0779-3_18-1

Viral infections, primarily from rotavirus, cause 75–90 % of infectious diarrhea cases in the industrialized world. Bacterial pathogens cause another 10–20 % of cases, with as many as 10 % of these occurring secondary to enterotoxigenic *Escherichia coli* (e.g., traveler's diarrhea). Parasites such as *Giardia intestinalis* and *Cryptosporidium* cause fewer than 5 % of cases [31]. In the United States, routine rotavirus vaccination has led to a 60–75 % reduction in pediatric rotavirus hospitalization since 2006. With the continued decline of rotavirus-associated gastroenteritis, noroviruses (Norwalk-like viruses) have become the leading cause of medically attended acute gastroenteritis in children younger than 5 years in that country [32].

Clinical Picture

The clinical presentation is the mainstay of diagnosis, and therefore careful history and physical examination will serve to differentiate gastroenteritis from other causes of vomiting and diarrhea in children. These will also help in estimating the degree of dehydration. Diarrhea is the main presenting symptom and is usually defined as three or more watery or loose stools in 24 h. The duration of diarrhea, the frequency and amount of stool, the time since the last episode of diarrhea, and the quality of stools must also be determined. Frequent, watery stools are more consistent with viral gastroenteritis, while stools with blood or mucous are indicative of a likely bacterial pathogen. Similarly, a long duration of diarrhea (>14 days) is more consistent with a parasitic or noninfectious cause of diarrhea. Vomiting is another important symptom, the duration of vomiting, the amount and quality of vomitus (e.g., food contents, blood, bile), and the time since the last episode of vomiting must be determined. Signs of systemic infection must be noted (fever, chills, myalgias, rash, rhinorrhea, sore throat, cough). Abdominal pain is another important symptom that the child or parent can report; in general, pain that precedes vomiting and diarrhea is more likely to be due to an abdominal pathology other than gastroenteritis. Urinary symptoms including frequency (measured by the number of wet diapers), time since last urination, color and concentration of urine, and presence of dysuria should be sought. Some important points in the general appearance and behavior are important to determine the degree of dehydration and subsequent management (weight loss, level of thirst, level of alertness, increased malaise, lethargy or irritability, quality of crying, and presence or absence of tears with crying). Travel history and recent antibiotic use are other important points in the history that may suggest the possibility of traveler's diarrhea or *C. difficile* infection [31, 33].

Management

Signs and symptoms of dehydration are important to determine the severity of dehydration. Both the Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics (AAP) recommend using a simple dehydration scale to classify the total body water loss occurring with dehydration as minimal/none (<3 %), mild/moderate (3–9 %), or severe (>10 %). Abnormal capillary refill (>2 s), decreased skin turgor, and abnormal respiratory pattern (hyperpnea) have been the most reliable signs of determining the severity of dehydration. The vast majority of children presenting with acute gastroenteritis do not require serum or urine tests, as they are unlikely to be helpful in determining the degree of dehydration. Laboratory values may be helpful in evaluating severe dehydration, for which intravenous fluids and electrolyte supplementation (especially potassium, bicarbonate, and sodium) are needed [31, 34]. Prevention of dehydration is the cornerstone of gastroenteritis treatment in children. A child with minimal or no dehydration should be encouraged to continue his or her usual diet plus drink adequate fluids. Early oral rehydration therapy using an oral rehydration solution (ORS), before the child becomes more severely dehydrated, is important and can be done at home.[5] The best way to accomplish early treatment is to train the physician's office staff to explain how to use an ORS when caregivers call for help at the beginning of a child's illness. Clear liquids, such as water, sodas, chicken broth, and apple

DOI 10.1007/978-1-4939-0779-3_18-1

juice, should not replace an ORS because they are hyperosmolar and do not adequately replace potassium, bicarbonate, and sodium. These fluids, especially water and apple juice, can cause hyponatremia. An ORS is composed of sodium, dextrose, and bicarbonate in a ratio that does not overwhelm the hyperactive bowel with a hyperosmolar solution, but that replaces the electrolyte loss. In general, antidiarrheal medications should not be used in children with acute gastroenteritis because they delay the elimination of infectious agents from the gastrointestinal tract

Prevention

Handwashing has been shown to reduce the incidence of gastrointestinal illness. Rotavirus vaccine is recommended as a routine immunization at 2, 4, and 6 months of age [35].

Pinworm Infestation (Enterobiasis)

Pinworm infection is caused by a small, thin, white roundworm called *Enterobius vermicularis*. Although pinworm infection can affect anyone, it most commonly occurs among children, institutionalized persons, and household members of persons with pinworm infection. Pinworm is the most common worm infection in the United States. Humans are the only species that can transfer this parasite. Pinworm eggs can survive in the indoor environment for 2–3 weeks. People who are infected with pinworm can transfer the parasite to others for as long as there is a female pinworm depositing eggs on the perianal skin. A person can also re-infect themselves [36, 37].

Clinical Presentation

A person infected with pinworm is often asymptomatic. However, perianal itching is the most common presentation. When the infection is heavy, it can present as a secondary bacterial infection in the perianal area due to the irritation and scratching. Often the patient will complain of bruxism and insomnia due to disturbed sleep. Infection of the female genital tract has been reported [36, 37].

Diagnosis and Treatment

Because of the life cycle of the pinworm, eggs and worms are often scarce in the stool; therefore, examining stool samples is not recommended. Identifying pinworm can be done by finding the female worm, which is about 10 mm long, in the perianal region 1 or 2 h after a child goes to bed at night, or by using a low-power microscope to identify ova on cellophane tape. The ova are obtained in the early morning before the child arises by patting the perianal skinfolds with a strip of cellophane tape, which is then placed sticky side down on a glass slide and viewed microscopically. This procedure should be repeated on five successive mornings; if necessary, eggs may also be identified by examining scrapings from underneath the patient's nails.

Any one of three antiparasitic medications (mebendazole, pyrantel pamoate, and albendazole) can be used for treatment. A single dose of any of these medications is given followed by another single dose 2 weeks later. The medications do not reliably kill pinworm eggs. Therefore, the second dose is to prevent re-infection by adult worms that hatch from any eggs that are not killed by the first treatment. Repeated infections should be treated by the same method as the first infection. In households where more than one member is infected or where repeated, symptomatic infections occur; it is recommended that all household members be treated at the same time. In institutions, mass and simultaneous treatment, repeated in 2 weeks, can be effective. Handwashing after using the toilet, changing diapers, and before handling food is the most successful way to prevent pinworm infection. In order to help prevent the spread of pinworm and possible re-infection, people who are infected should bathe every morning to help remove many of the

DOI 10.1007/978-1-4939-0779-3_18-1

eggs on the skin. Showering is a better method than taking a bath, because showering avoids potentially contaminating the bath water with pinworm eggs. Infected people should not co-bathe with others. Infected patients also must cut their fingernails regularly and avoid biting the nails and scratching around the anus. Frequent changing of underclothes and bed linens first thing in the morning is a great way to prevent possible transmission of eggs in the environment and risk of reinfection. These items should not be shaken and carefully placed into a washer and laundered in hot water followed by a hot dryer to kill any eggs that may be present [36, 37].

Attention Deficit/Hyperactivity Disorder

Attention deficit/hyperactivity disorder (ADHD) is a disorder of poor attention and/or impulse control that typically present in early childhood and has significant impact upon child functioning across environments. It is comprised of three different subtypes, ADHD-Predominately Inattentive, ADHD-Predominately Hyperactive/Impulsive, and ADHD-Combined, based upon presentation of symptomology.

ADHD: Predominately Inattentive

ADHD-Predominantly Inattentive is comprised of nine criteria, and six or more criteria must be present for at least 6 months. These symptoms must differ from normal developmental patterns and have a significant impact upon daily functioning. For children 17 years and older, only five of the nine criteria must be met for diagnosis [1].

Criteria include:

1. Poor attention to details and/or makes careless errors
2. Difficulty maintaining attention in daily activities, mind wanders
3. Appears distracted, does not appear to listen
4. Difficulty following/completing instructions, starts but does not complete tasks
5. Difficulty with organization, difficulty with sequential tasks, does not meet deadlines
6. Avoids activities that require sustained effort/focus
7. Frequently loses important items (homework assignments, books, extracurricular items)
8. Easily distracted by external activities
9. Forgetful in day-to-day activities, poor memory for obligations [1]

ADHD: Predominately Hyperactive/Impulsive

ADHD-Predominantly Hyperactive/Impulsive is comprised of nine criteria, and six or more criteria must be present for at least 6 months. These symptoms must differ from normal developmental patterns and have a significant impact upon daily functioning. For children 17 years and older, only five of the nine criteria must be met for diagnosis [1].

Criteria include:

1. Fidgety, difficulty sitting still, fine-motor hyperactivity in fingers/hands/legs
2. Leaves seat when expected to remain seated (classroom, dinner table)
3. Runs around and/or climbs on items (furniture, people), older children are restless
4. Excessively loud during activities, inability to play quietly
5. Moves frequently, unable to remain still, restless, appears to have excessive energy
6. Excessively talkative, does not share "talk-time"
7. Answers questions before they are completed, speaks out of turn, interrupts others
8. Difficulty waiting for their turn in activities
9. Interrupts others activities (disrupts others conversations or activities, uses other peoples things without permission, takes over/leads others activities without permission) [1]

ADHD: Combined Presentation

ADHD-Combined Presentation is comprised of 18 criteria, and 12 or more criteria must be present for at least 6 months. These symptoms must differ from normal developmental patterns and have a significant impact upon daily functioning. For children 17 years and older, only ten of the 18 criteria must be met for diagnosis [1].

To meet criteria for the disorder, symptoms must be present prior to 12 years of age, and impairments must be present in at least two environments (home, school, community, and/or employment for older teens) although symptom severity may vary across environments. Prevalence rates of ADHD in children range from 5 % to 8.5 %, and a portion of children with the disorder report symptoms into adulthood [1]. Symptoms of hyperactivity/impulsivity typically

present during the toddler years, while symptoms of inattention are identified once the child enters school, and symptoms impede academic performance [1–3]. Symptoms of hyperactivity tend to decrease with age, while symptoms of impulsivity and inattention remain constant. ADHD is twice as common in males compared to females, and males have higher rates of hyperactivity/impulsivity, while females have higher rates of inattention [1]. Rates of ADHD are higher in children with first-degree relatives who also have an ADHD diagnosis. Children with ADHD are at an increased risk for cognitive (lower academic attainment), behavioral (increased impulsive behaviors, incarceration), emotional (difficult interpersonal relationships), and psychological (conduct disorder, personality disorders, substance use) impairment compared to peers without ADHD [1–3].

ADHD: Cognitive-Behavioral Treatments

There are multiple cognitive-behavioral treatment (CBT) strategies to manage the symptoms of ADHD. It is preferred that CBT strategies be implemented prior to medication management and should be noted that CBT strategies may require a substantial time investment prior to observing symptom reduction. For symptoms that are severe and significantly influence the child across environments, it may be appropriate to implement both CBT strategies and medication management simultaneously and then decrease medication management as CBT methods become more consistently implemented and effective. Children with ADHD should be provided with tasks in small, manageable segments to increase the likelihood of success. Parents should provide verbal directions in developmentally appropriate language, and the child should repeat the directions to assure comprehension. Directions should be provided one at a time, and parents may advance to multi-step commands once symptoms are more manageable [2, 3]. Behavioral charts and token economies are affordable and efficient methods to monitor and manage ADHD symptoms. Behavioral charts should be developed for both home and school environments and elsewhere as appropriate. Children should be involved in determining problematic behaviors to decrease, desirable behaviors to increase, and consequences (positive and negative) for these behaviors. When children are involved in this process, they are more likely to be invested in behavioral change and to be motivated by the consequences [2, 3].

ADHD: Medication Management

Stimulant medications are typically prescribed for children with ADHD as these medications are affordable and fast acting with an immediate decrease in symptoms. The general rule with stimulant medications, especially in children, is to begin with the lowest possible dose and monitor for both improvements in symptomology and the presence of negative side effects (changes in sleep, appetite, irritability, etc.). If the child tolerates the medication with minimal and manageable side effects, then the dose may be increased in small intervals until a therapeutic level is obtained. Extended release (XR) medications are preferable to immediate release (IR) medications for several reasons. First, XR medications are taken once daily, typically with the morning meal at home prior to the beginning of the school day, and this limits social embarrassment for the child who must leave the classroom midday for a second dose of IR medications. Secondly, XR medication effects do not dissipate midday, compared to IR medications, at which time symptoms resume and may cause impairment. Thirdly, XR medications have lower abuse potential, and this should be considered when prescribing to children or adolescents at risk for medication abuse or diversion. Parental abuse or diversion of child IR medications is also a concern and should be considered. For children with severe ADHD symptoms, an evening IR medication may manage symptoms during homework assignments or afterschool activities. These medications should initially be started on a weekend compared to a school day to allow parents to monitor ADHD

symptoms and side effects and acclimate the child to the medication prior to use within the school environment. Psychosocial education should be provided regarding taking ADHD medications at the appropriate time due to impact upon sleep. Families should be encouraged to adhere to medication holidays on the weekends, school holidays, and summer breaks if possible. If medication holidays are observed, then prescriptions should be written for a 20–24-day supply instead of the standard 30-day supply. Parents should be educated regarding the potential for abuse or diversion, and medications should be kept in a safe location and monitored.

There are two approved stimulant medications for children 3 years of age and older (Adderall and Dexedrine) and multiple stimulants medications for children 6 years of age and older (Adderall, Concerta, Daytrana, Desoxyn, Dexedrine, Focalin, Intuniv, Metadate, Methylin, Ritalin, Strattera, and Vyvanse) [4]. Medication use prior to 3 years of age is discouraged due to developmental concerns.

Learning Disabilities

Learning disorders (LD) primarily affect cognitive functioning, although behavioral and emotional functioning are also impacted. There are three types of learning disorders, impairment in reading, written expression, and/or mathematics, based upon symptomology. Learning disorders are comprised of six criteria and one or more symptoms must be present for at least 6 months. Symptoms must differ from normal developmental patterns and have a significant impact upon daily functioning despite intervention [1].

Criteria include:

1. Imprecise, protracted, labored reading
2. Difficulty comprehending the significance of what has been read
3. Difficulties with spelling
4. Difficulties with written expression/writing structure
5. Difficulties understanding mathematic concepts
6. Difficulties understanding mathematical theory [1]

Symptoms of LD fall on a continuum from normal developmental difficulties when learning new material to abnormal behaviors that exceed expected difficulties when learning new material. Children must perform beneath academic expectations as corroborated by standardized intellectual and/or achievement assessments. Prevalence rates across all three types of learning disorders range from 5 % to 15 % in school-aged children [1]. Symptoms typically present during early school-age years when fundamental academic skills are being taught. However, the extent of symptomology may not become prominent until later academic years when exceedingly difficult educational endeavors are impacted by limited academic skills [1]. Symptoms are chronic without substantial academic intervention. Learning disorders are two to three times more common in males compared to females [1]. Rates of LDs are higher in children with first-degree relatives who also have LDs. Environmentally, children's academic attainment mirrors parental academic attainment. Children with LD are at an increased risk for cognitive (lower grades, less likely to graduate), behavioral (disruptive behavior trying to avoid cognitively demanding tasks), emotional (frustration, tearful), vocational (under-employed, unemployed, lower salary), and psychological (anxiety) impairment compared to peers without LDs [1, 5].

Learning Disorders: Cognitive-Behavioral-Emotional Treatments

Prior to implementing cognitive-behavioral treatments (CBT), it is crucial that the child completes intellectual and achievement standardized assessment to ascertain the specific types of learning difficulties as this will direct treatment planning. Based upon assessment results, providers will likely be requested to complete paperwork (504 Plans, Individual Educational Plans, and/or Student Assistant Team Plans) for academic accommodations. Tutors for educational needs

and a child psychologist/psychiatrist may be helpful in providing support for the child/family as they manage these disorders. Parental psychosocial education is invaluable to decrease parental anxiety/worry regarding the diagnosis and provide methods parents may employ to support their child as they manage symptomology. Cognitive components focus upon managing children's negative self-cognitions and altering teaching methods to be more effective for the child. Behavioral components include distributing assignments into more management segments, providing clear directions for assignments, assisting the child with mastering academic concepts, providing extra time to complete assignments and advance knowledge of major assignments, and implementing consequences (positive and negative) for effort and successes [5]. Emotional regulation components include teaching methods to self-soothe when frustrated or anxious such as progressive muscle relaxation and controlled breathing techniques.

Learning Disorders: Medication Management

At present, there are no medications that reduce the symptoms of learning disorders. However, medications may decrease symptoms of comorbid disorders, such as attention deficit/hyperactivity disorder or anxiety disorder, which may impede the learning process.

Temper Tantrums

Temper tantrums frequently occur during childhood and typically consist of verbal, physical, and emotional components. There are no specific or minimal criteria for this disruptive behavior. Components of temper tantrums will vary by developmental and chronological age and may evolve over time.

Components include:

1. Verbal: screaming/shouting, yelling, arguing, crying, whining, fussing
2. Physical: throwing self on floor, kicking, stomping feet, hitting self or others, hitting or throwing objects, biting self or others, breaking items, running away, pushing/pulling, pouting or other facial expressions
3. Emotional: anger, sadness, frustration, fear [6–10]

The age of onset, duration, frequency, and severity of temper tantrums should be considered when rendering a diagnosis. The majority of children engage in temper tantrums with age of onset occurring most frequently between 2 and 4 years of age, but temper tantrums may continue into adolescence [7, 8]. Prevalence rates of temper tantrums decrease with age as children more effectively manage their verbal, physical, and emotional responses to events [11]. Temper tantrums persisting past 5 years of age, lasting longer than 15 min, consisting of severe behaviors, and occurring in excessive of five times daily are likely indicative of abnormal development [7]. Temper tantrums are either reactive (responding to an event) or proactive (initiating an event) [12] and function to express an emotional response to an event, seek parental attention, avoid completing an undesired task, or to obtain a desired item [7]. Due to children's limited coping strategies, these emotional responses manifest as inappropriate verbal or physical behaviors [7, 8].

Temper Tantrums: Cognitive-Behavioral-Emotional and Medication Treatments

The treatments for temper tantrums, oppositional defiant disorder, and conduct disorder are similar and are located under conduct disorder.

Oppositional Defiant Disorder

Oppositional defiant disorder (ODD) is a pattern of angry or irate mood, argumentative and/or defiant behaviors, and/or spitefulness. There are eight

criteria, and four or more criteria must be present for at least 6 months and have a significant impact upon daily functioning. For children 4 years and younger, symptoms must be present on most days per week. For children 5 years and older, symptoms must be present at least once weekly [1].

Criteria include:

Anger/irate mood
1. Frequently loses temper
2. Easily aggravated
3. Angry and bears grudges

Argumentative/Defiant
4. Argues with others (peers, adults, authority figures)
5. Intentionally refuses to comply with reasonable requests from authority figures
6. Intentionally engages in annoying behaviors
7. Blames others for their misconduct

Vindictiveness
8. Spiteful or revengeful toward others at least twice in the last 6 months [1]

Symptoms of ODD fall on a continuum from normal developmental behaviors (conflict with siblings/peers and parents/authority figures) to abnormal behaviors (chronic, frequent, severe behaviors) that cause significant impairment. Prevalence rates of ODD range from 1 % to 11 % with an average of approximately 3 % in children [1]. ODD is 1.4 times more common in males compared to females, but equal rates are reported between genders in adolescence [1]. Rates of ODD are higher in children from household environments with harsh, unpredictable/unstable, and/or neglectful parenting practices. Rates of ODD are also higher in children raised in fragmented environments (foster care, kinship care, etc.) or multiple households (divorced parents). Children with ODD are at increased risk for difficulties across environments including home (family members, romantic partners), employment (supervisors, work colleagues), and community (coaches, religious persons) impairment compared to peers without ODD [1].

Temper Tantrums: Cognitive-Behavioral-Emotional and Medication Treatments

The treatments for temper tantrums, oppositional defiant disorder, and conduct disorder are similar and are located under conduct disorder.

Conduct Disorder

Conduct disorder (CD) is a chronic and continual pattern of behaviors in which social norms are violated and the basic rights of others are disregarded. There are 15 criteria and three or more criteria must be present for the last 12 months with at least one criteria present in the last 6 months. There are three disorder subtypes based upon age of onset including childhood onset (at least one symptom prior to 10 years of age), adolescent onset (no symptoms present until 10 years of age), and unspecified onset (unable to determine age of onset) [1].

Criteria include:

Aggression toward people/animals
1. Frequently engages in bullying, threatening, or intimidation practices
2. Instigates physical altercations
3. Used an instrument (weapon) that could cause life-threatening injury
4. Physically aggressive toward people
5. Physically aggressive toward animals
6. Stolen property while engaged in confrontation with an individual (mugging, etc.)
7. Forced others into sexual activities

Destruction of property
8. Engaged in arson with the intent of causing personal or property damage
9. Intentionally destroyed other's property (other means than arson)

Deceitfulness or theft
10. Illegally entered someone's home, building, or automobile
11. Uses deceit to attain items/favors or to avoid punishment/obligations
12. Stolen property while not engaged in confrontation with an individual (shoplifting, etc.)

Serious violations of rules

13. Breaks parental curfews prior to 13 years of age
14. Ran away from home at least twice or once staying away for an extended period of time
15. School truancy prior to 13 years of age [1]

Prevalence rates of CD in children are difficult to determine. Approximately 3–7 % of children and adolescents demonstrate verbal/physical aggressive behaviors, but these behaviors may not be sufficient to warrant a CD diagnosis [12]. Symptoms often present in early childhood but become problematic in middle childhood and adolescence, and symptom onset after 16 years of age is uncommon [1]. Individuals with this disorder typically first had a diagnosis of ODD. Rates of CD are higher in males compared to females [1]. Rates of CD are higher in children with first-degree relatives who also have a CD diagnosis. Environmentally, rates of CD are higher in children from household environments with harsh, unpredictable/unstable, neglectful parenting practices, excessive discipline, abuse, frequently changing caregivers, and a history of parental criminal behavior [1]. Community factors influencing CD symptoms include peer rejection, membership in delinquent peer groups, and high rates of community violence. Children with severe CD symptoms are at an increased risk for cognitive (negatively interprets events, overly suspicious of others), behavioral (verbal/physical altercations, poor self-regulation), emotional (poor emotion regulation, easily frustrated, irritable), psychological (substance abuse), and legal-social (extensive legal issues, incarceration, engagement in high-risk activities) impairment compared to peers without CD [1].

Temper Tantrums, ODD, and CD: Cognitive-Behavioral-Emotional Treatments

There are multiple cognitive-behavioral treatments (CBT) and emotional regulation strategies to manage symptoms of temper tantrums, ODD, and CD. These treatments vary in intensity dependent upon the severity of the disorder. Parent training is crucial as parenting practices, such as being too lenient/too strict, lack/excess of parental monitoring, poor parental role modeling, parental difficulties with stress management, lack of parental consistency, and/or developmentally inappropriate child expectations have a significant impact upon children's disruptive behaviors [12]. These behaviors also increase when children lack a routine, experience unexpected changes to routines, or when the child is tired, hungry, or ill. Parenting styles should be modified to be more effective, less critical, and enhance the parent–child relationship [12]. For minor behaviors, parents may ignore the behavior unless the child or another person is in danger and address the behavior once it has subsided. Children with verbal/physical aggression frequently misperceive events as intentionally aggressive, and treatment components are derived from this belief system. Cognitive components including increasing perspective taking, evaluating their contribution to events, improved communication skills, negotiation strategies, social skills development, and developing multiple, more efficacious methods to manage events. Behavioral components include working with the family to develop household/school/community expectations and consequences (positive and negative) for compliance or noncompliance with these expectations. Emotional components include learning methods to decrease symptoms of anger, such as progressive muscle relaxation and controlled breathing, and by increasing emotional range by identifying, labeling, and expressing emotions appropriately [13–16].

Temper Tantrums, ODD, and CD: Medication Management

At present, there are no medications that reduce the behaviors labeled as temper tantrums, ODD, and CD. However, medications may reduce symptoms of comorbid disorders, such as anxiety disorder or depressive disorder, which may affect symptomology. Providing medications that have abuse potential, particularly to those with ODD

and CD such as stimulants for ADHD, should be carefully considered.

Specific Phobias

Phobias are classified within anxiety disorders and are an unreasonable and disproportionate fear response to an item/event. There are several criteria for specific phobia, but no minimum criteria are required to meet a diagnosis.

Criteria include:

1. Anxiety regarding a specific item or event, in children this is typically manifested by crying, tantrums, immobilization, or attaching to a security figure.
2. The item/event typically elicits an immediate anxiety response.
3. There is an attempt to avoid the item/event or the item/event is tolerated with extreme anxiety.
4. The anxiety response is disproportionate to the realistic threat of harm to the item/event.
5. The anxiety response or avoidance of item/event is present for at least 6 months.
6. The anxiety response or avoidance impacts functioning across environments.

Types of specific phobias:

1. Animals (snakes, dogs, spiders, etc.)
2. Natural environment (storms, thunder/lightening, heights, water, hurricanes, earthquakes, etc.)
3. Blood-injection-injury (dentist, doctor, needles, etc.)
4. Situational (airplanes, elevators, etc.)
5. Other (clowns, darkness, vomit, choking, etc.) [1, 17]

Specific phobia may present after experiencing a trauma, observing others experience a trauma, experiencing an unexpected panic reaction to an item/event, or information transmission of an event. Children do not typically realize that the fear is unreasonable although older children and adolescents may recognize their fear response is disproportionate [17]. Prevalence rates of specific phobias are approximately 5 % in children and 16 % in adolescents [1]. Specific phobias typically present between 7 and 11 years of age and decrease with age but may remain present in adulthood [1]. Specific phobias are twice as common in females compared to males [1]. Females are more likely to experience animal, natural environment, and situational phobias compared to males [1, 17]. There are no gender differences in blood-injection-injury phobias [1, 17]. Rates of specific phobias are higher in children with first-degree relatives who also have a specific phobia diagnosis. Environmental influences include overprotective parenting practices, loss/separation from parental figure, child abuse and neglect, and past negative interactions with the item/event. Individuals with blood-injection-injury phobia are less likely to access necessary medical treatments. Individuals with specific phobias are at increased risk for experiencing difficulties in home, employment, and community activities.

Specific Phobia: Cognitive-Behavioral-Emotional Treatments

Cognitive-behavioral treatment (CBT) options are similar to those implemented for anxiety. Cognitive restructuring involves identifying negative thoughts regarding specific phobias, challenging negative thoughts with evidence, and changing the thoughts to be more accurate. Behaviorally, the child should receive instruction on relaxation techniques, such as controlled breathing and progressive muscle relaxation, to implement during exposure exercises and decrease physiological response to the phobia. Emotion regulation strategies include expanding emotional range (fear) from all-or-none thinking to understanding that emotions exist on a spectrum and, hence, emotional responses also exist on a spectrum. Once CBT and emotional regulation strategies have been mastered, a hierarchy of exposure exercises related to the specific phobia, ranging from minor to major, should be developed and implemented coupled with CBT strategies to desensitize the phobia [17].

Specific Phobia: Medication Management

There are no medications for specific phobias, and treatment options should primarily focus upon CBT options. If the child's specific phobia is present along with anxiety, then a medication may be considered once CBT methods have been implemented and residual symptoms remain. Often an SSRI may reduce symptomology. However, in children only fluoxetine is currently approved by the FDA, and there is concern for an increased risk of suicidal ideation/actions in this age group [12].

Tics

Tics are motor, vocal, or a combination of both and occur as a sudden movement or uttered sound during otherwise normal behaviors. Tics are often repetitive with multiple repetitions of the same movement or sound. They may be classified as simple, such as eye blinking or nose twitching, or complex, with a series of movements in the same sequence. Tourette's syndrome is the most severe of the tic disorders and involves motor and vocal tics. Children with tics usually have awareness of the urge to engage in the motor or vocal tic and may temporarily be able to suppress this urge. Prevalence rates of tics range from 5 % to 25 % in school-age children, with chronic tics occurring in fewer than 1 in 500 children. The age of onset is typically between 5 and 18 years of age and most commonly occurs between 7 and 10 years of age [18]. Tics wax and wane and generally tend to decrease with age. Rates of tics are higher in children with first-degree relatives who also have a tic disorder diagnosis. Tic disorders are more common in male children compared to female children. The age of onset, duration, frequency, and severity as well as whether tics are motor, vocal, or combined should be considered. These factors help determine whether tics are the transient type that occur in up to 25 % of children or are more worrisome. Early onset, severe, multifocal tics that cannot be suppressed are more likely to indicate a secondary cause and should be investigated. Motor and phonic tics may indicate Tourette's syndrome. Abrupt onset, persistent tics and those that are more severe should prompt a search for secondary causes. Most tics are mild in severity, but even mild symptoms can affect children across environments. Transient tics can occur in chronic tic disorder, postinfectious autoimmune neuropsychiatric disorder associated with strep or postencephalitis states. Tics often occur with ADHD and are also a common side effect of ADHD medication. Tourette's syndrome can be associated with behavioral problems, ADHD, OCD, and learning disabilities [18, 19].

Tics: Cognitive-Behavioral and Medication Treatments

Cognitive-behavioral treatments (CBT) may be helpful with or without the use of medications. Tics may be treated with typical neuroleptics such as pimozide (Orap) or haloperidol (Haldol), atypical neuroleptic/antipsychotics such as risperidone (Risperdol) or aripiprazole (Abilify), or some antihypertensives such as clonidine or guanfacine (Intuniv) [18, 19].

Stuttering

Stammering or stuttering is a speech flow or fluency disorder in which speech patterns are disrupted by involuntary repetitions and prolongation of sounds, syllables, words, or phrases as well as involuntary silent pauses or blocks during which the child is unable to produce sounds. The origin of stuttering is unknown, but causes may include stressful life events or lack of grammar skills. Stuttering may also result from medical conditions, brain injury or trauma, mental health problems, or emotional trauma. Stuttering usually occurs across home, school, and/or work environments. Stuttering disorder typically presents in childhood and may be transient or lifelong; 75 % of preschoolers who stutter report symptom remission as they age. Stuttering is four times more common in males compared to females.

Risk factors for stuttering include first-degree relatives with stuttering disorder, the presence of other speech or language disorders, and fear about stuttering on the part of the child or family. Stuttering increases in frequency and severity if the person is excited, tired, or under stress. In situations in which they may feel self-conscious, hurried, or pressured, the symptoms may worsen. Large groups or talking on the telephone may be difficult for many people who stutter. Children with stuttering disorder are at increased risk for academic (lower participation rates), emotional (low self-esteem), social (avoidance of speaking situations), peer (risk for being bullied, teased), employment (passed up for promotion), and psychological (difficult communication patterns, anxiety, phobia) impairment compared to peers without stuttering disorder [20, 21].

Stuttering: Cognitive-Behavioral Treatments

Goals of treatment include increasing the child's ability to speak fluently, communicate effectively, and participate fully in daily activities. A certified speech and language pathologist utilizing a series of standardized assessments should evaluate stuttering. Evaluations should include the frequency and timing of disfluencies, speech rate and language skills, and child reactions and coping strategies regarding disfluencies. Speech and language therapy teaches specific skills to improve oral communication including controlling and monitoring the rate of speech, practicing smooth fluent speech at a slow rate, and using short sentences and phrases. Follow-up and maintenance treatments are important to maintain treatment gains [20, 21].

Thumb-Sucking

Thumb-sucking is a developmental behavior found in infants. At birth, infants reflexively suck on objects placed in their mouths. Sucking during feedings provides pleasure, comfort, and warmth, and sucking on the thumb, finger, or pacifier becomes associated with a strong oral sensation of soothing and pleasure. Ultrasounds have shown thumb-sucking behavior in utero, as early as 15 weeks gestation. The sucking reflex disappears at about 4 months of age. Since thumb-sucking is not purely reflexive, so it may persist but typically resolves by 5 years of age. There are no differences in thumb-sucking rates between genders [22]. Children who suck their thumbs, especially older children, are at an increased risk for social (bullying, teasing), communication (deficits due to pronunciation difficulties), psychological (stress, anxiety), and medical (dental disorders, open bite, high-arched palate, and infections) problems compared to peers who do not suck their thumbs [22–24].

Thumb-Sucking: Cognitive-Behavioral Treatment and Medication Management

Dental evaluation and intervention of thumb-sucking is necessary if the permanent teeth are presenting and there is alteration in dentition or if the child is embarrassed by the habit. Dental interventions include the use of special mouth guards and over-the-counter products that are bitter tasting and can be applied to the nails to deter thumb-sucking. Cognitive-behavioral treatments (CBT) include identification and management of triggers such as stress or fatigue and offering the child an alternate comfort measure (hugs, reassuring words, pillow or stuffed animal). Furthermore, use of positive reinforcement (extra bedtime stories, reward board with stickers) in conjunction with verbal reminders regarding the behavior without scolding, criticizing, or ridiculing may reduce thumb-sucking. Use of a special verbal or physical signal when parents identify the behavior in public can help avoid embarrassment. Peer pressure may also assist with cessation of thumb-sucking in older children [22–24].

Nail-Biting

Onychophagia, or nail-biting, is a common childhood behavior that is difficult to modify. Approximately 23 % of 3–6-year-olds and 50 % of

10–18-year-olds in the USA engage in nail-biting at some time point. Most people cease biting their nails by 30 years of age without intervention [25]. Nail-biting is more common in males compared to females, especially after 10 years of age. Nail-biting is classified under obsessive-compulsive and related disorders [1] and involves putting the nail into the mouth so that contact occurs with one or more teeth. Mild forms have been compared to nervous habits such as fidgeting. More severe forms may result in physical damage and could be considered self-mutilating behavior. Nail-biting may occur in times of stress, excitement, boredom, or inactivity and may be an unconscious activity that occurs when involved in another activity such as reading, watching TV, or talking on the phone. Children with a first-degree relative who has a mental health disorder are at an increased risk for nail-biting. Nail-biting may be seen with other stereotypical behaviors including lip biting, bruxism, head banging, skin biting, and hairpulling. Nail-biting may be present in children with ADHD, ODD, OCD, separation anxiety disorder, enuresis, tic disorder, intellectual disability, major depressive disorder, and pervasive developmental disorder. Medically, nail-biting may result in infection around the cuticles, damaged or bleeding nails, damaged gums, and digestive system problems if the nails are swallowed. Prolonged nail-biting can lead to deformity of the nail from damage to the nail bed. In severe cases, the nail is bitten until it is lost, then the fingers are bitten, and the cuticle and nail bed skin is chewed [25, 26].

Nail-Biting: Cognitive-Behavioral Treatments and Medication Management

The majority of people who engage in nail-biting are motivated to treat this behavior and have often tried, without success, to stop nail-biting. Nail-biting is difficult to treat and medications and habit reversal treatments have not shown consistent long-term effectiveness. Cognitive-behavioral treatments (CBT) include identification and management of stressors, alternative behavior substitution, stimulus control therapy, keeping nails trimmed and filed, wearing gloves or adhesive bandages, snapping rubber bands on the inside wrist as a negative physical response, and identification and treatment of comorbid psychological conditions (anxiety, OCD, impulse control disorders) that impact symptomology. There are several over-the-counter products that are bitter tasting and can be applied to nails to deter from nail-biting behaviors [25].

Pica

Pica is a disorder characterized by the consumption of non-food items that do not have nutritional value and are not culturally sanctioned.

Criteria include:

1. Repeated eating of non-food substances (e.g., chalk, clay, cloth, coal, dirt, gum hair, metal, paint, paper, pebbles, soap, string, or wool) for at least 1 month.
2. The eating behavior is inappropriate to the patient's developmental level and is not culturally or socially supported.
3. If the eating behavior occurs in the context of another mental disorder (e.g., autism, intellectual disability, or schizophrenia) or general medical condition (including pregnancy), the severity of the eating behavior warrants additional clinical attention.

Pica is more common in children, pregnant women, and in low-socioeconomic populations. In children, there are no significant gender rate differences. Cultural practices may be associated with the ingestion of a nonnutritive substance. For example, in African cultures, the ingestion of kaolin (white clay) is common and is not associated with psychopathology. Depending on what is ingested, complications such as lead poisoning, infections, and bowel obstructions may occur. Pica may also occur with anemia or with lower than normal nutrient levels, and as such hemoglobin, iron, and zinc levels should be evaluated [27].

Pica: Cognitive-Behavioral Treatments and Medication Management

If the pica is not culturally based, treatment of any underlying nutrient deficiency is the first step in treatment. Once all nonpsychotic causes for pica are eliminated, the use of SSRIs may be considered. Positive reinforcement of normal behavior and aversion therapy has been used [27].

Sleep Disturbances

Sleep disturbances, including insomnia, nightmares, sleep terrors, and sleepwalking, are common childhood disorders. Prevalence rates vary, but estimates are that at least half of all children will experience a sleep disorder at some time [28].

Sleep Disturbances: Insomnia

Insomnia is defined as difficulty with sleep onset, sleep maintenance, and/or early wakening.

Criteria include:

1. Difficulty with one or more of the following:
   (a) Difficulty with sleep onset (in excess of 20–30 min to fall asleep)
   (b) Difficulty maintaining sleep, frequent awakenings with difficulty returning to sleep (awakening for 20–30 min and unable to return to sleep)
   (c) Early morning awakenings and difficulty returning to sleep (wakening at least 30 min earlier than expected, unable to return to sleep, and obtaining less than 6.5 h of total sleep)
2. Sleep difficulties cause significant distress across environments.
3. Occurs three or more nights weekly.
4. Occurs for at least 1 month (specify: episodic) or 3 months (specify: persistent).
5. Sleep difficulties occur despite having enough sleep time scheduled.
6. Insomnia is not better accounted for by another disorder [1].

Insomnia typically presents in early adulthood but does present in childhood and adolescence on occasion. Insomnia is more prevalent in females compared to males, and children with anxiety tend to have higher rates of insomnia. Insomnia can be situational or chronic with episodes of reoccurrence and is strongly influenced by environmental stressors. Children with insomnia tend to have poor sleep hygiene habits, including spending excessive amounts of time in bed not sleeping, inconsistent sleep schedule (lacks regular sleep-wake times), and napping during daytime hours [1, 28–30].

Sleep Disturbances: Sleepwalking and Night Terrors

Sleepwalking, night terrors, and nightmare disorder are classified as parasomnias and are reflective of central nervous system immaturity.

Criteria include:

1. Recurrent episodes of partial wakening from sleep, typically occurring in the first third portion of the sleep cycle, accompanied by one or both of the following:
   (a) Sleepwalking: Recurring episodes of leaving the bed while still asleep and walking around the room, house, etc. During these episodes, the individual has a "blank face," does not respond verbally to others efforts to communicate, and is difficult to wake.
   (b) Night terrors: Recurring episodes of extreme fear that occur while asleep and results in immediate wakening, usually with a frightening scream. Usually accompanied by physiological factors such as rapid heart rate, rapid breathing, and sweating. The individual is difficult to calm during these episodes.
2. Little to none of the dream sequence is remembered.
3. Amnesia to the event.
4. Disorder is not better accounted for by another disorder [1].

Sleepwalking

Sleepwalking episodes are typically brief, less than 10 min, but can last up to 1 h in duration. The primary diagnostic feature is motor movement occurring during a sleep phase, which usually comprises leaving the bed and walking around the residence, but on occasion leaving the residence has been noted. Upon wakening, the individual is initially confused but quickly regains appropriate cognitive and behavioral functions. While sleepwalking, children may engage in normal, daily activities. Prevalence rates of children with at least one episode of sleepwalking range from 10 % to 30 %, with 2–3 % of children sleepwalk frequently, and prevalence rates decrease with age. Rates of sleepwalking are higher in females compared to males. Rates of sleepwalking are higher in children with a first-degree relative with a history of sleepwalking and/or night terrors [1, 28, 30].

Sleep Terrors

Sleep terrors are typically brief, less than 10 min, but can last longer, especially in children [1]. During these episodes, the individual experiences intense fear, resulting in physiological and behavior responses. Their eyes are often open, giving the appearance they are awake when they are not. The child is difficult to awaken and/or comfort, and once awakened, they have amnesia or only fleeting images of the night terror. Typically, the child will sit up in bed and scream and cry inconsolably. They report a feeling of fear and desire to escape. Sleep terrors typically occur only once nightly although they can, on rare occasions, occur several times nightly. Sleep terrors are uncommon during daytime nappings. Sleep terrors are more common in males compared to females in childhood. Prevalence rates are 37 % at 18 months of age and 20 % at 2.5 years of age, and rates tend to decrease with age. Rates of sleep terrors are higher in children with a first-degree relative with a history of night terrors or sleepwalking. Children with sleep terrors are at increased risk for cognitive (poor concentration, academic underperformance), behavioral (falling asleep in class), and psychological (anxiety, depression, mood liability) impairment compared to peers without sleep terrors [1, 28, 30].

Sleep Disturbances: Nightmare Disorder

Criteria include:

A. Recurring episodes of lengthy, unsettling, and well-remembered dreams with typical themes including evading threats to well-being, sense of security, or injury that usually occurring during the second half of sleep.
B. Upon wakening, the individual typically becomes cognitively alert and is able to describe their nightmare in great detail.
C. Symptoms are not better accounted for by another disorder.

Prevalence rates of nightmare disorder range from 1 % to 4 % in preschool children, and rates increase in adolescence. Nightmare disorder is twice as common in females compared to males [1]. Age of onset is typically between 3 and 6 years of age with rates peaking during late adolescence and subsequently decreasing. Nightmares may occur several times nightly and also during daytime naps. Nightmares tend to be lengthy, intricate, and story-like sequences of dreams that the child is able to recall, appears realistic, and results in a negative emotional state. Nightmares typically involve some degree of fear and avoiding or coping with a perceived threat to safety. Children often experience mild physiological symptoms including increased heart rate, breathing, and sweating [1, 28–30]. Nightmare disorders increase with environmental, family, and community stressors. Children with fevers and sleep deprivation have higher rates of sleep disorders [1]. Children with nightmare disorder are at an increased risk for social (peer rejection), behavioral (daytime sleepiness, aggression, poor impulse control), psychological (anxiety,

depression), and cognitive (academic impairment, slowed reaction times, decreased memory, poor attention) impairments compared to peers without nightmare disorder [1, 28–30].

Sleep Disturbances: Cognitive-Behavioral Treatments

There are multiple cognitive-behavioral treatments (CBT) to reduce sleep disturbances. Prior to implementing CBT strategies, the child's sleeping environment and routine should be assessed. Information gathered should include sleep-wake cycles and nap times and is the child given adequate opportunity to obtain sufficient amounts of sleep with the presence of a bedtime routine that is calming and predictable, does the child have their own bed, and do they feel safe when they are asleep.

Cognitive factors, including acute and chronic psychosocial stressors, should be addressed including home, school, and community factors and children's perception of their sleep disorder. Behavioral factors include establishing and enforcing sleep-wake cycles that do not vary by more than 1 h daily, eliminating co-sleeping if present, minimizing or eliminating caffeinated beverages after lunchtime, engaging in calming activities 1 h prior to bedtime, modifying the sleep environment to be dark and quiet, eliminating the use of electronic devices 1 h before sleep time and no access to electronics during sleep times, and maintaining a sleep diary to assess for sleep patterns [29]. Emotional regulation components include teaching methods to self-soothe when frustrated or anxious such as progressive muscle relaxation and controlled breathing techniques.

Musculoskeletal Problems of Children

Trista Kleppin[a]*, Teresa Cvengros[b] and George G. A. Pujalte[c]
[a]Mount Sinai Hospital, Chicago, IL, USA
[b]Family Medicine Residency, Department of Family and Community Medicine, Mount Sinai Hospital, Chicago, IL, USA
[c]Department of Family and Community Medicine, Mount Sinai Hospital in Chicago, Chicago, IL, USA

Most family physicians see many musculoskeletal complaints in their office, but they should be aware that children have some conditions that are unique and may not be encountered in adults. This chapter will discuss generalized and regional musculoskeletal conditions, including fracture patterns, gait concerns, and overuse issues encountered among children and adolescents.

Generalized Musculoskeletal Conditions

Common Fracture Patterns

Physeal Fractures

Fractures involving the growth plate of children are called "physeal fractures." These need to be managed with care because they may result in premature closure of the growth plate. Typically, these injuries occur in girls 9–12 years old and boys 12–15 years of age, with fractures of the distal radius, distal tibia, and distal fibula being the most common [1]. Physeal fractures are usually diagnosed using plain radiographs, often with the help of comparison x-rays of the nonaffected limb. They are generally categorized according to the Salter-Harris classification [2] (Fig. 1). A useful mnemonic is [3]:

- S ("Straight across") – Type I
- A ("Above") – Type II
- L ("Lower" or "BeLow") – Type III
- T ("Two" or "Through") – Type IV
- E ("End") or ER ("ERasure of the growth plate") – Type V

Management will depend upon the location of the fracture, but, generally, all types are managed in consultation with orthopedic specialists. The lower numbered Salter-Harris fractures tend to have fewer complications and better outcomes. A nondisplaced Type I or II fracture is usually immobilized and casted. However, if they are displaced, they will need reduction within 1 week of the injury, followed by immobilization with casting for 3–4 weeks. Salter-Harris types III-V need prompt orthopedic evaluation because they usually require open reduction. Nonsteroidal anti-inflammatory drugs (NSAIDs) are usually used for pain management, although there are studies that indicate that acetaminophen may be better, as NSAIDs have been shown to be detrimental to bone healing.

Buckle Fractures

Buckle fractures are sometimes referred to as "torus fractures." These fractures result from longitudinal compression, such as that which occurs when one falls on an outstretched hand. The bony cortex does not

*Email: tklep0021@gmail.com

DOI 10.1007/978-1-4939-0779-3_20-1

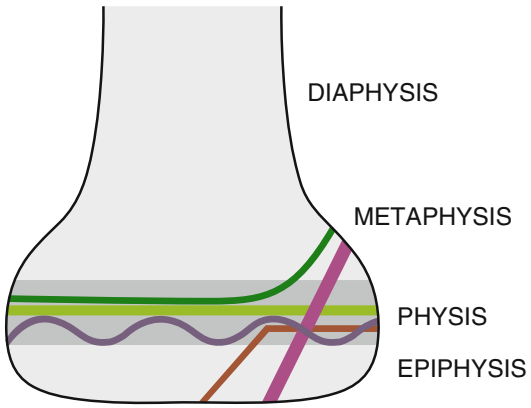

Fig. 1 Salter-Harris classification is defined by the location of the fracture relative to the growth plate (*the gray zone*). Type 1 (*yellow*) is a separation of the growth plate (*STRAIGHT across*). Type 2 (*green*) is a fracture ABOVE the growth plate into the metaphysis. Type 3 (*orange*) is a fracture that extends LOWER than the growth plate into the epiphysis. Type 4 (*pink*) is a fracture that extends THROUGH the epiphysis, physis and metaphysis. Type 5 (*purple*) is a fracture that "ERASES" the growth plate due to compression injury (Image adapted from mnemonic, which was reprinted from Ref. [3], Copyright (1999), with permission from Elsevier)

actually break [1]. The most common sites are the distal radius, distal tibia, fibula, and femur. Splinting is usually sufficient as buckle fractures are generally stable. However, they should be followed by an orthopedist. Casting may be done for 3 weeks to ensure healing if the child is likely to be noncompliant with the splint or if he/she is extremely active.

Plastic Deformation Fractures

A plastic deformation fracture occurs when the longitudinal forces overcome a bone's ability to recoil, leading to a bowing deformity. The most common locations are the ulna, radius, and fibula. Simple casting for 4–6 weeks is indicated if the deformation is less than 20° or the child is under 4 years old, as the angulation will self-correct. Reduction and/or surgical intervention may be needed if the deformation is greater than 20° or if the child is over 4 years old [4].

Greenstick Fractures

Greenstick fractures are fractures that do not extend completely through a bent bone, breaking one cortical surface without disrupting the other side. These fractures are considered unstable and have high rates of re-fracture [5]. The most common location of a greenstick fracture is the forearm. Orthopedics referral is needed, with regular follow-ups. Nondisplaced forearm fractures should be splinted until seen by an orthopedist for casting in a long arm cast for 3–4 weeks, followed by short arm casting for another 2–3 weeks [6].

Apophyseal Avulsion Fractures

Common apophyseal injuries such as Osgood-Schlatter disease, Sinding-Larsen-Johansson syndrome, and Sever's disease increase the risk of apophyseal avulsion fractures; repeated traction on the fibrocartilage can lead to a portion being pulled off the bone [7]. Most avulsion fractures, such as tibial tuberosity and inferior pole of the patella, result from an acute injury. These fractures need to be immobilized and often warrant an orthopedic referral to evaluate for the need for surgical intervention, to remove or reattach the avulsed bone, especially if there is displacement.

Table 1 Stress fracture sites

Low risk sites	High risk sites
Second to fourth metatarsal shafts	Pars interarticularis of lumbar spine
Posteromedial tibial shaft	Femoral head
Proximal humerus	Superior side of femoral neck
Ribs	Patella
Sacrum	Anterior cortex of tibia
Pubic rami	Medial malleolus
	Tarsal navicular
	Proximal fourth and fifth metatarsal
	Great toe sesamoids

Table 2 Risk factors for stress fractures

Modifiable	Nonmodifiable
Low physical activity	Female
Increasing volume and intensity of physical activity	Irregular menses
Low BMI	Older age
Low dietary calcium intake	Prior stress fracture
Poor biomechanics	Family history of osteopenia or osteoporosis

Stress Fractures

Stress fractures are most commonly seen in young females but may also affect males. They are caused by overuse,which leads to microfractures. The majority of patients are able to attribute the onset of pain to a recent increase in activity level. On exam, there will be tenderness over the affected bone, with or without surrounding edema. However, if it is difficult to palpate the local area of bone due to overlying tissues, applying stress on the bone that is suspected to be involved may elicit pain, thereby making the diagnosis of stress fracture more likely. Plain radiographs maybe ordered. However, these usually remain normal until 2 weeks after the onset of pain. If there is a high clinical suspicion with negative radiographs, magnetic resonance imaging (MRI), a bone scan, or a single photon emission computed tomography (SPECT) scan may be ordered, especially if time is a factor, as when a sports event is looming. Management will depend on the site of fracture. Conservative treatment with ice, acetaminophen, limited weight-bearing, and splinting is done for low-risk sites, whereas fractures in high-risk sites (Table 1) should be evaluated by an orthopedist [8]. Identifying modifiable risk factors (Table 2) when a stress fracture is suspected is extremely important for the management and prevention of another one.

Apophyseal Injuries (Apophysitis)

Apophysitis of the Hip

An apophyseal injury of the hip occurs in active adolescents, usually athletes in track, soccer, or gymnastics [9]. The injury can involve the anterior superior and anterior inferior iliac spines, iliac crest, or ischial tuberosity (Fig. 2). Typically, the patient will present with a dull pain in the hip that is associated with activity, with or without a history of trauma. On examination, there may be some localized tenderness. If a bruise is present, an avulsion fracture should be suspected. Radiographs of the hip and pelvis are usually obtained to rule out other causes of hip pain. Treatment is based on severity of symptoms but must include avoidance of the aggravating activity. If limping is predominant, limitations on weight bearing can be made. Children and adolescents should be enrolled in a rehabilitation program

DOI 10.1007/978-1-4939-0779-3_20-1

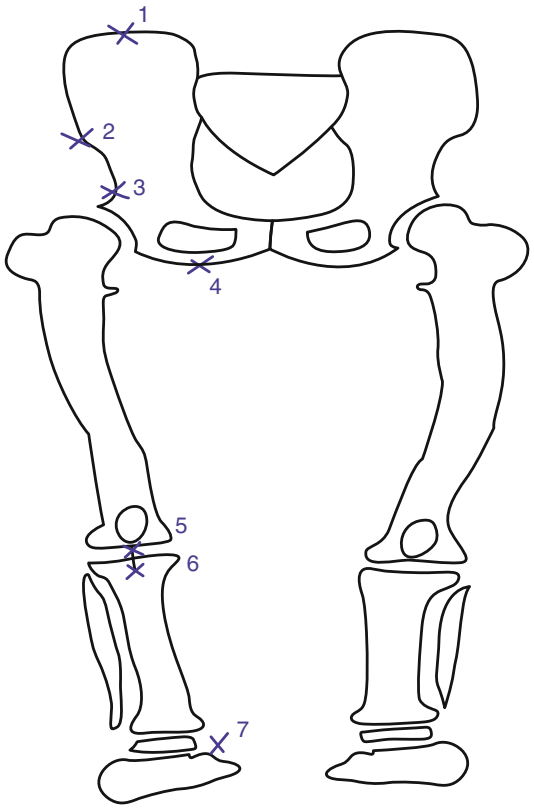

Fig. 2 Apophysitis locations. *1*. Iliac crest; *2*. Anterior superior iliac spine; *3*. Anterior inferior iliac spine; *4*. Ischial tuberosity; *5*. Inferior pole of patella (Sinding-Larsen-Johansson); *6*. Tibial tuberosity (Osgood-Schlatter disease); *7*. Calcaneus (Sever's disease)

focused on stretching and strengthening. Return to play should only be advised once full range of motion is achieved without pain, which may take anywhere from 4 to 6 weeks [9].

Sinding-Larsen-Johansson Syndrome

Sinding-Larsen-Johansson syndrome is an apophyseal injury that occurs at the inferior pole of the patella (Fig. 2) after repeated microtrauma [10], usually in boys between the ages of 10 and 12 years old. They may complain of pain that is worse when walking up or down stairs or jumping. Usually, the only abnormal finding upon examination of the knee is tenderness and swelling at the inferior patellar pole. Fragmentation may be seen on anteroposterior (AP) and lateral plain radiographs. Treatment is geared towards pain control with NSAIDs, decreasing the inflammation with ice, and quadriceps rehabilitation. Resolution of symptoms may take 3–18 months [11].

Osgood-Schlatter Disease

Osgood-Schlatter disease is a common cause of gradual-onset anterior knee pain in children aged 9–13 years old. It can lead to limping, usually during growth spurts. Children often describe the pain as worsening with activities such as running, climbing, or jumping, but improving with rest. There is often tenderness to palpation over the tibial tubercle (Fig. 2) and reproduction of pain with resisted knee extension. Sometimes, a prominence may be palpated over the tibial tubercle. Radiographs, AP and lateral views, are usually not necessary but are done to exclude other conditions, especially if the pain worsens at night, which is not typical of Osgood-Schlatter's. The symptoms often resolve once the growth plate has closed. Until then, treatment includes ice, pain control with NSAIDs, and physical therapy [12]. If pain

DOI 10.1007/978-1-4939-0779-3_20-1

persists, referral to orthopedics may be considered for potential injection of 12.5 % dextrose [13] or even surgical removal of the bony prominence. Referral to orthopedics is needed if the patient is unable to lift his/her heel off the table without bending the knee; this suggests an issue with the extensor mechanism which may require surgery [14].

Sever's Disease

Sever's disease is considered an irritation of the calcaneal apophysis (Fig. 2), usually presenting in active adolescents (9–11 year olds) who participate in sports which require a lot of running. The patient will often complain of unilateral or bilateral heel pain related to activity. Examination reveals tenderness of the calcaneal apophysis with weakened dorsiflexion and the gastrocnemius-soleus flexibility can be decreased. Imaging maybe done to rule out other conditions such as a unicameral bone cyst, if symptoms present unilaterally [14]. Management includes rehabilitation exercises and pain management with NSAIDs to help decrease the inflammation. The patient should be advised not to take any pain medication before activities so as not to mask the pain. Return to activities should only be done once pain subsides. Use of a ¼ inch heel lift with icing for 20 minutes per day can also provide relief [14]. Should symptoms persist after 4–8 weeks of treatment, casting for 3–4 weeks may be considered [9].

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) occurs when subchondral bone and cartilage separate from the underlying bone. The most common locations of OCD are the knee and ankle, but it can also occur at the elbow, talus, and distal humerus. The patient will generally describe vague pain associated with swelling, clicking, and sometimes locking that gets worse with activity. On examination, there is tenderness over the lesion. When OCD occurs in the knee, the Wilson test may be positive and there may be an antalgic gait [14]. The Wilson test is performed by having the patient lie supine and extend the knee from a 90° angle while internally rotating the tibia. It is considered positive when there is knee pain as the knee is extended with the tibia internally rotated; however there is no pain when the same maneuver is performed with the tibia externally rotated. The medial femoral condyle will be tender to direct palpation when the knee is flexed to 90°. Plain radiographs should be obtained. If suspected in the knee, tunnel, and lateral views should be included. MRI can be useful to visualize articular cartilage integrity. When the cartilage is intact, management can consist of modifying activity or placing the patient on crutches for 6–8 weeks [15]. Surgery might be needed to avoid early onset of degenerative joint disease if the child is already skeletally mature or if the articular cartilage has some damage. Orthopedic referral is indicated if the lesion is larger than 2 centimeters (cm) because such lesions can lead to complications, including early-onset degenerative joint disease [14].

Growing Pains

Growing pains are the most common cause of episodic musculoskeletal pain in children, with a prevalence of 3–37 %. These nonarticular leg pains occur at night in healthy active children 3–12 years of age, with a peak of 6 years [16]. These leg pains are often felt in the calf, but may also be felt in the foot, ankle, knee, or thigh. The pain episodes may last from minutes to hours. They are usually bilateral and are more common in boys and among children with laxity of the ligaments. The pain may be more likely to occur if the child has been particularly physically active during the day. The etiology is unknown, but it may be an overuse syndrome. There are no associated systemic symptoms such as weight loss, fevers, or fatigue [14]. The diagnosis is based on the clinical picture and a normal physical exam. If there are atypical symptoms, such as unilateral leg pain, further studies such as CT, MRI, x-rays, bone scan, or lab work should be obtained to rule out pathology. The differential diagnoses of growing pains include fractures, osteomyelitis, malignancy, metabolic systemic disease, and osteonecrosis; these should be

DOI 10.1007/978-1-4939-0779-3_20-1

excluded before a diagnosis of growing pains is made [14]. Treatment of growing pains consists of comforting the child, local massage, and analgesics. In a recent study, there was reduction of pain after vitamin D supplementation [17].

Regional Musculoskeletal Conditions

Neck and Back Problems

Spondylolysis and Spondylolisthesis

"Spondylolysis" is defined as the separation of the vertebral pars interarticularis, most commonly at L5, which may be unilateral or bilateral. About 25 % of cases progress to spondylolisthesis, which is the bilateral defect that allows the vertebral body to slip anteriorly. There are several risk factors for spondylolysis including occult spina bifida at S1, Scheuermann kyphosis, and a family history of spondylolysis. These conditions are common among adolescent athletes with repetitive flexion and extension movements of the back, causing an achy back pain that radiates into the buttock and posterior thighs. Symptoms improve with rest but higher grade slips can present with neurologic manifestations, such as urinary incontinence [14].

A positive Stork test suggests spondylolysis (Fig. 3). It is performed by asking the patient to hyperextend his/her back while standing on one leg; a positive test reproduces the back pain [18]. Palpation of the spinous processes can reveal a prominent process, suggesting significant spondylolisthesis. Observation of the gait may reveal high-grade spondylolisthesis in some patients, as they may walk with their hips and knees flexed (the Phalen-Dickson sign [19]). Plain radiographs with AP, weight-bearing

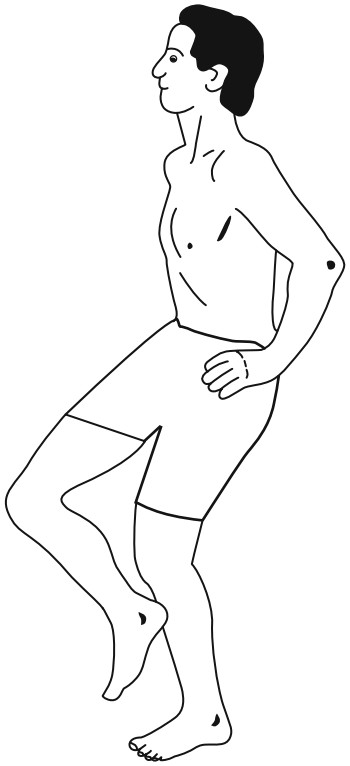

Fig. 3 The Stork Test: Ask the patient to lean backwards while standing on one leg; considered positive if the back pain is reproduced on the same side the patient is standing on

Other defects, such as sclerosis or lysis in the pars, are best visualized in this "neck." (**b**) "Scotty dog." *A* = superior articular process (ear); *B* = pedicle (eye); *C* = pars interarticularis (neck); *D* = lamina (body); *E* = inferior articular process (front leg). (**c**) Severity of spondylolisthesis and slip angle (With kind permission from Springer Science+Business Media: Bracker and Achar [20])

lateral, and oblique views of the lumbosacral spine may help reveal the "Scotty dog" sign (Fig. 4), which is associated with spondylolysis [1]. If not well-visualized, additional imaging may be needed. If neurologic symptoms are present, obtaining an MRI is often helpful.

Symptomatic spondylolysis should be managed with activity restriction, possibly with thoracolumbosacralorthosis (TLSO) for pain management, and aggressive physical therapy. Treatment of spondylolisthesis will depend on the grading of slippage; however, early cases can be managed like spondylolysis. Those with greater than 50 % slippage and who are skeletally mature are candidates for spinal fusion. However, if there are neurologic signs, neural decompression may be needed in addition to spinal fusion [14].

Idiopathic Scoliosis

Idiopathic scoliosis is defined as an abnormal lateral curve of the spine. This is further divided into subcategories based on the age of the child at diagnosis: infantile (0–3 years), juvenile (4–9 years), and adolescent ($\geq$10 years). These children may present after a school screening, which is currently not supported by the United States Preventive Services Task Force (USPSTF), or due to obvious asymmetry of the back, noted by others. It is important to establish when the asymmetry was first noticed, any associated symptoms, and signs of puberty. The Adams forward bend test is commonly used to assess the rotational component of scoliosis, in combination with a scoliometer. The test is done by standing behind the patient, asking the patient to bend forward to reach for his/her toes and then assessing for any asymmetry. When clinically suspected, scoliosis films (standing posteroanterior [PA] and lateral films of the entire spine) are needed to assess for the Cobb angle and skeletal maturity, via the Risser scale (Fig. 5) [22]. Lateral bending films are sometimes obtained for pre-operative evaluation.

When there is low risk for progression in adolescent idiopathic scoliosis, the primary care physician can manage and follow with repeat scoliosis radiographs every 6–9 months. Orthopedic referral is indicated when there is any of the following [23]:

- More than 7° of trunk rotation
- A premenarcheal girl, or a boy between 12 and 14 years old, with a Cobb angle of 20–29°
- A Cobb angle of 30° or more in any patient

DOI 10.1007/978-1-4939-0779-3_20-1

Fig. 5 Measurement of the scoliosis angle (Cobb 1948). Horizontal lines are drawn parallel to the endplates of the neutral vertebrae at the end of the curve. Where perpendicular lines intersect, the angle of scoliosis is measured. In this case, the angle of Cobb measures 32° (From Ludwig K., Nierhoff C [21]. With kind permission from Springer Science and Business Media)

- Any patient with a progression of 5° or more of the Cobb angle

Management of these patients will vary between bracing and surgical intervention. If surgery is performed, activity is usually restricted for several months after surgery.

Scheuermann Disease

Scheuermann disease or juvenile kyphosis is the anterior wedging of at least 5° in three adjacent thoracic vertebral bodies, usually found during early adolescence. It is associated with spondylolysis. It presents with subacute pain that worsens after activity and at the end of the day without a clear precipitating event. Upon examination of the child, a sharp angulation of the thoracic or thoracolumbar spine is observed, especially as the child bends forward. Some may call these patients "hunchbacked." Radiographs of the spine while standing, especially lateral views, are important for diagnosis. If the angulation is less than 60°, conservative management is usually tried, with hyperextension rehabilitation. However, for curves greater than 60°, bracing is often employed for as long as the vertebral end plates are not fused [24].

DOI 10.1007/978-1-4939-0779-3_20-1

Elbow Problems

Osteochondrosis of the Elbow

Osteochondrosis of the elbow is also referred to as "Panner's disease." It is generally found in the dominant arm of young males between the ages of 7 and 12 years old [25]. They may complain of sudden onset lateral elbow pain that is reproducible on palpation. There may be decreased range of motion with extension. Plain radiographs, with AP and lateral views, may show an irregular joint surface with fragmentation of the capitellum. Panner's disease is managed by cessation of activities that place stress on the joint until imaging and physical exam show evidence of full healing, usually in about 6–12 weeks.

Radial Head Subluxation

Subluxation of the radial head is a common injury in preschool children aged 1–4 years old. It is commonly called "pulled elbow" or "nursemaid's elbow" because it occurs from traction on the forearm while pronated and with the elbow extended. The child will have been observed not using the affected arm as usual. For an unknown reason, it is more common in the left arm [26]. On examination, the child is often observed holding the affected arm closely to the body, with the elbow extended. Tenderness is often present over the anterolateral aspect of the radial head. Plain radiographs with AP and lateral views are often obtained to exclude other causes or more serious bony injuries; still, the diagnosis can be made by history and physical exam alone. Management is reduction by either one of two methods: hyperpronation or supination with flexion [27]. In the hyperpronation method, the examiner supports the elbow and places steady pressure on the radial head while gripping the distal forearm with the opposite hand and hyperpronating the forearm. The supination with flexion method is also performed by supporting the arm at the elbow and applying pressure on the radial head but the opposite hand maintains traction on the forearm; in one smooth motion, the elbow is fully supinated and flexed. The child will usually resume normal activity with the arm within 5–10 minutes after reduction. Orthopedic referral is indicated after several failed attempts at reduction, at which point obtaining radiographs and placing the arm in a sling are recommended until evaluation by the specialist.

Gait Abnormalities

Normal Gait and Alignment

In order to recognize abnormal gait, it is important to be able to identify the natural progression of alignment and gait in children. From birth, the legs are slightly in varus (10–15°) and will gradually straighten to the neutral position at around 12–18 months of age. The legs then become valgus, with a peak of around 3–4 years old. By 11 years old, the valgus alignment improves to 5–7° [14]. Normal gait has two phases: stance and swing. These phases should be symmetrical when comparing the lower extremities with the stance taking up 60 % of the time of the entire gait [1].

Metatarsus Adductus

Intoeing is commonly secondary to metatarsus adductus, which is seen more in first children. It is thought to be due to excessive uterine molding from the primigravid uterus. Although the children rarely have symptoms, parents tend to be concerned and may bring them in for a checkup. Examination may show an intoeing gait, often bilateral, and deep medial creases on the feet. Careful evaluation is extremely important since treatment is based on severity. To determine severity, the examiner should use the heel bisector method (Fig. 6), which entails drawing a line that divides the heel in half, and continuing the line to see where it lands in relation to the toes [14]. Normally, the line will fall between the second and third toes. In mild cases, the line will fall in the middle of the third toe. In moderate cases, the line will be

DOI 10.1007/978-1-4939-0779-3_20-1

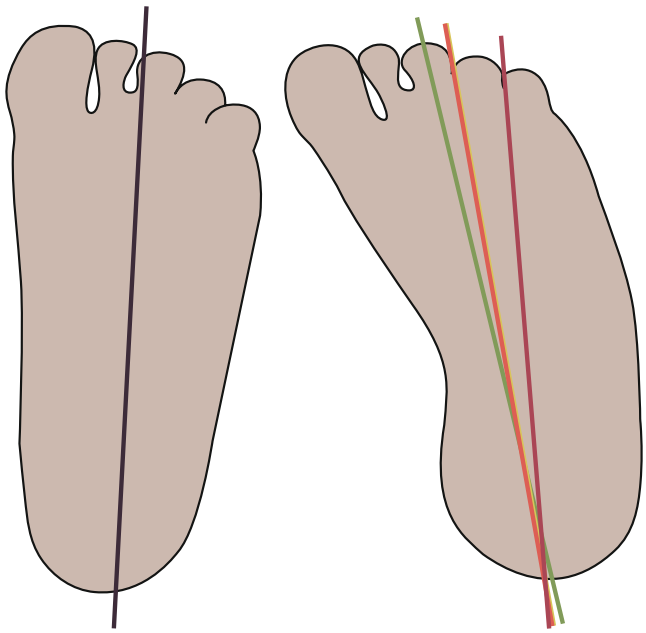

Fig. 6 Heel bisector method for determining metatarsus adductus severity. On the left, shows a normal heel bisector line drawn in black. On the right, a comparison of where the heel bisector line will fall in relation to the toes for mild (*green*), moderate (*orange*) and severe (*red*) metatarsus adductus

between the third and fourth toes. In severe cases, it will fall between the fourth and fifth toes. Imaging is usually not necessary but is done to exclude other causes in toddlers or older children who have persistent symptoms.

The majority of metatarsus adductus cases will self-resolve, but some may need treatment. Mild cases that can be passively corrected should be kept under observation. Stretching exercises should be performed by the parents at each diaper change for moderate cases that can be passively corrected by regularly moving the foot into a neutral position. The exercise entails applying laterally directed pressure on the first metatarsal head for ten seconds. The parent should be instructed to perform it five times a day on each foot [28]. Severe cases that are rigid maybe treated with serial casting for 6–8 weeks, with good outcomes if started before 8 months old.

Tibial Torsion

Internal tibial torsion is a common cause of intoeing in toddlers, and may be associated with metatarsus adductus and genu varum. The thigh–foot angle (TFA) should be estimated by measuring the angle between the longitudinal axis of the femur and the foot (Fig. 7). A TFA greater than 20° is excessive but will normally correct without any intervention at around 5 years of age [29]. Only when the torsion is severe (TFA more than 85°) should surgical intervention be considered.

Femoral Anteversion

Children greater than 4 years old will commonly have in-toeing secondary to femoral anteversion. Sitting in the classic "W" position [30] with their knees together and feet on either side can contribute to the femoral anteversion. While walking, the child's legs appear if they were internally rotated; when running the legs will flip outward ("egg-beater" or "windmill" pattern). The hip will exhibit increased internal rotation with range of motion testing. Radiographs are usually unnecessary. Most cases require nothing more than observation, given that 85 % will spontaneously resolve usually by 11 years of age [31].

DOI 10.1007/978-1-4939-0779-3_20-1

Genu Varus

"Genu varus," also known as "bow-leggedness," is a common concern among parents because of the way it affects the appearance of the child's legs. Genu varus may cause children to walk with intoeing or have frequent falls. Depending upon the age of the child, genu varus could be completely benign, as all children are naturally born bowlegged. Genu varus may persist until the child is about 2 years of age. During this period, the recommended management is simply observation and reassurance. Pathologic causes include conditions such as Blount disease, nutritional rickets, trauma, metabolic bone disease, or even a neoplasm. Physical examination is useful in helping to distinguish pathologic versus physiologic etiologies. Asymmetric bowing with a lateral thrust upon walking is suggestive of a pathologic cause [32]. Radiographs of the entire lower extremity are known as teleograms and should be obtained while standing if suspecting a nonphysiologic cause. If a pathologic cause is found, it is recommended that the child be referred to an orthopedist or the specialist for the underlying etiology. The follow-up for an otherwise physiologic genu varus in a child should be every 4–6 months to ensure resolution.

Blount's Disease

Blount's disease is a pathologic cause of genu varus that is differentiated from physiologic bowing on physical exam and radiographs. Risk factors include African American lineage, early walking, and obesity. These children will present with an asymmetric angular alignment of the lower extremities and walk with a lateral thrust [32]. The teleograms will show the bowing deformity of the proximal tibia and medial beaking, with a downward slope of the proximal tibial metaphysis. There are two subtypes of Blount's disease: infantile and adolescent. The infantile type is usually diagnosed before the age of 4 years old and is bilateral, whereas the adolescent type can be unilateral or bilateral. The infantile type can be managed with braces to decrease the compressive forces and has a better prognosis if treatment begins before 3 years of age. If the varus deformity does not correct with bracing, then a referral to an orthopedist

DOI 10.1007/978-1-4939-0779-3_20-1

is warranted. In contrast, the adolescent form is more appropriately managed by an orthopedist because surgery is more likely as a possible treatment.

Genu Valgus

"Knock-kneedness," or "genu valgum," can also often present to a primary care clinician's office due to parental concern with the appearance of a child's legs and the clumsiness associated with this condition. Occasionally, the child may complain of pain in the knee or foot. Like genu varus, genu valgum is part of the normal progression of development, usually seen between the ages of 2 and 5 years old. When there are no other concerns of a potentially pathologic etiology such as trauma, a systemic condition, or a neoplasm, observation and reassurance is recommended. Worsening genu valgum after 4 years of age should raise suspicion regarding a pathologic cause. Clues found upon physical examination that make a pathologic cause more likely include [32]:

- Unilateral genu valgum
- Height that is below the third percentile
- Greater than 8 cm between the medial malleoli when the knees are extended, patellas pointed straight, and the femoral condyles are touching
- A medial thrust on ambulation

Similar to genu varus, when a pathologic cause is suspected, it is appropriate to obtain teleograms. The parents should be reassured if physiologic genu valgum is suspected, as it generally self-corrects when the patient is between 4 and 7 years of age. However, obese children should be followed regularly since they run a higher risk of developing worsening genu valgum [14]. Referral to orthopedics should be done for pathologic cases as they can lead to long term consequences such as meniscal tears and higher rates of osteoarthritis.

Hip Problems

Developmental Dysplasia of the Hip

Formerly termed "congenital hip dysplasia," developmental dysplasia of the hip (DDH) refers to the abnormal development of the acetabulum and the proximal femur, which may occur as the child is developing and not always congenitally, hence the change in terminology. DDH may present at birth, with an abnormal gait as a toddler or activity-related hip pain in adolescents. Every newborn and child should be evaluated routinely for this condition until the child is walking normally.

The newborn hip exam should be performed on an infant who is not wearing clothes or diapers and should include the Barlow and Ortolani maneuvers. The Barlow maneuver is considered positive if there is a palpable clunk while the hip is adducted with posteriorly-directed pressure, which signifies that the hip is dislocatable. The Ortolani maneuver should follow the Barlow maneuver and is considered positive if a palpable click is felt when abducting the hip while lifting the trochanter anteriorly, which assumes that the hip is reducible. Classically, Barlow and Ortolani maneuvers were performed together because when both are positive diagnostic specificity increases to 99 %; however, a recent re-evaluation of examination techniques suggests that Ortolani's test is more important [33]. In children over 3 months of age, DDH is highly suspected if passive abduction of the hip is less than 45° [34]. Additional maneuvers include the Galeazzi and Klisic tests, which can help in detecting DDH in older children. The Galeazzi test is performed by having the patient assume the supine position with hips and knees flexed so that the feet are side by side and flat on a surface; the position of the knees are observed. The test is considered positive if the knee of the affected side is lower than the other. The Klisic test is performed by imagining a line

DOI 10.1007/978-1-4939-0779-3_20-1

between the anterior-superior iliac spine and greater trochanter to see where if falls in relationship to the umbilicus; if the line falls below the umbilicus, the test is considered positive. Children who have a positive Trendelenburg pelvic tilt test may also have DDH.

In the first 6 weeks of life, many newborns may have "clunks" due to normal physiologic laxity that may raise suspicion for DDH. Ultrasound screening for DDH is typically performed for infants younger than 4–6 months, however, should usually be postponed until at least 3–4 weeks of life to allow the normal laxity to resolve [35]. Older children and adolescents may be screened with plain radiographs. Confirmed cases should be referred to orthopedics. Treatment may involve utilizing a Pavlik harness and proceeding to surgery if it fails or if the patient is older than 18–24 months.

Transient Synovitis

Hip pain in a child aged 3–8 years old after a recent upper respiratory infection should raise suspicion for transient synovitis. Males are twice as likely to suffer from this condition than are females. Generally, the child will appear well but will have limited range of motion of the hip. If fever is present, it is often low grade. Basic laboratories including a complete blood count (CBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) should be obtained. The Kocher criteria [36] (refuses to bear weight on affected side, fever $\geq$ 101.3 F, ESR $\geq$ 40 mm/h, and WBC $>$ 12,000 cells/microL) are very useful in helping to guide the clinician. The likelihood of the presence of septic arthritis rises with each criterion met, and the presence of all four criteria makes the diagnosis of septic arthritis almost certain. Ultrasonography can be performed to identify if a joint effusion is present. If septic arthritis is not suspected, patients can be observed closely. If any signs or symptoms suggesting septic arthritis arise subsequently, then joint aspiration is recommended. Transient synovitis is managed conservatively with NSAIDs. Most patients make a full recovery within 1 week [37]. The child may return to activity as he or she tolerates it.

Septic Hip

As in adults, septic arthritis can be very damaging to the joint and therefore should not be missed. When septic arthritis occurs in the hip of a child, typically he or she will be ill appearing and often febrile ($>$101 °F). The child may refuse to weight-bear or move the affected limb due to severe pain. Obtaining blood to check white blood cell count, ESR, and CRP is important. A high score using the Kocher criteria suggests septic arthritis [36] and typically the CRP is higher than 2 mg/dL. To confirm the diagnosis, an ultrasound guided hip aspiration should be done with synovial fluid and blood cultures. Ideally, these should be done before starting antibiotics. Intravenous antibiotics should not be delayed, however, if the hip aspiration cannot be done in a timely fashion. Coverage should include the most common pathogens including *Staphylococcus aureus*, *H. influenza* type B, and *Streptococcus pneumonia*. Some patients may require repeated drainage of the hip joint so that blood flow is not compromised by the increased intraarticular pressure.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) must not be missed in children presenting with nonradiating, aching pain in the hip, groin, or upper thigh. There is usually no trauma associated with SCFE but the pain worsens with activity and can cause patients to limp or even be unable to bear weight. SCFE is commonly found in obese adolescent males ($>$95th percentile for weight). Examination will show a limited range of motion [14]. Often the gait is altered. If the SCFE is unilateral, the patient may walk with a Trendelenburg gait; if involvement is bilateral, a waddling gait may be observed [38]. Plain radiographs of the hip with AP and lateral views should be obtained to confirm the diagnosis (Fig. 8). Upon diagnosis, immediate orthopedics referral is warranted because complications of SCFE include osteonecrosis of the femoral head and femoroacetabular impingement.

DOI 10.1007/978-1-4939-0779-3_20-1

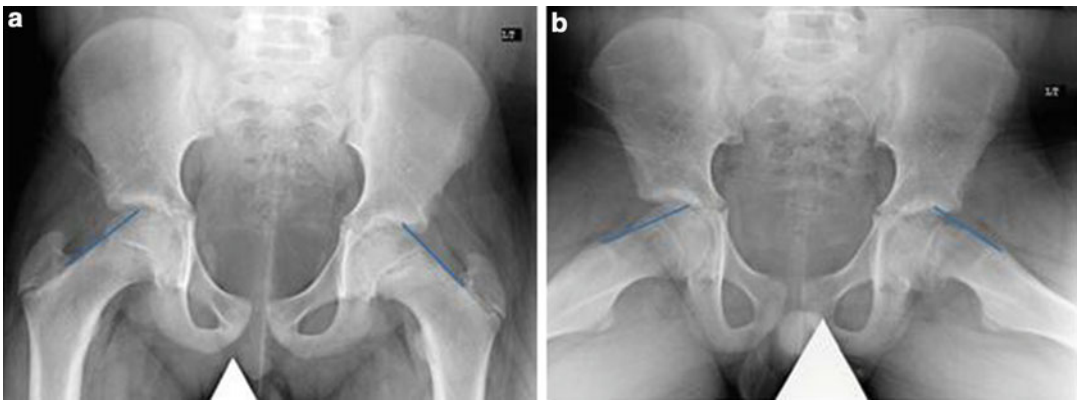

Fig. 8 Slipped capital femoral epiphysis. Image (**a**) is the anteroposterior (*AP*) view. Image (**b**) is the frog leg lateral view. The *blue line* on the AP (Klein's line) drawn along the femoral neck demonstrates the relative varus of the femoral epiphysis. A similar line drawn on the lateral demonstrates the relative posterior displacement of the left femoral epiphysis compared to the normal right hip (From Lee, M. [39]. With kind permission from Springer Science and Business Media)

Fig. 9 Perthes disease lucent crescent (*arrowhead*) of the outer femoral head on a frog-leg view in an 8-year-old boy (From Oestreich AE and Crawford AH [40]. With kind permission from Springer Science and Business Media)

Legg-Calve-Perthes Disease

Legg-Calve-Perthes disease (LCPD) is avascular necrosis of the proximal femoral head that typically presents in boys between the ages of 4 and 8 years old. Parents will often bring them in after the patients have been limping for about 3 weeks. The child may complain of groin pain radiating to the proximal thigh. Observation of gait may reveal an abductor lurch, while evaluation of range of motion will show a decrease in hip abduction and internal rotation. Although early LCPD may not show up on plain radiographs, they should still be done with AP and frog leg views. If radiographs are normal and clinical suspicion remains high, an MRI should be ordered. The frog leg views may show a crescent sign (Fig. 9), which is a late sign of LCPD.

Although most cases are unilateral, LCPD can be bilateral. If found to be bilateral and symmetrical on imaging, additional workup is required with imaging of the hands, knees, and spine to rule out epiphyseal dysplasia [14]. Orthopedic referral should be made for any child older than 6 years or children younger

DOI 10.1007/978-1-4939-0779-3_20-1

than six who have significant involvement of the femoral head. Early stages of LCPD can be managed with activity restriction, pain control, and close follow-up to monitor range of motion. Physical therapy may be prescribed to maintain range of motion. Containment treatment can be done for those with poor prognosis (i.e., children greater than 6 years of age at onset) [41]. Containment treatment involves various methods of keeping the femoral head within the socket to allow remodeling of the femoral head as it heals.

Foot Problems

Toe Walking

Toe walking can be a parental concern, although the children are usually asymptomatic. In idiopathic cases, the child will start walking on time but will walk on his/her toes. This condition usually resolves itself in 3–6 months. However, if upon examination, passive dorsiflexion is less than 10°, an Achilles tendon contracture might be present. An Achilles tendon contracture is treated with serial short leg casting over 6 weeks, with each cast increasing the amount of dorsiflexion of the foot and ankle. Rehabilitation is also appropriate for those with mild contractures. Imaging is usually only performed if the history is unclear or if there is a question raised upon examination. An orthopedic surgery referral should be initiated if there is suspicion of a fixed heel cord (Achilles contracture) or if toe walking is unilateral, as this almost always has a pathological etiology [14].

Talipes calcaneovalgus

Positional calcaneovalgus feet or talipes calcaneovalgus is a very common among newborns, secondary to the uterine positioning [1]. After birth, the foot appears hyperdorsiflexed with eversion. Imaging is not necessary unless the case is questionable, in which case obtaining simulated weight-bearing radiographs is appropriate. The majority of cases will self-resolve, but casting may be necessary if the foot and ankle cannot be plantar flexed past the neutral position.

Talipes equinovarus

Talipes equinovarus, also known as "clubfoot," can be caused by many etiologies, including congenital and neuromuscular disorders. Parents usually raise concerns due to the appearance of the foot; however, early on, children are asymptomatic. If left untreated, talipes equinovarus can lead to difficulty wearing normal shoes, pain, and a gait disturbance. Physical examination may demonstrate high arches, forefoot adduction, heel varus, and ankle equinus. It is important to assess the rigidity of the foot. Imaging with weight-bearing AP and lateral views is obtained in older children but not necessary in infants. Children with talipes equinovarus are usually managed by orthopedists with the Ponseti method, which entails long leg casting and subsequent bracing [42].

Pes Cavus

"Pes cavus" refers to abnormally high-arched feet. Children with pes cavus will have difficulty wearing shoes and complain of pain in the forefoot. Examination should include an evaluation of the alignment of the ankle, heel, midfoot, and toes. In many cases, there will be calluses under the metatarsal heads. When pes cavus is suspected, AP and lateral films should be obtained to evaluate the alignment by passing a line from the axis of the talus to the first metatarsal, which will show an increased angle. All children with pes cavus should be referred to orthopedists; however, while awaiting their visit, arch supports and shoe modifications may be helpful [14]. Rehabilitation can also be prescribed to strengthen the foot muscles and to promote range of motion. When these measures fail, surgery may be a consideration.

Table 3 Orthotics for pes planus (flatfoot) [43, 44]

Stating Orthotic type	Type of Support Given
Internal heel wedges	Applied medial provide hindfoot inversion
University of California Biomechanics Laboratory (UCBL) orthosis	Provides longitudinal arch support by encompassing heel and hindfoot
Heel cup	Provides calcaneal support

Flexible versus Rigid Flatfoot

Parents are often concerned if their child's foot is flat. There are different types of flatfoot and it is important to determine if the condition is flexible or rigid flatfoot, because the management can vary. Flexible flatfoot is rarely symptomatic; if it is, the patient will usually complain of an inability to keep up with his or her peers or feel discomfort in the medial hindfoot related to activity. Performing the Jack test is a quick and easy way to make the differentiation: the child is asked to stand on his/her toes and the clinician observes whether the foot's arch is restored [14]. If it is, then it is considered flexible; if it is not, then it is rigid. In children who have symptoms, it is appropriate to obtain plain radiographs (AP, lateral, and oblique views) to rule out other causes.

Management of flexible flatfoot can be done by the primary care clinician as most cases improve on their own, therefore, reassurance is key. However, if symptoms persist, shoe inserts can be prescribed to give arch support (Table 3). Rigid flatfoot usually requires some intervention, whether it be orthoses, serial casting, or even surgery. Management of rigid flatfoot should be geared towards its cause and may even require orthopedic referral.

Tarsal Coalition

Tarsal coalition is one cause of rigid flatfoot. It is due to abnormal connections between two tarsal bones. Symptoms usually start late in childhood and can be related to a change in activity. Parents may observe that the child is walking with a limp. Upon examination, rigid flatfoot is found with restricted hindfoot motion. Radiographs including AP, lateral, and oblique views should be obtained to confirm the coalitions. If they are not well visualized, a computed tomography (CT) scan may be ordered to confirm the diagnosis. Management depends upon the severity of symptoms. If there are minimal symptoms, observation is appropriate; mild to moderate symptoms may require a short leg walking cast for 4–6 weeks [14]. Cases that are persistent after nonsurgical treatment may require surgical intervention to remove the coalition.

Freiberg Disease

Osteonecrosis of the metatarsal head is called Freiberg disease, which typically presents in adolescent girls. It most commonly affects the second metatarsal head but may also affect the third or the fourth metatarsal head [45]. The patient may describe a feeling a dull, aching pain in the forefoot that is worsened with activity and can be related to a trauma. There will be tenderness and edema of the metatarsal head with pain on dorsiflexion. Although plain radiographs can show fragmentation of the metatarsal head with flattening, this usually does not appear until 2–3 weeks after the onset of symptoms. Management depends on the severity of symptoms. For mild symptoms, modification of activities may be sufficient. However, if the pain becomes particularly bothersome, short-term casting may be needed. In persistent cases, surgery may be done to remove loose bodies or realign the bone [14].

Kohler Disease

Similar to Freiberg disease, Kohler disease is osteonecrosis, but of the navicular bone. In most cases, it is unilateral and presents more commonly in males between the ages of 4 and 8 years old. Patients may

DOI 10.1007/978-1-4939-0779-3_20-1

present with foot pain and limping. On examination, there is tenderness on the medial arch. Observing the child's gait may reveal a limp, with the affected foot turned out more than the other while walking. Plain radiographs show a smaller navicular. Patients tend to do well without treatment, as the condition can spontaneously resolve. Those with more pain can be treated with a short-term walking cast for 4–8 weeks [46].

Developmental Surveillance

The 1st year of life is marked by the highest rate of growth and development. The brain doubles in size in the 1st year of life and increases in size by another 15 % in the 2nd year. Developmental skills are acquired at a very high rate in infancy so that even minor disruptions in development at this stage can have serious long-term implications [1]. The goal of developmental surveillance in infancy is early identification of any deviations or disruptions to the normal growth and developmental trajectories. Identification should then lead to developmental and medical evaluation. Early intervention in children has been shown to improve functional outcomes for children with developmental delays [2].

The American Academy of Pediatrics recommends that developmental surveillance be incorporated into every well-child visit through the 5th year of life [3]. Developmental surveillance includes identifying risk factors for developmental delay, eliciting parental concerns, the clinical assessment of developmental milestones, and the administration of screening instruments.

Common risk factors for developmental delay include genetic diseases, congenital malformations, and prenatal factors such as congenital infections and exposure to drugs. Environmental factors include maternal depression, nutritional deficiencies, and toxic stress. A family history of genetic syndromes or developmental

Table 1 Risk factors for developmental delay

Genetic and chromosomal abnormalities	Chromosomal defects: Down Syndrome, Fragile X syndrome, Klinefelter's syndrome, Noonan syndrome, Williams syndrome, Angelman syndrome, Rett syndrome, Prader-Willi syndrome Inborn errors of metabolism, mitochondrial diseases, lipid storage diseases, etc. Muscular dystrophy syndromes
Congenital malformations	Lissencephaly, holoprosencephaly, thyroid agenesis, etc.
Intrauterine exposures	Drugs and toxins: alcohol, illicit drugs, teratogens Congenital infections: (TORCH) Malnutrition (IUGR), placental insufficiency
Perinatal and postnatal conditions	Prematurity Birth asphyxia or birth trauma Neonatal infections especially CNS infections Emotional deprivation Experiential deprivation Sensory deprivations: hearing or visual impairment Malnutrition, iron deficiency Exposure to toxins: lead poisoning Severe congenital heart disease requiring surgery

delay is important in assessing the risk for developmental delays (Table 1).

The classification of "streams of development" remains helpful as a framework for understanding and evaluating development in infancy and early childhood. The streams of development include the domains of gross motor, fine motor, social, and language development. A fifth dimension of intellectual and cognitive development is sometimes added to assess global function and intelligence.

Neurodevelopment generally follows a predictable course. For example, motor development tends to progress in a cephalocaudal and proximal to distal fashion. However, individual variations are common.

Assessment of development begins by obtaining history from the parents and should include soliciting concerns about their child's development, eliciting the history of developmental milestones, in addition to clinical observation of the child. Parental assessment of their children's development and concerns about the child's development have been shown to correlate strongly with the presence of developmental delay [4, 5]. Observation of the child–parent interaction is important in the assessment of children during developmental surveillance and may improve the identification of developmental delays. Examination of the child should include a comprehensive assessment. Growth pattern should be carefully assessed by studying the growth curve. Dysmorphic features or skin lesions should be noted.

The first step in evaluating developmental delay is to determine if the child has an isolated delay in one of the streams of development or a global delay affecting more than one stream of development. This will narrow the differential diagnosis and help in directing a referral if needed.

Motor milestones are generally easily observable during the visit such as neck control, sitting, standing, or walking [6]. Fine motor milestones such as object manipulation can also be observed during the exam. Verbal and social skills may be more difficult to elicit from the child during the brief visit in the unfamiliar environment of the doctor's office, and the clinician may have to rely on parental report for those milestones (Table 2).

Developmental screening instruments: the American Academy of Pediatrics recommends the administration of a standardized developmental screening instrument at 9, 18, and 30 months, and the administration of an autism screening tool at 18 and 24 months. The USTSPF recently found that there is insufficient evidence to support recommendations for or against screening for autism or speech and language disorders [7].

Table 2 Normal Developmental Milestones

Age	Gross motor	Fine motor	Social emotional	Language
2 weeks		Coordinated and effective sucking. Hands fisted near face	Soothed by maternal voice and when picked up	Startles to voice
2 months	Lifts head off bed in supine position Head lag present	Hands fisted	Social smile	Coos in response to social interaction
4 months	Lifts chest off the table Steady head control when sitting No head lag when pulled to sit	Un-fisted	Laughs aloud with pleasurable interaction with parents	Vocalizes when alone
6 months	Tripod sit Leads with head when pulled to sit, Rolls over in both directions	Transfers object from hand to hand	Babbles, Gestures for up	Babbles interactively
9 months	Crawls on hands and knees	Inferior pincer grasp	Searches for family: where is mama?	Mama, dada, nonspecific
12 months	Walks awkwardly	Mature pincer grasp	Proto-imperative pointing (points to a subjects he/she wants)	Mama, dada plus 3 words
15 months	Walks well Recovers to standing from stooping		Proto-declarative pointing: (points to share experiences with parent)	Uses 3–5 words, names 1 object Mature jargoning
18 months	Runs awkwardly Throws a ball Walks upstairs with hands held	Feeds self with a spoon	Points to 3 body parts	Uses 10–25 words. Names one picture on demand
24 months	Runs well Kicks a ball Throws a ball overhand	Follows a 2-step command	Parallel play	50 words or more, 2-word sentences, 50 % intelligibility, knows own name
30 months	Jumps in place Kicks ball throws ball overhand	Imitates horizontal line Takes clothes off	Imitates adult activities	Knows pronouns (refers to self as I) and prepositions (up, in, out)
36 months	Rides a 3 wheeler Catches ball	Copies circle Feeds self with a spoon	Starts sharing Knows name and gender	200+ words, 75 % intelligibility, 3-word sentences uses plurals, names body parts

Several developmental screening instruments are available. Developmental screening instruments have been found to be superior to clinical surveillance in the identification of children with developmental delays [8].

Repeated testing is important since some of the more subtle developmental delays may become apparent with time.

Developmental red flags

Rolling over before 3 months	Indicates increased tone
Not walking by 18 months	Muscle weakness
No words by 18 months	Speech delay: hearing impairment, cognitive delay, ASD, etc.
Hand laterality before 12–18 months	Weakness of the other side
Not sitting by 7 months	Muscle weakness
Isolated fine motor delay	Visual impairment

Management of children with a suspected developmental delay should not be delayed while a specific diagnosis is sought. Under the Individuals with Disabilities Education Act, IDEA, children from birth to 3 years can receive services with a general diagnosis of developmental delay. The management of children with developmental delays often requires a multidisciplinary approach. Children with severe developmental delays are prone to a host of complicating conditions such as seizure disorders, feeding difficulties, respiratory complications, and musculoskeletal complications. Care coordination is extremely important in the management of these children.

Support is also needed for families who care for children with developmental delays to help manage the added physical and emotional burden and manage the needs of other typically developing children in the family.

Approach to the Infant or Child with Motor Delay

A thorough history including gestation history, perinatal history, and family history can provide important information. Prematurity is an important and common risk factor for developmental delays, with 11–12 % of babies in the USA born prematurely [9]. Therefore, premature babies require close developmental surveillance.

Physical examination should include documentation of growth parameters including the head circumference, assessment for dysmorphic features, and a detailed neurologic and developmental exam. It is important to remember that delays in achieving motor milestones can sometimes be caused by medical problems. These might include, for example, a delay in walking caused by developmental dysplasia of the hip, nutritional deficiencies such as rickets, or hypothyroidism [10].

The neurologic exam should assess for tone, reflexes, and motor or sensory deficits. Increased muscle tone is usually associated with central nervous system lesions, and neuroimaging should be considered. Decreased muscle tone in the presence of developmental delays may be due to hypothyroidism or muscle disease, and work up for these conditions may be indicated [11]. An increase in the level of creatine kinase (CK) indicates muscle disease and is the hallmark of muscular dystrophy in the context of motor delay [12].

Many genetic and metabolic conditions are associated with developmental delay that is detectable shortly after birth or may develop later in infancy with arrest of development or developmental regression. These conditions include conditions such as mitochondrial diseases or lipid storage diseases.

Red flags in the evaluation of motor delay that are indications for urgent referral to a pediatric neurologist include high CK levels indicating

muscular dystrophy and the presence of muscular fasciculation indicating spinal muscular dystrophy. Loss of motor milestones is always abnormal and generally indicates a degenerative brain disorder. Patients in these categories are at risk of rapid deterioration of muscle tone that may threaten their vital functions such as swallowing and respiration.

Management of children with motor delay depends on the diagnosis. Children with motor delay regardless of the cause, however, usually will benefit from physical and occupational therapy, which aims to maximize function and prevent secondary developmental losses as a result of the original insult. Mobility and physical competence are essential for the exploratory behavior necessary for the development of other motor, social, and cognitive skills. Studies have documented that improved physical capacity results in significant improvements in language and problem-solving skills [13].

Speech Development and Speech Delay

Language development starting in the second half of the 1st year is largely dependent on the volume and quality of auditory input and the social environment. A positive social response to an infant's vocalizations is critical for the continuation of attempts to talk. Additionally, intact motor skills are necessary for the production of speech. Evaluation of speech delay starts with the assessment of auditory input, including hearing tests and assessment of the social environment. Assessing the nature of caregiver interactions with the infant is a critical part of the evaluation of speech delay in infants. Mental retardation or cognitive disability, regardless of the cause, often presents with speech delay.

Evaluation of the child with suspected speech delay should include assessment for the presence of congenital and genetic syndromes. Many of these syndromes are associated with speech delay. Speech delay is also a common presenting feature of autism spectrum disorder (ASD) and may or may not be associated with cognitive delay. Whether or not another diagnosis is present, early speech delay is associated with later language and reading disorders and the development of behavioral problems in late childhood and adolescence [14].

Detection of receptive or expressive language delay should prompt referral to an early childhood intervention program. The presence of associated social skill deficits or other features of ASD should prompt a referral to a specialist in developmental pediatrics.

Cognitive Impairment

Cognitive impairment is classified as mild, moderate, severe, and profound. The causes of cognitive impairment include genetic, metabolic, prenatal exposure to toxins or infections, and postnatal CNS insults. The more severe types of cognitive delay are more likely to have an identifiable etiology, whereas mild delays are more commonly idiopathic. In most children with moderate to severe cognitive impairment, other developmental delays are evident, allowing detection in infancy and early childhood. On the other hand, it is not uncommon for a child with borderline or mild intellectual disability to escape detection until after they enter school.

In addition to a thorough history and physical examination as outlined above, the workup of a child with isolated cognitive impairment should include genetic testing [15]. Referral for early childhood intervention services should be made early in the course of diagnosis while further evaluation proceeds.

Oral Health

Dental caries has been called a "hidden epidemic." The Family Physician is often the first point of care for infants and children and their families, and can be important in helping to provide oral preventive care and counseling during the most critical period for the development of dental disease. Disparities in the incidence of dental caries and access to dental care are more pronounced in the USA than those for general health. Six groups of children who are at high risk for dental caries have been identified: [16].

1. Children with special health care needs
2. Children of mothers with a high incidence of caries
3. Children with demonstrable caries, plaque, demineralization, or staining
4. Children who sleep with a bottle or are breastfed through the night
5. Later order offspring
6. Children in families of low socioeconomic status

The American Academy of Pediatrics recommends that primary care providers be trained in performing oral health assessments on all children beginning at 6 months of age to identify known risk factors for early childhood dental caries and also to provide anticipatory guidance and dental referral by 1 year of age (Table 3).

Table 3 Anticipatory guidance for prevention of dental caries

Preventive strategies	Counseling points
Dietary counseling	Exclusive breast feeding for 6 months Continue breast feeding until 1 year or more Discourage bottle in bed Wean bottle by 1 year Avoid sugary drinks Limit 100 % juice to 4–6 oz/day Only water between meals Model healthy eating habits
Oral hygiene	Model oral hygiene and consistent brushing Brushing twice daily with a smear of fluoride toothpaste Supervise brushing until age 8
Fluoride	Drink fluoridated tap water Use fluoride toothpaste Apply fluoride varnish 2–4 times per year starting with the eruption of the first tooth
Establish a dental home	Refer to a dentist by the first birthday
Dental injury prevention	Cover furniture corners Proper use of car safety seats Awareness of electrical cord risk for mouth injuries Use mouth guards in contact sports

Pediatric Autoimmune Neuropsychiatric Disorders Associated with Group A Streptococcal Infections (PANDAS)

The first neuropsychiatric syndrome linked to group A streptococcal (GAS) infection was Sydenham's chorea, associated with rheumatic fever [17]. More recently, other neuropsychiatric manifestations have been described in association with GAS [18].

PANDAS describe a subgroup of children who present with acute onset obsessive compulsive disorder (OCD) or tic disorders that follows an episode of Group A streptococcal infection. Additionally, children may have an acute episodic exacerbation of a preexisting OCD or tic disorder following GAS infections. In many situations, the neuropsychiatric symptoms resolve promptly after the successful treatment of GAS infection. The association is proposed to be immune mediated, although an etiologic association between GAS infection and neuropsychiatric symptoms has not been proven. Proposed criteria for diagnosis [19] are listed in Table 4.

This phenomenon is strictly limited to the pediatric age group, which is necessary to make the diagnosis. Some authorities recommend testing for GAS in any child presenting with acute neuropsychiatric symptoms such as tics or OCD, or with episodic exacerbations of existing OCD or tic symptoms. Appropriate treatment of GAS is discussed elsewhere. Treatment with immune

Table 4 Criteria for diagnosing PANDAS

1.	Presence of a tic disorder or OCD
2.	Prepubertal age of onset (3–12)
3.	Temporal association between symptom exacerbation and streptococcal infection
4.	Abrupt onset of symptoms and episodic course of symptom severity
5.	Presence of neurologic abnormalities during periods of symptom exacerbation

modulating drugs is not recommended outside of research settings [19]. Symptoms of OCD and tic disorder should follow standard treatment guidelines. The response to therapy is similar in patients with and without associated GAS infection.

Although antibiotic prophylaxis is effective and recommended for the prevention of Sydenham's chorea, it is not recommended in the prevention of PANDAS pending studies that explore the pathophysiology of its relationship with GAS and studies of treatment outcomes.

Lead Poisoning

Lead is a heavy metal that does not occur naturally in the body and has no physiological role. Lead is toxic to all living cells, and the accumulation of certain levels of lead leads to dysfunction in almost all organ systems in the body. Lead poisoning is particularly important in children, who are particularly susceptible to its toxic effects. Children have mouthing behaviors that increase their risk of ingesting lead particles in dust or on objects. Additionally, children absorb lead more readily from the intestine, especially when they are iron deficient, which is also common in early childhood. More importantly, the developing brain is highly susceptible to the toxic effect of lead even at low levels. Potentially, lead exposure can lead to permanent and irreversible learning and behavioral problems.

Although lead poisoning has decreased in the USA since the 1970s following the elimination of lead from gasoline, paint, and the food canning process, certain pediatric population groups remain at high risk for lead poisoning, however. For those children, the CDC recommends routine screening at 12 and 24 months and at any time until 5 years of age if they have not been tested before [20]. These high risk groups include

1. All children who live in areas with $\geq$27 % of housing built before 1950
2. Populations in which the percentage of 1- and 2-year-olds with elevated blood lead levels is $\geq$12 %
3. Children who receive services from public assistance programs for the poor such as Medicaid or the supplemental food program for women, infants, and children (WIC)
4. Children who screen positive by parental questionnaire

Blood lead levels above 5 mcg/dl should initially be confirmed with a venous sample. If confirmed, it should prompt a home visit by the health department to inspect the home, daycare, or any other place the child spends any time in for lead. Finding of any source of lead should lead to proper treatment and abatement of the source of lead followed by follow-up of the blood level of the child to ensure that the levels decline. Any other children living in the same household should also be tested.

Blood lead levels above 45 mcg/dl should be treated [21, 22]. Treatment is through chelation. There are several compounds used to treat lead poisoning and different regimen recommendations depending on the severity of the intoxication. Because of the side effect profile of chelation drugs and the lack of experience among many clinicians in the use of these agents, the services of a toxicologist with expertise in chelation might be helpful when managing these patients [23].

Health Care of the Adolescent

W. Suzanne Eidson-Ton

Contents

The care of adolescent patients is similar to care for any other patient in many ways. However, adolescence is a period of rapid change as teenagers' transition from childhood to adulthood, with all of the concomitant physical, sexual, and emotional changes. It can be quite a chaotic time for both teens and their families. For family physicians, the primary role is often to help smooth this transition by helping families and their teenagers understand all of the changes happening, supporting teens in safe and healthy risk taking, and encouraging the gradual differentiation that is occurring.

Ideally, all visits with teenagers will include time with the family together, time with the adolescent alone, and time with the parent/guardian(s) alone. Especially in new patient adolescent visits, it is very important to establish the extent of confidentiality to which teenagers have a right, and the limits of that confidentiality. It is also important for teens to understand what services they may consent to and receive without their parent/guardian(s)' knowledge or consent. This will vary from state to state, but will usually include some reproductive services and perhaps limited mental health and drug/alcohol services. It is important to know local laws regarding consent of minors, so that one can appropriately counsel and treat adolescent patients and their families. An overview of minor consent laws by state in the US can be found at: http://www.gutmacher.org/sections/adolescents.php.

P.Paulman, R.Taylor (eds.), *Family Medicine*,
DOI 10.1007/978-1-4939-0779-3_22-1

Regarding confidentiality, it is best practice to start a new patient visit with both the teen and her/his parent/guardian(s). It is important to begin the visit by letting the family know that they will be seen all together first in order to discuss everyone's concerns. It is also recommended to let them know early in the visit that the teen will then be seen alone, explaining that he/she has a legal right to confidentiality about anything s/he discloses unless he/she tells the physician that s/he plans to hurt him/herself, someone else, or that someone is hurting her/him. As mandated reporters, family physicians must report suspected child abuse to the appropriate authorities (Child Protective Services – CPS) and must treat suicidal or homicidal intent as would be done with any other patient. Otherwise, whatever the teen discloses to the physician must be kept in confidence. This does not mean, however, that secrets should be encouraged between teens and their parent/guardian(s). In fact, in many situations, it is helpful to encourage teens to talk with their parent/guardian(s) about the things they have shared, and the physician can offer to be present during the discussion, if the teen thinks that would be helpful.

Some early adolescents may be quite intimidated to meet with a provider alone, but this is an important pattern and precedent to set, so that they and their parent/guardian(s) understand that this will happen at every visit. For very emotionally immature adolescents, the physician may meet with them very briefly, only to determine if there is anything else that requires discussion and to screen for abuse. There are always, of course, exceptions to the rule. For example, developmental delayed adolescents who spend all of their time with trusted adults may not need extensive time alone with the physician; however, it is best practice to check in with them alone if possible and appropriate.

Example of interacting with an early adolescent:

Greeting

Particularly as teenagers gain emotional maturity, it is important for them to understand that their healthcare provider respects them as individuals and understands that they have autonomy in many decision-making aspects of their lives. This will help establish a trusted therapeutic relationship with the teen and allow for better use of motivational interviewing for risk reduction when necessary. One easy way to show respect is to greet the teen first upon entering the room and then asking her/him to introduce those accompanying him/her (if one does not already know them). This may not be as effective with emotionally immature teens, but as they get older, it can be very helpful. See box for sample introduction and confidentiality discussion with a new teen patient.

Provider: Hello, you must be Mary Smith. It is nice to meet you. I am Dr. Jones.

Mary (shyly) – age 14: Hi.

Provider: Mary, can you please introduce me to this woman with you today?

Mary: Oh, that's my mom.

Provider: Thank you. Mrs. Smith, I presume?

Mother: Yes. But you can call me Jane.

Provider: Wonderful to meet you, Jane. I am Dr. Jones (shaking hands). Before we get started, I would like to explain to you both how we operate with teen visits. I will talk with you both, first, and hear about both of your concerns, and then I will meet with Mary alone for a bit just to talk. For the physical exam, Mary, you may decide if you want your mother in the room.

Mary: Oh, yes, please.

Provider: Alright, no problem. I do want you to both know that, legally, at her age, Mary does have a right to confidentiality. So, I won't tell anyone else what Mary tells me without her permission. The only exceptions are if Mary tells me that she plans to hurt herself or someone else, or if she tells me that someone is hurting her. In those situations, I am obligated to notify other appropriate people or authorities. Do either of you?

History taking for an adolescent patient is similar to that of any other patient, particularly when the parent/guardian(s) are in the room. It is best to

direct questions to the teen whenever possible and then obtain details and clarifications from the parent/guardian(s) as necessary. One can start by asking the teen if he/she have any concerns s/he would like to address, and then, subsequently, asking the parent/guardian(s) what they would like to address in the visit. As with any well child visit, the provider should ask about diet, exercise, screen time (including TV, computers, cell phones, video games, etc), developmental issues (level in school, grades), and safety concerns (bike helmets, water safety, seatbelts). Regarding physical development, girls should be asked about breast development and menses. Boys and girls should be asked about hair growth. The immunization record should be reviewed for any needed boosters or updates. Once the patient's concerns and the parent/guardian(s)' concerns have been heard and understood and the past medical, surgical, medication, allergy and family histories have been obtained, the parent/guardian (s) should be asked to step out of the room while the physician speaks with the patient alone. If there is some hesitancy or concern from the parent/guardian(s), one can explain that this is a routine part of visits with all adolescents and is recommended by all major medical associations. The parent/ guardian(s) may be further reassured that the goal of this is not to be secretive, but to help teenagers begin to take some responsibility for their health and their relationship with their health care provider. In almost all cases, these explanations are enough to ease parent/ guardian (s)' mind. If the parent/guardian(s) are very resistant, and the teenager is relatively young, one may rarely elect to forgo the individual meeting with the teen, but should ask the family to prepare for this at their next visit.

Prior to the individual time with a teenager, it is a good idea to remind the adolescent about his/her right to confidentiality and the limits to that confidentiality. The primary issues to address during the individual meetings are psychosocial health issues. These include body image, mental health, sexual development and health, safety concerns, and substance use. It is important to touch on each of these issues at each visit, as teens are not seen in the office often, unless there is a problem or they need a sports or school physical. Further, adolescents are rapidly changing and answers will most certainly change from visit to visit. There are several acronyms that have been developed to help providers remember all of the areas to address. The best known is probably the HEADSSS assessment [1]. H stands for home, E is for education, A is for activity, D is for diet (body image), drugs, alcohol and tobacco, the first S is for safety, the second S stands for sex and sexuality, and finally, S for Suicide (depression). This acronym covers most important topics and is easy to remember. However, although in general it proceeds from least intimate to most intimate topic, home can be a sensitive topic for some teens, and school may be a safer way to start. Also, for the most part HEADSSS focuses on risk factors, rather than acknowledging the teen patient's strengths. An alternative acronym that the author prefers [2] is shown in the side bar with letter explanation and sample questions. As is evident, this acronym begins with strengths, which is a wonderful way to begin a conversation with any patient, and the information obtained can be particularly useful if necessary to counsel the teen about risk reduction related to the other questions. Another difference in this acronym is the word *Emotion* rather than *Suicide*, which is much more neutral, and can prompt physicians to ask patients questions about rating their life and other less loaded questions first.

Psychosocial History (SSHADESS)

S – *Strengths*: What are your strengths? What are you good at? What would your friends say that they like about you?

S – *School*: What grade are you in? At which school? Do you like school? Why/why not? Favorite subject? Friends at school? Do you feel safe at school? Any problems with bullying? Is there a trusted adult you can talk with at school? What do you plan to do after you graduate (or leave school)?

H – *Home*: Do you feel safe at home? Do you have your own or share a room? Is there a trusted adult you can talk with at home? Is there a gun in your home?

A – *Activity*: What do you do after school and on the weekends? How much screen time do you have? Are you involved in sports or other regular exercise? What do you do to have fun with your friends?

D – *Diet/body image*: What do you like to eat? How often do you eat? Do you eat breakfast? How often do you eat meals with your family? Do you think that your body is about the right size, or would you like to gain or lose weight? Do you see yourself as a boy or girl? & ***Drugs/alcohol/tobacco*:** Do you know anyone who smokes? Do you smoke? (Ask similar questions for alcohol and drugs.) *For teens who do use alcohol or drugs*, quantify amount and ask: Where do you use? With whom?

D – *Drugs/alcohol/tobacco (continued)*: Do you ever drive after using or ride with someone who has used?

E – *Emotion*: How do you feel on most days? If you would rate your life on a scale of 1–10, what number would you give your life? Why? (If less than 10), How could it be better? (If depression or low self-esteem red flags), Do you ever feel like hurting yourself?

S – *Safety*: (Already partially addressed under school and home.) May talk about bike helmets, neighborhood safety, gang activity, seatbelts, never riding with impaired drivers, etc.

S – *Sexuality and Sex*: This topic depends heavily on the sexual and emotional maturity of the teen. However, be aware that even young teens are known to sometimes be involved in sexual activity with their peers.

(Younger ~ 10–14): Do you find that you are attracted to any of your peers? If yes, are they boys or girls? Do you have a boyfriend or girlfriend? Do you ever touch physically? As below, if appropriate.

(Older ~ 15–21): Have you ever had sex? Do you currently? With boys or girls or both? Do you have intercourse? Oral, anal, vaginal? Barrier protection? Contraception?

While the above illustrates a list of sample questions one can use, the goal is to have a conversation with teenage patients. The questions help the physician to open up the conversation. The objective of the physician should be to understand your patient's thoughts and feelings about all of these topics, in order to support them in their healthy choices and/or normalcy (most teens want to be "normal"); to help them problem solve around issues such as safety; or to motivate them to make safer, healthier choices, if they are at risk. Risk taking and experimentation during adolescence is a normal developmental process [3]. Unfortunately, reckless risk taking is a major cause of accidental death or injury in adolescents [4]. Health care providers can help teens understand how and be motivated to take risks in the safest possible ways. Physicians should also encourage adolescent patients to discuss these issues with other trusted adults as much as possible.

In addition to the questions presented, it is important to assess conflict resolution strategies for teens in their relationships, both in their families, as well as in any romantic relationships. These questions should be asked of girls and boys to screen for possible intimate partner violence (IPV) but also to counsel teens of both genders on healthy conflict resolution strategies. Possible questions for these issues are below.

> *What happens when there are disagreements at home? Do you feel safe in your relationships with adults and peers? Do you feel safe with your boy/girlfriend? (if appropriate) What happens when you and your girl/boyfriend argue or disagree? Do you ever feel controlled by your boy/girlfriend?*

Finally, when working with teens and their families, it is important to be aware that many adolescents may be LGBTQ (lesbian, gay, bisexual, transgender, or questioning [their sexuality]). For this reason, it is important to ask all questions around sex and sexuality in gender neutral terminology. Family physicians can help adolescents and their families understand that there is nothing wrong or abnormal about being LGBTQ. Unfortunately, LGBTQ teens have higher rates of risky behavior, higher rates of being bullied or physically assaulted, and higher rates of depression

and suicide, with transgender teens having the highest rates among all of these groups [5–9]. Acceptance and support from their family is one of the strongest protective factors for LGBTQ teens, so encouraging family discussion and understanding (as much as is safe and possible) is ideal. Information for families struggling with these issues can be found at The Family Acceptance Project website: http://familyproject.sfsu.edu/home. A brief on-line training module for healthcare providers of LGBTQ adolescents can be found at http://www.lgbthealtheducation.org/wp-content/uploads/Module-4-Caring-for-LGBTQ-Youth.pdf. Other resources for caring for LGBT youth can be found at http://prh.org/teen-reproductive-health/arshep-downloads/#transgender.

The physical exam in adolescence need not be more invasive that the physical exam performed in other well child exams in the absence of problems or specific issues. It is still important to monitor growth, and particularly to calculate the BMI (body mass index) in order to screen for overweight or obesity issues. Obesity is a growing public health problem in children and adolescents. In 2011–2012, 20.5 % of 12–19 year olds were found to be obese [10]. There is no evidence that screening adolescents for scoliosis in the absence of symptoms or problems is effective, and therefore, routine screening is not recommended [4].

The physical examination of adolescents should generally include an inspection of the breasts and genital region for Tanner staging and observation of any abnormalities. However, there is no reason to do a more invasive genital exam unless needed for diagnosis of abnormal symptoms. The USPSTF (U.S. Services Preventive Task Force) recommends against testicular exam for screening for cancer in adolescents. Similar all major organizations including the USPSTF, ACOG (American College of Obstetrics and Gynecology) and the ASCCP (American Society for Colposcopy and Cervical Pathology) recommend beginning cervical cancer screening no earlier than 21 years of age, regardless of sexual history. It is important to

Table 1 Tanner stages for girls

	Average age (years)	Breast	Pubic hair	Other
Stage II	10–11	Bud (thelarche)	Long, soft, light hair near labia	Peak growth velocity follows
Stage III	12–13	Further growth of areola and tissue, no separation	More hair and more darkly colored	Menarche may occur late in this stage
Stage IV	14–15	Areola/nipple complex separates from breast tissue – secondary mound	Hair become course	Menarche usually occurs in this stage
Stage V	16–17	Larger breast with single contour	Full adult distribution	Menarche may occur here

Adapted from Ref. [11]

Table 2 Tanner stages for boys

	Average age (years)	Testes	Penis	Pubic hair	Other
Stage II	11–12	Testes enlarge and scrotal sac darkens	Minimal- no growth	Long, soft hair	–
Stage III	12–13	Further growth	Growth, especially in diameter	More hair and more curly	–
Stage IV	15	Further growth	Continued growth	Hair become courser	Some axillary and facial hair
Stage V	16–17	Adult in size	Adult in size	Full adult distribution	20 % at peak growth velocity

Adapted from Ref. [11]

Table 3 Nutritional needs of adolescents

	Girls – early adolescence	Girls – late adolescence	Boys – early adolescence	Boys – late adolescence
Calories (kcal)	1600	1800	1800	2200
Fat (% kcal)	25–35	25–35	25–35	25–35
Lean Meats (oz)	5	5	5	6
Vegetables (cups)	2	2.5	2.5	3
Fruits (cups)	1	2	1.5	2.5
Grains (oz)	5	6	6	7
Fat free milk/dairy (cups)	3	3	3	3

Adapted from Ref. [15]

screen sexually active girls for gonorrhea and chlamydia, but this can be done with urine PCR testing, so there is no need for a pelvic exam unless symptoms are present, or suspicion of another problem exists [4].

Physical sexual development is generally categorized using Tanner staging. Tanner Stage 1 is the preadolescent stage. For Tanner stages, see charts below (adapted from 11). The data presented here are reported averages, but there is a wide range of "normal" and some evidence that girls in the USA and other developed nations are reaching these stages at earlier ages than previously, possibly related to more available calories [12] (Table 1 and 2).

After the physical exam, if the parent/guardian (s) are not already present, the physician can usually have them join the adolescent for the summary and closure of the visit. Prior to inviting the parent back, the physician should answer any questions the teen has and remind the patient about confidentiality and the services that he/she can seek without parental permission. As with other well child exams, there are several preventive and anticipatory guidance issues to consider. Regarding immunizations, the CDC (Centers for Disease Control) recommends a Tdap (tetanus, diphtheria and pertussis) booster, the first dose of meningococcal conjugate vaccine, and the HPV (human papilloma virus) vaccine series for all girls and boys at age 11–12 years. A booster of the meningococcal vaccine is recommended at age of 16 years. In addition, the influenza vaccine should be administered annually. Immunocompromised teens require a different vaccination schedule. See details at http://www.cdc.gov/vaccines/schedules/.

Regarding immunizations, HPV vaccine requires particular attention. The current immunization rates are very low for both sexes. In 2013, 57 % of girls received one dose but only 38 % received the full 3-dose series. The rates were even lower for boys, at 35 % and 14 %, respectively [13]. In order to increase the rates in HPV vaccination, and decrease the rates of cervical and other HPV-related cancers (including oropharyngeal, anal, vulvar, and penile cancers), primary care providers must be more effective at offering and counseling families about the vaccine. Many parent/guardian(s) believe that there is no need to vaccinate their children against a sexually transmitted disease since they are not sexually active. While physicians, may educate parent/guardian (s) that vaccination should be done before exposure for maximal effectiveness, parent/guardian(s) may believe that this will increase sexual promiscuity in their teenagers. A recent study, however, demonstrated that there was no increase rate of sexually transmitted infections in a large group of adolescent girls after HPV vaccination [14].

Anticipatory guidance for parent/guardian (s) during the teen years is very important, but often skipped in adolescent visits. A thorough discussion of diet recommendations, exercise, and limiting screen time is warranted, particularly for teens with or at risk for obesity. There are many web-based resources for nutrition and activity in adolescence, several are available

through the CDC website at http://www.cdc.gov/healthyyouth/npao/index.htm or at http://www.nutrition.gov/life-stages/adolescents/tweens-and-teens. See Table 3 below for basic details of the American Heart Association recommended diet for teenagers [15].

In addition to a healthy diet, adolescents should participate in moderate to vigorous exercise for at least 60 min daily. The 2007 National Youth Risk Behavior Survey found that fewer than 25 % of high school students were meeting these physical activity recommendations. So it is important for physicians to discuss physical activity with teen patients and their families. Finally, regarding screen time, the American Academy of Pediatrics recommends less than 2 h of media per day for all children. While the recommendation is that all screen time be reduced, a recent study found that only TV watching was associated with increased risk of diabetes in an at risk population of adolescents [16]. In general, however, the fewer hours spent in front of any screen, the more physically active a child will be. A healthy lifestyle, including a nutritious diet and regular exercise not only benefits adolescent physical health, but there is evidence that is also important for optimal cognitive function and emotional wellbeing as well [17, 18]. Parent/guardian (s) and teens should understand the relationship between diet, physical activity, and screen time and physical and mental health.

While counseling regarding lifestyle factors affecting obesity is very important, physicians cannot ignore the social determinants of health that affect obesity rates. Obesity is more common in low income households, and obesity rates correlate with levels of poverty. A recent article using GPS with adolescents found a complex relationship between teen's neighborhoods and their food consumption, but one clear association was a relationship between distance to convenience stores and teen fruit/vegetable consumption [19]. In addition to assisting individual adolescents and their families, physicians can work at the local and community level to address such disparities in access to healthy food and safe places to exercise and play.

Parenting strategies and discipline are topics that should be discussed with the parent/guardian (s) of adolescents whenever possible. Many parents continue to use the parenting skills they used when their children were younger. However, given that the adolescent stage of development is concerned with identity development and differentiation for teens, these parenting strategies often are no longer very successful. The Center of Children on Families at the Brookings Institute has found that adolescents with parent/guardian (s) with certain parenting styles tend to be more successful as adults. (See below for parenting styles) [20]. Adolescents with parent/guardian (s) who parent in an Authoritative style have lower risk taking behavior and higher school achievement [20]. For parent/guardian(s) with difficulties around these issues, a separate counseling appointment is sometimes necessary. The physician can also speak with parent/guardian (s) without the adolescent present if they feel more comfortable speaking about their concerns when alone. The main objective of counseling parent/guardian(s) should be to improve their authoritative parenting skills. Important authoritative parenting skills include age appropriate parental monitoring, appropriate discipline and communication of family values, as well as warmth and regard. Self-efficacy in their parenting is also important. There are many resources for parent/guardian(s) to improve their parenting skills of adolescents, particularly those of communicating with their children. Some examples of helpful websites are:

A Parent's Guide to Surviving the Teen Years at kidshealth.org/parent/growth/growing/adolescence.html. Communicating with Your Teen at ohioline.osu.edu/hyg-fact/5000/pdf/5158.pdf.

Parenting Styles

Authoritative: High emotional support with consistent discipline ("positive parenting")

Authoritarian: Discipline but with low emotional support ("dominating")

Indulgent: High emotional support without discipline ("permissive")

Uninvolved: Low discipline and low emotional support ("disengaged")

In order to be supportive of their adolescent children, parent/guardian(s) need to understand that the major developmental task of adolescence is individuation towards independence. They can be most effective when they communicate well and guide their children in making good choices. One simple suggestion is have parent/guardian (s) consider how they would react to their teens' situations if they were their coach rather than their parent. COACH is also an acronym parents can use. (See below). It is very important that parent/guardian(s) know that adolescents are still greatly influenced by their parent/guardian(s) when making decisions, even if it seems that the opinions of their peers matter more [20].

COACH to Improve Parenting

C: Create Confidence

O: Observe

A: Advise

C: Calmly let them experience life

H: Help them debrief after experiences

In summary, in order to be most effective in the healthcare of adolescent patients, it is necessary to have therapeutic relationships with both the adolescent patient as well as her/his parent/guardian (s). Family physicians who care for all individuals in the family unit are uniquely suited to establish these relationships. Addressing adolescent health needs in a respectful and confidential way is a must, but supporting parent/guardian(s) in their relationships with their teenage children and the authoritative skills that are most effective is also necessary for optimal health outcomes for youth.

Selected Problems of Aging

Archana M. Kudrimoti and Lanyard K. Dial

Contents

General Principles

Definition/Background

The population of the world is aging due to decreasing fertility and mortality rates. By 2030 one in five Americans will be above the age of 65. The fastest-growing segment of all age-groups is that of age 85 and above in the USA. Seniors disproportionately use all aspects of health services. Clinicians treating this population face the challenge not only of treating chronically ill adults but also in helping to delay or prevent the onset of chronic disease. This chapter provides information on issues that are common to this population and are valuable to the family physician who cares for these patients.

Selected Clinical Issues

Frailty

Pathophysiology

As our population ages, addressing frailty will become an essential aspect of elderly care. Frailty, defined as a chronic progressive condition with a spectrum of varying severity and heterogeneity, is a geriatric syndrome of weakness, weight loss, and low activity associated with adverse health outcomes especially in response to a stressful environment [1, 2].

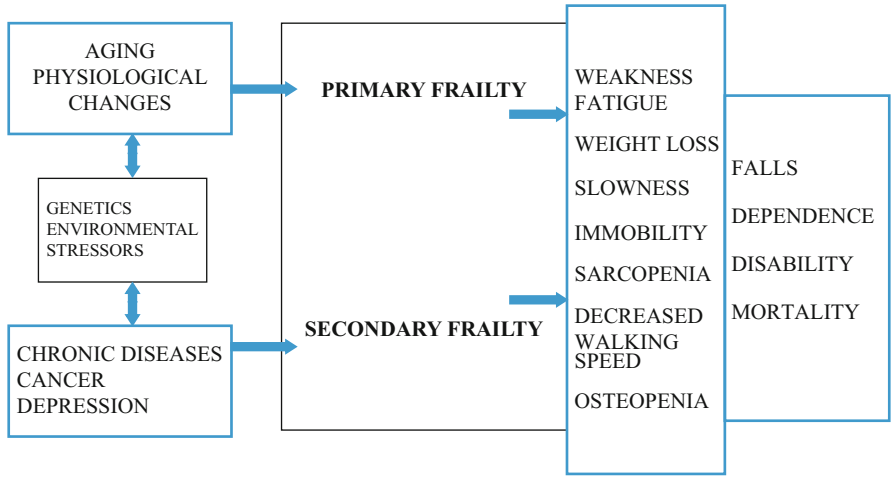

Fig. 1 Model for frailty

The overall prevalence of frailty in community-dwelling older adults aged 65 years and over in the USA ranges from 7 % to 12 %. This subset of the older population responds poorly to external stressors, lacking the ability to bounce back from acute illness. This in turn increases their risk of dependency. The prevalence of frailty is higher among women and in African Americans. Primary frailty is due to intrinsic physiological dysregulation that has reached beyond a threshold of normal recovery. Research in recent years has shown that there are altered physiological, genetic, cellular, and molecular changes in the body of the frail elder. These result in increased risk of poor outcomes, namely, falls, disability, dependence, and death (Fig. 1).

Secondary frailty is the result of complex interactions between multiple comorbidities and physiological changes during stress and aging. Of elderly people above 65 years of age 75 % suffer from three or more chronic conditions. Chronic conditions, including coronary artery disease, congestive heart failure, hypertension, peripheral vascular disease, chronic obstructive pulmonary disease, arthritis, cancer, diabetes, and HIV/AIDS, all increase the risk of disability and frailty. In both primary and secondary frailty, changes in the body occur, leading to decreased muscle mass (sarcopenia), loss of muscle strength, slowed motor performance (such as walking speed), decreased physical activity, worsened exercise tolerance (low energy or fatigue), and inadequate nutritional intake.

Diagnosis

In a clinical setting, the presence of frailty can be assessed by identifying at-risk elders through a detailed history, physical examination, and comprehensive geriatric assessment. There are many validated tools available to use in clinical settings to screen for frail elders [3, 4] (See Table 1). The first manifestation of frailty tends to be weakness, slowed walking speed, and/or decreased physical activity. Walking speed has been shown to predict mortality, mobility disability, and is a good screening marker. Frail elders meet three or more of five phenotypic criteria: weakness as measured by low grip strength (based on gender and body mass index), slowness by slowed walking speed (takes greater than 6–7 s to walk 15 ft), low level of physical activity (expends less than 270 kcal/ week for females and less than 383 kcal/ week for males based on activity scale), low energy or self-reported exhaustion, and unintentional weight loss (more than 10 lb in a year) [1, 2]. Disability is measured by impairment in activities of daily

Table 1 Frailty assessment tools

Frailty assessment tool	Content
Frailty Phenotype [40]	Uses signs and symptoms to assess by predefined criteria- Frail if 3of 5 criteria present
Clinical Frailty Scale [41]	Uses physical and functional indicators – 7 point scale to quantify degree of frailty
Vulnerable Elders Survey [42]	Thirteen questions, considers age, self-rated health, limitations in physical function, and functional disabilities- identifies at risk community dwellers for health deterioration
Groningen Frailty Indicator [43]	The GFI is a validated, 15-item questionnaire with a score range from zero to fifteen that assesses the physical, cognitive, social, and psychological domains. A GFI score of four or greater is considered the cut-off point for frailty
Edmonton Frail scale [44]	Multidimensional assessment instrument that includes the timed-up-and go test and a test for cognitive impairment
SHARE- FI frailty instrument [45]	Measures five items including grip scale- Has a web-based calculator
Tilburg Frailty Indicator [46]	Has two parts, Part A measures life course determinants and multi-morbidity and Part B measures physical, social and psychological domains of Frailty
Comprehensive Geriatric Assessment [47]	Standard CGA-good correlation with clinical frailty scale
Frailty Index (Deficit accumulation Index) [48]	The Frailty Index is composed by a long checklist of clinical conditions and diseases. Score is based on total accumulated deficits
FRAIL scale [49]	Easy to remember F=Fatigue, R=Resistance (unable to climb one flight of stairs),A=Ambulation (inability to walk one block), I=more than 5 Illness, L=loss of weight (5 %)

Table 2 Definitions of ADLs and IADLs

Activities of daily living (ADLs)	Instrumental activities of daily living (IADLs)
Ability to perform basic self-care tasks: *Dressing* – ability to dress oneself appropriately *Eating* – ability to self-feed *Ambulating* – ability to move in one's environment *Toileting* – ability to use toilet facilities *Hygiene* – ability to clean oneself, including hair and teeth	Ability to use instruments and interact with the environment to perform tasks necessary for independent function: *Shopping* – ability to obtain necessary terns for care (food, clothing, hygiene needs) *Housekeeping* – ability to keep environment clean *Accounting* – ability to manage money and simple finances *Food preparation* – ability to prepare foods for eating *Transportation* – ability to use modes of transportation to get necessary items

living (ADL) and instrumental activities of daily living (IADL) (Table 2), and comorbidity is defined by the presence of two or more diseases. Frailty is a distinct entity and so can sometimes exist without the presence of disability or chronic comorbidities.

Management

Frailty is managed by a team-based, multidisciplinary approach targeting biological, sociobehavioral, and environmental stressors and is associated with improved outcomes especially with respect to polypharmacy, falls, functional status, decreased nursing-home admission, and mortality [5]. Preventing and minimizing immobility and maintaining physical activity and muscle mass is critical in older adults at risk of frailty. Resistance, or strengthening exercise supplemented by aerobic exercise and balance training [6] (e.g., tai chi) and nutritional support, particularly protein supplementation, appears to be important to both the prevention and management of frailty. Decreasing the stress of environments such as hospitals by reducing iatrogenic

adverse events and polypharmacy during acute illness is also important. The role of micronutrient supplementation and hormone replacement therapy is not clear [7]. Addressing depression and various physical comorbidities is important to frailty management [8, 9]. Prescribing various appetite stimulants and anabolic agents to undernourished older adults needs further investigation. The management approach should consider issues that are particular to each individual, including interactions among conditions, and treatments, the patient's own preferences, goals, and prognosis as well as the feasibility of each management decision and its implementation [7].

Although frail elderly patients as a group have higher rates of morbidity and mortality, it is important to recognize that many frail elders will live for a number of years at a functional level. Understanding any functional losses that frail elderly may have sustained and pairing their needs with an appropriate level of services is important to maintain their quality of life. Early referral to palliative services when indicated may prolong survival and improve quality of life.

Table 3 Diseases associated with chronic constipation in the elderly

Neuropsychiatric disorders	Non-neuropsychiatric disorders
Multiple sclerosis	Hypothyroidism
Parkinson's disease	Diabetes mellitus
Spinal cord injury	Hypercalcemia
Autonomic neuropathies	Hypokalemia
Depression	Systemic sclerosis
Stroke	Obstructing colonic lesions like cancer
	Dehydration

Table 4 Three medications associated with constipation

Anti-cholinergics -Tricyclic antidepressants
Anti-convulsants
Anti-hypertensives -Calcium channel blockers Diuretics
Anti-parkinsonsian drugs
Opiates
5-HT_3-antagonists
Nonsteroidal anti-inflammatories
Chronic laxative abuse
Bismuth, Iron, Lithium, Iron, Aluminum antacids

Constipation

Constipation is one of the most common gastrointestinal disorders seen in elderly. In adults older than 60 years the prevalence is 33 %, whereas the overall prevalence among adults of all ages is about 16 %. Physicians typically define chronic constipation as infrequent bowel movements, usually less than 3 per week, for at least 3 of the prior 12 months. Patients may complain of a myriad of symptoms including hard stools, feeling of incomplete evacuation, abdominal discomfort, bloating and distension, excessive straining, sense of anorectal blockage during defecation, and the need for manual maneuvers and the use of laxatives [10, 11].

Types and Risk Factors

Constipation may occur in isolation or due to specific disorders. Primary constipation can be divided into three main types based on colon transit time and ROME 3 symptom criteria: normal transit, outlet dysfunction or defecatory disorder, and slow transit constipation [10]. There can be overlap of these primary types of constipation. The self-reported prevalence of secondary constipation increases with age and occurs more commonly in females than males. Less exercise, a sedentary lifestyle, diseases that create immobility, and the use of a variety of medications are the most significant risk factors in the elderly for secondary constipation (Tables 3 and 4).

Evaluation

Evaluation of constipation begins with a detailed history and physical examination, including a visual survey of perineal area, a digital anal examination, and a detailed medication review. This initial assessment will help to identify secondary causes of constipation . Further diagnostic tests are directed toward symptoms and history and physical exam findings to rule out organic causes. Primary constipation is usually diagnosed after

initial workup identifies no obvious etiology. The presence of any concerning symptoms such as bleeding per rectum, weight loss, and abnormal test results like anemia should prompt urgent direct visualization of colon. Colon transit study or manometric evaluations may be indicated in refractory cases of constipation [11].

Management of Constipation

Nonpharmacological Management

Most elderly will improve by increasing physical activity, fluid intake, increasing fiber slowly to 25–30 g in their diet, and the cessation of any offending medications. It is important to remind individuals to respond to the urge to defecate after drinking warm, caffeinated beverages in the morning, and to develop a daily routine for toileting. Foods high in soluble fibers such as grains, bran, nuts, beans, fresh fruits, and vegetables like prunes will help by adding bulk to the stool.

Pharmacological Management

When lifestyle, dietary changes, and nonpharmacological interventions are insufficient to ameliorate symptoms, a variety of over-the-counter and prescription medications are available to treat constipation. A stepwise approach with initial bulking agents and an osmotic laxative should be considered before adding stimulants (Table 5). Bulking agents cause increases in stool volume, a decrease in colon transit time, and an improvement in stooling consistency. Osmotically active agents are nonabsorbed agents whose main side effects are increased bloating and gas. Stimulants alter colonic motility and can alter fluid and electrolyte transport into the stool. They should be restricted in their use to two to three times a week to prevent overstimulation and atony of the bowel. The last resort for severe constipation is the addition of rectal suppositories and/or enemas to stimulate colon evacuation. In elderly with cardiac and renal problems, use of phosphate enemas more than the recommended dose (one enema in 24 h) can lead to electrolyte abnormalities and dehydration and rarely death. Lubricants are avoided in elderly as they can cause lipoid pneumonia if aspirated and anal leakage.

Newer agents like chloride channel activators (Lubiprostone) and guanylate cyclase C activator (Linaclotide) act at the receptor level in the gut and increase intestinal fluid, accelerated stool transit, and relaxation of the smooth muscle and may be indicated in select cases of chronic constipation. Serotonin 5-HT4 receptor agonists (Prucalopride) act by increasing intestinal motility and are available in Europe and Canada [12].

Sleep-Related Disorders in Elderly

Older adults consider quality sleep an essential part of good health [13]. Late-life insomnia is common in elderly. There is a common misconception that sleep disruption is an expected phenomenon of aging. Higher prevalence of sleep disruption is noted in the elderly as it is related to coexistent physical and psychosocial conditions and not solely due to physiological changes. It appears that there is bidirectional relationship between sleep disorders and multiple comorbidities and psychiatric disorders [14]. The most common sleep complaints among older adults are difficulty falling asleep, nighttime awakening, early morning awakening, and daytime sleepiness. Certain sleep disorders do increase in prevalence with age, such as sleep-related breathing disorders (i.e., sleep apnea) [15], periodic limb movement disorder [16], restless legs syndrome, and circadian rhythm sleep disorders. At least one-half of community-dwelling older adults use OTC and/or prescription sleeping medications [17].

Compared with younger adults, older adults generally take longer to fall asleep and have more nighttime wakefulness and more daytime napping. This is due to intrinsic age-dependent changes and interactions between circadian arousing processes and the homeostatic sleep drive. An earlier bedtime and earlier wake time are also common due to advanced circadian rhythms and reduced amplitude of circadian rhythm. Older adults also have less N3, or slow-wave, sleep (which is the deeper stage of sleep) than younger adults and increases in light stages of sleep [18].

Sleep-related disorders can be identified by routinely asking simple screening questions related to sleep habits, snoring, sleep quality, leg

Table 5 Drug therapy for constipation

Drug groups and specific medications	Common doses	Comments
Bulk agents		Effective at 12–72 h, inexpensive, causes gas and bloating
Bran Methylcellulose (Citrucel) Psyllium (Metamucil, Konsyl) Barley Malt extract Calcium polycarbophil (FiberCon)	1 cup/ day 1–4 tbsp./day 1–4 tbsp./day 12–32 g bid 1 tab qd- qid	
Lubricants		
Mineral oil	Contraindicated in Elderly	
Osmotic/Hyperosmolar agents		Effective in 24–48 h, non- absorbable, treats moderate to severe constipation PEG effective in 1 h
Lactulose (Cephulac) Sorbitol (70 %) Polyethylene glycol (Metamucil)	15–30 ml qd -bid 15–30 ml qd- bid 6–25 g once per day	
Stimulants		Most effective. most work within one hour, Senna takes 8–12 h- long term uses of Anthraquinones causes melanosis coli, GI cramping
Anthraquinones-senna (Senokot) Bisacodyl (Dulcolax) Glycerin	Two tablets once daily to 4 Tablets twice daily 10-mg suppositories or 5–10 mg by mouth up to 3 times/week. Suppository; up to once daily	Rectal irritation
Saline Laxative		Effective in 1–3 h, Magnesium toxicity
Magnesium (Milk of Magnesia)	15–30 ml once or twice daily	
Enemas		Effective within 30 min Last resort in healthy patients; used frequently in combinations with stimulants in patients who are demented, hospitalized, or on chronic narcotics Mechanical trauma, electrolyte problems
Tap water Phosphate enema (Fleet) Soap suds enema Mineral oil retention enema	500 ml per rectum 1 unit per rectum 1500 ml per rectum 200–250 ml per rectum	
Secretagogues		Opioid induced constipation Diarrhea, nausea headache
Lubiprostone (Amitiza) Linaclotide (Linzess)	24 mcg BID 145 mcg once daily	
Serotonin 5-HT4 receptor agonists		Not approved by FDA available in Canada and Europe

movements in sleep, and daytime sleepiness or fatigue. Assessment of coexisting medical problems and medications that affect sleep should be considered. Polysomnography may be indicated when sleep apnea, periodic sleep disorders, or narcolepsy is suspected. Wrist actigraphy can be used in identifying circadian rhythm disorders and in nursing-home residents, in whom traditional sleep monitoring can be difficult to obtain [9].

Management of sleep-related disorders is guided by the specific diagnosis and any associated medical comorbidities. Sleep hygiene

measures can help with milder insomnia. The strongest evidence currently supports cognitive-behavioral therapy for chronic insomnia which generally combines stimulus control, sleep restriction, and cognitive restructuring [9]. Short-term hypnotic therapy can be considered, but long-term use has been associated with increased adverse events like falls [19], cognitive impairment, and impaired driving [20, 21]. Obstructive sleep apnea (OSA) is a treatable condition that is associated with cardiovascular disease, including hypertension, stroke, myocardial ischemia, arrhythmias, cardiovascular events, and all-cause mortality [22]. OSA is also associated with motor vehicle crashes, and there is some evidence suggesting a link to cognitive impairment [23]. Older patients whose sleep apnea is associated with congestive heart failure or respiratory disease should be referred to a sleep specialist.

Social and Functional Issues

The vast majority of Medicare beneficiaries have one or more chronic conditions and geriatric syndromes, which are defined as unique, multifactorial health conditions in elderly that increase their risk of dependency and disability. Our health care system is organized in such a way that most sites of care like hospital, outpatient, and nursing homes work in silos and there is not much incentive to improve care coordination [24]. Therefore, innovative cost-effective models that consider comprehensive geriatric evaluations and those that improve the quality of care and safety of the elderly should be developed and financed by current health care system [25] (Fig. 2).

In acute care settings, systematic approaches using multicomponent multidisciplinary interventions decrease morbidity in hospital and improve functional outcomes [26–28]. In some situations hospital at home provides safe, economic, and effective alternatives to inpatient care in the community [9, 25]. Targeted interventions that improve care transitions before and after discharge, the use of home health services, caregiver support, case management, comprehensive discharge planning that includes follow-up, medication reconciliation, and education have all been shown to reduce in-hospital readmission and improve clinical and functional outcomes [25, 29].

The Program of All-Inclusive Care for the Elderly (PACE) [30, 31] is a model of care that provides inpatient, outpatient, and long-term services to frail community-dwelling adults requiring intensive care, typically only available in a nursing home setting. Interdisciplinary teams provide care across the continuum and cater to complex medical and social needs of the elderly.

Outpatient Comprehensive Geriatric Assessment (CGA) [26] and Geriatric Evaluation and Management (GEM) [25] are supplemental services designed to identify all of a person's health conditions affecting their physical, cognitive, functional, and social capabilities and also to help with development of comprehensive treatment plans. Geriatric Resources for Assessment and Care of Elders (GRACE) is a Patient Centered Medical Home–based model with enhanced geriatric care which provides home-based CGA by an interdisciplinary team, who coordinate complex health care needs with the patient's primary care provider and community liaison [29, 31].

Community-Based Assistive Services and Living Arrangements

The population of older adults is characterized by heterogeneity across measures of health status, functioning, and socioeconomic position. The options available to a particular individual are dependent on many variables including the seniors' specific needs, their caregiver support in terms of family and friends, their financial and insurance status, available assistive services, and living arrangements. The goal for the physician is to assist the patient in finding the appropriate services and living arrangements (Fig. 2) [9, 32].

Assistive Services

Informal support for seniors comes from family and friends. Formal support services are part of every community. There are a variety of formal assistive services designed to support seniors who are living in noninstitutionalized settings. Support

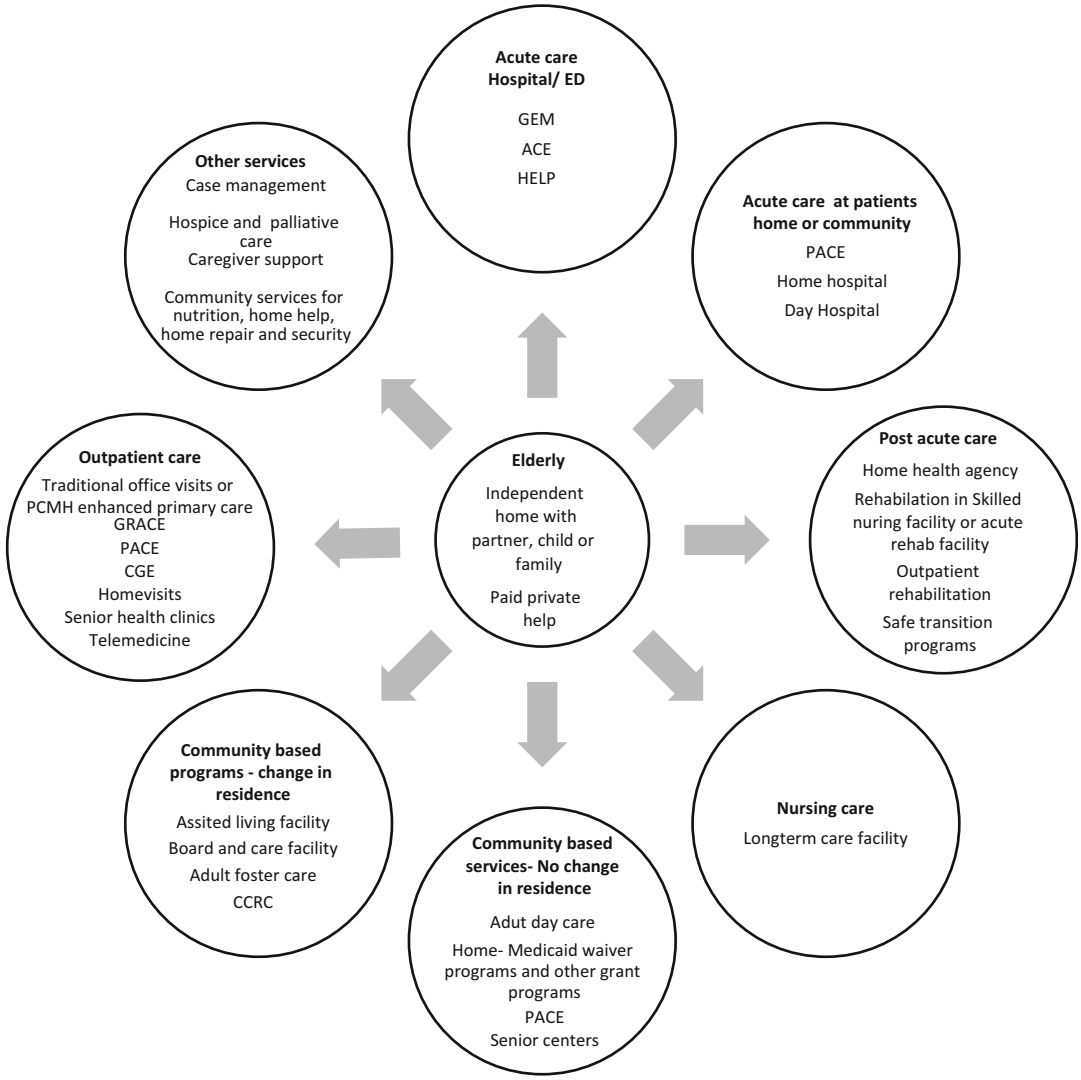

Fig. 2 Services available for elderly across various healthcare settings. *GEM* geriatric evaluation and management, *ACE* acute care of elderly, *HELP* Hospital elder life program

services come from both governmental organizations and private organizations. Information and referral services are available to find the types of services that people need (Table 6).

Alternative Living Arrangements

Many seniors find themselves in need of living arrangements other than the single family home/apartment because of failing health. There are a variety of options, depending on the level of services needed.

Independent living facilities – Independent living facilities (ILFs) are for the senior who needs minimal services but prefers to have them centralized. Such housing usually is an apartment or a bungalow that is associated with a facility

Table 6 Formal community-based support services for seniors

Community-based services	Description
Senior centers	Central location for group activities for seniors such as games, crafts, health fairs, etc.; usually has a congregate meal program
Adult day care	Provides daytime supervised activities for seniors in a group setting; some can accommodate patients with dementia. Non skilled custodial care to custodial car not covered by Medicare
Day hospitals	Provides daytime supervised activities for seniors in a group setting plus medical services (usually multidisciplinary rehabilitation services or nursing services for parenteral medication). Covered by Medicare like Home health services
Nutrition programs	Provides meals to seniors; can be at congregate sites such as day care or senior centers; can be home delivered program such as Meals-on-Wheels
Housekeeping services	Provides simple housekeeping services such as house cleaning, washing, shopping, or food preparation
Home repair services	Provides necessary home repair services such as installation of safety equipment (bath railing, locks), repair of steps or simple plumbing or electrical needs
Security services	Provides for easy contact to emergency services; commonly a necklace or button that contacts local emergency room.
Telephone contact services	Provides for a daily telephone call to ensure that the individual is in no need
Transportation services	Provides transportation for seniors into the community; sometimes limited to appointments for health care needs
Case management	Provides a coordinator of care for a senior who can assist in financial and social service needs
Respite care	Provides for short-term care for a senior so that a live-in caregiver can have a break (respite) from care

providing services in a centralized location. Usually ILFs provide for a congregate meal service, exercise facility, group activities, and a group transportation system. Many of these facilities provide for an easy transition to a more intensive assisted living mode.

Board and care facilities – The board and care facilities are also called group homes or residential care facilities. These are living arrangements in which a number of unrelated seniors live together providing for a reduced cost of services and greater care supervision. The residents can have their own room, or share a room, and have access to a cooperative living room, dining room, and kitchen. There is nonprofessional staff support at these facilities that does the housecleaning, meal preparation, and can assist residents in the taking of medication. These facilities are frequently licensed by the state.

Assisted living facilities – Assisted living facilities are growing in popularity. They are also known as personal homes, residential homes, and domiciliary care. An assisted living facility offers an independent living arrangement with 24 h support from licensed professional staff. Medication administration and management can be directed by either nonskilled or nursing staff depending on state license requirements. They have fewer regulations and are mostly funded by private long-term care insurance. Costs are not reimbursed by Medicare except in a few states. Usually people share living rooms, dining rooms, and recreational facilities but live in their own apartment-like room. This living arrangement is intended to provide seniors with increasing help from staff as they age while they remain in the same environments.

Continuing-care retirement communities (*CCRCs*) – CCRCs are all-inclusive facilities that provide the levels of care necessary for the aging individual. They require substantial financial resources that are typically funded through upfront "entry fees" and a fixed monthly expense, or a variable monthly expense depending on the level of services needed. Most provide for

independent living, assisted living, and more supervised living including a skilled nursing facility. Financing is mostly private, but some facilities may have Medicare or Medicaid funded beds for skilled care.

How to Help Seniors Understand Medicare

Medicare Structure

Medicare is federal health insurance that is administered by the Centre of Medicare and Medicaid services (CMS) for people 65 or older, people under 65 with certain disabilities, and people of any age with end-stage renal disease (ESRD) requiring dialysis or a kidney transplant. It was enacted into law in 1965 and is currently the nation's largest source of payment for medical care, insuring almost 54 million beneficiaries.

Medicare comprises four benefits. Medicare Part A covers hospital, skilled nursing-home, home-health, and hospice services. Medicare Part B covers physicians, nurse practitioners, social workers, psychologists, therapists, laboratory tests, and durable medical equipment. Medicare Part D covers some of the cost of prescription medications. Medicare Part C provides the benefits offered under Medicare Parts A and B through Medicare Advantage (MA) plans, which are managed care plans. Most MA plans also offer Medicare Part D benefits. Medigap supplemental insurance plans are available that cover Medicare Part A and Part B deductibles and coinsurance costs [33]. Medicaid is a joint federal and state program that provides health insurance (including long-term custodial care in nursing homes) to people of all ages who have low incomes and limited savings [34].

The Affordable Care Act (ACA) of 2010 laid out several changes to the financing, coverage, and costs of health care for older adults. While the details will evolve over the years some of the major changes include creation of the Center for Medicare and Medicaid Innovation (CMI), which has been charged with testing and implementing new care and payment models such as the Accountable Care Organization and the Patient Centered Medical Home, partial closure of the coverage gap in the Medicare Part D, extended coverage for preventive care services, and expansion of Medicaid (beginning in 2014), in which many more Medicare beneficiaries will be qualified as dually eligible, eliminating many of their out-of-pocket expenditures.

Medicare Finances

In 2013, Medicare accounted for 14 % of the federal budget and 20 % of national health care spending, 23 % on physician services and 27 % of hospital payments. Of all Medicare revenue 89 % comes from people younger than 65 years old through taxes and interest on the Medicare trust fund, and only 11 % comes from monthly premiums, deductibles, and copayments. Total Medicare benefit payments for 2013 were 583 billion dollars [35]. Approximately 85 % of patients with Medicare have some form of supplemental insurance to help pay for deductible costs, copayments, and uncovered expenses (especially prescription drug costs). Of patients 15% have Medicaid supplemental insurance, 35 % have an employer-sponsored plan, 25 % have purchased a private supplemental plan (so-called Medigap policy), and 10 % have supplemental plans through a variety of public (state and federal) programs. In 2010, the average Medicare beneficiary spent $4,734 out of pocket. This figure includes premiums for Medicare and other types of supplemental insurance and costs incurred for medical and long-term care services [36, 37].

Covered Services

Medicare is an extensive insurance plan with coverage extending from hospital to home and from physicians to therapists. Its coverage is complex and subject to a variety of deductibles and copayments (Table 7). Neither Part A nor Part B of the Medicare program covers routine dental or foot care, hearing aids, eyeglasses, orthopedic shoes, cosmetic surgery, acupuncture, or custodial nursing home care. The preventive services that are covered 100 % are yearly wellness visits, a fecal occult blood test, pap smear, Herpes zoster vaccination, screening mammogram, blood tests

Table 7 Six health coverage in elderly at a glance

Plan	Medicare Part A	Medicare Part B	Medicaid	Medicare Part D	Medicare Part C	Medigap
Coverage	Hospitals- first 60 days per benefit period Postacute care in skilled-nursing facility 100 days Hospice Home care ("medically necessary") Durable medical equipment (80 % covered)	Home care ("medically necessary") Durable medical equipment Diagnostic laboratory tests Diagnostic imaging tests Physicians, nurse practitioners Outpatient PT, OT, ST Outpatient services, supplies Emergency care Ambulance services Preventive services Outpatient mental health care	Hospital as well as outpatient and preventative services as outlined in Part B. Vary state to state	Prescription plan for generic and brand name drugs Starting in 2011, the coverage gap ("doughnut hole") will gradually be closed over the next 10 years. In 2012, beneficiaries will pay 50 % of the cost of brand name medications and 93 % of the cost of generic medications while in the coverage gap	Covers Hospital Part A and outpatient services Part B and drug benefits May have additional preventive services	Medicare supplemental insurance plan Pays copays and deductibles for Medicare Part A and Part B Can choose own provider PPO and HO
Funds	Federal Payroll taxes	Federal Income tax and premiums	State and federal tax dollars	Insurance plan and Medicare	Private Insurance plan	Private Insurance plans
Monthly premium	None	104–355 $ per month based on income	None	Varies 12–70 $ Plus plan premium based on income	varies	Varies by plan and health status
Deductible	1216 $ (may be covered by secondary insurer)	147 $ per year	None	Max of 320$	varies	varies
Other expenses	Pay partial or full after 60 days (unless dual eligible)	20 % copayments for some services	20 % copay in some states	Copay and copayments varies	varies	
Comments	Hospice-Patient makes co-payments of $5.00 per outpatient prescription and 5 % of cost of respite care		Major payor for nursing home care in many states		Medicare advantage Can choose own provider PPO or HMO	Does not cover vison, dental care or LTC

for diabetes and cardiovascular disease, and influenza and pneumococcal vaccinations; glaucoma screening, sigmoidoscopy or colonoscopy or barium enema, measurement of bone mass, hepatitis B vaccination, and medical nutrition therapy for diabetes and kidney disease [33].

Assessing Older Drivers

Currently, motor vehicle injuries are the leading cause of injury-related deaths among 65- to 74-year-olds and are the second leading cause (after falls) among those aged 75 to 84years. Older adult drivers have the highest fatality rate per crash and per mile driven among all age-groups. Driving is a cornerstone issue for many seniors as it provides access to shopping, medical services, food, and socialization. The inability to drive may increase the risk of social isolation and negatively affects well-being.

Inquiry about driving should be routine part of history taking. The initial screen should include review of medications and an assessment of any medical illness that might affect driving ability. A collateral history from family members about unsafe driving behaviors or traffic violations may be required. Those at risk should have driving-related factors assessed. These include vision, cognition, and somatosensory skills. Table 8 lists the most commonly cited causes of potential or mild functional losses correlated with driving impairment. Licensing, and testing, and mandatory medical reporting requirements vary from state to state in the USA. Physicians often play a key role in identification and referral of potentially unsafe drivers [38].

Once the physician has determined that the individual elder is at risk, then a discussion should ensue with the patient and their family about reasons for restricting driving and possible evaluation and remediation through driving rehabilitation services or adult driving classes [39]. In many states, the Department of Motor Vehicles has a driving competency assessment program that requires seniors to take written and performance tests to determine continued licensure. In states where this is unavailable, it is important to consider assisting the patient and family with alternate modes of transportation and available services to help compensate for the loss of driving independence. Ongoing assessment at follow-up is crucial to identify depression, isolation of the patient, and caregiver stress.

Table 8 Potential or mild functional losses associated with increased driving risks

Cognitive loss	Visual-spatial losses more important than memory in early disease Slowed central processing of information ("slowed reaction time")
Motor loss	Loss of grip strength and wrist function Limitations in rotation of neck Limitation in upper and lower extremity motion/strength
Sensory loss	Visual loss – visual fields, central acuity, night vision, and increased glare Hearing loss – especially bilateral hearing loss Patients with combined visual and hearing loss at highest risk
Loss of consciousness	Any seizure disorder Medical diseases (cerebrovascular, cardiac arrhythmias, diabetes, medication use, alcohol use) that have caused loss of consciousness within last year

[b]The Medically At-Risk Driver Centre, Department of Family Medicine, Faculty of Medicine and Dentistry, University of Alberta, Edmonton, AB, Canada

Elderly patients present a unique challenge to the family physician. They commonly present with multiple problems that are each multifactorial. A systematic approach is needed to assess and manage the common problems of the elderly. More complete reviews may be found in textbooks of geriatric medicine [1, 2].

Urinary Incontinence

A standardized definition of urinary incontinence (UI) by the International Continence Society states that UI is the complaint of involuntary loss of urine, which is objectively demonstrable and is a social or hygienic problem [3]. UI affects 15–30 % of older adults in communities and 50 % of those in nursing homes [4]. In the hospital, the prevalence of UI in the senior population is less well reported and varies from 30 % to 60 %. UI is underreported, with an estimated 50 % of patients not seeking help. This may be due to embarrassment or the belief that UI is a normal part of aging. There are significant clinical, psychosocial, and financial impacts associated with UI, including depression, anxiety, sexual dysfunction, work impairment, social isolation, and reductions in quality of life. The estimated total national cost of UI in the United States in 2007 was $65.9 billion, with projected costs of $76.2 billion in 2015 and $82.6 billion in 2020 [5].

In the elderly, bladder capacity and force of contractility decrease as a result of the aging process while the post-void residual (PVR) volume may increase [6]. There also may be uninhibited bladder contractions. These physiological changes do not cause UI, but are predisposing factors for UI. There also are age-associated changes in vasopressin and atrial natriuretic hormone that lead to the elderly excreting most of their fluids later in the day and at night, resulting in one to two episodes of nocturia [7].

Types of Urinary Incontinence

When evaluating a patient with UI, a key initial step is determining if the condition is due to a transient or an established cause. A transient cause should be sought because treatment will usually restore continence.

Transient Urinary Incontinence

Transient causes of UI probably account for 33 % of cases in the community-dwelling elderly, around 50 % of cases of hospitalized elderly patients, and a significant number of patients in long-term care [3]. For acute-onset cases of UI, there often is a treatable cause. The mnemonic “DIAPPERS” is used to recall possible causes of transient UI [8]:

*D*elirium
*I*nfection – urinary (symptomatic)

*Email: lesley.charles@albertahealthservices.ca

DOI 10.1007/978-1-4939-0779-3_24-1

*A*trophic urethritis/vaginitis
*P*harmaceutical/*p*rostate
*P*sychological, especially depression
*E*ndocrine (or excess fluid intake/output)
*R*estricted mobility
*S*tool impaction

Established Urinary Incontinence

With established UI, the incontinence is chronic. There are five major types of established UI to consider. These are urge, stress, overflow, functional, and mixed incontinence.

Urge incontinence (overactive bladder) is the most frequent type of established UI in older adults [7]. Symptoms include a sudden, uncontrollable need to void. Urge incontinence can result in the loss of large or small amounts of urine, often on the way to the washroom. There also may be symptoms of frequency, nocturia, and enuresis associated with urge incontinence. Urge incontinence is the result of abnormal detrusor muscle contractions.

Stress incontinence is losses of small volumes of urine with increases in intra-abdominal pressure (e.g., sneezing, coughing, lifting). There are two key types of stress incontinence: anatomic stress incontinence and intrinsic sphincteric deficiency. Anatomic stress incontinence is caused by anatomical changes resulting in bladder and bladder neck hypermobility. These changes often are associated with vaginal childbirth or postmenopausal status. Anatomic stress incontinence is commonly seen in older women in ambulatory clinic settings and long-term care [7]. Risk factors include pelvic prolapse, cystocele, or urethrocele. Intrinsic sphincteric deficiency, the second type of stress incontinence, is caused by functional damage to the urethral sphincter mechanism. This may be the result of prior pelvic or bladder surgery, radiation, or trauma.

Overflow incontinence is the third major type of incontinence. Overflow incontinence is thought to be the second commonest type of established UI in older men. With overflow incontinence, the bladder cannot empty properly and becomes overdistended. Presenting symptoms include dribbling, weak urinary stream, intermittency, hesitancy, straining, frequency, and nocturia resulting in the loss of continual, small volumes of urine. The most common cause of overflow incontinence in men is bladder outlet obstruction from prostatic enlargement (e.g., benign prostatic hypertrophy or prostate cancer). In women, cystoceles or uterine prolapse can less commonly cause obstruction incontinence. Urethral or bladder neck stricture or stone also may cause overflow incontinence in women. A second cause of overflow incontinence in both sexes is detrusor hypocontractility which may be from a neurogenic or non-neurogenic cause. With age, the detrusor may have become fibrotic and replaced by connective tissue. Neurogenic causes include peripheral neuropathy from diabetes mellitus, pernicious anemia, alcoholism, and mechanical damage to the spinal nerves from a herniated disk, spinal stenosis, or a tumor.

Functional incontinence, the fourth type of UI, occurs in patients with normal urinary functioning. It may result from a decline in physical or cognitive functioning or may be a result of psychiatric illness.

Mixed incontinence, the final type of UI, typically is a combination of urge and stress incontinence. As such, mixed incontinence shares both the causes and symptoms of both stress incontinence and urge incontinence.

Evaluation

All patients with UI must be evaluated for any transient-reversible causes. This should include a history, physical examination, and urinalysis. The history will cover the UI symptoms including duration, frequency, timing, precipitants, and the amount of urine lost. Associated symptoms such as frequency, urgency, nocturia, dysuria, hesitancy, straining, poor stream, and hematuria should be ascertained. In

DOI 10.1007/978-1-4939-0779-3_24-1

order to exclude potentially serious underlying conditions, patients with UI should be asked about onset of incontinence, abdominal or pelvic pain, hematuria, lower extremity weakness, changes in gait, cardiopulmonary and neurologic symptoms, weight changes, and mental status changes. Alcohol and caffeine intake also should be noted. Additional history should be inquired regarding sense of prolapse, prior surgery, urinary tract infection symptoms, parity and mode of delivery, vaginal symptoms, and bowel habit and constipation. A structured medication review also should occur. The effect of UI on quality of life should be determined. In frail older adults, asking about functional status, mood changes, mobility, changes in cognitive status, and medication changes is especially important [9].

The physical examination includes abdominal, neurologic, and genitourinary tract examinations. The bladder must be palpated. The family physician should assess both cognitive function and nerve roots S2–3 during the neurologic examination. In men, the genitalia should be examined to look for abnormalities of the foreskin, glans penis, and perineal skin. A rectal examination should be performed, testing for perineal sensation, sphincter tone, fecal impaction, and prostatic enlargement. In women, a pelvic examination should be undertaken to assess perineal skin and muscle tone and to determine if there is pelvic prolapse or a pelvic mass. The cough stress test should be performed to assess if there is urine loss with a full bladder [10]. Examination also should include a post-void residual (PVR).

The type of UI should be identified. If the cause of UI is still unclear, a daily voiding diary may help to clarify the type and severity of the UI. Referral to a specialist should be considered in these cases. Referral to a continence specialist or further investigation with urodynamics could be considered if the diagnosis is uncertain or if treatment has not been successful. If there is persistent hematuria without infection, the patient may require cystoscopy. Referral to a specialist could be considered if surgery is being contemplated to clearly identify the underlying type of UI (e.g., transurethral resection of the prostate or gynecological surgery).

Treatment

There are three main approaches to treatment of UI: behavioral, pharmacological, and surgical [7].

Behavioral techniques include toilet assistance, bladder education/retraining, pelvic floor muscle exercises, biofeedback, and electrical stimulation. Toilet assistance can include scheduled toileting or prompted voiding. Bladder education involves delayed and timed voiding, urge suppression, and fluid/diet alterations. Bladder training may be useful for urge and stress UI. Prompted voiding often is used in frail or cognitively impaired patients. For stress incontinence, pelvic floor muscle exercises or Kegel exercises are useful. Vaginal cones (weights that are inserted into the vaginal vault and held in place) also can be used to strengthen the pelvic floor muscles. Patients should consume six to eight cups of fluid per day and limit caffeine and alcohol intake. Non-pharmacologic treatments for overflow incontinence include intermittent catheterization, indwelling urethral or suprapubic catheters, external collection systems, and protective undergarments. Chronic indwelling catheters should be viewed as a last resort when all else has failed or when there is accompanying local skin breakdown.

In terms of pharmacological therapy, anticholinergic or antimuscarinic agents help relax the bladder and increase bladder capacity. These agents are used for incontinence with detrusor overactivity (e.g., urge incontinence). Medications available for urge UI include oxybutynin (Ditropan), tolterodine (Detrol), fesoterodine (Toviaz), solifenacin (Vesicare), darifenacin (Enablex), propiverine (Mictonorm), and trospium (Sanctura). Before starting any of these medications, ensure a normal post-void residual (PVR) volume as urinary retention may occur. Systematic reviews of randomized trials have found that antimuscarinics compared with placebo have a modest benefit over placebo in reducing urgency UI. In the largest systematic review to date, which included 94 randomized trials, fewer than 200 women per 1000 treated with medications achieved continence. Similar efficacy was demonstrated for all antimuscarinic agents (darifenacin [Enablex], fesoterodine [Toviaz], oxybutynin [Ditropan], solifenacin [Vesicare],

DOI 10.1007/978-1-4939-0779-3_24-1

tolterodine [Detrol], and trospium [Sanctura]). The role of topical estrogen replacement therapy in UI treatment in women remains unclear. That is, there is widespread anecdotal evidence that topical estrogen replacement therapy is effective in treating UI in postmenopausal women but the literature is contradictory. Vaginal pessary is another nonsurgical treatment often used in elderly women for prolapse. The local pressure effect of these can cause erosions so they should be used with estrogen therapy [11]. In men with overflow incontinence, two classes of medication have been shown to decrease symptoms: alpha-adrenergic antagonists and 5-alpha reductase inhibitors. The alpha-adrenergic antagonists include terazosin (Hytrin), tamsulosin (Flomax), prazosin (Minipress), or doxazosin (Cardura). Patients on alpha-adrenergic antagonists must be monitored for orthostatic hypotension, dizziness, peripheral edema, tachycardia, nasal congestion, impotence, and first-dose syncope. The 5-alpha reductase inhibitor finasteride (Propecia, Proscar) also can be quite helpful.

Surgery can be used for various clinical scenarios of UI. Retropubic suspension and sling can be used for stress incontinence. If overflow incontinence is due to obstruction (e.g., benign prostatic hypertrophy), surgery may be required (e.g., transurethral prostatectomy).

Falls

Falls are the leading cause of fatal and nonfatal injuries among the elderly in the United States. In 2012 alone, falls cost approximately $30 billion in direct medical costs. [12]. The incidence of falls increases with age from 30 % to 40 % per year in patients over 65 years living in the community to 50 % for those over 80. In those over 70 years, 41 % of falls result in minor injury with 6 % resulting in major injury. Five percent of falls in older patients will lead to hospitalization.

All community-dwelling seniors should be screened annually for falls by asking the following question: “In the past year, have you had a fall (including a slip or trip where you lost your balance and ended up on a lower level)?” If the answer is “yes” to more than one slip, trip or fall, an injurious fall, or balance and mobility problems, conduct a multifactorial falls risk assessment. The reason the assessment is multifactorial is because falls in older adults most often are not due to a single cause. A fall history and their circumstances should be completed including date, time of day, location, circumstances (e.g., what the patient was doing at the time of a fall, patient’s perception as to the cause, associated symptoms preceding such as chest pain, shortness of breath, palpitations, dizziness), and circumstances after the fall (e.g., loss of consciousness, injuries, post-fall interventions, severity of the fall, duration of any changes in activities of daily living [ADL]/mobility status, and in the patient’s confidence in walking and/or fear of falling). Some find the “SPLATT” [13] mnemonic useful:

*S*ymptoms
*P*revious falls
*L*ocation
*A*ctivity
*T*ime
*T*rauma

History also should include medications currently taken, the use of alcohol, the presence of acute and chronic medical conditions, function (e.g., assessment of basic and instrumental activities of daily living), mobility, and lower urinary tract symptoms (LUTS) (e.g., urinary urgency, frequency, nocturia, and urge incontinence). Certain LUTS (i.e., urge incontinence, mixed incontinence, overactive bladder, nocturia) increase the risk of falls among older individuals by up to twofold [14–16]. A comprehensive medication

DOI 10.1007/978-1-4939-0779-3_24-1

review by a physician, nurse practitioner, or pharmacist should be conducted on all elderly patients who have had multiple falls or an injurious fall. All medications, their doses, and frequency of use should be reviewed at least annually [17]. The 2012 American Geriatrics Society Beers Criteria for Potentially Inappropriate Medication Use in Older Adults noted that the following medications may exacerbate a history of falls or fractures: anticonvulsants, antipsychotics, benzodiazepines, nonbenzodiazepine hypnotics, tricyclic antidepressants, and selective serotonin reuptake inhibitors [18]. Moderate risk medications that are more weakly associated with falls include anticonvulsants and cardiovascular agents (e.g., antihypertensives, antiarrhythmic medications, beta blockers, peripheral vasodilators, and nitrates).

The physical examination should cover the following: a neurologic examination including mental status, lower extremity strength (e.g., Can the patient stand from sitting without using their arms?), vision, vestibular function (e.g., detection of movement-provoked dizziness by first shaking the head side to side and then nodding it up and down, a head impulse test if trained to do it and there are no contraindications such as severe cervical arthritis), lower extremity sensation and reflexes, a search for extrapyramidal signs (e.g., tremor, rigidity, akinesia, and postural instability), and coordination. A musculoskeletal examination focusing on the lower extremities (e.g., joints, range of motion, pain, deformities) and feet/footwear (e.g., foot problems such as plantar fasciitis, hallux valgus, bunions, ingrown toenails, onychogryphosis, and multiple foot problems) are associated with an increased risk of falling. In-home falls have been associated with being barefoot or wearing socks without shoes and proper-gripped slippers. A cardiovascular examination should include assessment of heart rate and rhythm, orthostatic pulse, and postural blood pressure (prone and supine). Regular eye assessments should be encouraged. Assessment for osteoporosis including asking about prior osteoporotic fractures and any past bone mineral density tests should be done. Inquiry about historical heights and measurement of current height also should be done, with a historical height loss of greater than 6 cm suggesting the presence of vertebral fractures. Measurement of the occiput-to-wall distance should be done, with an occiput-to-wall distance of greater than 5 cm indicative of the presence of kyphosis which may be the result of vertebral fractures. An assessment of rib to pelvis distance should be conducted, with two fingerbreadths or less suggestive of the presence of vertebral fractures [19]. Screening tools such as the Timed Up and Go test [20] can be used to predict risk of fall. Once an older adult has been identified as having decreased lower extremity strength or impaired balance, based on either simple observation or outcomes from fall risk screening tools, referral to a physiotherapist is recommended for a detailed assessment of the physical factors which may be contributing to fall risk.

There are a number of interventions that can reduce the risk of falls in seniors. In elderly patients with impaired vision, interventions include good lighting, use of contrasting paints or carpet to mark the edge of stairs, and advising on the avoidance of wearing bifocals while walking. Treatment of orthostatic hypotension also is an important consideration with treatment dependent on the most likely cause. History taking should focus on the type of dizziness: Vertigo (a false sense of motion often described as a spinning or whirling sensation), disequilibrium (feeling off balance or wobbly), or presyncope (a feeling of lightheadedness or feelings of blacking out or fainting). For many elderly patients, categorization of dizziness may be difficult in that the patient may have multiple types of dizziness. Cause of vertigo includes benign paroxysmal positional vertigo (BPPV). Orthostatic (postural) hypotension is a possible cause of presyncope. There are multiple possible causes of disequilibrium such as stroke, Parkinson's disease, sensory impairments (e.g., peripheral neuropathy), and adverse effects of medications. Management is directed at the cause. If syncopal falls are suspected, referral to a cardiologist is recommended. In general, elderly individuals should wear shoes with low heels and firm slip-resistant soles both inside and outside the home.

Treatment of osteoporosis also is important, with supplemental vitamin D recommended. Hip protectors (devices that absorb and shunt the energy of the impact of a fall away from the greater trochanter)

DOI 10.1007/978-1-4939-0779-3_24-1

have a role in preventing hip fractures among those at high risk of falls if the patient is willing to wear them. High-risk older adults in long-term care facilities may benefit from their use, but their utility in preventing hip fractures among the elderly in the community is not proven [21]. Physiotherapy is recommended for older patients with lower extremity weakness and/or impaired gait and balance. For the elderly patient living alone or left alone for long periods, an emergency response system should be offered. A home safety checklist for assessment of environmental risks can be used by elderly patients and/or their families. Referral to an occupational therapist may be made for high-risk elderly patients [22].

In summary, the most efficacious interventions reported for elderly patients who are at high risk for falls include adaptation or modification of the home environment, discontinuing or tapering psychoactive medications, discontinuing or tapering of other medications (e.g., anticholinergics, benzodiazepines, hypnotic sedatives, and antihypertensives), minimizing postural hypotension, management of foot problems and footwear, and exercise, especially balance, strength, and gait training. See Fig. 1 for an algorithm in the prevention of falls in older persons living in the community from the American Geriatrics Society and British Geriatrics Society [23].

Orthostatic Hypotension

Orthostatic hypotension (OH) is defined as a "sustained reduction of systolic blood pressure of at least 20 mmHg or diastolic blood pressure of 10 mmHg within 3 minutes of standing or head-up tilt to at least 60° on a tilt table" ([24], p. 46). It is estimated to be present in up to 70 % of institutionalized elderly and 6 % of community-dwelling elders [24]. Measuring the blood pressure after sitting (not lying) will miss some cases of OH. However, there is some controversy regarding how long to wait after standing before measuring BP. Generally the standing BP is measured at 1 minute (for screening purposes, a single 1-minute reading is usually sufficient) and 3 minutes after standing.

The recommended approach is to diagnose the underlying cause of OH and manage it. An important step is to review medications and discontinue or reduce medications that may be contributing to the problem. Ensure adequate fluid intake. Modify salt restriction where appropriate. Use compensatory strategies (e.g., elevate head of the bed, rise slowly, dorsiflex feet before getting up). Use pressure gradient stockings (preferably thigh high) where appropriate. Consider pharmacological therapy (e.g., fludrocortisone [Florinef], midodrine [Orvaten, ProAmatine]) if the above strategies are unsuccessful and there are no contraindications. See the Finding Balance website (http://www.findingbalancealberta.ca/intervention-a-management-of-medical-risk-factors-for-falls).

Polypharmacy

There are varied definitions of polypharmacy, from using inappropriate prescriptions to using five or more prescriptions. Depending on the definition, the incidence of polypharmacy varies from 5 % to 78 % [25]. Inappropriate drug prescribing may lead to avoidable adverse drug events (ADEs). ADEs should be considered to be the cause for any new symptom in an older adult until proven otherwise. ADEs occur two to three times as frequently in older persons. Patients taking fewer than three drugs have a 1–2 % risk of ADEs whereas those taking more than six drugs have a 13 % risk of ADEs. Thirty percent of admissions to hospital are because of adverse drug events. ADEs increase hospital length of stay, increase costs, and increase mortality. The annual costs of drug-related morbidity are estimated to be $177 billion in 2000 [26]. Drug-related hospitalizations cause 2.4–6.5 % of all medical admissions in the United States in the general population. ADEs are increased in the elderly due to age-related changes in pharmacokinetics and

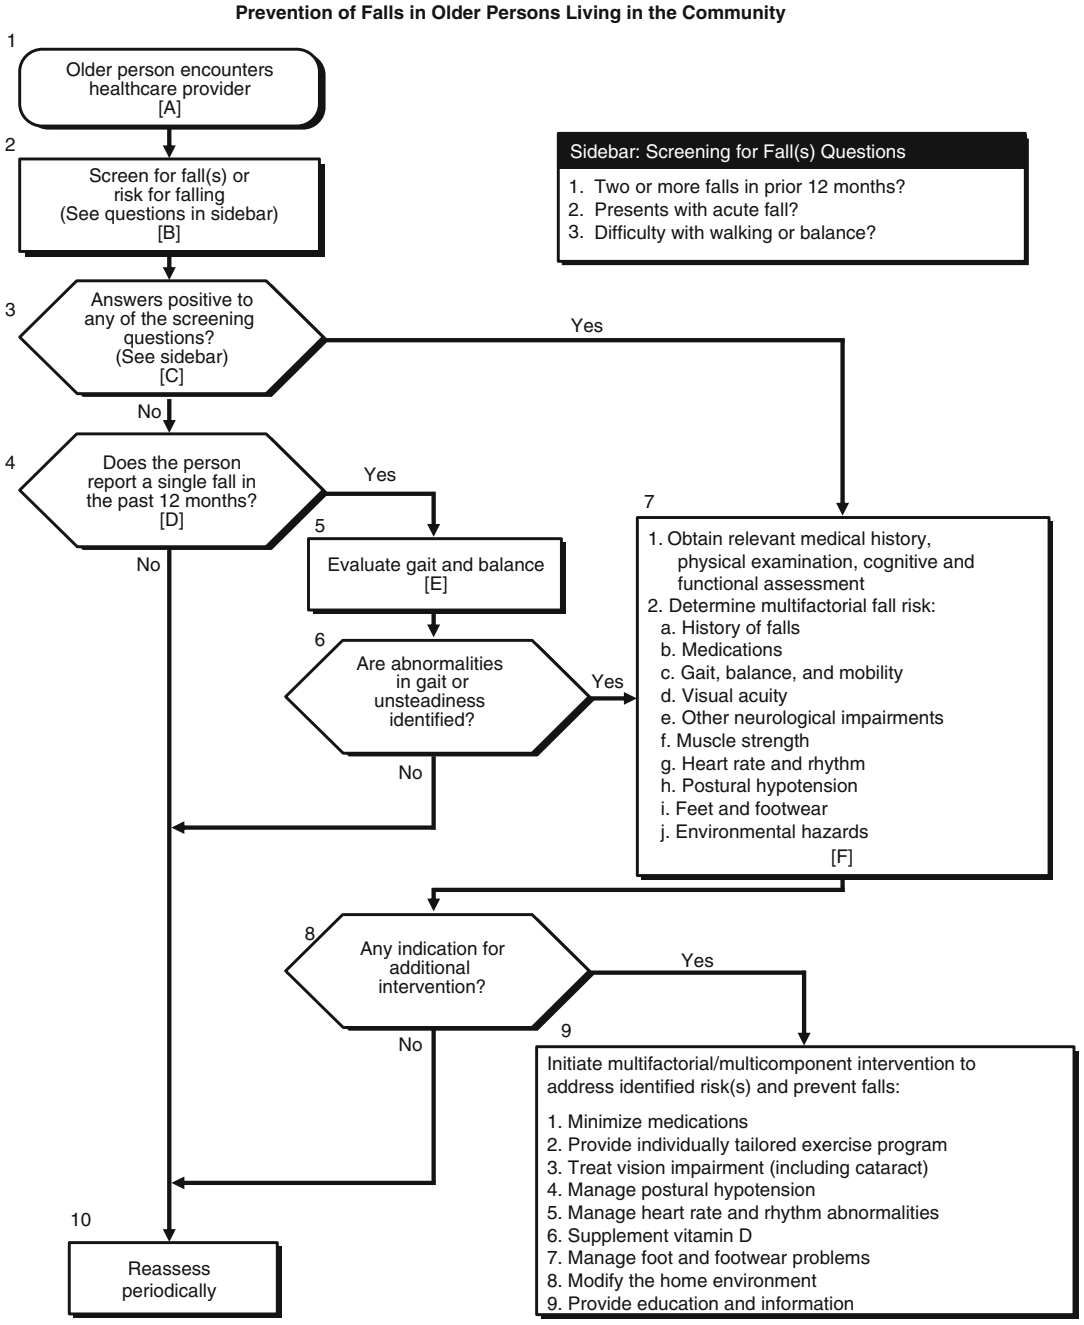

Fig. 1 Prevention of falls in older persons living in the community. This is an algorithm for screening and assessment of falls in older persons, developed by the Panel on Prevention of Falls in Older Persons of the American Geriatrics Society and British Geriatrics Society (Originally published in [18]; with kind permission of © John Wiley and Sons 2011. All Rights Reserved)

pharmacodynamics, increased comorbidities, polypharmacy, and nonadherence. Moreover, drug trials frequently exclude older adults. As a result, approved drug doses may not be appropriate for the elderly population.

An example of prescribing guidelines for the elderly is the 2012 Beers criteria. It categorizes the medications/classes that should be avoided in those aged 65 years or older. It was developed from an interdisciplinary panel of 11 experts who applied modified Delphi method to the systematic review process and grading of evidence to reach consensus. Fifty-three medications or classes were identified and

DOI 10.1007/978-1-4939-0779-3_24-1

divided into three categories: potentially inappropriate medications or classes to avoid, medications to avoid with certain diseases/syndromes, and medications to be used with caution in older adults. Some noteworthy additions of drugs to avoid in the 2012 Beers criteria include all short-acting benzodiazepines (regardless of dose), glyburide (DiaBeta, Micronase), megestrol (Megace), metoclopramide (Metozolv, Raglan), and sliding-scale insulin. New drug-disease interactions added include cholinesterase inhibitors in syncope, selective serotonin reuptake inhibitors in falls or fractures, and pioglitazone (Actos) or rosiglitazone (Avandia) in congestive heart failure [27]. There also is the Screening Tool of Older Persons' Prescriptions (STOPP) criteria [28].

Drug categories to avoid in the elderly, regardless of the consensus criteria used, include the following [29]:

1. Anticholinergics (e.g., tertiary tricyclic antidepressants, gastrointestinal antispasmodics, antimuscarinics, antipsychotics, first-generation antihistamines)
2. Sedatives/hypnotics (e.g., barbiturates, long- and short-acting benzodiazepines) not be prescribed for chronic usage
3. Anti-inflammatories (avoid chronic usage)
4. Opiate-related analgesics (e.g., pentazocine [Talwin], meperidine [Demerol])
5. Antiarrythmics class Ia, Ic, and III (e.g., disopyramide [Norpace] with anticholinergic, negatively inotropic side effects; amiodarone [Cordarone, Nexterone, Pacerone]; digoxin [Lanoxin, Lanoxicaps] $>$ 0.125 mg/day)
6. Cardiovascular (e.g., alpha blockers, alpha agonists, immediate-release nifedipine [Adalat, Afeditab, Nifediac, Nifedical, Procardia], spironolactone [Aldactone] $>$ 25 mg/d with risk of hyperkalemia)
7. Anti-infective (e.g., nitrofurantoin [Furadantin, Macrobid, Macrodantin] with reduced creatinine clearance/pulmonary toxicity)
8. Endocrine (e.g., desiccated thyroid/cardiac, testosterone cancer risk, sliding scale/hypoglycemia, megestrol [Megace]/deep venous thrombosis, oral hypoglycemic agents/glyburide [DiaBeta, Micronase] with low blood sugars)

Strategies for Appropriate Prescribing

There are several recommended strategies for appropriate prescribing in the elderly [30, 31]. The strategies are as follows:

1. Maintain an up-to-date drug list with indications for all prescriptions, over-the-counter drugs, and herbal supplements.
   - Consider non-pharmacologic options.
   - Regularly review the need for the drug and stop the drug, if possible.

     Medication reconciliation is crucial for transitions of care. It is a process that identifies medication discrepancies, informs prescribing decisions, and prevents medication errors. The process has three steps: verification (medication use history, accurate list), clarification (medications and doses are accurate), and reconciliation (identify any discrepancies between what is ordered and the patient list, making changes to orders, documenting changes, communicating updated list to the next provider). This medication reconciliation process decreases medication errors by 70 % and ADEs by 15 %.

     Structured Medication Review (SMR) [32] is a regularly scheduled discussion between a patient and their doctor/pharmacist/nurse to review ALL medications to address how each medication is working, how each medication is taken, and patient concerns. A SMR should be done when the patient asks for a review, if they are on $>$5 meds or have $>$3 comorbidities, they have

DOI 10.1007/978-1-4939-0779-3_24-1

received medications from more than one physician, and/or there has been a medication change in the last 12 months.

2. Know the actions, adverse effects, and toxicity profiles of medications prescribed; avoid and be vigilant of high-risk drugs as identified by the 2012 Beers criteria.
3. Start new medications at a low dose and titrate up based on tolerability and response; give a time-limited trial for new medications to determine if the medication is working ("start low and go slow").
4. Prioritize medication prescribing – consider the patient's life expectancy/prognosis/quality of life and time to benefit, and modify treatment for the elderly according to life expectancy [33, 34].
5. Avoid using one drug to treat the side effects of another (e.g., prescribing cascade). Consider adverse drug effects as a potential cause for any new symptom.
6. Attempt to use a single drug to treat two of more conditions (e.g., mirtazapine [Remeron] for depression and weight loss in the elderly).
7. Avoid using drugs from the same class or with similar actions.
8. Educate the patient/caregiver about each medication.
   - Know the patient's cognitive function, health literacy, access to care, and financial status/cultural factors/preferences.
   - Provide written information and engage in medication reconciliation ("teach me back" strategy).
   - Arrange a home visit to review medications with a transitional team member if needed.
   - Educate prescribers/MD.
9. Maintain the simplest medication regimen regarding number of medications, routes, and frequency of administration (once or twice daily dosing is best).
10. Communicate with other prescribers (teamwork between physicians and pharmacists leads to best outcomes); encourage one prescriber to be responsible primarily for monitoring of prescription information to be clearly communicated in a timely manner.
11. Use systems that support optimal prescribing behavior.
    - Drug utilization reviews.
    - Automated drug alerts providing information on potential drug interactions or dose problems.
    - Smartphone reference guides for drug-drug interaction tools.
    - Pharmacist-led interventions for medication review.
    - Pharmacist-led interventions and multidisciplinary care (e.g., involving a geriatrician) have been found to be effective in improving appropriate prescribing.

Underutilization (Underprescribing)

Underprescribing of medications also is a significant issue in the older adult population. One study defined underuse of a medication as "the omission of a drug when there is a clear indication and no contraindication" [35, p1096]. It has been found that up to 50 % of older adults in a long-term care facility had not been prescribed some recommended therapy [36]. Part of the problem related to underprescribing in the older adult population is due to published guidelines on treatment and management of medical conditions. The vast majority, if not all, guidelines on drug prescribing are directed at single disease entities while older adults have multiple comorbidities. Pain and osteoporosis are commonly undertreated in the elderly.

DOI 10.1007/978-1-4939-0779-3_24-1

Pain Management

Pain management is an important issue in the elderly in that pain impacts function and quality of life. Chronic pain is reported by 20–50 % of patients in primary care [37]. Assessment of pain in the elderly patient can be difficult especially if there is cognitive impairment or dementia. In addition, acute pain syndromes (e.g., myocardial infarction, acute abdomen) may present atypically in the frail elderly.

WHO Analgesic Ladder

Pharmacologic approaches are the cornerstone of treatment of acute and chronic pain. The World Health Organization (WHO) analgesic ladder organizes drug therapy into three steps: (1) nonopioid drugs (aspirin, acetaminophen [Tylenol], nonsteroidal anti-inflammatory drugs [NSAIDs], COX-2 inhibitors), (2) low-dose opioids, and (3) higher-dose opioids [38]. The recommendation is for treatment to begin with nonopioids, with opioid drugs added as necessary. It is important to realize that when acetaminophen-opioid combinations are used (e.g., acetaminophen with codeine [Tylenol no. 3], acetaminophen with oxycodone [Percocet]), patients should receive no more than 4 g of acetaminophen per day. NSAIDs and aspirin should be avoided in the elderly if possible due to frequent side effects. When pain is localized to specific joints, the alternatives to systemic NSAIDS are topical NSAIDs and adjuvant therapies that fit between nonopioids and opioids (e.g., tramadol [ConZip, Rybix, Ryzolt, Ultram]).

Opioids

Patients, including the elderly, who have pain most of the day, should receive their drugs regularly and not on an "as needed" basis (e.g., acetaminophen). The decision to start opioids may be considered for noncancer pain in those with moderate to severe chronic pain that is adversely affecting function and quality of life. The decision to use opioids needs careful consideration. Patients should be stabilized on short-acting opioids before switching to equianalgesic doses of long-acting opioids. Opioid side effects include nausea and vomiting, constipation, pruritus, and CNS effects. A bowel routine should be initiated in all patients taking opioids, with an osmotic laxative such as polyethylene glycol the recommended first-line treatment. For those experiencing sedation, a dose reduction of 25 % or opioid rotation may help. An opioid equianalgesic table should be used (see Table 1). In rotating to an opioid other than methadone (Dolophine) or fentanyl (Sublimaze), the equianalgesic dose should be reduced by 25–50 %, for methadone (Dolophine) 75–90 %, and for fentanyl (Sublimaze) equal dose. As of July 2012, the US Drug and Food Administration introduced a Risk Evaluation and Mitigation Strategy (REMS) for all extended-release hydromorphone (Dilaudid), morphine (Avinza, Kadian, Oramorph, Roxanol), oxycodone (Oxecta, Oxyfast, Roxicodone), oxymorphone (Opana), tapentadol (Nucynta), fentanyl (Sublimaze), and methadone (Dolophine). The REMS involves provider training, patient counseling, and distribution of a medication guide for patients with each dispensing. See the REMS website: http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm111350.htm.

Neuropathic Agents

For neuropathic pain, gabapentin (Gralise, Neurontin), pregabalin (Lyrica), or tricyclic antidepressants (TCAs) should be considered as first-line treatment. Serotonin-norepinephrine uptake inhibitors (SNRIs) should be considered first or second line. Gabapentin (Gralise, Neurontin) is effective for post-therapeutic neuralgia and diabetic neuropathy. The drug is started at a low dose and slowly titrated up to effect. Pregabalin (Lyrica) may achieve faster pain control as less time is needed to titrate to a full dose. Other anticonvulsants including topiramate (Topamax), lamotrigine (Lamictal), levetiracetam (Keppra), phenytoin (Dilantin, Phenytek), sodium valproate (Depacon), zonisamide (Zonegran), tiagabine (Gabitril), and clonazepam (Klonopin) should be considered second line, and the research for them is not as strong as

DOI 10.1007/978-1-4939-0779-3_24-1

Table 1 Opioid equianalgesic table [39]

Drug	Intramuscular dose (mg)	Oral dose (mg)
Morphine (Avinza, Kadian, Oramorph, Roxanol)	10	30
Hydromorphone (Dilaudid)	1.5	7.5
Codeine	130	200
Oxycodone (Oxecta, Oxyfast, Roxicodone)	15	20
Oxymorphone (Opana)	1	15
Methadone (Dolophine)	10	20

for gabapentin (Gralise, Neurontin) and pregabalin (Lyrica). An exception would be carbamazepine (Carbatrol, Equetro, Tegretol) for trigeminal neuralgia. Tricyclic antidepressants (TCAs) (e.g., amitriptyline [Elavil], nortriptyline [Pamelor]) may be used for neuropathic pain though their anticholinergic side effects must be considered. Venlafaxine (Effexor) has evidence for use in diabetic neuropathy and polyneuropathies, but not for postherpetic neuralgia. Duloxetine (Cymbalta) has evidence of effectiveness in diabetic neuropathy, fibromyalgia, low back pain, and osteoarthritis.

Since the experience of pain comprises both physical and psychological components, it has been shown that combination therapies are more effective than single therapies [40]. Other adjunctive therapies to be considered in a multifaceted approach are behavioral medicine (e.g., cognitive behavioral therapy, biofeedback, relaxation therapy, and psychotherapy), exercise, acupuncture, physical and occupational therapy, chiropractic, ultrasound, and electrical neuromodulation (e.g., transcutaneous electrical nerve stimulation, spinal cord stimulation, heat/cold, nerve blocks, Botox, steroid injections).

Nutrition

Nutrition is of vital importance to patients of all ages. It can be particularly important for the elderly as they require fewer calories, but not fewer nutrients, to maintain their weight and health. Approximately 15 % of older outpatients and more than 50 % of older inpatients are malnourished, with up to 71 % of elderly patients at nutritional risk. Dehydration is common among the elderly. This is partly because the sense of thirst diminishes with age. However, there are a variety of other factors contributing to dehydration in the senior population, including voluntary limitation of oral intake due to urinary urgency or frequency or limited access to nutrition due to impaired mobility or cognition.

Weight loss in older adults also is a concern. Weight loss is usually a combination of inadequate dietary intake, decreased appetite, muscle atrophy, and inflammatory effects of disease. Malignancy is the second commonest cause of weight loss in the senior population (16 %), with depression the commonest (18 %). Physiological factors include a decrease in the acuity of taste and smell with aging, which lessens the enjoyment of eating.

Inadequate dietary intake can include social factors such as poverty, isolation, and difficulty obtaining groceries. Medical factors include poor dentition or poorly fitting dentures which may lead to chewing difficulties. Swallowing disorders are more common in older persons, and gastrointestinal motility declines with age. Other risk factors for malnutrition include certain medications (e.g., opioids and diuretics) and dementia. Conditions such as pressure ulcers, chronic infections, malabsorption, sepsis, malignancy, endocrine disorders, end-organ disease (e.g., congestive heart failure, end-stage renal disease, chronic obstructive pulmonary disease, hepatic failure), rheumatological disorders, and

DOI 10.1007/978-1-4939-0779-3_24-1

alcoholism can increase metabolic demands and result in malnutrition. "MEALS ON WHEELS" is a useful mnemonic for the causes of weight loss in the older adult [41]:

*M*edications (e.g., digoxin, theophylline, serotonin reuptake inhibitors, antibiotics)
*E*motional (e.g., depression, anxiety)
*A*lcoholism, elder abuse
*L*ate-life paranoia or bereavement
*S*wallowing problems
*O*ral factors (tooth loss, xerostomia)
*N*osocomial infections (e.g., tuberculosis, pneumonia)
*W*andering and other dementia-related factors
*H*yperthyroidism, *h*ypercalcemia, *h*ypoadrenalism
*E*nteral problems (e.g., esophageal stricture, gluten enteropathy)
*E*ating problems
*L*ow-salt, *l*ow-cholesterol, and other therapeutic diets
*S*ocial isolation, *s*tones (chronic cholecystitis)

Weight loss is of concern in seniors given its associated mortality in this population. A weight loss as low as 5 % over 3 years is considered clinically significant if there is 2 % or greater decrease of body weight in 1 month, 5 % or greater decrease in 3 months, or 10 % or greater in 6 months [32]. There are many screening tools that can be used to assess for malnutrition in the elderly patient. One simple test in the highest quartile for sensitivity (>83 %) and specificity (>90 %) is the Malnutrition Screening Tool (MST). It asks two short questions: "Have you been eating poorly because of decreased appetite?" and "Have you lost weight recently without trying?" Older adults are less able to adapt to underfeeding, experiencing less frequent hunger, and not regaining lost weight. This results in chronic, persistent weight changes.

Decreased appetite (anorexia) in the elderly is related to the physiologic factors identified above. Cachexia is a more complex metabolic syndrome related to illnesses that result in loss of muscle with or without fat mass. The illnesses include cancer, end-stage renal disease, chronic pulmonary disease, congestive heart failure, and AIDS. Cachexia is different than starvation, sarcopenia, psychiatric, gastrointestinal, or endocrinological causes of weight loss. With cachexia, there is inflammation and catabolism, often making cachexia resistant to intervention. Sarcopenia is loss of muscle mass, strength, and function that is unrelated to underlying illness. Sarcopenia is present in over 50 % of adults 80 years of age and older. It is caused by endocrine changes (e.g., decreased testosterone and estrogen), cytokine changes, decreased physical activity, chronic disease, inflammation, insulin resistance, and nutritional deficiencies (particularly low protein intake).

Nutritional Assessment

Nutritional assessment is important in the senior population. Weight loss can be identified via serial weights. A dietary referral can be made to get a more formal dietary intake assessment. A complete history (including any new medications, diagnoses, or social issues) and physical examination are recommended on a regular basis. Anthropometric measures such as weight, height, body mass index (BMI), and skinfold thickness can be helpful for the initial assessment. Laboratory tests, including a complete blood count (CBC), electrolytes, creatinine, glucose, thyroid-stimulating hormone (TSH), serum albumin, liver function studies (LFTs), and cholesterol levels, may be obtained. Transferrin and prealbumin levels are more sensitive measures of short-term undernutrition. Erythrocyte sedimentation rate (ESR)/C-reactive protein (CRP) should be done if cachexia is suspected. Chest/abdominal X-rays and abdominal

DOI 10.1007/978-1-4939-0779-3_24-1

ultrasound may be considered. The strongest predictors of malignancy as a cause for the weight loss are age >80 years; white blood cell count >12,000/mm^3; albumin <3.5 g/dl; alkaline phosphatase >300 IU/L; and lactate dehydrogenase >500 IU/L. In patients with significant ongoing weight loss, a CT chest/abdomen/pelvis should be considered, bearing in mind comorbidities and frailty status. If early satiety is present, gastroscopy should be considered. Referral to a dietitian for assessment and intervention is recommended when the body mass index (BMI) is less than 22 for age 65 years and older and if there is an unplanned weight loss of >2 % in 1 month or >10% in 6 months.

Other indicators that place senior clients at nutritional risk and require monitoring or community services include poor appetite; changes in dental health or difficulty in biting and/or chewing; difficulty accessing groceries or making meals due to access, finances, or mental health illness; or concerns with meal patterns including routine skipping of meals or lack of variety in food intake.

Treatment of Nutritional Deficiencies

An important step in addressing nutritional deficiencies in seniors is identification and treatment of the cause of those deficiencies. Consider removing any dietary restrictions (e.g., restrictions for those on a cardiac diet or diabetic diet). Inquire if shopping and meal preparation are being accommodated and if assistance with feeding is required. Ensure that recommended foods fit the patients' ethnic or religious preferences. Increase nutrient density of foods. Protein content can be increased with milk, whey powder, egg whites, or tofu. Fat content can be increased by adding olive oil to sauces, vegetables, grain, or pasta. If these fail to increase weight, snacks should be added. Consider liquid supplementation. These have been shown to increase weight (more so in patients at home or in long-term care) and to improve mortality except those living at home. When there is refusal or inability to swallow, enteral tube feeding with a small-bore nasogastric tube (NGT) or percutaneous enteral gastrostomy (PEG)/jejunostomy (PEJ) tube may be considered. The decision on which of these methods to use depends on patient preference, suspected length of time the feedings will be necessary, and patient tolerance. Feeding can occur in a continuous fashion or with intermittent bolus feeds. There is an increased risk of aspiration with both NGT and PEG feeding. Total parenteral nutrition (TPN) is indicated in the elderly patient when there is an inability to use the gut to meet nutritional needs. Complications associated with TPN are more likely to occur in the elderly population.

Appetite stimulants may play a role in addressing nutritional deficiencies. In seniors with cancer, megestrol acetate and steroids have been used. In older patients treated with megestrol acetate (Megace), observation for congestive heart failure and deep vein thrombosis is needed. Dronabinol (Marinol) has been shown to increase appetite in patients with AIDS.

Pressure Ulcers

Pressure ulcers are defined as ischemic soft-tissue injuries that result from pressure over bony prominences (e.g., sacrum, calcaneus, ischium). Pressure ulcers are a significant problem for older adults in long-term care and critically ill patients. Patients with spinal cord injuries or stroke are at particular risk for the development of pressure ulcers. Pressure ulcers are associated with pain, reduced quality of life, and increases in morbidity and length of stay in hospital. The best treatment for pressure sores is prevention, but even under the best conditions, prevention is not always possible.

DOI 10.1007/978-1-4939-0779-3_24-1

Assessment and Staging of Pressure Ulcers

Pressure ulcers should be assessed for stage, size, exudates, necrotic tissue, sinus tracts, and granulation. The National Pressure Ulcer Advisory Panel is the most common system of staging ulcers, with staging as follows:

Stage 1 – Localized, non-blanching erythema.
Stage 2 – Partial thickness loss of dermis.
Stage 3 – Full-thickness tissue loss and fat may be visible.
Stage 4 – Full-thickness skin loss with exposed bone, tendon, or muscle.

Treatment of Pressure Ulcers

Prevention of pressure ulcers is focused on positioning and regular turning of bed- or chair-bound seniors at least every 2 hours. Once a pressure ulcer has developed, positioning and support surfaces need to be reviewed and changed as needed. Wound care with debridement of any necrotic tissue is necessary. Negative-pressure wound therapy may be considered. The wound should be monitored on a daily basis including the ulcer itself, the dressing, and the area around the ulcer. Monitoring for the presence of pain and complications such as infection is needed. Older adults with pressure ulcers commonly are in a catabolic state and need protein and calorie optimization. While vitamin C and zinc are commonly prescribed to promote wound healing, there has been no conclusive research supporting this treatment. Pressure-relieving support surfaces also are utilized to promote wound healing. These include non-powered surfaces like foam; overlays of foam, air, or water; and powered mattresses. There is moderate quality evidence for ulcer prevention through the use of alternative foam mattresses but low-quality evidence for the use of alternating pressure mattress, sheepskin, gel pads in surgery, and suspension beds in the intensive care unit (ICU) [42]. Attention to pain control is important.

Dressings

Stage 1 pressure ulcers can be dressed with transparent films for protection. Stage 2 pressure ulcers require an occlusive or semipermeable dressing to maintain a moist environment. The treatment of Stage 3 and 4 pressure ulcers depends on the amount of exudate, desiccation, necrotic tissue, or infection. If there is heavy exudate, an absorptive dressing (e.g., alginates, foams, and hydrofibers) is required. For desiccated wounds, saline-moistened gauze, transparent films, hydrocolloids, and hydrogels are needed. Debridement of all necrotic tissue is important. This can be achieved via sharp debridement with scalpel or scissors, mechanical via wet-to-dry dressings, enzymatic using collagenase/fibrinolysin or deoxyribonuclease, or autolytic via semiocclusive (transparent) or occlusive dressings (hydrocolloids or hydrogels). Most pressure ulcers will heal with treatment. Using the above measures, over 70 % of Stage 2, 50 % of Stage 3, and 30 % of Stage 4 pressure ulcers are healed at 6 months [43]. However, surgery is sometimes required using skin grafts, skin flaps, musculocutaneous flaps, and free flaps.

Transitions of Care

As people grow older, they often struggle to achieve a balance between maintaining independence and accepting help. Most older adults would like to live at home for as long as possible. However, caregivers may find that they are overwhelmed and exhausted with providing care to an older family member. It also is important that caregivers receive support to ensure they can continue to provide care while also maintaining their own well-being.

DOI 10.1007/978-1-4939-0779-3_24-1

Determining Support Needs

Elderly patients living at home often have challenges in day-to-day routines including personal care such as bathing or more difficult tasks like transportation, grocery shopping, managing money, and/or house maintenance. The elderly patient and family should be advised to seek out supports and resources before they are needed or before the situation becomes urgent. Information about supports and resources may be in a variety of formats – online, telephone, and referral-based as well as in person. The availability of some supports and resources may depend on where the older person lives. Things that elderly patients should consider in determining needs:

1. Preferences: What is important to me? What do I value?
2. Support network: What help can my family and friends provide?
3. Eligibility: What services am I eligible for?
4. Availability: What services are available in my community?
5. Finances: What can I afford?
6. Timing: How much time do I have to make a decision?

Community Supports

Community supports are available in many communities that allow patients to maximize their potential and function in their home environment for as long as possible. Community supports occur in many settings, such as faith-based programs, community-driven programs (e.g., leagues or groups), local programs (e.g., Seniors Association, Meals on Wheels), advocacy groups, and through national programs (e.g., Alzheimer Society). Some community supports may include services that are available with or without cost (e.g., equipment and homemaking services).

Healthcare Resources

Healthcare resources are typically more formal and structured than community supports. They usually require a referral and may include a cost. These types of resources include the following: home care, in-home professional health services, day programs, day hospitals, mental health services, respite services, rehabilitation services, equipment assessments, and publicly funded housing supports.

Levels of Care

When older adults can no longer manage to live in their own homes, various levels of care are available. Levels of care often are based on the type and amount of care needed. It is never too early to discuss alternative types of housing and to begin planning for the future. The Continuing Care system provides various types and levels of care for older adults that support their independence and quality of life. In Canada, for example, there are three settings in which the Continuing Care system provides accommodation, healthcare, and personal services. These settings are Home Living, Supportive Living, and Facility Living. Careful assessment is important because a less restrictive environment may be a better solution and because patients and families often are not aware of these options. Family physicians should evaluate patients thoroughly, focusing on their functional abilities. A mental status examination is important, as

DOI 10.1007/978-1-4939-0779-3_24-1

patients may appear relatively intact on casual questioning but actually suffer from severe cognitive impairment.

Home Living

Home living services provide home care for the elderly who live in their own home, apartment, or another independent setting. Home living can provide in-home professional support services such as nursing and rehabilitation, personal support services, and equipment. Examples of personal support services include medication, bathing, or grooming assistance.

Supportive Living

Supportive living combines accommodation services with other supports and care. Supportive living settings vary by size and types of services provided. It can include meals, housekeeping, and social activities. Residents pay a fee to cover the cost of accommodation and needed services. Residents also can receive professional and personal support services through home living (home care). These support services can be provided by private for-profit, private nonprofit, or public operators. Examples include seniors' lodges, group/personal care homes, private supportive living, and designated supportive living. Designated supportive living settings have additional health and personal care services.

Facility Living

Facility living includes long-term care facilities such as nursing homes and auxiliary hospitals. Care and accommodation services are provided for people with complex health needs who are unable to remain at home or in a supportive living setting. In facility living facilities, residents pay an accommodation fee to cover the costs of providing accommodations and services such as meals, housekeeping, and building maintenance. Health services in long-term care are publicly funded.

Older Drivers

On a per capita basis, elderly drivers' fatal crash rates begin to increase at 70 years of age. Factors contributing to the higher crash rates of elderly drivers include impairments in functional abilities to drive (e.g., sensory, motor, cognitive) as a result of age-related changes in driving skills, the presence of one or more medical conditions, and/or the drugs used to treat those conditions. Recent evidence implicates the role of medical conditions more so than age-related changes [44]. In particular, drivers with cardiovascular disease, pulmonary disease, diabetes, psychiatric disorders, visual disturbances, musculoskeletal disorders, neurological conditions, and cognitive impairment were at greatest risk for at-fault crashes in a large population-based study [44]. The higher crash and fatality rates of older drivers have prompted calls for tighter legislation for older drivers, particularly at the time of license renewal. It also has resulted in the need for a test or tests to evaluate the driving competence of elderly drivers.

Evaluating Older Drivers

The medical community often is called upon to provide an assessment of "fitness to drive." To assist with this process, a number of medical associations have developed medical fitness to drive guidelines (e.g., the Canadian Medical Association's Determining Medical Fitness to Operate Motor Vehicles: A Guide for Physician – 9th Edition [45] and The American Medical Association Physician's Guide to Assessing and Counseling Older Drivers [46]). Medical history should cover history of coronary artery disease, stroke, movement disorders, seizures, diabetes, sleep disorders, arthritis, and the presence of illness such as dementia. Prescription and over-the-counter use should be documented. Research has shown that

DOI 10.1007/978-1-4939-0779-3_24-1

benzodiazepines increase motor vehicular crashes (MVCs) by fivefold, antidepressants 1.8 times, and opioids 1.5 times [38]. Alcohol and other substance use should be ascertained in any assessment of fitness to drive.

Driving history should cover how often the senior drives, MVCs or traffic violations in the last year, and getting lost while driving. If a caregiver is present, they can be asked if they have accompanied the patient as a passenger recently and whether they have any concerns about the patient's driving.

A physical examination should be done to look at mobility (gait and balance), function, vision, and cognition. The neck, shoulders, and wrists should be examined for range of movement. Common tests for assessment of "cognitive fitness to drive" include the Mini-Mental State Exam (MMSE), Trails A and B, and clock drawing. However, none of these tests is very predictive although the American Academy of Neurology suggests an MMSE score of $\leq$24 identifies patients at risk of unsafe driving. Recently, a paper and pencil test (the SIMARD MD) has been developed to assist healthcare professionals in identifying cognitively impaired drivers with good predictive properties on identifying those failing and passing an on-road test and those who are indeterminate and in need of further assessment [47]. Mandatory reporting of moderate to severe dementia is required in some US states and 7 of the 10 provinces and all three territories in Canada. On-road testing may pick up more unsafe drivers than cognitive testing. However, unless they are specifically adapted for drivers with cognitive impairment, regular road tests such as the Department of Motor Vehicles on-road tests may fail to detect safety issues in this population of drivers due to overlearned skills [48].

The primary care physician is an essential partner in assessing driving competency. While many families have concerns, they often do not feel able to discuss it with their family member. In the interests of maintaining the physician-patient relationship and if the patient has already been referred to geriatrics for cognitive assessment, assessment of and discussions related to fitness to drive may be done by the specialist. If drivers have a physical disability not due to cognitive impairment or dementia, vehicle adaptations can be made to address this disability (e.g., peripheral neuropathy [foot drop]). Breaking bad news and driving cessation support programs have been developed and can be useful for patients and their families [49].

Alzheimer Disease and Other Dementias

Richard M. Whalen*
Department of Family Medicine, Eastern Virginia Medical School, Norfolk, VA, USA

General Principles

Dementia is a common problem seen by family physicians. There is no disease-modifying agent currently available for treating progressive dementias such as Alzheimer's. Cognitive-enhancing medications can be offered on a trial basis but have very limited benefit. Management should focus initially on patient and family education and early discussion of goals of care. Physicians should look to evidence-based guidelines to help provide high-value interventions for the prevention and management of common complications of dementia. These include depression, delirium, agitation, falls, adverse medication effects, and burdensome, distressing interventions near the end of life. Advanced dementia can be devastating for both the patient and family. Support from a trusted family physician during this difficult time can be invaluable.

Approach to Care: Older adults should undergo routine cognitive screening in venues such as the Medicare Wellness Visit. Screening can be done through a number of available tools including the Mini-Cog (3-item 5-min recall and clock draw) [1]. If the initial screening is abnormal, a more detailed, quantifiable test such as the Montreal Cognitive Assessment (MoCA) or the Mini-Mental Status Exam (MMSE) should be considered. These are more widely accepted as reliable for tracking disease progression and statistical responses to treatment. Evaluation for reversible causes of cognitive impairment should also be done (Table 1). If this is negative, it is highly probable that the patient suffers from one of the common non-reversible dementias. A consultation should be considered if the diagnosis is in doubt.

Definition/Epidemiology

Estimates of dementia prevalence vary widely due imprecise diagnosis and documentation. Estimates on average are about 4 % for people aged 55–65, 10 % aged 65–75, 20 % aged 75–85, 30 % aged 85–90, and 40 % aged >90. In 2013 there were approximately five million people in the USA with dementia. This number is expected to increase to 15 million by 2050 [3].

The 2013 revision of the Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-5) introduced neurocognitive disorder (NCD), mild or major, to replace the diagnoses mild cognitive impairment (MCI) and dementia. The main rationale was the perceived stigma attached to the diagnosis of dementia, especially in younger persons. It recognizes that the term dementia is still appropriate for the use in settings where it is customary [4].

The diagnostic criteria for dementia are [4]:

1. Cognitive impairment involving at least one of the following domains: memory, language, complex attention, executive function, perceptual (visual-spatial) motor function, and cognitive behavior.
2. This must a decline from a prior level of function.
3. Reversible causes of cognitive impairment including delirium have been ruled out.

DOI 10.1007/978-1-4939-0779-3_25-1

Table 1 Reversible dementia/cognitive impairment

Drugs	Any medication with anticholinergic, sedating, or other CNS effects should be suspect. Renal impairment will magnify side effects. Effects may be additive so polypharmacy should be addressed even if there is not a single "smoking gun" medication. See Beers List for further details [2]
Eyes/ears	Lack of sensory input over time will hasten cognitive decline. Severe hearing or visual impairment can lead to an incorrect diagnosis of dementia if a hurried clinician does not adjust their assessment appropriately
Metabolic	Thyroid disease and B_{12} deficiency should be ruled out. Renal function, CBC, and liver function tests are also recommended
Etoh	Alcohol abuse can cause short-term memory impairment and other neurologic deficits. Deficits may improve at least partially with cessation
Normal pressure hydrocephalus	This usually presents with gait instability and possibly urinary incontinence before dementia becomes apparent. The gait is usually wide based with steps close to floor ("magnetic") and normal arm swing. This differs from a parkinsonian gait with limited arm swing due to bradykinesia and rigidity
Tumor/trauma	Tumors or trauma, including subacute or chronic subdural hematoma, may present with cognitive impairment. There are usually additional neurologic signs
Infections	Testing for neurosyphilis is no longer routinely recommended for all dementia patients. It should be considered if presentation is atypical with early neuropsychiatric symptoms or if HIV positive. HIV dementia is common in late stage disease
Affect/ depression	Depression can result in low scores on cognitive tests due to lack of engagement (**Pseudodementia)**. Long-standing depression can cause true cognitive impairment due to diminished social and mental stimulation
Sleep apnea	This is now recognized as potentially contributing to cognitive decline, although it is usually a minor factor

4. There is loss of independence due to impaired functional status in activities of daily living (ADLs) or independent activities of daily living (IADLs).

If criteria 1–3 are present but independent functioning is preserved, even with the help of compensatory strategies by the patient, the diagnosis is MCI, not dementia. About 30 % of people with MCI will progress to dementia within 5 years. MCI can be amnestic (memory impaired) or non-amnestic. The progression to dementia is highest in research settings if patients have amnestic MCI with biomarkers suggestive of Alzheimer's pathology (see below) [5].

DSM-5 has added additional specifications for the likely etiology of the dementia (Table 2). There is significant overlap of the most common dementia etiologies (Fig. 1).

It is now recognized that Alzheimer's pathology develops years before clinical symptoms of MCI or subsequent dementia. This pathology includes beta-amyloid deposits outside of neurons, Tau protein tangles within neurons, and hippocampal shrinking. The National Institutes of Health (NIH) working group on Alzheimer's has therefore proposed the revision of Alzheimer's disease diagnosis and staging. Three stages are identified: preclinical, MCI, and clinical disease [5].

Biomarkers which are usually abnormal in all three stages of AD include amyloid PET scans, structural MRI, and CSF proteins. They are now being used in research of therapies designed to impact the pathological processes. NIH recommends that these biomarkers not be used outside the research setting because there are currently no effective treatments to modify them and standardized interpretation guidelines are not fully developed [5].

DOI 10.1007/978-1-4939-0779-3_25-1

Table 2 Common dementias and their characteristics

Progressive (neurodegenerative) dementias: The underlying pathology inevitably progresses, although at varying rates. A terminal stage will be reached unless death from another cause supervenes. There is significant overlap among AD, LBD, and VaD (Fig. 1)	
Alzheimer's disease (AD) (65–70 %)	Characterized by insidious onset with short-term memory decline as the earliest deficit in most people. Language and visual-spatial changes may be the initial deficit in about 5 %. Pathologic changes begin years before clinical features develop. There is overlap with LBD and VaD, especially in older age groups (Fig. 1)
Lewy body dementia(LBD) (15–20 %)	Characterized by visual hallucinations and spontaneous fluctuations in mental status. REM sleep disorder (vivid dreams physically acted out) may be the earliest sign. Most people will develop parkinsonian features eventually, which may be subtle If cognitive impairment develops after the onset of Parkinson's disease, it is known as **Parkinson's disease with dementia (PDD)**
Frontotemporal dementia (FTD) (5 %)	Age of onset is generally earlier than AD and DLB, often in the 40s or 50s. There also appears to be a hereditary component more frequently. There are three subgroups. The most common is FTD-behavioral variant (Pick's disease) which affects personality and behavior early in the course when memory may be well preserved. Less common are semantic dementia and primary progressive aphasia which affect speech and language initially
Prion disease (<1 %)	Caused by communicable pathogens, sometimes from cow brains, known collectively as prions. Creutzfeldt-Jakob disease (CJD) is the most common form
Secondary dementias: (may be stabilizable)	
Vascular (VaD) (15–20 %), usually a cofactor rather than the primary etiology	Deficits vary depending on location and extent of the stroke(s). More likely to be the primary etiology in the oldest age group (>90) It is important not to confuse expressive aphasia or dysarthria with dementia if nonverbal communication is preserved
Alcohol (<5 % as primary factor)	Short-term memory deficits most prominent in chronic overuse. Ataxia also is common. Dementia may partially improve after alcohol cessation
Brain injury from isolated trauma (TBI) or hypoxia (<1 %)	Multiple presentations depending on extent or site of brain injury. Cognitive deficits may be subtle if injury or hypoxia was relatively mild. Usually is not progressive
Chronic traumatic encephalopathy (<1 %)	Due to repeated trauma such as concussions in athletic injuries. May have changes similar to FTD, with personality changes a prominent early feature and Tau proteins on pathologic study. May have insidious onset and progression

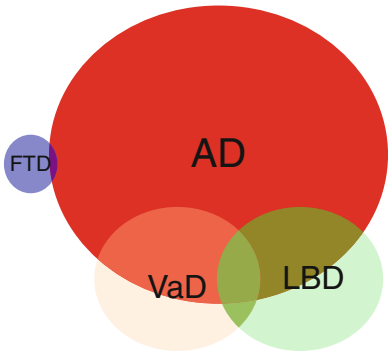

Fig. 1 Prevalence and overlap of common dementias. **Alzheimer's disease (AD) = 65–70 %. Lewy body dementia (LBD) = 15–20 %. Vascular dementia (VaD)- = 15–20 %. Frontotemporal dementia (FTD) = 5 %**

DOI 10.1007/978-1-4939-0779-3_25-1

Approach to the Patient

History and Physical Examination

A focused history and physical should be performed if cognitive impairment is suspected based on abnormal screening tests or symptoms reported by the patient or family. Key areas are:

History of Present Illness: Time course regarding onset/progression of cognitive change or other symptoms is critical. Insidious onset and slow progression of symptoms are characteristic of AD, LBD, and FTD. A family member is usually needed to provide a reliable report of this. More abrupt onset is of concern for stroke or other secondary or reversible causes of cognitive impairment (see Tables 1 and 2).

Family History: A positive family history of FTD increases the likelihood of FTD as the etiology, especially if behavior/personality changes are presenting symptoms. About 20 % of FTD is inherited though an autosomal dominant gene [6]. FH of AD or LBD/PDD confers a more modest increased risk. Age is by far the highest risk factor for these.

Medical History: This should include history of stroke, Parkinson's, depression, syphilis, HIV, Down's syndrome (which frequently leads to AD) or other neuropsychiatric disorders).

Medications: A careful medication review will often reveal additive CNS side effects from multiple medications.

Social History: Screening for alcohol abuse is important. Risk factors for cardiovascular disease such as smoking, poor diet, and lack of exercise are also associated with increased risk for MCI and dementia. Social isolation increases the risk for dementia.

Speech/Affect/Memory: Fluent speech with socially appropriate, normal affect but impaired short-term memory is suggestive of MCI or early AD. Blunted speech which may be socially inappropriate at times should raise concern for FTD. LBD/PDD may have more blunted speech or more difficult with retrieving long-term memory facts than AD with better short-term memory in early and middle stages. Flat affect or lack of engagement during the assessment may indicate depression (pseudodementia).

Gait/Motor/Sensory: These should be normal in early-middle stage AD. PDD will have clear parkinsonian features as by definition these develop before the dementia. Parkinsonian features usually develop at some point in LBD but may be subtle. Gait changes with a wide-based, shuffling ("magnetic") gait with good arm swing are suggestive of NPH. The arm swing in Parkinson's is usually diminished due to rigidity or bradykinesia. Neurosyphilis signs may include diminished proprioception with high-stepped gait or weakness (tabes dorsalis) or small pupils that don't react (Argyll Robertson pupils). Upward gaze palsy in a patient with parkinsonism is diagnostic of progressive supranuclear palsy, a Parkinson's plus syndrome that usually leads to dementia.

Treatment

Prevention and Early Detection

The best evidence for preventing or delaying onset of mild cognitive impairment and subsequent dementia supports healthy diets, exercise, and cognitive stimulation [7–9]. Vigorous exercise has also been shown to increase hippocampal volume in short-term studies. Hippocampal shrinkage is one of the prominent biomarkers for early Alzheimer's. The likely mechanism is increased levels of BDNF (brain-derived neurotrophic factor) through exercise [8]. This reinforces the key role of family physicians in promoting healthy lifestyles for patients of all ages to reduce risk for a wide range of serious diseases.

The use of biomarkers such as amyloid PET scans to detect preclinical AD is not recommended as management would not change due to current lack of disease-modifying medical therapy. *ApoE4* gene presence is not a reliable predictor of AD and should not be checked.

DOI 10.1007/978-1-4939-0779-3_25-1

Medications

Cognitive Enhancers: The most commonly used medications are cholinesterase inhibitors (CIs). These include donepezil, rivastigmine, and galantamine. They have at most modest benefit on symptoms with no disease-modifying activity. There is no effect on delaying the progression of MCI to dementia or prevention of the most devastating aspects of end-stage disease [5]. A targeted literature review of CIs and memantine was used for the 2008 American Academy of Family Physicians (AAFP) and American College of Physicians (ACP) Clinical Guidelines. It concluded that the average change in cognitive score (on MMSE or other tests) with donepezil was "statistically significant but not clinically important" ([10], p. 372). There may be a small subset of patients with clinically significant improvement. There was no significant difference between the CIs [10]. It reached the same conclusion about lack of clinically important improvement on cognitive testing for memantine ([10], p. 375). More effective cognitive enhancers have not been introduced since 2008. There is evidence for modest improvement in behaviors and functional status in some studies. The clinical significance of this is also not clear [10]. CIs are used primarily for AD and LBD. They have no benefit in FTD, and they may even increase agitation [6].

Current guidelines suggest that these medications can be offered on an individualized trial basis if the patient/family desire it after discussion of their limited benefits, potential side effects, cost, and the patient's overall prognosis [10]. If the patient and/or family desire a trial, they should be reassessed after several months. If there is no apparent benefit per patient or family and improvement or stabilization on an MMSE or other test is not verified, discontinuation should be considered.

Common side effects of donepezil and other CIs are GI related, including dyspepsia and poor appetite. There is also an increased risk of syncope [2]. A common conundrum involves a patient with dementia on a CI with poor appetite and weight loss. Is it due to the medication or disease progression? A trial of medication discontinuation should be considered.

Memantine is FDA indicated for moderate to severe dementia. Adding this to donepezil or other CIs has been a common practice. Adding memantine to donepezil did not improve effectiveness in the largest study to date [11]. Common side effects of memantine include headache, confusion, and hallucinations. Like the side effects of CIs, these may be difficult to differentiate from disease progression. A trail of discontinuing should be considered if these occur.

Antipsychotics: These should be used rarely in dementia due to concerns about serious side effects such as sedation, falls, confusion, and limited evidence for efficacy [2]. There is now an FDA black box warning for antipsychotic use for behavioral disturbances in dementia due to increased risk of death. They can be helpful in patients having severe distress from delusional agitation or psychosis that does not improve with other interventions. They should be used with extreme caution in patients with LBD/PDD, who frequently have severe neuroleptic sensitivity due to their dopamine deficiency from Parkinson's.

Antidepressants: Selective serotonin reuptake inhibitors (SSRIs) have better evidence for treating "agitation" than antipsychotics [12]. Depression is common in all patients with incurable serious health problems which may explain some of their effectiveness. They also have antianxiety effects. Citalopram has the best evidence for efficacy [12]. There is a theoretical concern for QT prolongation with citalopram so the FDA recommends that doses above 20 mg a day not be used in the elderly. Sertraline is an alternative if QT prolongation is a concern. Other antidepressants may also be helpful if SSRIs are not effective or well tolerated. Tricyclic antidepressants should be avoided in most patients due to higher rates of sedating and anticholinergic side effects.

Benzodiazepines: These should be used with extreme caution due to increased confusion and fall risk [2]. A short-acting medication such as lorazepam can be useful in limited settings such as before personal care for patients who become severely distressed or physically combative during bathing or dressing in spite of nonpharmacologic interventions.

DOI 10.1007/978-1-4939-0779-3_25-1

Table 3 Management of behavior issues in dementia

1. "Agitation" should prompt a search for an *unmet need* (such as pain, need for toileting, constipation, thirst, hunger, urinary retention, fear, or loneliness) before considering treatment with medications. Fear of bathing, showering, or being undressed by a "stranger" is especially common. Allowing the patient to have as much control as possible over how and when this will be done is helpful Psychotropic medications should be reserved for delusional agitation not amenable to behavioral strategies and which causes severe distress or potential physical harm to the patient or caregiver
2. **Wandering** behaviors will occur at some point in most patients. Environmental modifications to allow safe walking in an enclosed area and daily vigorous exercise are the most effective interventions. Safe return bracelets are recommended for all ambulatory patients. Medications are of no benefit Searching for a dead spouse or other relative is common and should be redirected to a positive conversation about that person. Trying to convince the patient that their spouse or parent has died is usually counterproductive
3. **Incontinence:** Most patients with dementia have functional incontinence due to loss of cognitive awareness about needing to use or find the bathroom. Treatment should be scheduled toileting, with adult briefs as a back-up measure. Overactive bladder medications do not address the root cause. They also have potentially serious anticholinergic side effects
4. **Sleep:** Nighttime awakening and wandering are stressful for caregivers and often prompt a request for sedating medications which should be avoided due to adverse side effects (see Beers list). Melatonin is safe and usually has modest benefit in establishing a more regular sleep cycle. Avoiding daytime naps, vigorous exercise, and not going to bed early are the most effective interventions. Families should be educated about the normal decline in hours of sleep needed with aging (average of 6–7 h a day for people >80)
5. Support groups are a valuable resource for family education and support in dealing with challenging behaviors and other dementia care issues. Early referral to the local Alzheimer's Association or other support groups should be strongly considered

Hypnotics: Melatonin is the body's natural sleep hormone and should be first-line therapy. Effects are not as dramatic as with sedating medications, but there is a much better safety profile and no risk of dependence. It is more effective given nightly, 1–2 h before sleep, rather than as needed. Zolpidem and similar hypnotics have adverse effects in the elderly similar to benzodiazepines and should be avoided. Antihistamines including diphenhydramine have similar risks, as well as more adverse anticholinergic effects [2].

Behavioral/Psychological Issues

Disruptive or distressing behaviors eventually develop in most patients with dementia. The most challenging issues for many families and other caregivers are wandering, agitation, incontinence, and disrupted sleep patterns. There are behavioral and environmental interventions which can be very helpful (Table 3). Medications should be a last resort.

Anticipatory guidance by their physician early in the disease process can help families prepare to access community and other resources which will help improve care and reduce caregiver stress. Families often benefit from counseling to help deal with grief about losing the loved one they knew before dementia changed them so much. Spiritual and psychosocial support is available to patients and families in all hospice programs.

End-Stage Dementia

Recent research has demonstrated that progressive dementias have a disease trajectory that is similar to other terminal illnesses such as advanced cancer [13]. Prior discussion of the goals of care by the family

DOI 10.1007/978-1-4939-0779-3_25-1

Table 4 Management of end-stage dementia. End stage dementia is characterized by loss of interest in food, difficulty in recognizing family members, and increased susceptibility to aspiration pneumonia and other infections. It is now generally recognized as a terminal disease process [13]

1. Early discussion of goals of care	All adults should be encouraged to prepare an advance directive while mentally competent. It should include their wishes about care if a terminal illness develops. This should include wishes about life support including tube feedings if advanced dementia develops. This will prevent family distress when facing these decisions without knowing their loved one's wishes [14] Education about the ultimately terminal course of neurodegenerative dementias such as Alzheimer's should be included in this discussion. Many forms are available to facilitate this, such as Five Wishes. Goals of care should routinely be reviewed in Medicare Wellness Visits or other venues if not yet established
2. Nutrition	Feeding tubes have not been found to be of benefit in advanced dementia and do not prevent aspiration [16]. Impaired swallowing signals a very poor prognosis and focus should shift to pleasure feedings and other comfort measures. Sweets and cold, soft foods such as ice cream are usually best appreciated and tolerated at this stage Orders such as NPO (nothing by mouth) should be avoided as this may lead to a misperception by families that we are "starving" the patient. "Pleasure feeds as tolerated" is a preferred alternative. Mouth swabs with fluid of choice should be offered in the final stage. This can be especially comforting for family members Education should focus on the fact that not eating is part of the natural course of the disease and the body responds by shutting down bodily functions including the thirst center. The body begins producing endorphins (natural opioids) to help transition to a comfortable death
3. Hospitalizations	Hospitalizations of nursing home patients with advanced dementia for pneumonia or other complications are common and have not been shown to improve outcomes. They are associated with worsening confusion and debility while in the hospital. Treatment at the nursing facility after discussing the risk/benefits of hospital transfer with the family is generally recommended
4. Hospice/palliative care	Hospice care improves pain and other comfortable dying measures in end-stage dementia [17]. Patients meet hospice criteria when life expectancy is <6 months as evidenced by loss of interest in food with weight loss, recurrent infections, skin breakdown, multiple falls, severely diminished speech and understanding, or other dementia complications

physician is instrumental in avoiding non-beneficial and potentially uncomfortable and emotionally distressing interventions in hospitals or other settings as the disease progresses [14, 15]. Difficult decisions about life support or hospital transfers are often faced in a nursing home or hospital. Whenever possible, the family physician should try to provide care or support in those settings directly as attending physician or via a social visit or phone call. Specific management issues are detailed in Table 4.

Summary

Family physicians will see increasing numbers of patients with dementia as our population ages. They are well suited to evaluate and manage the majority of patients with dementia. Referral to subspecialists for ongoing care has not been shown to improve outcomes [18]. It should be considered in atypical cases where the diagnosis is in doubt.

Routine cognitive screening is a required component of Medicare Wellness Visits. This will help family physicians improve early detection and prompt evaluation for reversible causes. Most cases unfortunately will not be reversible. Efforts should then focus on family education and preventing complications of

DOI 10.1007/978-1-4939-0779-3_25-1

dementia. Avoiding adverse medication effects and promoting exercise to help reduce falls and disruptive behaviors are effective low-cost interventions.

A cornerstone of family medicine is the universal promotion of healthy diets and exercise for disease prevention. These, along with cognitive stimulation, are currently the most effective interventions for delaying the onset and progression of most dementias. The use of imaging or other biomarkers to detect early or preclinical dementia may become important in the future if disease-modifying medical therapies become available.

Early discussion of patient and family goals of care regarding their wishes if dementia progresses is critical to avoiding unwanted burdensome care in end-stage disease. Hospice or other comfort-focused care support is strongly recommended when this stage is reached to help reduce patient and family suffering.

General Principles

Definition/Background

Elder abuse is defined by the National Center on Elder Abuse to be "any abuse and neglect of persons age 60 and older by a caregiver or another person in a relationship involving an expectation of trust" [1]. A growing body of literature shows that elder abuse is a significant problem throughout the world [2–5]. In the United States, the number of people over 85 years of age is expected to increase an estimated 400 % over the next 40 years resulting in a significant increase in the number of elder abuse cases [6]. For many abused and neglected older individuals, a visit to their family physician may be the only point of contact with a professional capable of identifying the problem and appropriately intervening.

Estimates regarding the incidence of elder abuse vary, in large part because of different reporting guidelines and research objectives [7]. Major studies have reported the incidence of elder abuse at 7.6–10 %, but when the more difficult to measure categories of financial abuse and self-neglect are included, the incidence is thought to be significantly higher [8, 9]. Disturbingly, it is estimated that 80 % of elder abuse cases went unreported to adult protective services (APS) agencies [7]. The risk of death among elderly individuals who experience abuse is three times greater than that of the general population [1]. Although the US Preventive Services Task Force found in 2013 that there was insufficient evidence to assess the balance of harms and benefits of screening all older or vulnerable adults for abuse and neglect, professionals in every state have a professional and legal obligation to report suspected abuse. Multiple agencies, including the Joint Commission, American Medical Association, and National Center on Elder Abuse, recommend routine inquiry about elder abuse [10, 11]. Only 2 % of cases reported to APS come from physicians, suggesting that physicians need to do a much better job of reporting elder abuse [12]. Increased physician awareness of the problem, knowledge of patient and perpetrator risk factors, and recognition of barriers to identifying elder abuse will increase appropriate physician intervention and decrease the sequelae of this condition.

This chapter discusses the definitions of abuse, risk factors for abuse associated with both the elderly and their caregivers, barriers that elderly patients and their physicians face when dealing with abuse issues, assessment of suspected elderly abuse victims, reporting guidelines, and treatment and prevention strategies.

Abuse Categories

Commonly used definitions related to elder abuse and neglect are as follows: [13]

Physical abuse: Willful infliction of physical pain or injury.
Sexual abuse: Nonconsensual sexual contact, including rape, unwanted touching, sexual advances, or innuendoes.

Karl E. Miller: Deceased.

DOI 10.1007/978-1-4939-0779-3_26-1

Psychological abuse: Conduct resulting in mental or emotional anguish. This includes threats to institutionalize or withhold medication, nutrition, or hydration.

Financial or material exploitation: Misappropriating an older person's assets for someone else's benefit. Examples include theft, fraud, blackmail, and coercion.

Neglect: Failure to provide the goods or services necessary for maintaining health and avoiding harm or illness. Neglect can be active, such as intentional refusal to provide for basic needs associated with activities of daily living (hygiene assistance, medications, food), or it may be passive and unintentional, which can be the result of caregiver ignorance or inability to provide for the patient's basic needs.

Self-neglect is frequently omitted or reported separately in statistical summaries. Self-neglect has been described as "behavior of an elderly person that threatens his/her own health and safety" [14].

There is some disagreement in the literature as to the most common form of elder abuse. However, the available literature indicates that all forms of elder abuse are very underreported, in particular psychological [15], financial [16], and self-neglect [17]. In general, race- and ethnicity-based differences have not been observed in studies, with the exception of higher rates of physical mistreatment among nonwhite older adults [18]. It is important to recognize depression as a precipitating cause of self-neglect. Emotional abusiveness is considered foundational to most other forms of elder abuse [3].

Risk Factors

There are a number of characteristics common to victims of abuse and neglect. These include cognitive impairment, functional dependency, poor physical health or frailty, low income, trauma, behavioral problems, psychiatric illness or psychological problems, and past abuse [19, 20]. Cognitive impairments greatly limit an individual's ability to care for themselves, impair their decision-making capabilities, and limit their autonomy – all of which are risk factors for being victims of abuse. Identifying individuals with early-onset dementia is a very important component of any geriatric assessment [7]. While cause and effect relationships are difficult to establish, there does appear to be a significant association between the presence of a psychiatric illness and elder abuse [8].

An awareness of characteristics for those who are at risk of abusing or neglecting others is important for family physicians. Those include male sex of the caregiver, financial dependence on the victim, a history of violent acts, a history of substance abuse, and a current or prior history of psychiatric disorders [19]. Caregiver burnout is another important risk factor which family physicians, who often care for the entire family, are in a better position to notice than other healthcare professionals [7]. While caregivers may be able to cope with day-to-day demands, they may decompensate when a crisis develops or may become exhausted over time [7]. Arranging for supportive services to assist caregivers will help the entire situation including decreasing the risk of elder abuse. Because of significant dependence upon others, nursing home patients are particularly vulnerable to abuse and neglect [21]. Evidence supports a multifactorial etiology of elder abuse involving risk factors associated with the elder person, the perpetrator, their relationship, and environmental factors [19].

Identification Barriers

Patient Related

Although there is a relatively high level of awareness of the term "elder abuse," a large proportion of elderly individuals do not associate abusive behaviors in their personal lives with elder abuse [22]. It is not

DOI 10.1007/978-1-4939-0779-3_26-1

uncommon for elderly people to rationalize day-to-day infringements of their rights as "minor" violations that seem inoffensive when compared to the "real" acts of violence reported in the media [23]. Coping strategies identified in elder abuse patients include hope that the relationship with the perpetrator will improve [24]. A challenge in diagnosing elder abuse is that risk factors for abuse, such as social isolation and cognitive impairment, are also barriers to making an accurate diagnosis. Cognitive impairments may prevent individuals from recognizing the abusive nature of their situation [7]. Many elderly abuse patients are dependent upon caregivers or other individuals for transportation and/or assistance with activities of daily living. They may worry that reporting mistreatment will only make matters worse or result in nursing home placement and therefore not talk about their concerns with their primary physician [7]. Patients with early dementia may suffer from paranoid delusions, leading the physician to suspect abuse or, alternatively, inappropriately dismiss a patient's reports of abuse. Every effort should be made to provide appropriate treatment and also to ensure that elder abuse is not occurring despite suspected or actual delusions.

Physician Related

Physician barriers to reporting elder abuse include a lack of clinician education and comfort regarding the subject [25]. Poor understanding of the risk factors for elder abuse results in physicians having decreased ability to recognize elder abuse [26]. Physicians underestimating the prevalence of elder abuse, not knowing how to assess abuse, and not having developed a systematic plan to respond to elder abuse are also barriers [26]. Physicians may be concerned that reporting elder abuse can impair the physician-patient relationship, potentially decrease the patient's quality of life, and decrease the physician's ability to decide what is in the best interest of the patient [27]. Professionals struggle with ethical dilemmas created by elder abuse, especially when the victim does not want to cooperate with an investigation [28]. Family physicians however must be aware that they can potentially greatly assist a victim of elder abuse through appropriate interventions.

Assessment

Appropriate assessment of elderly patients suspected of being abused includes a careful history and a targeted physical examination. Although it is important to have a low threshold for suspicion of elder abuse, it is important to also note that a number of medical conditions can mimic abuse in older persons. These include allergic reactions, osteoporotic fractures, vaginal bleeding due to atrophy, and anorexia caused by mental illness [29]. Whenever possible, the initial portion of the history should be taken with both the patient and caregiver present. This allows for the physician to observe their relationship, with particular attention given to anxiety on the part of the patient or an overbearing attitude on the part of the caregiver [7]. Observing the caregiver and patient interaction can help in assessing if elder abuse is occurring. A potential red flag for possible elder mistreatment is a caregiver who often interrupts the patient to answer for him or her; however, such behavior does not always indicate elder abuse and instead may be helping to compensate for the patient's cognitive impairment [29]. Defensiveness and/or irritability of the caregiver may be a sign of burnout [30]. The physician should begin by asking open-ended questions such as "Can you tell me what happened?" [29].

Following the interview with both the patient and caregiver present, the patient must be interviewed privately [29]. Information should be obtained regarding current health status, living arrangements, financial status, emotional stressors, and social support. A history of alcohol and drug abuse, for the patient as well as other members of the household, should also be included [31]. A sexual history for any unwanted advances or sexual contact must be obtained [29].

DOI 10.1007/978-1-4939-0779-3_26-1

Anyone suspected of being abused should have a comprehensive physical examination. The patient should be completely undressed for the examination in order to perform a full dermatological evaluation. General signs in an elderly individual that suggest abuse include appearance of poor physical care and signs of psychosocial distress. Particular attention should be given to the patient's general appearance, skin integrity, neurological status, and musculoskeletal and genitourinary systems [29]. A complete skin examination is very important and should include an evaluation for bruising on flexor surfaces, bruising at different stages, and burns or other signs of unexplained trauma [32]. Two-thirds of injuries that occur in elder abuse affect the upper extremity and maxillofacial region [33]. Assessment of neurological status is also important, with special attention to cognitive function. Assessment of ambulatory skills is important in helping to ascertain if injuries from reported falls are consistent with the history or more consistent with abuse. Musculoskeletal examination should consider possible signs of injury that cannot be explained by the patient's history. A thorough forensic examination should be performed by someone trained in the evaluation of victims of sexual assault when that is suspected [34].

No consensus currently exists for a single standard algorithm for the evaluation and management of elder abuse [29]. The Elder Abuse Suspicion Index (EASI) is a screening instrument that can be used in cognitively intact patients, has been tested in the clinical setting, and has a sensitivity of 0.47 and a specificity of 0.75 [35]. The EASI has five patient-answered questions and one physician question. If cognitive function is impaired or unknown, initial screening with an instrument such as the Mini-Cog or Mini-Mental State Examination is recommended [29]. If cognitive dysfunction is confirmed, then further assessment should be performed to clarify the cognitive impairment prior to screening for abuse since the answers to questions might not be reliable [29]. Research is being conducted to develop effective, proven protocols which will improve the ability to accurately diagnose and assess elder abuse [29].

It is very important to document all findings when elder abuse is suspected. In addition to the routine detailed clinical note, documentation, including a diagram of all injuries and pictures if possible, should be included [7]. Radiographs should be obtained when possible if fractures are suspected along with a CT scan if the patient suffered a head injury. If clinical findings suggest malnutrition, then laboratory testing (e.g., complete blood count, blood urea nitrogen, creatinine, total protein, and prealbumin and albumin levels) should be requested to document findings consistent with malnutrition [7].

Management

Whenever feasible, the physician should discuss any concerns related to suspected abuse or neglect directly with the patient. Hospitalization of the patient may be necessary to provide treatment and protection pending further evaluation or legal investigation [29]. Family physicians may need to involve Adult Protective Services (APS) and other local services as part of a multidisciplinary approach to assisting elderly abuse patients [29]. Possible interventions include changing the patient's living situation to a nursing home, to a board and care facility, or with another family member if possible. A conservatorship can be prepared for patients with dementia. In a conservatorship, a person is appointed by a judge to protect and manage the financial and/or daily life of a patient with significant physical or mental limitations. Hospital social workers and case managers can offer significant assistance and are generally knowledgeable regarding available community resources. Continued involvement of the family physician even after the patient has been referred to an outside agency can greatly improve outcomes.

DOI 10.1007/978-1-4939-0779-3_26-1

Prevention

Prevention of elder abuse begins by being aware of the risk factors for elder abuse, allowing the family physician to better identify those at risk. Family physicians who have developed long-term relationships with patients and their families have a distinct advantage in assessing and addressing patient as well as caregiver risk factors [7]. Home healthcare professionals can further improve this assessment by observing both the elderly patient and the caregivers in the home environment. Collaboration between the office and home-visit information can be very useful in identifying situations at high risk for development of elder abuse as residents of assisted living facilities often have a poor awareness of available supportive services. Improving awareness of these resources could be a strategy to decrease the frequency of elder abuse [36].

Community Services

It is important to use a multidisciplinary approach that involves coordination with professionals from community agencies trained to deal with abuse and neglect situations from both the medical and social perspective. An awareness of the resources available in one's community is critical to making these connections. Online resources are available to assist physicians with elder abuse and include the Administration on Aging, American Medical Association, and Eldercare Locator [29].

Reporting Guidelines

Unlike child abuse, where legal statues clearly protect the rights of minors, elder abuse happens to adults who are usually presumed to be legally competent to make autonomous decisions. While it is important for this autonomy to be respected, physicians must also balance this right with the potential risk of injury and other complications if the suspected abuse is not reported [7].

All states require healthcare professionals to report suspected elder mistreatment [37], but the pertinent statues for elder abuse vary widely [38]. Reports made in good faith are protected from civil liability. Failure to report, however, can be considered negligence and is potentially punishable by fines, imprisonment, or loss of license.

An effective approach to reporting elder abuse includes working with adult protective services, having an accurate and accessible directory of community resources, and providing educational material for patients and families that includes a description of the warning signs of caregiver stress and available community supportive services [26]. By following guidelines for the detection and management of suspected abuse, physicians can improve their care for elder abuse victims and reduce the potential conflict between family members and the legal system.

Conclusion

A 2005 survey of family physicians and internists found that 80 % of respondents did not recall any medical school or residency training in how to diagnose and address elder abuse [39]. Proper care of elderly individuals at risk for abuse can and should be provided by family physicians. An awareness of the risk factors, barriers, signs and symptoms, and management approaches to elder abuse by primary care physicians can potentially help many patients in need.

Child Abuse and Neglect

Arne Graff*
Mayo Child and Family Advocacy Program, Mayo Clinic, Rochester, MN, USA

Introduction and Approach

In 2012 there were 3.4 million cases of child abuse or neglect reported to agencies in the United States. Of this number, the majority were related to neglect (78.3 %), 18.3 % to physical abuse, and 10 % to sexual abuse [1]. The estimated cost of child abuse and neglect in the United States is 124 billion dollars [2]. While recent research suggests some reductions in the incidence of abuse and neglect, the occurrence of child maltreatment remains a major public health concern, both because the incidence remains high and because of the potential long-term implications for the physical and mental health of victims of abuse. Children under 1 year of age are most likely to be victimized. Children under the age of 3 are at greatest risk for death due to maltreatment or neglect. Children of African-American or Native American heritage are at greatest risk of victimization [1]. Approximately 47 % of all victims are under 5 years of age.

Risk factors that may place a child at increased risk of abuse include caregivers living in poverty, caregivers suffering from mental health problems or drug abuse, and domestic violence in the home. Characteristics of children who are more likely to be abused include those suffering from a disability, chronic illness, behavior problems, or a child who is a premature infant [1].

Child maltreatment is classified as abuse (physical, sexual, emotional, and others) or neglect. Definitions for what constitutes each of these areas are made by federal agencies and defined by each state (including each Indian Nation). It is important for the physician to be aware of the rules and laws for the jurisdiction in which they practice or to have a resource to discover this information if needed.

Mandated reporting, likewise, is defined and legislated by each state and includes professional reporting requirements in each jurisdiction and the method of reporting (phone call and/or written report) and also the time frame required for reporting. It is the responsibility of the physician to know what the laws are for the state in which they practice. The physician is generally provided immunity from legal risk if the filing of suspected abuse is carried out as specified in the state's requirements and for the safety of the child.

There are many reasons that providers have difficulty in differentiating abuse from other causes. First, there are many medical conditions that can mimic abuse such as toddler fractures, lichen sclerosus, and metabolic disorders. Second, many of the "injuries" are unwitnessed, and therefore, the cause of the injury is unknown. Third, children heal much more quickly than adults, so the injury may completely resolve or change dramatically over the course of several days before the physician has an opportunity to examine the child. And lastly, some children either lack the vocabulary skills to offer an explanation or are not ready to disclose at the time of the event.

Offenders are most often people who have contact with or access to the child; 80 % of offenders are parents [1]. Women are the perpetrators 53.5 % of the time. Most offenders are between the ages of 18 and 44. While assessing a child's injury, the physician must keep in mind that the offender may in fact be one or both of the caregivers accompanying the child to the exam. If it is determined that abuse has occurred, determinations and arrangements for custody of the child are the responsibility of law

*Email: graff.arne@mayo.edu

DOI 10.1007/978-1-4939-0779-3_27-1

enforcement and child protective services. Prior to the victim leaving the provider's care, that decision should be made and documented.

A child's disclosure of abuse is a statement, drawing, or other means of communication about the abuse or neglect that he or she has experienced. Disclosure is often delayed for a variety of reasons. These include fear of retaliation, failure to understand the import of events, bribing or grooming by the offender, and fear of not being believed. It is important to appreciate that disclosure to the provider may be the only evidence of maltreatment. Verbatim documentation in the medical record of the statements made by the child to the provider is critical. Always consider that multiple types of abuse may have been inflicted on the child.

All children who are victims and over 4–5 years of age should undergo a brief mental health screen to determine the risk of self-harm.

If abuse or neglect is discovered, other children in the environment must also be considered to be possible or potential victims, requiring a safety plan and evaluation.

The effects of maltreatment can include acute problems such as a fracture, organ injury, or burn. At the time of the exam, there may only be limited findings, particularly in an infant or small child, and not be apparent until a later time manifesting as a behavior, learning disability, or another health issue. The Adverse Childhood Experiences study [2] has shown that repeated childhood exposure to adverse events such as physical, sexual, or emotional abuse can substantially increase the risk of future health problems. These include high-risk behavior (drug abuse, sexual activity, law violations) as a teenager, mental health disturbances as an adult (PTSD, depression, anxiety, chemical dependency), and physical health problems (chronic lung disease, ischemic heart disease, cancer, and others).

Physical Abuse

Physical abuse may present as bruises, burns, fractures, head trauma, or other injuries.

It is important for the physician to recognize the limits of the physical examination in young children. For example, due to the relative elasticity and deformability of their bones, fractures cannot be excluded without obtaining radiography in children under 2 years of age. In children under a year of age, a normal neurological exam is not sufficiently sensitive to rule out intracranial injury.

Bruises

A bruise age cannot be determined by examination [3]. The color of the bruise does not determine the age of the bruise accurately. Any bruise should be recorded in the physicians' notes and include comments on color, size, shape/pattern, swelling, tenderness, underlying bony elements, and absence of bruising in other areas such as normal trauma/contact areas for that child's developmental abilities. Past history should include a family history (genetic disorders, bleeding disorders), history of easy bruising, surgical bleeding problems (circumcision), medications, etc. A patterned bruise is very suspicious for an inflicted injury. The pattern may be consistent with the history (a slap causing outline of fingers, solid circumferential bruise with grab/choke) [4]. The absence of bruising, such as inside of the gluteal crease, may reflect a child's anticipation of, and response to, being struck, as opposed to an accidental explanation for buttock bruising, such as a fall. The examination should carefully look for physical findings to suggest other disorders, such as Ehler-Danlos or Menkes' syndromes [5].

Victims of abusive bruising are at significant risk of associated fractures (28 %). Children under the age of 2 should have a radiological evaluation, regardless of the physical exam findings.

Any follow-up care should note the presence or absence of new bruising after the victim is placed in a safe environment.

DOI 10.1007/978-1-4939-0779-3_27-1

Workup for bruising injuries should include:

1. Child under the age of 2: Radiological skeletal survey and repeat skeletal survey in 2–3 weeks [29]. A non-contrasted CT of the head should be obtained on any child suspected of having an inflicted head injury and those below 6 months of age with any inflicted injury. If the CT is positive for signs of trauma, a dilated eye exam should be obtained. An MRI of the head might also be considered.
2. Child over the age of 2: Consideration of radiographs of specific bones, consideration of CT or MRI of the head if indicated from the history or physical exam.

Laboratory testing to consider might include a PT, PTT, and CBC with platelet count, von Willebrand panel, and possibly platelet function testing. Hematology consultation might be considered if abnormalities are noted on these tests. If there are concerns for an abdominal injury, appropriate radiological studies (usually CT with intravenous contrast); liver enzyme, amylase, and lipase tests; and urinalysis might be considered,

Burns

The differential diagnosis for a burn is very similar to bruising, in which the differential can extend to conditions that include genetic, infectious, accidental contact, or medication causes [3, 6]. The provider must consider the developmental abilities of the child in the evaluation (a toddler reaching into hot water, school-age child playing with lighters/matches) and gather information regarding the injury including clothing worn at the time, position of child (standing, sitting), the type of agent causing the burn (solid, water, viscous fluid, cold exposure, electrical, chemical), when the injury occurred, and what treatments have been used on the wound [4]. Law enforcement may be able to provide the physician with the temperature of the hot water that allegedly caused the burn (remembering that at 156° a child can sustain a third degree burn from hot water in 1 s) [5]. The appearance and location of the injury may help to confirm or disprove the history of injury mechanism that is provided. Also the absence of burn areas should be noted (clenched fist or curled toes in an immersion burn, sparing some area of fingers and toes) as it may suggest whether or not the injury was inflicted or accidental. Patterned burns should be noted. Burn age cannot be determined by examination. There is an association between inflicted burns and fractures [7].

The workup for burns should be the same as that for bruises including consideration of CT, MRI, and skeletal surveys in the evaluation of injuries.

Fractures

The differential diagnosis for a fracture includes medical conditions as well as accidental or non-accidental causes. The history of how the injury occurred is often unavailable, and the physical exam may be noncontributory, depending on the age and developmental maturity of the victim as it is not uncommon for a child, under the age of two who has fractures, to have no findings on exam (bruising, swelling, or deformity) [4, 8]. The history should include questions regarding a family history of metabolic bone disease [3].

The mechanics of the observed fracture must also be considered (spiral fractures suggest a rotational-type injury; a transverse fracture suggests a force perpendicular to the bone; corner metaphyseal fractures suggest shaking or rotational injury history) and the low mineralization of the bone of the infant can limit the usefulness of x-rays until healing begins [6]. Therefore, the provider must be aware of the limitations of radiographs in young children, and repeat radiographs in 2–3 weeks should be considered [5, 9]. Fractures concerning abuse include fractures in a nonmobile child, fractures of multiple ages/stages (of healing), and unusual fractures (sternal, vertebral). In addition, no history of injury or a history that is inconsistent with the injuries observed should raise the clinicians' suspicion.

DOI 10.1007/978-1-4939-0779-3_27-1

With the finding of multiple fractures, consideration of the presence of a metabolic bone disease might trigger laboratory testing or consultations with genetic or endocrine specialists.

The screening and laboratory testing should include phosphate, alkaline phosphatase, PTH, vitamin D, and calcium. Testing for osteogenesis imperfecta should be deferred unless family medical history, physical findings (easy bruising, hearing loss, growth deficiency, blue sclera), or genetics consultation suggests that it is indicated.

Radiographs should involve a skeletal survey or individual bone x-rays. The skeletal survey should include both the initial films and a repeat skeletal survey in 2–3 weeks. Repeat testing is done to look for healing fractures not identified on the initial films (due to the limited mineralization of an infant's bones), as well as to identify normal variants that initially appear to be a fracture but show no interval healing changes on the repeat films. The skeletal survey should follow the recommendations set by the American College of Radiology [5, 7, 9]. The testing should include individual x-rays of the upper and lower segments of the arms and legs and obliques of the chest to evaluate the ribs for posterior fractures, as well as complete views of the spine. Skeletal surveys are indicated for all children, under the age of 2, with physical abuse concerns. For the abuse victim over the age of 2, a good medical exam and specific bone x-rays (where deformity or tenderness is identified) can be ordered. If an adequate examination is not able to be completed, a skeletal survey for children between 2 and 5 years of age might be considered. Bone scans are rarely indicated due to the radiation dose involved. In addition, growth plate enhancement may potentially obscure corner metaphyseal fractures in bone scans. Radiographs should be reviewed with a radiologist regarding unusual healing patterns and possible normal variants. Due to variations in radiographic manifestations of healing, the ability to precisely date the age of fractures may be limited, but are improved with follow-up radiographs that assist in narrowing the window of time in which the fracture occurred.

Head Trauma

Findings of intracranial injury in an infant without an adequate history of injury must raise the question of non-accidental trauma. The diagnoses of inflicted head trauma or non-accidental head trauma may be used instead of reference to "shaking," as the physician may not know the exact mechanism of injury. The presence of a subdural hematoma (SDH), retinal hemorrhages, and a brain injury does not prove abusive head trauma. The physician must consider each of the injuries as well as other injuries and evidence in the evaluation. In addition, an assessment of medical conditions that might cause the clinical picture should be considered. The initial testing often begins with a non-contrasted CT of the head, as it may demonstrate intracranial bleeding [10]. Soft tissue swelling and fractures using CT bone windows can offer additional information. Further evaluation of the intracranial injury may require an MRI of the head and neck to discover more subtle injuries and to detect ligamentous injury suggesting acceleration/deceleration injury [11]. The purpose of the testing is to assist with both acute care and also to predict possible future potential medical problems. For example, a young infants' prognosis might be improved after injury by early intervention with resources such as physical and occupational therapy. If an MRI is performed, the test should be delayed for 1–3 days after the CT if possible in order to have a better opportunity to observe changes such as diffuse axonal injury [11, 12]. One cannot accurately determine the age of a SDH based on CT or MRI but they may provide an approximate window of time for the injury to have occurred within. The mechanics of abusive head trauma involve acceleration/deceleration as the cause for the tearing of bridging veins and the resulting SDH [13]. The findings of significant brain injury after a short fall (under 5 ft) or no history of injury, in an otherwise healthy infant or child, are very uncommon and suggest a non-accidental cause [10, 11, 13].

Evaluation should include lab testing to include coagulation profile; urine organic acid and serum amino acid testing; liver function testing; amylase, lipase, and UA testing [14], and testing to evaluate the

DOI 10.1007/978-1-4939-0779-3_27-1

abdomen for possible injury. Consultation with genetic specialists may be indicated as part of any evaluation for other causes of intracranial bleeding.

Retinal hemorrhages (RHs) may be observed in both accidental and non-accidental trauma. A complete dilated eye exam should include the presence and location of the RH and the presence of other findings such as retinoschisis. Photodocumentation should be obtained of any hemorrhages if possible. Other causes of RH, including genetic or infectious conditions, should be considered and ruled out. An examination by an ophthalmologist should be completed within 72 h of hospital admission [15, 16].

Sexual Abuse

One in six males will experience sexual abuse and as many as three out of six females. Disabled children are 1.7 times more likely than other children to be the victims of sexual abuse [1]. A physician should become familiar with the laws of the jurisdiction in which they practice (age of consent and ability to seek STI evaluation or contraception without parental consent). Sexual abuse not only involves acts of penetration but also includes voyeurism, exhibitionism, and pornography (being exposed to pornography or being photographed). Trafficking involves the use of a child in prostitution. This has become a significant national problem in the United States [17].

Screening for possible abuse should involve a complete history and a forensic interview. It is important to remember that younger children will provide a history that may be very concrete, so that "touching" can refer to abuse, but also may refer to wiping the genital area after urination or a bowel movement, the application of medication, and so on. For this reason the forensic interview is best conducted by someone specifically trained in interviewing children. When collecting a history from the caregivers, it is important to ask about any known or possible exposure to sexual material in the child's environment (video, television, etc.).

Disclosures of sexual abuse are most often delayed, sometimes by many years. The offender often works to maintain a relationship with the child, in order to ensure the child's silence about sexual acts. Although a child's disclosure may be made piecemeal, the physician should document the information. Disclosures given during the medical interview may be admitted to court as hearsay evidence and may be the only evidence available.

The history should be as complete as possible, including both acute events and past medical history to document any exam findings that might be related to medical causes or previous accidental injuries. Up to 95 % of exams will be normal by the time the child/teen is examined (due to healing, pubertal changes, and so on) [18]. It is important to remember that a "normal exam" does not rule out prior sexual abuse or penetration. Most often normal findings can be reported in the physicians' note as "consistent with the disclosure." The disclosures given during the visit should be recorded verbatim in the medical record, with the use of quotation marks to signify this ("grandpa touched me here"). When evaluating possible reports of abuse, an evaluation for normal childhood behavior (exploratory between children of similar ages and imitation of observed sexual acts on TV or other media) should be done. The physician should also have a guideline for determining the urgency of an examination. The guidelines may be mandated by local jurisdictional requirements. For example, immediate evaluation should be carried out after a reported or suspected sexual act has occurred within the last 72 h in a prepubertal child, the presence of any reported bleeding or purulent drainage, suicide risk, or suspicion of the child being in an unsafe environment.

The physical examination for a child who may have been a victim of sexual abuse [19, 20] should include Tanner staging, a complete head to toe exam, and a colposcopic evaluation of the anogenital area, if this is available. A speculum exam is not usually indicated unless there is bleeding or purulent drainage,

DOI 10.1007/978-1-4939-0779-3_27-1

in which case evaluation (for the prepubertal child) should be carried out under moderate sedation. The exam should evaluate the entire anogenital area, noting bruising, abrasions, lacerations, etc. An examination with a specialized ultraviolet light source (not a Wood's lamp which is not sufficiently specific to detect the presence of semen) should be done at the beginning of the exam, for identification of areas to collect specimens for the forensic kit [21]. The physician should be familiar with the required components of the forensic sexual assault kit, since these differ depending on legal requirements. The term "intact hymen" is an obsolete term and should not be used in the exam or impression. The examiner must have the experience and skills to know the difference between changes due to trauma and those due to normal variants or medical conditions. Any findings, consistent with injury (to the anogenital areas), should be reexamined in follow-up, at 2–4 weeks, to show resolution of the injury (and to rule out a medical condition that might mimic an injury).

The anal exam should include a visual inspection and colposcopic exam. Looking at the tone of the sphincter and perianal area for changes (flattening of the rugae, abrasions, fissures, bruising) is important. The physician must be familiar with normal variations including venous stasis, funneling, and diastasis changes as well as being aware of the rapid healing that occurs in this area.

Laboratory testing for pregnancy, sexually transmitted diseases and updating tetanus vaccine, as well as providing any wound care, should be considered for each victim. Some testing may need to be repeated in the future, such as HIV, RPR, or hepatitis B or C. The physician must determine whether prophylaxis is indicated for pregnancy and STIs such as HIV, hepatitis, or others.

Medical Child Abuse

Previously, this type of abuse was called Munchausen by proxy. This form of abuse involves excessive use of medical care (and/or ancillary services) at the request of the caregiver that may have harmful effects on the child [22]. This may include demands of the parent for surgical procedures, multiple specialty consultations, or hospitalizations for symptoms attributed to the child by the caregiver. The actual incidence is unknown as the identification and prosecution of this type of maltreatment can often be very difficult to demonstrate or identify. Key points in making the diagnosis include a comprehensive review of all records and tests and discussion with previous health care providers regarding the diagnosis and any suspicions of involvement by the caretaker in producing symptoms or unusual behavior [23]. Looking for patterns that might include excessive or missing medical visits, unusual and recalcitrant unexplained symptoms, and unexplained deaths in family members or siblings may also raise red flags for this condition.

Neglect

Neglect differs from child maltreatment as it involves an omission of care, rather than an act of commission. With neglect, the needs of the child are not being provided for. As with abuse in general, the age group under 3 is at greatest risk. It is important to remember that during the first 3–4 years of life, much of a child's emotional development, nutrition/growth, and skill development are occurring. Neglect may result in the window of development being missed. This results in long-term medical and mental health consequences [23]. There are many types of neglect including educational, supervision, clothing, housing, dental, and others. The physician often becomes involved for concerns involving growth, including obesity and failure to thrive, and medical neglect [30]. Having an understanding of the barriers that the caregiver is experiencing is needed before success at reunification and safety for the child may be achieved. Referral does not always result in the removal of the child or prosecution of the caregivers. The physician must remember that reporting neglect can often be very beneficial to a family which is struggling, as services can be brought into place to assist them.

DOI 10.1007/978-1-4939-0779-3_27-1

Failure to thrive is a clinical diagnosis and the workup should include both organic and nonorganic causes. The workup of this condition should include bringing together all of the previous records of the child from birth to present (including the nursing notes), for review. History obtained from the caregiver should be detailed and include family medical history, past medical history, diet history, and social, cultural concerns and development. In addition, the caregivers' impressions of the child's growth and development should be sought. A review of all growth parameters should be completed, and any changes in the slope of the growth curves can be analyzed. Hospital evaluation is not often indicated for the evaluation, but should be considered in severe cases.

Laboratory testing should be considered both to exclude organic causes of FTT and to more completely assess any associated conditions, such as iron deficiency anemia, which may arise as a result of poor nutrition [24, 25]. These should be determined on a case-by-case basis. Likewise, consultations may be indicated, and often evaluation, and subsequent care, requires a multidisciplinary team that may include nutritionists, public health workers, subspecialty pediatric providers, social services, and extended family.

Obesity has become a major health concern in the United States, with up to 30 % of the pediatric population having significant weight problems, putting them at risk for medical complications. Obesity can be caused by neglect [26]. Initial steps include interventions for both child and caregiver, consideration of dietary consultation, public health involvement, lab testing, and close follow-up. If the child has complications from the obesity, particularly if they are potentially life threatening, the physician should file an abuse and neglect report promptly.

Medical neglect [6, 27] occurs when the caregiver chooses to not follow instructions or provide medical care for a child that either has the potential to have a negative health impact or has caused actual harm to the child. The care recommended must (1) be available and (2) have greater benefit than risk. An example would be the need for ongoing laboratory testing for a child on a chemotherapeutic drug that might have harmful liver or bone marrow effects and the parent refuses to allow testing.

Barriers to obtaining care must be identified and assistance may be sought from multiple agencies. Clearly outlining the care plan and the expectations of the outcome of treatment, as well as the reasons for the testing or medications, and then documenting in the clinic notes that the caregivers "understand and agree to the care plan" provide documentation for the providers to work for should the caregivers fail to follow through with the plan of care.

Prevention

Reducing the risk of abuse and neglect can be part of the physicians' practice in a number of ways. First, and most important, the physician should maintain a holistic view of the patient and family in day-to-day clinical practice, observing and being aware of the early family dynamics and stresses that may lead to child abuse. It is important to help the caregivers recognize that it is okay to be frustrated, but having a healthy method of dealing with the frustration or having the ability to contact the physicians' clinic to discuss options is the correct way to deal with it. Second, becoming involved in training projects such as the Period of PURPLE Crying [28], to help reduce the non-accidental head injuries or to be willing to provide community education and support on areas of child abuse and neglect, will raise the consciousness of the entire community. It is also important for physicians to continue to update their knowledge on this subject through education and training.

Summary

Child abuse and neglect are an everyday part of primary care practice. The physician must recognize and be able to respond to the abuse or neglect in a timely manner, in order to ensure the safety of the child. Consider consultation or curbsides with a child abuse expert early on in the course of care, since you must

DOI 10.1007/978-1-4939-0779-3_27-1

be able to explain your evaluation and treatment in court. Also become familiar with the resources available in your region (Children's Advocacy Center, Child Abuse Pediatrics experts).

The effects of child abuse can reverberate across the lifetime of the patient. The physician must continue to monitor and anticipate the possibility of problems in adolescence and adulthood because of previous exposure to abuse. Mental health services, by a mental health provider trained in trauma-focused therapy, are critical in helping both the family and the victim move forward and perhaps to have healthy relationships in the future.

Intimate Partner Violence

Amy H. Buchanan*
Loyola University Health System, Maywood, IL, USA

Intimate partner violence (IPV) is a serious but preventable form of violence that affects millions of Americans. Intimate partner violence, as defined by the CDC, is physical, sexual, or psychological harm by a current or former partner or spouse. It can occur among heterosexual or same-sex couples and in teen and elderly couples and does not require cohabitation or sexual intimacy [1].

Background

IPV is, at its core, about control and power. It is not merely tempers flaring and out-of-control behaviors perpetrated by individuals with anger management issues; it is an attempt by one member of a relationship to establish and systematically maintain control and power over the other.

Prevalence

While previous estimates of IPV have been inconsistent due to differing IPV definitions, survey strategies, and limited numbers of respondents, the large-scale National Intimate Partner and Sexual Violence Survey sought to clearly define IPV as well as capture a broad range of IPV behaviors. This has yielded some of the most comprehensive epidemiologic data on IPV to date. They identified five major subtypes of IPV:

1. Physical violence
2. Sexual violence
3. Stalking
4. Psychological aggression
5. Control of reproductive or sexual health

According to this study, 35.6 % or approximately 42.4 million American women have experienced physical violence, sexual violence, or stalking at some point in their lifetime. Among men, lifetime prevalence is 28.5 % [1]. While the vast majority of male victims experienced only physical violence, the types of abuse suffered by females were distributed more evenly among physical violence, sexual violence, and stalking. Additionally, women experience more severe forms of IPV than men and are thus more likely to be severely injured, sexually assaulted, or murdered [2]. Additionally, about half of all American women and men have been the victim of psychological aggression or emotional abuse by an intimate partner during their lifetime [1].

Intimate partner violence occurs across age, ethnicity, gender, and economic lines and among both heterosexual and homosexual couples. Nonetheless, there are both individual and social factors that affect the prevalence of IPV. Young age and low income have been found to be consistent demographic factors linked to men abusing their partners. Additional individual risk factors for becoming an abuser include

*Email: abuchanan2@lumc.edu

DOI 10.1007/978-1-4939-0779-3_28-1

low academic achievement, delinquency in adolescence, heavy alcohol use, depression, personality disorders, and witnessing or experiencing violence as a child [3].

There are also community risk factors for IPV. While IPV may be present in all socioeconomic groups, women living in poverty are disproportionately affected [3]. Poverty likely exerts multifactorial pressures on individuals and marriages, leading to frustration, hopelessness, marital discord, and higher IPV rates. How a community responds to IPV also affects its prevalence. Communities that punish abusers as well as those who offer victims sanctuary and support have the lowest rates of IPV. Cultural and societal factors may furthermore give rise to higher levels of violence among intimate partners. Women are more likely to be beaten by their husbands in societies where men have economic and decision-making control in the household, where divorce is uncommon, and where women commonly do not work outside of the home, and in places where individuals commonly use violence to resolve conflict [3].

Cycle of Abuse

In an abusive relationship, the partner being abused tends to fall into something known as the cycle of abuse. This cycle includes three phases, a tension building phase, an abusive or explosion phase, and the apology phase, commonly known as the "honeymoon" period. Once initiated, the cycle repeats over and over again convincing the victim to stay in the relationship because the abuser apologizes, makes amends, and promises never to repeat the abusive behavior again. The victim is hopeful the abuser is capable of change, but the honeymoon period ends, tension builds, and more abuse occurs. Over time this cycle starts to spin faster and violence escalates.

Subtypes of IPV

Physical Violence

A range of violent behaviors are included in physical IPV. Acts of violence may include slapping, shoving, hairpulling, hitting, and being beaten, restrained, burned or choked, or harmed with knife or gun. One in three American women has experienced some form of physical violence by an intimate partner in her lifetime [1]. Physical violence often escalates over time, placing the victim at an increasing risk for injury and death the longer she remains in a violent relationship.

Sexual Violence

Sexual violence may include rape (forced penetration or being made to penetrate someone else), sexual coercion, any kind of unwanted sexual contact, or forced participation in unwanted sexual experiences. Nearly one out of ten American women reports being raped by an intimate partner in her lifetime, and one in six has experienced another form of sexual violence by an intimate partner. Sexually abused individuals report feelings of extreme guilt and embarrassment thus making it very difficult for them to disclose the abuse.

Stalking

Victimization by stalking may take many forms but can be defined as a pattern of harassing or threatening tactics used by a perpetrator that both is unwanted and causes fear or safety concerns for the victim. A perpetrator can stalk a victim in person, showing up at the victim's home, school, or workplace when unwanted. They may follow them, watch from a distance, and even sneak into the victim's home, leaving frightening or threatening items or messages behind. Stalkers also commonly use phone calls, texts, emails, or messages via social media to send the victim unwanted or disturbing messages. Approximately 16 % of women and 5 % of men in the United States report that they have experienced stalking in their lifetime to the point of feeling very fearful or worried that he or she or a loved one would be harmed or

DOI 10.1007/978-1-4939-0779-3_28-1

killed. While stalking can be perpetrated by a stranger, two thirds of female victims report being stalked by a current or former intimate partner [1].

Psychological Aggression

Acts of psychological aggression are varied, but all aim to exert control, erode the victim's self-esteem, instill fear, and garner power for the abuser over his or her partner. The most commonly reported behaviors include name-calling and use of insulting language, humiliation, angry behaviors that seem dangerous, and being kept track of by demanding to know one's whereabouts. In all, 48 % of women and men report psychological abuse by an intimate partner during their lifetime [1]. Abusers may isolate their partners, not allowing the victim to leave home, drive, or use the telephone, keeping them from family or friends. They may make threats of violence toward the victim, their children, pets, or other family members. Abusers can destroy precious keepsakes, steal money, and hide medicine. When particularly desperate to maintain control in the relationship, especially when victims announce they are leaving, abusers may even threaten suicide, hoping to capitalize on their partner's guilt and convincing them to stay.

Control of Reproductive or Sexual Health

An IPV perpetrator may undermine his partner's ability to control her reproductive choices in order to maintain a position of power in the relationship. Forced sex, unwillingness to use contraception, and interference with access to reproductive health services have been documented in many relationships that include IPV. Thus, IPV is associated with unwanted pregnancy, sexually transmitted infections, miscarriages, repeat abortions, and poor pregnancy outcomes [4].

Consequences of IPV

According to the World Health Organization, which has studied the pandemic of IPV in many countries worldwide, violence in a relationship has profound effects that extend far beyond the health and happiness of the victim. It has been tied to a large number of diverse negative health outcomes, some immediate and some long term.

Physical effects of IPV include cuts, bruises, and sprains that may result from hitting, punching, pushing, or thrown items. Broken bones, deep lacerations, organ damage, and permanent physical disability may result from more severe beatings or use of weapons [3]. While many victims present to a hospital emergency room for care of these injuries, others are forced to delay treatment or are denied treatment altogether.

In addition to the immediate physical injuries of IPV, there are many other associated health consequences with long-term effects. Individuals who suffer from IPV are more likely to have sexually transmitted infections (STIs), pelvic inflammatory disease, and unintended pregnancies. Chronic pain syndromes like fibromyalgia, neurological disorders including migraines, and gastrointestinal disorders are also increased [5].

Victims of IPV often develop long-term mental health problems as a result of the chronic trauma they endure. Individuals who are abused by their partners are more likely to suffer from depression, anxiety, phobias, sleep problems, eating disorders, psychosomatic disorders, substance abuse, and post-traumatic stress disorder (PTSD) [3]. Abused women are also at heightened risk for suicide and suicide attempts [3].

Homicide by an intimate partner is the most serious form of IPV. In most cases, the man in a relationship exhibits possessive, jealous behavior and obsesses over his partner. Tension and conflict build over time culminating in a major event that leads the man to act. The triggering event is often the woman's

DOI 10.1007/978-1-4939-0779-3_28-1

announcement that she is leaving. The time immediately after a woman leaves an abusive partner is the most dangerous for her and her children [6].

In 2007, intimate partners committed 14 % of all homicides in the United States. The total estimated number of intimate partner homicide victims was 2,340. In fact, 45 % of all women and 5 % of men who were murdered died at the hands of an intimate partner. Minorities are at higher risk with black women being more than four times more likely than white women to be killed by a current or former partner [7].

In one study, 82 % of the men who killed their intimate partners were known to the authorities, either the police or medical or mental health officials. Female victims of murder had used a health-care agency in the months just prior to their deaths. These frequent contacts with helping agencies by both victims and perpetrators represent real opportunities for intervention and prevention of IPV homicide [8].

Even more disturbing are cases of familicide in which one intimate partner murders the other and the children and then kills him- or herself. Thankfully, these cases are rare but nonetheless usually garner widespread media coverage. In almost all of these cases, the killer is a white, non-Hispanic man, has access to a gun, and has previous history of abuse [9].

Special Populations and Considerations

LGBTQ Couples

Lesbian, gay, bisexual, transsexual, and queer (LGBTQ) abuse victims have unique concerns and needs that are often misunderstood or ignored. Research indicates that individuals who self-identify as lesbian, gay, or bisexual have an equal or often higher prevalence of IPV compared to self-identified heterosexuals, with bisexual women being disproportionally impacted. Bisexual women reported significantly higher rates of physical violence, sexual violence, and stalking by an intimate partner (61 % lifetime prevalence) than did their heterosexual or lesbian counterparts (35 % and 44 %, respectively) [10]. The same study found that 26 % of gay men and 37 % of bisexual men experienced IPV during their lifetime.

Transgendered individuals are at even higher risk for IPV. Approximately 2/3 of all transgendered people report violence at home with more male-to-females (67 %) than female-to-males (38 %) reporting abuse. Most transgendered victims were particularly unlikely to report violence to police due to fear of revictimization [11].

This fear of poly-victimization commonly exists across LGBTQ populations and refers to scenarios in which individuals are first abused by their intimate partners and later suffer more abuse at the hands of insensitive or homo-/trans-phobic law enforcement agents or health-care providers. This can compound their experience of trauma, can cause reluctance to seek out any kind of help, and requires the need for additional services to provide thorough support.

Abusive partners may employ tactics unique to the LGBTQ community. They may threaten to “out” their partner which may cause a profound impact on the victim’s relationships with family, friends, or employers. Abusers may further block access to hormones or interfere with a transgendered individual’s surgical treatments [11].

LGBTQ victims face additional challenges if they decide to reach out for help. As previously noted, they may meet resistance, ridicule, or frank discrimination from available helping agents. Even well-intentioned service providers may be incompetent regarding LGBTQ-specific language and culture. Many domestic violence shelters and services have been set up to exclusively aid and protect the stereotypical female victim from her male partner. Thus, there are many shelters where lesbian or transwomen are not welcome and even fewer shelters that can assist male victims.

DOI 10.1007/978-1-4939-0779-3_28-1

Pregnant Women

Just as perpetrators may exert control over matters of contraception and sexual health, they may also seek to control the outcome of a pregnancy. Some women are forced to have abortions, while others who might desire termination are denied access by their partners. Between 3 and 9 % of women experience abuse during pregnancy. Pregnant women who are young, single, members of minority race or ethnicity, and living in poverty are at higher risk with IPV rates skyrocketing to nearly 50 % during pregnancy [12].

Patterns of IPV for women may change when they are pregnant. Approximately 1/3 report pregnancy being a relatively protected period with less abuse, while the remaining 2/3 report either no change or an escalation of abuse [13].

IPV can lead to devastating consequences for both the mother and the developing infant. Many IPV victims face ongoing challenges in obtaining adequate care. In fact, victims of IPV are 30 % more likely than their non-abused counterparts to receive inadequate prenatal care [14], missing more appointments and experiencing late entry to care.

Aside from reduced medical care during pregnancy, abused women are more likely to have poor nutrition and inadequate weight gain. Certainly concomitant maladaptive coping behaviors such as smoking and use of alcohol and illicit substances play a role in poor maternal health. These factors may lead to low birth weight and preterm labor, both of which are well-established risk factors for infant morbidity and mortality [12]. Also, the stress of experiencing abuse during pregnancy may alter a woman's hypothalamic-pituitary-adrenal axis. Animal models show that such stress in the perinatal period leads to heightened secretion of hormones, including corticotropin-releasing hormone, which may stimulate early labor and restrict uteroplacental perfusion [15].

The most devastating consequences of IPV in pregnancy are fetal death and maternal homicide and suicide. IPV may contribute to spontaneous abortions and fetal loss as a result of blunt physical or severe sexual trauma to the mother by an abusive partner. Among pregnant women, 54.3 % of suicides and 45.3 % of homicides were associated with IPV [12].

Children

While child abuse is a topic covered in a separate chapter in this text, it is important to note that minors often suffer consequences when IPV is present in the home. Certainly, there can be an overlap of IPV and child abuse co-occurring with the abuser victimizing both partner and children. However, even when no direct physical harm befalls the children in the home, there is evidence that interparental violence leads to immediate and long-lasting negative outcomes for children witnessing it. As the level of verbal and physical violence escalates for a mother, her children suffer more conduct problems, more emotional problems, and develop lower levels of social functioning [16]. It is also important to note that during adolescence, many children start to form their own intimate partner relationships. Without intervention and help, these children may start to apply the same violent patterns they have learned at home in these relationships [17].

Teens

Teen dating violence is a widespread issue with 9 % of high school students reporting being hit, slapped, or physically hurt by a boyfriend or girlfriend in the past year [18]. Teens often think that certain behaviors like teasing, name-calling, and even physical fighting are playful, acceptable parts of a normal relationship. Over time, these behaviors may escalate to more serious forms of physical and sexual abuse and stalking. Among adult IPV victims, 22 % of women and 17 % of men report their first abusive relationships occurred during their teen years [1]. Programs aimed at the education of teens to promote healthy dating relationships may be a key to reducing violence in adulthood.

DOI 10.1007/978-1-4939-0779-3_28-1

HIV

IPV can increase a woman's risk for acquiring human immunodeficiency virus (HIV). Higher rates of HIV in IPV victims may be due to forced sex with an infected partner or compromised negotiation of safe sex practices. Additionally, IPV victims, constantly under threat of further abuse and in a state of chronic stress, often resort to maladaptive behaviors that further increase their risk for HIV [19]. They report higher rates of intravenous drug use, treatment for other sexually transmitted infections, prostitution, and anal sex, all of which are known HIV risk factors [20]. Furthermore, among HIV-positive patients, associations have been found between IPV, poor HAART adherence, and faster CD4 cell count decline due to chronic stress and depression. This leads to disease progression and increased morbidity and mortality [21].

Immigrants

Immigrant women are more likely to be socially isolated and living in poverty, both risk factors for abuse. Unfortunately, there are numerous factors among immigrants that make it especially difficult to seek or obtain help. Identified barriers include threats of deportation by the abuser, language differences, worries about discriminatory or insensitive treatment, and a lack of familiarity with legal rights and the US social system [22]. It is also recognized that some cultures have very strict and highly paternalistic views on marriage and gender roles. While health-care providers need to be culturally sensitive, violence and abuse are not excused by these cultural norms and need to be addressed for the safety and protection of all victims. Providers or community advocates who speak the victim's language and have an understanding of the victim's cultural practices are most adept at successfully uncovering IPV and offering appropriate services and support.

Disabled Persons

Acts of domestic and sexual violence are committed at higher rates against disabled individuals with twice as many disabled women experiencing nonconsensual sex by an intimate partner [11]. It is also important to note that the intersection of violence and disability may be glaringly apparent with some acquiring their disability as a result of IPV and then returning to live with and depend upon the abuser for aid [11]. Abusers are more likely to commit controlling acts upon partners with disabilities, such as limiting access to services and health care, withholding help with basic ADLs, and forced isolation. People with disabilities may lack access to shelters that are well equipped to manage their medical as well as social needs. Deaf individuals or those with limited speech capabilities may face challenges in basic communication, while those with limited mobility may be unable to travel to places of aid due to environmental barriers such as lack of wheelchair ramps or elevators.

Public Health and Economic Burden

IPV is a clear public health and economic issue and the Affordable Care Act identifies IPV screening as a national health priority, alongside diabetes, HPV and cervical cancer, HIV, and other sexually transmitted infections [23].

With regard to business and economics, IPV reduces work productivity and leads to absenteeism. Nearly a quarter of employed women report that IPV has affected their work performance at some point in their careers [24]. There are also unfortunate instances in which domestic violence and stalking issues migrate out of the home and to a victim's place of employment. Companies must provide resources and support to these victims and take measures to ensure a safe work environment for all employees.

DOI 10.1007/978-1-4939-0779-3_28-1

Human resources staff should be trained to recognize potential signs of IPV, respond with support and advocacy, and, when appropriate, engage with law enforcement.

Even though IPV is generally thought of as a social and medical issue, it is possible to attach a true dollar cost to IPV in the United States. In a 1995 study, IPV against women alone cost $5.8 billion. Updated to 2003 dollars, costs would total over $8.3 billion [25].

Prevention

Although this type of violence exists in most countries and communities worldwide, interestingly there are some societies where IPV is virtually absent [3]. These societies can give advocates and victims hope that with proper organization of social relations, education, and programming, IPV can be successfully minimized.

The CDC asserts that IPV is preventable. Therefore, emphasis is being placed on interventions that prevent violence before it occurs. Many prevention programs target our nation's youth. Several are specifically aimed at promoting healthy dating relationships among adolescents and teens. These initiatives seem promising in that they address issues of respect, gender roles, and conflict resolution while promoting self-esteem and self-advocacy. Other programs target bystanders and witnesses of IPV, encouraging a more proactive role to support victims of violence [26]. Education of first responders is also necessary.

Screening

In order for any health screening initiative to be successful, physicians must recognize the importance of screening and make it a routine part of history taking. A meta-analysis of IPV screening practices showed that across medical specialties, screening rates were problematic. Only 1.3–12 % of patients reported being screened for IPV by their primary care physicians. And for obstetricians and gynecologists, among the most active in advocating for IPV victims, only 10 % of patients reported having been screened [27].

Most commonly, physicians stated that they did not screen because they either had a poor understanding of IPV in general, they feared offending patients, they did not have adequate time to perform a screening, or they felt that there were inadequate resources and interventions for victims if IPV was uncovered [27].

Starting in 2013, the United States Preventive Services Task Force (USPSTF) recommended that clinicians screen women of childbearing age for IPV and provide or refer women who screened positive to intervention services. This recommendation is given a Grade B rating [5].

Physicians reluctant to screen based on time constraints should feel reassured that the screening tool most recommended by the USPSTF is quick and efficient to administer. With just four questions, the HITS instrument has high levels of sensitivity and specificity. It may be administered by the clinician verbally or by the patient in written form, and with the HITS acronym, it is simple to recall (**H**urts, **I**nsults, **T**hreaten, **S**cream) (Fig. 1).

Even with a convenient screening tool, a challenge worth noting in performing IPV screening of any kind is that patients are not likely to divulge violence in the presence of their abuser. Unfortunately, the batterer, in an effort to maintain control over the victim and to protect him- or herself from legal repercussions of abuse, often accompanies the victim to the emergency room and to primary care visits.

DOI 10.1007/978-1-4939-0779-3_28-1

HITS Tool for Intimate Partner Violence Screening: Please read each of the following activities and fill in circle that best indicates the frequency with which you partner acts in the way depicted.					
How often does your partner?	Never	Rarely	Sometimes	Fairly often	Frequently
1. Physically hurt you	O	O	O	O	O
2. Insult or talk down to you	O	O	O	O	O
3. Threaten you with harm	O	O	O	O	O
4. Scream or curse at you	O	O	O	O	O
Scoring	1	2	3	4	5
Each item is scored from 1-5. Thus, scores for this inventory range from 4-20.					
A score of greater than 10 is considered positive.					

Fig. 1 HITS tool for intimate partner violence screening (HITS is copyrighted in 2003 by Kevin Sherin, MD, MPH and printed with permission) [28]

He or she may hover and refuse to leave the patient alone and may insist on answering questions for the patient. These factors reinforce the necessity for taking the history in private, and astute physicians may need to employ some subterfuge in order to get the patient alone. Asking for a urine sample, for instance, is a simple way to separate the couple. While the abuser may think his partner may be just going to the restroom, the physician may instead bring the patient to another exam room to gather a more thorough violence history in private.

It is also interesting to note that most patients will not spontaneously divulge IPV in their current or former relationships, yet want physicians to ask them about the topic in a supportive and confidential manner [29]. Incorporating an IPV history into routine history taking can identify IPV and build rapport between patient and physician. A sensitive and specific inquiry into IPV communicates to the patient that such issues are important to the provider. Even if a victim initially denies abuse, choosing to remain silent at the first inquiry, a seed of trust and support is planted, and he or she may open up at a future visit.

The HITS tool is a screening tool. It is not diagnostic, and should a patient screen positive, more detailed follow-up questioning is critical to better understand the full scope of abuse and immediate risk to the patient. When asking about IPV, providers need to provide a secure sense of confidentiality, offer support and make it clear that abuse is never the victim's fault, give judgment-free counsel, and offer to follow up. Like most items in the medical history, questions should begin open-ended (e.g., "tell me more about your home life" or "describe your relationship with your significant other") and then transition to more closed-ended, specific inquiries ("does your partner hit or push you?" or "have you been forced to have sex against your will?"). Because victims often do not talk about abuse unless specifically asked, clinicians should expect that open-ended questions may not always be high yield. If that is the case, the provider should be prepared to lead the conversation with a series of direct, closed-ended questions. Simple yes or no questions are far easier for reluctant patients to answer than having to verbalize all of the details of their abuse unprompted.

DOI 10.1007/978-1-4939-0779-3_28-1

Management

As previously mentioned, physicians are often unaware of and disillusioned by possible interventions for IPV victims. In most American communities, there are services in place for abused individuals and their families, though services may vary and can be more difficult to access in some communities.

Resources

For help with assisting IPV victims, the National Domestic Violence Hotline is a good place to start. IPV victims, or health-care providers on their behalf, can call the 24-h hotline (800-799-SAFE (7233)) for help and support or visit the website (http://www.thehotline.org) for a listing of agencies nearby. It is also helpful to have a printed list of local agencies that the patient can discreetly take with her. Most local agencies are able to support victims in various ways. They may offer safe shelter, emotional support and counseling for all family members, free legal advice and advocacy, and access to local law enforcement if legal recourse is desired. Physicians should be able to either refer to such an agency or help give direct assistance if no convenient local agency exists. Health-care providers should not be forceful when making referrals or suggestions; rather, they need to allow their patients to decide how and when to proceed.

Safety Plans

While referrals and follow-up are necessary for long-term care and support, health-care providers must also suggest a safety plan for the victim to put into place immediately. Safety plans typically involve making preparations to escape acute danger and flee to a place of safety. Patients should be encouraged to pack a bag containing a few days of clothing for themselves and, when applicable, their children. The bag should also contain spare keys, copies of important legal documents (passports, birth certificates, and other identification), some money, and any necessary medication. Physicians should ask IPV victims to consider where they might go should they need to flee. Retreating to the home of a known family member or close friend may make it easy for the abuser to find the victim, so a relatively secret or unexpected location tends to be a safer option. If the victim has children old enough to understand, the safety plan should be discussed with them. They may also benefit from a secret safety word that could be used in front of the abuser to signify the need to leave and retreat to safety.

Documentation

Once recognized, IPV must be documented in the patient's chart. The victim may feel uneasy about the private details of her/his life being recorded, so it is important to reassure her/him that the records are confidential and may only be accessed with her/his permission. Proper and thorough documentation of IPV is crucial as the medical record may need to be referenced to receive certain services or be utilized in legal proceedings. Historical components should be written precisely and chronologically. Statements in the medical record should be objective and, as much as possible, done using the patient's own words. Avoid medical jargon and, in paper charts, write with clear penmanship. Describe the patient's behavior and any injuries observed in detail. It is advisable to use drawings or photographs when possible and with permission to clarify the exact location and type of injuries present. Placing a coin or ruler next to an injury helps to notate size and scale in photographs, and, when possible, the patient's face should be visible. When able, take all photographs before treatments are administered.

Reporting

Reporting of IPV is not as standardized and simple to understand as child abuse, for example, in which general mandatory reporting laws exist nationwide. Unlike a child or a disabled person who is unable to speak for and make decisions for him- or herself, mandatory reporting of IPV is problematic in many ways

DOI 10.1007/978-1-4939-0779-3_28-1

and thus is not a law in the majority of states. Mandatory IPV reporting undermines a victim's autonomy, interferes with confidentiality, and harms the rapport and trust built between the patient and physician.

Another reason that most states do not have mandatory reporting of IPV is that it has not been shown to improve outcomes. Calling the police or local agencies has been shown not to help but rather puts victims at increased danger due to retribution by their abuser.

IPV reporting laws vary from state to state, but generally fall into four categories:

1. States that require reporting of injuries caused by weapons
2. States that mandate reporting for injuries caused in violation of criminal laws, as a result of violence, or through non-accidental means
3. States that specifically address reporting in domestic violence cases
4. States that have no general mandatory reporting laws

In addition to understanding your state-specific laws, certain IPV situations might require unique considerations. For instance, teen dating violence might meet criteria for mandated reporting under child abuse or statutory rape laws. IPV of a physically or mentally impaired adult or elder might also meet mandatory reporting requirements. IPV of a LGBTQ individual might be appropriately deemed a hate crime.

Even with an understanding of state laws, health-care providers often recognize that implementation and policies can vary locally. Providers need to have knowledge of local reporting mandates and should consider contacting local IPV coalitions and law enforcement agencies to fully understand how the laws are specifically implemented in their particular municipalities [30].

Sexual Assault

Lisa M. Johnson*
Department of Family Medicine and Rural Health, Florida State University College of Medicine, Tallahassee, FL, USA

Introduction

Sexual assault is an act of violence and aggression and represents a complex problem with medical, psychological, and legal aspects. Because definitions vary among states, the term sexual assault is sometimes used interchangeably with rape. The Federal Bureau of Investigation's definition of rape recognizes that victims of rape and perpetrators may be of either gender and includes oral and anal penetration as well as penetration with an object. This definition also includes instances in which the victim is incapable of giving consent because of temporary or permanent mental or physical incapacity (including due to the influence of drugs or alcohol) or because of age. Physical resistance is not required on the part of the victim to demonstrate lack of consent [1, 2].

Occurrence

In a nationally representative survey of adults, nearly 1 in 5 (18.3 %) women and 1 in 71 men (1.4 %) reported experiencing rape at some time in their lives. There is a lifetime prevalence of rape of 13 % for women and 6 % of men. 42.2 % of female rape victims were first raped before age 18 years. Among female rape victims, perpetrators were reported to be intimate partners (51.1 %), family members (12.5 %), acquaintances (40.8 %), and strangers (13.8 %). Among adult women surveyed in 2010, 26.9 % of American Indian/Alaska Natives, 22 % of non-Hispanic blacks, 18.8 % of non-Hispanic whites, 14.6 % of Hispanics, and 35.5 % of multiracial women experienced an attempted or a completed rape at some time in their lives. Among male rape victims, perpetrators were reported to be acquaintances (52.4 %) and strangers (15.1 %) [3].

Impact

The potential short-term and long-term health effects of sexual violence are well established. Potential short-term effects include injury, sexually transmitted diseases, and pregnancy. Long-term effects include somatic complaints, psychiatric disorders, and such health risk behaviors as substance abuse, suicidal ideation, and chronic physical health problems.

Studies also report impaired physical, sexual, and psychosocial functioning, decreased quality of life, increased risk for re-victimization, and problems with access and use of health-care services [4]. Female victims of sexual assault are more likely to engage in risky health behaviors such as hazardous alcohol use and use of sexual behavior to regulate negative affect [5].

DOI 10.1007/978-1-4939-0779-3_29-1

Female Victims

Women aged 16–24 years are four times more likely to be assaulted than women of any other age [6]. Among college women, sexual assault is a significant public health problem. 11–20 % report that they experienced completed sexual assault perpetrated by threat or force, or the incident occurred when they were incapable of consenting. Female victims in underrepresented minority groups may experience more PTSD symptomatology and may be more likely to believe that their community blames them for the assault [7]. Because the incidence of sexual violence in some racial and ethnic minority populations is higher than many white populations, it is important to understand the role played by health and community disparities when planning emergency care interventions and for preventing adverse health outcomes [4].

Female veterans experience high rates of sexual assault during their service in the military. They are eligible to receive lifetime care at any Veterans Health administration facility for health problems related to military sexual assault [8].

Male Victims

Prevalence rates of male sexual assault are difficult to calculate, as few victims report their assault to the police or medical services [9]. It is estimated that 1 in 71 or 1.4 % of men report experiencing rape at some point in their lives [3]. While sexual assault of males occurs less frequently than females, it is not limited to all male populations such as jails or prisons. While most perpetrators of male sexual assault are male, women are perpetrators too. A comparison of data between male and female victims shows that both groups are assaulted by strangers at the same rate, but males are more likely to have more than one assailant. A higher proportion of victims are identified as gay, bisexual, or having consensual sex with men. Many assaults of men involve anal rape. Men are more likely to be assaulted by acquaintances. The motivations of their assailants include sexual gratification, conflicted feelings about sexual orientation, humiliation of the victim, and exercising power and control [10].

Intimate Partner Violence

An intimate partner is a current or former spouse, an opposite or same sex cohabitating partner, or a boyfriend, girlfriend, or date. Intimate partner violence entails physical, sexual, or psychological harm by a current or intimate partner, and it affects millions of people per year. Intimate partner violence is commonly associated with sexual assault. Sexual assault that occurs within an intimate partner relationship has been shown to result in an increase in PTSD symptomatology [11]. It is commonly believed that sexual assault is more traumatic when committed by an unknown assailant; however, sexual assault in marriage or dating relationships has been found to be equally detrimental to women's physical and mental health [12, 13].

The Family Physicians' Role

In 2011, the American College of Obstetricians and Gynecologists recommended that health-care providers routinely screen all women for a history of sexual assault, paying particular attention to those who

DOI 10.1007/978-1-4939-0779-3_29-1

report pelvic pain, dysmenorrhea, or sexual dysfunction. Prevention of long-term physical and mental consequences can be prevented by early identification of victims [1].

The physician conducting an evidentiary evaluation of a sexual assault victim must comply with state and local statutory or policy requirements involving the use of evidence gathering kits. If a sexual assault victim communicates with the physician's office, she/he should be encouraged to immediately go to a medical facility, not to bathe, change her clothing douche, urinate, defecate, wash out her mouth, clean her fingernails, smoke, eat, or drink [1, 14].

The time limits for evidence collection depend on the jurisdiction and range from 72 to 120 h. The evaluation and treatment of sexual assault victims are time-intensive and should optimally be provided by a team that includes an emergency physician or other medical provider overseeing care and treating injuries, a trained sexual assault examiner, and a social worker or rape crisis counselor who has expertise in acute reactions to rape and can assist in offering support, describing options, and explaining the hospital process. Physicians should understand that it is not their responsibility to determine whether a sexual assault has occurred since such a determination will be made through the legal system [15].

Care of the Victim

When a history of sexual assault is obtained, the clinician may expect that recounting of the incident and various health-care procedures such as pelvic or rectal exams may trigger anxiety reactions [1]. A carefully recorded history should be obtained from the victim. The history should include general medical history, sexual history, and OB/GYN conditions, including current pregnancy or risk of pregnancy. The health-care provider should document the victim's emotional condition.

General body trauma is more frequent than genital trauma in up to two thirds of rape victims who present to the ED [15, 16]. Injuries may include blunt or penetrating injuries to the head, face, torso, or extremities as well as defensive injuries such as lacerations, abrasions, or bruises.

The collection of evidence is a multistep process that can take several hours and is optimally performed by specially trained personnel. The purpose is to collect and record evidence including DNA to support the victim's report of the assault. Evidence collection requires the patient's consent at each step, and the examiner should explain each step of the process to the victim. A detailed examination of the entire body should be performed with injuries being photographed or drawn accompanied by a written description and location of each. Sheets in which the victim is transported should be preserved and folded. Before a Foley catheter is placed, evidence that may contain DNA can be collected from the vagina or penis. Standardized evidence collection kits contain forms for documentation to assist examiners.

Because a meticulous pelvic examination is required, anesthesia may be required to enable patient cooperation. With witnesses present (and named in the record), inspect the perineum and vulva for abrasions, ecchymoses, and lacerations. Over 90 % of victims will have trauma at one or more of four locations: posterior fourchette, labia minora, hymen, and fossa navicularis. Tears occur most frequently on the posterior fourchette and fossa. Abrasions are usually seen on the labia and ecchymoses are most often seen on the hymen.

An alternate light source (ultraviolet illumination) should be used to check the patient and her clothing for semen. Positive areas should be blotted with saline-moistened filter paper, labeled, and packaged separately. Pubic hair should be combed, and both the comb and material obtained should be packaged together. Pubic hair cuttings should be obtained, as well as scrapings from under the fingernails.

Each specimen should be packaged separately and labeled with source, patient's name, and date. All assembled items should be sealed individually and then sealed together in a large container to verify that they were unaltered during transfer to the law enforcement agency. The person who accepts the evidence

DOI 10.1007/978-1-4939-0779-3_29-1

should sign for the material, and this transfer should become part of the chart. In brief, the record should reflect the chain of evidence.

The vaginal speculum should be moistened with saline only, and careful inspection of the vagina should be performed. Saline-moistened cotton swabs may be used to obtain fluid from the vaginal pool and the endocervix and placed in labeled, corked sterile glass tubes for culture for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. The same fluid should be applied to glass slides and air-dried but not fixed. Next, deposit 2 mL of saline in the vaginal vault, and with aspiration, search for motile sperm (often motile even 4–6 h after ejaculation). If the mouth or anus was penetrated, similar specimens should be obtained. Blood should be drawn for VDRL and blood type. HIV as well as hepatitis (B and C) testing at this time and later should be offered. Proper labeling of all samples is essential [17].

A pregnancy test is advisable if the patient may have become pregnant during the assault. The risk of pregnancy after rape is approximately 5 %. Emergency contraception (EC) should be provided. Progestin only EC (1.5 mg of levonorgestrel) administered as a one-time dose within 120 h after unprotected intercourse has been shown to be 98.5 % effective in preventing pregnancy. The best efficacy is within 72 h of the sexual assault [15].

There are long-term health consequences that are associated with sexual assault such as increases in somatic symptoms, diminished levels of function, alterations in perceptions of health, and decreased quality of life. Some women may present with complaints of chronic pelvic pain, dysmenorrhea, or sexual dysfunction without disclosing a history of sexual assault [1].

STI Prevention

All patients should be offered prophylaxis for STIs [18] (Table 1). The most common sexually transmitted infections reported in sexual assault victims include trichomoniasis, gonorrhea, and *Chlamydia trachomatis* [19]. The HIV status of assailants is usually unknown and tends to be of great concern to the victim. And although it is infrequent, cases of HIV transmission following sexual assault have been

Table 1 STI prophylaxis after sexual assault

Cefixime 400 mg orally in a single dose
or
Ceftriaxone 250 mg IM in a single dose
plus
Azithromycin 1 g orally in a single dose
or
Doxycycline 100 mg orally twice a day for 7 days
Plus
Metronidazole 2 g orally in a single dose
Postexposure hepatitis B vaccine (without HBIG) – at the time of the initial exam, at 1–2 months and at 4–6 months after the first dose
If the survivor appears to be at risk for HIV transmission (start within 72 h of assault) – lab work prior to start: pregnancy test, HIV test, CBC, and CMP
Tenofovir 300 mg orally daily + **emtricitabine** 200 mg PO daily
Plus
Raltegravir 400 mg orally twice daily
or
Dolutegravir 50 mg PO daily for 28 days

DOI 10.1007/978-1-4939-0779-3_29-1

described [20, 21]. Genital or rectal trauma, multiple traumatic sites involving lacerations, or deep abrasions and the presence of preexisting genital infection or ulcers in the victim increase the risk of HIV transmission [22]. Health-care providers should carefully consider several factors when deciding to recommend the initiation of postexposure prophylaxis (PEP) after sexual assault, such as whether or not a significant exposure has occurred during the assault, knowledge of the HIV status of the alleged assailant, and whether the victim is willing to complete the PEP regimen. Clinicians should recommend HIV PEP when significant exposure may have occurred. PEP should also be offered in cases of bites that result in visible bleeding. PEP should be started as soon as possible, ideally within 2 h of the assault. Some guidelines restrict initiation of PEP to 36 h after the exposure as it is noted that there is diminished efficacy of the regimen by delaying its initiation. The patient's HIV status should be tested within 72 h of the initial assault and then repeated at 3 months and 6 months. The health-care provider should provide HIV risk reduction and primary prevention counseling whether or not PEP was initiated [23]. HBIG should be administered if the assailant is known to be hepatitis B positive; otherwise, active immunization alone for hepatitis B may be considered.

Emotional Reactions and Psychological Sequelae

After the assault, a rape trauma syndrome often occurs. The initial or disorganization phase may last days to weeks. The victim may experience physical reactions such as generalized pain, eating and sleeping disturbances, and emotional reactions such as anger, fear, anxiety, guilt humiliation, embarrassment, self-blame, and mood swings. The second or delayed phase is characterized by flashbacks, nightmares, and phobias as well as somatic and gynecologic symptoms. This phase often occurs in the weeks and months after the event [1, 24].

Longitudinal data indicate that sexual assault survivors are at increased lifetime risk for posttraumatic stress disorder (PTSD) 30 %, major depression (30 %), and contemplation of suicide (33 %) or an actual attempt (13 %). Risk factors for PTSD after rape include previous depression, alcohol abuse, and increase severity of injury during the assault [15, 25]. Health-care providers should enlist the input of social workers or rape crisis counselors to help evaluate the patient's immediate and future emotional needs and formulate a plan for safety after the patient is discharged home.

Follow-Up

Sexual assault victims should be referred for both medical follow-up (testing for pregnancy, HIV, and hepatitis) and psychological or psychiatric support. Rape crisis centers can provide ongoing support, free confidential counseling, and legal services. Some states require mandatory reporting of rape (with identifying information either included or removed) or weapon-related injuries in a competent adult. All jurisdictions require reporting the assault of a child or an elderly or disabled person.

Prevention

Prevention of sexual assault is a societal issue. Programs that are effective address public attitudes about relationships and sexuality and teach conflict resolution skills. Teaching women life skills may decrease their vulnerability to sexual assault or re-victimization. Support and safety programs, transportation

DOI 10.1007/978-1-4939-0779-3_29-1

policies and procedures, campus and community safety programs, and crime prevention programs have all been shown to decrease the incidence of sexual assault.

Recognizing that a sexual assault has occurred and providing the victim effective care represents primary prevention of re-victimization and secondary prevention for the victim. Prosecution rates are improved when care is provided by victims' advocates, as well as by physicians, and other health-care professionals particularly nurses who have been trained in programs such as Sexual Assault Nurse Examiners can provide accurate collection and documentation of forensic evidence [26, 27].

Conclusion

Sexual assault is an act of aggression by the powerful on the less powerful. Although both women and men can be sexually assaulted, women are at greatest risk. Family physicians must be prepared to recognize and treat victims of sexual assault. Treatment of the woman who has been sexually assaulted should address legal, medical, and psychosocial aspects of care and should be coordinated with law enforcement, victims' advocates, psychological support, and other trained medical personnel [25, 27, 28].

Introduction

Stress is a continually growing concern in our society. The impact of stress on mental health and physical illness can be significant and a major factor in healthcare costs in the United States. A large percentage of Americans report feeling moderate-to-high stress levels on a daily basis [1]. When stress extends to include family and social aspects of one's life, complexities can exist beyond just individual coping of a situation or event. Stress has been seen by both patients and physicians as influencing health outcomes. However, stress is often difficult to define and study, in relation to both physical symptoms and external causes [2]. Family stress can be viewed as a disturbance in the ongoing state of a family system. This disturbance can occur both outside of the system (e.g., war, unemployment, natural disaster) and inside the family system (e.g., death, divorce, chronic illness). This systemic stress creates a change in the family's routine functioning [3]. Normative stressors (e.g., birth of a child, job transition, loss of an older adult) in families are considered to be common and predictable sources of stress. Nonnormative family stressors (e.g., early widowhood, job loss, natural disaster) are uncommon and unexpected and may occur at times other than those expected in the life cycle of the family or its members [4, 5]. How well the family unit copes with these two types of stressors largely impacts both the short-term and long-term

adjustments and well-being of both the unit and the individuals in it.

Divorce and abuse have been cited as two of the most stressful events that commonly occur in families [6]. Numerous problematic outcomes and life adjustment problems have been found in individuals following divorce. Divorce has long been linked to physical and emotional health problems in adults. Increases in depression, dysthymia, and alcohol abuse have been reported, based on both the quality of the relationship prior to divorce and financial resources of the family [7, 8]. Greater health risks and the incidence of suicide also increase as a result of divorce [9]. Childhood adjustment can be affected greatly by parental divorce; it is reported that 25 % of children from these families experience high levels of problem behaviors [10]. Additionally, intimate partner violence has long-term health consequences for survivors, even after the abuse has ended. The effects of abuse can lead to negative outcomes such as poorer overall health, lower quality of life, and higher use of healthcare services than the general population [11].

Family strain has an impact on multiple levels of member's lives. The relationship between parental stress and parenting practices can have strong effects on the behavioral outcomes of children. Parental responses to stress can lead to subsequent internalizing and externalizing behaviors in their children, especially those with serious medical or health conditions, such as diabetes [12] or asthma [13]. Stress within families also has significant financial and occupational consequences. Work and family are particularly significant sources of stress, given that a large percentage of adults devote large amounts of time to these two areas of life [14]. The high time demands of work environments have strong impacts on the mental, physical, and relational well-being of the worker and their family members [15]. Families who experience financial strain endure the added challenges of obtaining adequate healthcare and other resources. Other internal and external sources of stress can have major ramifications on the adjustment and well-being of members over time (Table 1).

Table 1 Examples of internal and external family sources of stress

Internal factors	External factors
Death in the family	Natural disaster
Divorce or separation	Community risks/crime
Financial problems or job loss	Lack of access to care/ insurance coverage
Accident/disability/ illness	Migration/immigration
Miscarriage	Economic recession/ depression
New members in the household	Changes in the workplace
Caregiving	War
Abuse/neglect	Political issues

A chronic illness or a medical issue can prompt the onset of family stress in various ways. For example, caregivers of family members with chronic illness often experience high levels of stress. According to the National Alliance of Caregiving [16], more than half of caregivers in America reported feeling overwhelmed by the amount of care required by an aging or chronically ill family member. Additional life events and stressors can influence a family's ability the cope with a serious or persistent illness. Physicians should view the etiology of family stress from a variety of perspectives and consider its effects on multiple members of the family unit.

Theoretical Frameworks of Stress and Health

Family Systems Theory

For much of the twentieth century, clinical practice of individual symptoms and conditions was largely focused on etiology and considered to be rooted in the psychopathology of the individual. With time, a new systemic paradigm emerged, seeing one's problems as interconnected to other members and relationships in the family system, breaking away from the deterministic, linear, and causal views of individual dysfunction [17]. Bowen [18] further advanced the concept of considering families to be cohesive systems,

highlighting the fact that the problems (mental, emotional, or physical) of one individual in a family cannot be understood in isolation from another but rather that the family must be thought of as one emotional unit. Recently, physicians are becoming better informed of the inter-relational and systemic causes of disease and illness, understanding the connections of illness with areas such as family dysfunction, relational stress, mental health issues, parent-child relationships and spirituality. For families experiencing a member with chronic illness or disability, systems theory not only pertains to the determinants of health within the family system but other relationships with healthcare professionals, insurance providers, and other agencies that may be involved in the patient's care [19].

McDaniel et al. [20] highlighted the following concepts and questions to help physicians apply systems theory into practice with families:

- **The Family as a System**
  - Who are the members of the patient's family?
  - When it comes to daily support, who does the patient consider as family?
- **Family Stability**
  - What does the family do to maintain balance and security for its members?
  - If change occurs too quickly, what will happen to the family's stability?
- **Family Change**
  - What does the family do to facilitate the needed change?
  - If change does not occur quickly enough, what will happen to the family?
- **The Relational Context of the Symptom**
  - How do the patient's symptoms influence the family?
  - How does the family influence the patient's symptoms?

Mind-Body-Environment

Antonovsky has been largely credited for being one of the first researchers to explore the physiological response to stress. His work largely focused on the search for health (salutogenesis) rather than pathology (pathogenesis) in individuals enduring situations of extreme trauma. Individuals who have specific dispositions may make individuals more resilient to global stressors on an everyday basis [21]. Antonovsky believed that health, stress, and coping are interrelated factors, and professionals should not focus solely on the factors that cause disease [22]. George Engel [23] gave further attention to biobehavioral health, rejecting the traditional medical model of disease and addressing the importance of exploring the psychosocial dimensions of one's health. According to Engel, areas of one's psychological and social life often have an interchangeable connection to physical health outcomes. The boundaries between health and disease, or well and sick, are ambiguous at best. Thus, certain cultural, social, and psychological considerations must be taken into account to define the impact that the stress of illness and disease has on one's life.

Another model of health and stress that has been advanced is the diathesis-stress model [24]. Individuals may be seen to have particular vulnerabilities to stress, given a set of life circumstances both individually and systemically. If the combination of stress and vulnerabilities exceeds a certain threshold, it is more likely that an individual will develop a particular disorder (Fig. 1). The model combines both genetic endowment and environmental factors, along with the reaction to the onset of stressful life events. Certain protective factors (social networks, self-esteem, community) may buffer against the susceptibility to particular stresses that could initiate or exacerbate a given disorder or condition.

These mind-body frameworks are critical for healthcare providers to conceptualize when working with patients and family members. Working from a biopsychosocial model gives physicians an idea of why some individuals view sickness as an "illness," while others may regard these issues as

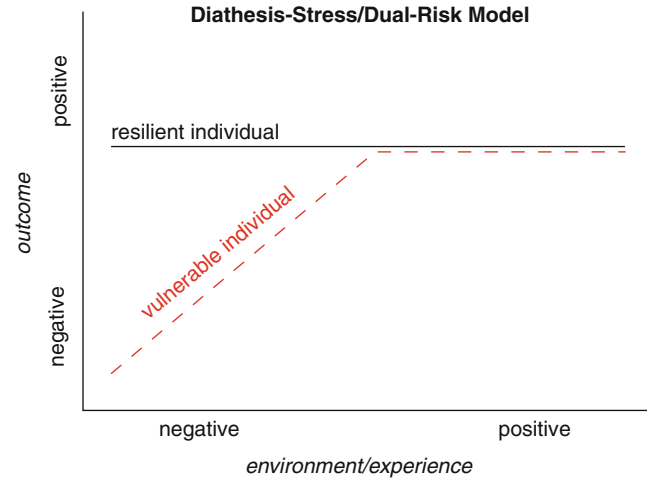

Fig. 1 Diathesis-stress model

"problems of living." Additionally, physicians can benefit from asking patients and their family members about past stressful events and how they have coped around these events as a unit. Identifying these positive areas of coping around stressful events could provide useful information when establishing treatment goals and in developing suggestions for behavioral and lifestyle changes that patients can make over time.

Developmental and Multigenerational

Families often lack a clear perspective of time when problems or crises occur. Members may be stuck in past events, feel immobilized by current situations, or become fearful of possible future events that may occur. From a developmental life cycle framework [25], symptoms and dysfunction in a family system are examined from a systemic perspective. Several stressors have been said to impact the long-term functioning and well-being of members over time. Some stressors derive from family history that is passed down through generations (e.g., secrets, legacies, genetic abilities and disabilities, and religious beliefs and practices). Others are comprised of developmental, unpredictable, and historical events that occur across an individual lifetime (e.g., trauma, chronic illness, accidents, natural disaster, war, and economic circumstances).

Stress may also be transmitted between family members and across generational lines. A family's behavior and response to illness cannot be comprehended apart from its history [26]. A multigenerational assessment of family stress helps to clarify both strengths and vulnerabilities in family members, while identifying "high-risk families" who are often burdened by past unresolved issues. Tracking key events, organizational shifts, and coping strategies around illness can help explain and often predict future coping strategies of the entire system [27].

Having both a developmental and multigenerational lens of patient care broadens the narrative of illness and health-related symptoms across the life span. A useful tool for physicians in the assessment of health and stress in families is the medical genogram. This diagram offers physician a quick way to evaluate health risks, pursue preventative measures or treatment, and assess the family history in a more comprehensive and systematic manner.

Crisis and Adaptation

There is wide variation in how families adjust and adapt to a triggering event or crisis. One of the first family stress frameworks to address adjustment and adaptation emerged from Hill's classic work on the family response to war and separation, where he advanced the use of the ABCX family

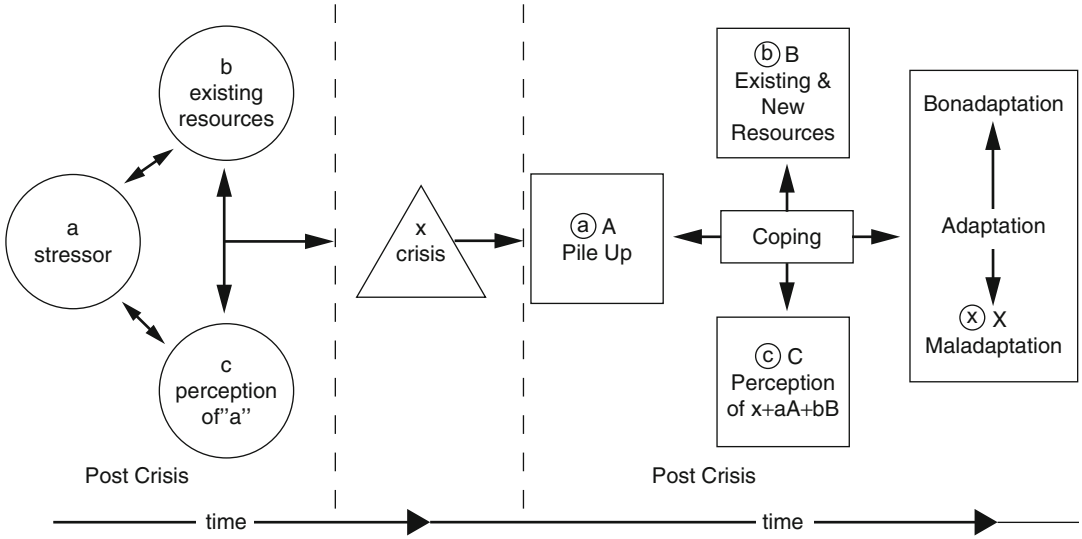

Fig. 2 The double ABCX model [29]

crisis model [28]. Stress is not seen as an inherent characteristic of an event but rather is a function of the family's response to the event and the residual effects over time. Hill hypothesized that when a stressful event or crisis impacts the family unit, the availability of resources and perception of the event will determine the level of stress that the family system will endure. McCubbin and Patterson [29] expanded this model, including a second level of coping and adaptation after a stressor (Fig. 2).

The ABCX model is a useful conceptualization for family physicians when assessing the resources and coping strategies of families after an illness. When families are going through the "crisis period" of an illness, physicians and healthcare professionals can work on normalizing this period of stress and vulnerability in families. This is an important stage that occurs after a patient is diagnosed with a serious or chronic illness and when outside resources and help regarding medical support, medication management, travel, and healthcare access become important factors to consider.

Effects of Stress on Health

Stress can happen inside and outside the family system and it can be normative or nonnormative. The human body is uniquely equipped to handle the demands of an acutely stressful event. The body sets off a series of hormonal responses to prepare the body for action either flight or fight. This response is mediated by the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system (SNS). These systems work together to send signals to all areas of the body to prepare for the possibility of fight or flight [30]. These acute responses are lifesaving when confronted with a survival situation. In the current modern lifestyle, the need for an acute response to a life-and-death situation is uncommon; nevertheless, when the body perceives stress of any kind, the same systems are activated and the entire body is affected. The response is intended to be short term. When there is no break in the stress or no perceived break in stress, the acute stress response does not resolve. Chronic stress hormone elevation may then result in significant health problems [31].

Acute Stress

The entire body is affected by heightened hormonal and nervous system responses to an acute stressful event. The initial response begins with the nervous system and hormonal response. The brain and nervous system are significantly impacted. There is an increase in alertness and a sense of anxiety. Short-term memory, concentration, inhibition, and rational thoughts are all suppressed to enhance quick reaction time for the fight-or-flight response. In this state, social and intellectual demands become challenging. The hippocampus is processing long-term memories to discover episodes that might be similar. The brain moves to an increased state of arousal [31]. When activated the adrenals work to release stress hormones. In addition to the hormones that are being produced in the endocrine system, the liver increases blood glucose levels for the energy needed for the fight-or-flight response.

As the acute stress continues, muscle tension increases as blood supply is diverted to prepare the body for action. The respiratory system responds by increasing respirations to meet the oxygenation demands. This enhances the sense of anxiety and panic that is needed to respond to the flight or fight. The heart and circulation are affected. The heart rate rises and contracts more strongly. Blood pressure rises in response to the acute stress. The blood vessels dilate directed toward large muscles and heart vessels to increase blood flow to those parts of the body that are essential to the fight-or-flight response [33].

As the hormonal and nervous system focuses on the acute needs of the fight-or-flight response, other areas of the body are affected by decreased blood flow. The gastrointestinal tract receives less overall blood supply and has a response to the increase in hormones. There is an increase in acid production and sensitivity to heighten hormonal states that can increase epigastric pain and lead to nausea. These results are observed in stress-related bowel disorders [34]. Lastly in the acute stress state, the reproductive organs are affected. There is decreased blood supply to the genitals [33]. In females, stress hormones interfere with the hormonal regulation of the menstrual cycle. Acute stress can lead to changes in menstrual cycles, menopausal symptoms, and reduced sexual desire.

Once the acute event is resolved, these responses should resolve and return to a resting state. The modern day dilemma is when the perceived acute stress is never resolved, safety is never achieved and the physiologic response changes from an acute state to a chronic exposure to heightened arousal and elevated stress hormone levels. There is growing evidence that these effects exacerbate chronic conditions and may predispose to the development of some chronic conditions such as hypertension or diabetes.

Chronic Stress

The effects of chronic stress can be difficult to study. Studies of the effects of stress can be observed in humans as early as in utero. The effects of chronically elevated cortisol have been observed to result in adverse birth outcomes that include low birth weight, prematurity, and all-cause mortality. In addition, infants born to mothers with elevated cortisol levels also have elevated cortisol, suggesting a lasting effect of stress transferred from mother to child [35].

Chronic stress may have negative effects at any age. A recent study of post-hip fracture geriatric patients found that those with depression as a marker of chronic stress demonstrated reduced bactericidal functioning of monocytes [36]. There is an increased susceptibility to infections secondary to lower white blood cell counts in response to stress.

Exacerbations of the chronic disease process due to chronic stress are evident in many diseases. Diabetes, for example, is very sensitive to elevated cortisol levels. This leads to insulin resistance and elevated blood sugars [37]. Stress can cause feelings of increased anxiety, which in turn will exacerbate many psychiatric diseases. When left unresolved, stress can lead to chronic anxiety disorders and/or chronic major depression. There is an overall loss of pleasure and accomplishment and the disruption of the serotonin system in the brain. Tension headaches, backache, shoulder

Table 2 The effects of stress

System	Acute stress effect	Chronic stress effect	Diseases worsened
Mood and memory	Increased anxiety	Panic attacks	Anxiety
	Decreased short-term memory	Memory problems	Depression
Musculoskeletal system	Tension	Pain	Tension headaches
			Chronic pain
Respiratory	Tachypnea	Shortness of breath	Asthma and COPD exacerbation
Cardiovascular	Elevated blood pressure	Hypertension	Hypertension
	Tachycardia		CAD
			ACS
Endocrine	Elevated hormones	Hyperglycemia	Diabetes
	Elevated blood glucose		
Gastrointestinal	Constipation	GERD	Irritable bowel syndrome
	Diarrhea		Inflammatory bowel disease flares
	Increased gastric acid		
Sexual and reproduction	Male erectile dysfunction	Decreased libido	ED
	Female menstrual changes		PMS
			Menopause

pain, and chronic pain syndromes can all develop from chronically tense muscles [32].

The increased respiration rate during stress can trigger asthma or COPD exacerbations and worsen respiratory diseases overall. Irritable bowel syndrome has been linked to stress. Those with inflammatory bowel disease can experience increase in flares under stress [34].

Now that we have seen the effects of chronic stress on disease, the question is, can chronic stress cause disease? This is a little harder to make a direct link, but the evidence is growing. In a state of chronic stress, eating habits are affected. When under chronic stress, there is hormonally induced craving for foods high in caloric intact and carbohydrates. Carbohydrate in particular increases tryptophan and can increase serotonin combating the hormonal effects of chronic stress. Chronic exposure to elevated cortisol also boosts abdominal fat and weight gain [31]. There is also a decrease in physical activity after exposure to chronic stress. As depression and anxiety worsen, sleep disorders are exacerbated. Chronic stress may also lead to many negative life choices and leads to an overall increased risk of chronic disease. There is an increased risk of developing type 2 diabetes.

Lastly, the evidence that chronic stress has effects on cardiovascular health cannot be ignored. The lifesaving increase in heart rate and blood pressure in an acute stress response loses any benefit over the long term. It is well established that stress can contribute to the development of atherosclerotic vascular disease, by several mechanisms. There is also evidence to support the possible contribution of an inflammatory response mediated by chronic stress hormones [38]. The coronary arteries are also very sensitive to the stress hormones released during the acute response [33]. The effects go beyond the increase in heart rate and blood pressure. There can be alteration in cardiac rhythms. There is an effect on cholesterol and impaired fat clearance. There is evidence that vessel intima-media thickness increases and there is a release of inflammatory markers into the bloodstream during the stress response (Table 2).

Chronic stress exacerbates many chronic conditions. Chronic stress may lead to negative lifestyle choices that contribute to risk factors for chronic disease. Once acute stress is identified, helping patients manage the acute phase and prevent long-term chronic stress is beneficial to the overall health of all family members.

Counseling Strategies for Patients and Families

By attending to the biopsychosocial framework of health, the patient and family can be helped to minimize the effects of family stress and to develop strategies for coping in the future. Physicians could benefit from utilizing specific counseling skills for psychosocial issues beyond routine screening and assessment at visits. Specific approaches such as behavioral techniques, solution-focused strategies, motivational tools, or educational resources can help both patients and families cope with stress-related issues around illness and health. The following sections will highlight these approaches when working directly with the patient as well as the family system.

Treatment Approaches

Motivational Interviewing

Patients and families are often reluctant to change coping mechanisms in response to stress and crisis management that have been developed over time. When a patient or family member feels "stuck in the situation," it may be due to deficient coping techniques or perhaps their perception of the problem. The ways in which physicians and other professionals can talk with patients and families about health and personal issues can influence their motivation to change certain behaviors. Motivational interviewing (MI) is an effective, evidenced-based approach that delivers these therapeutic benefits to patients, family members, clinicians, and healthcare professionals [39]. As a patient-centered method for enhancing motivation to explore change and challenging ambivalence, MI has expanded to also elicit and strengthen change for individuals around illness [40]. MI has been found to have numerous applications to chronic illness and health issues (sexual health, weight loss, medication adherence, diabetes) as well as mental health and family-related issues (depression, OCD, alcohol abuse, anger management, domestic abuse).

Healthcare professionals using motivational interviewing should implement the following key steps [39]:

- Assess the patient and/or family member(s) ambivalence about change.
- Recognize change talk when you hear it in conversation (e.g., desire, ability, reasons, need, commitment, taking steps).
- Use open-ended questions and reflective listening skills to get more depth of patients' perspectives.
- Meet the patient and/or family member(s) at their stage of change around the particular issue.

Brief Therapy

Pressures of time and schedules often force physicians to have suboptimal encounters with their patients, especially in primary and ambulatory settings. Patients may have limited time to provide in-depth information on their presenting problems and tend to focus solely on complications and symptoms rather than strategies and solutions. Solution-focused brief therapy (SFBT) has become a helpful intervention approach for patients and family members to recognize strengths in order to reduce the intensity of symptoms and identify solutions [41]. SFBT has been implemented in family services around mental health and family-related issues, public social services, prisons, residential treatment centers, schools, and hospitals [42]. Behavioral health professionals and other providers who use this framework ascribe that patients possess the necessary skills needed to improve their lives, but may need help remembering times that they have coped with a particular problem successfully. Solutions are seen as different ways of viewing their lives, that their problems are not to be solved by professionals, but that solutions are mooted and discovered primarily by the patient and/or family [43].

Healthcare professionals using brief therapy should implement the following key steps:

- Helping patients and family member(s) recognize the times when stress around the illness, disease, or issue was reduced or did not exist
- Identifying a list of resources and strengths that the family already has available
- Cocreating a treatment plan, where the patient, family, and provider are working together on outlining goals
- Developing small, attainable goals that the patient and family can achieve over time

Cognitive Behavioral Therapy

For some patients, interventions around behavior changes and improved cognitive awareness are warranted to improve health outcomes. Professionals may choose to deliver advice and treatment planning that is more directive and behaviorally oriented in nature. Cognitive behavioral therapy (CBT) is a widely utilized behavioral intervention in medical settings around not just chronic or life-threatening conditions [44–46] but for self-regulation and stress reduction around mental health and family-related stress [47, 48]. Although behavioral approaches can provide effective outcomes for patients and families, this therapy modality has been largely underutilized in primary care. One reason may be the time-limited environments that physicians typically work within [49].

Healthcare professionals using cognitive behavioral therapy should implement the following key steps:

- Support the thoughts, feelings, and emotions of patients and families working through an illness or stressful life event.
- Identify certain triggers or barriers that impact negative thoughts and reactions to presenting problems.
- Set behavioral goals, where the family can learn to reduce maladaptive behaviors in a time-limited fashion.

Mindfulness

When stressful triggers or life events arise, patients need to attend not only to their cognitions and thoughts but also physical symptoms throughout their body. Physicians can reduce the patient's stress or worry of future events and situations but using interventions of awareness and attunement to focus on the "here and now." Mindfulness work is an effective process where one's awareness is on the present moment, paying close attention to the thoughts, feelings, bodily state, and environment around them [50]. In patient and family care visits, this intervention is about teaching individuals how to respond to stressful events more reflectively instead of reflexively. Mindfulness-based stress reduction (MBSR) has integrated meditation work into psychological and family-related issues with patients. Originally, MBSR was a group-based program that helped patients suffering from severe chronic pain and stress-related symptoms.

Healthcare professionals using mindfulness should implement the following key steps [51]:

- *Body scan*: gradual attention throughout the entire body, focusing on sensations through body regions with periodic breath awareness and relaxation strategies.
- *Sitting meditation*: mindful attention of breathing and a state of nonjudgmental awareness of cognitions and thoughts.
- *Yoga practice*: breathing exercises, simple stretches, and posture work that is intended to strengthen and relax muscles.

Family Psychoeducation

Low levels of health literacy can lead to increase individual and family stress. Misunderstanding and miscommunication of health-related information also add to the stress of patients and families dealing with health concerns. Psychoeducational interventions can help educate patients, family

members, and caregivers about the specifics of an illness or condition, as well as what areas the family can help provide additional care. This information offers families additional resources to cope around a particular crisis event or diagnosis and provides general problem-solving skills. Particular guidelines [52] can be delivered around illness management, medical adherence, and assistance with daily issues, and expansion of the patient/family member's social network is emphasized. Many psychoeducational interventions given to patients, family members, and other caregiver individuals are not delivered by behavioral health professionals [53].

Healthcare professionals using psychoeducation should implement the following key steps:

- Ask the patient and/or family member(s) what they know about the issue and what professionals have discussed the issue with them.
- Deliver basic information in clear and understandable terms for everyone to understand.
- Allow for the family to ask follow-up questions or clarify any unfamiliar words, terminology, or medical jargon.
- Provide literacy-appropriate health education materials.

Intergenerational Approach

Stress in families can be transmitted through multiple generations, where individual family members have been unable to cope with life events. Bowen's theory [26] was a way to observe the emotional unit of a family, observing these systems on a continuum, ranging from extremely impaired to high functioning. When anxiety and stress occur in a family system, members will adjust the amount of dependence they have on each other to attempt to resolve the given crisis or situation. This therapeutic approach looks at the family system beyond just symptom reduction, exploring how the family will be able to function in a more healthy fashion around a stressful event such as illness or disability.

Specific processes that physicians can attend to by using this approach include:

- **Level of differentiation in family members**: Members with a well-differentiated "self" can stay calm and clear headed in the face of anxiety and stress. Poorly differentiated members have to rely heavily on these members during times of crisis.
- **Triangulation**: A triangle is a three-person relationship system and the smallest stable relationship system. During times of stress or crisis, two members may pull a third person into their subsystem to resolve a conflict or to mediate tension.
- **Family projection process**: This describes the primary way that parents transmit their emotional turmoil and feelings onto their child. This process can impair the functioning of multiple children and cause onset of clinical symptoms.
- **Emotional cut-off**: This concept describes how individuals manage their unresolved emotional issues with parents, siblings, or family members by completely cutting off ties with the person or group.

Collaborative/Integrative Care

The family physician is situated in a system of care that, when used, can greatly facilitate the amelioration of conditions affecting the health of the patient. Integrative care, a key component of the patient-centered medical home, affords the physician access to expanded resources for assisting patients. Physicians who utilize healthcare professionals in their team can coordinate more effective services and care for patients and families [54].

In the area of coping with family stress, one resource that helps patients and families work through crisis and illness situations is a medical family therapist. The field of medical family therapy has gained increasing prominence in helping to address the psychosocial aspects of illness in individuals and families. Approaching primary care from both the biopsychosocial and systemic perspective, medical family therapists are trained to intervene with individuals and families to address both mental disorders and interpersonal

dysfunction. As part of the collaborative care team, medical family therapists can provide support services ranging from behavioral consultations to short-term interventions to intensive individual and family psychotherapy [55].

Managing Mentally Ill Patients in Primary Care

Laeth Nasir

Contents

General Principles

Definition/Background

Because mental illness is so common and may cause as much or more disability than many chronic medical illnesses, psychological assessment is integral to the evaluation of each patient in the Family Medicine paradigm.

Most perturbations in the psychological state of patients presenting to the attention of the family physician are, like most physical illnesses, transient or minimal and not likely to significantly impact health. Sometimes these issues can be more pervasive; many of these are related to the patients' social and existential milieu. Finally, there are patients who display symptom clusters of a quality, severity, and chronicity most consistent with classically described psychiatric conditions. Differentiating between these groups of patients may be difficult. Symptoms may fluctuate significantly over time, so at times they meet criteria for a diagnosis of a psychiatric disorder, and at other times they do not. Longitudinal follow up may be helpful to assess the importance of symptoms in a given patients' life.

While contemporary psychiatric classifications of illness represent the pinnacle of our current understanding of the neurobiological basis of many psychiatric conditions, they often do not comport with the patients' own lived experience, do not fit easily into the realities of the primary care setting, and may not be very successful in

bringing about satisfactory patient-centered outcomes [1–3]. Assumptions that the psychiatric populations seen in primary care and tertiary care are identical may result in a "category fallacy" when using standard criterion-based diagnosis systems used in subspecialty care [4]. While it is important for the physician to try to focus on the assessment of behaviors that are observable, measureable, and therefore reproducible, this unavoidably reductionist approach excludes or discounts many factors that might be important to the patient, and may risk medicalizing normal human experience.

It has been suggested that an alternate, pragmatic system of classification of patients with mental health problems be developed to better categorize the range of disorders seen in primary care [5].

Regarding the treatment of mental health issues, it is increasingly recognized that measures and outcomes that are important to clinicians and health systems may not always be the yardsticks that are meaningful to patients. In-depth studies of patient outcomes have identified that some aspects of the organization of mental health practice may actually interfere with a patients' ability to fully recover from mental illness. Individuals with chronic mental health issues often end up living in "virtual institutions" where all aspects of their identity are directly linked to the mental illness through their social network and housing, for example. Ultimately, mental illness, and its associated dysfunction becomes inextricably linked to their sense of self, which can be a barrier to improvement [6].

With this fact in mind, many health systems worldwide are rethinking and overhauling their approaches to the management of psychiatric illness. The "recovery" movement recognizes that many individuals with chronic mental illness will never achieve "normality." Instead, aiming for reintegration of these patients into society in order that they might attain a meaningful and fulfilling life becomes an important focus.

When encountering a possible mental health problem, the family physician often faces a series of very challenging tasks. The multidimensionality of undifferentiated patient presentations often makes the assessment of these patients highly complex. In addition, the ability of the physician to articulate the problem in a way that makes sense to the patient, and then to negotiate a narrative that provides an opportunity to use the resources available to develop solutions to the patients' problems is one of the keys to providing the highest quality mental health care in the primary care setting. An overreliance on reductionistic models, based on rigid criteria may not be helpful in many cases, and may be associated with high rates of nonadherence, ineffective treatment, and premature termination of care [7].

Epidemiology

Mental health problems are very common. National surveys estimate that in 2012, 4 % of adults in the United States suffered from a mental illness that significantly affected day-to-day living, and in that same year, 18.6 % of all adults suffered from some kind of mental disorder classifiable according to the DSM [8]. Data from both the United States and international sources reveal that the majority of patients with a mental health problem never come to medical attention, instead seeking care through informal channels that may include friends, family, and alternative practitioners. Of those who do seek medical attention, only a fraction are seen by professionals specializing in mental health care [9, 10]. This means that most people with mental health issues who go to a doctor present to the primary care physician, and will never interact with a mental health professional. Additionally, many patients who do ultimately receive mental health treatment from a subspecialist subsequently drop out of care [11]. Overall, it is estimated that at least 90 % of medical mental health care worldwide is delivered by primary care physicians [5].

High levels of morbidity and mortality are observed among patients with serious mental health issues, and these are a particular cause of concern for the family physician. Several studies have documented significant reductions in life expectancy among patients with chronic mental illness. This excess mortality is thought to be due

to the behavioral clustering associated with these conditions that include smoking, substance abuse, poor diet, and lack of exercise [12–14]. Other data suggest that disruptions in neurohormonal systems caused by mental illness may also contribute to morbidity [15]. In addition, long term effects of certain psychiatric medications may increase risks of obesity, metabolic syndrome, and its attendant conditions [16]. The monitoring, prevention, and treatment of these conditions is often overlooked in caring for these patients. A review of interventions to reduce health-risk behaviors and medical conditions among patients with schizophrenia and bipolar disorders found that there was good evidence to support behavioral interventions for weight loss, and the use of varenicline and bupropion for smoking cessation [17]. However, only a few studies have been carried out in patients with psychiatric illness, particularly in primary care settings and more work is needed to explore the effectiveness of interventions for prevention in these populations [18].

Approach to the Patient

Patients presenting to primary care with mental health problems typically differ in important ways from the ones seeking help from subspecialty psychiatric care. In the subspecialty psychiatric setting, virtually all patients have accepted a psychiatric dimension to their illness, and so volunteer emotional symptoms as a matter of course. In contrast, in the primary care setting, patients are much less likely to relate affective or behavioral symptoms, instead focusing on a combination of somatic complaints and social factors. Very often, they do not perceive the emotional and psychiatric aspects of their condition. The willingness of individuals to consider a psychiatric dimension of their illness varies widely, and may be influenced by among other things, the feelings of disempowerment and stigma associated with mental illness [19]. In addition, cultural, social, or personality characteristics particular to individuals or groups of patients may discourage recognition or acceptance of a psychiatric diagnosis. Also, the illness itself may interfere with insight. This may result in unconscious or conscious attempts to rationalize, discount, conceal, or disguise symptoms that they may perceive to be "psychiatric" in nature. Failure of the physician to ferret out the condition then provides the patient with "evidence" that the problem is a (more acceptable) physical one. It is not unusual to encounter patients who are so resistant to the idea of a psychiatric component to their illness that they demand further extensive testing to detect unlikely physical illnesses, refuse, or (more commonly) fail to adhere to treatment, or simply find a different, and hopefully more malleable practitioner.

This dynamic highlights the central role that establishing trust and the development of a common understanding between physician and patient has in improving rates of treatment of mental health problems [20]. Trust is usually developed through ongoing and bidirectional communication that gives coherence to the patients' own experience, allows them to develop an acceptable context in which to place their illness, and ideally to develop a narrative of coping or healing.

Among those who are reluctant to consider a mental health explanation for their symptoms, rolling with the patients' resistance, "planting a seed" and allowing them to consider the issue at leisure will often result in their being much more amenable to consideration of an emotional or psychiatric dimension of their condition in future visits.

One approach that has been quite successful for this author, when faced by resistance in the face of a likely psychiatric diagnosis is to tell the patient for example: "I'm not certain what is causing this condition," and provide a differential diagnosis that includes both possible physical causes and psychiatric condition(s). "What I would like you to do is over the next week or two is to have you monitor and record your symptoms, and also record what is going on during the day, including any issues that result in stress to see whether they affect your symptoms."

Diagnosis

Screening for mental health problems is frequently carried out in the primary care setting in high-income Western countries. Using standardized instruments for the diagnosis of depression, for example, improves the detection rate of this condition; in the absence of screening, only about 50 % of cases are detected [21]. Screening may also allow patients another avenue by which psychological discomfort can be articulated and brought to the attention of the physician. However, controversy exists regarding the costs and benefits of screening for many mental health conditions in primary care, and may depend on whether resources are available to ensure that the problem can be treated effectively if it is discovered [22]. However, little evidence is available to assess the efficacy or acceptability of this kind of screening in many cultures.

The detection of mental health issues in the primary care setting depends largely on characteristics of both the patient and the physician. Although the well-documented lack of detection and treatment of mental health issues in primary care is widely assumed to result solely from a knowledge deficit on the part of physicians, the widespread ineffectiveness of educational interventions suggests that there are a number of more important issues that result in the outcomes observed [5]. In most general medical settings, there are a number of barriers that may interfere in making a diagnosis of a mental health condition. These include the poor fit of psychiatric classification systems in primary care as mentioned above, variations in the training or other characteristics of the physician, the undifferentiated nature of many mental health presentations, patient characteristics, and systems barriers.

Since most current workflows in primary care are not designed to deliver mental health care in a way that differs paradigmatically from the care of most physical disorders, the system in which the physician works is often the major barrier to addressing and treating these problems. Time pressure is one of the most commonly cited of these. It is well recognized that the number of complaints presented by a patient in the primary care setting is directly proportional to the nonrecognition of mental health problems. One solution which is becoming more popular is the development of "colocated mental health services" in which detection of a mental health problem results in the patient being comanaged with a mental health professional who has the time and specialized training to focus solely on the mental health issue that is suspected or identified.

The availability of appropriate triage options or medications is another barrier. Many physicians may correctly surmise that there is little to be gained by making the diagnosis of a stigmatizing psychiatric condition if it is unlikely that the patient is going to receive successful treatment for it, or if the perceived social costs to the patient of making a diagnosis will outweigh the benefit of treatment [23]. In some countries, psychiatric medications may not be available in the primary care setting, and cost may be another limiting factor in many settings. Lack of availability of counseling services also may be a problem. Other barriers to the treatment of mental health problems in primary care have been recognized, including one study that found an association between lower rates of recognition of a mental health problem and the use of electronic health records [24].

These systemic barriers may lead some physicians to avoid "the can of worms" posed by a potential mental health issue. This may lead them to implicitly collude with the patient by accepting the validity of the patients' somatized "ticket of admission" to the doctor, and instead of addressing it, to ignore it or to defer addressing the problem.

History

A unique characteristic of primary care is the longitudinal relationship shared by the physician, patient, the family, and ideally the community. This has a number of advantages that include the ability to observe symptoms at intervals, the time to develop trust and a shared understanding and narrative about the condition, and the ability to

contextualize both the diagnosis and treatment. A longitudinal relationship also may have the disadvantage of "foreknowledge" that may result in the clinician discounting apparently new discordant information or observations that arise during the course of a familiar relationship.

Review of the patients' past medical record, when it is available, is often very helpful. It is quite common for patients with undiagnosed behavioral problems to make frequent visits to various practitioners and care settings with vague or recurrent mild or undiagnosed illnesses. However, it should be noted that at least one study has found that the majority of patients with undiagnosed physical symptoms presenting to primary care do not have a mental disorder [25]. A thorough evaluation of the record may reveal a previous clinicians' recorded suspicion of a mental health problem, though follow up may not have occurred. Alternatively, prescribing patterns of previous physicians – such as the frequent prescription of benzodiazepines – may suggest that they had considered the possibility of a mental health condition that they may not have directly addressed or recorded.

Patients presenting to the physician with a previously diagnosed mental health condition are also commonly seen. Not infrequently, patient records are unavailable or may be inadequate. While many patients may have a good understanding of their illness and can recount their history and treatments, others may suffer from enough impairment or deficient communication skills that it is difficult to get a good idea of the patients' past history, and what previous treatments have been attempted. Others may minimize or conceal their history to avoid memories of a painful chapter in their lives, or to avoid a possible negative judgment by the physician. At times, it is only after a trusting relationship has developed that the history of a mental health problem emerges.

A careful history around current and past use of substances is warranted. Substance abuse is often comorbid with other mental health issues, and may be even more difficult to uncover than the associated psychiatric condition. Comorbidity of mental health and substance use disorders complicates the course and worsens the prognosis of both disorders [26]. Patients with a past history of substance abuse are prone to relapse in the face of exacerbations in their mental health condition.

Mental health conditions are often brought to the attention of the physician by family members, or other concerned individuals in the patients' social environment. The role of collateral informants is often invaluable in determining prior functioning, premorbid personality traits, and family history. These may provide critical clues to the diagnosis, and an assessment of the problems' severity. Further, friends or family members may help to negotiate appropriate treatments with the patient. Finally, understanding the support and social capital that the patient enjoys may be important in assessing prognosis.

Physical Examination

Findings on the general physical examination are very important. Psychiatric symptoms can be due to many conditions – ranging from the side effects of over-the-counter supplements to genetic, metabolic, neurologic, immunologic, and malignant disorders. Even after the diagnosis of a primary psychiatric disorder is made, the physician must keep an open mind about the presence of an underlying physical illness. A slowly progressive occult illness may initially manifest with a mental health problem and remain hidden for some time despite negative initial evaluations for organic disease. The old adage that even people who somaticize develop a "serious" physical illness eventually must also be kept in mind.

Dress, mannerisms, affect, and hygiene may all provide clues to the patients' illness, background, or the image that they want to project to the examiner. Subtle abnormalities in cognition or mental status might point to the diagnosis of a neurological condition such as frontotemporal dementia or psychosis. Many chronic illnesses, such as Parkinson's chronic lung disease and patients with cardiovascular or cerebrovascular disease are associated with very high rates of mental health diagnoses, particularly depression. The clinician should maintain a high index of

suspicion for comorbidity in these patients. The association of neuroleptic medications with development of the metabolic syndrome may lead to obesity, hypertension, and acanthosis nigricans. Other stigmata such as tardive dyskinesia, jaundice, gingival hypertrophy, petichiae, or pallor due to the adverse effects of medications may be apparent on physical examination.

Laboratory and Imaging

It is always correct to acknowledge that any investigations should be guided by the results of the history and physical exam. When making a diagnosis of a psychiatric condition in a patient with an unrevealing history and physical examination, this author will often obtain baseline laboratory testing to include a complete blood count, comprehensive metabolic panel, and thyroid stimulating hormone, in order to screen for occult conditions which may be difficult to detect with less invasive measures.

Many patients with serious mental illness may have a long history of chronic medical conditions, abuse and social adversity; the physician should be alert for associated illnesses such as sexually transmitted or blood borne infections, and chronic infections such as tuberculosis. Additionally, routine health maintenance measures, such as lipid measurements and mammograms, while sometimes requiring additional diligence to ensure that these are adhered to by the patient, should not be neglected. In addition, patients taking certain medications chronically for psychiatric problems may require periodic laboratory testing to detect toxicity, and the family physician should be familiar with routine testing recommendations for these medications.

Differential Diagnosis

As mentioned above, the differential diagnosis of psychiatric conditions is vast; psychiatric symptoms may be a manifestation of virtually every category of illness including malignancies, rheumatological conditions, toxic ingestions, infections, injuries, and endocrinopathies.

Particularly common issues in primary care that should be specifically considered include occult substance abuse, sleep apnea, and social difficulties such as abuse or family stress. The family physician must maintain a reasonable level of suspicion for an underlying physical or social condition, while maintaining equanimity in the face of some level of uncertainty.

Treatment

In the past few years, the development of various evidence based clinical guidelines for the treatment of mental health issues have both provided guidance to primary care physicians and have also tended to constrain their roles to the making of diagnoses, providing prescriptions for medication, and referral to specialty services. Often, little acknowledgement is given to evidence indicating that individual patient characteristics may be more important than protocol driven factors in the delivery of this care [27].

Increasingly, treatment strategies focusing on long-term recovery from mental illness, with less emphasis on pathology, deficits, and medication in the treatment of these conditions are gaining ground. It is recognized that the recovery from mental illness is a highly personal and subjective experience, and that clinician centered outcomes, such as an enumeration of symptoms might be less important in defining outcomes. The longitudinal relationship that physician and patient enjoy can be used to develop a meaningful narrative of the illness, out of which many possible and sometimes unexpected solutions can arise. In this paradigm of treatment, professional knowledge and resources that can include medications, social support, meaningful work, and relationships can be used as tools to facilitate the process of recovery and achieve the ultimate goal of the attainment of a life that has value and meaning to the patient.

Medications\Immunizations and Chemoprophylaxis

Many patients with mental illness will require ongoing treatment with psychotropic medications in order to maximize their social and occupational functioning. These medications, while central to treatment, can result in side effects, which may range from trivial to life threatening. Side effects are a major cause of discontinuation of medications, and nonadherence is common [28]. Particularly among patients who are on multiple medications at high doses, the family physician must maintain vigilance for drug interactions and other adverse reactions to medications. The cost and availability of various medications may be another significant barrier to medication adherence. Community health workers or agencies may help to ensure that barriers are minimized so that interventions are not compromised.

Attention to immunization status is important, particularly among patients who are institutionalized, chronically malnourished (such as those who misuse substances) or are frankly immune compromised.

Referrals

The standard model for the treatment of difficult mental health problems in the primary care setting has been to refer the patient to a psychologist, counselor, or psychiatrist, in much the same way that any other specialty referral is made. There are several disadvantages to this approach. Chief among them is the fact that in the primary care, patients often do not follow up with these appointments [29]. Another disadvantage is frequent suboptimal coordination and communication between providers. Discontinuities in treatments, opinions, or approaches can easily become a new source of anxiety and difficulty for the patient who may suffer from several mental and physical problems that require ongoing services for both sets of conditions. In an attempt to remediate some of these issues, the "collaborative care" model of mental health care has been piloted in a number of settings. In this model, behavioral practitioners, who may be nurse specialists, counselors, social workers, psychologists, or psychiatrists work in a team with the physician. When a determination is made that additional and focused mental health attention is required, the physician may make a direct "warm" handoff of the patient to another mental health provider, thereby "breaking the ice" and giving the patient assurance that the carers are communicating and that the physician has confidence in the team. Close communication among members of the group, sometimes in the presence of the patient, ensures that the approach to care is as cohesive and seamless as possible. While this approach has been demonstrated to be effective for patients with depression, anxiety, and perhaps bipolar disorders in the outpatient setting, there is no evidence that it is effective in patients with schizophrenia [30, 31]. In addition, issues around the optimal implementation of these models and their cost-effectiveness are still unclear [32].

Community Mental Health Agencies

With the movement away from hospitalization and institutionalization occurring worldwide, there is an increasing need for patients to be cared for in the community. The services these agencies, organizations, or teams provide can differ, but can include domiciliary and supervised care, halfway houses, day care facilities, support groups for patients and caregivers, and sheltered work. The advantages of community agencies include focused attention to the social and economic reintegration of individuals with psychiatric disorders into the community. A recent review suggested that there are improvements in social functioning, quality of life, and psychiatric symptoms among patients with severe mental illness who were deinstitutionalized, although these changes were modest [33].

Counseling

The delivery of counseling for mental health issues by family physicians is a time-tested strategy in primary care, providing good short-term

outcomes, although long-term efficacy is less clear [34]. Advantages of the delivery of counseling by the physician in the office setting include the ability to deliver interventions in a timely and strategic manner, and without necessarily having to make a potentially stigmatizing diagnosis. In recent years, a number of approaches and brief interventions have been developed that can be successfully implemented by the family physician in a time-limited encounter. These include motivational counseling, journaling, and solution-focused therapy.

Although the presence of dedicated mental health providers in the clinical setting may be very helpful in the provision of counseling to patients with mental health issues, mental health counseling that is explicitly labeled as such may be associated with stigma among patients [35]; one study showed a discrepancy among the numbers of patients who reported their willingness to receive counseling from a dedicated mental health provider versus those who actually sought and received counseling at a 1 year follow up [36]. Another reported a significant discrepancy between provider and patient as to whether mental health counseling had been delivered [37]. Counseling for mental health issues was also significantly less likely to be delivered to African American patients in the primary care setting, although other types of counseling were delivered at equal rates in different ethnic groups [38]. Although these findings, taken together may be indicative of various barriers to the delivery of mental health counseling in primary care, it could also be a manifestation of the effects of implicit negotiations between patient and physician regarding patient acceptance of various interventions.

Patient Education and Activation

Psychoeducation is a critical part of management of psychiatric disorders, and in many cases, is the only intervention required for many of the mental health conditions encountered in primary care. Education, normalization, and reassurance by the physician allows for patient and family self-regulation.

Prevention

Mental illness, like many physical illnesses have multiple contributing causes which are poorly understood. It is clear that both heredity and environmental factors, most notably adverse childhood experiences influence the development of both physical and mental illness in adulthood [39, 40]. Various interventions to reduce exposure to adverse experiences in childhood, such as parent training programs, have been demonstrated to result in improved mental health outcomes in children. The impact of social determinants of health on the development of mental illness is increasingly recognized [41]. These factors include poverty, suboptimal housing, and poor education.

Family and Community Issues

The importance of the role of family and community in the perceptions and treatment of patients with mental health problems cannot be understated. Culture fundamentally influences the ways in which mental health problems are perceived, as well as framing the relative risks and benefits of diagnosis and treatment.

The involvement of family and other sources of informal support are often very important to recovery, should be specifically explored by the physician with the patient. These sources of support should be engaged as early as possible in the treatment process.

Anxiety Disorders

Phyllis MacGilvray[a]*, Raquel Williams[b] and Anthony Dambro[c]

Anxiety disorders are characterized by an excessive fear response; these disorders are extremely prevalent among the general population and have a 2:1 female predilection [1]. Functional impairment is common with these disorders and, along with depression, is among the leading causes of disability and work-related absences. As such, it is postulated that the economic burden of anxiety disorders is greater than any other psychiatric disorder, due to the high prevalence and cost of medical and psychiatric treatment [2]. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), defines fear as "the emotional response to real or perceived imminent threat" and anxiety as "anticipation of future threat." Fear typically induces surges of autonomic arousal and thoughts of immediate danger and escape, whereas anxiety typically manifests as muscular tension and avoidant behaviors. The anxiety disorders listed in the DSM-5 tend to be highly comorbid with other psychiatric conditions [1]. The DSM-5 chapter on Anxiety Disorders no longer includes obsessive-compulsive disorders, post-traumatic stress disorder, or acute stress disorder, which had been included in this section in the DSM-IV/DSM-IV-TR. Due to their relevance, these associated disorders will be discussed briefly in this chapter. Relevant changes to anxiety disorders in the DSM-5 are outlined in Table 1. Of note, the DSM-5 requires a minimum of 6-month duration of symptoms that are not attributable to another medical condition and mental disorder or induced by a substance or medication to meet diagnostic criteria for anxiety disorders. An exception is noted in symptom duration for children with separation anxiety disorder and selective mutism, with a required duration of 4 weeks and 1 month, respectively. Panic disorder and agoraphobia have been unlinked in the DSM-5, and panic attacks can now be listed as a specifier, applicable to all DSM-5 disorders [1]. Many anxiety disorders develop in early childhood and typically persist into adulthood if not adequately treated. These disorders differ from developmentally normative fear or anxiety in magnitude of reaction and/or persistence beyond developmentally appropriate periods. A thorough grasp of a proper differential diagnosis and treatment of anxiety disorders can be daunting; however, it may be easier to conceptualize various anxiety disorders from the perspective of the developmental spectrum, using age of onset to help guide a differential [1, 3, 25].

Separation Anxiety Disorder

Separation anxiety disorder is categorized by excessive and developmentally inappropriate fear or anxiety triggered by separation from home or attachment figures. There is persistent fear or anxiety of potential harm toward the attachment figure and/or worry about events that could lead to loss of or separation from attachment figures. Persistent reluctance to separate from home may lead to poor academic performance or inability to perform tasks of daily living. Repeated nightmares about separation and physical complaints of headache, nausea, or abdominal pain are common when impending separation is anticipated.

Table 1 Summary of DSM-V Anxiety Differential by age of onset

Disorder	Age at onset	DSM-5 changes
Separation anxiety disorder	Preschool–adolescence	Newly classified DSM-5
Selective mutism	Less than 5 years	Newly classified DSM-5
Reactive attachment disorder	9 months–5 years	Reclassified under Trauma- and Stressor-Related Disorders
Disinhibited social engagement disorder	2 years–adolescence	Reclassified under Trauma- and Stressor-Related Disorders
Specific phobia	Early childhood < age 10 years	Anxiety no longer is seen as "unreasonable"; now "out of proportion to danger or threat"
Social anxiety disorder (social phobia)	Adolescence	"Generalized" specifier deleted and replaced with "performance only" specifier
Panic disorder	Early adulthood	Panic disorder and agoraphobia unlinked in DSM-5
Agoraphobia	Early adulthood	Panic disorder and agoraphobia unlinked in DSM-5
Generalized anxiety disorder	Early adulthood	No change
Substance-/medication-induced anxiety disorder	Variable	Diagnoses merged in DSM-5
Anxiety disorder due to another medical cause	Variable	No change
Other specified anxiety disorders	Variable	Merged from "NOS" DSM-IV-TR
Unspecified anxiety disorder	Variable	Merged from "NOS" DSM-IV-TR
Obsessive-compulsive and related disorders	Late adolescence–early adulthood	New classification; includes new disorders
Post-traumatic stress disorder	Early childhood–adulthood	Reclassified under Trauma- and Stressor-Related Disorders
Acute stress disorder	Early childhood–adulthood	Reclassified under Trauma- and Stressor-Related Disorders
Adjustment disorders	Early childhood–adulthood	Reclassified under Trauma- and Stressor-Related Disorders

The onset of separation anxiety disorder can start as early as preschool, but is more commonly diagnosed during childhood and less commonly in adolescence. The disturbance must last for at least 4 weeks in children and 6 months in late adolescence. Individuals may exhibit sadness, social withdrawal, and a constant demand for attention. Independent activities also may be affected (i.e., school avoidance, fear of sleeping alone, leaving for college) and should be explored. Other social stressors to consider include school bullying, bereavement, or exposure to a recent traumatic event. This disorder is often comorbid with generalized anxiety disorder, specific phobia, PTSD, social anxiety disorder, agoraphobia, OCD, and personality disorders [1].

Selective Mutism

Selective mutism usually presents before the age of 5 years and is characterized by a consistent failure to initiate speech in specific social situations where there is an expectation for speaking (e.g., school) even though the individual speaks in other situations. Occasionally, a diagnosis of selective mutism may be delayed until a child enters school and more attention is placed on social interactions. The disturbance must be present for at least 1 month, but not the first month of school, and is not due to lack of knowledge of, or comfort with, the spoken language required. Communication disorders and/or intellectual

DOI 10.1007/978-1-4939-0779-3_32-1

disabilities should be considered in the differential diagnosis. Social anxiety disorder is a common comorbidity and should be identified and treated if present [1, 4].

Reactive Attachment Disorder

Reactive attachment disorder is classified under Trauma- and Stressor-Related Disorders in DSM-5 [1]. It typically presents between the ages of 9 months and 5 years and is characterized by noticeably inappropriate or disturbed attachment behaviors. The affected child rarely or minimally turns preferentially to an attachment figure for comfort, support, or nurturance. There is an absence of expected comfort seeking and response to comforting behaviors. A paucity of positive emotions during routine interactions with caregivers is a frequent observation. This disorder is commonly comorbid with social neglect and developmental delay [1].

Disinhibited Social Engagement Disorder

Also classified under Trauma- and Stressor-Related Disorders in DSM-5, disinhibited social engagement disorder presents in children between the ages of 2 years and adolescence. This disorder encompasses a pattern of behavior that involves culturally inappropriate or overly familiar behavior with strangers, violates cultural and social boundaries, and is associated with a history of serious social neglect. Comorbid conditions include cognitive delays, language delays, and attention-deficit hyperactivity disorder (ADHD) [1].

Specific Phobias

Specific phobias involve the manifestation of marked fear, anxiety, or avoidance in the context of specific objects or situations. Individuals with specific phobias commonly have fears of more than one situation or object. Specific phobias may develop after a traumatic event; however, the trigger is not always identifiable. There are various types of specific phobias: objects, animals, natural events, and situational. Symptoms usually develop in early childhood, predominantly before age of 10 years, and usually fluctuate in occurrence. Symptoms which persist into adulthood tend to be persistent and are unlikely to remit. Specific phobia, though low in prevalence, remains a commonly experienced disorder in late life [1].

Social Anxiety Disorder (Social Phobia)

Social anxiety disorder (social phobia) is characterized by marked fear, anxiety, or avoidance of social situations where possible scrutiny by others may occur. Examples may include meeting new people, eating in public restaurants, and speaking or performing in public. The specifier of "performance only" was added in the DSM-5 to denote fear that is restricted to speaking or performing in public. The average age of onset for social anxiety in the United States is 13 years. This disorder is associated with an elevated school dropout rate. Lack of employment is a strong predictor for social anxiety disorder. Depression is a common comorbidity in social anxiety disorder, as well as the use of substances to help mitigate social fears [1].

DOI 10.1007/978-1-4939-0779-3_32-1

Panic Disorder

Panic disorder is characterized by recurrent unexpected panic attacks, which may result in behavior changes related to the attacks or persistent concern about subsequent panic attacks. Panic attacks are described as intense surges of fear and discomfort that peak quickly and then dissipate. Symptoms of a panic attack include four or more of the following: palpitations, diaphoresis, trembling, shortness of breath, choking sensation, chest pain, nausea/abdominal discomfort, lightheadedness, heat/cold intolerance, paresthesias, derealization or depersonalization, fear of losing control, and fear of dying. The attacks can be expected, in response to a typical trigger, or be completely unexpected. The median age of onset in the United States is 20–24 years. Panic disorder is frequently comorbid with other anxiety disorders, depression, and bipolar disorder. Panic disorder is associated with high levels of social, occupational, and physical disability. Individuals with panic attacks or a diagnosis of panic disorder in the past 12 months have a higher risk of suicide [1].

Agoraphobia

Agoraphobia is defined as individuals who are fearful and/or anxious about being in open spaces (e.g., public venues), standing in line or in a crowd, using public transportation, or being alone outside the home. The onset of agoraphobia is typically early adulthood. The situational fear encompasses thoughts of inability to escape or of becoming embarrassed. The course is typically persistent and chronic, with only 10 % remission reported. Approximately a third of affected adults are homebound and unable to work. Common comorbidities include other anxiety disorders, depressive disorders, post-traumatic stress disorder (PTSD), and alcohol use disorder [1].

Generalized Anxiety Disorder

Generalized anxiety disorder (GAD) is characterized by excessive and persistent worry that is difficult to control, causes significant distress and/or impairment, and occurs most days for at least 6 months. GAD is twice as common in women as it is in men and is the most common anxiety disorder among the elderly population [5, 6]. The typical age of onset is early adulthood. Symptoms include restlessness, feeling on edge, fatigue, poor concentration, irritability, muscle tension, and insomnia. GAD is typically comorbid with substance abuse, PTSD, and obsessive-compulsive disorder (OCD). Major depressive disorder that is comorbid with GAD portends a more severe and prolonged course of illness and a greater functional impairment [22]. GAD is also common among patients with chronic pain and with unexplained chronic physical illness [1, 3].

Other Anxiety Disorders

This group of disorders includes the following: substance-/medication-induced anxiety disorder, anxiety disorder due to another medical cause, other specified anxiety disorders, and unspecified anxiety disorder. Substance-/medication-induced anxiety disorder presents with symptoms of panic and anxiety that have developed during or immediately following intoxication and/or withdrawal of a substance or medication. Anxiety disorder due to another medical condition is explained by the physiological effect of an underlying medical condition (e.g., hyperthyroidism, arrhythmia, asthma, seizure disorders).

DOI 10.1007/978-1-4939-0779-3_32-1

Other specified anxiety disorders and unspecified anxiety disorders do not fit criteria for one of the aforementioned anxiety disorders [1].

Obsessive-Compulsive and Related Disorders

This group of disorders includes obsessive-compulsive disorder (OCD), body dysmorphic disorder, hoarding disorder, trichotillomania (hair-pulling disorder), excoriation (skin-picking) disorder, substance-/medication-induced OCD, OCD due to another medical condition, and unspecified OCD. Age of onset is typically late adolescence or early adulthood, but can present in late childhood as well. The presence of recurring intrusive and persistent thoughts (obsessions) and repetitive behaviors or mental acts that result (compulsions) are a hallmark of this collection of disorders. The specifics of OCD vary by individual, but there are common themes which include contamination obsessions and cleaning compulsions; symmetry obsessions with repeating, ordering, and counting compulsions; religious, aggressive, or sexual obsessions and related compulsions; and harm obsessions and related compulsions [1, 7].

Body dysmorphic disorder is characterized by a perceived flaw in physical appearance that is minor or absent. Repetitive acts of checking the mirror, excessive grooming, and reassurance-seeking behaviors are common [1].

Hoarding disorder is described as significant difficulty with discarding possessions, irrespective of value, resulting in an intense need to save items. Symptoms include accumulation of items that congest and clutter living spaces to the point that their intended use is compromised [1, 7].

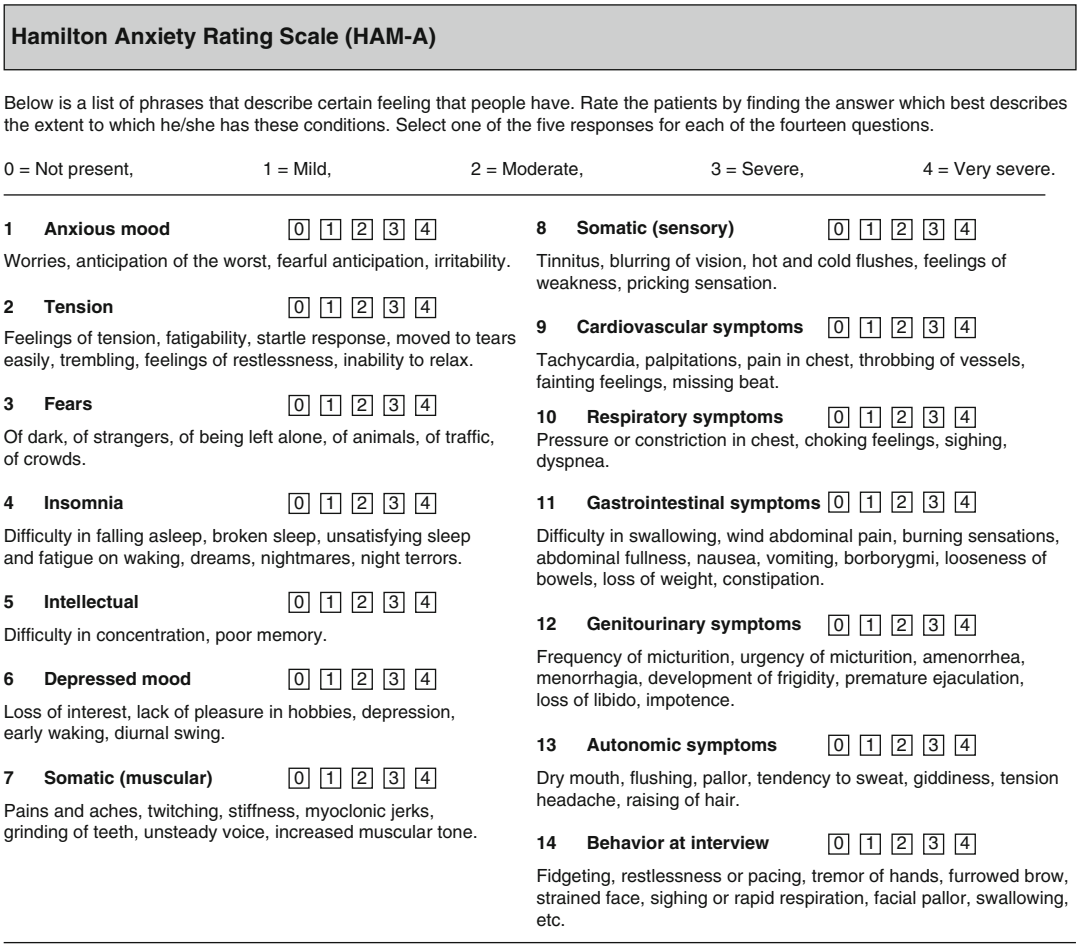
Trichotillomania (hair-pulling) disorder involves recurrent hair pulling with resultant hair loss, despite repeated attempts to stop the behavior. Excoriation (skin-picking) disorder involves recurrent picking of the skin despite repeated attempts to cease. These two disorders are usually preceded by feelings of anxiety or boredom [1, 7, 8].

Substance-/medication-induced OCD involves symptoms related to intoxication or withdrawal of a substance or medication. Symptoms resulting from OCD due to another medical condition are specifically associated with that medical condition. Other specified OCDs and unspecified OCD have atypical presentations and uncertain etiologies which do not meet criteria for diagnoses listed above [9].

Post-traumatic Stress Disorder (PTSD)

PTSD is listed under the category of Trauma- and Stressor-Related Disorders in the DSM-5. The hallmark of PTSD is the development of specific symptoms when exposed to one or more traumatic events involving actual or threatened death, serious injury, or sexual violation. Symptoms of PTSD vary in clinical presentations and may involve dysfunction in five domains: intrusive thoughts, mood changes, dissociative reactions, avoidance, and marked alterations in arousal. The prevalence of PTSD is highest in those with increased risk of traumatic exposure, such as veterans, police, firefighters, emergency medical personnel, and victims of violent crime. Symptoms can begin within 3 months after exposure to a traumatic event; however, symptoms can also present much later before criteria for a full diagnosis of PTSD are met. Acute stress disorder and adjustment disorder are classified similarly but fall short of meeting all requirements for PTSD [1].

DOI 10.1007/978-1-4939-0779-3_32-1



Hamilton Anxiety Rating Scale (HAM-A)

Below is a list of phrases that describe certain feeling that people have. Rate the patients by finding the answer which best describes the extent to which he/she has these conditions. Select one of the five responses for each of the fourteen questions.

0 = Not present, 1 = Mild, 2 = Moderate, 3 = Severe, 4 = Very severe.

1 Anxious mood 0 1 2 3 4
Worries, anticipation of the worst, fearful anticipation, irritability.

2 Tension 0 1 2 3 4
Feelings of tension, fatigability, startle response, moved to tears easily, trembling, feelings of restlessness, inability to relax.

3 Fears 0 1 2 3 4
Of dark, of strangers, of being left alone, of animals, of traffic, of crowds.

4 Insomnia 0 1 2 3 4
Difficulty in falling asleep, broken sleep, unsatisfying sleep and fatigue on waking, dreams, nightmares, night terrors.

5 Intellectual 0 1 2 3 4
Difficulty in concentration, poor memory.

6 Depressed mood 0 1 2 3 4
Loss of interest, lack of pleasure in hobbies, depression, early waking, diurnal swing.

7 Somatic (muscular) 0 1 2 3 4
Pains and aches, twitching, stiffness, myoclonic jerks, grinding of teeth, unsteady voice, increased muscular tone.

8 Somatic (sensory) 0 1 2 3 4
Tinnitus, blurring of vision, hot and cold flushes, feelings of weakness, pricking sensation.

9 Cardiovascular symptoms 0 1 2 3 4
Tachycardia, palpitations, pain in chest, throbbing of vessels, fainting feelings, missing beat.

10 Respiratory symptoms 0 1 2 3 4
Pressure or constriction in chest, choking feelings, sighing, dyspnea.

11 Gastrointestinal symptoms 0 1 2 3 4
Difficulty in swallowing, wind abdominal pain, burning sensations, abdominal fullness, nausea, vomiting, borborygmi, looseness of bowels, loss of weight, constipation.

12 Genitourinary symptoms 0 1 2 3 4
Frequency of micturition, urgency of micturition, amenorrhea, menorrhagia, development of frigidity, premature ejaculation, loss of libido, impotence.

13 Autonomic symptoms 0 1 2 3 4
Dry mouth, flushing, pallor, tendency to sweat, giddiness, tension headache, raising of hair.

14 Behavior at interview 0 1 2 3 4
Fidgeting, restlessness or pacing, tremor of hands, furrowed brow, strained face, sighing or rapid respiration, facial pallor, swallowing, etc.

Fig. 1 Hamilton Anxiety Rating Scale (HAM-A)

Screening Tools for Anxiety Disorders

The Hamilton Anxiety Rating Scale (HAM-A), Fig. 1, was one of the first rating scales to measure severity of anxiety symptoms. It is widely used today in clinical and research settings. The 14 included items measure psychic and somatic anxiety. Each item is scored 0 (not present) to 4 (severe), with a total score range of 0–56. Less than 17 indicates mild severity, 18–24 mild to moderate severity, and 25–30 moderate to severe [10]. It has been criticized, however, for its indiscriminate view of anxiety and depressive symptoms and their lack of congruency with the DSM-IV-TR and DSM-5 [11].

The Generalized Anxiety Disorder 7-item scale (GAD-7), Fig. 2, is an efficient screen that is utilized in primary-care clinics for screening and tracking anxiety disorder treatment and progress. It has been identified as a useful tool with strong validity for identification of probable causes of generalized anxiety disorder [12].

Treatment

The recommended first-line treatment for anxiety and related disorders is listed in Table 2. In general, the greatest therapeutic benefit is derived from a combined model of pharmacotherapy and psychological

DOI 10.1007/978-1-4939-0779-3_32-1

Generalized Anxiety Disorder 7-item (GAD-7) scale

Over the last 2 weeks, how often have you been bothered by the following problems?	Not at all sure	Several days	Over half the days	Nearly every day
1. Feeling nervous, anxious, or on edge	0	1	2	3
2. Not being able to stop or control worrying	0	1	2	3
3. Worrying too much about different things	0	1	2	3
4. Trouble relaxing	0	1	2	3
5. Being so restless that it's hard to sit still	0	1	2	3
6. Becoming easily annoyed or irritable	0	1	2	3
7. Feeling afraid as if something awful might happen	0	1	2	3
Add the score for each column		+	+	+
Total Score *(add your column scores)* =				

If you checked off any problems, how difficult have these made it for you to do your work, take care of things at home, or get along with other people?

Not difficult at all _____
Somewhat difficult _____
Very difficult _____
Extremely difficult _____

Fig. 2 Generalized Anxiety Disorder 7-item (GAD-7) scale

therapy [7, 13]. Achieving true remission is rare in these disorders. Goal-directed therapy should be emphasized and the use of combination therapy optimized to reduce individual morbidity and mortality [13]. Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) treat a broad spectrum of symptoms and have efficacy for common comorbidities, making them excellent first-line options [7, 13]. A few of the antidepressants listed may be more activating than others (i.e., fluoxetine, sertraline, SNRIs) [14, 15]. The recommendation for pharmacotherapy is to start at the lowest dose possible and titrate up or increase slowly to minimize side effects and determine the lowest effective dose [15]. If discontinuation is needed, tapering is recommended to reduce withdrawal side effects.

Over-the-counter herbal remedies may be considered as adjunctive therapy. The most common agents include valerian (*Valeriana officinalis*), kava (*Piper methysticum*), passionflower, St. John's wort (*Hypericum perforatum*), and *Rhodiola rosea*. While efficacy data is lacking, these agents have not demonstrated harm. Due to the concern of potential liver toxicity with the use of kava, a double-blind, randomized, placebo-controlled study showed kava to be well tolerated, with the exception of a small increase in headaches, and moderately effective for GAD [16].

DOI 10.1007/978-1-4939-0779-3_32-1

Table 2 First-line treatment of anxiety and related disorders

Diagnosis	Treatment(s)	Comments
Anxiety disorders		
Separation anxiety disorder	SSRI 1. Fluoxetine (Prozac) up to 40 mg/day[a] 2. Paroxetine (Paxil) up to 50 mg/day[b] Psychotherapy 1. CBT[c]	Currently, no FDA-approved medications for separation anxiety; however a trial of SSRI is considered reasonable
Selective mutism	SSRI 1. Fluoxetine (Prozac) up to 60 mg/day Psychotherapy 1. CBT[c]	
Specific phobias	Psychotherapy 1. Exposure therapy[d]	
Social anxiety disorder	SSRI 1. Fluoxetine (Prozac) 2. Paroxetine (Paxil) 3. Sertraline (Zoloft) SNRI 1. Venlafaxine (Effexor) Psychotherapy 1. Exposure therapy[d]	
Panic disorder	Psychotherapy 1. CBT[c] SSRI 1. Fluoxetine (Prozac) 2. Paroxetine (Paxil) 3. Sertraline (Zoloft) SNRI 1. Venlafaxine (Effexor)	
Agoraphobia	Psychotherapy 1. Exposure therapy[d]	
Generalized anxiety disorder	SSRI 1. Escitalopram (Lexapro) 2. Paroxetine (Paxil) SNRI 1. Duloxetine (Cymbalta) 2. Venlafaxine (Effexor)	
Obsessive-compulsive and related disorders		
Obsessive-compulsive disorder	SSRI 1. Fluoxetine (Prozac) 2. Sertraline (Zoloft) 3. Paroxetine (Paxil) Psychotherapy 1. CBT[c]	Higher doses of SSRI treatment are often needed in some cases
Body dysmorphic disorder	Psychotherapy 1. CBT[c]	
Hoarding disorder	SSRI 1. Paroxetine (Paxil) TCA 1. Clomipramine	No specific pharmacotherapy can be recommended strongly at present; however, a trial of an SSRI is considered reasonable

Table 2 (continued)

Diagnosis	Treatment(s)	Comments
Trichotillomania	SSRI 1. Fluoxetine (Prozac) Antipsychotics 1. Aripiprazole (Abilify) 2. Quetiapine (Seroquel) Supplements 1. N-acetylcysteine (dosing range, 1200–2400 mg/day) Psychotherapy 1. HRT[e]	
Excoriation disorder	SSRI 1. Fluoxetine (Prozac)	
Trauma- and stressor-related disorders		
Post-traumatic stress disorder	SSRI 1. Paroxetine (Paxil) 2. Sertraline (Zoloft) Psychotherapy 1. Exposure therapy[d]	

[a]Ages 7–17 years
[b]Ages 8–17 years
[c]*CBT* cognitive behavioral therapy. Emphasizes the relationship between cognitions (thoughts), somatic experiences (physical complaints), and behavior in anxiety-provoking situations
[d]Exposure therapy. Utilizes repeated exposure to feared stimuli and memories surrounding a traumatic event and aims to help the patient to experience a decrease in fear and an increase in mastery of anxiety symptoms by incorporating mental processing, psychoeducation, and breathing relaxation exercises
[e]*HRT* habit reversal therapy. A CBT approach that consists of awareness training and stimulus control [7, 8, 9, 13, 15, 16, 23, 24, 25, 26]

Complementary and Alternative Methods

Yoga

Modern yoga is defined as "a systematic practice and implementation of mind and body in the living process of human beings to keep harmony within self, within society, and with nature." [17] Yoga is most well known to the Western world for its characteristic poses. Though there are many different ways that yoga may be practiced, common to all traditional schools of yoga are a regimen of poses, breathing techniques, and meditation.

A systematic review of 17 peer-reviewed articles published from 2011 to 2013 concluded that yoga is a promising modality for stress management. Twelve of the 17 articles reviewed were randomized control trials. The number of subjects ranged from 20 to 205. The outcome measures, length of treatment, and type of yoga varied greatly among the studies [17]. This systematic review did not address any particular anxiety disorder diagnosis.

Exercise

Aerobic exercise provides psychological benefits of self-mastery, goal attainment, and socialization. Positive attributes of physical exertion include anxiolytic effects and resistance to both physiological and emotional consequences of psychological stressors. Data-supporting psychological benefits of

DOI 10.1007/978-1-4939-0779-3_32-1

physical exercise have historically been observational. Cross-sectional and longitudinal studies demonstrated the strongest support for use in mild to moderate anxiety disorders. Data were lacking for efficacy in panic disorder [18].

Acupuncture

Acupuncture is one of many practices used in traditional Chinese medicine that has been embraced by Western culture for the treatment of a variety of conditions. In the practice of acupuncture, thin needles are inserted into specific points on the skin to produce their therapeutic effect. In traditional practice, stimulating these points alters the flow of "Qi" or "life energy" which, in turn, alters the function of the entire human organism.

Though many studies have demonstrated the beneficial effect of acupuncture in treatment of anxiety disorders, high-quality evidence is still lacking. Common concerns raised in reviews are location of acupuncture points used, type of acupuncture used, duration of treatments, frequency of treatments, and adequate control groups [19].

Mindfulness

Mindfulness is perhaps one of the most studied interventions for stress and anxiety. Mindfulness, rooted in Buddhist teachings, is described as a cultivation of the practice of moment-to-moment awareness and observation of thoughts and feelings with an attitude of acceptance [20]. This can be practiced in daily situations such as driving a car or washing dishes, while more formal practice is typically termed meditation. Mindfulness practices also share common elements with cognitive behavior therapy (CBT).

In a literature review of 17 articles published from 2009 to 2014, mindfulness-based stress reduction techniques were found to have a positive effect on indicators of stress in otherwise healthy individuals [20]. A recent small study on the self-reported informal practice of mindfulness techniques correlated with lower anxiety severity, worry, and improved quality of life [21].

Summary

Anxiety disorders, obsessive-compulsive and related disorders, and trauma- and stressor-related disorders account for significant morbidity and mortality among mental health patients. Specifically, the anxiety disorders account for the majority of cost burden due to their high prevalence and the increasing cost of appropriate therapies. Timely and accurate diagnoses followed by appropriate treatment are of the utmost importance due to the pervasive nature of these disorders and their effects. Most disorders are best treated with combination therapy: CBT or exposure therapy coupled with first-line pharmacotherapy. Alternative herbal therapies lack significant efficacy data, but are considered safe for use and may be considered. While strong evidence may be lacking for yoga and acupuncture, data seems to indicate a positive effect on the course of anxiety disorders, and they should be considered as adjuncts to treatment for patients who are open to them. Mindfulness techniques appear to have the most robust support from current evidence, which is not surprising given the degree of overlap with the well-established practice of CBT.

Depressive and bipolar disorders are medical conditions which are often first diagnosed and treated in primary care settings [1, 2]. Hence, family physicians are in a frontline position to provide optimal care for patients who suffer from these disorders. This chapter will provide succinct and practical information on the diagnosis and most effective pharmacologic and nonpharmacologic treatments of these disorders in a primary care setting. Newer therapies, such as deep brain stimulation and special populations, will also be discussed.

Epidemiology

Mood disorders, such as major depressive disorder, persistent depressive disorder (PDD; formerly dysthymic disorder), and bipolar disorders are quite common [3]. The lifetime prevalence of having any type of mood disorder is 20 %. In 2012, it was estimated that 10.4 million adults aged 18 or older in the USA had at least one major depressive episode resulting in severe impairment in the past year. This represented 4.5 % of all US adults (see Fig. 1).

In general, mood disorders are more common in women, in those with a family history of psychiatric illness, and in those individuals who have comorbid medical disorders. The majority of patients with mood disorders first present to non-psychiatrists, such as family physicians, often

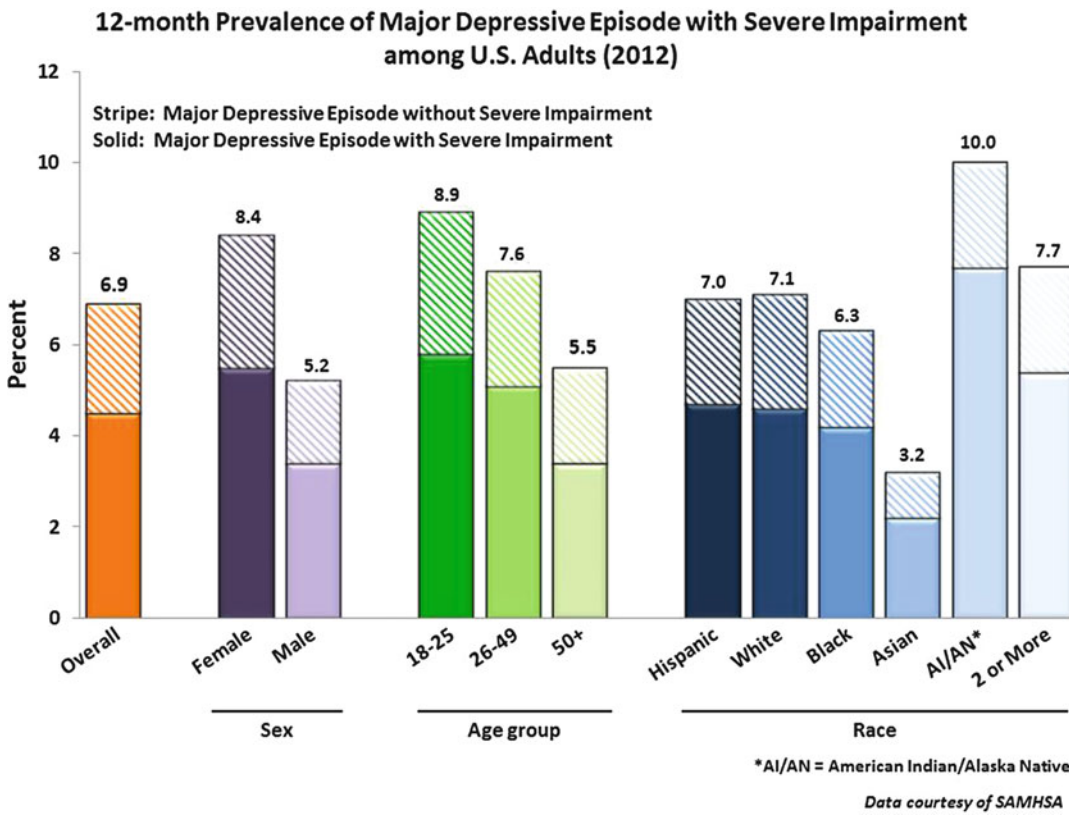

Fig. 1 National Institutes of Health 2012. Results from the 2012 National Survey on Drug Use and Health: http://www.nimh.nih.gov/health/statistics/prevalence/major-depression-with-severe-impairment-among-adults.shtml

complaining of somatic, rather than mood symptoms (e.g., pain, GI upset, headache, etc.).

Risk and Prognostic Factors

While the exact causes of depressive and bipolar disorders remain unclear, risk factors have been identified for the development of depressive disorders and classified into three major categories. These are temperamental, environmental, and genetic/physiological. Within these areas, neuroticism (negative affectivity), adverse childhood events, and a family history of depression are some of the strongest risk factors [4]. First-degree relatives of people with major depression (MD) have an increased risk of MD. The variance in liability to MD is accounted for by additive genetic effects and environmental influences specific to an individual [4].

A family history is also one of the strongest risk factors for bipolar disorders, and there is an average tenfold increased risk among first-degree adult relatives of individuals with bipolar I or bipolar II disorders [5]. Twin studies are generally consistent in observing greater concordance among monozygotic twins than dizygotic twins, which may provide evidence that susceptibility genes contribute to the familiality of bipolar disorder [6].

Bipolar I disorders are also more common in countries with a higher socioeconomic status and among separated, divorced, and widowed individuals than married or single individuals, although the direction of this association remains unclear [4].

Psychological theories propose the idea that individuals with these disorders are more likely to engage in more "depressogenic" cognitive styles and more cognitive distortions in response to stressors than do non-depressed individuals. In addition, newer theories are evolving which examine the role of inflammatory markers resulting from oxidative stress and the negative impact of poor nutrition on the development and maintenance of these disorders, as well as other genetic, physiologic, and environmental precursors of depressive and bipolar disorders.

Diagnostic Criteria

Depressive Disorders

The *Diagnostic and Statistical Manual* of the American Psychiatric Association Fifth Edition (DSM5) now divides mood disorders into two categories: depressive disorders and bipolar and related disorders [4]. A major depressive disorder is diagnosed if the patient has experienced depressed mood or loss of interest and at least four additional symptoms (see Fig. 2) for at least 2 weeks and has never experienced a manic, hypomanic, or mixed episode.

In children and adolescents, the mood may be irritable rather than sad. Once the diagnosis has been made, specifiers which note severity, course, and specific aspects of the depressive episode (including psychotic features, anxious distress, peripartum onset, and others) are also noted. As with all DSM5 disorders, symptoms cannot be due to another psychiatric disorder, physiological effects of a substance, or another medical illness and must cause clinically significant distress or impairment in important areas of functioning.

In *Persistent depressive disorder*, formerly "dysthymic disorder," the essential feature is a depressed mood that occurs for most of the day, for more days than not, for at least 2 years (at least 1 year for children and adolescents). This disorder represents a consolidation of DSM-IV-defined chronic major depressive disorder and dysthymic disorder in the DSM5. Major depression may precede persistent depressive disorder, and major depressive episodes may occur concomitantly during persistent depressive disorder. Individuals whose symptoms meet major depressive disorder criteria for 2 years should also be given a diagnosis of persistent depressive disorder in addition to major depressive disorder; a diagnosis often termed, "double depression."

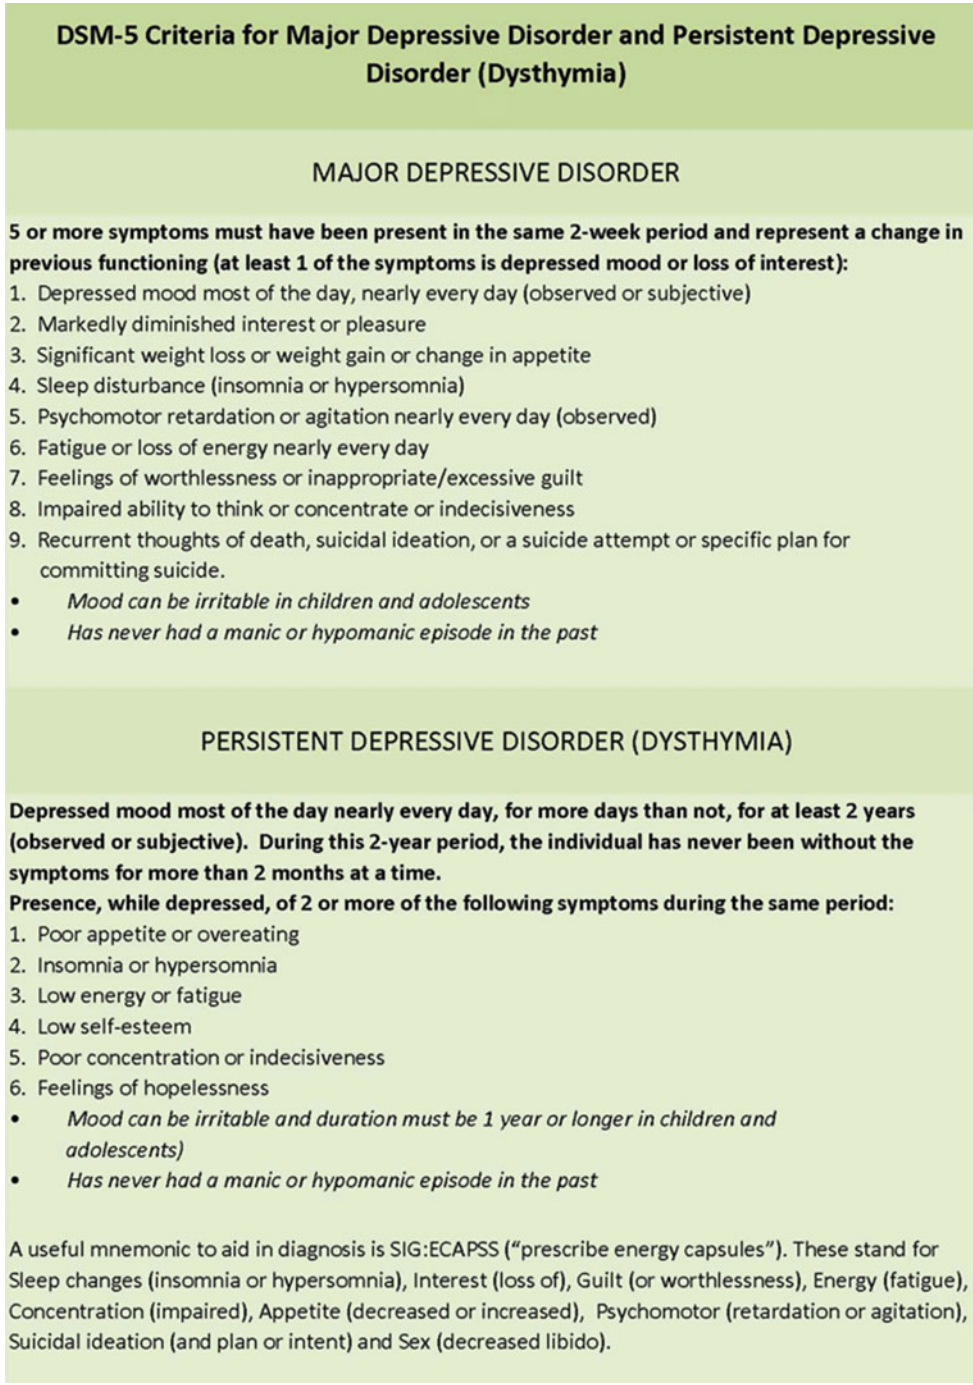
In primary care, a large number of patients present with somatic, rather than mood, symptoms. It is important that the family physician ask patients who present with insomnia and fatigue about accompanying depressive symptoms. In addition, depression is often comorbid with, or can result from, other medical conditions, or due to the side effects of medications. In the DSM5, subthreshold depressive symptoms which meet many but not all the criteria for a depressive disorder can also occur and is now termed "unspecified" rather than "not otherwise specified." Once depression is suspected, it is of critical importance to also assess whether or not the patient has experienced a manic, hypomanic, or mixed episode in the past, as treatment for unipolar and bipolar depression differs significantly.

In addition to taking a detailed history and using SIGECAPSS as a mnemonic, there are short assessment instruments readily available online at no cost. One of these, the Brief Patient Health Questionnaire (PHQ-9) [7], is widely available and has a sensitivity of 88 % and a specificity of 88 % for major depression. PHQ-9 scores of 5, 10, 15, and 20 represented mild, moderate, moderately severe, and severe depression, respectively [7]. This brief assessment has been translated into many different languages and is available here: http://phqscreeners.com/pdfs/02_PHQ-9/English.pdf.

Scoring instructions for the PHQ-9 are available at http://www.phqscreeners.com/instructions/instructions.pdf.

It should be noted that the PHQ-9 is only a screening test for depression. If positive, the clinician should then conduct a careful diagnostic interview, using DSM5 criteria, to make a diagnosis of a depressive disorder.

The most recent (2009) US Preventive Services Task Force (USPSTF) guidelines



DSM-5 Criteria for Major Depressive Disorder and Persistent Depressive Disorder (Dysthymia)

MAJOR DEPRESSIVE DISORDER

5 or more symptoms must have been present in the same 2-week period and represent a change in previous functioning (at least 1 of the symptoms is depressed mood or loss of interest):

1. Depressed mood most of the day, nearly every day (observed or subjective)
2. Markedly diminished interest or pleasure
3. Significant weight loss or weight gain or change in appetite
4. Sleep disturbance (insomnia or hypersomnia)
5. Psychomotor retardation or agitation nearly every day (observed)
6. Fatigue or loss of energy nearly every day
7. Feelings of worthlessness or inappropriate/excessive guilt
8. Impaired ability to think or concentrate or indecisiveness
9. Recurrent thoughts of death, suicidal ideation, or a suicide attempt or specific plan for committing suicide.

- *Mood can be irritable in children and adolescents*
- *Has never had a manic or hypomanic episode in the past*

PERSISTENT DEPRESSIVE DISORDER (DYSTHYMIA)

Depressed mood most of the day nearly every day, for more days than not, for at least 2 years (observed or subjective). During this 2-year period, the individual has never been without the symptoms for more than 2 months at a time.

Presence, while depressed, of 2 or more of the following symptoms during the same period:

1. Poor appetite or overeating
2. Insomnia or hypersomnia
3. Low energy or fatigue
4. Low self-esteem
5. Poor concentration or indecisiveness
6. Feelings of hopelessness

- *Mood can be irritable and duration must be 1 year or longer in children and adolescents)*
- *Has never had a manic or hypomanic episode in the past*

A useful mnemonic to aid in diagnosis is SIG:ECAPSS ("prescribe energy capsules"). These stand for Sleep changes (insomnia or hypersomnia), Interest (loss of), Guilt (or worthlessness), Energy (fatigue), Concentration (impaired), Appetite (decreased or increased), Psychomotor (retardation or agitation), Suicidal ideation (and plan or intent) and Sex (decreased libido).

Fig. 2 DSM5 criteria for major depressive disorder and persistent depressive disorder (dysthymia)

recommend screening children 12–18 and adults for depression when staff-assisted depression care supports are in place to ensure accurate diagnosis, effective treatment, and follow-up. "'Staff-assisted depression care supports' refer to clinical staff that assist the primary care clinician by

providing some direct depression care, such as care support or coordination, case management, or mental health treatment." Per the USPSTF report, "the lowest effective level of staff-assisted depression care supports consisted of a screening nurse who advised resident physicians of positive screening results and provided a protocol that facilitated referral to behavioral treatment." (Please see http://www.uspreventiveservicestaskforce.org/Page/Document/RecommendationStatementFinal/depression-in-adults-screening.)

Bipolar and Related Disorders

Bipolar disorders are often underdiagnosed in primary care. In the DSM5, three distinct types of bipolar disorders are recognized: bipolar I disorder, bipolar II disorder, and cyclothymic disorder. As with the depressive disorders, categories for the diagnosis of substance-induced mood disorders, bipolar, and related disorder due to another medical condition and unspecified bipolar and related disorders are also available in the DSM5.

Bipolar I Disorder

Bipolar I disorder is the most severe form of this illness. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder, even though this manic episode may have been preceded by and may be followed by hypomanic or major depressive episodes. While the overwhelming majority of those with bipolar I disorder also have episodes of major depression, only the presence of a manic episode is needed to make this diagnosis.

DSM5 criteria for a manic episode include:

A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week and present most of the day, nearly every day (any duration if hospitalization is necessary). During this period, three (or more) of the following symptoms (four if the mood is irritable) are present:

1. Inflated self-esteem or grandiosity
2. Decreased need for sleep
3. More talkative than usual or pressure to keep on talking
4. Flight of ideas or racing thoughts
5. Distractibility
6. Increase in goal-directed activity (or psychomotor agitation)
7. Excessive involvement in activities that have a high potential for painful consequences (spending money, sexual indiscretions, substance abuse, etc.)

These symptoms must represent an unequivocal change in functioning and cannot be due to another psychiatric illness, physiological effects of a substance, or another medical condition and must cause significant distress and impairment in functioning.

Note: A useful mnemonic to aid in the diagnosis of a manic episode is DIGFAST (see Fig. 3).

Once the diagnosis of bipolar I disorder has been made, specifiers for the current or most recent episode (manic, hypomanic, depressed, or unspecified), as well as severity (mild, moderate, severe, psychotic, remission), are also recorded. Additional specifiers are then noted if applicable (rapid cycling, anxious distress, mixed features, psychotic features, and others).

Bipolar II Disorder

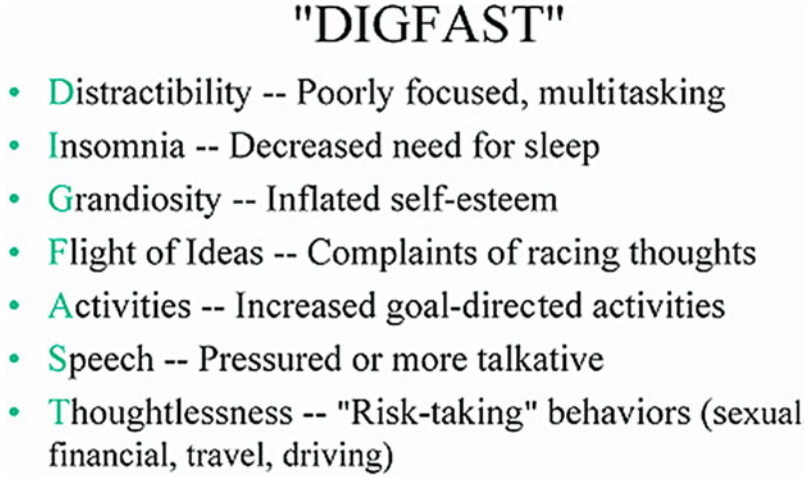
Bipolar II disorder consists of a pattern of recurring mood episodes consisting of one or more major depressive episodes and at least one hypomanic episode:

DSM5 Hypomanic Episode

For a diagnosis of bipolar II disorder, a patient must meet the criteria for a current or past hypomanic episode and a current or past major depressive episode.

A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least four consecutive days and present most of the day, nearly every day. During this period, three (or more) of the following symptoms (four if the mood is irritable) are present:

Fig. 3 DIGFAST



1. Inflated self-esteem or grandiosity
2. Decreased need for sleep
3. More talkative than usual or pressure to keep on talking
4. Flight of ideas or racing thoughts
5. Distractibility
6. Increase in goal-directed activity (or psychomotor agitation)
7. Excessive involvement in activities that have a high potential for painful consequences (spending money, sexual indiscretions, substance abuse, etc.)

These symptoms must represent an unequivocal change in functioning and cannot be due to another psychiatric illness, physiological effects of a substance, or another medical condition and must cause significant distress and impairment in functioning. Please see previous section for criteria for major depressive episode.

In order to make this diagnosis, the major depressive episodes must last at least 2 weeks, with symptoms present more days than not, and the hypomanic episodes must last at least 4 days. As with bipolar I disorder, the patient may not perceive their elevated mood as problematic; however, others (family members, co-workers) may be quite distressed by the individual's unstable behavior. Patients with bipolar II disorder often first present with major depression, which again underscores the importance of asking about a previous history of manic or hypomanic episodes. A mnemonic which can be used to help to differentiate unipolar from bipolar depression is WHIPLASHED (see Fig. 4).

Cyclothymic Disorder

A diagnosis of cyclothymic disorder is given when a patient has numerous episodes of hypomanic and depressive symptoms over the course of at least 2 years (or 1 year in children and adolescents) which do not meet the full criteria for a diagnosis of a bipolar or depressive disorder but cause a significant impairment in functioning. Cyclothymic disorder is a bipolar spectrum disorder which usually begins in adolescence or early adulthood. There is a 15–50 % risk that an individual with this disorder will subsequently develop bipolar I or bipolar II disorder [4]. This diagnosis might be considered for those patients whose clinical symptoms cause concern yet who do not demonstrate a positive screen on assessment measures.

The authors highly recommend using the *The Pocket Guide to the DSM-5 Diagnostic Exam* to aid in diagnosing depressive and bipolar and related disorders in your patients: http://www.appi.org/Book/Subscription/JournalSubscription/id-3310/The_Pocket_Guide_to_the_DSM-5%C2%AE_Diagnostic_Exam

In addition, many other excellent screening tools for these disorders can be found online at no cost at: http://www.integration.samhsa.gov/clinical-practice/screening-tools.

Table 4. WHIPLASHED SCREEN for BIPOLAR DEPRESSION (8)

W	orse or "wired" when taking antidepressants
H	ypomania, hyperthymic temperament,* or mood swings by history
I	rritable, hostile, or showing mixed features during the presenting depression
P	sychomotor retardation appears to be more common in bipolar I depression than in unipolar major depression; however, several studies note that psychomotor agitation is more common in bipolar II than in unipolar major depression
L	oaded family history: Mood swings, bipolar disorder, alcoholism
A	brupt onset and/or termination of depressive bouts, or relatively brief depressive episodes (less than 2 to 3 months)
S	easonal or postpartum pattern of depression
H	yperphagia and hypersomnia
E	arly age at depression onset (younger than 25 years)
D	elusions, hallucinations, or other psychotic features

Note: More than 5 positive, go on to administer other assessment measures and DSM5 criteria to further diagnose bipolar depression

Fig. 4 WHIPLASHED screen for bipolar depression [8]

Suicide

Tragically, depressive and bipolar disorders often lead to suicide, making them potentially fatal illnesses if left untreated. One large analysis of 40 separate postmortem studies found that 45 % of those who died by suicide had seen a primary care provider within the month before their death, and 77 % had such contact within the past year [9]. Older adults who died by suicide were even more likely to have had recent contact with a primary care provider. Hence, it is extremely important to ask depressed and bipolar patients about suicidal intent. It should be noted that asking about suicidal ideation does *not* increase the risk of suicide. The SAD PERSONS screen assesses risk factors for suicide (S = Sex-male, A = age >60, D = depression, P = previous attempt, E = ethanol/other drug abuse, R = rational thinking (loss of), S = suicide in family, O = organized plan/access, N = no support, S = sickness (chronic pain/disease)). The Columbia Suicide Severity Rating Scale is another excellent resource: http://www.integration.samhsa.gov/clinical-practice/Columbia_Suicide_Severity_Rating_Scale.pdf.

Newer approaches for assessing suicide risk are also rapidly emerging, such as a mobile application for Apple and Android devices, "Suicide Safe," from the Substance Abuse and Mental Health Services Administration (SAMHSA) website http://store.samhsa.gov/apps/suicidesafe/ and a blood test which may predict suicidal behaviors by examining certain combined epigenetic and genetic biomarkers [10] among others.

Differential Diagnosis

Detection and treatment of mood symptoms depends on properly identifying the potential etiology underlying the presenting complaint. Nonpsychiatric conditions that can give rise to

mood symptoms include environmental triggers, neurologic disorders, other psychiatric disorders, and medical comorbidity. Potential medical causes are diverse ranging from cardiovascular disorders to nutritional deficiencies. Psychosocial stressors may contribute to the acute onset of mood symptoms with major life changes or bereavement causing adjustment difficulties. Cognitive disorders, such as the neurodegenerative disorders, may present early in their course with noticeable alterations in mood. Excluding organic causes of depression to a reasonable degree of certainty is always the first step in making a diagnosis.

Substance use, personality, anxiety, and the somatoform disorders can all have an impairing mood component as a hallmark of their pathology. Treatment would include addressing the specific concerns in these populations such as assisting with the withdrawal syndrome, detoxification, and maintenance of abstinence in the patient with a substance use disorder.

Bereavement may present with symptoms consistent with depression. The DSM5 removed the bereavement exclusion from its criteria, as many individuals may develop depression after a loss. Studies suggest that if treated promptly, symptom presence would be shorter. For this reason, if symptoms of a full, major depressive episode are present following bereavement, clinical judgment should be exercised to determine if the patient requires treatment. A preponderance of data support treating those meeting criteria for a major depressive disorder during the period of 2–12 weeks following bereavement [11].

Treatment Principles

The primary goal for the treatment of depression in the primary care settings is complete remission of depressive symptoms. The primary care clinician must allow an adequate trial of each medication before determining if the patient has failed that particular medication. An adequate trial includes sufficient length of time for the medications to demonstrate a response, which can be as early as 1–2 weeks in eventual responders to greater than 4 weeks in some individuals [12]. Obtaining measurements of response with the use of screening instruments to monitor response and progression toward remission may be beneficial in enhancing the quality of care and clinical outcome for patients. The PHQ-9, mentioned earlier in this chapter, and the Hamilton Rating Scale for Depression (HAM-D) are examples of a self-rated and a clinician-rated scale, respectively.

The primary care physician will be able to provide successful care to a bipolar patient depending on various elements such as illness severity, comorbidities, personal experience, ancillary support from the institution where the physician is practicing, and complexity of the case. Primary care physicians need to decide which level of care will be required; for example, would acute or long-term treatment be provided by them, or would a psychiatrist need to be involved through a referral or collaborative care?

For most patients, acute and maintenance treatment will require pharmacological management. The objective of providing acute treatment is to reduce symptoms with adequate safety, making sure the medication is well tolerated. Monotherapy is commonly the first line of treatment, but many times, combination therapy will be required to manage the symptoms of bipolar disorder.

Treatment

Biologic Therapies

Depressive Disorders

Many pharmacologic agents are used to treat depressive symptoms including selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs). The clinician must make several decisions before recommending a specific antidepressant. Which medication will target the depressive symptoms with fewest side effects will need to be determined. Access to the medications (insurance formularies), their cost, and the ease of

dosing will play an important part in the implementation of a treatment protocol.

Selective Serotonin Reuptake Inhibitors

The SSRIs (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline, and vortioxetine) are first-line agents in the treatment of major depressive disorder. Well-tolerated by many, these medications are widely prescribed for many psychiatric disorders. Physicians who have experienced using these medications will anticipate and use potential side effects to their advantage such as using a sedating medication with a patient with complaints of insomnia [12]. See Table 1 for further useful information on this topic.

The interactions of SSRIs with other medications will be important for the treating clinician to monitor on a continual basis. Constant surveillance is important for patient safety, as well as education about the signs/symptoms of toxicity secondary to their use of an antidepressant [13].

Serotonin-Norepinephrine Reuptake Inhibitors

The SNRI medications (desvenlafaxine, duloxetine, levomilnacipran, and venlafaxine) are used to treat depressive symptoms in refractory cases, as part of an augmentation strategy with an SSRI. They are also used as monotherapy if patients have a partial or non-response to an SSRI. Many clinicians believe that the SNRIs can be helpful in patients with comorbid anxiety and pain syndromes.

Tricyclic Antidepressants and Monoamine Oxidase Inhibitors

The TCAs (amitriptyline, desipramine, doxepin, imipramine, nortriptyline, and protriptyline) and MAOIs (isocarboxazid, phenelzine, selegiline, tranylcypromine) are still widely used because of the wealth of data on their use, low cost, and effectiveness. Their higher incidence of side effects when compared to newer agents and their higher lethality in overdose has relegated these agents to a second-line use in most treatment plans when first-line medications have failed [14].

Other Antidepressants

Antidepressants with different mechanisms of action from the SSRIs/SNRIs (bupropion, mirtazapine, trazodone, and vilazodone) are also widely prescribed. Bupropion is often used to augment other antidepressants or as monotherapy to offset sexual side effects that may be experienced during treatment for depression. Mirtazapine is often prescribed as an adjunct, or monotherapy, for patients with insomnia and /or anorexia. Trazodone is another agent that is widely used for insomnia, even more so than for its antidepressive qualities [14]. Recently the role of ketamine infusion has been explored in psychiatric clinical settings for severe depression with a rapid improvement in symptoms [15]. A list of medications currently approved for treating major depressive disorder is below (Table 2):

Augmentation

Partial response to pharmacotherapy is common in many patients. When a patient has an initial response to an antidepressant medication, with the dosage and treatment length being optimized, a plateauing effect may take place with stagnation in further improvement. Instead of switching to another medication in the same class, the physician may consider augmentation strategy. Augmentation of antidepressants, with other agents, has demonstrated efficacy in several circumstances, including being added to a regimen when a patient has partial response to treatment, the patient is unable to tolerate higher doses of the base antidepressant, or if switching to a different medication is not practical. Several medications are used in augmentation strategies for the treatment of depressive symptoms including mood stabilizers (i.e., lithium), atypical antipsychotics (i.e., aripiprazole), tri-iodothronine, stimulants (i.e., modafinil), and hormone replacement (i.e., testosterone in men) [16].

Alternative/Complementary Options

Knowing about the use of alternative treatments by patients is of paramount importance to the treating physician. Understanding the potential interactions with other recommended therapies may guide the treatment plan. Data for the efficacy

Table 1 Indications for Selected Antidepressants

Antidepressant	Anxiety	Panic disorder	Sleep disorder	OCD	Pain	Fibromyalgia	Fatigued	Extra
SSRI								
Citalopram (Celexa)	+			+				Off label: GAD, binge eating, alcoholism, hot flashes, PMDD
Escitalopram (Lexapro)	+			+				
Fluoxetine (Prozac)		+		+		+	+	PMDD, bulimia, off label: hot flashes, Raynaud's migraine ***assoc, w/weight loss
Paroxetine (Paxil)	+	+		+				Social phobia, stuttering, PMDD ***causes most sex dysfunction, orthostatic hypotension, and weight gain from SSRIs
Sertraline (Zoloft)	+	+		+				PMDD, off label: pruritis ***most GI upset from SSRIs
Fluvoxamine		+		+				PTSD, social phobia
SNRI								***can all cause insomnia/agitation and sexual dysfunction
Venlafaxine (Effexor)	+	+					+	
Desvenlafaxine (Pristiq)								Venlafaxine works the same and is cheaper
Duloxetine (Cymbalta)	+				+	+		
Atypicals								
Bupropion (Wellbutrin)								Appetite suppressant, smoking cessation, few sexual side effects, seasonal affective disorder, ADHD (off label)
Trazodone (Oleptro)			+					Off label: aggressive behavior, etoh withdrawal, prevention of migraine

Mirtazapine (Remron)			+					Off label: PTSD, hot flashes ***associated with weight increase
TCAs								**beware of long QT, EPS, agranulocytosis ***sex dyfxn -contraindicated in older patients, hypotensive patients, or heart-diseased patients
Amitriptyline					+			Off label: postherpetic neuralgia, migraine prophylaxis, eating disorder **assoc w/wt gain, anticholinergic SE
Clomipramine				+				Off label: premature ejaculation **assoc w/wt gain, anticholinergic side effects
Doxepin	+	+						**assoc w/wt gain
Imipramine				*				Pediatric-nocturnal enuresis **assoc w/wt gain
Trimipramine								**assoc w/wt gain
Desipramine							+	Off label: postherpetic neuralgia, vulvodynia, eating disorder **assoc w/weight loss
Nortriptyline								Off label: chronic urticarial, angioedema, pruritis, smoking cessation, ADHD, postherpetic neuralgia

Warning:
· Paxil – do not take in first trimester of pregnancy; associated with birth defects
· Prozac – neonatal persistent pulmonary htn >20 weeks gestation, neonatal serotonin syndrome 3rd trimester, growth suppression in pediatric patients
TCAs – order EKG first to look for long QT
2014 Lillian Sarfati, MD. In Allespach H, Sarfati L, "DSMS: Depressive, Bipolar & Related Disorders (What You Need to Know Now)." 2014 AAFP Scientific Assembly Washington, DC.

Table 2 FDA-approved medications for major depressive disorders [16]

Medication	Dose range	Half-life	Considerations
Amitriptyline (TCA)	10–300 mg	10–28 h	Substrate for CYP450 2D6, 1A2
Bupropion (other)	75–450 mg, depends on formulation	4–10 h parent; active metabolite 20–27 h	Multiple formulations: immediate release (IR), sustained release (SR), extended release (XL). Inhibits CYP450 2D6
Citalopram (SSRI)	10–40 mg, 10–20 mg if >60yo	23–45 h	Weak inhibitor of CYP450 2D6
Desipramine (TCA)	10–300 mg	24 h	Substrate for CYP450 2D6, 1A2
Desvenlafaxine (SNRI)	50–400 mg	9–13 h	Minimally metabolized by CYP450 3A4
Doxepin (TCA)	1–6 mg	8–24 h	Substrate for CYP450 2D6
Duloxetine (SNRI)	20–60 mg	12 h	Substrate for CYP450 2D6, 1A2
Escitalopram (SSRI)	5–20 mg	27–32 h	No significant CYP450 interactions
Fluoxetine (SSRI)	10–80 mg	2–3 days for parent drug, active metabolite 2 weeks	Inhibits CYP450 2D6, 3A4
Imipramine (TCA)	10–300 mg		Substrate for CYP450 2D6, 1A2
Isocarboxazid (MAOI)	10–40 mg	Up to 21 days	Significant interactions with other drugs that block serotonin reuptake
Levomilnacipran (SNRI)	20–120 mg	12 h	Substrate for CYP450 3A4
Mirtazapine (other)	7.5–45 mg	20–40 h	No significant CYP450 interactions
Nortriptyline (TCA)	10–150 mg	36 h	Substrate for CYP450 2D6
Paroxetine (SSRI)	10–60 mg	24 h	Inhibits CYP450 2D6
Phenelzine (MAOI)	15–90 mg	Up to 21 days	Significant interactions with other drugs that block serotonin reuptake
Protriptyline (TCA)	10–60 mg	74 h	Substrate for CYP450 2D6
Selegiline (MAOI)	6–12 mg/24 h	18–25 h	Transdermal patch used for depression
Sertraline (SSRI)	25–200 mg	22–36 h parent drug; 62–104 h for metabolite	Inhibits CYP450 2D6, 3A4
Tranylcypromine (MAOI)	10–40 mg	Clinical action up to 21 days	Significant interactions with other drugs that block serotonin reuptake
Trazodone (other)	50–600 mg	Biphasic half-life: 1st phase 3–6 h, 2nd phase 5–9 h	Substrate for CYP450 3A4
Venlafaxine (SSRI)	(IR) 37.5–375 mg; (XR) 37.5–225 mg	3–7 h parent drug; 9–13 h for metabolite	Immediate release, extended release formulations
Vilazodone (other)	10–40 mg	25 h	Substrate for CYP450 3A4
Vortioxetine (SSRI)	5–20 mg	66 h	Substrate for CYP450 2D6

Table 3 FDA-approved treatments for bipolar disorder [18, 19]

Acute mania	Acute bipolar depression	Bipolar maintenance
Lithium	Olanzapine/fluoxetine	Lithium
Chlorpromazine	Quetiapine, XR	Lamotrigine
Valproic acid, ER	Lurasidone[a]	Olanzapine
Olanzapine[a]		Aripiprazole[a]
Risperidone[a]		Quetiapine, XR (adjunct)
Quetiapine, XR[a]		Risperidone long-acting injection[a]
Ziprasidone		Ziprasidone (adjunct)
Aripiprazole[a]		
Carbamazepine, ECR		
Asenapine[a]		

[a]Adjunctive and monotherapy. ER, ERC, XR: extended release formulations

of substances such as St. John's wort, high-dose folate, omega-3 fatty acids, and S-adenosyl methionine (SAMe) are limited. Therefore, they cannot be recommended as first-line options [17]. Therapeutic massage, physical exercise, meditation, and acupuncture/acupressure are also widely used with good effect but limited evidence [17].

Bipolar and Related Disorders

Management of bipolar disorder varies according to the current presentation of the patient, and it should be tailored to either acute or maintenance treatment. Both phases of the illness may entail depressive or manic symptoms, and this will determine the appropriate intervention to choose (please refer to list below) (Table 3):

Acute Treatment

Mania. The goal of treatment of a manic episode is to achieve rapid relief of symptoms resulting in full remission in a safe setting. Most often, hospitalization during a manic episode is required in order to maximize patient safety. Pharmacologic therapy is the cornerstone of treatment for a manic episode, and monotherapy can be implemented using mood stabilizers or antipsychotic agents. The FDA-approved mood stabilizers include lithium, valproic acid, and carbamazepine. Lithium should be titrated slowly to prevent toxicity and is associated with moderate improvement of symptoms in 40–80 % of patients after 2–3 weeks of treatment [20]. Valproic acid and carbamazepine have similar efficacy in decreasing symptoms as lithium, but have a more rapid onset of action. Over 50 % of patients treated with these two medications experience improvement in their manic symptoms.

Of the first-generation antipsychotics, only chlorpromazine has been FDA approved to treat acute mania. Due to frequent side effects, second-generation antipsychotics are used more often. Of the second-generation antipsychotics, risperidone, quetiapine, ziprasidone, aripiprazole, and asenapine have been approved for use as monotherapy in acute mania. All of them, except for ziprasidone, have also been approved for use as adjunctive treatments to mood stabilizers. Attention should be directed to the development of akathisia, somnolence, weight gain, and other extrapyramidal symptoms such as tardive dyskinesia when using these agents.

Depression. Only three agents have been approved for the treatment of bipolar depression. These include olanzapine + fluoxetine combination, quetiapine and quetiapine XR, and lurasidone. Of these, only quetiapine is approved to treat acute depression in patients suffering from bipolar II [21] and is the only medication approved as monotherapy to treat manic episodes.

Although the use of antidepressant medications may seem the appropriate choice for treating depression in patients with bipolar disorder, there is scarce evidence for their use in the literature, with randomized controlled trials showing that antidepressants are not better than placebo in this

situation [22], and they may precipitate mania or hypomania if used as monotherapy.

Mixed States. When patients meet criteria for mixed features, valproic acid is a good choice for treatment. Lithium has not shown benefit with this presentation or during rapid cycling and should be avoided.

Maintenance Treatment

Depression

In terms of unipolar depression, a general rule of thumb is that once a patient has been asymptomatic for 6 months to a year, continue to treat for 12 months for those who have had one episode of major depression, 2–3 years for those patients with two episodes of major depression, and consider lifetime maintenance treatment with antidepressants for individuals who have experienced 3 or more major depressive episodes in their lives.

Bipolar Disorder

For bipolar disorders, after an acute episode has been controlled, maintenance treatment should be implemented to prevent recurrence of symptoms, and the current recommendation is to continue lifelong treatment. Only two mood stabilizers are approved as monotherapy for maintenance in bipolar disorder: lithium and lamotrigine. Lamotrigine has been shown to prevent recurrence of depressive symptoms, but has been linked to Stevens-Johnson syndrome. Monitoring for the development of a rash is advised. Lithium has proven to decrease the incidence of suicide, but has been linked to many side effects, including renal and thyroid problems and teratogenicity. Lithium blood levels should be monitored carefully, and close attention should be given to medication interactions, as it has a very narrow therapeutic index.

While no medications have been approved to treat cyclothymic disorder, mood stabilizers may be considered on a case-by-case basis.

In addition to mood stabilizers, five second-generation antipsychotics have also received approval for treatment: olanzapine monotherapy, aripiprazole monotherapy and adjunctive treatment, quetiapine adjunctive treatment, risperidone long-acting injectable monotherapy and adjunctive treatment, and ziprasidone as adjunctive treatment. It is important to mention that if the primary care physician does not have experience or does not feel comfortable using any of these medications for the treatment of bipolar disorder, they should defer the care of the patient to a more experienced provider.

Psychological Therapies

In the past 40 years, 400 randomized controlled trials have investigated the beneficial effects of psychotherapies for adult depression. These modalities include cognitive-behavioral and interpersonal therapies and newer approaches, such as acceptance and commitment therapy and cognitive bias modification. It appears all of these therapies are equally effective, and a growing number of studies are focused on scaling up of psychological services, including the training of lay counselors, telephone-based psychotherapies, and internet-based counseling [23]. It should be noted that medication therapy may not be the optimal choice for many patients with depression. Specifically, for patients with mild to moderate symptoms who do not exhibit severe impairments in overall functioning, psychotherapy may be more efficacious than pharmacologic treatment and should be considered as a first-line recommendation.

For individuals with bipolar disorders, psychoeducation focusing on the recognition of early warning signs of relapse appears to be an effective adjunct to medication management. Cognitive-behavioral therapy, family-focused therapy, and interpersonal therapy have also been found to be particularly efficacious when used as adjuncts to pharmacotherapy to improve both symptoms and overall function [21].

Physician-Administered Counseling Strategies

Family physicians are in an excellent position to teach patients selected cognitive-behavioral interventions, such as cognitive restructuring. This can be accomplished by simply teaching patients that their distorted, negative, reactive thoughts create distressful feelings which, in turn, lead to

increased pain and other uncomfortable somatic symptoms and subsequently to unhealthy and maladaptive behaviors. Cognitive restructuring consists of asking the patient, "What can you tell yourself. . .or what would the wise, rational, nonreactive part of you tell you to make you feel less distressed (e.g., angry, sad, anxious, etc.)?" [24]. The patient may be given "homework" to practice changing thoughts to change feelings and then asked about their success or struggles in doing this exercise at each visit. Other counseling techniques which family physicians can successfully implement in an office-based setting with depressed and bipolar patients include brief mindfulness and diaphragmatic breathing exercises [24].

Other Non-pharmacological Interventions

Electroconvulsive therapy (ECT) is a well-documented and effective treatment for major depressive and bipolar disorder. It remains the gold standard of treatment for refractory depressive disorders and should be considered a first-line treatment for major depressive disorder presenting with catatonia, severe suicidality, severe psychosis or agitation, peripartum depression, and situations where a rapid response to treatment is required. For bipolar disorder, benefit has been demonstrated in studies of patients in both manic and depressive states of their illness [25].

Deep brain stimulation (DBS) is a newer intervention designed to reduce depressive symptoms but is limited to specific clinical settings and will benefit from more data on its efficacy [26]. Vagal nerve stimulation (VNS) is usually reserved for treatment-refractory cases, but has no positive RCTs proving its efficacy [13]. Repetitive transcranial magnetic stimulation (rTMS) was approved by the FDA in 2008 to treat major depressive disorder in patients who failed one, but no more than two standard antidepressant trials. rTMS involves creating a powerful electrical current near the scalp delivered by repetitive pulses (microseconds) of an MRI-strength (close to 1.5 Tesla) magnetic field from a coil placed over the scalp. Sessions usually last 20–40 min, 5 days a week, typically for 6 weeks. This procedure is carried out while the patient is awake, resting in a specially equipped chair. More research is needed to test the efficacy and safety of this procedure in patients with bipolar disorder.

Light therapy is effective for the treatment of seasonal affective disorders [17].

Social Treatments

As discussed throughout, depressive and bipolar disorders can have a catastrophic impact on interpersonal, occupational, and physical functioning. However, patients should be made aware that these illnesses can be treated to remission and that their family physician will be there to support them throughout. It is important to involve social work as needed and to inquire about other support networks. By its nature, depression—whether unipolar or bipolar—is an extremely isolating illness, and every attempt should be made to engage patients in available resources, such as local or online support groups, twelve-step programs (e.g., Emotions Anonymous: http://www.emotionsanonymous.org/), and organizations such as the Depression and Bipolar Support Alliance http://www.dbsalliance.org/site/PageServer?pagename=home.

Special Populations

Children and Adolescents

A conservative approach is usually best with individual, group, or family therapy being the first treatment modality, adding in pharmacotherapy for the treatment-resistant or severe cases. It is recommended that when treating children and teens with depression and bipolar disorder, a child psychiatrist should be consulted early on; however, if this is not possible, caution with prescribing in these populations should be observed, as many psychotropic medications are not FDA approved for use in children. Children and

adolescents differ in their pharmacokinetics from adults and require special consideration when diagnosing and treating mood disorders. Children can present with more irritability and somatic complaints than concerns about their depressed mood. Children tend to have a faster elimination rate for medications because of their greater liver/kidney parenchyma to body size, increased body water, and decreased amount of adipose tissue [27]. This faster rate of clearance means that a steady state is reached sooner, but the medications may require more frequent dosing to maintain the steady state. In addition, when prescribing antidepressants for children/teens, parents/caregivers should be given medication guides which discuss the potential warning signs of these medications. These guides are available at: http://www.fda.gov/drugs/drugsafety/informationbydrugclass/ucm096273.htm.

Older Adults

Older individuals may have confounding manifestations of other medical conditions that may resemble depression, including fatigue, decreased energy, decreased appetite, or psychomotor retardation. For this reason, a careful look should be taken to each individual case to discern between those symptoms caused by depression and those caused by a medical problem. A depression screening form especially tailored for older adults is the Geriatric Depression Scale (GDS) which may be more accurate for this population. It is important to note that depression is not a normal part of aging and it should be treated accordingly. Older adults that are diagnosed with depression at a later age for the first time should be treated at least for 2 years before treatment tapering is considered, in order to decrease the risk of recurrence.

It is important, when assessing older adults, to understand that medical and neurological comorbidities may confound recognition of the clinical features of bipolar disorder as well. It has been reported that elderly persons with bipolar disorder suffer from more medical illnesses than those without bipolar disorder [28]. These include cardiovascular disease, hypertension, type II diabetes, and obesity. Treatment considerations include minimizing or avoiding the use of medications that have anticholinergic properties, as these may affect the elderly individual by causing dry mouth, blurry vision, constipation, urinary retention, hypotension, tachycardia, cognitive impairment, and delirium. For depression and bipolar disorder, medications are generally started at half the dose that would be recommended for a younger adult and should be increased more slowly by half the recommended dose.

Pregnant and Lactating Women

The antenatal and postnatal periods are particularly vulnerable times for depression to impact the functioning of the mother. Untreated/undertreated antenatal depression is associated with a plethora of adverse outcomes including premature delivery, low infant birth weight, higher risk for developmental delay in the child, and decreased likelihood of breastfeeding initiation [29]. Postpartum depression is associated with impairment in the mother-infant attachment. Treatment has to weigh risk versus benefit, with detection of depression as early as possible in the pregnancy. The decision of which antidepressant to recommend to the pregnant patient will depend on many factors including previous response to treatment and severity of illness. Like most of the antidepressants, sertraline has a “C” classification for safety in pregnancy and may be continued during breastfeeding. Sertraline and paroxetine are the preferred first-line choices for lactating women secondary to their safety profile when compared to the other antidepressants [30]. Paroxetine has a “D” classification for safety in pregnancy and should be avoided in the first trimester.

The Suicidal Patient

Sonya R. Shipley*, Molly S. Clark and David R. Norris
Department of Family Medicine, University of Mississippi Medical Center, Jackson, MS, USA

General Principles

Definition/Background

Suicide is the intentional ending of one's own life that is oftentimes the end result of another pathologic process such as substance abuse, mood disorders, or psychosis. Suicidality itself may be divided into a continuum of seriousness ranging from thoughts of death to passive and then active suicidal ideations which include a plan to suicide attempts and finally to completed suicide [1]. A related though somewhat separate entity is chronic suicidality often seen in the context of personality disorders [2].

Epidemiology

In 2011, suicide was the 10th leading cause of death in the United States, accounting for the loss of nearly 40,000 lives. In the 15–34 age group, it was second only to unintentional injury as a cause of mortality. Suicide drops out of the top 10 causes of death only in the group of people 65 and older, though the absolute number remains high [3].

Suicide rates vary by age, race, and gender. Teens and those in the fourth decade of life are the most likely to die by suicide. Females are twice as likely to attempt suicide, while males are four times more likely to be successful in an attempt. White Americans attempt suicide at 10 times the rate of African-Americans or Pacific Islanders, while Native Americans have roughly twice the rate of other minority groups [4]. Groups that perceive themselves to be socially isolated, such as homosexuals, are also at increased risk [5].

Approach to the Patient

Assessment of suicide risk is a clinical decision that can only be made after a comprehensive evaluation. In 2014 the United States Preventive Services Task Force reiterated their previous I-statement regarding routine screening for suicide risk in the primary care setting, given insufficient evidence to evaluate benefit versus harm. However, this recommendation is only for screening of asymptomatic persons [6]. Many patients who die by suicide have seen a healthcare provider in the preceding month [7]. Physicians should therefore remain alert for suicidal ideation among their patients, particularly among those with risk factors that are discussed below.

Diagnosis

History

Historical information may be divided into risk factors that increase the likelihood of a suicide attempt, while protective factors decrease the relative risk.

Table 1 Risk factors for suicide [9, 11]

Biological and cultural	
Male gender	Caucasian, Native American, Native Alaskan
Late adolescence, or age >60 years	Family history of suicide
Major illness or chronic disease	
Environmental	
Recent loss of loved one	Access to means (such as firearms)
Exposure to suicide	Unemployment, or other financial stressors
Social stressors including isolation or recent humiliation	
Psychiatric	
Depression esp. with comorbid anxiety disorders	
Bipolar disorder, esp. mixed episodes	Personality disorder
Schizophrenia, esp. with command hallucinations	
Hopelessness, anhedonia	Other psychoses
Substance use disorder	Previous suicide attempt
Social	
Social isolation	Never married, widowed, or divorced

Risk Factors

Risk factors for suicide include biological, environmental, psychiatric, and social factors, though there is considerable overlap between categories. A general list of risk factors may be found in Table 1. Several risk factors deserve particular attention because of their significance. Despite psychiatric treatment, patients who have made a previous suicide attempt are at significantly increased risk for the remainder of their lives. In the year following an attempt, these patients are 100 times more likely to die by suicide than members of the general population [8]. Psychiatric disorders, especially depression with anhedonia and/or anxiety, bipolar disorder with a mixed episode, and personality disorders, also confer a significantly increased risk [9]. Finally, any patient with a known or suspected substance use disorder should receive special attention during episodes of depression, stress, or following stated suicidal ideation [10]. Substances are believed to contribute to suicide risk either by enabling actions the victim may otherwise be unable or too afraid to take or by their effects of impairing judgment, increasing impulsivity, and worsening depressive symptoms.

Protective Factors

There are a variety of protective factors that decrease the likelihood of suicidal behavior. These include access to healthcare, the availability of psychological treatment, a sense of being connected to family and community, being married, and cultural and religious beliefs that oppose suicide. Each of these factors provides a reason for continued living and offers hope that the symptoms of depression will improve.

Laboratory and Imaging

Laboratory and imaging orders may be considered to diagnose or exclude possible medical conditions that could be contributing to the presenting complaint of suicidal ideation. For example, obtaining a urine drug screen and blood ethanol level may be helpful in determining further risk for suicide due to impaired judgment, confirm or refute elements of the differential diagnosis such as substance dependence, and provide guidance on treatment options [12].

DOI 10.1007/978-1-4939-0779-3_34-1

Special Testing

There are no validated clinical decision-making tools to assess suicide risk as the interplay of the various risk and protective factors is complex [13]. Many physicians fear inquiring about suicidal thoughts, even among patients who are known to be at high risk. This is due, at least in part, to a belief that by asking the physician may actually cause the patient to consider suicide; in fact studies have shown the opposite to be true. Patients are not more likely to make a suicide attempt if asked about ideation. In fact, many are actually relieved that their physician has inquired about a topic that they may have been too afraid to broach [14]. Direct inquiry about suicidal thoughts has also been associated with improved identification of those at risk for suicide [15]. Physicians should be alert for patients at risk for suicide and should not hesitate to discuss suicidal thoughts with their patients.

Treatment

Behavioral

When evaluating a patient who is experiencing suicidal ideation, the primary care physician must determine where the patient is on a spectrum of risk for completing suicide. According to the US Preventive Service Task Force recommendation statement, the assessment for risk of suicide is complicated by the fact that individual risk factors alone provide little predictive value about whether or not an individual will complete suicide [6]. Furthermore, there is a paucity of data on what specific components should be included in a risk assessment in order to reliably predict suicide [16]. Therefore, a two-step process to guide physicians in evaluating patients who are at risk for suicide has been developed: the suicide risk assessment and the suicide risk formulation [12].

In a suicide risk assessment, information is gathered from the patient that may include general medical history, history of suicide attempts, any current or previous mental health diagnoses or treatment, family history, current symptoms, observed behaviors, information from family and associates, mental health screening tools, and the medical record. The use of alcohol, illicit substances, prescription medication abuse, and other psychosocial stressors (such as potential loss or recent loss of employment, divorce, recent diagnosis of terminal illness, etc.) should also be assessed. The assessment of suicidal ideation may include inquiries into the specificity of plan, lethality of the plan, and access to means. Additionally, a review of protective factors (i.e., resources available to the patient that tend to be protective against suicide), such as social support, religious beliefs, dependent children, willingness to seek help, etc., is important. This information then can be synthesized for the suicide risk formulation [12, 13]. The more information that is gathered in the suicide risk assessment, the better the physician will be able to estimate the patient's level of risk [13]. While there are no standard assessment questions, some questions physicians can consider within the suicide risk assessment are whether the patient has had recent or current thoughts of self-harm or death, if there is a plan to engage in self-harm, do they have access to method(s), is there intention to follow through with the plan, if there have past attempts, if there is a family mental health history, and what has kept them from engaging in self-harm [17, 18].

There is no particular guideline to help physicians prepare the suicide risk formulation, but rather the physician considers the additive interaction of all of the risk factors for a particular patient. Regarding risk level, the physician can consider whether a patient is at acute or chronic risk. Within the acute and chronic categories, the physician must then determine whether the risk is low, intermediate, or high [2] (see Table 2).

Following placement into a risk category, the physician can develop an appropriate treatment plan. For patients at high risk, treatment may be inpatient hospitalization for stabilization. Clinicians should have a plan in place for notification of emergency transport in an efficient manner, thereby reducing unnecessary

DOI 10.1007/978-1-4939-0779-3_34-1

Table 2 Risk categories for suicide [2]

Acute	
High risk	May include ideation with intent and/or serious risk factors that impair judgment
Intermediate risk	May have ideation and a collection of risk factors but lacks current intent
Low risk	No plan, intent, or behaviors indicating preparation for suicide
	May have had ideation but there are also protective factors present
Chronic	
High risk	Chronic mental health concerns that are uncontrolled
	Absent protective factors
	Unpredictable social stressors (relationship problems, job losses, lower socioeconomic status)
Intermediate risk	Have chronic mental health or health conditions that vacillate in stability but have protective factors and/or coping skills
Low risk	Have a history of mental health concerns but have protective factors/coping resources

Table 3 Suicide safety plan components [19]

Warning signs that symptoms are worsening or symptoms to monitor such as an increase in suicidal thoughts, depressive symptoms, progression to making a plan for how to commit self-harm, increased isolation, substance use, etc.
A list of coping skills/strategies that one can use to decrease symptoms. For example, the patient could generate a list of calming activities or hobbies that are enjoyable and accessible, make a list of reasons for not engaging in self-harm, and/or make a list of positive qualities, etc.
A list of social support resources (friends or family)
Removal of items that may be used to cause self-harm
List of resources such as crisis hotlines
Elicit any other resources that the patient might feel are helpful

patient waiting time or leaving against medical advice. The patient should be directly monitored until emergency services arrive. If the patient refuses inpatient hospitalization, involuntary admission or commitment may be required [2]. Laws for involuntary commitment differ among states and jurisdictions.

Patients who are assessed to be in the acute but intermediate-risk category may be more challenging when developing a treatment plan. These patients may be offered inpatient hospitalization for monitoring and medication stabilization. However, they may refuse inpatient treatment as an option and may not be suitable to involuntary hospitalization due to the lack of current intent to engage in self-harm, have certain protective factors, and/or are able and willing to comply with an outpatient treatment plan. The outpatient treatment plan for these patients should be comprehensive and include a suicide safety plan, close follow-up with the specific goal of reassessment of suicidal ideation, and provision of emergency resources, such as the suicide crisis hotline, restricted access to means of self-harm, and inclusion of family/friends if possible (see Table 3). The suicide safety plan should be given to the patient and/or family members, if present, in order to ensure that the patient can refer back to the steps they need to take should their symptoms worsen and require intensive intervention. A referral to psychiatry and/or therapy services might be advantageous for the patient as these specialties have access to resources and treatment options that may be unavailable to primary care physicians [2, 19].

Patients who are considered at lower risk may be described as individuals who have suicidal ideation without a plan or intent and have protective factors, and there is confidence that the patient will seek services if their symptoms increase.

DOI 10.1007/978-1-4939-0779-3_34-1

There are patients who are at chronic risk for suicide due to persistent mental and/or medical illness, personality disorders, impulsivity, and engagement in substance abuse or dependence, those who have persistent psychosocial stressors, and/or those who have poor coping and problem solving skills. Treatment strategies for patients who are at higher and intermediate chronic risk include ensuring that they maintain follow-up in specialty care, are compliant with their current treatment plan, and have access to a specified suicide safety plan. Patients who are at low chronic risk may have adequate coping skills, social support, and other resources. These patients may benefit from preventive strategies such as monitoring their psychosocial environment for stressors and reiterating the availability of resources if needed [2].

Medication

The treatment plan for suicidal ideation may include initiation of medication with additional safety planning and plans for follow-up. Specialty services such as therapy and/or psychiatry consultation may also be offered [2]. If a selective serotonin reuptake inhibitor (SSRI) is initiated, the Food and Drug Administration (FDA) issued a black box warning that these medications may increase the presence of suicidal thoughts or actions during initiation of these medications in children and adults ages 18–25. However, it is important to remember that depression and other serious psychiatric illnesses are the strongest risk factors for suicide. Careful consideration of the benefit-risk ratio, detailed counseling, and close monitoring and follow-up of any patient thought to be at risk for suicide are central to management. Furthermore, other medications that hold potential for overdose or toxicity should be limited or monitored.

Prevention

Identification

Given the irreversible nature of completed suicide, prevention is of utmost importance; identification of patients at risk prior to an attempt is key. Primary care physicians must be alert for patients at risk for suicide. Those who commit suicide are likely to have been evaluated by a primary care clinician in the 30 days preceding death [7].

Multiple barriers exist to the disclosure of suicidal intent. These include fear of stigmatization and invasion of privacy by strangers. Truthful disclosure is encouraged by maintaining a comfortable longitudinal relationship with a provider. In the absence of previously established rapport, suicide risk assessment (either via clinical assessment or screening tool) should be done in a manner that is personal, employing both a caring attitude and genuine concern. Routine assessment by ancillary staff should be avoided as this may be perceived as impersonal and disrespectful, possibly resulting in failure to disclose suicidal thoughts to staff or clinicians [20].

General Considerations

In addition to identification of at risk patients, several other strategies may be employed to prevent suicide and suicide attempts. Restricting access to lethal methods through firearms control, detoxification of domestic gas, the restriction of the sale of pesticides, and limiting access to certain medications have been effective in reducing suicide rates [21, 22]. Installing barriers at common jumping sites has also been shown to reduce death by suicide [23]. Education of the general public is an important component of suicide prevention, serving to promote early identification and management of mental health conditions and to destigmatize mental illness [21, 22]. Community-based programs that integrate these principles, as well as promoting a system-wide approach to suicide prevention and supporting the implementation of

DOI 10.1007/978-1-4939-0779-3_34-1

comprehensive policy changes, have been successful in reducing suicide rates [24]. Media engagement in suicide prevention efforts can be accomplished through responsible reporting [21, 25]. The media can serve as a vehicle for public education on a large scale. However, imprudent media reporting also can potentially worsen suicide risk by inadvertently glamorizing suicide and by publicizing suicide hot spots that may attract vulnerable persons [22, 25].

Therapeutic Considerations

Several psychiatric disorders, including depression, are associated with an increased likelihood of suicide [9] (see Table 1). (To this end, the USPSTF recommends screening adolescents and adults for major depressive disorder (MDD) when adequate support systems and follow-up care are available [26, 27].) Failure to optimize treatment of conditions such as depression contributes to many suicide attempts [21, 22], and initiation of therapy with SSRIs or tricyclic antidepressants has been shown to reduce rates of attempted suicide [28].

Psychotherapy for suicide attempters including cognitive therapy and interpersonal psychotherapy plays a role in reducing suicide attempts [29, 30]. An additional psychotherapeutic modality, dialectical behavioral therapy, has also been shown to reduce suicide attempts, improve treatment adherence, and reduce utilization of healthcare resources in patients with borderline personality disorder [31].

Inpatient Considerations

Attempted and completed suicide by inpatients can be limited by several interventions. Ensuring a safe environment that is free of potential means as well as adequate and supportive supervision reduces suicide risk [32, 33]. The disruptive effect of impending environmental changes or transitions – e.g., discharge, staffing changes, and variation in personnel schedules – must also be minimized by ensuring quality staff communication [32].

Follow-Up Care

Post-discharge follow-up contact plays an important role in decreasing suicide risk [34]. After a failed suicide attempt, ensuring timely and frequent follow-up care (especially after ER evaluation or hospital discharge) can extend the amount of time between discharge and a repeat suicide attempt, thus allowing possible intervention and prevention of adverse events [35] (see Fig. 1).

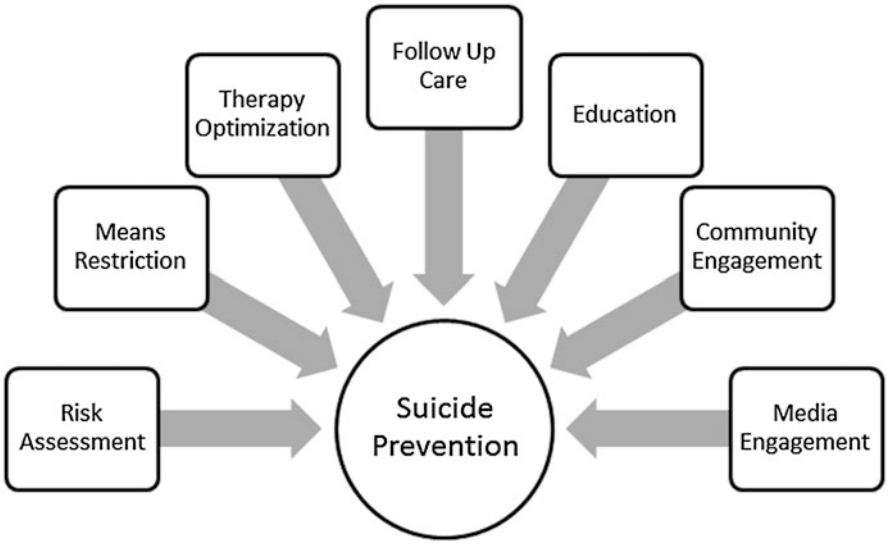

Fig. 1 Components of suicide prevention [20–22, 24, 25, 34]

DOI 10.1007/978-1-4939-0779-3_34-1

Emerging Environmental and Other Considerations

Emerging evidence supports several nontraditional suicide risk factors. Altitude has been proposed as a potential risk factor for suicide, presumably due to metabolic stress as a result of hypoxia [36]. Among elderly patients, lack of quality sleep seems to confer an elevated risk of suicide regardless of the presence of a mood disorder [37]. Chronic pain is an independent risk factor for suicide [38]. Similarly, glucocorticoid therapy appears to increase the risk of attempted or completed suicide [39]. Tobacco dependence and post-traumatic stress disorder (PTSD) are also emerging risk factors for suicide [40]. Recent prison release seems to be associated with increased suicide risk especially in the presence of comorbid mental illness or substance abuse [41]. Future approaches aimed at mitigating suicide risk may include strategies to modify these risk factors.

Family and Community Issues

Child survivors of parental suicide are at increased risk of suicidal ideation and hospitalization for suicide attempts [42, 43]. These children are also at risk for hospitalization related to depressive and anxiety disorders as well as other psychiatric symptoms and social maladjustment [43]. Children exposed to adverse experiences (e.g., domestic violence, divorce, a depressed or suicidal household member, or physical, sexual, or emotional abuse) are at increased risk of attempted suicide [44]. Of note, multilayered suicide prevention programs decrease the risk of moderate to severe family violence as well as overall risk for completed suicide [24]. Finally, the lifetime economic burden of suicide is great, costing in billions of dollars due to medical costs and lost productivity [45].

Somatoform Disorders and Related Syndromes

Pamela Pentin and Lili Dofino Sperry

Contents

General Principles

Introduction

Somatoform disorders as a group cause significant physical and emotional distress. They impair occupational and social function. They are associated with increased work absences, more time spent in bed, a lower quality of life, an increased risk for iatrogenic injury, and increased healthcare utilization and costs. The accompanying impairment is comparable to that seen with mood and anxiety disorders [1]. Fortunately, effective treatment strategies exist that can improve somatoform conditions, reinforcing the importance of identifying and engaging affected patients. This remains true despite the challenges inherent in the nature of managing symptoms with no identifiable tissue pathology.

Background: Evolution of Psychosomatic Disorders in the DSM

Appreciation for the interplay between "psyche" and "soma" dates back to ancient civilizations. The psychosomatic synergy has been conceptualized in numerous ways throughout the history of medicine and psychiatry. The criteria for diagnosis in the DSM were originally derived from criteria developed by Perley and Guze for a polysymptomatic form of hysteria coined Briquet's syndrome [2]. Briquet's syndrome is now

obsolete, but the historical context still infuses the new classification of somatization with disorders that reflect the past notion of "polysymptomatic hysteria," migrating medical providers toward a progressive skepticism of psychosomatic processes. The trend became even more pronounced as medicine became more evidence based within a biomedical model. But looking forward with large bodies of research now supporting psychosomatic medicine, the DSM-5 reflects a new and invigorated recognition of "psychosomatic processes."

The DSM-5 places particular emphasis on the role and influence of cultural factors on the experience of psychosomatic disorders. No single diagnostic label can accurately reflect the complexity of human disease or how distress is "embodied," and this in part led to the considerable changes in defining "somatoform disorders" in the current DSM-5. The DSM-IV disorders of somatization, hypochondriasis, pain disorder, and undifferentiated somatoform disorder have been removed and in most cases would now meet criteria for somatic symptom disorder (SSD).

The DSM-IV diagnosis of somatization disorders required a specific number of complaints from among four symptom groups. The SSD criteria no longer cite this requirement, simply requiring that somatic symptoms must be significantly distressing or disruptive to daily life and must be accompanied by excessive thoughts, feelings, or behaviors.

Another key change in the DSM-5 criteria is that an SSD diagnosis does not require the somatic symptoms to be medically unexplained. In other words, symptoms may or may not be associated with another medical condition. The DSM-5 narrative text description accompanying the criteria for SSD cautions "it is not appropriate to diagnose individuals with a mental disorder solely because a medical cause cannot be demonstrated." [3]

This change in emphasis removes the mind-body separation implied by DSM-IV and encourages clinicians to make a comprehensive assessment and use their clinical judgment rather than a checklist. The change also permits patients who suffer both SSD and another medical diagnosis to get the help they need.

Epidemiology

A large proportion of somatization encountered by the family physician is related to the presence of another psychiatric disorder, such as major depression or panic disorder. The Epidemiologic Catchment Area (ECA) study found that respondents with a lifetime diagnosis of somatization disorder had a much higher lifetime history of DSM-III panic disorder, obsessive-compulsive disorder, and major depression compared to those without a somatoform disorder. Since the ECA study there have been only sporadic population-based studies investigating this association. In most studies that do exist, a robust comorbidity between somatization and anxiety/depressive disorder was found. The comorbidity between somatization and other psychiatric and medical conditions has implications on treatment, and further studies of comorbidity will perhaps reveal the neurobiological underpinnings of somatoform disorders and help to determine whether these are independent entities or not [4].

Another variable that impacts incidence and prevalence is "care-seeking behavior." Community studies show that persons with somatization who seek health care have significantly more stressful life events and psychological distress and are more likely to meet criteria for depressive or anxiety disorders than those who do not seek out health care [5]. The ECA study found more than 50 % of persons reporting five or more medically unexplained symptoms met criteria for a psychiatric disorder, while only 5 % of respondents without these symptoms met criteria [6]. Further, the ECA study showed that community respondents with one or more psychiatric disorders were significantly higher utilizers of medical services than respondents without a psychiatric disorder.

The ECA study revealed that 58 % of those with a mental disorder had consulted their primary physicians in the past 6 months, twice as many as those without a mental disorder [7]. In fact, physical symptoms are a common diagnostic element of the clinical presentation of depression and anxiety; patients most commonly cite insomnia, pain,

fatigue, weakness, dizziness, dyspnea, palpitations, gastrointestinal complaints, paresthesias, tinnitus, and sexual dysfunction [8]. Also, there is a linear relationship between lifetime anxiety and depressive disorders and the number of current and lifetime medically unexplained symptoms [9]. It is critical to study comorbidity in the general population because it is so closely associated with treatment-seeking behavior [10]. More population-based longitudinal research will be needed to shed light on the temporal patterns of comorbidities and determine whether these are causal relationships or associations underlying risk factors.

Genesis of Somatization

The Stress-Diathesis Model

A number of theories have been postulated to explain the genesis of somatization, but there are two leading hypotheses. The first suggests that adverse childhood experiences contribute to the development of somatizing behavior by predisposing an individual to respond to stress somatically. The second hypothesis suggests that environmental stress leads to maladaptive communication of distress. In both theories *illness behavior* elicits care-giving responses from others and may direct attention away from other areas of conflict. Environmental influences include cultural attitudes that emphasize medical diagnosis and finding a "cure" for every affliction. Moreover, the severity of childhood adversity also seems to be associated with maladaptive high-risk behaviors such as smoking, drinking alcohol, and obesity, among other behaviors. Somatic symptoms have also been linked to personality traits such as neuroticism, harm avoidance, and high negative affectivity. Both learned and genetic origins for the traits of neuroticism and negative affectivity have been hypothesized [11]. Patients with personality disorders tend to have dramatic care-seeking behavior, and in some contexts being "sick" or in pain may be the only way to increase support from family members and medical providers and/or to attain financial stability.

Early Life Experiences

Adverse childhood experiences have a profound impact on the development of attachment styles, and these experiences can lead to somatoform behaviors. Insecure attachment, for example, is reflected in personality traits and interpersonal behaviors such as care-seeking behavior, which can be so maladaptive that it provokes hostility in others, further exacerbating care-demanding behavior [5]. Adverse childhood experiences can include childhood illness, parental illness, and childhood trauma. Substantial literature supporting the influence of social modeling on illness behavior [12] reflects how it can serve as a diathesis for maladaptive care-seeking behaviors.

Social Factors

How humans interpret and express any feeling or sensory perception is, in large part, determined by the social context in which it occurs, which in turn influences the responses of caregivers within the social system. The social context includes the influence of the health-care system on the "legitimacy" of the patient's condition (i.e., whether or not the individual is considered "sick"), and this in turn is influenced by medical provider attitudes, behaviors, and responses. Uncertainty of diagnosis, inadequate or excessive medical advice, or excessive reassurance may all contribute to the patient's beliefs. Many cultures stigmatize mental illness as being more volitional than physical illness. Carrying a diagnosis of a physical ailment removes stigma and legitimizes symptoms, allowing these symptoms to be "difficult or unable to treat." A physical diagnosis can thus increase functional disability and health-care utilization, making it an important public health concern.

Variations in prevalence of somatoform disorders may reflect the greater availability of, and greater patient faith in, high-technology diagnostic facilities and specialists in highly medicalized countries such as the United States [13]. Specialists are mainly concerned with detecting/excluding disease of the system they specialize in, rather than a global appraisal of the patient's ill health. Even when emotional disturbance is apparent, the

specialist will still often order an investigation to "exclude" a physical disease. Further negative investigations or treatment failures may then lead to another specialist referral and continued avoidance of the patient's emotional problems. The patient's access to specialist care is largely regulated by the primary care provider (PCP) who negotiates this care with the patient. This "gatekeeper" function of the PCP may also work at times to decrease the prevalence of somatization disorder. While the etiology of chronic somatization is poorly understood, somatization disorder cannot occur without medical complicity. So it is likely that the type of health-care system influences the prevalence of somatoform disorders [13].

A Biological Substrate for Somatization

New research suggests that many symptoms without identifiable pathology may be caused by disturbances in psychophysiologic brain-body pathways. An example of this is the abnormalities seen in smooth muscle tone in the gastrointestinal tract during stress in persons with irritable bowel syndrome [14]. Most recent research shows that the pathways are bidirectional. Changes in the brain secondary to stress cause functional abnormalities in the body and vice versa. Another example comes from the arena of chronic pain, where the ongoing pain experience creates pain memory which stimulates a large pain response region in the brain and ultimately a more intense pain experience.

The processes responsible for the association between subjective symptoms and inflammatory processes have been elucidated over the last decade [15, 16]. Associations between self-reports of fatigue and elevated inflammatory markers have been reported in patients with various diseases. A wealth of research has been conducted in the areas of cardiovascular disease and cancer, for example. The co-occurrence of decreasing energy, general malaise, and minor depression in the weeks that precede a myocardial infarction has been termed "vital exhaustion" [17]. Furthermore, high levels of inflammatory markers have been found in apparently healthy patients who score high on vital exhaustion [16]. The mechanism for this process is complex but can be summarized thusly: with inflammatory response, the brain's innate immune cells produce pro-inflammatory cytokines which are in turn responsible for the subjective and behavioral components of illness, which mediate the feeling of illness and thus the behavior of being ill. Studies of brain effects of cytokines show that, although cytokine-induced sickness behavior should resolve as the precipitant passes (e.g., an infectious process), the sickness behavior can persist when the innate immune system is chronically activated. This can culminate in major depression in vulnerable patients [18]. The same effect has been seen in patients whose hypothalamic-pituitary-adrenal axis is more responsive to their immune system [19]. The pathophysiology of immune-to-brain communication involves a cross-sensitization process of stressors and cytokines which likely plays an important role in somatic amplification.

The clinical relevance is again most obviously appreciated in the field of pain. The perception of pain is strongly amplified by the effect of pro-inflammatory mediators produced by activated glial cells in the spinal cord [20]. The medical implication of this mediation is that many somatized symptoms, including depressed mood, fatigue, and pain, may represent the expression of a previously sensitized brain cytokine system that is reactivated by infectious or noninfectious trauma.

At the therapeutic level, treatments that specifically target activation of the brain cytokine system are not yet available. However, evidence does exist to support pharmacological (e.g., antidepressants) and non-pharmacological (e.g., exercise) therapies that can attenuate somatic symptoms by downregulating inflammation [3].

Classification

The term somatization is commonly used in the medical literature and often defined as symptoms without organic cause. Reliance on a negative

definition has influenced how it is studied and classified. But the problem with the concept of psychogenesis is that psychological causation is sometimes believed to be an alternative to pathophysiologic causation, when in reality the two are probably synergistic.

Research findings argue against a defined dichotomy of patients meeting the criteria for the disorder or not meeting the criteria, but rather a spectrum of severity of somatization. As the number of symptoms increase, so do the psychological distress, the presence of depressive and anxiety disorders, and the degree of functional impairment. Controlling for demographic variables, medical utilization, disability, and concurrent DSM diagnosis, it seems that a spectrum of severity of somatization exists versus a qualitative break, once the criteria for somatization disorder are met [9, 11].

Conceptual Classification: A Continuum of Somatization

Distress and somatization are highly correlated [21]. As patients experience increasing distress, they develop multiple unexplained or disproportionately severe medical symptoms. This continuum manifests as acute and/or chronic presentations.

Acute Somatization

Difficult life events or circumstances tend to lead to psychological and physical discomfort, such as anxiety and nausea. Interestingly, throughout history and across cultures, it has been more common to express distress in somatic terms than in psychosocial terms (e.g., headache or abdominal pain) [22].

Stress-related symptoms account for a large percentage of visits to medical providers. Traditional techniques such as symptom management, reassurance, and a thorough history and physical diagnosis are generally adequate to address the patient's symptoms. Social support is known to provide a buffer between stress and distress [23], and individuals tend to seek support from their social system and from their physician. In most cases, distress resolves as the stressor resolves and there are no lasting sequelae. In the absence of a primary psychiatric condition, the diagnosis of adjustment reaction can be made to account for short-term residual sequelae.

Chronic Somatization

Unfortunately, there are many patients whose symptoms persist despite treatment of their acute or chronic medical and mental disorders and despite reassurance from their medical providers. This clinically "difficult" group often reflects a somatization disorder as well as other mental and organic conditions.

The severity and duration of somatization is intimately perpetuated by the medical system. The physician who orders invasive tests and treatment in pursuit of a biomedical diagnosis and cure may unintentionally promote somatizing behavior and lead to iatrogenic injury. Further complicating the picture, it can be difficult to diagnose, say, depression, when most symptoms can be accounted for by the presence of a medical condition. This difficulty is enhanced if somatization is considered only as a diagnosis of exclusion because treatable psychiatric factors magnifying the medical disorder can be missed.

Constellations

"Functional somatic syndromes" (FSS) have been used to label the constellation of symptoms that are grouped together for which no adequate medical explanation has been found. Every medical specialty has them: irritable bowel syndrome, chronic pelvic pain, tension headache, or atypical chest pain, among others. The FSS have many overlapping features but group into distinct enough clusters. Treatment of these is usually approached in the same way that somatization is, through multidisciplinary treatments that include pharmacological, behavioral, and lifestyle interventions.

DSM-5 Classification for Somatic Symptom and Related Disorders

The DSM-5 classification includes somatic symptom disorder, illness anxiety disorder, functional neurological symptom disorder, psychological

factors affecting medical conditions, and factitious disorder.

Approach to the Patient

The family physician is often presented with the patient who has a cluster of symptoms for which no medical explanation can found. These patients are responsible for a high percentage of visits to specialists [24]. A challenging variable is that patients with similar tissue pathology vary considerably in their perception of symptoms and degree of functional impairment. Some patients minimize symptoms and others amplify them. It is no surprise that comorbid psychiatric illness and stressful life events are associated with amplification. The tendency of patients with comorbid chronic medical and psychiatric disorders to amplify symptoms can be diagnostically challenging for physicians and often leads to excessive and unnecessary medical testing. The challenge resides in that distress and disease both produce physical symptoms. Symptoms cannot be split into the dichotomy of "somatogenic" and "psychogenic."

To deepen the understanding of the role of psychosocial influences of symptoms, greater attention should be placed on the process of somatization, which links the physiology of distress and the psychology of symptom perception. The primary care doctor should take into account that somatization frequently coexists with medical illness, that there is a spectrum of somatization severity from acute to chronic, and that most somatization is transient and treatable [25].

Diagnosis

Somatic symptom disorder (SSD) is characterized by somatic symptoms that either are very distressing or result in significant disruption of functioning, as well as excessive and disproportionate thoughts, feelings, and behaviors regarding those symptoms. To be diagnosed with SSD, the individual must be persistently symptomatic (typically at least for 6 months) [26].

Operationalization of the DSM-5 diagnostic criteria for somatic symptom and related disorders (DSM-5, pp. 309–327).

Screening questions: *Do you worry about your physical health more than most people? Do you get sick more often than most people?*

If yes, ask: *Do these experiences significantly affect your daily life?*

If yes, ask: *Which is worse for you, worrying about the symptoms you experience or worrying about your health and the possibility that you are sick?*

1. Somatic symptom disorder
   (a) Inclusion: Requires at least one somatic symptom that is distressing. *Do you experience symptoms that cause you to feel anxious or distressed? Do these symptoms significantly disrupt your daily life?*
   (b) Inclusion: Requires at least one of the following thoughts, feelings, or behaviors, typically for at least 6 months:
      i. Disproportionate thoughts: *How serious are your health concerns, and do you think about them often?*
      ii. Persistently high level of anxiety: *Do you persistently feel a high level of anxiety or worry about your health concerns?*
      iii. Excessive investment: *Do you find yourself investing a lot more time and energy into your health concerns than you would like to?*
   (c) Modifiers
      i. Specifiers
         - With predominant pain
         - Persistent
      ii. Severity
         - Mild: one symptom
         - Moderate: two or more symptoms
         - Severe: two or more symptoms plus multiple somatic complaints or one very severe somatic symptom
   (d) Alternatives
      i. If a person is focused on the loss of bodily function rather than on the distress a particular symptom causes, consider conversion disorder (functional

neurological symptom disorder) (full criteria are in DSM-5, pp. 318–319). The criteria for this disorder include symptoms or deficits affecting voluntary motor or sensory function, clinical evidence that these symptoms or deficits are inconsistent with a recognized medical or neurological disease, and significant impairment in social or occupational functioning.

ii. If a person has a documented medical condition other than a mental disorder, but behavioral or psychological factors adversely affect the course of his medical condition by delaying recovery, decreasing adherence, significantly increasing health risks, or influencing the underlying pathophysiology, consider psychological factors affecting other medical conditions (full criteria in DSM-5, p. 320).

iii. If a person falsifies physical or psychological signs or symptoms, or induces injury or disease to deceptively present himself to others as ill, impaired, or injured, consider factitious disorder imposed on self (full criteria in DSM-5, p. 324).

iv. If a person falsifies physical or psychological signs or symptoms, or induces injury or disease to deceptively present someone else to others as ill, impaired, or injured, consider factitious disorder imposed on another (full criteria in DSM-5, p. 325).

2. Illness anxiety disorder
   (a) Inclusion: Requires all of the following symptoms for at least 6 months and the absence of somatic symptoms:
      i. Preoccupation: *Do you find yourself unable to stop thinking about having or acquiring a serious illness?*
      ii. Anxiety: *Do you feel a high level of anxiety or worry about having or acquiring a serious illness?*
      iii. Associated behaviors: *Have these worries affected your behavior? Some people find themselves frequently checking their body for signs of illness, reading about the illness all the time, or avoiding persons, places, or objects to ward off illness. Do you find yourself doing those things or things like those?*
   (b) Exclusion: If a person's symptoms are better explained by another mental disorder, do not make the diagnosis.
   (c) Modifiers
      i. Subtypes
         • Care seeking
         • Care avoidant
      ii. Course
         • Transient
   (d) Alternatives
      i. If a person endorses symptoms characteristic of a somatic symptom disorder that cause clinically significant distress or impairment without meeting the full criteria for a specific somatic symptom and related disorder, consider unspecified somatic symptom and related disorder (see DSM-5, p. 327). If you wish to communicate specific reasons that full criteria are not met, consider other specified somatic symptoms and related disorders (see DSM-5, p. 327). Examples include brief somatic symptom disorder, brief illness anxiety disorder, illness anxiety disorder without excessive health-related behaviors, and pseudocyesis.

3. Factitious disorder
   Intentional production or feigning of physical or psychological signs or symptoms where the incentive is to assume the sick role and external incentives are absent

Differential Diagnosis

Once an organic cause has been ruled out or otherwise not found, where the sick role as incentive may be present and motivating behavior, the

main differential diagnosis includes factitious disorder (FD) and malingering (presenting with symptoms for secondary gain). The distinction between these can be difficult to establish, and the diagnosis of FD can only be confirmed if observation of symptom-producing behavior occurs or is admitted by the patient [26]. These scenarios are infrequent; therefore, diagnosis usually is made on a high index of suspicion.

Tips for Establishing the Diagnosis from a Differential

- Consider to what extent the signs and symptoms are intentionally produced.
- Consider to what extent the signs and symptoms are related to substances (current substance use makes a primary diagnosis difficult because of its impact on so many levels of physiology).
- Consider to what extent the signs and symptoms are related to another medical condition.
- Consider to what extent the signs and symptoms are related to a developmental conflict or stage (symptoms interfering with a normal developmental stage or causing conflict related to the stage such as affecting puberty or menopause or psychologic developmental stages).
- Consider to what extent the signs and symptoms are related to a mental disorder: "normality" covers a wide range of behaviors and thoughts that vary across cultures and developmental stages. A mental disturbance must cause "clinically significant disturbance and dysfunction" in an individual's life [27] to be considered a disorder rather than a constellation of symptoms.
- Consider whether no mental disorder is present: when a patient's symptoms and presentation do not fulfill the met criteria for a specific mental disorder but cause clinically significant distress or impairment, consider alternatives. For example, if the distress has developed as a maladaptive response to an identifiable psychosocial stressor, consider an adjustment disorder

Treatment

Patients with persistent symptoms with no identifiable pathology can respond to antidepressant medications as well as cognitive-behavioral therapy [28]. It is important to develop simple, feasible, and effective interventions that can be delivered through primary care by providers without specialized psychiatric skills.

Level I Evidence Based on Systematic Reviews

Antidepressant Medication

In a review conducted by O'Malley et al., 94 randomized controlled trials compared medications typically used for depression, for the treatment of somatoform disorders: tricyclic antidepressants, SSRIs, non-antidepressant medications, and placebo. Most trials showed improvement with any and all antidepressant medication interventions. O'Malley's group concluded that multiple medications can be effective treatment for somatoform disorders [29]. However, the authors cautioned that high study withdrawal rates were seen, and few studies reported on the side effects that could potentially contribute to withdrawal from the study.

Psychological Treatment

Cognitive-behavioral therapy (CBT) is the most extensively studied intervention for somatoform disorders. A meta-analysis demonstrated that either individual or group therapy can be effective in reducing physical symptoms and psychological distress, as well as in improving functional status [28]. Interestingly, benefits in the reduction of physical complaints occurred whether or not psychological distress was ameliorated. Future studies may help determine the optimal timing and duration of CBT and may identify those patients most likely to accept and respond to therapy.

Psychodynamic psychotherapy, family therapy, and other forms of psychological therapy such as reattribution and problem-solving approaches have not been studied thoroughly. However, case studies and series of these interventions have been published suggesting some improvement in somatization symptomatology. However, the evidence remains scarce making it difficult to generalize the results.

Comprehensive Management

In summary, there is good evidence to suggest that the treatment of somatization can be effective at the primary care level and that various modalities of treatment can be effective, specifically CBT and antidepressant medication. Moreover, physicians can play an important role in breaking self-defeating cycles of behavior. Recognizing somatizing behavior and understanding its genesis may allow physicians to assume a more empathetic stance with difficult patients, particularly because research and experience support that patients with somatization truly suffer. Their suffering may not correlate with "tissue pathology" but they experience distress nonetheless from somatic fixation.

Principles for a Biopsychosocial Approach to Somatic Fixation

1. Use a biopsychosocial approach from the beginning.
   (a) Include psychosocial questions in the interview.
   (b) Proceed with a reasonable but appropriately limited medical work-up.
2. Ask about symptoms without letting symptoms guide the visit.
3. Develop a collaborative relationship that maintains patient engagement.
   (a) Suggest keeping a symptom diary.
   (b) Clarify expectations and do not promise easy answers.
   (c) Consider involving pertinent family members to enhance psychosocial input.
4. See the patient at regular intervals and discourage visits to other providers unless for a specific referral.
   (a) Schedule regular appointments not dictated by symptom occurrence or intensification.
   (b) When a referral is indicated, contact the consultant beforehand and be specific about the referral questions.
5. Negotiate a mutually acceptable diagnosis.
   (a) Elicit the patient's and family's thoughts about the diagnosis.
   (b) Explore what the diagnosis or symptoms mean to the patient.
   (c) Ask about expected treatments and outcomes.
   (d) Develop a treatment plan with the patient and family.
6. Ask about any stressful life events, challenges, or unresolved family problems, such as a history of abuse and/or trauma, unresolved grief, forms of over-functioning, and substance use abuse.
7. Invite the family to participate in the management of treatment, as below:
   (a) Request each person's observations and opinions.
   (b) Try to elucidate if the illness has changed the typical roles or balance of power in the family.
   (c) Try to understand any marital or transgenerational meaning of the symptoms.
   (d) Ask what each person is doing to help.
   (e) Ask how family life would be different if the patient were asymptomatic.
8. Emphasize the patient's and the family's strengths and areas of competence.
9. Avoid psychosocial fixation maintaining an integrated approach; use biomedical explanations that also have psychosocial meanings (e.g., stress, depressed immune system).
10. Monitor both the patient's and your own discomfort with uncertainty.

11. Assess progress by monitoring changes in the level of function rather than in symptoms.
12. Terminate the intensive phase of treatment slowly.

Selected Behavioral and Psychiatric Problems

Amy Crawford-Faucher

Contents

General Principles

Definition/Background

The diverse psychiatric disorders discussed in this chapter are unified by the fact that patients will generally not present to their family physician self-reporting their disorder, as many lack insight into the cause of their symptoms. With eating disorders, the family physician may be tipped off to the diagnosis by concerned family members or by physical signs and symptoms of the condition. Patients with personality disorders may elicit strong reactions from the physician and staff and may behave in ways that seem to contradict the achievement of good health. Within each group of disorders, there are specific diagnostic criteria described by the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [1, 2]. In either case, the specific psychiatric diagnosis may not be as important as is gaining general insights into the psychopathology and developing strategies to manage the patient medically.

Eating Disorders

Eating disorders encompass a range of abnormal thoughts and behaviors surrounding food, eating, and weight control. In anorexia nervosa and bulimia nervosa, distorted body image and sometimes an extreme fear of body fat are at the core of the condition. Binge-eating disorder is associated

with shame, obesity, and increased risk of metabolic syndrome. Pica, rumination disorder, and avoidant/restrictive food intake disorder are not associated with disturbed self-image but may cause significant medical complications. The prevalence of any eating disorder in the general population varies throughout the world but is thought to be about 1 %. They appear to be more prevalent in high-income, developed countries, but there are insufficient epidemiological studies from low- and middle-income countries [3]. There can be significant overlap among symptoms of eating disorders, and in some cases patients do not meet criteria for a single diagnosis.

Diagnosing an eating disorder can be challenging. Patients who seek help on their own often complain of the physical sequelae of low body weight and malnutrition, such as fatigue and constipation, or the psychological symptoms associated with starvation such as depression and anxiety. For the family physician, recognizing aberrant behaviors and thoughts and treating resulting medical complications holistically can assist the patient to get the comprehensive care that is needed for effective treatment.

Anorexia Nervosa

Anorexia nervosa (AN) is a disease that most commonly manifests in adolescence or early adulthood. While it has been traditionally associated with girls and young women in high-pressure, high-achieving families and societies, it is important to recognize that all ethnicities, children, boys, and older women and men can also be affected. The hallmarks of AN are persistent and inadequate energy intake to provide metabolic needs, intense fear of gaining weight or becoming fat, and disturbed self-perception of weight and shape. The DSM-5 recognizes subtypes including restrictive, where weight loss is achieved through dieting, fasting, and/or excessive exercise, and a binge-eating/purging type, where the person abuses laxatives, diuretics, or enemas to counteract any weight gain from binge-eating. It is also important to understand that variations exist: women with type 1 diabetes are at increased risk for eating disorders and may withhold insulin to achieve weight loss [4], and there are case reports of patients who develop anorexia after gastric bypass surgery [5]. The lifetime prevalence of anorexia is 0.5 % in US women. Some cultural groups, including Latino and African Americans, may express less "fat phobia." Asians may relate their decreased food intake to gastrointestinal disturbances. Anorexia is 10 times more common in females than males [6], and the age of onset is typically late adolescence.

Diagnosis

The DSM-5 has amended the requirements for diagnosing anorexia nervosa. It removed the requirement for amenorrhea and the need to be less than 85 % of expected weight. The new weight loss definition requires weight below a minimally normal level for age, sex, developmental trajectory (for children and adolescents), and physical health. The Centers for Disease Control and Prevention (CDC) and World Health Organization use body mass index (BMI) less than 18.5 kg/m^2 to define low body weight in adults, and WHO uses BMI less than 17 kg/m^2 for "moderate or severe thinness." Using a BMI-for-age percentage can be helpful for children and adolescents, with BMI-for-age less than the 5th percentile to suggest underweight. The DSM-5 cautions, however, that children above that cutoff can be affected by low weight if their growth is impaired.

Patients with anorexia rarely complain of weight loss. A hallmark of the disorder is distorted self-view and continued belief in either general obesity or fat target areas on the body. Extreme malnutrition causes physiological symptoms which may be distressing enough to bring the patient to medical attention, including amenorrhea, fatigue, constipation, early satiety or bloating, palpitations, fainting, and sometimes depression or anxiety. Starvation also impairs cognitive function which further impairs insight into the disorder.

On physical exam, in addition to significant emaciation, patients may show significant abnormalities in vital signs, including hypothermia,

Table 1 Physical and laboratory abnormalities in anorexia nervosa

Physical signs	Notes
Marked weight loss	Weigh patient in hospital gown; do not allow her/him to look at scale
Hypothermia	Temp <96 % F may indicate need for admission
Hypotension, orthostasis	SBP<90, positive orthostasis, consider admission
Sinus bradycardia	<50 BPM day, <45 BPM night, consider admission
Murmur	Mitral valve prolapse can develop with starvation
Dry, brittle hair and nails	Chronic malnutrition
Lanugo	Chronic starvation and hypothermia
Peripheral edema	Heart muscle wasting, response to refeeding
Abdominal bloating	Can occur with any refeeding
Lab and ECG abnormalities	
Sinus bradycardia, prolonged QTc	Combination predisposes to ventricular arrhythmias and sudden cardiac death
↓ glucose, potassium, calcium, magnesium, phosphorous	Particularly dangerous in the setting of prolonged QTc
↑ blood urea nitrogen (BUN), creatinine	Dehydration, prolonged activation of renin-angiotensin-aldosterone system
↑ alanine aminotransferase (ALT), aspartate aminotransferase (AST)	Steatosis from prolonged or severe starvation
↓ triiodothyronine (T3), ↑thyroxine (T4)/T3 ratio Normal TSH	Starvation-induced euthyroid sick syndrome; self-corrects with weight gain

References [7] and [8]

hypotension, and bradycardia. Skin may be dry, with thinning hair and sometimes lanugo. Peripheral edema may be present when the patient stops laxative or diuretic abuse or starts to regain weight. Laboratory abnormalities are also due to chronic starvation (see Table 1).

Behavioral changes may be reported by family members, as the patient may either lack insight or feel secretive about eating and or purging activities. The degree of functional impairment varies, as some are able to continue school, professional, and social activities. More severe cases may be significantly less able to function. The differential diagnosis includes other disordered eating patterns associated with major depression, substance abuse, or schizophrenia such as avoidant/restrictive eating, but these conditions are distinguished from anorexia by the lack of fear of gaining weight. Medical conditions predisposing to poor oral intake include gastrointestinal disorders, occult malignancies, or HIV disease.

Treatment

The type and intensity of treatment for anorexia depends on the severity of weight loss and medical complications. Those with extremely low weight, comorbid medical conditions, or significant laboratory and physical abnormalities need to be hospitalized for close monitoring as refeeding is started. The medical goals of treatment include replacing electrolytes and monitoring the refeeding process. Refeeding syndrome is a serious complication which can lead to significant fluid and electrolyte shifts that can predispose to heart failure and sudden cardiac death. Preventing refeeding syndrome requires a structured refeeding plan with careful increases in calories and protein. Comprehensive eating disorder centers use a variety of protocols, but many include nasogastric feeding until the patient is willing and able to eat sufficiently.

Psychiatric treatment for anorexia includes comprehensive refeeding, as the starved brain may lack the ability to develop insight about dysfunctional weight perceptions. Psychotherapeutic treatment of anorexia is crucial. The Maudsley method is a family based therapy that is effective in teens with anorexia, especially within the first three years of illness. Individual cognitive behavioral therapy (CBT) and group therapies are also widely used. Selective serotonin reuptake inhibitors can be used to treat comorbid depression and anxiety, but have not been shown to improve weight gain or prevent remission [7, 9].

Prognosis

Most patients with anorexia nervosa fully or partially resolve within 5 years of diagnosis, but up to 20 % may become chronic [10]. The crude mortality rate is 5 % per decade and often due to medical complications or suicide [1].

Bulimia Nervosa

Similar to anorexia, those with bulimia nervosa (BN) have negative feelings about their bodies and a distorted relationship with food. Unlike anorexia, patients with bulimia tend to be normal to overweight and consequently may not come to medical attention as dramatically. The hallmarks of the disorder include binge-eating with compensatory purging behaviors to avoid weight gain. Bulimia primarily affects young women and is more common than anorexia, with a prevalence in the USA of 2–3 %. It occurs with similar frequency in many other high-income countries. The underlying risk factors are similar to anorexia, but there is a higher burden of comorbidity with anxiety, depression, and borderline personality disorder [1, 6, 7].

Diagnosis

The DSM-V defines binge-eating as episodes of unnaturally large food intake that is accompanied by a feeling of loss of control about eating. This must occur at least weekly over 3 months to meet criteria. Purging through induced vomiting; inappropriate use of diuretics, emetics, or laxatives; or excessive exercise are also key to the diagnosis. Binging and purging behaviors may vary over time; some patients may continue to binge without subsequent purging, leading to crossover to binge-eating disorder. While some with anorexia exhibit binge-purge behavior, the disorders are distinct.

Medical complications can include menstrual irregularities or amenorrhea. Diuretic or laxative abuse can lead to significant electrolyte disturbances, especially hypokalemia, and consistent laxative abuse can lead to dependence on them for bowel movements. Tooth enamel erosion from repeated exposure to gastric acid is sometimes visible on the lingual surface of the teeth. Rare complications include esophageal tears, gastric rupture, and cardiac arrhythmias. Patients are often ashamed of the binging and purging and may try to hide their behaviors. In between binging episodes, patients may restrict or "diet" to avoid further weight gain.

Table 2 Abnormalities in bulimia nervosa

Physical exam signs	Notes
Normal or overweight, with fluctuations	From binging and purging
Dental enamel erosion, gum disease	Recurrent vomiting
Parotid gland enlargement	Recurrent vomiting
Calluses on knuckles, hands	Damage from teeth from recurrent self-induced vomiting
Edema	From activation of renin-angiotensin-aldosterone system from chronic laxative or diuretic abuse
Lab abnormalities	
↓ potassium, chloride, magnesium, metabolic alkalosis	From recurrent vomiting or laxative or diuretic abuse
↑ BUN, creatinine, ↑ creatine kinase (CPK)	Prolonged hypokalemia and reduced kidney perfusion from chronic hypovolemia

References from [7] and [8]

Treatment

The severity of electrolyte or GI abnormalities dictates the intensity of medical treatment. Patients with severe electrolyte disturbances require hospitalization for electrolyte monitoring and repletion, although they generally correct rapidly once purging has stopped. Treatment of laxative-induced constipation is managed with a combination of reassurance that bowel function will return and judicious use of an osmotic laxative (see Table 2). Cognitive behavioral therapy is the mainstay for treating bulimia. Adjunctive medication, especially high-dose fluoxetine (60 mg daily), seems to be effective in reducing binge-eating and purging [11].

Prognosis

The remission rate is 80 % for bulimia, but an increased crude mortality rate of 2 % per decade persists. Death is often due to suicide or, rarely, from medical complications.

Binge-Eating Disorder

Binge-eating is characterized by the same secretive, uncontrolled eating seen in bulimia, but without the accompanying purging. Those with binge-eating disorder report either a specific or generalized lack of control over what they eat that results in large amounts of food consumed quickly in the absence of physical hunger. As opposed to bulimia, where dieting often precedes binging, binge-eaters will diet after a binge. Binge-eating often results in overweight or obesity and leads to greater physical and psychosocial impairment than BMI-matched controls. Binge-eating disorder occurs in 0.8 % of men and 1.6 % of women in the general US population, although the prevalence is much higher among those seeking weight loss treatment. Therapies adapted from bulimia treatment include modified cognitive behavioral therapy and dialectical behavioral therapy. Additionally, some selective serotonin reuptake inhibitors may be beneficial, and topiramate (although limited by side effects) seems an effective addition to CBT for decreasing binge-eating and weight [11, 12].

Personality Disorders

Patients with personality disorders have habitual thoughts, emotions, and patterns of behaving that are maladaptive and result in impaired social functioning. These traits arise in adolescence or early adulthood and tend to be stable throughout life. Personality disorders often coexist with other psychiatric and substance abuse disorders, complicating treatment of both. Personality disorders are common, with a community prevalence of 4–13 % for any personality disorder, but are even more prevalent in medical settings, with estimates that 30–45 % of psychiatric outpatients and about 24 % of primary care patients could meet criteria for a personality disorder [13–15].

There are 10 distinct personality disorders described in the DSM-V, but a significant proportion of patients may exhibit traits of more than one disorder. As patients often lack insight into the source of their continued crises or instability, appropriate diagnosis can require repeated evaluations over time and input from others close to the patient. Given the potential for continuity and long-term doctor-patient relationships, family physicians may well see these patients more than any other specialty, including psychiatry. As patients with personality disorders can be challenging, it is important to develop strategies to recognize personality disorders and traits in order to provide the best care and minimize physician and staff frustration and burnout.

While personality disorders tend to be set from early adulthood, patients may generally function well and not come to clinical attention until later in life, often when support systems are lost. Personality disorders are distinguished from other psychiatric disorders by the fact that the fixed thought and behavior patterns occur persistently and not only in the context of a psychotic or mood disorder. Conversely, it is important to recognize that while patients may have personality traits that may be suggestive of a disorder, the threshold for diagnosis may not be reached unless those maladaptive responses cause impairment or distress.

Research is ongoing about other models of conceptualizing and categorizing personality disorders, but the DSM-V maintained its previous organizational structure for personality disorders, categorizing the disorders into clusters: A (paranoid, schizoid, schizotypal), B (antisocial, borderline, histrionic, narcissistic), and C (avoidant, dependent, obsessive-compulsive) [2].

There is growing evidence that despite the traditional view of the fixed nature of these disorders, some patients may improve symptomatically over time. The fundamental treatment for personality disorders is therapy. Cognitive behavioral therapy (CBT) and dialectical behavioral therapy (DBT) are commonly employed. CBT uses cognitive restructuring, skills training, and behavior

modification to help improve functioning. DBT is a form of CBT that is widely used in borderline personality disorder and in others with suicidality and incorporates individual and group therapy. It recognizes the patient's underlying extreme reactions to events and helps the patient accept the underlying predisposition and learn skills to help overcome damaging thoughts and behaviors. Treatment of some personality disorders, such as borderline personality disorder, has been studied more thoroughly than others. There are no FDA-approved medications for treating personality disorders, but there is some evidence for off-label use for specific associated symptoms such as impulsivity, aggression, or anxiety [16].

Cluster A Personality Disorders

Patients with cluster A personality disorders often appear eccentric and odd and as children and adolescents may have been loners who had poor peer relationships and may have been teased. Those with cluster A disorders may be less likely than the general public to establish primary care, as they are essentially mistrustful.

Paranoid Personality Disorder

Patients with paranoid personality disorder have a basic and pervasive mistrust of others that is characterized by suspicions of exploitation and doubts of trustworthiness and fidelity in friends, family members, and coworkers. These characteristics can make patients difficult to get along with and make close relationships difficult. Their response to perceived threats can make them litigious and also prone to fanatical worldviews. Prevalence in the general population is likely between 2 % and 4 % but may be lower in primary care populations as these patients may not seek care. Some case reports indicate improvement in functioning with CBT [17].

Schizoid Personality Disorder

Those with schizoid personality disorder often appear aloof and impervious to the needs of human interaction. They almost always choose solitary hobbies and jobs and may not have any close relationships beyond first-degree relatives. National surveys suggest a prevalence of 3–5 % of the general public but it is uncommon in clinical settings; patients may not see their personality traits as distressing and consequently do not seek treatment. Schizoid personality disorder is more common in families with schizophrenia, suggesting the possibility of a genetic influence.

Schizotypal Personality Disorder

Patients with schizotypal personality disorder come across as odd. They share the fundamental discomfort with intimacy with schizoid personality disorder but in addition may be eccentric and have distorted thoughts – "magical thinking" – that influences behavior and is outside of the cultural norm. They tend to be anxious in social situations and may have few close relationships. Patients with schizotypal personality disorder may seek treatment for anxiety or depression rather than for the disorder itself. The reported prevalence of about 4 % is higher in the general public than it is in psychiatric or primary care settings (up to 2 %). There is some evidence that low-dose atypical antipsychotic medications can improve executive function and reduce negative symptoms [16].

Cluster B

Cluster B disorders are characterized by manipulative and impulsive behavior, although the motivations for these behaviors is different; those with antisocial personality disorder manipulate others for power or acquisition, while those with borderline personality disorder will manipulate for attention and nurturing.

Antisocial Personality Disorder

Antisocial personality disorder (or psychopathy) is characterized by a pervasive disregard for the rights of others and is manifested by repeated illegal behavior, deceitfulness, impulsivity, aggressiveness, consistent irresponsibility, and lack of remorse. While the diagnosis cannot be made until age 18, evidence of conduct disorder starting by age 15 is part of the criteria. While the overall prevalence of this disorder is low –

0.6–3 % – not surprisingly, the rate is much higher among those in the criminal justice system, where just under 50 % of prisoners worldwide meet criteria [18]. The condition is also commonly associated with other psychiatric conditions and can complicate the treatment of the same. Evidence-based pharmacologic research is limited to therapies for impulsive aggression that suggest benefit from lithium and phenytoin [16].

Borderline Personality Disorder

Borderline personality disorder appears to be relatively uncommon in the general population – about 2 % – but comprise 6 % of primary care visits, 10 % of those in outpatient mental health clinics and 20 % of inpatient psychiatric patients [19]. The fundamental criteria of this disorder include pervasive instability of interpersonal relationships and self-image, resulting in significant impulsivity, including suicidality and self-mutilation. Those with borderline personality disorder constantly guard against real or imagined abandonment, and this fear drives intense and unstable relationships and a sense of constant crisis. Patients with borderline personality disorder may initially idealize certain providers or partners, only to suddenly "flip" and devalue them when the perceived support is not sufficient. There is significant overlap with other psychiatric disorders, including mood disorders, eating disorders (especially bulimia), and substance abuse.

Borderline personality disorder is the most studied personality disorder, with extensive evidence about therapy and psychopharmacologic treatments. CBT and DBT can be effective; evidence-based guidelines recommend selective serotonin reuptake inhibitors for impulsive aggression and have found some benefit from aripiprazole, mood stabilizers, and anticonvulsants, especially topiramate, on multiple symptoms. However, many of these medications require monitoring and can have significant side effects.

Histrionic Personality Disorder

Histrionic personality disorder manifests by patients who are excessively emotional and attention-seeking. They will use speech, dress, or sexual provocativeness or other means to maintain the center of attention. This resulting drama can impair job and relationships as they are needy for but cannot truly achieve intimacy. The prevalence is <2 % in the general population, but may be higher in primary care settings because of heightened medical concerns.

Narcissistic Personality Disorder

Narcissistic personality disorder is also uncommon – 0.8 % up to 6 % depending on the criteria used, but may be over represented in clinical populations. People with this disorder can be grandiose, with a sense of entitlement, belief that they are special and should only associate with other special or high-level people, and may lack empathy and be extremely sensitive to any criticism or defeat.

Cluster C

Cluster C personality disorders are all characterized by anxiety that is manifested in different ways. The avoidant, dependent, and obsessive-compulsive personality disorders may coexist with mood disorders which may drive patients to seek medical attention for anxiety, depression, or somatic complaints.

Avoidant Personality Disorder

Those with avoidant personality disorder have an inordinate fear of criticism, disapproval, or rejection that manifests as social inhibition and feelings of inadequacy. They can appear as very shy, quiet, and timid and may avoid new social or job-related experiences because of fear of ridicule. The reported prevalence is about 2 % in the general public. Treatment is not well studied, but small studies show improved functioning with both group and individual CBT [17].

Dependent Personality Disorder

Dependent personality disorder is characterized by a pervasive need to be cared for, paired with an inordinate fear of separation. Patients with this disorder have difficulty functioning independently, which can lead to problems at work and lead to submissive behaviors in relationships,

Table 3 Strategies for effective engagement and management of patients with personality disorders in primary care

Cluster traits	Manifestations in primary care encounter	Strategies
Cluster A traits		
Mistrust of others	Expect critical comments, litigious threats	Allow patients to vent frustrations without confirming or confronting paranoid beliefs
Difficult to engage in therapeutic relationship	May discount recommendations	Provide consistent, professional attitude without becoming too informal
Odd thoughts and behaviors	May have unusual health beliefs	Expect and tolerate eccentric beliefs and behaviors
Excessive social anxiety	May not get more comfortable with physician relationship over time	Provide clear explanations without becoming overly friendly, warm, or humorous
Cluster B traits		
Manipulative	May be drug-seeking or have frequent disability claims	Be empathetic, but set clear limits despite angry outbursts from patients; recognize the physician's need to "do something" in response to demands
Heightened emotional responses	Suicidal threats, gestures	Set safety goals and communicate to other team members
Somatization	Frequent office visits or calls for medical concerns	May do well with regularly scheduled and somewhat frequent follow-up to minimize emergency calls and crises
Cluster C traits		
Hypersensitive to criticism, shame, or rejection	May seem evasive with direct questions	Validate patient's concerns and encourage patient to report symptoms
Fear of losing control	May perseverate on details and miss big picture	Provide thorough and detailed evaluations, but do not highlight uncertainties in treatment or prognosis
Fear of separation	May be in abusive relationships	Provide reassurance, frequent scheduled follow-up

References [20–22]

including an unwillingness or inability to leave abusive relationships. In the primary care office, these patients may take a lot of time to feel cared for or seem unable to follow through with self-care recommendations. This disorder is uncommon, estimated at about 0.5 % in the general population.

Obsessive-Compulsive Personality Disorder

Those with obsessive-compulsive personality disorder are motivated by a pervasive need for control, which is manifested by preoccupation with order, perfectionism, and inflexibility. The self-imposed high standards can cause significant anxiety and dysfunction. This disorder is distinguished from obsessive-compulsive disorder (OCD) because it lacks the presence of compulsive behaviors. These patients may live below their economic means and may be prone to hoarding. The prevalence is thought to be between 2 % and 8 % of the general population, making it one of the most common of the personality disorders. Multiple psychotherapeutic treatments have shown benefit, and SSRIs may be effective in treating accompanying anxiety.

Management in the Family Medicine Practice

As patients may exhibit traits from multiple personality disorders, lack insight into the source of their distress, and not be willing to accept a diagnosis, managing patients with personality disorders can be challenging. It may take a long and trusting doctor-patient bond for a patient to accept

a referral to behavioral health. In the meantime, there are strategies the family physician can use when working with personality-disordered patients (see Table 3).

Autism Spectrum Disorders

Herbert L. Muncie[a]*, Emilio Russo[b] and David Mohr[b]
[a]Department of Family Medicine, Louisiana State University School of Medicine, New Orleans, LA, USA
[b]Department of Family Medicine, LSU Health Sciences Center New Orleans, New Orleans, LA, USA

General Principles

Definition/Background

Autism Spectrum Disorder (ASD) is a continuum of neurodevelopmental conditions distinguished by deficits in social communication and interaction with restricted, repetitive, and/or stereotyped patterns of behavior, activities, and interests. Dr. Leo Kanner first described early infantile autism in 1943 [1]. The ASD social deficits and behavioral patterns are usually apparent in early childhood but may not be recognized until they interfere with other social, educational, or occupational life functions.

Pathogenesis/Genetic

Although no single chromosomal abnormality or genetic mutation has been identified as causing ASD, strong evidence exists that ASD has a genetic component. ASD is more prevalent in ASD siblings and has a high concordance rate among monozygotic twins [2]. Further support for a chromosomal connection is the dissimilar sex distribution wherein males outnumber females 4–5 to 1. Genetic counseling and testing have a diagnostic yield of 30–40 % and should be discussed with ASD patients and families [3]. About 10 % of ASD patients have a known genetic condition (e.g., fragile X syndrome, tuberous sclerosis, or Rett syndrome) [4].

Pathogenesis/Neurobiological

Structural, functional, and environmental influences contribute to the development of ASD. ASD patients frequently have macrocephaly with 25 % having a head circumference greater than the 97th percentile. A trajectory of accelerated head growth during infancy later stabilizes. Increased neurons in the prefrontal cortex have been noted as have alterations in the prefrontal and temporal cortex organization. Neural connectivity and synaptic formation and activity abnormalities are also hypothesized. Functional abnormalities occur in connectivity patterns, serotonin synthesis, methods of processing, and deficits recognizing and understanding speech.

Environmental factors may affect underlying genetic and structural predispositions toward the development of ASD. Risk factors include increased maternal or paternal age, low birth weight, maternal metabolic conditions such as diabetes and hypertension, and exposure to valproic acid. Antenatal exposure to selective serotonin reuptake inhibitors (SSRIs) confers little or no risk of ASD. Vaccines, notably MMR, and thimerosal are not causally related to ASD [5].

Epidemiology

The prevalence of ASD has increased over the last five decades. Previously estimated to be 0.5 per 1,000 children, more recent studies report ASD prevalence to be 10–20 per 1,000 children. The Autism and Developmental Disabilities Monitoring Network (ADDM) is an active surveillance system in the United States collecting data on ASD prevalence in children aged 8 years from health and education records.

*Email: hmunci@lsuhsc.edu

DOI 10.1007/978-1-4939-0779-3_37-1

The 2010 ADDM report estimated a prevalence of 14.7 per 1,000 children, although the rate varied from 5.7 to 21.9 per 1,000 children over the 11 reporting sites. The overall rate is 1 in 68 children or 1 in 42 boys and 1 in 189 girls [6]. The reported data cannot serve as the actual prevalence of ASD in the United States [7]. While some of the prevalence increase is attributable to improved awareness and recognition, changes in diagnostic reporting practices account for much of the increase [8].

ASD prevalence is increased in siblings of children with ASD. Previously, the recurrence risk was estimated at 3–10 %, but more recent studies report 11–19 %. If two or more siblings have ASD, the recurrence risk is 33–50 % [9].

Although considered a pervasive developmental disorder, nearly half of ASD children have intelligence in the average range. Signs of ASD are often present before 18 months of age; however, the median age of ASD diagnosis is 53 months. The average interval between first documented evaluation and diagnosis is 13 months. Children with less disability are often diagnosed at a later age.

The American Academy of Pediatrics recommends universal screening at 18 and 24 months of age [10]. Early potential predictors of ASD are poor attention to human faces by age 6 months, little infant-parent interaction by age 12 months, and reduced flexibility in control of visual attention by age 7–14 months.

Classification

The *Diagnostic and Statistical Manual*, Fifth Edition (DSM-5), provides criteria for ASD diagnosis [11] (see Table 1). DSM-5 recommends assigning three levels of severity (requiring support, requiring substantial support, requiring very substantial support) for each domain of social communication/interaction and repetitive/restrictive behavior. DSM-5 further recommends specifying the presence or absence of intellectual impairment; language impairment; known medical or genetic conditions; other neurodevelopmental, mental, or behavioral disorders; and catatonia.

Approach to the Patient Evaluation

The impairments inherent to ASD make the correct approach vital to having an accurate diagnosis and subsequent management. Whether the evaluation is initiated after routine screening at a well-child visit or after parents vocalize specific developmental concerns, a posture of therapeutic attention to the family's questions and a favorable clinical environment are critical to an accurate assessment. A number of preparations increase the precision of the evaluation. A quiet examination room without loud equipment or clutter, avoidance of rooms with bright or fluorescent lighting, and understanding any triggers as communicated by the parents may serve to decrease overstimulation. Moreover, communication of these techniques to the staff has the potential to facilitate consistency and increase the chance of an effective evaluation [12, 13].

Diagnosis

Clinical Evaluation

At well-child visits, use validated screening tools and employ developmental surveillance. The Modified Checklist for Autism in Toddlers Revised with Follow-up (M-CHAT R/F) is essential to the early detection of children with developmental issues [10, 14, 15] (see Table 2). However, while validated, these tools don't replace the indispensible practice of offering a listening and responsive ear to concerned parents who report atypical behaviors. Upon discovery of developmental concerns or pursuant to reported

DOI 10.1007/978-1-4939-0779-3_37-1

Table 1 DSM-5 diagnostic criteria for autism spectrum disorder (299.00)

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive):
1. Deficits in social-emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate of respond to social interactions
2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication
3. Deficits in developing, maintaining and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers
B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive):
1. Stereotyped of repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypes, lining up toys or flipping objects, echolalia, idiosyncratic phrases)
2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day)
3. Highly restricted, fixated interests that are abnormal in intensity of focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed of perseverative interests)
4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights, or movement)
C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life)
D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning
E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level

Note: Individuals with a well-established DSM-4 diagnosis of autistic disorder, Asperger's disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication, but whose symptoms do not otherwise meet criteria for autism spectrum disorder should be evaluated for social (pragmatic) communication disorder

parental observations, an evaluation incorporating a multidisciplinary team should be initiated to confirm diagnosis, exclude other etiologies (see Table 3), and determine the presence of any comorbid conditions. It is appropriate to initiate specific behavioral interventions based on the patient's symptoms and parental concerns while awaiting a definitive diagnosis [14, 16].

When ASD is suspected, referral to developmental services is appropriate even prior to confirmation of ASD. More focused recommendations such as referral to a supervised community playgroup, administration of a temperament scale, or use of picture books, naming of objects, and storytelling may be reasonable depending on the nature of the parent's report.

History and Examination

Once a child screens positive for ASD, pursuit of definitive diagnosis is imperative. While this is typically a prolonged multidisciplinary process, the physician can expedite initiation of treatment and support for the patient and family. This process begins with a thorough and directed patient and family history.

DOI 10.1007/978-1-4939-0779-3_37-1

Table 2 M-CHAT-R™ questions

1. If you point at something across the room, does your child look at it?
2. Have you ever wondered if your child might be deaf?
3. Does your child play pretend or make-believer?
4. Does your child like climbing on things?
5. Does your child make unusual finger movements near his or her eyes?
6. Does your child point with one finger to ask for something or to get help?
7. Does your child point with one finger to show you something interesting?
8. Is your child interested in other children?
9. Does your child show you things by bringing them to you or holding them up for you to see – not to get help, but just to share?
10. Does your child respond when you call his or her name?
11. When you smile at your child, does he or she smile back at you?
12. Does your child get upset at everyday noises?
13. Does your child walk?
14. Does your child look you in the eye when you are talking to him or her, playing with him or her, or dressing him or her?
15. Does your child try to copy what you do?
16. If you turn your head to look at something, does your child look around to see what you are looking at?
17. Does your child try to get you to watch him or her?
18. Does your child understand when you tell him or her to do something?
19. If something new happens, does your child look at your face to see how you feel about it?
20. Does your child like movement activities?

A successful history begins by preparing questions and the environment for the evaluation. The interviewer should query the caregiver while always engaging and addressing the patient as much as possible. Use of distraction techniques (e.g., toys, television, or music) and the establishment of the patient's level and style of communication can facilitate this evaluation. For instance, asking "yes/no" questions or allowing the patient to demonstrate various developmental skills can elucidate the most effective means of obtaining historical accuracy.

ASD symptoms are commonly noted in the second year of life, but suspicion may develop earlier [17, 18]. According to DSM-V (see Table 1), symptoms must be present in the early developmental period though they may not be apparent until later when social demands exceed limited developmental capacity [11]. In fact, in less severe phenotypes, parents or teachers may not identify ASD until 4–6 years of age [19].

The history should focus on the DSM-V's ASD description and the presence of comorbid conditions. Questions regarding the categories of social impairment, any repetitive behavior patterns, their perceived impact on function, and overall severity are all helpful. Family history is important given the strong genetic component to ASD. The presence of the following conditions in family members should be noted: ASD, language delay, intellectual disability, fragile X, Angelman syndrome, Rett syndrome, Prader-Willi syndrome, tuberous sclerosis, Smith-Lemli-Opitz syndrome, mood disorder, seizures, OCD, schizophrenia, or tic disorders [20] (see Table 3). Moreover, ask about historical social data focused on stressors, specifically trauma and family supports [21].

A carefully conducted physical examination will identify comorbid conditions. Observing the patient's behavior adds valuable insight and critical diagnostic information more than a typical physical examination. An attentive clinician, concurrently with obtaining the history from the caregiver and patient, can glean this type of observation.

DOI 10.1007/978-1-4939-0779-3_37-1

Table 3 ASD differential diagnosis

Condition	Characteristics	Diagnostic testing
Global developmental delay/intellectual disability	Delay includes motor, speech, social, and intellectual components	MRI Cytogenetic screen/FraX Consider metabolic testing, subtelomeric arrangements tests, and rule out Rett syndrome
Social (pragmatic) communication disorder	Concerns limited to appropriate use of language	Advanced clinical evaluation may reveal if secondary to ASD or a primary pragmatic d/o
Developmental language disorder	Delayed language development with normal social interactions	Multidisciplinary assessment rules out ASD Formal hearing assessment to rule out hearing impairment
Language-based learning disability	Difficulty reading and writing	Speech language pathologist evaluation
Hearing impairment	Difficulty hearing spoken words Delayed language development	Formal audiometry
Landau-Kleffner syndrome	Acquired Primarily RECEPTIVE language regression	EEG specific changes MRI
Rett syndrome	Females Dramatic loss in speech and meaningful hand use after 6–18 months Deceleration of Head Growth	Genetic Testing for X-linked gene encoding methyl-CpG-binding protein 2 (*MECP2*)
Severe early deprivation/ reactive attachment disorder	Slow growth Withdrawn behavior Difficulty bonding with caregivers	History and physical exam concentrating on prior caregivers experiences
Social anxiety disorder	Minimal deficits in communication	Advanced clinical evaluation
Obsessive-compulsive disorder	Presence of obsession (ego dystonia) not just ritual and repetitive behaviors Minimal deficits in communication	Advanced clinical evaluation may reveal OCD as primary diagnosis or comorbidity with ASD

Impaired social communication is a hallmark of ASD. Delays and deviation in language development and diminished intent to communicate are frequently part of the initial presentation and may be noted during the clinical interaction. The child may have limited ability to show empathy or even awareness of other children. Individuals with ASD often lack joint attention – the ability to share interest, amusement, or attention with others. These patients commonly ignore nonverbal communication and have difficulty employing these cues or techniques. This further limits social interaction as their sense of boundaries and appropriateness is limited.

The second ASD component is the tendency toward restricted and repetitive behaviors. Certain repetitive, stereotyped motor mannerisms may be observed in the clinical setting, particularly if the child becomes uncomfortable during the exam. Individuals with ASD have difficulty with changes in normal routine, preoccupation with stereotyped or restricted interests, and tend to have aberrant processing abilities with regard to certain sensory or perceptual stimuli. Altered sensory perception may include preoccupation with licking nonfood objects, apparent indifference to pain, resistance to being touched, strong preference for certain textures, hypersensitivity to certain sound frequencies, and visual inspection of objects out of the corner of the eyes. Because these behaviors are difficult to capture in real time, a diagnostic tool with good sensitivity and high specificity may add value to the physician's clinical judgment [10]. However, given varying levels of scientific validation, the results should be correlated with the DSM-V diagnostic criteria and the entire patient context.

DOI 10.1007/978-1-4939-0779-3_37-1

Beyond the behavioral observation, evaluation of growth parameters, a skin examination, attention to dysmorphic features, and a neurological evaluation are part of the physical assessment. Approximately one fourth of children with ASD have a head circumference greater than the 97th percentile. Children whose repetitive behaviors affect diet or food consumption may show aberrant height or weight trajectories. Examination of the skin with a Wood's lamp may reveal the presence of hypopigmented macules consistent with tuberous sclerosis complex. Patients with ASD may have gait abnormalities, clumsiness, toe walking, or hypotonia [11].

Additional Evaluation

Once the diagnosis of ASD is confirmed, additional evaluation will be necessary to identify the presence of comorbid conditions and definitively exclude conditions in the differential diagnosis [22] (see Table 3). Although present in a minority of cases, a number of genetic conditions are associated with ASD with the most common being tuberous sclerosis complex, fragile X syndrome, and Angelman syndrome. Comorbid genetic conditions tend to be clustered in the subset of ASD patients with global developmental delay or intellectual disability. As such, it is reasonable to offer testing with chromosomal microarray (CMA) and DNA analysis for fragile X to all patients diagnosed with ASD. Further genetic testing, neuroimaging, metabolic testing, and EEG may be appropriate depending on the variables of gender, patient history, family history, and physical characteristics [3, 23]. Conversely, testing for yeast metabolites, gut permeability, nonlead heavy metals, trace elements, micronutrients, and immune abnormalities is not indicated regardless of presentation as no data support such analysis [24].

Treatment

ASD treatment must be individualized and multidimensional. Treatment will vary for pre- or nonverbal children versus verbal children, adolescents versus adults. The treatment goals are to reduce detrimental behavior, increase social skills, improve cognitive ability, and facilitate the child's development [25].

While ASD is considered a biological condition, the most effective treatments are behavioral and educational [26]. An excellent review of behavioral treatments has been published [27]. Medications have a minor role and do not address the core symptoms.

Behavioral Therapy

Behavioral therapy is most effective when it is applied early and is intensive in scope [28, 29]. The applied behavior analysis (ABA) method serves as the origin for behavioral therapy [30]. The Early Start Denver Model emphasizes developmental issues and relationship improvements [31]. This model enables development of intelligence, communication, and adaptive function and some improvement in language, daily living skills, and socialization. A pilot study found the earlier intervention is begun, the more the symptoms were reduced at age 36 months [32].

A less well studied approach uses structured teaching from the Treatment and Education of Autistic and Related Communication-handicapped Children (TEACCH) Model. Neither ABA nor TEACCH have evidence of superiority and may be more complementary than opposite [33]. In fact, the primary consumers of these services (parents, special educators, and administrators) favor a combination of approaches [33].

DOI 10.1007/978-1-4939-0779-3_37-1

Specific Domains

In addition to these broad treatment approaches, treatment of specific cognitive behavioral domains can be done. Nonverbal children could benefit from the Picture Exchange Communication System (PECS) [34]. Language development may be helped by joint attention on engagement training [35]. For toddlers, social synchronous engagement can be effective [36].

What Is a Comprehensive Intervention Program?

Comprehensive intervention programs address social communication, deficits in language ability, development of play skills, approaches to reduce maladaptive behaviors, and ongoing parental education [34]. Guidelines for nonmedical intervention are a guide to therapeutic interventions [34]. These guidelines indicate that

- ASD individuals should receive a comprehensive intervention within 60 days of ASD identification.
- The intervention must be individualized to the strengths and deficits of the individual.
- The program must address family concerns and offer opportunities for active family participation.
- The intervention should involve the individual a minimum of 25 h a week.

Specific guidelines to address social skill deficits include the following:

- Interventions targeting deficits in social communication and social skills should be offered to every ASD patient.
- Individuals with less verbal skills or whose language skills do not improve should be offered use of PECS.
- If PECS is unsuccessful, augmentative and alternative communication interventions should be considered.
- Auditory integration therapy is not recommended to address core deficits.

All intervention programs should include a baseline assessment and periodic follow-up assessments with a reliable and valid instrument. Consumers of autism services are vulnerable to unsupported effectiveness claims [37].

Vocational intervention is critical for transition into adulthood, but few randomized trials have been reported [26]. Therefore, no specific treatment recommendation can be made. Employment assistance should be offered to patients who have difficulty obtaining or maintaining a job.

Parental involvement in the behavioral treatment program is vital and has the advantage of bringing treatment into the home. This not only can benefit the child but may increase parents' and other caregivers' self-confidence [38].

Sensory integration therapy is often part of occupational therapy and may be one component of a more comprehensive program. Because its effectiveness has not been established, it is not a routine intervention [39].

Specific Behavioral Concerns

Irritability and Aggression

If behavioral therapy does not adequately control irritability or aggression and it is preventing the child from becoming socially functional, medication may be helpful (Table 4). Risperidone and aripiprazole are FDA approved for ASD-related symptoms. Using the Aberrant Behavior Checklist, risperidone decreased irritability [40].

DOI 10.1007/978-1-4939-0779-3_37-1

Table 4 Medications used with ASD

Behavior	Medication	Dosage	Adverse effects
Irritability, aggression	Risperidone Aripiprazol [40]	0.5–3 mg/day 2–10 mg/day	Weight gain, sedation, tremor, akathisia, extra-pyramidal syndrome, orthostatic hypotension, tachycardia, neuroleptic malignant syndrome
Repetitive behavior	Risperidone Aripiprazol [40] SSRI (multiple)	0.5–3 mg/day 2–10 mg/day Off-label unless OCD	As above As above Insomnia, agitation, disinhibition, dry mouth, headache, sexual dysfunction
Hyperactivity and inattention (ADHD-like symptoms)	Stimulants Atomoxetine Alpha-agonists (clonidine off label, guanfacine)	Multiple 0.5 mg/kg × 3 days, then 1.2–1.4 mg/kg/day Clonidine 0.1 mg Guanfacine 0.5–2 mg/day	Poor appetite, weight loss, irritability, insomnia Insomnia, orthostatic hypotension Hypotension, bradycardia, somnolence, dry mouth, irritability, constipation
Altered sleep – initial insomnia	Melatonin	0.3–6 mg/day	Headache, dizziness, nausea

Hyperactivity and Inattention

ASD children may have ADHD-like symptoms of hyperactivity and inattention. Stimulants and atomoxetine have limited benefit; however, they may produce more adverse events than in patients with ADHD [41].

Repetitive Behaviors

Repetitive behaviors are a common manifestation of ASD. Their presence does not always require treatment. If the behavior is interfering with social function or has not responded to behavioral intervention, medication could be appropriate.

The primary medications are risperidone and aripiprazole. While somewhat effective, caution is urged due to adverse outcomes. The selective serotonin reuptake inhibitors (SSRIs) have been used, but their efficacy is questionable [42].

Altered Sleep

ASD children may experience difficulty getting to sleep and at times staying asleep. Sleep disturbances can be very exhausting for the parents. The initial treatment would be improved sleep hygiene. This would include a consistent time going to bed, getting up, and having a common bedtime routine each night. A guideline is available for parents; however, it is not clear how effective these techniques are in improving sleep [43]. In a systematic review, melatonin did have some benefit. It provided about 70 min of overall sleep improvement and an earlier sleep onset of 66 min [44].

Prognosis

ASD patients have a two to eight times increased mortality risk. Higher intellectual ability has a better social prognosis. However, even without intellectual disability, occupational potential is usually limited.

Some patients will develop normal social communication, have few autistic symptoms, and have the diagnosis reversed, although rarely. The long-term outcome for much older ASD patients is currently unknown.

DOI 10.1007/978-1-4939-0779-3_37-1

Parents and usually mothers of ASD children will often experience depression and anxiety when their child is diagnosed with ASD as their role evolves from parent to advocate and often to therapist [45]. Some work is being done to help address these issues with mothers [46].

Common Allergic Disorders

M. Jawad Hashim*
Department of Family Medicine, United Arab Emirates University, Al-Ain, United Arab Emirates

Allergic diseases constitute a wide range conditions from allergic rhinitis to eosinophilic asthma, sharing immune-mediated pathophysiology, typically IgE mediated. Unlike chronic autoimmune diseases such as systemic lupus erythematosus, common allergic diseases tend to have an acute episodic presentation often precipitated by an environmental allergen.

Allergic Rhinitis

General Principles

Definition and Background

Allergic rhinitis is defined as a disease characterized by clear nasal discharge, nasal itching, sneezing, and airflow obstruction, due to IgE-mediated inflammatory reaction to inhaled allergens. In some cases, fatigue and malaise may occur in addition, leading to the common labels "hay fever" or simply "allergies." Typical allergens commonly implicated in allergic rhinitis include plant pollens, molds, dust mites, pet dander, and house pests. Commonly coexisting conditions include asthma, allergic conjunctivitis, atopic dermatitis, and obstructive sleep disorders.

Epidemiology

Allergic rhinitis is a highly prevalent condition that affects 15–30 % of population, with a higher burden of over 40 % in some areas [1]. The prevalence peaks in the teenage years to 40s, decreasing slowly in older age groups. Disease burden is possibly higher in childhood but is difficult to determine due to frequent upper respiratory tract infections and inability to self-report symptoms in this age. Epidemiologic variation seems to stem from geographic allergen distribution, reporting of symptoms, as well as heterogeneity in the disease itself. Even with the differences in regional prevalence, its incidence is increasing worldwide [2].

With its high prevalence, allergic rhinitis is a leading cause of productivity loss at work and school. The direct costs in the United States alone range from US$2–5 billion per year, a majority of which are drug prescriptions [3]. Allergic rhinitis often aggravates coexisting asthma and chronic sinusitis generating additional healthcare costs. The magnitude of disease burden is indicated by the very high volume of clinic visits and prescriptions needed for patients with allergic rhinitis: The indirect costs incurred by patients and their families stem from impaired productivity at work and school [4]. Some estimates place allergic rhinitis as causing a greater loss of productivity than any other disease, accounting for one-fourth of all lost productivity. The number of school days missed by children, either directly or indirectly due to allergic rhinitis, is around 800,000 to 2 million in the United States.

DOI 10.1007/978-1-4939-0779-3_38-1

Classification

Allergic rhinitis as a condition involving the nasal mucosa and upper airways classifies as a disease of the respiratory system. Further sorting into subcategories by specifying the triggering allergen aids in accurate diagnosis and treatment. Thus, allergic rhinitis may be listed as due to pollen, food, animal (cat or dog) hair and dander, and other allergen or, if allergen remains unknown, as cause unspecified. In patients with coexisting bronchial asthma, listing asthma as the primary diagnosis is recommended.

Allergic rhinitis is also subdivided into seasonal or perennial and intermittent or persistent. Seasonal allergic rhinitis, as the name implies, occurs during specific periods in the year such as spring or summer, typically linked to pollen production by plants in the geographic region, while symptoms of perennial allergic rhinitis can occur throughout the year being associated with persistent environmental allergens such as dust mites and house pests. Allergic rhinitis is considered intermittent if exposure or symptoms occur less than 4 days per week or less than 4 weeks per year [3]. If exposure or symptoms exceed these durations, the term persistent is applied. The distinction between intermittent and persistent helps gauge disease severity and guides treatment selection. Severity of allergic rhinitis is classified into mild and moderate to severe [5].

Approach to the Patient

The diagnostic approach to the patient with suspected allergic rhinitis consists primarily of careful history-taking with additional supporting information from physical examination and allergen testing. In patients who report identifiable triggers or have seasonal symptoms and exhibit a clinical response to antihistamines or nasal steroid sprays, the diagnosis of allergic rhinitis is fairly straightforward. More commonly, patients tend to have no clearly identifiable triggers from history. Coexisting allergic disorders such as atopic dermatitis and asthma as well as a family history of these or allergic rhinitis itself support the diagnosis of allergic rhinitis in the patient.

Diagnosis

History

The chief symptoms of allergic rhinitis are nasal congestion, nasal discharge, nasal itchiness, and sneezing. Associated symptoms include posterior discharge of nasal secretions (postnasal drip), sniffling, and itching in eyes. Patients may be able to identify triggering allergens that provoke episodes of rhinitis, such as pet dander and pollen. Others may indicate certain seasons coinciding pollen production, in which their symptoms tend to cluster; however, year-round pollen production can lead to perennial symptoms. Nasal discharge is typically watery in allergic rhinitis.

Patients often times complain of problems caused by posterior nasal discharge or postnasal drip. These troublesome symptoms include spasmodic cough, frequent throat clearing, coughing spells when talking, a sensation of choking, and aspiration of postnasal drip. Such symptoms may interfere with the quality of sleep. Hyposmia or anosmia is a common association.

Physical Examination

Findings suggestive of allergic rhinitis include clear nasal discharge and pale discoloration of the nasal mucosa. Nasal turbinates may appear swollen and boggy with a pale bluish or pink appearance. Nasal septal perforation may occur be due to inappropriate technique in using nasal steroid sprays or less common causes, such as Wegener's granulomatosis. Eyes may show conjunctival hyperemia with watery discharge. Children may exhibit darkening of periocular areas with mild puffiness termed "allergic shiners" and attributed to congestion in the veins of the eyelid. Repeated upward rubbing of the nose

DOI 10.1007/978-1-4939-0779-3_38-1

may cause a horizontal skin crease over the lower part of the nose. Physical examination may uncover coexisting asthma or atopic dermatitis.

Laboratory and Imaging

Plain x-rays of the sinuses are not recommended. Radiological imaging does not provide any specific diagnostic information relevant to allergic rhinitis. Imaging of the nasal sinuses and adjoining structures via computed tomography (CT) or magnetic resonance imaging (MRI) is indicated when complicated chronic sinusitis with extension of infection, nasal polyposis, or a neoplasm is suspected.

Special Testing

Proof of allergen sensitivity is not needed to start empiric treatment in patients with a likely diagnosis of allergic rhinitis. Allergy to an antigen is a clinical diagnosis. A positive skin or blood test, without symptoms of allergy, does not necessarily denote that the patient has an allergy to that antigen. Allergen sensitization testing is indicated when the response to 2–4 weeks of moderate intensity treatment is inadequate; when the diagnosis is unclear, to guide therapeutic adjustments; or when knowing the specific allergens could alter treatment recommendations.

Either laboratory blood testing or office-based skin testing can provide proof of sensitization to specific allergens. Both methods are considered to have similar accuracy; however, skin testing may have higher sensitivity. Furthermore, each of these two alternatives has certain benefits over each other. With blood testing, there is no risk of anaphylaxis, skin conditions such as atopic dermatitis and dermatographism can be ignored, patients can continue taking antihistamines, and the skills and equipment needed to perform skin testing are not needed. On the other hand, skin testing yields results without having to wait for the laboratory report and is less expensive. Nevertheless, as discussed above, the vast majority of patients with allergic rhinitis can be diagnosed and managed without allergen testing.

Skin testing requires technical skills of introducing specific allergens into the skin and observing for a wheal and flare response. Allergens are introduced into the patient's skin either using the prick (puncture) or, less commonly, intradermal injection and observed for wheal and flare formation in 15–20 min. Intradermal technique is more sensitive and is often used to follow up on negative skin prick testing. Other skin testing methods such as scratch testing are less reliable and are no longer used. As skin testing involves introducing antigens that stimulate mast cells to release histamines and other proinflammatory cytokines via IgE binding, allergic adverse reactions including anaphylaxis are potential concerns. Skin testing is therefore contraindicated in patients with severe or uncontrolled asthma as well as any severe illness such as unstable cardiovascular conditions. Current medications should be carefully documented as antihistamines, and tricyclic antidepressants may suppress the skin reaction. Finally, the standardization of allergen extracts and skin testing techniques is essential to ensure reliable results.

Blood testing involves ascertaining the serum for the presence of IgE to a set of specific allergens using an immunoassay. As enzyme-linked immunoassays are more commonly employed, the term "RAST" used to refer to radioactive labeled assays is becoming obsolete. Sampling nasal mucosal fluid for IgE or other inflammatory markers is not recommended in routine clinical practice. Serum testing for total IgE level and for non-IgE antibodies such as IgG is not helpful in the diagnosis of allergic rhinitis.

Differential Diagnosis

Upper respiratory viral infections such as acute rhinopharyngitis may produce similar symptoms especially rhinorrhea and sneezing but often have additional features such as fever, malaise, muscle aches, and a shorter duration. Recurrent viral infections especially in children should be differentiated from seasonal allergic rhinitis episodes with careful history-taking enquiring about the presence of environmental triggers and sick contacts.

DOI 10.1007/978-1-4939-0779-3_38-1

Chronic sinusitis, more accurately referred to as chronic rhinosinusitis and a potential [6] consequence of allergic rhinitis, is characterized by thick mucopurulent nasal secretions, unilateral (or sometimes bilateral) nasal discharge, sinus tenderness, and a duration of more than 2 weeks.

Since allergic rhinitis is sometimes difficult to distinguish from nonallergic rhinitis (e.g., vasomotor rhinitis or rhinitis medicamentosa), diagnostic uncertainty may remain in many patients. The proportion of nonallergic rhinitis may be as high as 50 % of all cases with chronic intermittent rhinitis. However, the exact demarcation between allergic and nonallergic rhinitis remains controversial [7]. Even among patients with allergic rhinitis, inflammatory responses in the nasal mucosa can be experimentally induced by nonspecific stimuli. This observation has led to claims that nonallergic rhinitis may only be a tendency to mucosal hyperresponsiveness rather than a specific disease entity. Again, a careful history may uncover irritant stimuli responsible for nonallergic rhinitis such as smoke, chemicals, temperature changes, and odors.

Unusual symptoms such as unilateral rhinorrhea, persistent anosmia, recurrent epistaxis, unilateral nasal blockage, or headache indicate a more concerning cause such as granulomatous diseases, chronic rhinosinusitis, nasopharyngeal tumors, or a cerebrospinal fluid (CSF) leak.

Treatment

Behavioral and Family Issues

Allergic rhinitis burdens patients and their families with considerable psychosocial difficulties due to its impact on quality of life. Reduced cognitive function affecting learning and work, impaired decision-making ability, and decreased self-esteem have been noted in these patients. Increased rates of learning disorders, attention, and conduct deficits [8] impair children with allergic rhinitis in particular when obstructive sleep disorder [9] and asthma are coexistent. Family physicians should be cognizant of these issues in discussing a holistic approach to managing this condition.

Environmental Measures

Reducing allergens in the home environment by removal of pets such as cats and dogs and house pests, for example, cockroaches, reduces the levels of the allergens but may have a limited effect on patient symptoms. Complete eradication of the allergen is usually not possible, and even reduction in levels is transient – replenishing within a few days – thereby raising issues of long-term feasibility. Intensive use of

Table 1 Treatment options for allergic rhinitis

Drug class	Drugs	Efficacy	Main adverse effects and cautions
Oral antihistamines, second generation	Cetirizine, loratadine, desloratadine, fexofenadine	Mild to moderate	Mucosal dryness, sedation
Intranasal steroids	Fluticasone, triamcinolone, budesonide	Moderate	Nasal dryness, epistaxis
Nasal antihistamines	Azelastine, olopatadine	Mild to moderate	Bitter taste, epistaxis, sedation, burning sensation
Oral decongestants	Pseudoephedrine, phenylephrine	Mild	Agitation, gastrointestinal disturbances, insomnia
Topical nasal decongestants	oxymetazoline	Mild to moderate	Rebound nasal congestion, rhinitis medicamentosa
Oral antileukotrienes	Montelukast	Mild	
Immunotherapy	Specific subcutaneous/sublingual allergens	Moderate	Allergic reactions including anaphylaxis

DOI 10.1007/978-1-4939-0779-3_38-1

multiple methods is more effective but often impractical. Measures such as frequent washing of pets, HEPA air filtration systems, impermeable vinyl bed covers, acaricides (insecticide sprays against house dust mites), frequent washing of floors, removal of upholstered furniture, and washing bedsheets in hot water at more than 55 °C can reduce allergen levels temporarily, but are associated with only limited or no improvement in symptoms.

Medications

Approach to Pharmacologic Treatment and Combination Medication Use

Severity and frequency (intermittent vs. perennial presence) of symptoms should guide medication selection (Table 1), with intranasal steroids being preferred for more severe cases over antihistamines. Second-generation antihistamines are recommended for regular use based on high-quality evidence, although short-term usage can be helpful in intermittent symptoms. Adding an intranasal steroid spray as needed may be effective during times of increased symptoms while antihistamines as an add-on to topical steroids remain unproven [10]. Switching to a different antihistamine sometimes seems to work in patients who are refractory to the initial agent. The choice between oral and nasal antihistamine should be decided based on patient preferences since efficacy appears to be similar. Despite the range of medication options available, effectiveness is often modest [11], and one-third to two-thirds of children and adults have limited or no response [12]. Such cases should be considered for allergen immunotherapy.

Oral Antihistamines

H1 antihistamines, although only moderately effective, are most commonly [11] used as the first line of treatment in allergic rhinitis primarily because of rapid onset of action, over-the-counter availability, and low cost. Additional benefits include once daily oral dosing and sustained control with regular use. These long-standing medications have proven efficacy in clinical trials for the relief of rhinorrhea, sneezing, nasal itching, and nasal discharge. Additionally, these agents ameliorate ocular itching and watery discharge in case of concomitant allergic conjunctivitis. It should be noted that antihistamines are less effective than intranasal steroids in the treatment of allergic rhinitis.

Antihistamines are classified into first-generation agents, such as diphenhydramine, chlorpheniramine, and hydroxyzine, and second-generation drugs, for example, loratadine, desloratadine, fexofenadine, and cetirizine, which tend to be nonsedating. Both groups are considered to have similar efficacy in allergic rhinitis. However, the use of first-generation agents is limited by their anticholinergic (muscarinic receptors) adverse effects such as drowsiness and dry mouth. Mucosal dryness even in the nasal passages can be marked at higher doses. Sedation can affect the ability to drive safely or work in high-risk situations such as at industrial sites. Even without the subjective perception of drowsiness, the level of performance can be impaired. Cognitive impairment and other adverse effects are most significant among the elderly.

Topical Nasal Antihistamines

Nasal antihistamines such as azelastine and olopatadine show effectiveness in reducing nasal congestion but may be associated with bitter taste, epistaxis, drowsiness, headache, and burning sensation in the nasal mucosa.

Oral Decongestants

Oral decongestants such as pseudoephedrine are available in combination with antihistamines, typically denoted by the suffix “D” in the trade name. They improve the modest relief of nasal blockage by antihistamines, but the combination may be associated with excessive mucosal dryness.

DOI 10.1007/978-1-4939-0779-3_38-1

Topical Nasal Decongestants

Topical decongestants such as oxymetazoline nasal sprays are modestly effective in reducing nasal stuffiness with an initial dose, an effect that decreases rapidly with continued use within a few days. Concern for rebound nasal congestion, termed rhinitis medicamentosa, with long-term use has led to recommendations for intermittent usage limited to 3 days at a time.

Intranasal Corticosteroids

Intranasal steroids such as fluticasone, triamcinolone, and budesonide nasal sprays are the most effective treatments available for allergic rhinitis, yet their effectiveness is only moderate and patients may need additional medications. Different agents in this class of medications appear to have similar efficacy, and the choice may depend on patient experience based on side effects such as aftertaste and odor. These drugs may take 1 week or more to show clinical improvement, and, as in inhalers for asthma, patient counseling about technique of application is important. Patients should be advised to flex the neck forward, keep the spray pointing posteriorly and slightly away from the nasal septum (facilitated by holding the canister in the contralateral hand), and pinch the other nostril while inhaling. Vigorous nasal inhalation and rinsing of nostrils should be avoided immediately afterward. Intranasal steroids are known to help relieve the symptoms of concomitant allergic conjunctivitis and to improve asthma control [13].

Adverse effects of intranasal corticosteroids include nasal dryness and epistaxis. There appear to be no long-term effects on nasal mucosa, hypothalamic-pituitary axis, bone growth in children, and the ocular lens [3].

Oral Antileukotrienes

Oral leukotriene receptor antagonists such as montelukast are not recommended as the primary treatment choice in allergic rhinitis due to limited efficacy [3]. Among patients with coexisting asthma, these agents may be justified in case of good clinical response. Leukotriene inhibitors show enhanced efficacy in allergic rhinitis when coadministered with an oral antihistamine.

Immunotherapy

Allergen-specific immunotherapy consists of subcutaneous or sublingual exposure to gradually increasing doses of one or more antigens over 3–5 years. This form of therapy is generally effective, and the effects last even after completion of the treatment. Apart from the inconvenience of twice-weekly injections, there is a rare chance of allergic reaction including anaphylaxis with subcutaneous treatment. The sublingual route appears to be safer and easier for patients as therapy can be administered at home [14]. Along with benefits of improvement in comorbid asthma and allergic conjunctivitis, new onset asthma and the development of other allergies are prevented by this modality.

Referrals

Consultation with an allergy specialist is recommended for patients with allergic rhinitis who are not well controlled after a 2–4-week trial of pharmacologic treatment with combination medications and those with severe disease. In patients with inferior turbinate hypertrophy and inadequate response to medical therapy, referral to an ENT surgeon for inferior turbinate reduction surgery may be helpful. Acupuncture may be considered in selected patients based on patient preference.

Counseling and Patient Education

Patients should be counseled about the potential adverse effects of antihistamines including sedation and impaired decision making. Patient counseling about appropriate technique, delayed onset of symptom relief, and the importance of regular daily use are critical in ensuring effectiveness of inhaled intranasal steroids.

DOI 10.1007/978-1-4939-0779-3_38-1

Prevention

There is insufficient evidence for or against the use of nasal rinsing [15], wearing a face mask outdoors, staying indoors especially early morning and after sunset, avoiding lawn mowing and leaf clearing, planting insect-pollinated flowers rather than wind-pollinated ones, drying clothes indoors, shampooing hair to remove pollen, and keeping windows closed during pollen season, although some patients find these helpful based on anecdotal experience. Relocating to other areas during high pollen seasons may not be a feasible option for many patients.

The use of impermeable mattress covers from birth onward does not prevent sensitization to dust mites in infants. Unfortunately, breastfeeding has not been shown reduce the incidence of allergic rhinitis in prospective studies.

Family and Community Issues

Awareness campaigns about allergic rhinitis in most communities appears worthwhile given its high prevalence, the availability of low-cost treatment options as well as the very high burden on school and work productivity.

Anaphylaxis and Anaphylactoid Reactions

Cole R. Taylor[a]*, Wesley Carr[b] and Sarah Gebauer[c]
[a]Department of Family and Community Medicine, Saint Louis University School of Medicine, Belleville, IL, USA
[b]SLU/USAF Scott Family Medicine Residency, St. Louis University School of Medicine, Belleville, IL, USA
[c]Department of Family Medicine, St. Louis University School of Medicine, Belleville, IL, USA

Definition/Background

Anaphylaxis is an acute, potentially life-threatening, multisystem syndrome that is characterized by the release of mast cell- and basophil-derived mediators into the circulation after exposure to an antigen [1]. Traditionally, anaphylaxis was used to describe immunoglobulin E (IgE)-mediated reactions while "anaphylactoid" was used to describe non-IgE-mediated reactions. Anaphylaxis and anaphylactoid reactions are clinically indistinguishable and the World Allergy Organization recently suggested that "anaphylactoid reaction" be eliminated, with anaphylaxis divided into immunologic and non-immunologic reactions [2].

The diagnosis of anaphylaxis is made clinically and can be based on three clinical scenarios that were identified via consensus at the National Institutes of Health in 2006: [1]

1. Acute skin or mucosal reaction *and at least one of the following*:
   (a) Respiratory compromise
   (b) Reduced blood pressure or symptoms of end-organ dysfunction
2. Two or more of the following that occur rapidly after exposure to a likely allergen:
   (a) Skin/mucosal involvement
   (b) Respiratory compromise
   (c) Reduced blood pressure
   (d) Gastrointestinal symptoms
3. Reduced blood pressure after exposure to a known allergen

Using data from the number of prescriptions for automatic epinephrine injectors, investigators have estimated that the prevalence of anaphylaxis is close to 2 % of the general population [3]. Recent studies also suggest that the prevalence is rising, most notably in younger age groups [4].

Potential triggers of anaphylaxis can include, but are not limited to, food, latex, insect stings and bites, medications (most commonly beta-lactam antibiotics and NSAIDs), immunotherapy, and physical factors such as UV light, cold, or exercise [5]. The more rapidly anaphylaxis develops, the more likely the reaction is to be severe and potentially life threatening [5]. Prompt recognition of signs and symptoms of anaphylaxis is critical, and epinephrine should be administered as soon as anaphylaxis is suspected [1].

History

The diagnosis of anaphylaxis is generally based on history and physical examination. A thorough yet efficient history is imperative to timely diagnosis. The provider should inquire about all exposures in the

*Email: cole.taylor@us.af.mil

DOI 10.1007/978-1-4939-0779-3_39-1

6 h prior to onset in order to identify possible causative agents [5]. This should include anything ingested in the prior 6 h, any insect sting or bite, any relation to exercise, the location of the event, and whether the event was related to heat or cold exposure. In children, foods most commonly cause anaphylaxis, whereas in adults, instigating agents may include drugs, foods, venom from stings or bites, exercise, and latex [6–8]. Any treatment that was implemented at the onset of symptoms should also be noted. Certain patient groups, including infants, teenagers, pregnant women, and the elderly, are at higher risk for more serious reactions [9, 10]. Other risk factors for severe reactions include poorly controlled asthma, concurrent use of certain medications (e.g., beta-blockers), and cardiovascular disease [9, 10].

Physical Exam

Initial evaluation should focus on patient stability and vital sign assessment. The remainder of the physical exam should focus on potentially involved organ systems, including lung auscultation, cardiac auscultation, tissue perfusion assessment, abdominal exam, skin exam, cognitive assessment, and inspection of the throat and mucus membranes. The most common physical exam finding is cutaneous urticaria and/or angioedema. Although significantly less common in children, cutaneous symptoms may be noted in 85–90 % of adult patients with anaphylaxis [5, 11, 12]. Physical examination findings are delineated in Fig. 1.

Ancillary Studies

Anaphylaxis should be diagnosed in a timely fashion, with history and physical being the primary mode of diagnosis. If suspected, empiric therapy should be initiated immediately, without waiting for ancillary testing results. Blood tests, such as tryptase levels, allergen serology, and blood counts, can be utilized by providers who are appropriately trained in their interpretation.

Differential Diagnosis

The differential diagnosis is broad, given the range of symptoms and severity that may occur. Anaphylaxis presentation may vary from mild urticarial rash to anaphylactic shock. Table 1 summarizes the differential diagnoses to consider in a patient with signs and symptoms of anaphylaxis [5].

Anaphylactic Triggers

Anaphylactic triggers can provoke a response through IgE-dependent and IgE-independent mechanisms (see Fig. 1).

Food

Food is the most common cause of anaphylaxis in the outpatient setting and accounts for 30 % of all fatal cases. Foods most commonly responsible for anaphylaxis include peanuts, tree nuts, shellfish, fish, cow's milk, soy, and egg. Asthma is a significant risk factor for more severe reactions related to food [5]. Special care must be taken by patients, parents, and caretakers to investigate the ingredients and contents of foods

DOI 10.1007/978-1-4939-0779-3_39-1

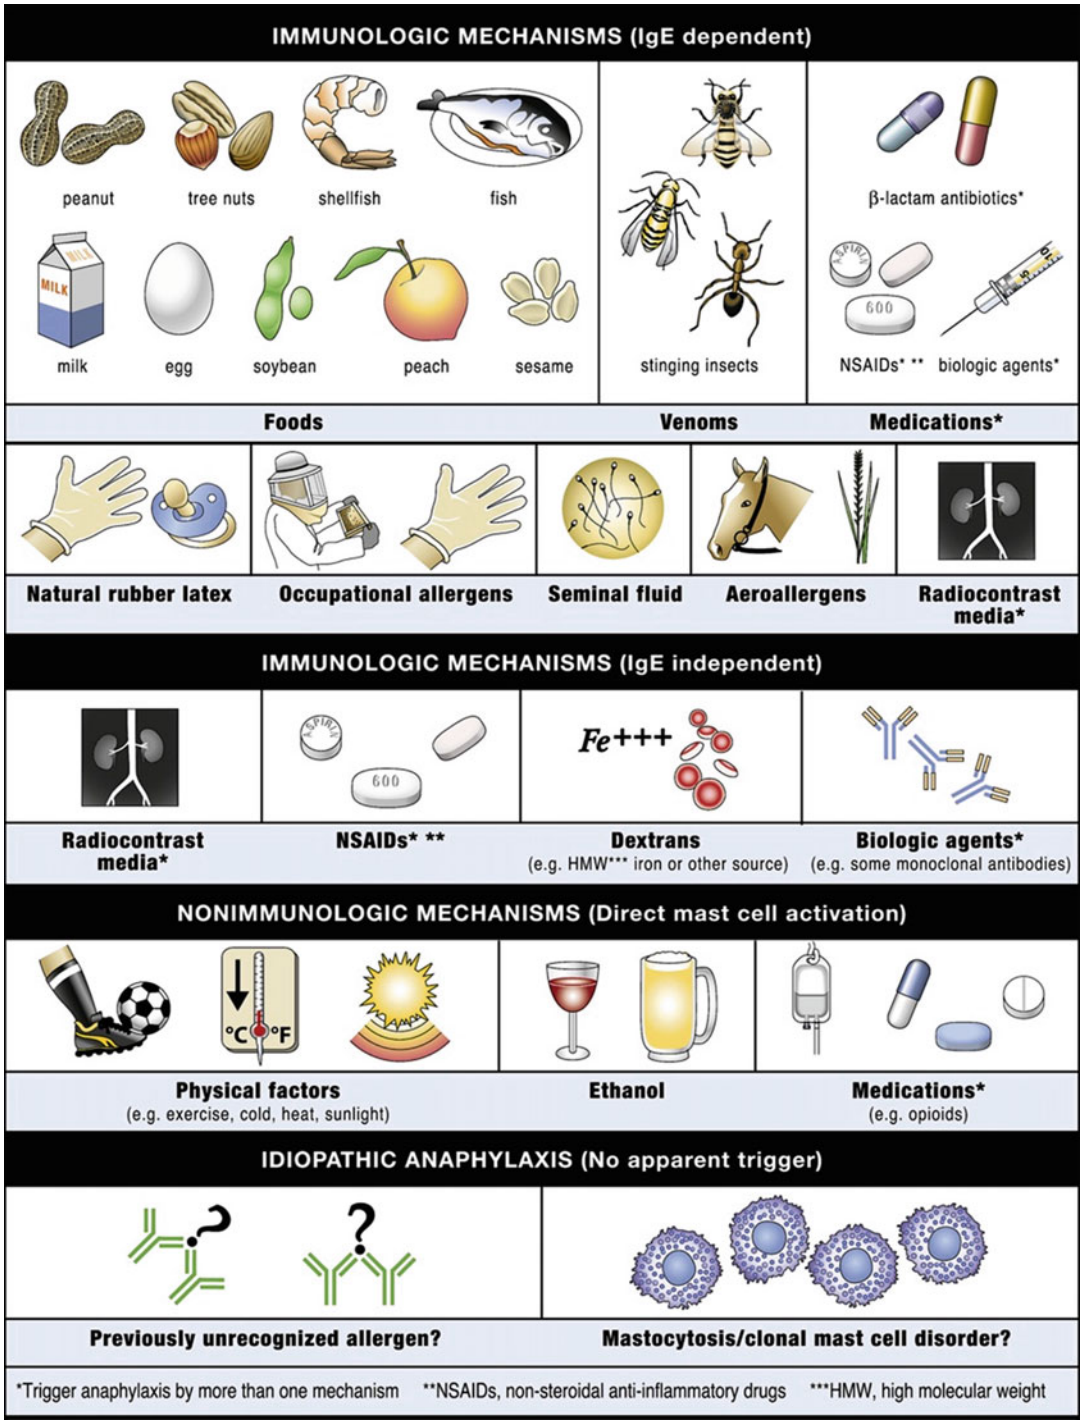

Fig. 1 Anaphylaxis mechanisms and triggers. Anaphylaxis typically occurs through an IgE-dependent immunologic mechanism, most commonly triggered by foods, stinging insect venoms, or medications. Medications can also trigger anaphylaxis through an IgE-independent immunologic mechanism and through direct mast cell activation. Radiocontrast media can trigger anaphylaxis through both IgE-dependent and IgE-independent mechanisms. Anaphylaxis triggered by seminal fluid or inhalant allergens is rare, and likely involves some systemic absorption of the allergen. In patients with idiopathic anaphylaxis, the possibility of a novel allergen trigger or of underlying mastocytosis or a clonal mast cell disorder should be considered. Table 1 Differential diagnosis of anaphylaxis

Common diagnostic dilemmas	**Flush syndromes**
Acute asthma[a]	Perimenopause
Syncope (faint)	Carcinoid syndrome
Anxiety/panic attack	Autonomic epilepsy
Acute generalized urticaria[a]	Medullary carcinoma of the thyroid
Aspiration of a foreign body	**Nonorganic disease**
Cardiovascular (myocardial infarction[a], pulmonary embolus)	Vocal cord dysfunction
Neurologic events (seizure, cerebrovascular event)	Hyperventilation
Postprandial syndromes	Psychosomatic episode
Scombroidosis[b]	**Shock**
Pollen-food allergy syndrome[c]	Hypovolemic
Monosodium glutamate	Cardiogenic
Sulfites	Distributive[d]
Food poisoning	Septic
Excess endogenous histamine	**Others**
Mastocytosis/clonal mast cell disorders[e]	Nonallergic angioedema
Basophilic leukemia	Hereditary angioedema types I, II, and III
	ACE inhibitor-associated angioedema
	Systemic capillary leak syndrome
	Red man syndrome (vancomycin)
	Pheochromocytoma (paradoxical response)

Adapted with permission from Elsevier [10]

[a]Acute asthma symptoms, acute generalized urticaria, or myocardial infarction symptoms can also occur *during* an anaphylactic episode

[b]Histamine poisoning from fish, e.g., tuna that has been stored at an elevated temperature; usually, more than one person eating the fish is affected

[c]Pollen-food allergy syndrome (oral allergy syndrome) is elicited by fruits and vegetables containing various plant proteins that cross-react with airborne allergens. Typical symptoms include itching, tingling, and angioedema of the lips, tongue, palate, throat, and ears after eating raw, but not cooked, fruits and vegetables

[d]Distributive shock may be due to anaphylaxis or to spinal cord injury

[e]In mastocytosis and clonal mast cell disorders, there is an increased risk of anaphylaxis; also, anaphylaxis may be the first manifestation of the disease

to prevent trigger-food ingestion by a patient with a known food allergy. While laborious and at times tedious, this avoidance strategy is the cornerstone of prevention with regard to food-induced anaphylaxis.

Latex

There are three specific groups of people who are considered high risk for allergic reactions to latex: healthcare workers, children with spina bifida and genitourinary abnormalities, and workers with occupational exposure to latex. Patients with spina bifida and those with a positive history of latex allergy should have all procedures performed in a latex-safe environment. When possible, powder-free latex gloves and non-latex gloves should be considered to minimize latex sensitization [5].

Anesthesia

The incidence of anaphylaxis during anesthesia has been reported to range from 1 in 4,000 to 1 in 25,000 [5]. Potential offending agents can include neuromuscular blocking agents, opioids, antibiotics, blood products, or other perioperative agents. Once recognized, these reactions are managed similarly to anaphylaxis in other situations [5].

DOI 10.1007/978-1-4939-0779-3_39-1

Exercise

Rarely, in some individuals, exercise is the immediate trigger for anaphylaxis. These individuals often report ingestion of specific trigger foods or medications prior to exercise. The diagnosis is typically based on history, and treatment includes avoidance of trigger foods or medications prior to exercising, exercising with a partner, carrying auto-injectable epinephrine while exercising, and stopping exercise at the onset of symptoms. Prophylactic medications are not effective in preventing attacks in the majority of patients [5].

Insect Sting

Anaphylactic reactions to insect stings occur in 0.6 % of children and 3 % of adults [13]. These insects include wasps, honeybees, hornets, yellow jackets, and fire ants. In those adults with a prior large local reaction to an insect sting, the risk of anaphylaxis with subsequent stings is 5–10 %. In those who have already had an anaphylactic reaction to an insect sting, the recurrence rates vary between 25 % and 70 % [5]. Because treatment with venom immunotherapy is 90–98 % effective in preventing further anaphylactic reactions, consideration for allergy referral should be made in all patients who present with an anaphylactic reaction to an insect sting [5]. In addition to allergy referral, patients should be counseled on insect avoidance measures and given auto-injectable epinephrine with instructions on its proper use.

Other Medications

Penicillin is the most common cause of drug-induced anaphylaxis. In patients who are proven to have penicillin allergy by skin testing, 4 % will react to a cephalosporin challenge [5]. Penicillin allergy is self-reported in 5–10 % of all patients, although as many as 85 % of these individuals will not react to penicillin skin testing and can tolerate this class of agents [14]. Referral to allergy for evaluation and possible skin testing should be considered for select patients at risk for serious reactions or when the suspected antigen is unclear.

Vaccines

The rate of anaphylaxis following vaccine administration has been reported to be less than one per one million doses [15]. Outpatient settings where vaccines are administered should be equipped with necessary training and equipment to treat an anaphylactic reaction.

Idiopathic Anaphylaxis

The diagnosis of idiopathic anaphylaxis is made when extensive evaluation, including a detailed history of exposures, fails to identify a trigger. The symptoms and treatment of idiopathic anaphylaxis are the same as those with an identified trigger. Glucocorticoids and histamine-1 (H1) antagonists have been shown to reduce the frequency and severity of episodes in these patients [5]. Patients with idiopathic anaphylaxis should be considered for allergy referral.

Primary Treatment

All anaphylactic reactions should be treated emergently, regardless of presenting severity, as symptoms may rapidly progress. A study of fatal episodes of anaphylaxis demonstrated respiratory and cardiac arrest occurred with a median time of 30 min for food reactions, while iatrogenic triggers had a median time of arrest of only 5 min [16]. Because of the unpredictable nature of reactions, a prompt and systematic approach must be consistently employed. Before any actions are taken, it is essential to remove any

DOI 10.1007/978-1-4939-0779-3_39-1

precipitating factors. An initial survey to assess airway, breathing, circulation, and consciousness (ABCs) should always be performed.

Epinephrine should be administered as soon as the diagnosis of anaphylaxis is suspected [5]. The preferred dose of epinephrine (1:1000) is 0.2–0.5 mL (mg) and the pediatric dose is 0.01 mg/kg, delivered intramuscularly (IM). Intramuscular thigh injections in the lateral thigh have been shown to achieve the fastest plasma concentrations. Therefore, the vastus lateralis (lateral thigh) is the preferred location. This dose may be repeated every 5–10 min until symptoms resolve. Delayed treatment may increase mortality.

To help combat hemodynamic instability, patients should be placed in a supine position with the lower extremities elevated to limit the amount of peripheral blood distribution [5]. Supplemental oxygen should also be initiated immediately and oxygenation monitored continuously with pulse oximetry. Once intravenous (IV) access is obtained, fluid resuscitation should be started with 1–2 l of normal saline (NS). If bronchospasm is present after administration of epinephrine, inhaled short-acting beta-2 agonists can be given. Antihistamines may be administered as an adjunct to epinephrine for supportive care, but should not be given in place of epinephrine when anaphylaxis is suspected. While there is no direct outcome data for their use in anaphylaxis, antihistamines may mitigate cutaneous and cardiovascular complications [17, 18]. Conversely, glucocorticoids confer no benefit in the acute care of anaphylaxis but may prevent a biphasic response [5].

In the event that patients remain unstable following initial treatment measures, certain steps should be taken. Respiratory interventions should be escalated in a stepwise fashion. Providers should establish a low threshold for endotracheal intubation and cricothyroidotomy given the risk of airway obstruction, but only if adequately trained personnel are available to perform these procedures.

Secondary Treatment

Once patients are stabilized from acute anaphylaxis, patients should be observed for signs of biphasic anaphylactic reactions. Biphasic reactions, defined as a recurrence of symptoms after previous signs and symptoms of anaphylaxis have resolved, occur in 1–23 % of patients and are more common with food-induced anaphylaxis. Most biphasic reactions occur within 8 h after resolution of initial anaphylaxis, but may take up to 72 h to present [19]. Therefore, recommended observation time for anaphylactic patients is 6–12 h, with longer periods for suspected food-related anaphylaxis. Regardless of severity, all patients presenting with anaphylaxis should be educated and sent home with auto-injectable epinephrine and referral to an allergist considered.

Prevention

The most important strategy to prevent recurrent anaphylaxis is patient education. The foundation of prevention is avoidance of triggers. Some triggers, like stings or agents required for medical procedures, cannot be avoided. Thankfully, pharmacologic prophylaxis and immunotherapy can be used to diminish the risk of resultant significant reactions.

Pharmacologic prophylaxis is frequently utilized before administration of radiographic contrast media (RCM). Given the widespread use of contrast-aided radiographic imaging in the USA (greater than ten million exams annually), prophylactic measures should be employed when the benefit of imaging outweighs the risk of an allergic reaction. The best supporting evidence involves the use of diphenhydramine and/or prednisone. A systematic review of randomized trials involving the two medications demonstrated a decrease in cutaneous and respiratory symptoms following contrast administration

[20]. While treatment regimens may vary, a common approach involves pretreatment with oral prednisone 50 mg at 13, 7, and 1 h(s) prior to a procedure in combination with oral, IM, or IV diphenhydramine 1 h prior to the procedure [21].

DOI 10.1007/978-1-4939-0779-3_39-1

Immunotherapy is another method that may minimize the risk of anaphylaxis with known triggers. It consists of repeated exposure to a particular allergen (or component of an allergen) to blunt the immune system's response. In the case of venomous insect stings, immunotherapy is 90–98 % effective in preventing systemic allergic reactions [5]. Consideration for referral to an allergist should be given for any patient with a previous systemic allergic reaction to an insect sting. Venom immunotherapy provides long-term protection and can potentially be terminated after 5 years with less than a 10 % risk of a subsequent severe reaction. However, indefinite venom immunotherapy may be appropriate in some clinical scenarios (i.e., near-fatal systemic reaction). Although the risk of a life-threatening adverse response to immunotherapy is very small, it should be performed only by professionals well trained in recognizing and treating anaphylaxis, in a setting with appropriate resources and equipment.

If the trigger is unknown, coordinated care with an allergist or immunologist is paramount. Regardless of the etiology, prevention should focus on early recognition, treatment with self-administered epinephrine, awareness of cross-reactivity, hidden allergies, risk of medical procedures, and overall risk of future anaphylaxis [22]. An epinephrine auto-injector should always be provided with instruction on appropriate use after an episode of acute anaphylaxis. A recent study demonstrated a concerning knowledge deficit in the use of auto-injectable epinephrine among both patients and general practitioners [23]. Additionally, 19 % of children who were treated with auto-injectors received no epinephrine intramuscularly [24].

Preparedness is the final component to prevention. A concerted effort should be made to inform others at home, school, work, etc. about an individual's tendency for anaphylaxis. Medical bracelets or information sheets with emergency phone numbers are available options. In addition, a comprehensive anaphylaxis emergency action plan is made available by the American Academy of Allergy, Asthma & Immunology (AAAAI) and should be provided to all patients who present with an episode of anaphylaxis (Fig. 2).

Epstein-Barr Virus Infection and Infectious Mononucleosis

Alexys J. Hillman*
Primary Care Clinic, Brian Allgood Army Community Hospital, Yongsan Garrison, South Korea

General Principles

Background

The Epstein-Barr virus (EBV) is a double-stranded linear DNA virus. Its DNA core is enclosed by an icosahedral nucleocapsid and by a viral envelope. As a member of the Herpesviridae family, EBV is specifically a gamma herpesvirus [1]. There are two subtypes of EBV, EBV-1 and EBV-2, sometimes referred to as EBV types A and B. These are genetically very similar and are not often distinguished from each other in clinical practice [2].

One of the defining characteristics of the gamma herpesvirus class is its infection of and latency within lymphoid tissue. EBV primarily infects B lymphocytes, integrating itself into the genome and remaining latent. It can also infect natural killer (NK) cells and T lymphocytes, though with less efficiency [1–3]. It is the cause of heterophile-positive infectious mononucleosis, often referred to simply as "infectious mononucleosis" (IM). Colloquial names for it include "mono" and "the kissing disease," due to its primary method of transmission. EBV was the first virus discovered to contribute to the development of several types of malignancies in humans [4].

Epidemiology

Although greater than 90 % of the world's population has antibodies to EBV, the clinical course and significance of EBV varies significantly between developing and industrialized countries. In developing countries, as well as members of lower socioeconomic status living in industrialized countries, there is extensive transmission of the virus in infancy and early childhood; the majority of children develop antibodies by the age of three and do not typically experience symptomatic infection. In the industrialized world, EBV typically causes IM primarily among adolescents and young adults, with estimates of yearly incidence ranging from 100 to 500 per 100,000 adolescents in the United States [2, 5]. Worldwide the incidence is 20–70 per 100,000 annually. Adults over the age of 30–40 are less frequently symptomatic; when symptoms in this age group occur, it is often among those suffering from immune deficiency states such as AIDS.

Clinical Presentation

EBV has an incubation period of approximately 30–50 days. The prodromal phase is characterized by the insidious onset of symptoms that include fatigue, malaise, and myalgia, typically lasting 1–2 weeks. Fever may or may not occur during this time and may last more than a month [2]. Sore throat, lymphadenopathy, and the typical prodromal symptoms form the classic triad of IM, occurring in over 80 % of patients [3]. The pattern of lymphadenopathy is generalized, present in 90 % of patients, and may include epitrochlear adenopathy.

*Email: alexys.j.hillman.mil@mail.mil

DOI 10.1007/978-1-4939-0779-3_40-1

Table 1 Factors increasing likelihood of IM

Pharyngitis with abnormal liver enzymes
Atypical lymphocytosis >10 % (specificity 92 %)
Lymphocytosis >50 % (specificity 85 %)
Palatal petechiae
Splenomegaly
Posterior cervical lymphadenopathy

Additional signs include splenomegaly in over 50 %, petechiae present at the junction of the hard and soft palate, tonsillar exudates, hepatomegaly, and a maculopapular rash which may last anywhere from 15 to 50 days. Also typical of IM is the eruption of a copper-colored maculopapular rash specifically in response to amoxicillin, which may have been given for presumptive strep throat. In adults, signs such as fever, transaminitis, hepatomegaly, or pneumonitis may be more common than the lymphadenopathy and pharyngitis typical of adolescent cases [6]. Table 1 summarizes the symptoms whose presence increases the likelihood of a diagnosis of IM.

Symptoms, particularly malaise and fatigue, may last for months. Rarely, patients may develop chronic active EBV infection (CAEBV). This condition is defined by the presence of symptoms accompanied by markedly elevated titers of EBV antibody, indicating active replication that persists for more than 6 months. Guidelines were proposed in 2005 for the diagnosis of CAEBV, including (1) persistent or recurrent IM-like symptoms; (2) unusual pattern of anti-EBV antibodies, specifically IgG against EBV VCA (greater than 1:640) and early antigen (greater than 1:160), and/or detection of EBV DNA in affected tissues, including blood; and (3) no other known disease process present to explain chronic illness at diagnosis [7].

Diagnosis

The clinical diagnosis of IM most commonly relies on the presence of typical symptoms in the presence of a positive heterophile antibody test ("monospot") [8, 9]. The complete blood count (CBC) often reveals 20 % or greater atypical lymphocytes; the white count may be normal or mildly elevated [2]. Lymphocytosis is more likely to be seen in older patients [6].

In certain instances, the heterophile antibody test can be falsely negative. In children under the age of 12, the test may be positive in only 25–50 % of patients. The test is particularly insensitive in those below 2 years of age. It may also be negative in up to 25 % of patients during the first week of infection, as well as 5–10 % of patients in or after the second week [2]. Infections such as toxoplasmosis and cytomegalovirus may cause false-positive heterophile antibody tests. Furthermore, antibodies may persist for 1 year or more. However, when positive in the presence of IM symptoms, test sensitivity is approximately 85 % and specificity approaches 94 % [3]. If EBV is strongly suspected but heterophile antibody testing is negative, EBV-specific antibodies can be obtained for confirmation of infection.

Differential Diagnosis

Table 2 summarizes the differential diagnosis of IM caused by EBV. It can be difficult to distinguish between disease entities clinically, particularly toxoplasmosis and cytomegalovirus (CMV). In high-risk populations, such as pregnant patients, it is prudent to pursue confirmatory testing due to the risk of TORCH infections to the fetus.

DOI 10.1007/978-1-4939-0779-3_40-1

Table 2 Differential diagnosis for infectious mononucleosis

Diagnosis	Differentiating characteristics
Cytomegalovirus, toxoplasmosis	Can be clinically indistinguishable
	Usually heterophile antibody negative
	Clinical suspicion requires further testing in pregnant women due to risk of congenital infection
HIV	Weight loss, mucocutaneous ulceration, rash 48–72 h following fever
	Concurrent symptomatic infection from EBV more likely in adults with HIV/AIDS
	Presence of oral hairy leukoplakia (OHL) is specific for HIV
Streptococcal pharyngitis	Exudative pharyngitis, positive rapid strep or throat culture
	More typically anterior cervical lymphadenopathy than posterior
Adenovirus	Heterophile negative
	Less systemic lymphadenopathy
Viral hepatitis	Jaundice is more common, particularly in hepatitis B
	More common among middle-aged adults than EBV
Rubella	Presence of pink maculopapular rash that begins on the face then spreads to the body
	Clinical suspicion requires further testing in pregnant women due to risk of congenital infection
Leukemia	Very high or very low white blood cell count
	Hemolytic anemia
	Moderate to severe thrombocytopenia
Drug effect	Phenytoin, carbamazepine, isoniazid, minocycline

Streptococcal pharyngitis can usually be distinguished by the presence of exudative pharyngitis, as this is more common in strep pharyngitis than in IM; it can, however, still occur in IM. Cervical adenopathy commonly involves the posterior cervical chain and may be generalized, as opposed to streptococcal pharyngitis, which tends to cause anterior cervical adenopathy [2, 4]. These two are best distinguished from each other by a rapid test for streptococcal antigen and/or throat culture.

Laboratory findings more suggestive of EBV include atypical lymphocytosis greater than 20 % and lymphocytosis of greater than 50 %. Not uncommonly, EBV infection may result in hematologic abnormalities such as hemolytic anemias or cytopenias. Similar findings may be seen in leukemia.

Complications

During the acute infection, the most worrisome complications include hemolytic anemia, encephalitis, meningitis, Guillain-Barré syndrome, myocarditis, pneumonitis, and acute interstitial nephritis. Airway compromise from pharyngitis or tonsillitis is rare but may be life threatening [2, 3, 5]. Finally, although rare, the risk of splenic rupture is greatest in the first 21 days after infection. This becomes an important consideration for return-to-play guidelines for athletes as well as military trainees, who often fall within the age range for EBV infection (see Community and Family Considerations).

In terms of long-term complications, lymphoproliferative disorders and other malignancies are of concern, particularly among immunocompromised individuals. Impaired immunity presumably allows increased viral replication over time, enhancing the ability of EBV to transform cells. While the complications of infection tend to affect the B-cell line, they remain varied and have the potential to affect almost every system. For example, nasopharyngeal carcinoma, particularly the undifferentiated type, is prevalent in Southern China, among Caucasians in North Africa, and the Inuit of North America [2].

DOI 10.1007/978-1-4939-0779-3_40-1

EBV-related thymic cancer has been identified in the United States, as well as leiomyosarcoma, Burkitt lymphoma, and other B-cell lymphomas. Oral hairy leukoplakia is a manifestation of EBV replication and can be seen in adults with HIV/AIDS. Children with AIDS can develop lymphoid interstitial pneumonitis, leading to dyspnea and respiratory distress [2, 3, 6, 10].

Evidence exists that suggests an association between EBV and the development of multiple sclerosis [11–13]. However, the exact relationship remains to be elucidated. It is likely multifactorial, to include age at infection and genetic susceptibility or predisposition. Lingering fatigue can also be a complication of IM, creating implications for the patient's subsequent ability to participate in school, work, and play. Females are particularly affected [14, 15]. It is important to note that to date no evidence exists to link infectious mononucleosis with chronic fatigue syndrome. Chronic active EBV infection is distinct from chronic fatigue syndrome.

Additionally, there exists evidence linking psychologically stressful events within the 6 months prior to infection with the severity of EBV infection symptoms and subsequent time to recovery [14]. A systematic review of the literature showed that while premorbid psychological diagnoses did not seem to correlate with length of illness or failure to recover, female sex and older age both appeared to contribute to prolonged time to recovery and distress following the active phase of illness. Furthermore, poor physical conditioning, lower physical functioning, and longer absence from work or school were consistently associated with prolonged illness [16].

Management

Supportive care is the mainstay of treatment for infectious mononucleosis. Acyclovir, while effective in reducing replication rate of the virus and oral shedding, does not alter the disease length or severity of symptoms [17]. NSAIDs, oral hydration, and salt water gargles may help provide symptomatic relief. Bed rest can be offered to those with especially severe fatigue, though evidence suggests that this may hinder recovery.

Tonsillar enlargement causing difficulty breathing may be treated by hydration, humidified air, a short course of corticosteroids, and elevation of the head of the bed. Suggested dosing of steroids is prednisolone one milligram per kilogram orally for 7 days with subsequent tapering over 7 days [2]. Significant swelling with respiratory compromise may necessitate intubation and/or tonsillectomy. Corticosteroids can also be considered in cases of thrombocytopenia with bleeding, autoimmune hemolytic anemia, seizures, and meningitis. Corticosteroids should not be used in uncomplicated cases of EBV [2, 3, 6].

Prevention

Symptoms may not present until weeks after the initial inoculation. Thus, prevention of transmission can be difficult. Advice against kissing children on the mouth due to the intermittent asymptomatic oral shedding of the virus would seem to be a sensible intervention. Toys, particularly in daycare settings, should be kept clean to prevent transmission by fomites.

Furthermore, although transmission through sexual contact has been reported, it has not been associated with development of clinically significant disease. Studies have demonstrated the coexistence of EBV with the human papilloma virus (HPV) in cervical neoplasms [18]. There has not been, however, an established link to the development of cervical cancer.

Vaccines against EBV are currently being studied. However its clinical application is likely to be for the prevention of complications, specifically malignancies, rather than reducing rates of primary infection [2].

DOI 10.1007/978-1-4939-0779-3_40-1

Family and Community Issues

For active patients, including athletes and those serving in the military, activity restriction can help protect against splenic injury or rupture, given the prevalence of splenomegaly in IM. There are no conclusive studies that establish firm guidelines regarding return to play for athletes recovering from IM. Recommendations vary, but include restriction from contact sports and high-risk activities for four weeks from symptom onset. Light activity may be resumed if the patient is afebrile and hydrated and has no spleen or liver enlargement. Complete return to play should be considered only if the patient feels well, as malaise and fatigue can persist for months after the infection resolves [2, 3, 5, 19, 20].

Viral Infections of the Respiratory Tract

Shailendra Prasad*, Elizabeth Lownik and Jason Ricco
Department of Family Medicine and Community Health, North Memorial Family Medicine Residency, University of Minnesota, Minneapolis, MN, USA

General Principles

Definition/Background

Viral infections of the respiratory tract are common events in all age groups and are the leading cause of mortality in children under 5 years of age in developing countries [1]. These infections cause significant economic burden, with estimated direct and indirect medical costs in the US exceeding $70 billion annually [2, 3]. Children under the age of 5 have an average incidence rate of four to six viral respiratory infections/year and the rate gradually decreases to one to two/year in most adults [4].

Epidemiology

Respiratory viruses spread mainly through direct contact with infected individuals, predominantly through respiratory droplets. While respiratory infections tend to be present throughout the year in warmer areas, in temperate climates these are seen most often in the winter months (see Fig. 1) [5] Although some of the new and emergent infections may arise from an animal host, the majority of the respiratory viral infections are spread from other humans. Most of the illnesses are introduced to families by young, school-age children or other caregivers with secondary infections occurring following these initial cases.

Pathophysiology

Respiratory infections caused by viruses are transmitted primarily by droplets. These viruses can attach to the upper or lower respiratory tract and induce an IgA-mediated immune response in the mucous secretions of the respiratory tract and an IgG-mediated response in serum. Respiratory viral infections generally induce adaptive immune responses that should be protective. However, repeated respiratory infections are due to the large numbers of serotypes of each virus, or antigenic variations in viruses such as the influenza virus, and their ability to induce similar, non-specific clinical signs.

The clinical presentation of respiratory viruses can vary, however their clinical symptoms are often very similar. Table 1 describes common clinical presentations and the viruses that cause these [4, 6–8].

Laboratory Testing

Respiratory viruses may be identified using viral cultures or by rapid tests identify antibodies to the virus [9]. Viral cultures are reserved primarily for research purposes given the time for culture growth, the cost, and often their relatively low sensitivity. Clinical diagnosis of respiratory viral infections remains the standard in clinical practice. Rapid tests are being used more frequently in the clinical setting to identify influenza and RSV infections and initiate targeted treatments, however rapid virus detection does not reduce antibiotic use or cost [10].

Bronchiolitis	RSV	Human metapneumovirus Influenza Parainfluenza	Bocavirus Coronavirus Adenovirus

[a]Influenza includes – fever, cough, myalgia and malaise

Laboratory tests are increasingly being used to differentiate viral from bacterial infections, since early use of antibiotics may be advantageous in the latter. C reactive protein (CRP) and procalcitonin levels in blood are two of the tests used. While procalcitonin-guided treatment algorithms have been shown to decrease antibiotic use [11], CRP is neither specific nor sensitive enough to differentiate a bacterial respiratory infection from one that is caused by a virus [12].

DOI 10.1007/978-1-4939-0779-3_41-1

Common Cold

Definition/Background

The common cold, an acute infection of the upper respiratory tract that is usually self-limited, is the most frequent human infection [13, 14]. There are over *one billion* colds every year in the United States, and it is estimated that the common cold results in 20 million days of absence from work and 22 million days of absence from school each year [14, 15]. Typical common cold symptoms consist of nasal congestion and discharge, sore throat, cough, sneezing, and sometimes headache, with symptoms usually lasting less than 10 days in duration. These symptoms are fairly nonspecific and can easily be confused with allergies or early symptoms of more serious diseases. However, taking a detailed history, particularly identifying sick contacts, is usually helpful in distinguishing the common cold from other illnesses.

Causes

Although numerous viruses have been identified as etiologies of the common cold (see table of viral prevalence by illness presentation), rhinoviruses are by far the most common viruses detected across all age groups in the setting of common cold symptoms, accounting for 30–50 % of all cases [4, 14, 16]. Coronaviruses account for 10–15 % of cold cases, and influenza viruses are detected 10–15 % of the time. Given that cold viruses such as respiratory syncytial virus also are responsible for many flu-like illnesses, there is significant overlap in viral etiologies of the common cold and flu syndromes [4, 14].

Clinical Manifestations

Rhinovirus infections typically begin with a sore throat, soon followed by nasal congestion, rhinorrhea, cough, and sneezing. As the illness progresses, sore throat symptoms tend to resolve quickly, and the initially watery rhinorrhea becomes increasingly purulent. Fever is uncommon among adults with colds, but is more frequent in children with viral respiratory infections. Common cold symptoms peak in severity within 2–3 days of onset, and have a mean duration of 7–10 days [14].

Diagnosis

The diagnosis of the common cold is primarily based on clinical symptoms alone, and is often correctly made by adult patients themselves. Diagnosis in children and infants can be more difficult, especially in the early course of a febrile illness. Streptococcal pharyngitis can resemble early common cold symptoms, but the nasal congestion and drainage usually seen in common cold are atypical in streptococcal pharyngitis [14, 16]. Given the wide range of overlap in symptoms caused by different respiratory viruses, influenza included, it is often impossible to identify a specific viral etiology for cold symptoms in a particular patient. Although rapid detection of viral pathogens with real-time polymerase chain reaction can increase diagnostic accuracy, it has not been shown to reduce antibiotic use or costs, and therefore is of limited use in everyday clinical practice [10].

Treatment

The approach to treatment for the common cold focuses on symptomatic relief as well as prevention. Antibiotics are ineffective and inappropriate treatment for the common cold and should be avoided in adults and children [17, 18]. Over the counter cough and cold medications should be avoided in all children younger than 4 years due to the potential for harm and lack of benefit. Products shown to improve cold symptoms in children include vapor rub, zinc sulfate, *Pelargonium sidoides* extract, and buckwheat honey, although the quality of the evidence varies. Ineffective treatments for children include both inhaled and oral corticosteroids and *Echinacea*. Among adults, decongestants, antihistamine/decongestant combinations, and intranasal ipratropium have been shown to improve cold symptoms [17, 18].

DOI 10.1007/978-1-4939-0779-3_41-1

Additionally, non-steroidal anti-inflammatory drugs have been shown to relieve discomfort due to colds but not to improve respiratory symptoms [19]. When taken within 24 h of symptom onset, zinc has been shown to reduce the duration of common cold symptoms in healthy adults [20]. *Echinacea* plant preparations have not proven effective in treating common colds among adults [21]. In supplementation trials, regular use of vitamin C did not decrease the incidence of common colds, but did have a positive effect on symptom duration and severity. Therapeutic trials of vitamin C during a cold have not shown a significant effect on common cold symptom reduction, but it may be worth considering in individual cases given its favorable safety profile and low cost [22].

Laryngitis

Definition/Background

Inflammation of the larynx can be caused by a variety of conditions, including: viral or bacterial infection, acid reflux, voice misuse and overuse, toxic inhalation or ingestion, postnasal drainage, or coughing from any cause. Acute laryngitis, defined as inflammation of the larynx or vocal cords lasting less than 3 weeks, is one of the most common disorders of the larynx. Symptoms include lowering of the normal pitch of the voice or hoarseness, usually lasting from 3 to 8 days. Other symptoms of an upper respiratory infection are common along with laryngitis, and the condition has been linked to changes in the weather [23].

Treatment

Although acute laryngitis is usually caused by a viral infection, there are no useful clinical criteria to distinguish between viral and bacterial causes such as *Moraxella catarrhalis*, *Haemophilus influenzae*, or *Streptococcus pneumoniae.* Viral laryngitis is likely caused by the same viruses as the common cold (i.e., rhinovirus, coronavirus). Treatment is largely supportive, and includes voice rest, corticosteroids, and proton pump inhibitors [24]. Antibiotics are often prescribed for acute laryngitis. However, a recent systematic review concluded that antibiotics are of no benefit in the treatment of acute laryngitis [23].

Influenza

Definition/Background

Influenza is an acute respiratory illness caused by the influenza virus. In temperate climates, seasonal epidemics of influenza occur annually during the winter months, while in tropical climates influenza cases occur intermittently throughout the year [24]. Worldwide, three to five million people develop influenza each year and approximately 250,000–500,000 die of influenza-related illness [25]. The Epidemiology and Prevention Branch in the Influenza Division at the Centers for Disease Control and Prevention (CDC) tracks and reports influenza activity in the United States in a weekly report throughout the influenza season [26]. In the USA, influenza can peak in the colder weather months with most peaks occurring in February (see Fig. 2) [28]. Influenza results in significant economic costs as well as morbidity and mortality. Between 1976 and 2007 in the USA, estimated deaths attributable to influenza ranged from 3,000 to 49,000 per year, with the majority of deaths occurring in those aged >65 years [28].

Causes

The influenza virus is a single stranded RNA virus from the Orthomyxoviridae family that comes in three subtypes: A, B, and C. Human influenza virus types A and B cause the epidemics of human disease, while influenza virus type C causes a mild respiratory illness similar to the common cold [29]. The influenza

DOI 10.1007/978-1-4939-0779-3_41-1

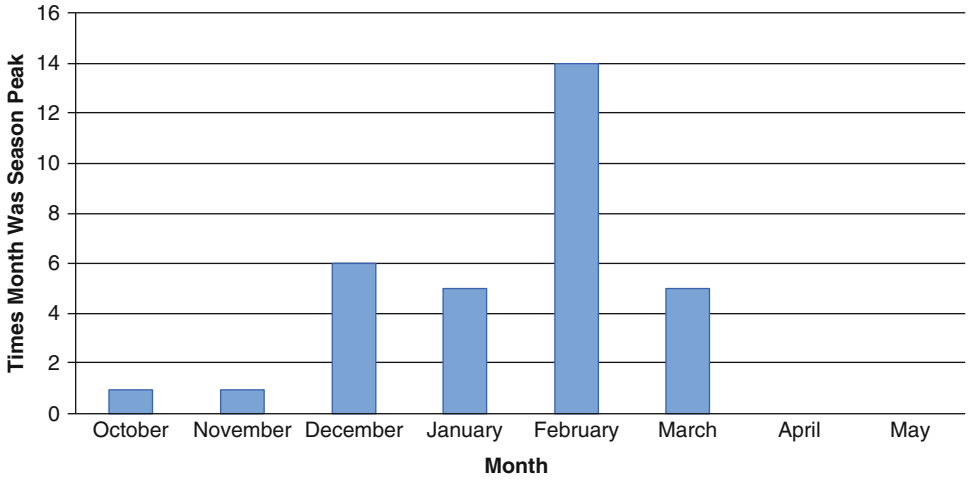

Fig. 2 Peak month of flu activity 1982–1983 through 2013–2014 [27]

A virus is further classified by the type of surface hemagglutinin (H) and neuraminidase (N) antigens that are expressed [30]. The appearance of new combinations of the H and N antigens results in "antigenic shifts" that have the potential to cause pandemics of human illness due to a lack of pre-existing immunity [29]. Within the last decade, two new strains of influenza A have emerged and resulted in pandemics- the H1N1 strain in Mexico in 2009 and the H7N9 strain in China in 2013 [31].

Prevention

Vaccination is the preferred public health method for prevention of influenza. Both inactivated influenza vaccine (IIV) and live attenuated influenza vaccine (LAIV) are available each season and are created from the circulating influenza A and B virus isolates that are anticipated to circulate in the following season according to recommendations of the World Health Organization [32]. Current recommendations call for annual influenza vaccination for all individuals greater than 6 months of age. The LAIV is recommended over the IIV for children ages 2–8 when immediately available if the child has no contraindications to the live attenuated vaccine. When vaccine supply is limited, preference should be given to those at higher risk, including children age 6–59 months, adults >50 years of age, those with immunosuppression or other severe chronic disease including morbid obesity, women who are or will become pregnant during the influenza season, residents of long-term care facilities, and Native Americans/Native Alaskans [32]. At this time, vaccination demonstrates a minimal effect on symptomatic influenza in otherwise healthy adults, with one case prevented for every 71 adults vaccinated [33]. However, universal vaccination is encouraged to improve herd immunity to influenza thus protecting high-risk individuals [34].

In certain situations, the antiviral medications oseltamivir or zanamivir can be used as an adjunct to vaccination for prevention of influenza. In a meta-analysis of prophylaxis trials, both medications demonstrated a significant reduction in the risk of symptomatic influenza in individuals and in households [35]. However, due to concern for increasing viral resistance, the CDC does not recommend the routine use of chemoprophylaxis for prevention of influenza, but rather recommends judicious use for those with known exposure who are at high risk for influenza complications or for whom the influenza vaccine is contraindicated [34].

DOI 10.1007/978-1-4939-0779-3_41-1

Clinical Manifestations

Infection of the respiratory tract by influenza virus classically results in acute onset of systemic and respiratory symptoms such as fever, cough, sore throat, nasal congestion, headache, myalgias, or malaise [32]. However, infection by influenza virus can be asymptomatic or cause other syndromes such as the common cold, pharyngitis, or pneumonia. Other viruses such as respiratory syncytial virus, adenovirus, or coronavirus can also cause an influenza-like illness [30]. The majority of those who get influenza will recover within 3–7 days, but cough and fatigue may persist beyond 2 weeks. Some develop complications such as pneumonia (either viral or a secondary bacterial infection), which can be life threatening, particularly for those at high risk. Influenza infection can also exacerbate other underlying chronic diseases such as asthma, COPD, and congestive heart failure.

Diagnosis

If influenza is suspected clinically and the patient would benefit from antiviral treatment (see below), a presumptive clinical diagnosis of influenza should be sought. Reverse transcriptase polymerase chain reaction (RT-PCR) is the most sensitive and specific method of influenza diagnosis according to the Infectious Disease Society of America, however the test is slow and can often take several days for a definitive result. Rapid influenza diagnostic tests (RIDTs) are antigen tests with results often available quickly enough to be clinically relevant. However, the results have poor sensitivity: in a meta-analysis of 159 studies of RIDT's compared to RT-PCR or viral culture, the RIDT's demonstrated a pooled sensitivity of 62.3 % (95 % CI 57.9–66.6 %) and a pooled specificity of 98.2 % (95 % CI 97.5–98.7 %) [36]. For this reason, a positive RIDT result can be considered adequate to make the diagnosis, but a negative RIDT result should not be used to exclude the diagnosis of influenza when clinically suspected.

Treatment

Four pharmacologic agents are available to treat influenza in the United States: the neuraminidase inhibitors zanamivir and oseltamivir, and the adamantanes amantadine and rimantadine. Amantadine and rimantadine are only effective against influenza A, and due to high rates of resistance (>99 % for influenza A H3N2 or H1N1) their use is not currently recommended [34]. Zanamivir (inhaled) and oseltamivir (oral) are effective against both influenza A and B and still demonstrate low rates of resistance [37]. Treatment with one of these agents is recommended as soon as possible for patients with known or suspected influenza who are hospitalized, manifest severe, complicated, or progressive illness, or are at high risk for complications, including adults >64 years of age, children <2 years of age, persons with severe underlying chronic illness or immunosuppression, or several other high risk groups (Table 2) [34]. One recent meta-analysis demonstrated small, non-specific effects on reducing the total duration of influenza symptoms without a demonstrated reduction in complications for otherwise healthy adults with influenza treated with oseltamivir or zanamivir [35]. The use of a neuraminidase inhibitor for treatment of proven or suspected influenza in an otherwise healthy adult without risk factors for severe disease should be determined by clinical judgment and shared decision making.

Acute Bronchitis

Definition/Background

Acute bronchitis is a self-limited infection of the epithelial cells of the bronchi characterized by the presence of cough, with or without sputum production. The symptoms of acute bronchitis can overlap with other clinical syndromes of upper and lower respiratory tract infections. Symptoms generally last for

DOI 10.1007/978-1-4939-0779-3_41-1

Table 2 Persons at high risk for complications from influenza [34]

Children aged <5 years (especially those aged <2 years)
Adults aged ≥65 years
Persons aged ≤18 years who are receiving long-term aspirin therapy
Individuals with chronic pulmonary (including asthma), cardiovascular (except hypertension alone), renal, hepatic, hematologic (including sickle cell disease), metabolic disorders (including diabetes mellitus) or neurologic and neurodevelopment conditions (including disorders of the brain, spinal cord, peripheral nerve, and muscle such as cerebral palsy, epilepsy (seizure disorders), stroke, intellectual disability (mental retardation), moderate to severe developmental delay, muscular dystrophy, or spinal cord injury)
Immunosuppressed individuals, including that caused by medications or by HIV infection
Pregnant or postpartum women (within 2 weeks after delivery)
American Indians/Alaska Natives
Morbidly obese individuals (i.e., BMI ≥40)
Nursing home, or other chronic-care facility residents

2 weeks, but the associated cough may persist for up to 8 weeks [38]. In the USA, acute bronchitis is the ninth most commonly encountered diagnosis in the outpatient setting [39].

Causes

The majority (>90 %) of cases of uncomplicated acute bronchitis are due to a viral infection [40]. Influenza A and B viruses, parainfluenza virus, respiratory syncytial virus, coronavirus, adenovirus, rhinovirus, and human metapneumovirus have all been identified, though in the majority of cases no causative agent is isolated [41]. *Bordetella pertussis*, *Mycoplasma pneumoniae*, and *Chlamydophila (Chlamydia) pneumonia* cause acute bronchitis in approximately 5–10 % of adult cases [40]. Though pneumonia-causing pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis* are sometimes isolated from patients with acute bronchitis, their role is unclear and they do not appear to be etiologic agents of bronchitis in otherwise healthy adults [40, 41].

Diagnosis

The diagnosis of acute bronchitis is based on clinical evidence of a lower respiratory tract infection with a cough persisting at least 5 days without evidence of pneumonia [41]. In the absence of abnormal vital signs or physical exam findings consistent with pneumonia, a chest radiograph is not necessary unless the patient is elderly or otherwise immune suppressed [41]. Other alternative diagnoses such as asthma, pharyngitis, sinusitis, influenza, and pertussis should be ruled out when clinically appropriate.

Treatment

Antibiotic treatment of acute uncomplicated bronchitis is not recommended [40]. Systematic reviews of the available evidence have demonstrated that, though there may be a modest reduction in duration of cough-related symptoms, this is unlikely to be clinically significant [38]. Overall there is no benefit to using antibiotics for acute bronchitis in otherwise healthy individuals, unless there is clinical suspicion for pertussis as the etiologic agent [40]. Clinical judgment should guide the determination of antibiotic use for those who are elderly or who have chronic respiratory comorbidities.

In spite of this recommendation, approximately two thirds of patients with acute bronchitis are prescribed antibiotics in the United States [42]. Procalcitonin-guided therapy has been shown to safely reduce antibiotic use in lower respiratory tract infections (including pneumonia, asthma, COPD, and uncomplicated acute bronchitis) in the primary care setting and can help guide treatment if bacterial infection is a concern [43].

DOI 10.1007/978-1-4939-0779-3_41-1

Special Populations: Children, Elderly, and the Immunocompromised

Children tend to have more episodes of respiratory infections than adults and, while many have 4–6 infections/year, 15 % of children may have up to 12 infections in a year. Children who attend daycare have a 50 % more respiratory infections than those who do not [44]. The majority of infections in children are self-limiting with supportive care the only treatment required.

Viral respiratory infections are particularly concerning in the elderly and the immunocompromised. Secondary infections including pneumonia and sepsis cause increased morbidity and mortality in these populations. All-cause mortality is also increased with influenza in this population [45]. Among the institutionalized elderly, respiratory syncytial virus (RSV), parainfluenza, and influenza are important causes of respiratory illness. Along with respiratory precautions and hand hygiene, increased efforts towards immunization of the elderly and their caregivers are important to decrease morbidity in this population.

New and Emergent Respiratory Infections

The ease of travel and the interdependency of markets have brought new challenges of spreading infectious pathogens. It is in this context that the practicing physician should be aware of the growing threats of emergent respiratory infections and their pandemic potential. Severe acute respiratory syndrome-coronavirus (SARS-CoV), avian influenza viruses H5N1, H7N9, and H10N8, swine-origin influenza A H1N1, human adenovirus-14, and the Middle East respiratory syndrome-coronavirus (MERS-CoV) are a few of the viruses that are concerning for relatively high mortality rates and the potential to result in pandemics [46]. Some of these are zoonotic, affect the lower respiratory tract, and have high morbidity and mortality rates. The most effective methods of preventing these emerging viruses at this time include the scrupulous adherence to respiratory precautions and an awareness of regional spread and outbreaks [32].

Prevention

Respiratory viral infections are predominantly transmitted through infected droplets. Following general hygienic practices helps to decrease transmission. These include regular hand hygiene, minimizing contact with sick individuals, and avoiding the sharing of personal items. Following “cough etiquette,” including covering the nose and mouth with a tissue while coughing, proper disposal of tissue, and prompt hand washing, is also shown to decrease spread of respiratory infections [47]. Currently, an effective vaccine is available only for influenza. Other measures of prevention include antivirals for close contacts of those with influenza and use of palivizumab, a monoclonal antibody, in high-risk individuals to prevent respiratory syncytial virus (RSV) infections.

Family and Community Issues

Antibiotic resistance in the healthcare setting is a growing threat to public health, and, as of 2013, two million people become infected and 23,000 people die each year from antibiotic-resistant infections [48]. In part, antibiotic-resistant infections stem from the prescribing of antibiotics when they are not needed, as in the case of viral respiratory tract infections. To avoid inappropriate use of antibiotics for viral

DOI 10.1007/978-1-4939-0779-3_41-1

infections, physicians should strive to adhere to clinical guidelines and decision-support tools combined with laboratory testing when indicated to determine risk for a bacterial infection.

Commonly, patients or parents will request antibiotics for viral infections, and physicians can feel pressured to prescribe antibiotics to address social stressors such as school or work absences. In this situation, family doctors need to clearly communicate that treating viral infections with antibiotics is ineffective and may be harmful. Additionally, pointing out negative or reassuring findings on exam and giving a specific diagnosis ("viral pharyngitis" or "viral upper respiratory infection" instead of "just a virus") can help with counseling patients. Lastly, it is important to acknowledge the suffering and discomfort caused by viral infections, to proactively offer treatment for symptoms, and to outline the normal course of the illness with clear indications for follow-up if symptoms do not resolve within an expected timeframe [49].

Rhinosinusitis and Tonsillopharyngitis

Kathryn M. Hart*
Department of Family and Community Medicine, University of Maryland School of Medicine, Baltimore, MD, USA

Rhinosinusitis

Sinusitis is characterized by mucosal inflammation of the sinuses which is almost always accompanied by inflammation of the nasal passages. Since nasal mucosa is contiguous with paranasal sinus mucosa, the term *sinusitis* is often used interchangeably with *rhinosinusitis* [1]; the latter term will be used in this chapter. Rhinosinusitis can be acute (less than 4 weeks' duration), subacute (4–12 weeks), or chronic (greater than 12 weeks) [2].

Epidemiology

Rhinosinusitis is extremely common; in a 2008 national survey, 1 in 7 adults reported having been diagnosed with rhinosinusitis in the previous 12 months [3]. The estimated prevalence of chronic rhinosinusitis in the USA ranges from 2 % to 16 % [4]. Women are disproportionally affected compared to men, and both acute and chronic rhinosinusitis are most prevalent in middle-aged adults compared to any other age group [3]. Primary care physicians and specialists manage rhinosinusitis with equivalent technical efficiency, with primary care physicians providing less costly treatment [5]. Chronic rhinosinusitis has a high economic burden; in 2007, total expenditures in the United States were estimated to be $8.6 billion [4].

Risk Factors

Rhinosinusitis is more common in patients with comorbid asthma and allergic rhinitis [6]. Other predisposing factors are listed in Table 1 [2]. Studies investigating the relationship between smoking and rhinosinusitis are conflicting [4].

Microbiology

The vast majority of cases of acute rhinosinusitis are viral in etiology. The incidence is high; the average adult is affected an estimated 2–5 times per year. Secondary bacterial infection is uncommon and complicates only 0.5–2 % of cases [7]. The two most common bacterial causes of rhinosinusitis are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Less common pathogens include *Moraxella catarrhalis*, *Streptococcus pyogenes*, and *Staphylococcus aureus* [1].

Clinical Presentation

The classic clinical presentation of rhinosinusitis includes nasal congestion, mucopurulent nasal discharge, facial pain or pressure, and fever. Associated symptoms include anosmia, hyposmia, aural fullness, cough, headache, and toothache [2, 8].

Diagnosis

The diagnosis of bacterial rhinosinusitis is clinical. Previous studies have used criteria based on symptoms (Table 2) [1, 9]. The diagnosis of rhinosinusitis requires the presence of at least two major criteria or one

*Email: khart@som.umaryland.edu

DOI 10.1007/978-1-4939-0779-3_42-1

Table 1 Predisposing factors for rhinosinusitis

Systemic	Viral URI
	Allergy/asthma
	Immotile cilia (e.g., Kartagener syndrome)
	Cystic fibrosis
	Immune disorder
	Gastrointestinal reflux disease
Local	Trauma
	Rhinitis
Mechanical	Choanal atresia
	Deviated septum
	Polyps/foreign body
	Hypertrophy of turbinate or adenoids

Source: Ref. [2]

Table 2 Conventional criteria for the diagnosis of sinusitis

Major symptoms	Minor symptoms
Purulent anterior nasal discharge	Headache
Purulent or discolored posterior nasal discharge	Ear pain, pressure, fullness
	Halitosis
Nasal congestion or obstruction	Dental pain
Facial congestion or fullness	Cough
Hyposmia or anosmia	Fever (for subacute or chronic sinusitis)
Fever (for acute sinusitis only)	Fatigue

Source: Ref. [1]

major plus two minor criteria. Diagnoses made by these criteria correlated with radiographic evidence of sinus involvement, but did not distinguish between a bacterial and viral etiology. For this reason, the Infectious Diseases Society of America (IDSA) has adopted guidelines based on characteristic patterns that take into account duration, severity, temporal progression, and "double sickening" to differentiate bacterial from viral rhinosinusitis [1]. The diagnosis of bacterial rhinosinusitis requires any of the three following clinical presentations: (a) *persistent* symptoms or signs compatible with acute rhinosinusitis lasting for at least 10 days without improvement, (b) *severe* symptoms or either fever of at least 39 °C or purulent nasal discharge or facial pain lasting for at least 3–4 consecutive days at the onset of illness, and (c) *worsening* symptoms or signs including new onset of fever, headache, or increased nasal discharge that were initially improving 5–6 days following an upper respiratory infection.

Physical Exam

The IDSA guidelines mentioned previously are the cornerstone of diagnosis, but the following physical exam findings support a suspected diagnosis of bacterial rhinosinusitis: purulent nasal discharge, nasal obstruction, sinus tenderness, nasal mucosal erythema and edema, and/or infraorbital venous pooling [8, 10, 11]. No validated studies have examined the predictive value of specific signs more likely to be associated with a bacterial rather than viral etiology [1].

DOI 10.1007/978-1-4939-0779-3_42-1

Diagnostic Imaging and Laboratory Studies

Although rhinosinusitis is a clinical diagnosis, there are particular settings in which imaging may be useful. Plain radiography is universally recognized as neither useful nor cost effective [12]. Computed tomography is the preferred imaging modality. Imaging may be considered in the following situations: severe or recurrent disease, suspected complications, immunocompromised states, and prior to surgery [7–9]. It should be noted, however, that the severity of symptoms does not correlate with CT findings [13]. Nasal endoscopy, while it allows for better visualization of nasal purulence compared to anterior nasal exam, is often impractical for primary care physicians and is not essential for diagnosis [12]. Cultures obtained from endoscopic aspirates or sinus puncture are considered the gold standard for confirming a bacterial versus viral etiology [14] in order to identify causative organisms in patients with complicated rhinosinusitis, who are immunosuppressed, or who are refractory to treatment [7, 9]. However, these tests are invasive and lack feasibility in primary care settings [14].

Treatment

Antimicrobial Therapy

Antibiotic therapy should be initiated once the clinical diagnosis of bacterial rhinosinusitis has been established by the IDSA criteria previously described. Antibiotics initiated in this setting shorten the duration of illness, offer more prompt symptomatic relief, and prevent recurrence and suppurative complications [1]. Standard-dose amoxicillin-clavulanate (875 mg/125 mg twice daily), rather than amoxicillin alone, is recommended as first-line treatment due to the high prevalence of β-lactamase-producing *H. influenzae* [1]. However, standard-dose amoxicillin-clavulanate is inadequate for penicillin-non-susceptible (PNS) *S. pneumoniae*, which have a mutation in the penicillin-binding protein 3 that is unaffected by the addition of a β-lactamase inhibitor. Thus, in patients with certain risk factors, high-dose amoxicillin-clavulanate (i.e., 2 g/125 mg twice daily) is recommended as first-line treatment. Risk factors for PNS include residence in geographic regions with high (≥10 %) endemic rates of PNS *S. pneumoniae*, severe infection (e.g., signs of systemic toxicity with fever of ≥39 °C [102 °F]), age >65 years, recent hospitalization, patients who are immunocompromised, or antibiotic use within the past month [1]. Respiratory fluoroquinolones are also highly active against PNS *S. pneumoniae* and *H. influenzae*, but are not superior to β-lactam antibiotics [1]. Options for patients with β-lactam antibiotic allergy include doxycycline (100 mg twice daily or 200 mg daily), levofloxacin (500 mg daily), or moxifloxacin (400 mg daily).

Adjunctive Therapies

Symptomatic management may include analgesics, antipyretics, intranasal glucocorticoids, hydration, and possibly nasal saline irrigation [1, 15].

Intranasal glucocorticoids are helpful in reducing or relieving symptoms compared to placebo when used as monotherapy or as an adjunct to antibiotics. Higher doses have a stronger effect on relieving symptoms without a significant increase in adverse effects [16].

The benefit of nasal saline irrigation is unclear, but is relatively safe and may reduce time off from work. Minor adverse effects, such as dry nose and irritation, are experienced by fewer than half of users. The optimal concentration, frequency, volume, and technique for irrigation have not been determined [17].

There is little evidence that topical or oral decongestants provide benefit as adjunctive treatment to antibiotics based on symptom scores, histologic changes, or radiographic findings [1]. However, some patients do report symptomatic improvement, so decongestants may be considered for patients with viral rhinosinusitis for whom antibiotic therapy is not indicated [1]. Topical decongestants should be used with

DOI 10.1007/978-1-4939-0779-3_42-1

caution, however, since they can trigger rebound congestion and inflammation, especially when used for more than 3 days.

There is also scant evidence that antihistamines provide significant relief in patients with rhinosinusitis, but they may be beneficial in patients with concomitant allergic rhinitis [1]. First-generation antihistamines should be avoided in the elderly, who are more susceptible to anticholinergic effects [18].

Both decongestants and antihistamines should be avoided in children under 2 years of age. The use of these medications may increase morbidity, and a small number of deaths in this population have been reported [19].

Mucolytics thin mucus and improve nasal drainage, but there is no evidence supporting their effectiveness in rhinosinusitis [8].

Systemic steroids or leukotriene inhibitors may be considered in chronic rhinosinusitis, especially in patients with nasal polyps [2, 20, 21].

Chronic Rhinosinusitis

There is a lack of consensus about treatment for chronic rhinosinusitis, likely due to its inherent heterogeneity [12, 15]; therefore referral to an otolaryngologist is warranted in cases of acute rhinosinusitis that do not improve after maximal medical therapy or recurrent infections (defined as 3–4 episodes per year) [1, 7]. In such cases, predisposing medical conditions, such as immunodeficiency, allergic disease, diabetes mellitus, or immotile cilia syndrome, should be considered.

Surgical Management

Surgery is reserved for patients with chronic rhinosinusitis who have failed maximal medical therapy (typically defined as therapy for 4–6 weeks) or who have underlying anatomic abnormalities as well as clear demonstration of rhinosinusitis by CT imaging or endoscopic examination [2, 15]. 90 % of adult patients experience symptomatic improvement after surgery. Surgical intervention is rarely indicated in children [2].

Tonsillopharyngitis

The subjective complaint of sore throat is often described clinically as pharyngitis, but multiple contiguous anatomic structures – including the tonsils, adenoids, nasopharynx, posterior pharynx, uvula, and soft palate – are stretched with swallowing and perceived as odynophagia when inflamed [22]. Thus, in this chapter, discomfort, pain, and scratchiness of the throat will be referred to as one entity: *tonsillopharyngitis*.

Epidemiology

Tonsillopharyngitis is among the most common reasons for primary care visits [23], accounting for 6 % of visits by children to family physicians and pediatricians [24]. Throat-related symptoms were the 14th most common reasons for physician visits in 2010 [25] and the 9th most common reason for emergency room visits in 2011 [26]. The estimated economic burden of group A streptococcal tonsillopharyngitis specifically has been estimated to be between $224 and $539 million annually, with children missing an average of 4.5 days of school and parents missing 1.8 days of work in order to care for them [27].

DOI 10.1007/978-1-4939-0779-3_42-1

Etiologies

Infectious

The most common cause of tonsillopharyngitis is viral infection. Common viruses include rhinovirus, coronavirus, adenovirus, parainfluenza, influenza, echovirus, reovirus, respiratory syncytial virus, herpes simplex virus, coxsackievirus, and Epstein-Barr virus [28, 29]. Bacterial causes include streptococci, *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae*. Group A streptococcus (GAS) is the most common bacterial cause. Thrush, most commonly caused by *Candida* species, can also cause sore throat [28].

Inflammatory

Inflammatory causes of tonsillopharyngitis include laryngopharyngeal reflux, allergic rhinitis with postnasal drip, foreign body, chronic mouth breathing, mucositis, muscle tension dysphonia, vocal cord granuloma, rheumatoid arthritis, gout, pemphigus, and Kawasaki's disease [28].

Clinical Presentation of GAS Tonsillopharyngitis

The characteristic presentation of GAS tonsillopharyngitis includes abrupt onset of sore throat, odynophagia, fever, headache, abdominal pain, nausea, and vomiting [23]. Physical exam findings may include tonsillopharyngeal erythema and exudate, a beefy-red and swollen uvula, soft palate petechiae, anterior cervical lymphadenopathy, and a scarlatiniform rash.

Laboratory Diagnosis

The Infectious Disease Society of America (IDSA) guidelines recommend testing for GAS tonsillopharyngitis by rapid antigen detection test (RADT) and/or culture to distinguish GAS from viral tonsillopharyngitis, except when features such as oral ulcers, rhinorrhea, cough, and/or hoarseness strongly suggest a viral etiology [30]. In children and adolescents, a throat culture should be sent after a negative RADT to rule out infection, since the sensitivity of throat culture is 90–95 % while that of the RADT is 70–90 %. A backup culture is not necessary after a positive RADT, as the test is highly specific (approximately 95 %) [30].

Complications of GAS Tonsillopharyngitis

Suppurative Complications

Peritonsillar abscesses are most commonly seen in patients between ages 20–40 with recurrent or chronic tonsillopharyngitis that has been inadequately treated [29]. The abscess develops in the space between the lateral aspect of the tonsil and the pharyngeal constrictor muscle [29]. Peritonsillar abscess can be difficult to distinguish from severe tonsillopharyngitis, as both can present with asymmetric tonsillar hypertrophy and drooling. The hallmark of peritonsillar abscess, however, is trismus, which results from inflammation and pus that has tracked above the pterygoid region [28]. Other characteristic symptoms include a muffled "hot potato" voice, severe unilateral sore throat, edema of the ipsilateral soft palate, and deviation of the uvula [28]. When the diagnosis is in question, ultrasonography (transcutaneous or intraoral) or CT imaging can aid in identifying an abscess and thus distinguish from peritonsillar cellulitis [31]. If there is concern for spread of infection into the lateral neck, contrast imaging with MRI or CT is indicated.

Retropharyngeal abscesses affect younger children, typically between 1 and 5 years of age. The characteristic presentation includes neck stiffness, dysphagia, odynophagia, and high fever following

DOI 10.1007/978-1-4939-0779-3_42-1

an upper respiratory infection [28]. The airway can be affected and, depending on the degree of obstruction, can manifest as a muffled voice, drooling, trismus, stridor, tachypnea, or tripod positioning. There may be external neck swelling. Immediate consultation with an otolaryngologist and anesthesiologist is warranted given the potential for life-threatening airway compromise. Once the patient is stable, imaging should be obtained. CT of the neck with contrast is the modality of choice [28].

Other suppurative complications of GAS tonsillopharyngitis include cervical lymphadenitis, sinusitis, otitis media, and mastoiditis [32].

Nonsuppurative Complications

Nonsuppurative complications of GAS tonsillopharyngitis are postinfectious and immunologically mediated and include acute rheumatic fever, acute poststreptococcal glomerulonephritis, and poststreptococcal reactive arthritis [32].

Treatment of GAS Tonsillopharyngitis

All patients with uncomplicated GAS tonsillopharyngitis should be treated with antibiotic therapy. Treatment accomplishes three objectives: (1) prevention of both suppurative complications and acute rheumatic fever; (2) decreased communicability, which allows patients to return to work or school; and (3) shortened duration of illness [23]. First-line treatment options are penicillin (250 mg twice to three times daily in children, 250 mg four times daily or 500 mg twice daily in adolescents and adults) or amoxicillin (50 mg/kg daily with a maximum dose of 1,000 mg/day) for 10 days. Penicillin-allergic patients may be treated with a first-generation cephalosporin such as cephalexin (20 mg/kg/dose twice daily with a maximum of 500 mg/dose) or cefadroxil (30 mg/kg daily with a maximum of 1,000 mg/day) for 10 days, clindamycin (7 mg/kg/dose twice daily with a maximum of 300 mg/dose) for 10 days, or azithromycin (12 mg/kg once daily with a maximum of 500 mg/day) for 5 days [30]. There is no evidence that one antibiotic is superior to another [33].

Adjunctive treatment with acetaminophen or nonsteroidal anti-inflammatory agents can be useful in controlling fever and pain [23]. Complementary therapies, including acupuncture, herbal and dietary supplements, have not been shown to be beneficial [34].

Treatment of peritonsillar abscess includes hydration, incision and drainage under local anesthesia, and antibiotics aimed at both aerobic and anaerobic bacteria [28, 29]. Tonsillectomy is indicated if incision and drainage fails to completely drain the abscess [29].

Treatment of retropharyngeal abscess involves immediate intravenous antibiotic therapy aimed at gram-positive aerobes and anaerobes [28]. Small (<2 cm) retropharyngeal abscesses can often be treated with antibiotics alone, but if a patient fails to improve after 48 hours of therapy, incision and drainage is indicated [28].

Chronic Carriers, Recurrent Infection, and Asymptomatic Contacts

Chronic carriers have GAS present in the pharynx but no immunologic response to the organism [30]. In temperate climates during the winter and spring months, as many as 20 % of school-aged children are asymptomatic carriers. Antimicrobial therapy is generally not indicated in these patients, as they are not likely to be contagious or develop suppurative or nonsuppurative complications [30]. However, there are certain indications where eradication of GAS carriage should be considered: during a community outbreak of acute rheumatic fever, in the context of poststreptococcal glomerulonephritis or invasive GAS infection, during an outbreak of GAS tonsillopharyngitis in a closed or partially closed community, the presence of a personal or family history of acute rheumatic fever, in a family with significant anxiety about GAS infections, or when tonsillectomy is under consideration solely because of carriage [30].

DOI 10.1007/978-1-4939-0779-3_42-1

There are several explanations for patients with recurrent episodes of GAS tonsillopharyngitis: repeated viral infections in a chronic GAS carrier, noncompliance with antibiotic therapy, or a new infection acquired from a close contact [30]. Test of cure is not indicated, as antibiotic failure is rare if taken as prescribed. If "ping-ponging" of infection within a family is suspected, simultaneously obtaining RADT or cultures from all members and treating those that are positive is reasonable [30].

Asymptomatic contacts should not be treated. Antibiotic prophylaxis of household contacts with penicillin has not been shown to decrease the incidence of developing subsequent GAS tonsillopharyngitis [30].

Tonsillectomy

Tonsillectomy is one of the most common procedures performed in the United States, with more than 530,000 carried out on children younger than 15 years of age each year [35]. The American Academy of Otolaryngology recommends tonsillectomy for children with 7 episodes or more of tonsillopharyngitis in the past year, 5 episodes or more per year in the past 2 years, or 3 episodes or more per year in the past 3 years. Tonsillectomy has been shown to improve quality of life in children with recurrent tonsillopharyngitis by reducing the number of throat infections, healthcare provider visits, and need for antibiotic therapy [35]. Children who have more severe or frequent episodes of tonsillopharyngitis may benefit more from tonsillectomy than less severely affected children [35]. Tonsillectomy may also be beneficial in patients with multiple antibiotic allergies, PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, and adenitis), and recurrent peritonsillar abscess [35]. There is limited evidence on the effectiveness of tonsillectomy in adults with recurrent tonsillopharyngitis [36], but there is some retrospective data that there is a positive and prolonged effect on quality of life, especially with regards to younger patients with more severe symptoms [37].

Sexually Transmitted Diseases

Courtney Kimi Suh*
Department of Family Medicine, Loyola University Stritch School of Medicine, Maywood, IL, USA

General Principles

Definition/Background

Sexually transmitted infections (STIs) are of great healthcare and economic burden to the United States. In fact, most sexually active men and women will contract an STI at least once in their lifetime [1]. According to 2008 US estimates, STIs resulted in 16 billion dollars of direct medical costs [2]. Additionally, 19.7 million new infections occurred, with 50 % occurring in individuals 15–24 years of age [3]. Overall, human papillomavirus (HPV) is the most common sexually transmitted infection. Other common infections include chlamydia, gonorrhea, hepatitis B virus, herpes simplex virus type 2 (HSV-2), human immunodeficiency virus (HIV), syphilis, and trichomoniasis [1]. Chlamydia, gonorrhea, and syphilis infection rates continue to increase in numbers over the years although this may be related to improved screening practices [4]. Family physicians have a responsibility to improve prevention, detection, and treatment of STIs in order to decrease transmission and prevent subsequent morbidity and mortality.

Chlamydial Infection

Chlamydia is a sexually transmitted infection caused by *Chlamydia trachomatis*, which can infect the cervix, urethra, rectum, lung, and eye. Chlamydia is a frequent cause of pelvic inflammatory disease (PID), infertility, chronic pelvic pain, and ectopic pregnancy and may facilitate the transmission of HIV in women. In men, chlamydia commonly leads to epididymitis and orchitis [5]. Chlamydia continues to be the most commonly reported STI in the United States since 1994, with approximately 1.4 million cases in 2012. Females have higher rates of infection and, in both genders, the highest rates of infections occur in the 15–24-year age group [4].

Screening

The CDC recommends that all sexually active women younger than 25, and older women with risk factors, such as multiple or new sexual partners, be screened annually [6]. In addition, all pregnant women should be screened at least once in pregnancy. The CDC recommends annual screening for men who have sex with men (MSM) but makes no recommendation regarding men who have sex with women [7].

Clinical Presentation

Female patients may complain of vaginal discharge, bleeding, or dysuria; however, most chlamydia infections are asymptomatic. Physical exam may reveal mucopurulent or purulent discharge with or without a friable cervix; however, a normal exam does not exclude infection. Male patients are also predominantly asymptomatic, with only 2–4 % of infected men reporting symptoms such as penile discharge, pruritus, or dysuria. Male and female patients who have receptive anal intercourse may present

*Email: cosuh@lumc.edu

DOI 10.1007/978-1-4939-0779-3_43-1

with rectal pain, discharge, or bleeding [5]. Additionally, male and female patients who engage in orogenital sex may have pharyngeal infection, but symptoms are rare [8].

Diagnosis

In women, diagnostic testing can be performed through endocervical samples, provider or patient-collected vaginal samples, or urine specimens. In men, specimens from a urethral swab or urine sample are sufficient. Pharyngeal and rectal specimens can also be taken for cell culture when appropriate. Nucleic acid amplification testing (NAAT) is the most sensitive testing available and can be used on almost all specimens; however, research is still in progress to confirm the efficacy of NAAT in pharyngeal and rectal swabs. NAAT, cell culture, direct immunofluorescence, EIA, and nucleic acid hybridization can all be used on endocervical and urethral samples. All documented chlamydia infections must be reported to the CDC.

Treatment

Patients should be treated for chlamydia immediately after diagnosis of chlamydia or gonorrhea for presumed coinfection with chlamydia. Patients should be instructed to abstain from sex for 7 days after completion of therapy and until sexual partner(s) have also been treated adequately. Ideally, the antibiotics should be available to the patient at the physician's office, and the first dose should be directly observed. Patients who are likely to fail to comply with a 7-day course of treatment should receive single-dose treatment. All patients who test positive for chlamydia should also be evaluated for other sexually transmitted infections and instructed on the need for repeat testing for chlamydia in 3 months to identify reinfection. Repeat testing for chlamydia earlier than 3 weeks after treatment is not recommended because of the persistence of nonviable antigen leading to falsely positive results [7].

The following antibiotics and regimens are recommended [7]:

Preferred regimen	Dosage	Instructions	Duration
Azithromycin	1 g	By mouth in a single dose	1 day
Doxycycline	100 mg	By mouth twice daily	7 days
Alternative regimen			
Erythromycin base	500 mg	By mouth four times daily	7 days
Erythromycin ethyl succinate	800 mg	By mouth four times daily	7 days
Levofloxacin	500 mg	By mouth once daily	7 days
Ofloxacin	300 mg	By mouth twice daily	7 days

Pregnancy

Pregnant women with chlamydia can be treated safely with azithromycin or the alternative erythromycin dosing if needed. Additionally, infected pregnant patients should be retested 3 weeks after treatment for a test of cure and undergo repeat testing in the third trimester of pregnancy if risk factors are present [7].

Sexual Partners

Ideally, the patient's sexual partner should undergo clinical evaluation, testing, and counseling regarding STIs in addition to antibiotic therapy. However, in certain circumstances, the family physician may consider implementing Expedited Partner Therapy (EPT). EPT is the clinical practice of treating sexual partners with prescriptions or medications without requiring a clinical examination or testing. This is particularly useful when sexual partners will not obtain appropriate medical care for any reason. The option to use EPT is legal in most states within the United States; however, a family physician must check their own state law prior to engaging in EPT. Additionally, EPT should only be utilized in very selective

DOI 10.1007/978-1-4939-0779-3_43-1

cases in the MSM population due to the risk of concurrent undiagnosed HIV and should never be used in partners who may be at risk for severe infections [9].

Gonorrhea

Gonorrhea infection is caused by the bacteria *Neisseria gonorrhoeae*, a gram-negative diplococcus. Gonorrhea can cause urogenital, anorectal, pharyngeal, and conjunctival infections [4]. Like chlamydia, it can lead to PID and its complications and increase the risk of transmission of HIV in women [10]. Additionally, *N. gonorrhoeae* can cause disseminated gonococcal infections and, rarely, endocarditis and meningitis [4]. Even more concerning, gonorrhea is becoming resistant to fluoroquinolones and cefixime, limiting options for treatments [11, 12]. There were 334,826 cases of gonorrhea reported in the United States in 2012, making it the second most common reported STI [4]. There are a slightly higher number of cases in women than men. This infection occurs most commonly in persons between the ages of 15 and 24 years.

Screening

The CDC recommends that all sexually active women with risk factors, such as multiple or new sexual partners, be screened annually [4]. In addition, all pregnant women with risk factors should be screened at least once in pregnancy. The CDC recommends annual screening for men who have sex with men (MSM) but makes no recommendation regarding men who have sex with women [7].

Clinical Presentation

Like chlamydia, gonorrhea is often asymptomatic in women. Women may present with vaginal discharge, dysuria, pelvic pain, or frequent heavy menses. Physical exam may reveal mucopurulent discharge, cervicitis, or adnexal or cervical tenderness. Unlike chlamydia, 90 % of men with gonorrhea exhibit symptoms including dysuria, penile discharge, or epididymitis. A rectal infection can be asymptomatic or result in anal pruritus, rectal pain, mucopurulent discharge, and tenesmus. A pharyngeal infection from oral sex can cause pharyngeal symptoms. Disseminated gonococcal infection affects 0.4–3 % of patients with gonorrhea. Patients may present with asymmetric joint pain and swelling along with a skin rash. In rare cases, untreated disease progression causes perihepatitis, meningitis, or endocarditis [10].

Diagnosis

Neisseria gonorrhoeae can be detected by culture and nucleic acid hybridization tests (NAAT) with female endocervical and male urethral swab specimens. NAATs can be used to detect infection in the above samples as well as provider or self-collected vaginal swabs and urine specimens. NAATs are not FDA approved for use in the rectum, pharynx, and conjunctiva; however, some NAATs are used in certain specialty laboratories due to their superior sensitivity over culture. In cases of suspected treatment failure, a culture must be performed to determine bacterial sensitivities. All documented gonorrheal infections must be reported to the CDC [7].

Treatment

Patients should be treated for gonorrhea immediately after diagnosis and also screened for chlamydia, syphilis, and HIV. Patients should be instructed to abstain from sex until completion of treatment and resolution of symptoms in both the patient and their sexual partner(s). The antibiotics should be available to the patient at the physician's office, and the first dose should be directly observed. Patients who are likely to fail to comply with a 7-day course of treatment should receive single-dose treatment. All patients

DOI 10.1007/978-1-4939-0779-3_43-1

who test positive for gonorrhea should also be evaluated for other sexually transmitted infections and instructed on the need for repeat testing for gonorrhea in 3 months to identify reinfection. If there is concern for treatment failure, a culture must be checked in order to confirm antibiotic susceptibility. If treatment failure is discovered, the case should be discussed with the local health department [7].

Because of emerging antibiotic resistance, the preferred treatment option for patients infected with gonorrhea is ceftriaxone 250 mg intramuscularly in one dose with the addition of either azithromycin 1 g orally in a single dose or doxycycline 100 mg by mouth twice daily for 7 days. If ceftriaxone cannot be used, there are two alternative options: cefixime 400 mg orally in one dose with either azithromycin 1 g orally in one dose or doxycycline 100 mg orally twice daily for 7 days or azithromycin 2 g orally in a single dose.

Penicillin/Cephalosporin Allergy

If the patient has an allergy to cephalosporins, azithromycin 2 g orally in one dose is administered. Because of concerns for resistance, any patient treated with an alternative therapy should have a test-of-cure culture 2 weeks after treatment and any positive cultures should undergo antimicrobial susceptibility testing [12].

Pregnancy

Infected pregnant women should be treated with the recommended or alternative dosing of a cephalosporin as well as concurrent treatment with azithromycin for presumptive coinfection with chlamydia. If the patient cannot tolerate a cephalosporin, she may take azithromycin 2 g orally in one dose as an alternative.

Sexual Partners

The patient's last sexual partner or any partners within 60 days prior to symptoms must be empirically treated for gonorrhea and chlamydia. Partners should undergo clinical evaluation, testing, and counseling regarding STIs in addition to treatment; however, they may be eligible for EPT [9]. Since the preferred treatment requires an intramuscular injection of ceftriaxone, partners can be treated with an alternative therapy [9]. Similar to chlamydia, EPT should only be utilized in very selective cases in populations at high risk for HIV and should never be used in partners who are exhibiting signs of more severe infection [9].

Trichomoniasis

Trichomoniasis, caused by the protozoan *Trichomonas vaginalis*, is the most common nonviral sexually transmitted infection in the world [13]. An estimated 3.1 % of the US population is infected but only 30 % develop symptoms of infection [4]. Although asymptomatic, trichomonas can result in infertility, pelvic inflammatory disease, and adverse birth outcomes in infected pregnant women. In addition like gonorrhea and chlamydia, trichomoniasis increases the sexual transmission of HIV, at least doubling the risk of acquiring HIV infection [13].

Screening

The CDC recommends screening for trichomonas in women with risk factors such as history of new or multiple partners, sexually transmitted infections, exchanging sex for payment, or injecting drugs [7].

DOI 10.1007/978-1-4939-0779-3_43-1

Clinical Presentation

Often, men infected with trichomonas exhibit no symptoms; however, they may present with nongonococcal urethritis. Women may complain of malodorous yellow-green vaginal discharge with associated vulvar irritation; however, most remain asymptomatic [7].

Diagnosis

For women, trichomoniasis may be diagnosed through direct microscopy of a wet prep of vaginal secretions; however, this is only 60–70 % sensitive. Two point-of-care vaginal swab tests are available: OSOM Trichomonas Rapid Test uses immunochromatographic technology and Affirm VP III uses DNA hybridization, both with sensitivities of >83 %. *T. vaginalis* is also detected through culture of vaginal secretions, liquid-based pap cytology, and NAAT or PCR of vaginal, endocervical, or urine specimens [7].

The diagnosis of *T. vaginalis* in men is more challenging, as wet preparation is not sensitive. Urethral swab, urine, or semen can be cultured; however, NAATs as discussed above can be used to detect *T. vaginalis* in men with superior sensitivity [7].

Treatment

Trichomonas is treated with metronidazole 2 g by mouth in a single dose or tinidazole 2 g by mouth in a single dose. An alternative treatment is to give metronidazole 500 mg by mouth twice daily for 7 days. Topical metronidazole is not an acceptable option, as it is less than 50 % effective in treating trichomoniasis. Patients should be instructed to abstain from sex until completion of treatment and resolution of symptoms in both the patient and their sexual partner(s). Although retesting for trichomonas 3 months after treatment can be considered in women, there are no guidelines recommending this. If *T. vaginalis* persists despite treatment and it is not due to reinfection, it should be considered to be resistant. If a patient fails metronidazole 2-g single-dose treatment, the patient can be treated with metronidazole 500 mg orally twice daily for 7 days. If patients fail this treatment, they should be given tinidazole or metronidazole at 2 g orally daily for 5 days. Failure to respond to these treatments may require specialty consultation.

In addition, patients with a critical allergy to nitroimidazoles, which include both metronidazole and tinidazole, must undergo desensitization [7].

Pregnancy

Vaginal trichomoniasis has been associated with adverse pregnancy outcomes, particularly premature rupture of membranes, preterm delivery, and low birth weight. Women can be treated with 2 g metronidazole in a single dose at any stage of pregnancy. Unfortunately, treatment with metronidazole has not been shown to reduce adverse birth outcomes, and, in fact, some limited data shows a possibility of increased prematurity or low birth weight after treatment with metronidazole [14, 15]. Treatment should be offered to prevent respiratory or genital infection of the newborn as well as further transmission to sexual partners; however, therapy can be deferred until after 37 weeks of gestation in asymptomatic women [7].

Sexual Partners

As with gonorrhea and chlamydia, the patient's sexual partner should undergo clinical evaluation, testing, and counseling regarding STIs in addition to treatment; EPT can be considered if necessary [9].

DOI 10.1007/978-1-4939-0779-3_43-1

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is characterized by inflammation of the upper genital tract in the female, which can include endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. It is the most common gynecologic reason for inpatient hospital admission in the United States [16]. Multiple organisms have been implicated in PID including *N. gonorrhea*, *C. trachomatis*, *G. vaginalis*, and anaerobes such as *B. fragilis*, most likely beginning with an ascending infection originating in the cervix and creating the opportunity for entry of other organisms [6, 13]. It is important to recognize PID in its early stages to avoid complications such as tubo-ovarian abscess, pelvic peritonitis, and long-term sequelae [7]. About 20 % of women with PID become infertile, 40 % develop chronic pain, and 1 % of those who do conceive have an ectopic pregnancy [16].

Clinical Presentation

Women may present with a wide range of symptoms ranging from no symptoms to vaginal bleeding or discharge to pelvic pain [6, 13].

Diagnosis

The diagnosis is typically made clinically. On exam, the patient should have at least cervical motion tenderness, uterine tenderness, or adnexal tenderness. Leukorrhea, vaginal discharge, cervical exudate, cervical friability, temperature >101 F (38.3 C), and elevated ESR or CRP are often seen. Known gonorrhea or chlamydia infection may also assist in making the diagnosis. However, because of the potentially severe consequences of untreated PID, these criteria are not required to make a clinical diagnosis. Sometimes, symptoms can present subtly, and the condition can have an indolent course. In cases requiring more invasive testing, PID may be diagnosed through ultrasound or MRI imaging showing thickened and fluid-filled Fallopian tubes or a tubo-ovarian complex, histopathology demonstrating endometritis, or laparoscopy showing abnormalities consistent with PID. Of note, negative cervical cultures do not exclude PID, as cultures may not be positive with upper reproductive tract disease [7].

Treatment

Women with PID can be treated in the outpatient setting unless they have signs of severe infection including nausea, vomiting, or high fever, are pregnant, cannot tolerate or have failed oral antibiotic therapy, have a tubo-ovarian abscess, or need observation to rule out a possible surgical emergency. Those who require hospitalization should receive parenteral antibiotic therapy for 24–48 h after clinical improvement. Those with a tubo-ovarian abscess should be observed for at least 24 h. Options for parenteral treatment are listed in the table below [7].

Parenteral Treatment

Recommended regimen	Subsequent oral therapy	Tubo-ovarian abscess present
Cefotetan 2 g IV every 12 h *or* Cefoxitin 2 g IV every 6 h *and* Doxycycline 100 mg PO/IV every 12 h	Doxycycline 100 mg every 12 h for a total of 14 days	Add oral clindamycin 450 mg every 6 h for a total of 14 days *or* Metronidazole 500 mg every 8 h for a total of 14 days
Clindamycin 900 mg IV every 8 h *and*	Doxycycline 100 mg orally twice daily for a total of 14 days	Choose clindamycin over doxycycline for subsequent oral therapy

(*continued*)

DOI 10.1007/978-1-4939-0779-3_43-1

Recommended regimen	Subsequent oral therapy	Tubo-ovarian abscess present
Gentamicin at 2 mg/kg of body weight in an IV or IM loading dose, followed by 1.5 mg/kg every 8 h	*or* Clindamycin 450 mg four times daily for a total of 14 days	
Alternative therapy		
Ampicillin/sulbactam 3 g IV every 6 h *and* Doxycycline 100 mg orally or IV every 12 h	Doxycycline 100 mg orally twice daily for a total of 14 days	Add oral clindamycin 450 mg every 6 h for a total of 14 days *or* Metronidazole 500 mg every 8 h for a total of 14 days

See Ref. [7]

All other patients can be treated in an outpatient setting with similar efficacy. If a patient fails to improve after 72 h, they should be reevaluated to reconfirm PID as the cause of their symptoms and then treated with parenteral antibiotics. Options for outpatient treatment are listed below [7].

Outpatient Treatment Options

Recommended regimen	Additional anaerobic coverage
Ceftriaxone 250 mg IM in a single dose *and* Doxycycline 100 mg PO twice daily for 14 days	+/− Metronidazole 500 mg PO twice daily for 14 days
Cefoxitin 2 g IM in a single dose *and* Probenecid 1 g PO in a single dose *and* Doxycycline 100 mg PO twice daily for 14 days	+/− Metronidazole 500 mg PO twice daily for 14 days
Parenteral third-generation cephalosporin (ceftizoxime or cefotaxime) *and* Doxycycline 100 mg PO twice daily for 14 days	+/− Metronidazole 500 mg PO twice daily for 14 days
Alternative	**Additional anaerobic coverage**
Ceftriaxone 250 mg IM in a single dose *and* Azithromycin 1 g PO once a week for 2 weeks	+/− Metronidazole 500 mg PO twice daily for 14 days

See Ref. [7]

Patients who are treated for PID should also be tested for HIV. If a patient tests positive for gonorrhea or chlamydia, he or she should be retested 3–6 months after treatment.

Penicillin Allergy

If a patient has a severe penicillin allergy and cannot take a cephalosporin, the patient can be treated with parenteral therapy or given a course of fluoroquinolone listed below, although this is not ideal given the emergence of quinolone-resistant *Neisseria gonorrhoeae*. Patients empirically treated with quinolones or another alternative regimen for gonorrhea should have a culture performed for test of cure 14 days after treatment. This will allow susceptibility testing of the organism in case of treatment failure [7].

DOI 10.1007/978-1-4939-0779-3_43-1

Treatment in Patients with Severe Penicillin/Cephalosporin Allergy

PCN allergic recommendation	Additional anaerobic coverage	If *N. gonorrhoeae* present is quinolone-resistant or has unknown susceptibility
Levofloxacin 500 mg orally once daily for 14 days *or* Ofloxacin 400 mg twice daily for 14 days	+/− Metronidazole 500 mg PO twice daily for 14 days	Add azithromycin 2 g orally as a single dose

See Ref. [7]

Sexual Partners

The patient's last sexual partner or any partners within 60 days prior to symptoms must be empirically treated for gonorrhea and chlamydia [7].

Syphilis

Syphilis is caused by the spirochete *Treponema pallidum*. Rates of syphilis dropped to their nadir in 2000; however, rates have been increasing since then. In 2012, a total of 15, 667 cases of primary and secondary syphilis were reported to the CDC, with 75 % of cases reported in MSM populations [4].

Clinical Presentation

Primary Syphilis

A patient infected with syphilis may present with a painless chancre at the site of inoculation anywhere from 10 to 90 days after infection. The chancre typically progresses from a macule to a papule to an ulcer with a clean base, and multiple lesions may occur. These lesions will resolve without treatment in 3 to 6 weeks. The patient may also demonstrate regional bilateral rubbery and painless lymphadenopathy [17].

Secondary Syphilis

The lesions of secondary syphilis occur several weeks after the primary chancre appears and may persist for weeks to months. There may be overlap between primary and secondary stages. Patients most commonly present with non-pruritic maculopapular skin rash involving the palms and soles; flat patches of mucocutaneous lesions in the oropharynx, larynx, and genitals; and lymphadenopathy. Patients may also demonstrate condyloma lata, which are heaped-up, wartlike papules in warm intertriginous areas. Infection can involve the liver and kidney with occasional splenomegaly. Alopecia, typically in a patchy "moth-eaten" pattern, may be seen [17].

Tertiary Syphilis

Although progression to tertiary syphilis remains rare, failure to consider the diagnosis is common. Late syphilis can occur within 1–20 years of infection and is characterized by gummatous syphilis, cardiovascular problems, or CNS disease. Gummas are granulomatous lesions that destroy mucosa, soft tissue, cartilage, bone, eye, and viscera. Cardiovascular complications include ascending aortic aneurysm, aortic insufficiency, or coronary ostial stenosis [17].

Neurosyphilis

Neurosyphilis occurs when *T. pallidum* spreads to the central nervous system, can occur at any stage of syphilis, and may be asymptomatic. Neurosyphilis can be divided into early and late stages. Early

DOI 10.1007/978-1-4939-0779-3_43-1

neurosyphilis can occur months to a few years after infection, presenting with acute syphilitic meningitis or meningovascular syphilis. Late neurosyphilis occurs decades after infection and may present as general paresis or tabes dorsalis. Ocular involvement can occur at any stage of neurosyphilis [17].

Latent Syphilis

Latent syphilis occurs when the host suppresses the infection so that no clinical signs or symptoms are apparent and serology is positive for syphilis. This can occur at any point within the primary and secondary stages of syphilis. Latent syphilis is categorized as early latent syphilis, late latent syphilis, or latent syphilis of unknown duration. Early latent infection denotes syphilis infection of less than 1-year duration. In order to classify a patient as having early latent syphilis, certain criteria must be met to assure that infection occurred within the past 1 year. If there has been previous serologic testing within the past year, there must be either seroconversion from previously negative results or a fourfold increase in titer. Additionally, latent syphilis can be categorized as early if the patient exhibited unequivocal symptoms of primary or secondary syphilis within the past year and initiated sexual contact with a confirmed infectious case of syphilis within the past year or the only possible sexual exposure occurred within the past year. Late latent syphilis, on the other hand, is infection that has been present for greater than 1 year. If there is uncertainty about the duration of latent syphilis, it is classified as latent syphilis of unknown duration, and treatment guidelines for late latent syphilis should be followed. Syphilis is much less sexually transmissible in the latent phase [17].

Diagnosis

Definitive diagnosis of syphilis is through dark-field examination of lesion exudate or tissue for *T. pallidum*. Presumptive diagnosis is also possible through the use of serologic testing; however, serologic testing may not be positive in early stages of primary syphilis. Additionally, both nontreponemal and treponemal tests must be used in conjunction in order to avoid false-positive results. Although the CDC recommends initial testing beginning with nontreponemal tests such as Venereal Disease Research Laboratory (VDRL) or RPR, some labs implement initial testing through treponemal tests. Because of the high rate of false positives, particularly in those with autoimmune conditions, older age, and injection drug users, positive nontreponemal tests must be confirmed with treponemal tests such as fluorescent treponemal antibody absorbed (FTA-ABS) tests, *T. pallidum* passive particle agglutination (TP-PA) assay, various EIAs, and chemiluminescence immunoassays. Nontreponemal tests are reported quantitatively which allows for identification of disease activity, reinfection, and response to treatment through trends in titers, which may eventually decline to become nonreactive over time. In contrast, treponemal tests should not be used to evaluate disease activity or treatment response, as the test will likely remain reactive regardless of treatment. Serologic testing cannot be used to reliably distinguish between stages of syphilis. All positive tests must be reported to local or state health departments [7].

Treatment

Primary and Secondary Syphilis

All stages of syphilis are preferentially treated with parenteral penicillin G. Primary and secondary syphilis in nonpregnant adults is treated with a one-time dose of benzathine penicillin G 2.4 million units intramuscularly. Within 24 h after treatment, patients may experience the Jarisch–Herxheimer reaction, an acute febrile illness with associated headache, myalgia, fever, or other symptoms, which can be treated symptomatically with fever and pain reducers as needed. In addition, all patients with syphilis should be tested for HIV infection. To assure appropriate treatment, patients need to have repeat evaluation and serology 6 and 12 months following treatment to assure a fourfold decrease in

DOI 10.1007/978-1-4939-0779-3_43-1

nontreponemal titer. In patients with an inadequate treatment response, the clinician should consider additional clinical and serologic follow-up, retreatment with weekly penicillin G 2.4 million units intramuscularly for 3 weeks, retesting for HIV, and CSF analysis [7].

If a patient is penicillin allergic and not pregnant, treatment with doxycycline 100 mg orally twice daily for 14 days or tetracycline 500 mg four times daily for 14 days is appropriate. Ceftriaxone 1 g daily IM or IV for 10–14 days may be an effective treatment for early syphilis. Azithromycin in a single 2 g oral dose is effective for treating early syphilis; however, due to resistance patterns, it should only be used when penicillin or doxycycline treatment is not feasible [7].

Tertiary Syphilis

Tertiary syphilis should be treated with benzathine penicillin G 2.4 million units intramuscularly given at 1-week intervals for a total of three doses. Before treatment, patients affected with tertiary syphilis should undergo a CSF examination. Guidelines for further follow-up of these patients vary; infectious disease consultation might be considered in these cases [7].

Neurosyphilis

Neurosyphilis is treated with aqueous crystalline penicillin G 3–4 million units IV every 4 h or 18–24 million units daily through continuous infusion for 10–14 days. There is also an alternative regimen of procaine penicillin 2.4 million units IM once daily with probenecid 400 mg orally four times daily for 10–14 days. After completion of this initial 10–14 days of treatment, patients may also receive additional benzathine penicillin 2.4 million units IM once per week for up to 3 weeks. All patients with neurosyphilis must be tested for HIV. Follow-up CSF studies to document a decrease in leukocytes must be completed at 6-month intervals to assure treatment response. The CSF cell count and protein should be normal after 2 years. If a patient is penicillin allergic, ceftriaxone 2 g IV or IM daily for 10–14 days is administered. If the patient cannot receive ceftriaxone due to cross-reactivity or other reasons, the patient must be desensitized [7].

Latent Syphilis

Early latent syphilis should be treated with benzathine penicillin G 2.4 million units intramuscularly in a single dose. Late latent syphilis or latent syphilis of unknown duration should be treated with benzathine penicillin G 2.4 million units intramuscularly given at 1-week intervals for a total of three doses. The management of a patient who misses one of the weekly doses of benzathine penicillin is unclear; however, current guidelines suggest that 10–14 days between benzathine penicillin doses may be acceptable. If intervals are longer than 14 days, the entire course of therapy must be restarted. Additionally, if the patient is pregnant and misses any of the three doses of penicillin, she must restart the entire course of therapy in order to reduce the possibility of transmitting syphilis to the fetus. If a nonpregnant patient with early latent syphilis is penicillin allergic, the patient may be treated with doxycycline 100 mg orally twice daily for 14 days or tetracycline 500 mg four times daily for 14 days. If the nonpregnant penicillin-allergic patient has late latent syphilis or latent syphilis of unknown duration, the patient should be treated with doxycycline 100 mg orally twice daily or tetracycline 500 mg orally four times daily for 28 days. Quantitative nontreponemal serologic tests should be repeated at 6, 12, and 24 months. If the titers increase fourfold, a high titer ($>$1:32) fails to decline at least fourfold in this time period, or if clinical signs of syphilis emerge, the patients must undergo CSF examination and be retreated for latent syphilis [7].

DOI 10.1007/978-1-4939-0779-3_43-1

Pregnancy

In order to prevent congenital syphilis in the fetus, all pregnant patients must be treated with penicillin as indicated above based on her stage of syphilis. If a pregnant patient is penicillin allergic, she must be desensitized and treated with the appropriate dosing regimen of penicillin.

Sexual Partners

Any sexual partner of a patient diagnosed with syphilis should be evaluated clinically and serologically. Because early stages of primary syphilis may be seronegative, partners of patients with syphilis who were exposed within 90 days preceding the diagnosis of primary, secondary, early latent, or latent syphilis of unknown duration with a high nontreponemal titer ($\geq$1:32) should be treated presumptively. If it has been greater than 90 days since exposure through sexual contact with a patient diagnosed with primary, secondary, early latent, or latent syphilis of unknown duration with a high nontreponemal titer ($\geq$1:32), the partner should be presumptively treated if serologic testing is not immediately available and follow-up is uncertain. In all other cases, the patient can be treated based on clinical and serologic findings. For the purposes of treatment of partners only, latent syphilis of unknown duration can be assumed to be early latent disease if titers are high. Long-term sex partners of patients with latent syphilis can be evaluated clinically and serologically for syphilis and treated based on their results [7].

Genital Warts

Genital warts affect 1 % of all sexually active men and women in the United States. Human papillomavirus or HPV causes genital warts and 90 % of genital warts are caused by HPV 6 or 11 [16]. Genital warts are transmitted through vaginal, anal, and oral contact and can be transmitted even if there are no visible warts [7]. Genital warts are highly contagious, as approximately 2/3 of sexual partners will develop clinical genital warts within 9 months of sexual contact [19].

Clinical Presentation

While genital warts are typically asymptomatic, patients may complain of pain or pruritus at the sites of the warts. Genital warts appear as flat papular lesions or pedunculated cauliflower-like growths on the anogenital mucosa [18].

Diagnosis

Diagnosis of genital warts is clinical, but a biopsy can be taken for definitive diagnosis if the patient is immunocompromised; if the lesions are atypical, pigmented, indurated, fixed, bleeding, or ulcerated; or if they worsen or fail to improve with standard treatment [7].

Treatment

Genital warts are treated for resolution of symptoms or for cosmetic concerns. While treatment is not definitive, it will often result in wart-free periods. Additionally, although treatment of warts has been shown to reduce HPV viral load, no studies have demonstrated that this reduces transmission to uninfected partners [7]. When left untreated, warts may resolve, remain the same in appearance, or increase in size and number [7].

There are multiple topical treatment modalities for genital warts; these can be divided into patient-applied and provider-applied, listed below. Clinicians can determine which method is most beneficial based on wart size, location, patient preference, and cost. Most genital warts respond within 3 months of

DOI 10.1007/978-1-4939-0779-3_43-1

therapy. Side effects of treatment include hypo- or hyperpigmentation, scarring, chronic pain, and rarely systemic effects [7].

Patient-Applied

Treatment	Instructions	Reapplication/ duration	Side effect	Special considerations	Safety in pregnancy
Podofilox 0.5 % solution or gel	Apply twice daily for 3 days followed by 4 treatment-free days	Repeat as needed for up to 4 cycles	Mild to moderate pain or local irritation	Wart area must be less than 10 cm^2, and volume of podofilox used must be 0.5 mL or less per day	Uncertain
Imiquimod 5 % cream	Once daily at bedtime three times a week; washed off 6–10 h after application	Treatment for maximum of 16 weeks	Redness, irritation, induration, ulceration/erosion, and vesicles		Uncertain
Sinecatechin 15 % ointment	Apply 0.5 cm strand of ointment to each wart three times daily	Treatment for maximum of 16 weeks	Erythema, pruritus/ burning, pain, ulceration, edema, induration, and vesicular rash	Avoid sexual contact while ointment is applied Not recommended for HIV-infected persons, immunocompromised persons, or persons with clinical genital herpes	Uncertain

See Ref. [7]

Provider-Applied

Treatment	Application instructions	Interval	Special considerations	Side effect	Safety in pregnancy
Cryotherapy with liquid nitrogen	May be used with topical or injected local anesthesia as needed	Every 1–2 weeks		Immediate pain, subsequent necrosis, and blistering	Safe
Podophyllin resin 10–25 %	Air-dry fully before contact with clothing. Wash area 1–4 h after application	Every week as needed	Application should be limited to $<$0.5 mL of podophyllin or an area of $<$10 cm^2 of warts per session. The area to which treatment is administered should not contain any open lesions or wounds		Unknown
Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80–90 %	Apply a small amount to wart; allow to dry fully (denoted by white frosting) before patient sits or stands	Every week as needed	Neutralize with soap or sodium bicarbonate if pain is intense. Use powdered talc, sodium bicarbonate, or liquid soap preparations if excess is applied		Unknown
Surgical removal by trained provider	Local anesthesia, electrocautery, or tangential excision with fine scissors or scalpel, laser, or curettage		Surgical therapy is most beneficial for patients who have a large number or area of genital warts		Safe

See Ref. [7]

DOI 10.1007/978-1-4939-0779-3_43-1

Alternative regimens include intralesional interferon, photodynamic therapy, and topical cidofovir. These treatment options presently have insufficient data and more side effects. Cervical warts must be biopsied to exclude high-grade squamous intraepithelial lesion, and there are other treatment recommendations for warts located in the urethral meatus, vagina, and anus [7].

Pregnancy

Pregnant patients with genital warts have limited options for treatment. Pregnant patients with genital warts can proceed through typical prenatal care and delivery; however, cesarean may be required for genital warts which may obstruct the pelvic outlet or cause excessive bleeding during vaginal delivery. Pregnant patients should be informed that rarely the HPV subtypes 6 and 11 associated with genital warts could be passed on to offspring, causing respiratory papillomatosis. It is uncertain exactly how the virus is transmitted from the mother; therefore, there are currently no recommendations to prevent transmission [7].

Prevention

As with all sexually transmitted infections, HPV infection and genital warts can be prevented through abstinence or limitation of the number of sexual partners. Condoms are not fully protective against HPV because all genital areas are not completely covered by a condom. The quadrivalent human papillomavirus vaccine is active against most subtypes of HPV that cause genital warts in men and women. Male circumcision is also thought to reduce transmission of HPV [7].

Genital Herpes

Herpes simplex virus (HSV) 1 or 2 causes genital herpes, although genital infection is most often caused by HSV-2. More than 50 million people in the United States suffer from HSV-2. Once contracted, HSV is a chronic lifelong illness with varying number of reoccurrences and intermittent viral shedding [7]. HSV infection increases the risk of HIV acquisition two- to fourfold due to the presence of open ulcerations in the mucosa. Rarely, HSV can result in disseminated infection, pneumonitis, hepatitis, blindness, encephalitis, and aseptic meningitis. The chronicity of HSV often causes psychological distress and stigma [20].

Screening

General screening for genital herpes is not recommended [7].

Clinical Presentation

Most patients have no or only mild symptoms. 87 % of infected individuals are unaware of being infected. Patients may notice one or more vesicles on the mucosa of the genitals, rectum, or mouth, which eventually ulcerate. These ulcerations may take 2–4 weeks to heal. Incubation after exposure ranges from 2 to 12 days; the primary outbreak is usually longer with more systemic symptoms of malaise, fever, and lymphadenopathy. Subsequent outbreaks may be preceded by hours to days of a prodromal tingling or shooting pains in the legs, hips, and buttocks before appearance of lesions [20].

Diagnosis

If a patient has a genital ulcer or mucocutaneous lesion, cell culture or polymerase chain reaction assay (PCR) should be taken from a vesicle. PCR assays are the most sensitive and can be used to determine the presence of HSV1 or HSV2. Because viral shedding is intermittent, a negative culture or PCR does not exclude a diagnosis of HSV infection. Tzanck preparation can be used; however, it is discouraged, as it is

DOI 10.1007/978-1-4939-0779-3_43-1

not sensitive or specific. A patient's serum can also be tested for type-specific serum antibodies. HSV-1 serum antibodies may be caused by a previous oral infection that often occurs in childhood. Patients with HSV-2 are more likely to have recurrences and have increased occurrences of asymptomatic viral shedding [7].

Treatment

Antiviral therapy can be given for suppression or treatment of individual episodes. There is no treatment available to completely eradicate latent virus or alter the course of recurrences after medication is discontinued [7].

A patient's first clinical episode of genital herpes should be treated with antiviral therapy due to the severity and length of symptoms. Patients may have severe genital ulcers and systemic or neurologic involvement. Treatment options for immune-competent individuals include acyclovir 400 mg orally three times daily, acyclovir 200 mg orally five times daily, famciclovir 250 mg orally three times daily, or valacyclovir 1 g orally twice daily, all with a duration of 7–10 days. Longer courses could be considered if needed for incomplete healing [7].

Suppressive therapy reduces the frequency of outbreaks by 70–80 % and decreases transmission of HSV-2 to sexual partners. There are several options for suppressive therapy in immunocompetent individuals including acyclovir 400 mg orally twice daily, famciclovir 250 mg orally twice daily, valacyclovir 500 mg orally once daily, or valacyclovir 1 g orally once daily; however, famciclovir may be less effective for the suppression of viral shedding [7]. Additionally, if a patient has 10 or more outbreaks per year, valacyclovir at the 500 mg dosing may be less effective. Because the frequency of outbreaks tends to diminish over time, the provider and patient should consider reevaluating the need for suppressive therapy yearly.

Patients who choose episodic therapy should be instructed to initiate therapy within 24 h of the first lesion or during the outbreak prodrome and given an ample supply of medication for convenient immediate therapy. Patients can take acyclovir 400 mg orally three times daily for 5 days or acyclovir 800 mg orally twice daily for 5 days or acyclovir 800 mg orally three times daily for 2 days or famciclovir 125 mg twice daily for 5 days, famciclovir 1,000 mg orally twice daily for 1 day, famciclovir 500 mg once followed by 250 mg twice daily for 2 days, valacyclovir 500 mg orally twice daily for 3 days, or valacyclovir 1 g orally once daily for 5 days [7]. Additionally, research shows that single-day, high-dose patient-initiated episodic therapy may offer yet another option for episodic treatment. Both famciclovir 1500 mg in a single dose and famciclovir 750 mg twice daily for one day have been shown to significantly reduce time of healing. The convenience of one-day treatment may improve patient adherence and may be particularly effective in patients who experience fewer recurrent episodes [21].

Rarely, patients develop severe disease which requires hospitalization and parenteral therapy with acyclovir 5–10 mg/kg IV every 8 h for 2–7 days or until clinical improvement is observed. The patient should then continue oral antiviral therapy to complete at least 10 days of total therapy [7].

Pregnancy

Pregnant women infected with herpes risk transmitting infection to the fetus, particularly if primary infection occurs later in pregnancy or active infection is present during labor [7]. Herpes infection requires multiple measures to decrease this risk, as newborn infection can be fatal. Patients are given antiviral therapy starting at 36 weeks of gestation and are delivered via cesarean if active lesions or prodromal symptoms are present during labor [20].

DOI 10.1007/978-1-4939-0779-3_43-1

Sexual Partners

Sexual partners of patients with HSV should be evaluated and counseled. If sexual partners are asymptomatic, physicians can offer type-specific serologic testing for HSV infection to determine HSV status [7].

STD Prevention

As a family physician, prevention of sexually transmitted infectious is critical not only through screening, early diagnosis, and treatment of infected patients and their partners but also through primary prevention by addressing behavior change. The family physician must always take a thorough sexual history and provide information on risk reduction in a compassionate and nonjudgmental manner. Patients can reduce risk of infection through abstinence, limiting the number of sexual partners, correct use of barrier methods such as male and female condoms, and vaccination when available. Additional information is available through the curriculum provided by the CDC on STD/HIV Prevention Training Centers found at http://www.stdhivpreventiontraining.org [7].

In the arc of a generation, physicians, chemists and pharmacists, nurses, public health specialists, community activists, patients, and their loved ones have transmuted an illness of immense suffering and certain death into a largely manageable illness, dependent on resources and health information.

Family physicians have a large role to play: patient care, transmission-reduction education, community health education, patient advocacy, and public health measures all require our expertise.

Up-to-date information is essential; protocol changes and new medications require frequent updates to provide the best care:

www.ucsf.edu/hivcntr (warm-line: Ron Goldschmidt)

www.cdc.gov

www.hivatis.org

www.iasusa.org

Natural History

The illness was first described on June 5, 1981, with the landmark *Morbidity and Mortality Weekly Report* www.cdc.gov/MMWR describing five cases of *Pneumocystis carinii* (now named *Pneumocystis jirovecii*) in Los Angeles, California. It is interesting to note that the MMWR writers note "all the above observations suggest the possibility of a cellular-immune dysfunction related to common exposure that predisposes individuals to opportunistic infections" well before the HIV was identified and named. In 1983 scientists discovered the virus that causes AIDS. The virus was at first named the human T-cell lymphotropic virus type III/lymphadenopathy-associated virus, and this name was later changed to HIV (human immunodeficiency virus). Of the retrovirus family, evidence of infection in humans has now been found as early as 1959 from human remains and lab specimens in central Africa. Two genetic strains of HIV have been identified, type 1 and type 2. HIV type 1 is the cause of 98 % of all infections worldwide.

HIV is spread from person to person through blood, semen, vaginal secretions, and breast milk. Sweat, urine, tears, and saliva are not considered infectious.

Sexual intercourse and needle sharing account for the vast majority of cases, with a smaller number of infants infected at birth or through breast milk. Rare accidental transmission via needle stick or blood exposure remains an occupational hazard as well.

The majority of cases in the USA are from man-to-man (men who have sex with men, MSM) transmission. Worldwide, sexual contact is the most common mode of transmission, though it is thought that parenteral sources such as injection drug use account for about 20 % of cases. Risk reduction can be achieved with "safer sex" (barriers or behaviors precluding semen or blood exposure), condom use, clean needles, and universal precautions for healthcare workers.

New data suggests that reduction of an infected person's viral load to an undetectable level dramatically reduces transmission, and recently preexposure prophylaxis (PrEP) for the prevention of infection of a person at risk (e.g., an uninfected person intimate with an infected partner) has been approved by the US Public Health Service Task Force. www.USPHTF Clinical Practice Guidelines 2014.

The HIV, upon transmission and breach of host defenses, infects the host CD4 cells (helper/inducer lymphocytes) of the immune system, and by enzymatic insertion into the CD4 replication genome replicates HIV, then destroying the CD4 cell. When enough CD4 cells have been destroyed, host defenses are severely weakened, and eventually the infected person becomes ill developing infections, malnutrition, and malignancies. Without treatment, the average time from infection to the development of an AIDS-defining illness is approximately 10 years, although this interval may vary greatly [1].

Screening and Diagnosis

An estimated 250,000 persons in the USA have HIV infection and are not aware they are infected [2]. In the USA, females, blacks, Hispanic/Latinos, and older individuals are more likely to

experience delays in diagnosis [3]. The public health implications of this are enormous: studies demonstrate that patients who are aware of their infection take much more care not to transmit the virus to others [4]. Worldwide, more than 30 million people are infected [5]. More than 75 % of all people infected with HIV are in sub-Saharan Africa, and AIDS is the leading cause of death for people between the ages of 15 and 59. Also, more than 60 % of people living with HIV in low-resource settings are unaware of their status [6].

HIV Testing

Both patient and the public health are served by HIV discovery: and the newest recommendations by the USPSTF recommend one time screening of all adults from ages 15 to 65 unless they decline (opt out) testing. Pregnant women should be tested as early as possible in each pregnancy, and for those at higher risk, should be tested in the third trimester as well [7]. High-risk individuals, for example, injection drug users, MSM, people who trade sex for money or drugs, and sexual partners of those with HIV, should be tested at least yearly [8]. In addition, testing should be considered in patients presenting with signs of immunodeficiency, weight loss, malignancies, and herpes zoster. In lower-resource settings where there is high prevalence of HIV, the WHO recommends universal screening in clinical settings and community-based screening where possible [9].

In the USA, direct to consumer in-home HIV testing is available utilizing saliva and is becoming more widely available in other countries [10]. Although the current home-based tests may vary in sensitivity and specificity and lack the option for direct patient counseling and assessment, research suggests that a variety of options for testing and reporting of results is important to remove some of the many barriers that currently exist to testing for the virus [11].

In June of 2014, the Centers for Disease Control and Prevention (CDC) updated testing recommendations, in which laboratories conducting initial testing for HIV should use an FDA-approved antigen/antibody combination immunoassay that detects HIV-1 and HIV-2 antibodies and HIV-1 p24 antigen to screen (a so-called fourth-generation assay). The p24 antigen is typically detectable by 1 to 2 weeks after transmission of the virus. If that testing is indeterminate, HIV nucleic acid (viral load) testing is employed. Western blot confirmation is no longer recommended [12].

Symptoms by HIV Stage

Acute HIV Infection

Acute infection represents a burst of viral replication and is marked by fatigue, fever, myalgias, and arthralgias, often with sore throat and swollen lymph nodes. Acute infection resembles acute mononucleosis. Symptoms occur typically 1–4 weeks after transmission, and because of the relatively nonspecific presentation, are often overlooked, and the disease goes undiagnosed. At this time, the HIV viral load is very high, but antibodies are typically not yet present, leading to an important diagnostic pearl: if suspected, acute HIV is best confirmed by obtaining HIV RNA (PCR "viral load") testing at this stage. Seroconversion, or the development of positive HIV antibodies, occurs within 4 weeks to 6 months after exposure and very rarely longer than 6 months after exposure.

Asymptomatic HIV Infection

After the acute HIV infection, patients usually enter a period of time lasting 7–10 years with minimal or no symptoms. The viral load declines to a low-level "set point" and the CD4 count slowly declines. The public health is in danger here: an infected person may have no knowledge or symptoms of his/her infection, and intimate partners are at risk.

AIDS

The viral load rises, CD4 count drops, symptoms start to appear: at first: rashes "red itchy bump

disease" thrush, lymphadenopathy, fatigue, night sweats, weight loss, herpes zoster, recurrent vaginal yeast infections, and unexplained diarrhea are common. When CD4 counts drop below 200 cells/mm^3 (normal range 400–2000 cells/mm^3) or if diagnosed with severe infection or malignancy (candidiasis of lungs or esophagus, invasive cervical cancer, cryptococcosis, cryptosporidiosis, tuberculosis, Mycobacterium avium, *Pneumocystis jirovecii*, progressive multifocal leukoencephalopathy, salmonella septicemia, toxoplasmosis, cytomegalovirus, chronic or severe herpes simplex, histoplasmosis, isosporiasis, Kaposi's sarcoma, lymphoma, wasting syndrome, or HIV-related encephalopathy), "AIDS" is now diagnosed. While useful in the past in determining severity of disease and for determination of disability, this designation is less useful today, but serves as a reminder of the importance of specific prophylaxis against *Pneumocystis jirovecii*, Mycobacterium avium, and toxoplasmosis in persons with advanced immune decline.

Conditions commonly seen in primary care that might raise suspicion for HIV in an individual not thought to be at risk otherwise might include: recurrent community-acquired pneumonia, multidermatomal herpes zoster or herpes zoster in a young individual, generalized lymphadenopathy, otherwise unexplained peripheral neuropathy, recurrent or severe herpes simplex, or extensive molluscum contagiosum. Patients with persistent fevers or cytopenias of unknown etiology should also be strongly considered for HIV testing.

Medical Management

Preexposure Prophylaxis (PrEP)

Both the CDC and the World Health Organization (WHO) recommend the daily use of preexposure prophylaxis (PrEP) for those individuals at higher than average risk for acquisition of HIV, along with other methods of risk reduction. This includes groups such as MSM, people in discordant relationships (where only one partner has HIV), and injection drug users at risk. PrEP has been shown to be highly efficacious in preventing virus transmission among those who are adherent to therapy [13]. Currently, only one antiretroviral combination (tenofovir/emtricitabine marketed as Truvada) is approved for this indication by the US FDA.

General guidelines for the use of PrEP include: exclusion of acute or chronic HIV infection before beginning therapy, repeating HIV testing at least every 3 months during therapy, obtaining baseline renal function testing, and rechecking renal function at least every 6 months [14].

Acute or Suspected Exposure (Postexposure Prophylaxis [PEP])

In primary care, it is not uncommon to encounter patients who have had an actual or suspected exposure to HIV. These exposures may be encountered in an occupational environment (such as a needlestick) or otherwise be potentially exposed through body fluid contact such as may occur with unprotected sex, sexual assault, or the use of shared needles or injection equipment. Levels of risk for transmission are variable and in the USA can be assessed by calling the National Clinician's Post Exposure Prophylaxis Hotline 24 h a day at 888-448-4911. While postexposure prophylaxis is generally safe, toxicity, sometimes severe, can occur which may include toxic epidermal necrolysis and severe hepatitis. Therefore it is important to weigh the risks and benefits of postexposure prophylaxis with each patient. Also, in cases where prophylaxis is unsuccessful, the selection of resistant strains of HIV may make treating the infection problematic. Therefore, PEP use should be avoided in people who have ongoing or repeated HIV exposures [15].

Postexposure prophylaxis should be started within 72 h of exposure and continued for 28 days. Optimally, a three-drug regimen is chosen to take into account factors such as efficacy, pill burden, and dosing frequency as well as cost. CDC and WHO recommendations are for three drugs, although WHO also states that two-drug regimens, while not optimal, are acceptable [16].

Table 1 Testing for HIV-positive patients

Test	Frequency
HIV serology – confirmatory	Initial visit
CD4 count	Initially, then at 3–6 months. If stable (see text) once yearly
Viral load	Initially, then every 3 months when on treatment. If stable (see text) once yearly
HIV resistance genotype	Initially and after treatment failure prior to change in treatment regimen
Complete blood count	Initially, then every 3–6 months
Lipid panel and serum glucose	Initially, then every 3–6 months
Chemistry panel	Initial visit, then every 6–12 months
Toxoplasma serology	Initially and if CD4 falls below 100 cells/mm^3
CMV and VZV serology	Initial visit
Syphilis serology	Initially, then yearly
Chlamydia and gonorrhea urine NAAT	Initially and every 3 months to yearly depending on risk
G-6-PD screening	Initial visit
PPD	Initially, then yearly if negative
Hepatitis serologies (A, B, and C)	Initial visit
Pap smear	Initially in 6 months and yearly if negative *x*2
HLA-B*5701	If consideration is being given to the use of abacavir
Coreceptor tropism assay	If consideration is being given to the use of a CCR5 antagonist

Evaluation of Patients with HIV

After diagnosis and upon entry into care, every patient should have: a complete medical history, physical examination, and laboratory evaluation, along with counsel about transmission, self-care, intimate partner care, and the public health. A baseline evaluation, as recommended by the Health and Human Services Panel on Antiretroviral Guidelines for Adults and Adolescents, includes: HIV antibody testing; CD4 T-cell count; plasma HIV RNA (viral load); CBC; chemistry profile; transaminase levels; BUN/Cr; urinalysis; serology for hepatitis A, B, and C viruses; glucose; lipids; and HIV genotypic resistance testing [17]. In addition, some authorities recommend HLA-B 5701 to screen for abacavir sensitivity; a tropism test (for future consideration of a CCR5 antagonist); chlamydia, gonorrhea, and syphilis testing; PPD/QuantiFERON/chest X-ray testing for TB (a PPD is considered positive for those living with HIV when induration measures 5 mm rather than the usual 10 mm); toxoplasmosis antibody testing; CMV and varicella serology; cervical pap smear (at 6-month intervals initially, then yearly after two negative smears); and an anal/rectal pap smear (to screen for HPV-related squamous cell carcinoma of the anus) [18] (Table 1).

Pregnancy testing is important for women of child-bearing age, along with a discussion of contraception and avoidance of HIV treatment regimens that may be teratogenic.

A patient-centered multidisciplinary approach is often necessary: HIV is a complex illness with enormous emotional and physical implications. Patients still fear job loss, insurance and medical cost, shunning and isolation, along with the fears surrounding illness and death or a foreshortened life. Coinfections, substance use, housing concerns, and mental illness may also be present,

and patients often are best served by a team and sometimes an advocate. Family physicians can be the advocate and team leader: continuity of care is good medicine against the fear of abandonment and shunning, and comprehensive care is critical to long-term health.

Immunizations include annual influenza vaccination, pneumococcal vaccination, hepatitis A and B vaccination for those vulnerable, latent or active TB treatment, and treatment for hepatitis B and/or C for those found to be coinfected. Live vaccinations are generally contraindicated: these include oral poliomyelitis, herpes zoster, varicella, measles, mumps, and rubella (at least until the immune system is restored). Human papillomavirus (HPV) vaccination, though not studied in persons living with HIV, is considered in some circumstances.

The CD4 count and HIV viral load are repeated at 1 month after initiation of highly active antiretroviral therapy (HAART), after therapy changes, then at 3–6 months, and later annually at follow-up visits for those found to have achieved:

- A consistently suppressed viral load (ideally fewer than 20 copies or "undetectable")
- A stable protective CD4 count (more than 300 cells/mm^3)
- No active illnesses

HAART

Despite the very rare suggestion of "cures" in the past, control of HIV is the goal for now. Very quickly after medical suppression of viral replication ceases, most patients experience a rapid return of detectable and increasing viral loads, then the inevitable destruction of CD4 cells and return to illness. Viral reservoirs are postulated, perhaps in the central nervous system, spleen, or marrow, that permit the virus to remain in dormancy during treatment, only to rapidly reappear "when the coast is clear."

The CDC now recommends that ALL patients infected with HIV, independent of viral load or CD4 count at diagnosis, are treated with highly active antiretroviral therapy (HAART), with the goal being an undetectable viral load and normal range CD4 count. Linkage into care and adherence to medications can be difficult and uneven, but clarification of treatment regimens and once-daily combination medications provide some promise for achieving this goal. Medications break viral replication through the use of replication enzyme inhibitors. The classes include:

- Nucleoside reverse transcriptase inhibitors (e.g., zidovudine, lamivudine)
- Protease inhibitors (e.g., tipranavir, ritonavir)
- Non-nucleoside reverse transcriptase inhibitors (e.g., efavirenz, nevirapine)
- Integrase strand transfer inhibitors (e.g., raltegravir, dolutegravir)
- Fusion inhibitors (enfuvirtide)
- CCR5 antagonists (maraviroc)

Four different fixed dose once-daily combination products are currently available. All treatment recommendations include medications from more than one enzyme group, to provide added protection against development of viral resistance and resurgence. Full treatment guidelines can be found at www.aidsinfo.nih.gov/guidelines and telephone guidance from the National HIV Consultation Service of the Department of Family and Community Medicine at San Francisco General Hospital at (800):933–3413.

Generic medication is now available in some of the enzyme inhibitor classes, costs are becoming more approachable, and AIDS Drug Assistance Programs (ADAP or Ryan White programs) and manufacturer patient assistance programs can help to provide medication access. Clinical research trials may appeal to some, and monitoring and medications are provided for those who consent to participate.

CD4 count monitoring and HIV viral loads after treatment has begun may suggest nonadherence or the development of resistance.

If a formerly undetectable viral load begins to rise and then becomes undetectable again, viral emergence from reservoirs may be to blame, or a period of nonadherence may be the cause. Protracted and continuing viral load elevation suggests nonadherence or the development of viral resistance, repeating a genotype resistance assay and switching to a different HAART regimen, is in order, along with a determination of the cause of nonadherence if possible, and a remedy. Despite the enormous risk of nonadherence, daily lifetime treatment is difficult and easily sabotaged. Depression, substance use, relationship stresses, homelessness, mental illness, transportation, insurance, and medication access can make adherence difficult for patients and medical caregivers alike.

Management of the Immunocompromised Patient

Prophylaxis

If the CD4 counts fall below 200 cells/mm^3, prophylaxis against *Pneumocystis jirovecii* (also abbreviated as PCP, referring to the former name of *Pneumocystis carinii*) with daily trimethoprim-sulfamethoxazole (TMP-SMX 1 DS tab daily) is recommended. For the sulfa allergic, dapsone and pentamidine can be considered. TMP-SMX has the added benefit for prophylaxis against toxoplasmosis. Below a count of 50 CD4 lymphocytes/mm^3, azithromycin is recommended for prophylaxis against *Mycobacterium avium* complex (MAC).

HIV Wasting and Fatigue

Muscle loss, weight loss, fatigue, and fevers/night sweats commonly affect those living with HIV. Causes can include: sepsis, infection, malignancy, malnutrition, malabsorption, vitamin D deficiency, and low testosterone. Thorough investigation including cultures, imaging, and lab work is required. Lipodystrophy, with adipose abdomens, and "buffalo hump," with facial wasting and lower extremity wasting is a hallmark of HIV and in some cases may be caused by antiretroviral therapy [19].

Skin and Mucosa

Often the first signs of HIV are evident on the skin. From common "red itchy bump disease" seborrhea, candida, and intertrigo to malignancies such as basal cell skin cancers, squamous cell cancers, melanomas, and Kaposi's sarcoma, aggressive culture, consultation, and biopsy are wise. Rapid expansion of molluscum contagiosum reflects declining immune defenses, as does the appearance of varicella zoster. Onychomycosis of finger and toenails may also be seen [20]. More commonly cellulitis, MRSA skin infections, felons, herpes infections, and hairy leukoplakia may make an appearance.

Eyes

In patients with CD4 counts of less than 50–100 cells/μL, 6–12 monthly ophthalmology exams are recommended by a provider skilled in HIV eye manifestations, which may include cytomegalovirus infection and risk of blindness [21].

Pulmonary

From the beginning of awareness about HIV, lungs have been an early and frequent host to disease. Tuberculosis treatment is a major and worrisome worldwide focus of HIV care. Pneumocystis heralds immune decline, and the lungs can also be host to Kaposi's sarcoma, Mycobacterium avium (and others), and numerous other forms of pneumonia. Pneumocystis usually requires bronchoscopy for definitive diagnosis, but is inferred by the characteristic pattern on chest X-ray ("snowstorm" infiltrate) insidious

dyspnea, and elevated LDH. In the age of HAART, it is increasingly recognized that conditions such as COPD, lung cancer, pulmonary hypertension, and bacterial lung infections may be increased among patients living with HIV [22].

Cardiac

With the advances in HIV care, patients are living longer, increasing their likelihood of cardiac disease. Many antiretroviral medications cause lipid disorders: along with tobacco use, viral cardiomyopathies, and inflammatory effects, cardiac disease has become a major threat to long-term health in this population [23].

Blood and Lymph

Lymphoma is one of the AIDS diagnostic illnesses and is seen in a high proportion of persons with advanced HIV disease. Anemia from medication, malnutrition, or toxicity to marrow is common (note that macrocytosis can be a surrogate marker of adherence, appearing as a side effect of zidovudine therapy). Thrombocytopenia and leukopenia commonly occur, perhaps as a direct effect of HIV infection, but requiring investigation as to their cause. Generalized lymph node enlargement is often evident in early HIV infection and may persist throughout the course of illness. Differential diagnosis of lymphadenopathy includes malignancy, infection, and reactive changes [24].

GI Tract and Liver

Lactic acidosis can result from antiretroviral treatment for HIV, presenting as fatigue, myalgia, nausea, and abdominal pain [25]. Pancreatitis is seen frequently in patients with HIV, both due to the infection and as a side effect of treatment [26]. Coinfection with hepatitis B and/or C infection requires coordinated management and, often, consultation. The liver is subject to inflammation as a side effect of antiretroviral therapy and infection from mycobacteria, fungi, and malignancy.

Renal

Renal impairment is an emerging concern, in large measure because of the nephrotoxicity of some HIV medications. Nonsteroidal anti-inflammatories can be problematic, along with the effects of hypertension, diabetes, and some antibiotic therapies. Specialized centers have now begun kidney transplantation in some cases of persons living with HIV and advanced kidney disease [27].

Musculoskeletal

Both HIV and antiretroviral treatment are thought to contribute to higher rates of osteopenia in patients living with HIV. Some authorities recommend screening for osteopenia in all males with HIV over 50, all postmenopausal women with HIV, and all patients with suspected fragility fractures [28]. Avascular necrosis of bone is not uncommonly seen [29].

Neurologic System/CNS

Central nervous system disorders can include toxoplasmosis, cryptococcus, CNS lymphoma, and progressive multifocal leukoencephalopathy (JC virus). AIDS dementia is a major concern, presumably from direct HIV infection of the brain. This manifests as impaired decision making, forgetfulness, confusion, and motor disorders. Both PML and AIDS dementia have some reversal potentially with HAART [30].

HIV in Children

The number of HIV-infected children in the USA declined by two thirds from 1992 to 1997 according to the CDC. In one of the great public health interventions of our times, and based upon the landmark study in 1994 by the Pediatric AIDS Clinical Trials Group (ACTG 076), zidovudine (AZT) given to HIV-infected women in the second or third trimester and continued during labor remarkably reduced rates of perinatal

transmission of HIV. Further updates reducing maternal-infant transmission (MIT) have refined this to even lower levels of transmission [31]. In high-income countries, mothers should abstain from breastfeeding and instead provide formula, as HIV may be transmitted to their infants in up to 40 % of cases. In low- and some middle-income countries, where the health risks of waterborne disease and costs of formula are prohibitive, exclusive breastfeeding for the first 6 months of life is recommended by the WHO and UNICEF [32].

All pregnant women should be screened for HIV as early as possible in each pregnancy. Women with HIV who take antiretroviral medication during pregnancy as recommended can reduce the risk of transmitting HIV to their babies to less than 1 % [31]. HIV disproportionately affects African American babies in the USA (www.cdc.gov/hiv/risk/gender/pregnantwomen/facts). Cesarean delivery is indicated if maternal HIV viral load is >1000 copies/mm^3 of blood. HIV may also be transmitted through breast milk, creating concern in those parts of the world where safe and reliable alternatives to breastfeeding may not exist. Small numbers of children have been infected through contaminated blood or blood products prior to screening of the blood supply in 1985 and through sexual or physical abuse by HIV-infected adults.

HIV infection is often difficult to diagnose in infants and children: symptoms may not be present, and antibodies present in the child's blood may be maternal in origin for the first 18 months. HIV PCR/viral load testing on an infant or child is more reliable, and serial testing may be indicated.

Signs and symptoms may include failure to thrive, delayed developmental milestones, neurologic complications, frequent infections, severe and recurrent candidal infections, and respiratory infections. In low-resourced parts of the world, AIDS orphans are a grim reminder of the impact of HIV infection on families and communities [33].

Treatment protocols for children and infants, using liquid formulations and weight-based dosing, can be found at www.aidsinfo.nih.gov/pediatricguidelines.

HIV in Women

Greater challenges may exist for women living with HIV: caring for family, access to medical care and treatment, social stigma, and gender-specific concerns are identified. Early research tended to exclude women from clinical trials, so less is known. HIV can cause higher incidence of cervical dysplasia, invasive cervical cancer, recurrent herpes infections, yeast infections, and HPV. More frequent pap screening is recommended, and support systems and advocacy are recognized as needs in many communities. Minority women are disproportionally affected by HIV, and for some, employment, insurance, and responsibilities of children create unique challenges [34] (www.womenshealth.gov/hiv-aids/).

HIV and Aging

About half of older people with HIV have been infected for 1 year or less. The rates of HIV in patients older than 50 years are 12 times higher for African Americans and 5 times higher for Hispanics compared with whites. Older people may be at risk because healthcare providers may not test for HIV in older folks, older people may lack awareness of their risk, many older people are newly single, and many have limited knowledge about safer sex. Of interest, older patients are found to have better medication adherence to HAART and respond well to antiretroviral treatment. Some illnesses impacted by aging patients living with HIV include dementia, depression, diabetes, hyperlipidemia, cardiac disease, infection, and medication interactions. Social isolation and stigma can be difficult in older adults, contributing to depression, substance use, and increased mortality [35] (www.AIDSinfo.net).

Summary of HIV for Family Physicians

Though complex, our role is vitally important, with immense satisfaction in both the individual relationships with our patients affected with HIV and in the health of our communities. In addition,

care for patients with HIV looks hopeful, with better medications, better disease management, less stigma, and longer healthier lives.

Bacteremia and Sepsis

Folashade S. Omole* and Omofolarin B. Fasuyi
Department of Family Medicine, Morehouse School of Medicine, East Point, GA, USA

General Principles

Public Health and Economic Burden

Sepsis is the sixth most common reason for hospitalization in the United States [1], with severe sepsis being the leading cause of in-hospital death [2]. Over 750,000 people develop sepsis annually, and almost one in four of these people die [1, 2]. Sepsis has an in-hospital mortality rate of approximately 16 %; this is eight times higher than other stays [1].

From 1997 to 2008, the cost of treating patients hospitalized for sepsis in the United States increased by almost 12 % annually. This increase may be attributed to an aging population with more chronic illnesses, greater use of invasive procedures, immunosuppressive drugs, chemotherapy, transplantation, and increasing microbial resistance to antibiotics. Hospitalization rates for sepsis increase with advanced age; patients over 65 years account for more than two thirds of sepsis hospitalizations in the United States [1, 3]. Globally, it is estimated that 18 million people are diagnosed with sepsis annually [4]. The case-fatality rate depends on the setting and severity of disease. Mortality can be as high as 30 % for sepsis, 50 % for severe sepsis, and 80 % for septic shock [5]. *Escherichia coli* is the most commonly identified organism in patients with a primary diagnosis of sepsis, while methicillin-resistant *Staphylococcus aureus* (MRSA) is most common for patients with a secondary diagnosis of sepsis [3].

Definitions and Classification

Bacteremia is the presence of viable bacteria in circulating blood. Bacteremia is usually associated with a symptomatic infection and is demonstrable by bacterial growth from an aseptically collected blood culture specimen [6]. Bacteremia often occurs transiently without any clinical consequences.

Systemic inflammatory response syndrome (SIRS) is an uncontrolled inflammatory response to an insult without probable or documented infection [7]. The clinical manifestations of SIRS are often identical to those occurring in sepsis and may occur in a number of conditions (Table 1). Therefore, it is important to exclude sepsis when SIRS is diagnosed. Excluding sepsis is often a challenge, as microbiological investigations are often negative for various reasons including antibiotic administration prior to sample collection or technical issues related to blood culture. Only 30–60 % of patients diagnosed with sepsis have positive blood cultures [9]. Negative or inconclusive blood cultures do not exclude the possibility of sepsis in patients when there is a high index of suspicion. In the clinical setting, the diagnosis of sepsis is often made retrospectively.

Sepsis is defined as a known or suspected infection plus systemic manifestations of infection [10].

Severe sepsis is sepsis with infection-induced organ dysfunction or infection-induced acute tissue hypoperfusion. Organ dysfunctions associated with sepsis include acute lung injury, acute kidney injury, coagulopathy, liver dysfunction, and cardiovascular abnormalities. Sepsis-induced tissue hypoperfusion abnormalities include hypotension, elevated lactate, oliguria, and altered mental status [10].

Septic shock is defined as sepsis-induced hypotension which is not responsive to adequate fluid resuscitation [9].

*Email: fomole@msm.edu

DOI 10.1007/978-1-4939-0779-3_45-1

Table 1 Causes of the systemic inflammatory response syndrome (SIRS) [8]

Differential diagnosis of sepsis
Anaphylaxis
Sterile inflammation, e.g., vasculitis, acute pancreatitis
Hypovolemia
Acute blood loss
Chemical aspiration
Acute respiratory failure
Acute myocardial infarction
Diabetic ketoacidosis
Adrenal insufficiency
Transfusion reaction
Acute mesenteric ischemia
Autoimmune disorder
Substance abuse or intoxication
Drug overdose
Inborn errors of metabolism

Multiple organ dysfunction syndrome (MODS) is a progressive organ dysfunction in an acutely ill patient such that homeostasis cannot be maintained without intervention. It is at the severe end of the severity spectrum of both SIRS and sepsis.

The sepsis spectrum begins with infection, which progresses to bacteremia, sepsis, severe sepsis, septic shock, and death.

Approach to the Patient

Clinical presentation: Early identification and appropriate evidence-based medical care are key to increasing the chance of survival and improving overall outcomes in sepsis [1, 10, 11].

The most common sites of infection are the respiratory, genitourinary, and gastrointestinal systems, as well as the skin and soft tissue [12]. These sites account for over 80 % of all cases of sepsis [13]. Among nursing home residents 65 and older, the urinary tract was found to be the most common source of sepsis [14].

Overall, fever is often the first manifestation of sepsis [12]. However, neonates, immunocompromised or chronically ill patients, and the elderly may have sepsis without meeting the sepsis criteria. Therefore, clinical suspicion is key to appropriate and timely diagnosis. In the elderly, for example, failure to eat, withdrawal, agitation, disorientation, and confusion may be early signs of sepsis [12, 15]. In neonates, exaggerated physiologic jaundice, tachypnea, poor feeding, and reduced tone may be the only manifestations of sepsis.

History taking focused on the chief complaint with a pertinent review of systems is often adequate for initial triage. However, some patient with sepsis may present with nonspecific constitutional symptoms necessitating a more detailed history.

Physical Examination A complete physical examination is indicated. This is important because sepsis from an infection in less obvious areas such as the pelvis or perineum may occur. However, a thorough physical examination should not delay early initiation of life-saving care. General and hemodynamic

Table 2 Sepsis spectrum diagnostic criteria [16]

Sepsis	Documented or suspected infection and some of the following:
	General variables:
	Fever > 38.3 °C
	Hypothermia (core temperature < 36 °C)
	Heart rate > 90/min or > 2 standard deviations (SD) above the normal value for age
	Tachypnea
	Altered mental status
	Significant edema or positive fluid balance > 20 mL/kg over 24 h
	Hyperglycemia (plasma glucose > 140 mg/dL or 7.7 mmol/L) in the absence of diabetes
	Inflammatory variables:
	Leukocytosis (WBC count > 12,000/μL)
	Leukopenia (WBC count < 4,000/μL)
	Normal WBC count with > 10 % immature forms
	Plasma C-reactive protein >2 SD above the normal value
	Plasma procalcitonin > 2 SD above the normal value
	Hemodynamic variables
	Arterial hypotension (SBP < 90 mmHg, MAP < 70 mmHg, or a SBP decrease > 40 mmHg in adults, or < 2 SD below normal for age)
	Organ dysfunction variables
	Arterial hypoxemia (PaO_2/FiO_2 < 300)
	Acute oliguria (urine output < 0.5 mL/kg/h for at least 2 h despite adequate fluid resuscitation)
	Creatinine increase > 0.5 mg/dL or 44.2 μmol/L
	Coagulation abnormalities (INR > 1.5 or aPTT > 60 s)
	Ileus (absent bowel sounds)
	Thrombocytopenia (platelet count < 100,000/μL)
	Hyperbilirubinemia (plasma total bilirubin > 4 mg/dL or 70 μmol/L)
	Tissue perfusion variables
	Hyperlactatemia (>1 mmol/L)
	Decreased capillary refill or mottling

variables that may indicate sepsis (Table 2) should be carefully noted to aid in the early identification of patients in the sepsis spectrum.

Diagnosis

Laboratory Workup and Imaging

Laboratory findings consistent with sepsis are as outlined in Table 2. Routine laboratory workup for sepsis includes two sets of blood cultures (drawn before starting antibiotics if possible). Urinalysis, urine culture, and cultures from other suspected sites (wound, respiratory secretions, CSF, or other body fluids) are also appropriate. Other laboratory tests and imaging studies should be individualized based on history and physical examination findings.

Lactate levels have been strongly correlated with mortality [17, 18].

DOI 10.1007/978-1-4939-0779-3_45-1

Table 3 Surviving Sepsis Campaign care bundles [10, 16]

To be completed within 3 h of presentation:
1. Measure lactate level
2. Obtain blood cultures prior to administration of antibiotics
3. Administer broad spectrum antibiotics
4. Administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L
To be completed within 6 h of presentation:
5. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) ≥65 mmHg
6. In the event of persistent arterial hypotension despite volume resuscitation (septic shock) or initial lactate ≥4 mmol/L (36 mg/dL):
(a) Maintain adequate central venous pressure (CVP) [a]
(b) Maintain adequate central venous oxygen saturation ($ScvO_2$)[a]
7. Remeasure lactate if initial lactate was elevated[a]

[a]Targets for quantitative resuscitation included in the guidelines are CVP of ≥8 mmHg, $ScvO_2$ of ≥70 %, and normalization of lactate

Differential Diagnosis

Various conditions can mimic sepsis. Although the differential is very broad, Table 1 includes common causes of SIRS other than sepsis.

Treatment

Aggressive and timely management of patients with sepsis is paramount. Expeditious transfer to an inpatient setting should occur. Intravenous fluid resuscitation can be started in the ambulatory setting. Blood culture collection should not cause delay in necessary care at any point. Empiric antibiotics should be started after blood culture sample collection and in any case within 1 h of arrival at the hospital or emergency room. The antibiotic choice can be based on the patient's history (e.g., recent antibiotics used), clinical context (community vs. health setting-acquired infection), most likely pathogens, local susceptibility patterns, and cost-effectiveness. Fluid resuscitation should be initiated and continued upon arrival to the emergency room or hospital. If septic shock is present, vasopressor therapy should be considered.

If a localized source of infection is detected, intervention (such as abscess drainage) should be undertaken as soon as possible within the first 12 h after the diagnosis is made [16].

The Surviving Sepsis Campaign (SSC) care bundle (Table 3) is a selected set of elements of care distilled from evidence-based practice guidelines. Using the bundle simplifies complex processes of care of patients with severe sepsis and has demonstrated marked improvements in survival rates after sepsis [19, 20].

Prevention

Patients at increased risk of sepsis should be appropriately vaccinated against pneumococci, *Haemophilus influenzae* type b, meningococci, and the influenza virus. The Centers for Disease Control (CDC) strategies for preventing infections include promotion of vaccination for diseases like pneumococcus and meningitis, smoking cessation programs to prevent community-acquired pneumonia, and strategies to prevent healthcare-associated infections [21]. Early identification and appropriate treatment of infection

DOI 10.1007/978-1-4939-0779-3_45-1

in all patients especially those at increased risk of sepsis reduces chances of progression to bacteremia and sepsis. Good nutrition and lifestyle changes (including regular exercise) boost the body's natural defense system and ability to fight infection. Hand hygiene and good general hygiene practices reduce the rate of infection transmission. Antibiotic stewardship reduces the prevalence of bacterial resistance in the community.

Family and Community Issues

Sepsis survivorship is a substantial and under-recognized public health problem with major implications for patients, families, and the healthcare system. Sepsis survivors often develop physical, cognitive, and affective deficits in the months and years after discharge. These new deficits are relatively more severe among patients who were in good health prior to hospitalization for sepsis [22]. Declines in the level of functioning impact many areas of a patient's life ranging from the ability to perform activities of daily living (ADL) to executive functioning. This may affect the structure and functioning of the family unit. Additional issues include caregiver fatigue, marital stress, and other psychosocial, medical, economic, and legal issues. It is important for family physicians to maintain vigilance for possible sequelae of sepsis among patients and their families beginning at the discharge planning phase of care. An understanding of immediate and long-term outcomes helps with managing expectations and setting goals of care especially when assessing options for short- or long-term care.

The focus of this chapter is on toxoplasmosis, Rocky Mountain spotted fever (RMSF), trichinosis, giardiasis, psittacosis, Ebola virus, Lyme disease, and hantavirus. Most of these illnesses are zoonotic in nature. Physicians should be familiar with their diagnosis, evaluation, and treatment.

Toxoplasmosis

Toxoplasmosis is an infection with a worldwide distribution, affecting immunocompetent and immunodeficient hosts, as well as pregnant women and newborn babies.

Etiology and Epidemiology

Toxoplasma gondii is an extremely successful protozoal parasite, which infects almost all mammalian species including humans. Approximately 30 % of the human population is chronically infected with *T. gondii.*

Toxoplasma gondii exists in four different stages: oocyst, which is the product of the parasite cycle in the cat's intestine. Subsequently, they are excreted in cat feces. In the soil, they transform into the infectious form, the tachyzoite, which penetrates all nucleated cells and replicates rapidly, causing tissue destruction. This stage is responsible for the clinical manifestation of the disease. The body's immune response transforms these tachyzoites into slowly replicating bradyzoites. This tissue cyst can be found in the brain, heart, and skeletal muscle.

A single cat can pass more than 100 million non-sporulated oocysts, which become infective within 1–5 days after defecation. Freezing, chemical, or physical treatment (such as chlorine or ozone treated) does not destroy sporulated oocysts; only heating >55 °C reliably destroys them [1].

There are four means of acquiring toxoplasmosis in humans: ingestion of infectious oocysts from the environment (soil contaminated with feline feces), ingestion of tissue cysts from an infected animal, contaminated fruits/vegetables, and contaminated water. Vertical transmission from an infected mother to her fetus is possible. The final method of acquisition is via blood transfusion or solid organ transplantation from an infected donor [2].

Ingestion of raw or undercooked food (including beef, goat, lamb, or pork) or drinking unpasteurized goat milk is responsible for the majority of toxoplasmosis cases in the USA and Europe. In other parts of the world, infection with toxoplasma is more likely due to environmental exposure. Once an individual is infected, the organism lies dormant in eye, muscle, or brain tissue and is not eliminated [3].

Clinical Features

Toxoplasma infections are divided into four categories: toxoplasmosis in the immunocompetent host, toxoplasmosis in the immunocompromised host, toxoplasmosis in pregnancy, and congenital toxoplasmosis.

Acquired Toxoplasmosis Infection in the Immunocompetent Host: Infection in this group is asymptomatic in 80–90 % of patients. On the other hand, if symptoms develop, the most common manifestation is bilateral, symmetric cervical adenopathy. Other associated symptoms are fever, chills, sweat, headaches, myalgia, pharyngitis, hepatomegaly, and splenomegaly (mononucleosis-like symptoms). This is a benign self-limiting course and may last from a few weeks to months. Acute toxoplasmosis may be mistaken for acute Epstein-Barr virus (EBV) or as *Cytomegalovirus* infection (CMV), especially since atypical lymphocytes can be seen in toxoplasmosis infection. Human immunodeficiency virus (HIV) also should be included as part of the initial evaluation. Other differential diagnoses might include syphilis, sarcoidosis, Hodgkin's disease, and lymphomas.

Toxoplasma gondii has the ability to disseminate through the bloodstream and can cross vascular barriers such as the ocular area, causing ocular toxoplasmosis (posterior uveitis or necrotizing retinochoroiditis). These lesions commonly

"heal" within 2–4 months after infection, leaving a hyperpigmented scar, a result of retinal pigment epithelium disruption. Acute retinal lesions may be associated with adjacent old scars indicating recurrent attacks.

Toxoplasmosis Infection in the Immunocompromised Host: In immunocompromised individuals, especially patients with acquired immunodeficiency syndrome (AIDS), usually when the CD4 lymphocyte count is below 100 cells/microL, the parasite can reactivate and cause disease. All patients with HIV should be screened for *Toxoplasma gondii* infection. The most common site of reactivation is the central nervous system (CNS), and the next is the retina. Toxoplasma infection is the most common CNS opportunistic infection in AIDS patients.

Cerebral Toxoplasmosis: Cerebral toxoplasmosis usually presents with clinical symptomatology such as fever, neurological deficit, confusion, and headaches. Laboratory evaluation includes serologic evaluation with immunoglobulin G (IgG). The majority of patients with cerebral toxoplasmosis are positive for IgG antibodies. Radiologic evaluation includes brain imaging (CT or MRI). Ring-enhancing brain lesions are often associated with edema, with predilection for the basal ganglia. While brain biopsy is the definitive test to confirm the infection, the morbidity associated with this procedure means that the diagnosis is usually made on the basis of the clinical picture, serology, and imaging findings. Cerebrospinal fluid (CSF) may demonstrate elevated protein and mononuclear pleocytosis. The differential diagnosis includes CNS lymphoma, cryptococcosis, mycobacterial infection, or bacterial abscess.

Chorioretinitis: Chorioretinitis usually presents with eye pain and visual deficit. An ophthalmologic evaluation reveals posterior uveitis, retinal lesions, and vitreous inflammation.

Toxoplasmosis in Pregnancy: Women of childbearing age may acquire toxoplasmosis, resulting in primary maternal infection. Fetal infection may occur from transmission of the parasite from mother to fetus before the development of a protective immunologic response in the mother.

During acute infection, the mother is usually asymptomatic, but when symptoms develop, they are vague: fever, malaise, myalgia, fatigue, and headaches. Lymphadenopathy is usually present. Pregnant women who have mono-like symptoms but are EBV serology negative should be tested for toxoplasmosis, cytomegalovirus, and, if at risk, for HIV.

Infections during pregnancy are most reliably diagnosed by blood samples at least 2 weeks apart using toxoplasma-specific IgG or IgM. A maternal primary toxoplasma infection poses serious risk to the fetus, but a reactivation of primary toxoplasmosis does not (congenital toxoplasmosis secondary to reinfection is rare). The majority of fetuses exposed to acute toxoplasmosis infection in the first trimester die in utero or develop severe neurological or ophthalmological sequelae. Fetuses infected in the second or third trimester tend to develop milder or subclinical findings at birth.

Congenital Toxoplasmosis: Neonates with congenitally acquired toxoplasmosis may have few, if any, manifestations on their physical exams and remain asymptomatic. The classic triad of intracranial calcifications, hydrocephalus, and chorioretinitis occurs in few of the infected newborns. If there is a high index of suspicion, then laboratory and radiologic evaluations are needed to diagnose congenital toxoplasmosis – ophthalmologic evaluation, seeking retinal scarring (focal necrotizing retinitis). CSF shows pleocytosis with mononuclear cells and elevated protein. Toxoplasma-specific IgM or isolation of *T. gondii* from the CSF can be attempted. Ultrasound of the head may reveal calcifications in brain parenchyma, but head CT is more sensitive in visualizing these lesions.

Differential diagnosis in the neonatal period includes other congenitally acquired diseases that include rubella, CMV, syphilis, and herpes infection.

Laboratory Diagnosis

The use of serologic tests to search for anti-*Toxoplasma gondii* is a primary method of diagnosis.

The tests most commonly used in routine laboratories for the detection of anti-*Toxoplasma gondii* IgG are the double sandwich enzyme-linked immunosorbent assay (ELISA), the indirect fluorescent-antibody assay (IFA), the indirect hemagglutination assay, and the direct agglutination test and for anti-*Toxoplasma gondii* IgM, double sandwich ELISA, immunosorbent agglutination assay (ISAGA), and IFA.

The Toxoplasma Serology Laboratory at the Palo Alto Medical Foundation (USA) www.pamf.org/serology/clinicianguide.html offers advice to clinicians about ordering and interpretation of test.

IgG Antibodies: usually appear between 1 and 2 weeks after acquiring the infection, peak within 1–2 months, and usually persist for life. A positive test confirms that an infection has occurred but does not indicate how long ago occurred. A number of tests looking for "avidity" to toxoplasma IgG antibodies have been introduced: antibody avidity to a specific antigen is lower in patients with recent infection and higher avidity in older infection. The dissociation test can distinguish low-avidity test antibodies (seen in recently acquired infection) from high-avidity antibodies (seen in infections >4 months old). Although there is a consensus that a high-avidity index can rule out acute infection, the interpretation of a low-avidity index is less clear [4].

IgM Antibodies: may appear earlier and decline more rapidly than IgG antibodies. False positives may result in cross-reactivity with rheumatoid factor (RF) and antinuclear antibodies (ANA). A major problem with a positive IgM test is the lack of specificity. A positive IgM is not an accurate marker of acute infection; it may persist for at least 12 years after acute infection. Also, another complication is the fact that several methods have a high frequency of false-positive results. Due to difficulties establishing an acute diagnosis in the immunocompromised, pregnant, or neonatal individual, it is suggested to follow up with infectious diseases or maternal-fetal specialist. An algorithm from the Centers for Disease Control and Prevention (CDC) for the immunodiagnosis of toxoplasmosis is shown below.

IgG result	IgM result	Report/interpretation for humans
Negative	Negative	No serological evidence of infection with *Toxoplasma*
Negative	Equivocal	Possible early acute infection or false-positive IgM reaction. Obtain a new specimen for IgG and IgM testing. If results for the second specimen remain the same, the patient is probably not infected with *Toxoplasma*
Negative	Positive	Possible acute infection or false-positive IgM result. Obtain a new specimen for IgG and IgM testing. If results for the second specimen remain the same, the IgM reaction is probably a false-positive
Equivocal	Negative	Indeterminate: obtain a new specimen for testing or retest this specimen for IgG in a different assay
Equivocal	Equivocal	Indeterminate: obtain a new specimen for both IgG and IgM testing
Equivocal	Positive	Possible acute infection with *Toxoplasma*. Obtain a new specimen for IgG and IgM testing. If results for the second specimen remain the same or if the IgG becomes positive, both specimens should be sent to a reference laboratory with experience in diagnosis of toxoplasmosis for further testing
Positive	Negative	Infected with *Toxoplasma* for more than 1 year
Positive	Equivocal	Infected with *Toxoplasma* for probably more than 1 year or false-positive IgM reaction. Obtain a new specimen for IgM testing. If results with the second specimen remain the same, both specimens should be sent to a reference laboratory with experience in the diagnosis of toxoplasmosis for further testing
Positive	Positive	Possible recent infection within the last 12 months or false-positive IgM reaction. Send the specimen to a reference laboratory with experience in the diagnosis of toxoplasmosis for further testing

http://www.cdc.gov/parasites/toxoplasmosis/

IgA Antibodies: may be detected in serum of congenitally infected neonates or in an acutely infected adults. This antibody can also remain

positive for several months or even a year. This test is more useful in diagnosing congenitally acquired toxoplasmosis in the fetus and newborn.

IgE Antibodies: can be used to diagnose toxoplasmosis in acutely infected newborn (congenital toxoplasmosis), children with congenital toxoplasma chorioretinitis, or adults. The duration of persistence of this antibody is less than IgM or IgA and may be useful in identifying recently acquired infection.

Polymerase Chain Reaction (PCR): has been used to detect *T. gondii* in various biological specimens such as CSF, vitreous/aqueous fluids, bronchoalveolar lavage (BAL) fluids, blood, and other tissues. PCR in blood samples appears to be a sensitive method for diagnosis of disseminated and cerebral toxoplasmosis [5].

When an individual gets exposed to *T. gondii*, any antibody test will be able to determine the presence or absence of the infection. A more difficult task is to determine whether an individual has acquired the infection recently or in the past. A true-negative IgM test effectively rules out a recent infection, but a positive IgM serology test might not be a representative of a recent infection; therefore, confirmatory tests should be performed.

Acute infection is suggested when there is a greater than fourfold rise in the IgG antibody in serum run in parallel or when there is a seroconversion of IgG and IgM antibodies from negative to positive. A single titer either IgG or IgM is insufficient to make a diagnosis of acute toxoplasmosis, so a confirmatory test is strongly suggested to rule out acute infection.

IgA antibodies are superior and more sensitive than IgM in the peripheral blood of newborn babies. It is strongly suggested to repeat another IgA at least 2 weeks apart to verify that no maternal contamination has occurred. Maternally acquired IgG antibodies should disappear between 6 and 12 months of life.

Treatment

In Immunocompetent Hosts: Treatment is not necessary unless symptoms are severe or they persist for several weeks. Usually a lower dosage is used than with immunocompromised hosts. Therapy is used for about 2–4 weeks. Treatment consists of pyrimethamine (100 mg loading dose, then 25–50 mg daily) in association with sulfadiazine (2–4 g/day orally three times a day). All patients receiving pyrimethamine need to receive leucovorin calcium (folinic acid 10–25 mg/day). Other alternatives are pyrimethamine with clindamycin (300 mg orally four times a day), pyrimethamine with azithromycin (500 mg orally daily), pyrimethamine with atovaquone (750 mg twice a day), and trimethoprim (10 mg/kg/day) with sulfamethoxazole (50 mg/kg day) T-S twice daily.

In Immunosuppressed Hosts: Higher doses are required for 6 weeks. After this therapy, dosage is reduced for chronic management (this regimen is for patients who respond well to therapy). For patients who deteriorate clinically in the first 48 h of initial therapy, or develop elevated intracranial pressure, or CNS midline shift, dexamethasone (4 mg every 6 h) should be used. Monitoring patients at this time should not be based on IgG serology but with clinical, neurological, and radiological modalities. If the patient does not improve in 10–14 days after therapy is started, then consideration for an alternative diagnosis needs to be made. Treatment consists of pyrimethamine (200 mg loading dose, then 50–75 mg daily), as well as leucovorin (10–25 mg daily), in association with sulfadiazine (1 g orally four time daily); initially therapy is for 6 weeks. Alternative therapy might include T-S (5 mg/kg of trimethoprim or 25 mg/kg of sulfamethoxazole) twice daily, pyrimethamine with azithromycin (1 g orally daily), pyrimethamine with atovaquone (1.5 g twice daily), and sulfamethoxazole with atovaquone. For severe inflammatory processes, dexamethasone may be considered in a dose of 4 mg orally every 6 h. The use of medication for primary prophylaxis is when the CD4 falls below 100 cell/ml.

In ocular toxoplasmosis, most ophthalmologists elect not to treat due to the fact that these lesions are old inactive ones or scars. If decision to treat is done by an experienced ophthalmologist, then pyrimethamine with sulfadiazine in

association to leucovorin for 4–6 weeks is adequate. Consideration for use of a steroid is made on a case-by-case basis.

During Pregnancy: If toxoplasma is identified by serology due to maternal symptomatology, then treatment is justified. Prenatal treatment reduces serious neurological sequelae of congenital toxoplasmosis but does not affect ocular disease, vision, or mother-to-child transmission. Conventional therapy is with spiramycin (1 g orally every 8 h) alone; another alternative is pyrimethamine with sulfadiazine (P-S) in association with leucovorin. P-S is no more effective than spiramycin. There is no evidence that early treatment reduces risk of intracranial lesions or chorioretinitis. Also, there is no evidence that prenatal treatment reduces the risk of chorioretinitis. There is clear evidence that there is a reduction in serious neurological sequelae [5]. Alternative regimens include using pyrimethamine (50 mg daily) with sulfadiazine (3 g /day twice daily) for 3 weeks and then alternating with spiramycin (1 g orally daily) for another 3 weeks until baby is delivered. Leucovorin is added when P-S regimen is used.

Neonates: Infants with congenital infection should be treated with P-S and leucovorin for 21 days and then followed by either azithromycin or spiramycin for 4–6 weeks. Alternating P-S with macrolides should be continued for a minimum of 6 months, although generally is continued for 1 year. If neonate has elevated protein in the CSF or has chorioretinitis, then prednisone (1 mg/kg/day) may be added. Healthy newborns delivered to mothers with elevated antibody titers should be treated with a macrolide alone, until serologic evidence for the diagnosis of T. Gondii is definite [6].

Rocky Mountain Spotted Fever

Family physicians should be cognizant that Rocky Mountain spotted fever (RMSF) is the most common rickettsial infection in the USA. Early diagnosis is critical since it has a high mortality rate if untreated [7].

Epidemiology

Rocky Mountain spotted fever (RMSF) is a zoonotic tick-borne disease in which humans are accidental hosts. RMSF is caused by *Rickettsia rickettsii*, an obligatory intracellular gram-negative bacterium. RMSF is transmitted by the American dog tick (*Dermacentor variabilis*), by the Rocky Mountain wood tick (*Dermacentor andersoni*), and by the brown dog tick (*Rhipicephalus sanguineus*); it is also transmitted by the *Amblyomma cajennense* ticks in Central and South America. Adult *Dermacentor* ticks act as both vector and reservoir for human infection. Ticks become infected by feeding on the blood of infected animals, through molting, or by transovarial passage. The organisms in turn invade the endothelial and smooth muscle cells of blood vessels which cause generalized vascular injury and activation of inflammatory and coagulation mechanisms. The majority of the reported cases of RMSF occur between April and September [8].

Clinical Features

The incubation period of RMSF is 2 days to 2 weeks. The initial diagnosis of RMSF is based on clinical manifestations. Early manifestations of the disease are spiking fever (95–100 %), severe headache (80–90 %), and myalgia, fatigue, gastrointestinal discomfort, and rash involving palms and soles (56–88 %) [9, 10]. Rash is present in 90–100 % of children with RMSF and usually appears on first or second day of illness [11]. Blanching red macular or papular rash usually starts on the wrists and ankles, spreading to palms and soles and then centripetally to arms, legs, and trunk. Within 2–3 days, it may become petechial and purpuric. In a few patients, the rash may progress to skin necrosis or gangrene of the digits or limbs, requiring amputation in severe cases. In some cases, individuals do not develop a rash at all [9, 12]. Neurologic involvement may include meningismus, encephalitis, focal neurologic deficits, hearing loss, seizures, and coma

[13]. Cardiac involvement is rare and may be manifested as myocarditis, pericarditis, or arrhythmias [14]. Pulmonary symptoms may include cough, dyspnea, frank pulmonary edema, adult respiratory distress syndrome, and pulmonary infiltrates on chest x-rays. Acute renal failure from hypovolemic hypotension may develop in severe RMSF.

RMSF may be confused with measles in unimmunized patients; the rash starts on the face and progresses to the rest of the body. Cough, coryza, and conjunctivitis are typical of the disease and very unusual in RMSF. Meningococcal rash may be petechial at one point, but usually becomes necrotic quite early. Meningococcemia usually presents with fulminant petechiae on hands and feet but can involve the entire body; meningeal signs are often marked.

Laboratory Diagnosis

The diagnosis of RMSF is mainly clinical because serological confirmation usually is delayed and inadequate (77 %) [15]. Most patients with RMSF have a normal white blood cell count at presentation. As the illness progresses, thrombocytopenia becomes more prevalent and may be severe; thrombocytopenia may result from increased destruction at sites of rickettsia-mediated vascular injury. Other findings that are common in advanced cases include hyponatremia, elevations in serum aminotransferases and bilirubin, azotemia, and prolongation of the partial thromboplastin and prothrombin times. Hyponatremia is a particularly common finding in patients with central nervous system involvement. The cerebrospinal fluid (CSF) analysis may demonstrate pleocytosis; elevated CSF protein is seen in approximately in one-third of patients.

Seroconversion usually occurs at least 2 weeks after the onset of symptoms. Indirect fluorescent antibody (IFA) is the most widely available and most frequently used test. IFA is 94–100 % sensitive after 14 days of illness [16]. The diagnostic titer is usually a dilution greater than 1:64 or a fourfold rise in titers between acute and convalescent sera collected more than 2 weeks apart and run in parallel. Detection of *R. rickettsii* antigen on skin biopsy specimen with direct immunofluorescence or rickettsial DNA in blood or tissue by PCR is used when available.

Treatment

Tetracycline (or related derivatives such as doxycycline) and chloramphenicol are the only two antibiotics with proven clinical efficacy in treating RMSF. Doxycycline is most successful when given in the first 5 days of illness. It is the drug of choice for treating adults (100 mg every 12 h for 7 days) and children (2.2 mg/kg/dose every 12 h, max 100 mg/dose). Chloramphenicol 50–75 mg/kg/day in four divided doses for 7 days is used when tetracycline is contraindicated; children should receive 12.5–25 mg/kg dose every 6 h. The drugs should generally be continued for 2 days after the patient has become afebrile. Tetracycline or chloramphenicol should be given intravenously in patients with marked nausea and vomiting or if otherwise severely ill. Fluid and electrolyte maintenance is important in managing this illness. Without treatment, death may occur within 8–15 days in 20 % of patients. Patients with the highest risk for fatal disease include children younger than 10 years of age or older than 70 years old, African-American males, alcoholics, and patients with G6PD deficiency [17].

Prevention

Some of the preventive measures include the use of protective clothing, tick repellants N, N-diethyl-3-methylbenzamide (DEET) on the skin, permethrin used on the clothes, and daily complete body tick check while in endemic areas. Removal of ticks requires care using forceps, grasping the tick as close to the skin as possible without compressing the body head, and then pulling straight outward with gentle traction.

Trichinellosis

Trichinellosis cases are much less common now than in the past. However, every year, approximately 20 cases are reported to Centers for Disease Control and Prevention (CDC) [18].

Etiology and Epidemiology

Trichinella spiralis, an intestinal nematode, is a common cause of trichinellosis. At present, 12 taxa including eight species and four genotypes (T6, 8, 9, 12) are recognized in the genus *Trichinella*. These taxa are divided into those that encapsulate in host muscle tissue and those do not encapsulate (*T. pseudospiralis*, *T. papuae*, and *T. zimbabwensis*). Among these, only six species and one genotype have been detected in humans. *T. spiralis* has a worldwide distribution, and pigs, rodents, and carnivores (e.g., fox, wild boar) are common hosts. *T. nativa* is common in arctic bears and walruses. *T. murelli* is common in carnivores in the USA and South Canada. *T. britovi* is common in carnivores and swine in Europe, Asia, and Africa. *T. papuae* is common in crocodiles and pig in Australia and Southeast Asia. *T. pseudospiralis* is common in swine, carnivorous birds, and animals in Europe [19].

In the USA, most swine are fed grain. Only a small proportion of swine are fed garbage. Those that are fed garbage may become infected with *T. spiralis*. Viable larvae in inadequately cooked meats particularly pork and wild game meats are ingested, passed into small intestine, and attached to the intestinal mucosal villi; once there, they develop into adult worms that mate and produce more larvae, which seed the skeletal muscles via the blood and lymphatic stream.

Clinical Features

Most infections are subclinical. However, infection with a heavy load of larvae may lead to clinical features of the enteric phase including diarrhea (most common), abdominal discomfort, and vomiting. The systemic phase usually begins 1–6 weeks after ingestion of the larvae and may present with fever (54 %), myalgia (70 %), facial or periorbital edema (28 %), headache, fatigue, and weakness [20]. Conjunctivitis, subungual hemorrhages, and maculopapular rash may be observed. The differential diagnosis of trichinellosis includes influenza, dermatomyositis, and viral gastroenteritis.

A history of recent consumption of raw or undercooked meat should raise suspicion for the diagnosis of trichinosis.

Laboratory Diagnosis

Eosinophilia is often seen about the second week of illness and may reach very high levels. Serum creatinine phosphokinase and lactate dehydrogenase levels may be elevated when muscles are involved. Organism-specific antibodies are generally detectable by 3 weeks after infection. Specific antibodies are usually measured by ELISA or immunofluorescence, further confirmed with the Western blot. If the diagnosis is still in doubt, muscle biopsy may be obtained from a tender, swollen muscle to detect larvae.

Treatment

The mainstays of treatment are anthelmintics, salicylates, and bed rest. The main anthelmintic drugs used against trichinellosis are albendazole (15 mg/kg/day in two doses for 10–15 days) or mebendazole (200–400 mg orally three times a day for 3 days, then 400–500 mg three times a day for 10 days – not available in the USA). These drugs are contraindicated in pregnancy and in children less than 2 years of age. Treatment is effective if given in early stages of infection. Jarisch-Herxheimer-like reactions have been reported with these drugs in severe infestations due to massive release of antigenic substances. Prednisone (30–60 mg/day for 10–15 days) may be used in severely ill patients.

Prevention

The mainstay of prevention of trichinosis is the proper cooking of meats. Although *Trichinella* larvae can be killed at 55 °C, meats should be cooked to reach a core temperature of 71 °C for at least 1 min until there is no trace of pink fluid or flesh. Exposure to freezing temperatures of −15 °C or lower for 3 weeks also sterilizes pork infected with *T. spiralis*.

Giardia

Giardia lamblia is a parasite capable of causing epidemic or sporadic diarrheal illness from contaminated water supplies, person to person (i.e., day care, mental institutions), contaminated food, or travelers where giardiasis is endemic.

Etiology and Epidemiology

Giardiasis is one of the most common intestinal protozoan infections in the world. The etiologic agent is *Giardia lamblia* (*Giardia duodenalis*, *Giardia intestinalis*), a flagellated protozoan which infects a wide array of hosts. It is the most common cause of waterborne outbreaks of diarrhea in the USA [21]. Infection occurs when cysts are ingested with contaminated water, food, or direct fecal-oral contact. Once in the stomach, the acid pH causes cysts to excyst into trophozoites in the proximal small intestine. There they replicate and can cause symptoms of diarrhea and malabsorption. The transmission cycle is complete when the trophozoites are exposed to biliary acid, transform into cysts in the jejunum, and then are passed in the feces [22].

There are eight different genotypes within *G. lamblia*, but only two types are capable of infecting humans (A and B), dogs are infected with genotypes C and D, cats with F, and livestock with type E. Previous exposure to G produces partial immunity to disease and leads to a reduced risk of reinfection and to reduced development of overt symptoms in secondary infection [23].

Clinical Presentation

The great majority of patients infected with *G. lamblia* are asymptomatic. Classical presentation usually begins 1–3 weeks after ingestion of cysts and includes abdominal pain and cramps, nausea, belching, bloating, flatulence (sulfur smell), and diarrhea. Fever and vomiting are rare, as are blood or mucus tinged feces. If patient remains untreated, diarrhea may persist for several months, having flare-ups of diarrheal disease interspersed with normal stools. Chronic infection can cause disaccharidase enzyme deficiency and brush-border damage causing fat malabsorption, lactose intolerance, vitamin A and K deficiency, and failure to thrive in children [24].

Laboratory Diagnosis

The microscopic ova and parasite (O&P) evaluation is the traditional method for stool parasite testing and is the cornerstone of diagnostic testing for intestinal protozoan evaluation. However, microscopy may be cumbersome and requires an experienced laboratory technologist. The Food and Drug Administration (FDA) has approved an antigen detection test for *Giardia*, *Cryptosporidium*, and *Entamoeba histolytica*. The only test cleared by the FDA so far is the multiplexed Luminex xTAG GPP [25].

Treatment

Several agents are used to treat giardia infection and include:

- Nitroimidazoles: Tinidazole (adults 1–1.5 g daily for 1–2 days, children 40 mg/kg/day for 1–2 days); most side effects include nausea, abdominal pain, anorexia, and stomatitis. This medication is not indicated for children. Metronidazole (Flagyl) (adults 250 mg/dose two to three times a day for 5–10 days) is quickly and completely absorbed after oral administration and penetrates body tissues/fluids such as saliva, breast milk, semen, and vaginal

secretions. Despite its widespread and accepted use against *Giardia*, the Food and Drug Administration (FDA) has not approved it for this indication. This medication is well tolerated; the most common side effects are gastrointestinal upset and a metallic taste.

- Furazolidone: Furazolidone (Furoxone) (adults 100 mg/dose four times a day, pediatrics 1.5 mg/kg/dose) is used for a 7–10-day course. It is approved for use against *Giardia*. Side effects might include nausea, vomiting, and diarrhea.
- Benzimidazoles: Albendazole (Albenza) (adults 400 mg/day for 5 days, pediatric dose 15 mg/kg/day) for 5–7 days. Mebendazole (Vermox) (adults and pediatrics 200–400 mg/day) for 5–10 days. One advantage of using albendazole is its efficacy against multiple helminths and relative lack of side effects.
- Paromomycin: Paromomycin (Humatin) is indicated for treatment of *Entamoeba histolytica* and *Trichomonas*. It is used in treatment of *G. lamblia* in resistant infections and pregnancy [26].

Ebola Viral Disease and Marburg Disease

Etiology and Epidemiology

Ebola (EBOV) and Marburg viruses (MARV) are the members of family *Filoviridae* causing Ebola virus disease and Marburg disease in humans and nonhuman primates. These are enveloped, non-segmented, negative-stranded RNA viruses. According to World Health Organization (WHO), until now, there have been only 25 epidemics of Ebola virus reported, but the 2014 outbreak was the largest epidemic ever reported. MARV currently consists of a single species: Lake Victoria MARV. The EBOV consists of five species; they are named according to the location of the first outbreak recorded by this strain: Zaire Ebola virus, Sudan Ebola virus, Ivory Coast or Tai Forest Ebola virus, Bundibugyo Ebola virus, and Reston Ebola virus. Zaire Ebola virus and Sudan Ebola virus have high fatality rates [27]. Reston virus is not pathogenic in humans. There is some evidence suggesting that bats can act as hosts and as a reservoir for filoviruses. MARV is often introduced into human populations by people who enter caves and mines, and EBOV may be introduced by hunting for or processing "bush meat" (the meat of wild animals that may include nonhuman primates).

Filoviruses are highly infectious and enter the body through mucous membranes or breaks in the skin or by direct parenteral transmission. Virus can be spread to others through direct contact with body fluids or fomites or from infected bats or primates. Body fluids including blood, feces, vomit, saliva, breast milk, urine, sweat, nasal secretions, semen, and genital secretions are infective. First, Ebola virus attacks the macrophages and dendritic cells and then is carried to regional lymph nodes via lymphatics and subsequently to the liver, spleen, and adrenal gland via the blood stream. EBOV may attack many organs causing necrosis (liver, spleen, adrenal, kidney, gonads, gastrointestinal tract, and endocardium).

In most infectious diseases, precautions and actions need to be initiated before a diagnosis is made to protect against the spread to others. Thoughtful screening of patients as well as staff returning from endemic areas is essential, especially to a person who has both consistent signs or symptoms and risk factors as follows: elevated body temperature or subjective fever or symptoms, including severe headache, fatigue, muscle pain, vomiting, diarrhea, abdominal pain, or unexplained hemorrhage, *and* an epidemiologic risk factor within the 21 days before the onset of symptoms. A comprehensive action plan to promptly and effectively identify, isolate, and treat a potential case has been developed from the Centers for Disease Control and Prevention (CDC). The link below provides valuable information pertaining to endemic areas, virus transmissibility, symptoms, current management, and isolation recommendations http://www.cdc.gov/vhf/ebola/index.html. Complete information is provided, including case definition, symptoms, transmission of the virus, infection control precautions, and diagnostic process. A specific

process has been outlined to maintain consistency, communicate with key staff, and promptly identify and isolate a potential case.

Early recognition is critical to controlling the spread of Ebola virus. Healthcare providers should evaluate the patient's epidemiologic risk, including a history of travel to a country with widespread Ebola virus transmission or cases in urban settings with uncertain control measures or contact within the preceding 21 days with a person with Ebola while the person was symptomatic.

If a diagnosis of Ebola is being considered, the patient should be isolated in a single room (with a private bathroom), and healthcare personnel should follow standard, contact, and droplet precautions, including the use of appropriate personal protective equipment (PPE). Infection control personnel should be contacted immediately.

If Ebola is suspected, the local or state health department should be immediately contacted for consultation and to assess whether or not testing is indicated and the need for initiating identification of contacts [28].

Clinical Presentation

The incubation period ranges from 2 to 21 days. Patients usually present with nonspecific symptoms such as fever (87 %), fatigue (76 %), anorexia (65 %), vomiting (67 %), diarrhea (66 %), abdominal pain (45 %), and unexplained bleeding (18 %) and also may present with cough, rhinorrhea, headache, or myalgia [29]. In the 2014 outbreak, the primary clinical presentation was gastrointestinal (severe diarrhea). Hemorrhagic manifestations include maculopapular rash and mucosal bleeding, usually in the gastrointestinal and genitourinary tracts. Altered mental status, septic shock, and bleeding are poor prognostic factors. Major causes of death are electrolyte imbalance, shock, and multi-organ failure. Fatalities typically occur in the second week after infection. Ebola virus disease should be considered in patients with the relevant clinical symptoms and exposures in an endemic area. Contacts are observed for 21 days and need not to be isolated before onset of symptoms. In the initial stages of presentation, Ebola virus disease is easily confused with influenza, gastroenteritis, malaria, typhoid, and other bacterial infections.

Laboratory Diagnosis

The main diagnostic test is detection of viral genome by reverse transcription polymerase chain reaction (RT-PCR). The virus is usually detectable 48 h after infection. Antigen capture ELISA may be used. Immunoglobulin G (IgG) and immunoglobulin M (IgM) antibodies are detected by ELISA later in the disease course or after recovery.

Treatment

Currently, the only treatment available is supportive care. Early treatment including fluid replacement, electrolyte balance, and management of concomitant infections improves survival. Rehydration with oral or intravenous fluids (Ringer's lactate solution is preferred) is based on the patient's hemodynamic status. Several gene-based vaccines including rAd5, CAdVax, VSV, and HPIV 3 (recombinant adenovirus, vesicular stomatitis virus, human parainfluenza virus) have been developed and need further human trials [30]. Some drugs like favipiravir, TKM-Ebola, BCX-4430, AVI-6002, and ZMapp have shown some efficacy and are still undergoing clinical experimental trials.

Prevention

Practice careful hygiene when in an epidemic area. Patient isolation and full-body protective clothing are required to prevent contact with infected body fluids. Healthcare personnel should wear appropriate personal protective equipment [PPE]: disposable water-resistant coveralls, a waterproof apron or impermeable gown, an N95 mask, a disposable full face shield, two sets of gloves, and impermeable foot and leg coverings.

It is recommended to use a powered air purifier respirator suit (PAPR) when performing medical procedures like intubation or airway suctioning. Avoid handling the body in burial or funeral rituals of people who have died from Ebola.

Lyme Disease

Lyme disease (LD) was initially diagnosed in the town of Lyme, Connecticut, after an unusual cluster of what appeared to be juvenile rheumatoid arthritis. Subsequently, a spirochete *Borrelia burgdorferi* (Bb) was isolated as the agent producing this new clinical entity. Lyme disease is the most common tick-borne illness in the USA. It is transmitted by the deer tick *Ixodes scapularis* in the East, mid-Atlantic, and Upper Midwest and by the *Ixodes pacificus* in the West Coast of the USA, and the *Ixodes ricinus* is the major European vector. The causative organism is a spirochete *Borrelia burgdorferi* (Bb) sensu lato, a fastidious microaerophilic bacterium. This organism has been classified into several genotypes including *B. burgdorferi* sensu stricto, *B. garinii*, and *B. afzelii* (Europe) [31].

Epidemiology

Most cases of LD in the USA occur in southern New England, southeast New York, New Jersey, eastern Pennsylvania, eastern Maryland, Delaware, and parts of Minnesota and Michigan. The *Ixodes* tick has a 2-year, three-stage life cycle: The larvae emerge from eggs laid in spring, hatch in early autumn, take their first meal, and become infected with spirochetes. Larvae molt into nymphs and during the next spring and summer take their second meal (most likely to transmit infection). In late summer, they transform into adult forms, and they take their third meal (also infectious). They then reproduce, thus repeating the life cycle again.

Several factors are associated with the risk of transmission of Bb from ticks to humans: the tick must be infected; the duration of tick attachment is a critical factor; after attachment, the tick feeds and becomes engorged, discharging its saliva into the bite wound; and the bacteria live in the midgut of the tick, which needs to be engorged with blood before the bacteria migrate to the salivary gland and the saliva, through which the organism is injected into the host [32]. The proportion of infected ticks varies greatly both in geographic area and the stage of the tick in its life cycle. How long the tick is attached (36–48 h) and whether or not it is engorged are two of the most important factors to consider when assessing the risk of transmission to humans.

Clinical Presentation

Lyme disease is classified into three different stages: early localized disease, early disseminated disease, and late disseminated disease. It is diagnosed in patients who have been previously exposed to an infected tick and who subsequently develop the typical signs and symptoms associated with LD affecting the skin, central nervous system (CNS), musculoskeletal system, and cardiac system.

The "primary lesion" or "early localized disease" occurs around the tick bite site. The infection is manifested as erythema migrans (EM), which is classically reported as a single lesion, uniform erythematous, and oval to circular rash with a median of 16 cm (5–70 cm), and it expands for several days to weeks to form a large annular erythematous lesion. The lesion is usually asymptomatic but may be pruritic and has associated symptoms such as fever, malaise, headaches, lymphadenopathy, and myalgia. The EM lesion is pathognomonic of Lyme disease. EM appears at the site of tick bite 3–30 days after inoculation. This lesion is found in 90 % of patients with evidence of infection with *Bb*. Another very rare skin lesion is *Borrelia* lymphocytoma, a bluish-red nodule appearing usually on the earlobe or nipples within months or years of an infection (reported from Europe) [33].

The "secondary lesions" of *Borrelia* infection or "early disseminated disease" usually presents with multiple EM lesions; these lesions are smaller but morphologically similar to the initial

lesion (EM). After the initial stage, the spirochete disseminates systemically via lymphatic system or bloodstream. In untreated disease, it affects extracutaneous sites such as joints, CNS, and cardiovascular system. Common manifestations of early disseminated disease include oligoarticular joint disease with arthralgia and myalgia (arthritis is usually a manifestation of late disease), typically with effusion affecting large joints usually the knee; it is asymmetric, accompanied by joint edema without erythema, and waxes and wanes causing joint dysfunction [34]. Neurologic involvement may include lymphocytic meningitis and cranial neuropathy – usually unilateral facial nerve palsy. Motor or painful sensory radiculoneuropathy known as Bannwarth's syndrome is more common in Europe. Lyme disease should be in the differential diagnosis of Bell's palsy in endemic areas. Cardiac involvement is a less common complication of systemic disease; the presentation may include chest pain, dyspnea, fatigue, palpitations, or syncope and may include some forms of atrioventricular block.

The late stages of borreliosis or "late disseminated disease" usually presents either as chronic arthritis (monoarticular or oligoarticular) or neurological symptoms such as encephalopathy or peripheral neuropathy. Acrodermatitis chronica atrophicans, a chronic sclerosing dermatitis, develops in patients infected with *B. afzelii* an uncommon manifestation in Europe but virtually unknown in the USA. It is usually located in the lower extremities and progresses slowly. The initial inflammatory phase is characteristic with a bluish-red discoloration of the skin located in the distal parts of extremities which then progresses to the atrophic phase, with epidermal thinning.

Post-Lyme symptomatology is characterized by symptoms and complaints for more than 6 months after adequate treatment. Musculoskeletal or radicular pain, dysesthesias, neurocognitive symptoms, sleep abnormalities, and fatigue have all been reported. No additional antimicrobial therapy is effective at this stage, but symptomatic management is recommended.

Differential Diagnosis: Several dermatological conditions can be confused with EM; they may include cellulitis (usually has edema, erythema, warmth, tenderness), erythema multiforme (most lesions are <2 cm in diameter with central clearing and also may have mucosal involvement), contact dermatitis (variable shape, location, and size of lesions usually located around neck, wrist, umbilical areas), spider bites (lesion is erythematous with variable size and associated with a necrotic ulcer), tinea (annular or ringlike lesion), and urticaria (raised erythematous lesion with serpiginous borders).

Diagnosis

Serology, polymerase chain reaction (PCR), and culture can be performed in order to diagnose *Borrelia* infection. Culture remains the diagnostic standard. Although it is not routinely available, it is useful in biopsy samples of EM lesions or plasma in multiple EM lesions. This is due to the fact that EM appears 3–30 days after the tick bite, while *Bb* antibodies appear 2–4 weeks after the bite. Individuals with EM may have negative serology but positive spirochetes in the blood. The Centers for Disease Control and Prevention (CDC) recommends serologic evaluation as the preferred initial diagnostic test. A two-tiered protocol using an enzyme-linked immunosorbent assay (ELISA) is initially followed by a more specific Western blot to confirm the diagnosis when the assay is positive or equivocal. If the ELISA test is negative, an immunoblot is not necessary. The ELISA test provides quantitative estimate of antibodies against Bb. The immunoblot produces information about specific proteins against Bb that are present (band). In order for a Western blot to be considered positive, it requires to have either two bands for IgM or five bands for IgG. PCR test has the highest sensitivity for Lyme disease in synovial fluid in patients with untreated Lyme arthritis. Urine antigen testing is not recommended [35]. IgM antibodies usually appear 2–4 weeks after infection, peak at 8–10 weeks after infection, and gradually disappear, but in some patients, these may persist for several years. IgG antibodies appear after 6 weeks post infection, peak after 4–6 months, and still are detectable after several years. A diagnosis of

Lyme disease should *not* be based solely on a positive serology (IgM), but on epidemiological data, as well as physical examination, since IgM and IgG may persist for years after effective treatment of LD. Repeat serology as a mode of documentation of treatment effectiveness is also not recommended. Lyme serology should not be performed in individuals with vague symptoms: chronic nonspecific maladies, i.e., fatigue, arthralgia, and neurocognitive deficits. Even if there is a positive serology for LD, an individual might have been exposed in the past, and the present symptoms may be related to another pathogen such as babesia, anaplasma, other borrelias, or viruses.

Treatment

Early disease characterized by EM is best treated with an oral antibiotic. Adults should receive doxycycline (100 mg twice a day), or amoxicillin (500 mg three times a day), or cefuroxime axetil (500 mg twice a day), or azithromycin (500 mg daily). Children older than 8 years of age can receive doxycycline (4 mg/kg/day twice a day, maximum dose 100 mg twice a day), and younger children should receive amoxicillin (50 mg/kg/day in three doses, maximum 500 mg per dose) or cefuroxime axetil (30 mg/kg/day in two doses, maximum 500 mg per dose) or azithromycin (10 mg/kg/day, maximum 500 mg per dose). Doxycycline is contraindicated in pregnancy and breastfeeding and in children younger than 8 years old. All of the above treatments should be for 14 days.

Early Disseminated Disease: Multiple EM, localized cranial nerve palsy, or carditis without heart block can also be treated with oral antibiotics. Parenteral ceftriaxone (2 g IV daily) in adults or children (50 mg/kg/day) is used for treatment of Lyme meningitis, myocarditis, and heart block in symptomatic individuals requiring hospitalization. Once symptomatology improves, then oral therapy is completed. Therapy is for 14–21 days.

Late disease such as arthritis, without neurologic involvement, can be treated with oral antibiotics as used for EM, but treatment should be prolonged for up to 28 days. Patients with neurologic symptoms including encephalitis, encephalomyelitis, or peripheral neuropathy with or without arthritis should be treated with parenteral antibiotics as in early disseminated disease for 14–28 days.

A Jarisch-Herxheimer reaction may develop after therapy is initiated (fever, sweating, myositis). In this case, the medications are generally continued, and nonsteroidal anti-inflammatory drugs are often beneficial.

The most common reason for lack of response to appropriate antimicrobial therapy used to treat LD is misdiagnosis (the patient does not have Lyme infection). Nonspecific symptoms (fatigue, arthralgia, or neurological maladies) may persist for several weeks even with successful treatment and should be treated with nonsteroidal anti-inflammatory medications.

Hantaviruses

Hantavirus is named after the Korean River, Hantaan, where the first outbreak was reported in 1951. The ensuing illness from infection has been referred to as Korean hemorrhagic fever. Hantavirus is one of the major classes of zoonotic pathogens and is a member of the *Bunyaviridae* family, which are negative-stranded, spherical, and enveloped RNA viruses [36]. The resulting diseases can cause significant morbidity and mortality and occur globally. Up to 200,000 cases involving hospitalization are reported annually, with most in China. In the USA, there have been outbreaks in the Southwest in 1993 (Sin Nombre hantavirus) and in Yosemite National Park, California, in 2012 [37]. In this outbreak, ten people were infected, three of whom died. Up to 14 viruses in this genus exist, with the most virulent ones causing hemorrhagic fever with renal syndrome (HFRS), with approximately a 15 % mortality, and hantavirus cardiopulmonary syndrome (HCPS), with greater than 40 % mortality.

Rodents are the primary hosts of hantavirus, and occasionally humans acquire the virus, likely via exposure to aerosols of various secretions or excretions. Bites can also transmit the virus.

Human-to-human transmission of hantavirus is exceedingly rare but possible. In the 1993 US outbreak, rodents that were trapped near the patients' homes had the same novel hantavirus genetic identification as those in infected patients' serum. Recent findings indicate that bats, moles, shrews, and other mammals may also serve as hosts [38, 39].

Clinical Presentation

Humans can be asymptomatic from the infection or develop severe reactions, in the form of either HFRS or HCPS. Early symptoms can be nonspecific with fever, fatigue, and generalized muscle aches, especially in the legs, back, and hips. Abdominal symptoms, headache, and dizziness may also occur during this early phase. These generalized symptoms resemble other viral syndromes and make early diagnosis difficult. Symptoms in the later phase of the infection with HCPS are cough and shortness of breath which are due to pulmonary edema and hypotensive shock. Renal dysfunction/failure with hemorrhage occurs in HFRS [40]. These two syndromes may overlap. Age, gender, genetic response, and immune status can affect the prognosis [41]. Males tend to get more symptoms than females, but females appear to have a higher mortality rate. Interestingly, infected rodents are not affected negatively by the virus.

Laboratory Findings

Usual findings are thrombocytopenia, increased hematocrit, leukocytosis, and elevated creatinine. IgG and IgM antibodies can be detected at the onset of clinical symptoms using ELISA, immunoblot, or immunofluorescence techniques. PCR techniques offer faster results.

Treatment

Treatment is generally supportive, with earlier intervention leading to better outcomes. The patient may need intubation and supplemental oxygen, as well as intravenous fluid therapy. Early dialysis helps in acute renal failure. Intensive treatment for hypotensive shock and pulmonary edema is also necessary to improve outcomes. Early administration of ribavirin may reduce renal damage. In China, inactivated virus preparations for active immunization have been used, but currently no licensed vaccines exist against hantavirus in the USA.

Prevention

In general, rodent control is via sealing gaps/holes in homes, setting traps, and keeping food in enclosed containers. An excellent resource for prevention can be found at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5109a1.htm.

Complementary and Alternative Medicine

Mathew Devine and Meg Hayes

Contents

Integrative medicine (IM) can be defined as healing-oriented medicine that takes account of the whole person (body, mind, and spirit). It emphasizes the therapeutic relationship and makes use of all appropriate therapies, both conventional and alternative [1]. The field of integrative medicine is a diverse collection of more than 1000 practices and principles that are used as a form of healing. In the 1990s, the term "integrative medicine" (IM) replaced the terminology complementary and alternative medicine (CAM). IM is now used to describe these techniques that were not previously identified as acceptable treatments in western medical practice.

In general, IM practices and techniques are not taught in allopathic medical schools. Since the US population is increasingly using integrative medicine principles and practices, some academic health centers have started to offer education in medical school and beyond. In 1997 an integrative medicine fellowship was started at the University of Arizona. Since that time other integrative medicine fellowships have been implemented and are available to primary care physicians. The Consortium of Academic Health Centers for Integrative Medicine (CAHCIM) currently represents over 60 academic health centers and affiliate institutions in the USA, Canada, and Mexico. Integrative medicine training is also available in a fourth year model for many family medicine residencies across the country. NIH-sponsored R-25 grants have also been awarded to many academic centers

Table 1 Top 10 most common integrative medicine therapies

Order of most commonly used therapies	Integrative medicine technique	Licensure status	Systemic review (s) of evidence
1	Natural products/herbal medications	Supplements are exempt from FDA approval	Yes
2	Deep breathing	Can be advised by any type of provider or self-taught	Yes
3	Meditation	Can be advised by any type of provider or self-taught	Yes
4	Osteopathic manipulation and chiropractic treatment	Licensure needed for D.O. and D.C. in the USA	Yes
5	Massage	Licensure required in most US states	Yes
6	Yoga	Certification available no formal licensure needed in the USA	Yes
7	Diet-based therapies	None unless seeing certified dietician or licensed naturopath	Depends on diet studied
8	Progressive relaxation	No formal licensure/certification required	Yes
9	Guided imagery	No formal licensure/certification required	Yes
10	Homeopathic therapy	Certification/diploma but no licensure required	Yes

to include some of these principles in their medical school curricula [1].

A study conducted in 2002 by the Centers for Disease Control and Prevention's (CDC) National Center for Health Statistics (NCHS) indicated that 62 % percent of adults used some form of IM therapy specifically for health reasons during a prior 12-month period, when the definition of IM therapy included prayer. When prayer specifically for health reasons was excluded from the definition, 36 % of adults used some form of IM therapy during the prior 12 months [2]. The same agency conducted another survey/study in 2007, and Table 1 lists the ten most commonly used IM treatment in US adults from 2002 to 2007 [3].

This chapter outlines current use of integrative medicine practices and provides a brief description of some of the more commonly used methods of IM. A full discussion of each of the methods is beyond the scope of this chapter. Table 2 lists other types of IM practices that are also performed but not as often as those listed on Table 1. Some of the items listed in Table 2 will be discussed in this chapter. Additional informational resources for all of the treatments discussed can be reviewed in Table 3. Guidelines for the selection of integrative medicine providers as resources for referral will also be reviewed. Since this area continues to grow and these techniques are sought and used by patients, family physicians are well advised to become knowledgeable in this area.

Natural Products/Herbal Medicine

Herbs, botanicals, and plants have been used medicinally by humans as far back as the earliest civilizations. The pharmaceutical industry has a long history of using plant-derived products to create their products. It has been estimated that 50 % the approved pharmaceutical drugs during the last 30 years are derived either directly or indirectly from natural products [4]. In 2007, the sales of herbal products accounted for more than 25 billion dollars in sales yearly, and they are used for many conditions [4]. The popularity of herbal medications relates to increasing availability and acceptability of IM by the general population, concerns regarding use of allopathic medications, increasing desire for preventative medicine, and

Table 2 Other types of IM treatments that are used that clinicians should be knowledgeable of

Integrative medicine techniques/ treatments	Licensure status	Systemic review(s) of evidence
Acupuncture	Licensure required	Yes
Aromatherapy	Not required	Limited
Ayurveda	Not required	Yes
Biofeedback	Not required	Yes
Energy psychology	Not required	Yes
Environmental medicine	Not required	Yes
Feldenkrais	Not required	Limited
Hypnotherapy	Required in select US states	Yes
Naturopathy	Required in most US states	Yes
Reflexology	Only in 2 states	Yes
Reiki	May need massage license in certain areas	Limited
Shiatsu	May need massage license in certain areas	Limited

self-advocacy by patients seeking alternatives to allopathic medications that have failed to treat conditions or have caused side effects. Herbal products may be viewed as "natural" and therefore healthier and safer than allopathic medications. Patients may not notify their physicians of their use of herbal medications for fear of nonapproval of this practice. Herb–drug interactions are well documented, and it is important for patients to be explicitly asked about all substances and treatments taken, whether prescribed or over the counter.

The most definitive source of information on herbal medicine is the German Commission E. This commission has examined the evidence for use of more than 380 herbs. Evidence considered included clinical studies, chemical data, experimental pharmacologic studies, traditional use, case reports, and other data available to assess the safety and efficacy of herbal medications. While criticism has been leveled that many of these sources lack scientific rigor, the Commission E monographs remain the most authoritative source of information on these widely used compounds. The monographs are available in paper and electronic formats [5].

Standardization of herbal medication is complicated by the natural properties of plants, which contain numerous chemical compounds. The conditions under which the plant is grown, harvested, and processed can affect the chemical composition, and the various components of the plant, leaves, roots, and flowers may have different effects or uses. In addition, often it is not known which of the components is responsible for the desired effect. Standardized extracts are available and should be used preferentially, but many herbal preparations are not labeled to include the precise composition [6]. In the USA, the Food and Drug Administration (FDA) does not regulate herbal substances. The 1994 Dietary Supplement Health and Education Act (DSHEA) placed herbal products into a new class identified as "dietary supplements" and limited the authority of the FDA to regulate herbs as they do medications [7]. Dietary supplements, including herbals and botanicals, vitamins, minerals, and amino acids, are exempt from FDA approval or monitoring, provided that they do not claim to treat or prevent disease. Dietary supplements must carry the following disclaimer: "This product has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease." Supplement labels can claim to maintain health or function, such as "maintains normal cardiovascular function," but cannot claim to "reduce blood pressure" without FDA approval. Table 4 lists documents ten of the most commonly used herbal medication, as well as contraindications and side effects [8].

Table 4 Uses of common herbal medications [8]

Herb	Uses/effects	Contraindications	Side effects	Systemic review (s) of evidence
Echinacea	Promotes natural resistance to infection – used many in upper respiratory infections	Systemic illness such as HIV, TB, and MS	Chills, fever, nausea, allergic reaction	Yes
Garlic	Hyperlipidemia	None	Avoid before surgery – potentiates warfarin	Yes
Ginkgo biloba	Dementia, cognitive impairment	With a known hypersensitivity to ginkgo; caution in depression	Stomach upset, headache, skin reaction	Yes
Saw palmetto	Symptoms of benign prostatic hypertrophy	None known	Gastric upset	Yes
Ginseng	Fatigue, weakness, physical performance	Hypertension, excessive caffeine use	Possible interaction with MAOI	Yes
Grape seed extract	Venous insufficiency, possibly with certain types of cancers	Not to be used with a known allergy to grapes	Headache, itchy scalp, dizziness, and/or nausea	No
Green tea	Cancer treatment, cognitive impairment, GI illnesses	Can interact with many medications	In excess can cause same SE as caffeine does	No
St. John's Wort	Mild to moderate depressive mood, anxiety	None known, but not recommended with other antidepressants, specifically MAOIs	Trouble sleeping, vivid dreams, fatigue	Yes
Bilberry	Vision impairment	Caution with diabetic and anticoagulant medications	Rash	No
Aloe	Dermatitis, wound healing	As PO supplement can act as laxative	Burning/skin irritation	Yes

Mind–Body Medicine

Prayer is the most widely used form of IM [2]. It is widely used by those afflicted with serious illnesses and diseases. Due to the large variation of prayers and it uses amongst different religions and cultures the full scope of this important treatment is beyond the scope of this chapter.

Four other common IM techniques (listed in Table 1) are from the field of mind–body medicine: deep breathing, meditation, progressive relaxation, and guided imagery. These four techniques support improved relaxation. It has been demonstrated that many of these techniques can impact the functioning of the autonomic nervous systems (ANS). Divided into the sympathetic and parasympathetic nervous systems, the ANS has long been thought to relate to bodily functions that operated below the level of one's conscious awareness or control. The following techniques are easily learned and can be incorporated into daily life for cost-effective health benefit:

1. **Deep breathing** and breathing exercises are useful in focusing a patient's attention on the process of inhalation and exhalation. For patients who suffer panic disorder and anxiety, this exercise gives a focus to the thought process. This focus can replace any troubling thought or images that may have preceded an episode of hyperventilation, while slowing the breath, prolonging the expiratory phase, and resolving an associated alkalosis.

2. **Meditation** is a term used for a broad practice that involves using techniques that help to promote relaxation, expand one's emotional capabilities, and improve mindfulness and internal health. This practice has roots from many different cultures and religions across the world. Due to the ongoing different styles of practice of meditation, there is no formal consensus on what is defined as the accepted criteria on the process and the outcomes that one needs to perform in order to achieve or be in a state of meditation.
3. **Progressive muscle relaxation** and body scans are used to reduce muscle tone. In progressive relaxation, the patient first holds tension in a muscle group for several seconds and then consciously relaxes it before moving on to repeat this exercise throughout the body. In body scan, the patient starts at the head or feet and consciously relaxes a portion of the body one segment at a time. These techniques can be aided by the use of a scripted audiotape to guide the patient through the complete exercise.
4. **Guided imagery** cues the imagination to stimulate physiologic changes. Just as one may experience sympathetic excitement with images such as a frightening scene in a movie, the opposite can be achieved with appropriate images. For example, learning to warm the hands by imagery suggesting the holding of a warm mug of cocoa or the ambient heat of a campfire can result in a significant temperature change in the fingertips due to increased blood flow.

Mind–body interventions pose little risk or contraindication. The interventions can offer significant symptom relief from chronic pain and distressing symptoms due to illness while providing patients with a powerful sense of control, thus engaging them in active participation in their health care. These techniques are frequently useful alone and may also be employed as adjunctive treatment to standard care. Mind–body interventions can be taught in brief office visits and have the potential to improve the quality and decrease the cost of health care [9].

Manual Medicine

Osteopathic and chiropractic manipulation as well as massage therapy are widely used for musculoskeletal complaints such as headache, neck, and low back pain. Manipulation has also been found to be of value in repetitive strain injury, chronic fatigue syndrome, lumbar back pain, fibromyalgia, rheumatoid, and osteoarthritis. The benefit of manipulation is likely due to both the local effects on muscles and ligaments as well as psychological relaxation, both of which can reduce pain and increase function [10]. Studies also demonstrate patient preference for manual treatment of acute low back pain, whether through osteopathic, chiropractic, or massage [2].

Osteopathic Manipulation

The field of osteopathy was started in 1874 by Andrew Taylor Still, MD, DO. The term "osteopathy" was created by Still since at the time his hypothesis was that the pathology of most conditions stems from the bones themselves. Though this theory was not proven to be true, other aspects of the field of osteopathic medicine are still currently part of the US landscape as an integrative medicine technique primarily for treatment of musculoskeletal conditions. Osteopathic practitioners are present throughout the world. The degrees of training and licensing process vary from country to country. In the USA, an individual must attend a 4-year medical school to receive a degree as a doctor of osteopathic medicine.

Once a D.O. degree is obtained in the USA, these physicians can practice the full scope of medicine. Integrated into the curriculum for US osteopathic medical students are the principles and practices of osteopathic manipulative technique (OMT). OMT is a body-based treatment that offers a conservative, noninvasive option for relieving pain while also attempting to improve function and mobility to the area being treated. OMT is an integrative medicine technique that has an evidence base for improvement of function

Table 5 Contraindications to performing osteopathic manipulation

Condition	Reason associated with condition to not perform OMT
Spinal osteomyelitis	If history of IV drug use and/or skin infection within the preceding 3 months caution prior to treatment should be performed
Spinal fracture	Caution advised if had spinal trauma within the preceding year and/or corticosteroid use exceeding 3 months duration within the last year
Herniated disk	Caution advised with a history of leg pain radiating below the knee, history of persistent numbness or weakness in the leg or legs, or history of claudication
Ankylosing spondylitis	If condition has not been identified, consider work up if patient has morning back stiffness and individual is younger than 40 years of age
Cauda equina syndrome	With a current history of bladder dysfunction, saddle anesthesia, or fecal incontinence treatment should not be rendered
Cancer	Treatment should be delayed until further work up is performed for patients with previous history of cancer, excluding nonmalignant skin cancer, and/or unexplained weight loss of at least 10 lbs or 5 % of body weight within the preceding year, and/or no relief of low back symptoms with conservative treatment for persons older than 50 years after 6 weeks duration
Pregnancy	Treatment can be used however would use caution with high velocity techniques

related to treating the following conditions: back pain [11], asthma [12], acute ankle sprain [13], and otitis media [14]. There are many other conditions that can be treated with OMT; however, most treatments tend to involve the spine. In addition, D.O.s are taught techniques that can be used over the entire body. Other common areas for OMT involve the following regions: pelvis, shoulders, knees, ribs, and the paranasal sinuses.

The use of OMT greatly depends on the field of medicine that a D.O. pursues. In the USA, there are specialty D.O.s that practice full-time manipulation therapy. Osteopathic physicians trained in primary care often use OMT as an adjunct to practice. If referral is considered, it is important to ask if the referring D.O. physician actively practices OMT and also to ensure that their skills are up to date.

The use of OMT is generally safe. Complications are reported to occur in approximately one in a million treatments [15]. Despite the safety record, it is important to carefully select patients to exclude those with contraindications to therapy. See Table 5 for contraindications to OMT.

There are multiple types of treatments that can be used for OMT. Treatment is tailored based on the location and type of pain/somatic dysfunctions that is being treated. Treatments can be performed using direct or indirect methods. If the practitioner engages the restrictive barrier, this is a direct treatment. If the practitioner moves tissue and/or joints away from the barrier, this is referred to as indirect treatment. OMT can also be performed with the patient assisting in the treatment (active), or when the patient is relaxed (passive), allowing the clinician to move the body tissues. Table 6 shows a list of the types of OMT treatments that are commonly used.

There is ongoing national research in primary-care-oriented OMT. These studies may provide further evidence for the use of OMT in the primary care setting. It is important to note that OMT is not only reserved for D.O. practitioners. Additionally, training in OMT can be integrated into allopathic residency training and is within the unrestricted scope of practice for MDs. Courses and curricula are available to teach MDs these techniques and principles.

Chiropractic Care

Chiropractic treatments focus on the relationship between the structure of the spine and healthy body function. Chiropractic treatment may include spinal manipulation, applications of heat or cold, dietary and activity recommendations, and the prescription of nutritional supplements.

Table 6 Commonly used osteopathic manipulation techniques

Treatment type	Brief description of treatment	Direct or indirect treatment	Active or passive
Myofascial release/ soft tissue technique	Directed to the soft tissue structures of the body	Both	Both
Muscle energy technique	Aimed the involved joint and muscles restriction of motion. Patient uses the opposite muscular to attempt to increase the barrier of restriction in the area being treated	Direct	Active
Counterstrain	Gentle technique that identified "tender points" in muscles, ligaments, or tendons, and then these areas are shortened with specific positioning and held for greater than 90 s at a time	Indirect	Passive
High velocity low amplitude	This technique uses a controlled force that is a quick movement over a small distance aimed at joints of the spine. There is a low velocity high amplitude technique that can apply a slow force over a greater distance as well	Direct	Passive
Cranial	Technique using the cranial bone motion and balancing the tension membranes of the nervous system	Both	Passive
Ligamentous articular strain	Similar to cranial technique except instead uses the ligaments attached to the joints of the body	Indirect	Passive
Facilitated positional release	Positional-based technique with the clinician providing a facilitated force in the form of compression/torsion to the soft tissue or spine for a brief interval	Indirect	Passive
Active release technique	Technique that patient is guided by clinician uses voluntary muscle contraction and possible respiratory effort as well	Both	Active
Visceral manipulation	Techniques to the viscera area to treat GI tract and pelvic organ dysfunctions	Direct	Passive
Fluid motion technique	Designed to move fluid in different parts of the body, examples include sinus drainage and lymph movement through thoracic channels	Indirect	Passive

Chiropractors have accredited education standards, and licensure is required to practice in every state. The profession enjoys a high level of recognition, with an estimated 1 in 15 Americans seeing a chiropractor annually. There are more than 50,000 chiropractors in practice in the USA, and the World Federation of Chiropractic has representation from 70 countries. Medicare, workers' compensation programs, and many private insurers cover chiropractic services.

Chiropractic treatment has integrated into the health-care system as the result of a professional emphasis on research that has defined the benefits and risks of spinal manipulation using accepted outcome measures. Studies have demonstrated beneficial effects of spinal manipulation on the duration and severity of acute low back pain and short-term positive results in chronic low back pain [16], although studies have not demonstrated substantial long-term effects on pain [17].

Referral to a chiropractor may be considered for treatment of acute, uncomplicated back and neck pain or for a short course of treatment for chronic pain and nonprogressive sciatica. Other conditions that may be improved include headaches that originate from the cervical spine and symptoms of otitis media [18].

Chiropractic treatment of nonmusculoskeletal conditions is controversial, and to date there are not adequate data on effectiveness. Anecdotal reports of improvement of menstrual cramps, asthma, and functional gastrointestinal symptoms exist, but it will be some time before data concerning any definitive effect in these disorders are available. Contraindications to chiropractic manipulation include conditions where bony structures are susceptible to trauma such as acute fractures, bone tumors, severe rheumatoid arthritis, and osteoporosis. Manipulation should also be avoided in patients with a progressive neurologic

deficit and in those who have a deteriorating condition without a clear diagnosis.

Massage Therapy

Massage therapy is the manipulation of soft tissue and connective tissue with the intention of maintaining or improving health by affecting changes in relaxation, circulation, lymphatic flow, and increased range of motion. Most states have licensing requirements that must be met before a practitioner can use the title "massage therapist." Empirical support exists for the efficacy of massage therapy in reducing pain, increasing alertness, diminishing depression and anxiety, enhancing immune function, and improving sleep patterns. Specifically, massage therapy has been found to be valuable in reducing anxiety levels in patients undergoing surgery under local anesthesia [19], facilitating mother–infant interaction for mothers with postpartum depression [10], and decreasing pain and anxiety and improving sleep in patients with low back pain [20].

Massage therapy can be considered for a number of conditions. Contraindications to massage include contagious or irritative skin disorders, edema due to heart or kidney failure, fever, infections spread by blood or lymph circulation, and leukemia or lymphoma.

Yoga

Yoga can be traced back to early civilizations in India. It focuses on the following principles: proper breathing (pranayama), proper relaxation (savasana), proper exercise (asanas), meditation (dhyana), and proper diet (vegetarian). There are many different styles of yoga, and none of them have been found to be superior over the other. Yoga has gained popularity in the USA and is used as method to try and improve health by focusing on controlling one's breathing, working on maintaining postures, and using meditation to help promote relaxation and balance.

Based on the survey in 2007 by the CDC, of those who reported participating in IM activities, yoga was used by 6.1 % [3]. There have been a large number of clinical trials testing the benefits of yoga. From all of the studies that have been published, yoga has performed most favorable in those that suffer from various chronic diseases. Each style has different certification, training, and ongoing continuing education requirements. To practice yoga in the USA, national or state licensure is not needed. Even though licensure is not needed, many practitioners pursue yoga certification that is available from multiple national or international organizations. These organizations operate independently are not part of any formal body to oversee all of the different types of yoga training and certifications.

Diet-Based Therapies

There has been increased understanding in diet-based therapies and food safety since the start of the twenty-first century. Depending on one's geographic region, it is important to be aware of the possible harmful exposures from one's environment. The possible environmental exposures could be from exposure to pesticides, growth hormones and antibiotics, as well as from genetically modified foods. These factors and others have led patients to seek out practitioners to see if they have sensitive or an allergy that needs treatment. These food allergies and reactions can promote or cause certain conditions to arise. Food allergy prevalence also appears to be increasing among children and adults [21].

There is a growing trend to use elimination diets to help restore health for an individual who has a food allergy or food reaction. An elimination diet is the process of removing certain foods from the diet to decrease inflammation and decrease ongoing immune-mediated reactions. Elimination diet should be discussed and planned with the patient. The process is usually to plan the elimination diet and to provide the patient with foods that they should avoid. Then depending on the intensity of the program, those foods are to be avoided for a set period – usually between 2 and 4 weeks [22]. If the symptoms improve during that time, then it is plausible that the food could

have been the agent that was causing the problem. However, with chronic problems, the condition may take longer than that time frame to improve. In this case, a challenge phase can be used to add the agent back into their diet to test whether the symptoms worsen or return if the food is reintroduced. After that time, a long-term diet plan can be created with the patient based on these results.

There is increasing evidence regarding foods that should be added to one's diet for certain health benefits. One example of this is the anti-inflammatory diet. It has been estimated that significant numbers of chronic conditions could be prevented by adhering to a healthy diet [23]. There are many types of anti-inflammatory diets. These generally focus on reducing the amounts of red meat, sodium, dairy, and carbohydrates in the diet. Specific dietary therapies that can be used for treatment are beyond the scope of this chapter.

Homeopathy

First developed in the eighteenth century, homeopathy has been rising in popularity since the latter part of the twentieth century. The basic tenets of homeopathy include curing illness with highly diluted substances that at full strength cause the symptoms being treated. The theory is that this process creates a "healing crisis" in which symptoms may worsen before improving. Occasionally the homeopathic medicines are too strong and require a substance or remedy to counteract the effect called an antidote. Many allopathic medications and treatments may function as antidotes and may make patients who are taking homeopathic remedies reluctant to take other medications.

Classical homeopathy is highly individualized and relies on the skill of the practitioner to determine the remedy for a particular person. Similar patients might require different approaches. This has complicated attempts to standardize treatments for scientifically controlled trials, and there is little work that compares homeopathy to allopathic medications [24]. Homeopathic medications are available over the counter for specific conditions, and because classical homeopathy is highly individualized, consultation with an experienced practitioner is recommended.

Numerous training courses and programs provide instruction in homeopathy, but no diploma or certification is currently recognized in the USA to practice homeopathy. There are no national standards or licensing requirements, but both allopathic and naturopathic physicians may use homeopathy as a part of their practice.

Traditional Chinese Medicine (TCM)

Qi (pronounced "chee") is thought to be the vital force that circulates throughout the 12 primary and 8 accessory channels known as meridians to protect, nourish, and animate living beings. Although TCM treatments are used to mend disease states, the central purpose, or higher wisdom, is to maintain the body's order and balance by preserving the conditions within which life thrives. Disease states are thought to result from internal and external causes that disturb balance, such as that between yin and yang. Treatment is aimed at correcting the imbalance through disbursement or replenishment of the disrupted element within the body. Traditional Chinese medicine (TCM) includes the practice of acupuncture, moxibustion (the burning of the herb mugwort to tonify acupuncture needles, or used alone to warm acupuncture points), massage, herbal therapy, and qi gong, a meditative physical exercise. All of these modalities are employed to improve the flow of qi. TCM practice is based on thousands of years of practice and recorded case histories, or "wisdom that has stood the test of time."

Acupuncture

For the treatment of pain, acupuncture analgesia has been shown to be more effective than placebo, indicating that there is a physiologic mechanism present [25]. Nearly every state in the USA has laws regulating acupuncture practice. There are 55 acupuncture schools in the USA [26]. Many

licensed physicians and dentists acquired their acupuncture licenses through continuing education, and several universities offer acupuncture courses to both post and predoctoral students of health science. It is postulated that the penetration of the acupuncture needle stimulates small-diameter nerves in muscles, which then send impulses to the spinal cord. These impulses activate three centers – the spinal cord, midbrain, and pituitary – to release endorphins and the monoamines serotonin and norepinephrine, which act to suppress pain transmission to the cortex at multiple synaptic levels [27]. Further, at the level of the pituitary gland, adrenocorticotropic hormone (ACTH) is released in equimolar amounts to endorphin, thus stimulating cortisol production by the adrenal cortex [28]. This may explain why acupuncture has been found to be helpful in the relief of bronchospasm in asthma and inflammation of arthritis.

The World Health Organization recognizes more than 40 conditions for which acupuncture may be useful (Table 7). Areas of active research regarding acupuncture treatment efficacy include addiction, stroke rehabilitation, hypertension, attention-deficit/hyperactivity disorder, and major depressive disorder. Americans most commonly seek acupuncture treatment for the relief of chronic pain, particularly for arthritis and low back pain [29]. Clinical studies have demonstrated efficacy in chemotherapy- and anesthesia-induced nausea and for postsurgical dental pain. In some cases, it has been found that the combination of acupuncture and standard pharmaceutical treatment is superior to either modality used alone.

In 1996 the FDA reclassified acupuncture needles from the investigational class III status to a class II device and required the use of sterile, nontoxic needles that bear a labeling statement restricting their use to qualified practitioners. Complications associated with acupuncture are relatively rare. The reported occurrence of adverse events is only about 50 cases over a 20-year period in the USA [19]. Reported complications have included pneumothorax and other organ injury, transmission of infectious disease, syncope, bleeding, dyspnea, chest pain, dermatitis, and migration of broken needle fragments [30]. Contraindications to acupuncture include bleeding disorders, skin infections, and valvular heart disease (insertion of semipermanent needles only). Electro-acupuncture should not be used for patients with pacemakers, cardiac arrhythmias, or epilepsy. Caution also must be exercised in pregnant women, as stimulation of some acupuncture points may stimulate uterine contractions.

Table 7 The World Health Organization recognizes traditional Chinese medicine (TCM) treatment of over 43 common disorders

Gastrointestinal disorders
Food allergies, peptic ulcer, chronic diarrhea, constipation, indigestion, gastrointestinal weakness, anorexia, gastritis
Urogenital disorders
Stress incontinence, urinary tract infection, sexual dysfunction
Gynecological disorders
Dysfunctional uterine bleeding, infertility in women and men, premenstrual syndrome
Respiratory disorders
Emphysema, sinusitis, allergies, asthma, bronchitis
Musculoskeletal and neurologic disorders
Arthritis, migraine headaches, neuralgia, insomnia, dizziness, low back pain, neck pain, shoulder pain
Cardiovascular disorders
Hypertension, angina pectoris, arteriosclerosis, anemia
Emotional and psychological disorders
Depression and anxiety, attention-deficit/hyperactivity disorder
Addictions
Alcohol, nicotine, and drugs
Eye, ear, nose, and throat disorders
Ear infection, serous otitis, sinusitis, tinnitus

Naturopathy

Naturopathy is not a single discipline, but represents a wide variety of practices and techniques that are combined into a philosophy of healing [31]. Naturopaths may utilize herbal medications, homeopathy, diet and exercise, stress management, hydrotherapy, massage, and many other modalities in an individualized approach for

each patient. Naturopathic physicians (NDs) are trained as primary care physicians in 4-year, accredited doctoral-level naturopathic medical schools. As of 2015, there are 17 US states, 2 US territories, and a number of provinces in Canada, Australia, and New Zealand that recognize licensure for NDs. The principles of naturopathy are as follows:

1. Holistic approach to patient care
2. Identification of underlying causes rather than symptomatic treatment
3. Use of therapy to promote the body's self-restorative powers
4. Emphasis on self-care and prevention
5. Interdisciplinary cooperation with other medical providers

Hypnosis

Hypnosis is a method of helping patients to move beyond conscious and subconscious blocks that may thwart their healing process. Under hypnosis, patients are active problem solvers who incorporate their moral and cultural ideas into their behavior while exhibiting a heightened responsiveness to the expectations expressed by the therapist [32]. This technique may be useful in such diverse situations as tobacco cessation, chronic pain, and irritable bowel syndrome.

Hypnosis is a collection of methods that can be carried out by a therapist or applied by self-methods. Although the process is mainly self-guided, most patients seek guidance from a therapist when seeking this treatment. This can be placed in the category of mind–body techniques, and it can be used to treat a variety of medical conditions.

The following are six main principles that are discussed by Dr. Steven Gurgevich in his *Hypnosis and House Call book* and DVD [33] (Table 8).

Table 8 Principles of hypnosis

Process involved in hypnosis	Description of process
Educate	Goal of this step to remove fear and to teach patient about the process of hypnosis
Tailor	This is when the practitioner is able to "tailor" the technique to participants unique needs and beliefs
Induce trance	The process of getting the participant to begin the hypnosis process; there are many ways this can be performed
Utilizing trance	The process of identifying and working on the problems that are the reasons that the participant sought this type of treatment
Re-alert	This step involves the reversal of the induction technique
Debrief	With the patient alert, there is a discussion regarding the process and next steps

There is a certification process to become certified in hypnotherapy. Currently certification and licensure are required in the following states: Colorado, Connecticut, Florida, and Washington. It is important that the practitioner also has a background in either the field of medicine, psychology, or social work. The American Society of Clinical Hypnosis (ASCH) is recognized as the organization that provides the training and education needed for a practitioner to obtain this certification. Although there are many studies that have been done in the field of hypnosis research, outcomes have had varying levels of success [33].

Biofeedback

This technique has been used since the mid-twentieth century and is used in an attempt to improve movement patterns for chronic illness or after injuries. The positive part of the treatment is that the patient is able to be given information on how to improve their condition during their sessions so that they can attempt to manage these conditions/problems better in the future.

Biofeedback training is used to assist patients and clinicians during rehabilitation. There is no formal licensure process that is required; but

certification exists. There are two types of biofeedback: physiological biofeedback and biomechanical biofeedback. Most of the research in this field focuses on the use of biofeedback in rehabilitation of patients with neurological disorders. EMG biofeedback is the most popular form of biofeedback. The evidence to support the use of biofeedback in rehabilitation appears promising; however, there is a lack of systematic reviews including a large number of RCTs examining this subject [34].

Feldenkrais Technique

Feldenkrais is a technique that was developed by Dr. Moshe Feldenkrais in the 1950s. He was trained a chemist and neurophysiologist. After having his own problems with knee pain, he studied and developed his method [35]. The Feldenkrais method can be done as a group or individually. The group lessons focus on one being aware of one's movements, and the practitioner leads participants through a sequence of movements. Even though the class is in a group setting, participants go at their own pace, and the process does not involve modeling a central instructor. The goal of the treatment is to identify and reeducate the mind and body and to essentially unlearn physical dysfunctions by using proper movements. Most sessions are between 30 and 60 min. The role of the Certified Feldenkrais Practitioner (CFP) is to direct attention to habitual movement patterns that are inefficient or strained. Then the CFP can teach the patient new patterns using gentle, slow, repeated movements that can be both active and passive in nature.

There is limited scientific evidence on the effectiveness of the Feldenkrais technique. To teach this technique, there is a certification process. Licensure is not needed, but to obtain the qualification of Certified Feldenkrais Practitioner (CFP), Feldenkrais teachers complete close to 1000 h of training. It is training that physical therapists commonly study to add to their approach when treating conditions that involve pain and movement dysfunctions.

Conclusion

Integrative medicine is a diverse collection of practices, procedures, and philosophies of healing. There is widespread use of IM, and there have been improvements in the scientific studies to confirm that these practices are safe and effective. Physicians should be aware of the IM practices used by their patients and work to become knowledgeable in the legitimate uses of alternative medicine. Physicians should remain open to discussion of IM with patients and assist them in selecting IM practices and practitioners that have demonstrated effectiveness and safety.

The Family Physician's Role in a Changing Health Care System

Marc Matthews* and Summer V. Allen
Department of Family Medicine, Mayo Medical School, Mayo Clinic College of Medicine, Rochester, MN, USA

Definition/Background

Primary care is at a crossroads. Our current delivery systems are unsustainable and lack the resiliency to survive in new environments where total cost of care, patient experience, and patient-centered outcomes are the primary determinants of success. In order for primary care to remain relevant and viable, new solutions must be created and new roles must be defined that are practical and transformative. These new roles and solutions must provide clear value with highly satisfying services that both meet the needs of the patient and provide for population health. Family medicine also must consider the ways in which care coordination can be improved. This is especially important in managing populations and subpopulations of patients with multiple chronic conditions. The cost of care must come down and quality must remain high in order to be able to deliver affordable care.

Family physicians have traditionally seen our value in maintaining a longitudinal provider-patient relationship. The historical value of primary care is the ability to form relationships with patients to provide proactive and timely care, avoiding costly inpatient hospital stays and tests. Recent studies have shown that when patients have access to primary care, there are fewer ER visits, hospital admissions, and lower overall cost of care with improved outcomes and quality of life [1]. However, regulatory and payment changes that started nearly a decade ago are now gaining momentum and will have significant impact on the ability of primary care providers to maintain this same depth of relationships with all of our patients. More people will now have access to health insurance, and because of this there will be increasing demand on a shrinking pool of primary care providers. Widely cited research shows that to accomplish all the necessary preventive services for the current average panel size would take 27 h a day. And yet, because the work necessary to keep people healthy is often not valued, increasingly family medicine practices have shifted to treating acute illnesses while long-term health goals may be deferred to maintain higher and higher volumes and productivity. Recent work has begun to redesign the models of primary care, aimed at allowing patients to have highly satisfying experiences with physicians who also remain fulfilled and happy in their careers.

It is clear that the healthcare system in the United States is changing. Because of this, the specialty of family medicine has a choice to make: redefine our roles to make us an essential and valuable part of this system or cling to outdated roles and risk irrelevancy.

The History of the Family Physician

The specialty of family medicine began as a reaction to a vacuum where there was an absence of continuous lifelong care that acknowledged the needs of individuals as part of a family, a community, and a society. This role evolved to become the symbol of a physician within communities and who was the expert who defined health in an individual's life.

*Email: matthews.marc@mayo.edu

DOI 10.1007/978-1-4939-0779-3_48-1

The formal concept of primary care originated in post-World War I Europe, where there was heavy demand for healthcare in an environment of minimal resources. The explicit description of a primary or general medical service as distinct from specialty care was first described in the Dawson report, published in Great Britain in 1920. This report describes a community-based physician who was responsible for leading a team that was tasked with maintaining the population's health- an ideal that we are starting to return to after almost 100 years [2]. It was not until 25 years later that primary care became the foundation of the health system of the United Kingdom, where 80 % of patients' interaction with healthcare is in the primary care arena [1].

Profound changes in twentieth century economies and demographics continued to have a significant impact on the practice of medicine. In the United States, the rapid expansion of the health insurance system led to a large influx of funding into the healthcare system. This allowed investment to improve and expand medical education and postgraduate training. These dual forces had the effect of increasing the number of physicians in the workforce while simultaneously attracting them to higher-paying specialty practices [3]. These changes in the healthcare workforce were not followed by changes in the consumption of healthcare, which continued to be driven largely by community-based primary care outside the walls of the new tertiary and quaternary academic medical centers. By the 1950s, the movement toward specialty care had progressed far enough to prompt the American Medical Association to call for a special effort to ensure the preservation of the generalist physician [3]. The first formal general practice residency programs were established in the 1960s, and the American Academy of Family Physicians was formally launched in 1971 [4].

In 1978, the World Health Organization (WHO) convened the first International Conference on Primary Health Care and defined primary care as

> . . .essential health care based on practical, scientifically sound and socially acceptable methods and technology made universally accessible to individuals and families in the community through their full participation and at a cost that the community and the country can afford. . .It forms an integral part of both the country's health system, of which it is the central function and main focus, and the overall social economic development of the community. It is the first level of contact for individuals, the family and the community. . .and constitutes the first element of continuing health care process [1].

As time has passed, we have learned more about the value of primary care and the essential features of high-quality care. As a result of this, the WHO updated the definition of primary care in 2008 to include comprehensive care, team-based care, integration into the community, and a special focus on prevention and health promotion [1]. Since it is a specialty that responds to the needs of the communities it serves, the role of the family physician will continue to evolve. The current role is probably best described as providing care that is based on "knowledge of the patient in the context of family and community that emphasizes disease prevention and health promotion" [5].

Up until very recently, Family Medicine physicians in the United States have been governed by a fee-for-service model. Practices were seen as successful based on visit volume and revenue in a system that perversely rewarded clinics when patients were sick rather than healthy. These incentives flew directly in the face of the philosophy and ethics of the profession leaving providers with a difficult dilemma: create a practice that is true to the values of Family Medicine or increase visits and volumes to survive financially.

DOI 10.1007/978-1-4939-0779-3_48-1

Market and Other Forces that Necessitate Changing the Role of the Family Physician

While providers have traditionally been held accountable to volume targets with revenue tied to how sick rather than healthy the patient is, changes in healthcare are quickly pushing Family Medicine, and all of primary care, to focus on health promotion instead of sick care.

In 2012, healthcare spending in the United States accounted for 16.9 % of gross domestic product (GDP), the highest percentage among OECD (Organisation for Economic Co-operation and Development) countries and more than 7 % higher than the OECD average [6]. The United States per capita spending in 2009 was $8,160, and the Center for Medicare and Medicaid Services (CMS) projects by 2018 per capita spending will be over $13,000 [7, 8]. Despite this extra spending, life expectancy in the United States is 1½ years less than the OECD average, and the gap between life expectancy in the United States and other OECD countries is increasing [6]. One of the reasons cited for the slower progress in life expectancy is a gap in primary care [6].

In contrast to the situation in the United States, countries that place a stronger emphasis on primary care as a promoter of health as opposed to being reactionary to illness demonstrate less health care spending per capita with improved outcomes. Spain adopted a national health system in 1986 and, with a primary care physician-to-population ratio similar to that of the United States, was able to lower health spending to 8.4 % of their GDP while demonstrating improved overall health [1]. Examples from other countries demonstrate that strong primary care with enhanced accessibility improves health outcomes, reduces hospital use, improves equity, and slows rates of cost growth for medical services. Countries such as Holland and the United Kingdom have further strengthened primary care by exempting practices from deductibles and cost sharing, by providing support for after-hours care and by providing monetary incentives to the primary care practices that support ready access to care and the formation of teams [9].

In the United States, society, the government, and healthcare payers have come to the conclusion that spending 1 out of every 3 tax dollars on health care is not sustainable for our nation [1]. The Institute for Healthcare Improvement (IHI) has attempted to address these issues with the development of the triple aim initiative, which focuses on increasing the quality of care, decreasing the total cost of care, and improving health outcomes for individuals and populations [10, 11]. This creates a new consumer focus and accountability that medicine, especially family medicine, must respond to. In addition, the Affordable Care Act (ACA) will expand healthcare insurance coverage to individuals who have likely not been regular utilizers of primary care services [12]. These two forces will have the effect of increasing the demand on primary care services while simultaneously increasing the accountability for the outcomes and value of these services.

In terms of payment reform, to date there have been three major payment models that have emerged as viable methods to address consumer and payer demands and have begun the stepwise process of evolution toward a total cost of care or population-based payment model. The first is value-based purchasing, increasingly used by Medicare, which is a pay-for-performance program that incentivizes provider performance in achieving predetermined measures of both process and outcome. By creating connections between reimbursement and outcomes, this payment model shifts the focus to the quality of healthcare and patient experience. Projections suggest that Medicare's value-based purchasing programs will continue to reduce the relative weight of clinical processes in reimbursement models while increasing the weight of outcomes and efficiency [13]. The second major model is the "bundled payment" system, wherein the payer disburses a single payment to cover an entire episode of care. Providers stand to gain in this payment model if they can provide the care for less than the proposed payment. The third major type of new payment model to emerge is the Accountable Care Organization (ACO), which refers to a network of affiliated providers who accept collective accountability for the total cost of care and the quality of that

DOI 10.1007/978-1-4939-0779-3_48-1

care for a defined population of patients. The purpose of ACOs is to reward providers for controlling or reducing the total cost of care through services that focus on prevention, care coordination, chronic condition management, palliative care, as well as patient and community engagement. In 2014, 67 % of the US population was living in a service area with at least one ACO, and 5.3 million Medicare beneficiaries were treated by an ACO [13].

Another important emerging market force that is currently affecting the evolution of primary care is the rapidly increasing shift toward consumerism in healthcare. As a result of changes in the insurance marketplace, more people have access to healthcare, and the relative share of personal responsibility for healthcare expenses is increasing. Trends in the marketplace are demonstrating that people are choosing leaner or higher deductible plans, effectively increasing their out-of-pocket expenses. With more of their own money at stake, patients are applying their comparison shopping savvy to healthcare choices and are looking for providers that can offer clear value, convenience, and new options for access. In some cases, prospective patients are ranking convenience and affordability far above continuity of care in their choice of provider [13].

A Proposed Model: Offering a Path to Innovation

In order to respond to these new market drivers and meet the needs of the patient as a consumer, healthcare organizations are beginning to apply this consumer lens to primary care and are discovering that consumers understand primary care as being divided into four distinct domains: Self-Care, Assessment/Detection, Treatment, and Management. Several successful systems are implementing a team-based model of care built around these four patient-focused domains.

The four domains can be envisioned as a continuum that patients move back and forth within while primary care seeks to provide the most appropriate service at the right time and place. The goal is to help individuals remain in the Self-Care domain autonomously with only infrequent intervention from the clinic or to help the patient regain the capacity to return to the Self-Care domain. This means the healthcare system will at times need to offer support and information in a different, less intensive, and possibly more effective way.

Currently, primary care spends significant time and energy in the Self-Care domain doing things to patients that are better suited to less intensive modes of care. Certain activities such as wellness exams and follow-up for healthy individuals with no risk factors may help to ensure continued assessment of risk factors and to sustain revenue streams. This is not intended to imply that primary care does not engage patients in the Self-Care domain; instead it implies that our current process may be inappropriate for effectively serving this patient population and that service offerings must be adjusted to meet the appropriate needs of our patients based on their clinical, social, and behavioral risk factors.

Systems such as Geisinger Health System, Kaiser Permanente, Group Health Cooperative, the Military Health System, the Mayo Clinic, and the national health services of several European countries have adopted a team-based care model as a way to meet patient needs in these four domains [14]. Team-based care models are also a positive way to respond to the needs of population health models, with their associated influx of data-driven care needs. However, the adoption of a team-based care model is often hampered by the persistence of fee-for-service reimbursement models, leaving physicians reluctant to delegate work to others or to consider nonvisit care options [14].

Key Characteristics of Ideal Family Physician of the Future

The ideal family physician of the future is the leader of a team but not necessarily always in charge. The ideal family physician understands their team, enables everyone to work at the top of licensure in support

DOI 10.1007/978-1-4939-0779-3_48-1

of patient health, and is acutely aware of their value and skill set within the team. The ideal family physician cares for patients as a member of the team that extends beyond the clinic proper to all of those who touch the patient in a healthcare capacity.

While the specialty must continue to evolve to meet the needs of the communities it serves, there are four key characteristics of the family physician that will be crucial for the future of the specialty.

First, family physicians must be advocates for understanding the true needs of the population of patients we serve. Patients' needs must be the driving force for any changes in our healthcare delivery systems. Although family physicians are often closer to our patients than physicians in other specialties, we cannot make the mistake of assuming that we know what our patients need. For instance, family physicians often indicate that our patients' deciding factor in choosing a primary care provider is continuity. However, patients are more likely to rank access, affordability, and convenience higher than continuity [13]. Understanding the true needs of our patients may lead to very different healthcare delivery systems than the ones we currently have. However, it is usually not sufficient to simply ask patients what they want or need. Like consumers in other industries, patients may not know or are not able to express their latent desires. So asking a patient advisory council for input or sending out patient surveys may not lead to the most innovative or transformative outcome. The family physician needs to be an advocate for utilizing the tools and skills that other service industries have used in order to successfully understand patient needs.

Second, the family physician needs to be a champion for change. For the foreseeable future, change is likely to be the only constant in many healthcare organizations. As advocates for the true needs and voice of the patient, family physicians can help shepherd their organizations through the requisite changes that will need to happen in response to healthcare reform. Our clinics and care teams will look to the physicians to champion the changes that will be necessary to allow family medicine to continue providing high-quality and high-value care.

Third, the family physician needs to be a care team leader. While often this is interpreted as being in charge of the care team, being a leader is much different. Care team leaders will be responsible for ensuring that populations of patients are getting evidence-based preventive services and chronic condition management through the most efficient and cost-effective methods possible. Care team leaders work with the patient and their family to diagnose a problem and then create an anticipatory treatment plan that can be executed by other team members. When a patient needs to be seen in the clinic, a care team leader ensures the patient is paired with the team member whose licensure most closely matches the patient's needs. Care team leaders remember to respect the patient and their relationship with the provider by taking the first few minutes of the visit to introduce the new team member and explain why they are the best care provider to meet the patient's needs. This reassures the patient that their family physician is still overseeing their care and gives the patient permission to engage with other team members. These warm handoffs never fail to soothe patient anxieties and may also help patients engage with new services that they would have otherwise been skeptical or apprehensive about. As the leader of the care team, physicians must provide the team with model collaborative and communicative behavior. The leader must demonstrate how to value each team member for their role and encourage the entire team to work at the top of their licensure in a way that benefits the patient. Excellent care team leaders support their team in a way that does not require direct oversight of each member's tasks but instead creates an environment of trust and collaboration that allows each team member to function autonomously and seamlessly within the group. In this way, it is also important for family physicians to participate in regular teaching to support their care team- remembering the adage that we are all teachers and we are all learners.

Lastly, family physicians will need to increase their depth of medical knowledge and skills to complement the impressive breadth of knowledge that they already possess. As both population demographics and the healthcare industry change, primary care will be expected to regularly care for the types of complex patients that were traditionally referred to specialty practices. Family physicians will need to

DOI 10.1007/978-1-4939-0779-3_48-1

become more comfortable in the management and coordination of complex chronic diseases that will increasingly be seen in the same patient, and often superimposed on significant social comorbidities. This type of management has not been within the scope of training for family physicians to date but should be considered as part of their future education. In order to help these patients, we must embrace the skills and talents of our team members and be comfortable in delegating care to the team member who has skills that are the most appropriate for the patient's needs. Like all members of the care team, family physicians must be prepared to do all the things we were trained to do and challenge ourselves every day. At times, for noncomplex patients this means stepping aside and allowing our teams to provide care when necessary. On the other hand, with complex patients this may mean that we need to stretch ourselves to provide high-quality care. Recognizing our full potential to make diagnoses, perform procedures, and manage complex chronic conditions is as important as understanding our limitations and reaching out and surrounding ourselves with trusted specialty partners when the need is beyond our training. Having trusted and collaborative relationships with specialty providers not only provides our patients with the highest quality of care but also allows us to learn through dialogue and cooperation. Being a family physician means being a member of a team. That team includes the formal care team of allied health staff and also the patient, their loved ones, and individuals we can go to with questions when we need support.

Conclusion

Family physicians have a clear value within society, and it is incumbent upon all of us to continue to demonstrate that value as the landscape shifts. The changing landscape provides us with a unique opportunity to reposition ourselves as a supportive force in maintaining health for our patients and the populations we care for. We can only survive as specialty if we understand how we can best fit within the changing ecosystem of healthcare. The future is bright for the family physician and the teams we support.

Patient-Centered Medical Home

Ivan Abdouch

Contents

Definition of the Medical Home

While the most commonly used term is "patient-centered medical home," others such as "primary care medical home," "personal medical home," "advanced medical home," and "healthcare home" also exist. Despite variances among these concepts, all share similar core values and principles. Except for direct quotes that refer to a specific medical home, the term "medical home" will be used for this chapter in an effort to be more inclusive.

The fact that each state has its own definition for the medical home illustrates that no universal definition exists. The medical home is difficult to define because it is not a place or an object. It is a concept that is intended and designed to encourage primary care physicians to achieve excellence by focusing all aspects of healthcare delivery on the patient. It does so by including specific elements – patient-centered, comprehensive team-based, and coordinated care that is accessible and is committed to quality and safety.

Perhaps the closest thing to a definition from the family physician perspective is offered by the policy statement from the American Academy of Family Physicians (AAFP):

> The patient-centered medical home is a transition away from a model of symptom and illness based episodic care to a system of comprehensive coordinated primary care for children, youth and adults. Patient-centeredness refers to an ongoing, active partnership with a personal primary care physician

> who leads a team of professionals dedicated to providing proactive, preventive and chronic care management through all stages of life. These personal physicians are responsible for the patient's coordination of care across all health care systems facilitated by registries, information technology, health information exchanges, and other means to ensure patients receive care when and where they need it. With a commitment to continuous quality improvement, care teams utilize evidence-based medicine and clinical decision support tools that guide decision making as well as ensure that patients and their families have the education and support to actively participate in their own care. Payment appropriately recognizes and incorporates the value of the care teams, non-direct patient care, and quality improvement provided in a patient-centered medical home. [1]

History of the Medical Home

While the medical home has gained recent attention, it is not a new entity and it did not suddenly appear. The original medical home concept was established by the American Academy of Pediatrics (AAP) in 1967, when it was designated to be one central source of a child's pediatric records, especially for children with special healthcare needs. The concept was expanded by the AAP in 2002 to include care that is accessible, continuous, comprehensive, family centered, coordinated, compassionate, and culturally effective [2]. Similar models were subsequently developed by the AAFP in 2004 [3] and the American College of Physicians (ACP) in 2006 [4]. This movement was influenced along the way by a number of events. Some of the key points include:

1978: The Declaration of Alma-Aita was introduced at the International Conference on Primary Health Care – the first international declaration of primary healthcare's key role in promoting the health of all people, subsequently supported by the World Health Organization [5].

1996: The Institute of Medicine (IOM) redefined primary care as "the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health needs, developing a sustained partnership with patients, and practicing in the context of family and community" [6].

2001: The IOM defined "patient-centered care" as "health care that establishes a partnership among practitioners, patients, and their families (when appropriate) to ensure that decisions respect patients' wants, needs, and preferences and that patients have the education and support they require to make decisions and participate in their own care." – a statement of recognition that patients and families are core members of the care team, and the medical practice should provide what they need in order to be full partners in the process of their care [7].

2002: The Future of Family Medicine project began and recommended that health system change should "include taking steps to ensure that every American has a personal medical home [. . . and] developing reimbursement models to sustain family medicine and primary care" [3].

2005: Dr. Barbara Starfield published a very influential article called "Contribution of primary care to health systems and health" in which she identified six primary care mechanisms that benefit health: (1) greater access to needed services, (2) better quality of care, (3) a greater focus on prevention, (4) early management of health problems, (5) the cumulative effect of the main primary care delivery characteristics, and (6) the role of primary care in reducing unnecessary and potentially harmful specialist care [8].

Principles and Characteristics of Medical Homes

With the medical home's history, the Declaration of Alma-Aita, the IOM definition of primary care and patient-centered care established, and the identification of specific mechanisms to target, the medical home movement gained momentum, and it was determined that guidelines were needed.

In 2007 the AAFP, AAP, ACP, and American Osteopathic Association (AOA) developed the "Joint Principles of the Patient-Centered Medical Home," listing elements to include in a medical home [9]. While characteristics may vary among practices, the characteristics that determine medical home status are more uniform because of these Joint Principles:

Personal physician – each patient has an ongoing relationship with a personal physician trained to provide first-contact, continuous, and comprehensive care.

Physician-directed medical practice – the personal physician leads a team of individuals at the practice level who collectively take responsibility for the ongoing care of patients.

Whole person orientation – the personal physician is responsible for providing for all the patient's healthcare needs or taking responsibility for appropriately arranging care with other qualified professionals. This includes care for all stages of life: acute care, chronic care, preventive services, and end-of-life care.

Care is coordinated and/or integrated across all elements of the complex healthcare system (e.g., subspecialty care, hospitals, home health agencies, nursing homes) and the patient's community (e.g., family, public, and private community-based services). Care is facilitated by registries, information technology, health information exchange, and other means to assure that patients get the indicated care when and where they need and want it in a culturally and linguistically appropriate manner.

Quality and safety are hallmarks of the medical home:

- Practices advocate for their patients to support the attainment of optimal, patient-centered outcomes that are defined by a care planning process driven by a compassionate, robust partnership between physicians, patients, and the patient's family.
- Evidence-based medicine and clinical decision-support tools guide decision-making.
- Physicians in the practice accept accountability for continuous quality improvement through voluntary engagement in performance measurement and improvement.
- Patients actively participate in decision-making and feedback is sought to ensure patients' expectations are being met.
- Information technology is utilized appropriately to support optimal patient care, performance measurement, patient education, and enhanced communication.
- Practices go through a voluntary recognition process by an appropriate nongovernmental entity to demonstrate that they have the capabilities to provide patient-centered services consistent with the medical home model.
- Patients and families participate in quality improvement activities at the practice level.

Enhanced access to care is available through systems such as open scheduling, expanded hours and new options for communication between patients, their personal physician, and practice staff.

Payment appropriately recognizes the added value provided to patients who have a patient-centered medical home. The payment structure should be based on the following framework:

- It should reflect the value of physician and nonphysician staff patient-centered care management work that falls outside of the face-to-face visit.
- It should pay for services associated with coordination of care both within a given practice and between consultants, ancillary providers, and community resources.
- It should support adoption and use of health information technology for quality improvement.
- It should support provision of enhanced communication access such as secure e-mail and telephone consultation.
- It should recognize the value of physician work associated with remote monitoring of clinical data using technology.
- It should allow for separate fee-for-service payments for face-to-face visits. (Payments for care management services that fall outside

of the face-to-face visit, as described above, should not result in a reduction in the payments for face-to-face visits).
- It should recognize case mix differences in the patient population being treated within the practice.
- It should allow physicians to share in savings from reduced hospitalizations associated with physician-guided care management in the office setting.
- It should allow for additional payments for achieving measurable and continuous quality improvements.

These principles have provided some standardized assurances of what medical homes will provide – patient-centered, comprehensive team-based, coordinated care that is accessible and committed to quality and safety. The application and impact of these elements are illustrated in Fig. 1.

As such, the medical home:

- Is accountable for meeting the large majority of each patient's physical and mental healthcare needs – prevention and wellness, acute care, and chronic care. This requires a team of care providers that include physicians, physician assistants, advanced practice nurses, nurses, pharmacists, nutritionists, behavioral health providers, social workers, educators, and care coordinators. In cases where having these individuals present is not practical, the medical home can be "virtual teams" where physicians and their patients are connected with providers and services in their communities.
- Is responsible for actively coordinating all facets of each patient's care, guiding them through the sometimes complex maze of specialty care, hospitals, home healthcare, and community service. This is especially important during transitions between sites of care. This is enhanced by maintaining means of clear and open communication among patients and families, the medical home, and members of the care team.
- Provides a variety of means for patients to access services such as shorter waiting times for urgent needs, enhanced visit availability, continuous telephone or electronic access to a care team member, and nontraditional methods of communication such as e-mail and telephone care. Patient preferences regarding access should be honored.
- Consistently uses evidence-based medicine, clinical decision-support tools, shared decision-making with patients and families, continuous performance measurement and improvement, monitoring and responding to patient outcomes and satisfaction, and practicing population health management.

The Role of Family Medicine in the Medical Home

The Future of Family Medicine report states, "The development of family medicine and its identity as a discipline has been grounded in the core values of continuing, comprehensive, compassionate, and personal care provided within the context of family and community." Placing this next to the IOM definition of primary care makes family physicians ideal for serving as team leader in the physician-directed medical home as specified in the Joint Principles.

The USA spends more on healthcare than any other country in the world, yet the life expectancy in the USA is no greater than most other countries that spend far less (see Fig. 2). The reason for this has been the subject of considerable study.

It has been proposed by many that a major contributor to these differences is the proportion of primary care to specialty care in the health system, i.e., systems with a higher primary care to specialty care ratio produce better outcomes at a lower cost. Evidence supports this proposal [8, 10–12].

Medicare claims data indicate that the more generalists per capita, the lower the costs and the better the quality of care (see Fig. 3), and, conversely, the more specialists per capita, the higher the costs and the lower the quality of care (see Fig. 4).

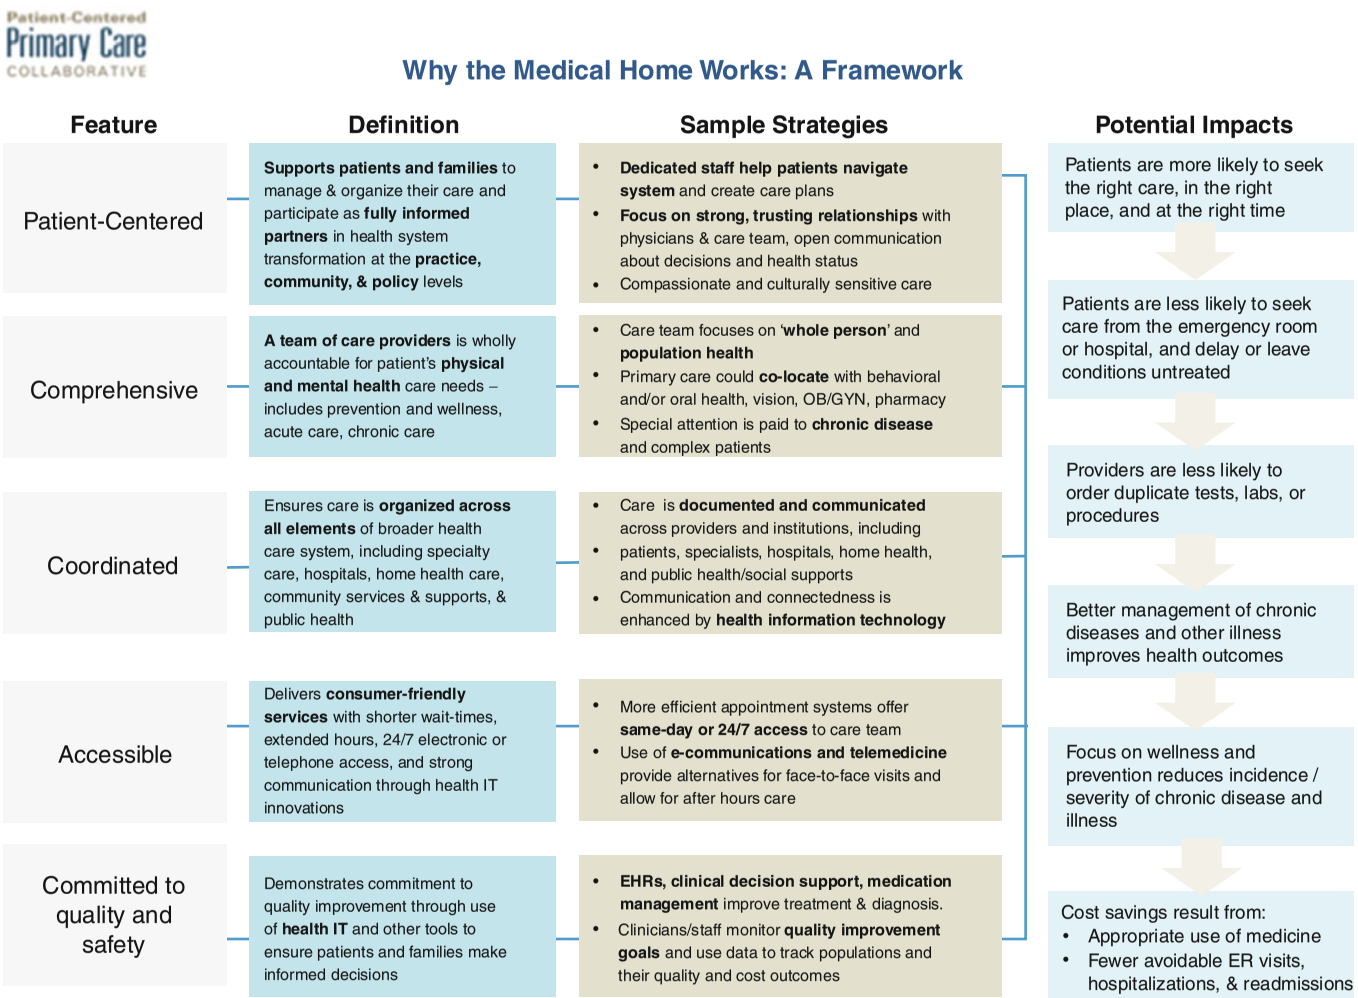

Fig. 1 Why the medical home works: a framework

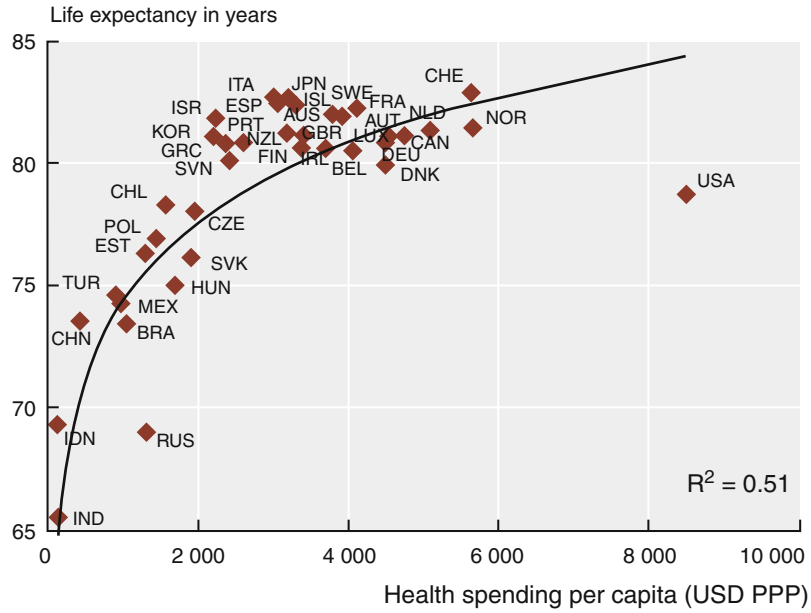

Fig. 2 Comparison among countries showing that the USA spends far more than all other countries with no gain in life expectancy over most other countries who spend far less

Studies conducted by Dr. Barbara Starfield demonstrated significant benefits of primary care [8, 10]. Examples include:

- Locations with stronger primary care systems in place have improved health outcomes over those with lesser primary care for all-cause mortality, cancer, heart disease, stroke, infant mortality; low birth weight; life expectancy; and self-rated health.
- Pooled results for all-cause mortality suggest that an increase of one primary care physician per 10,000 population was associated with an average mortality reduction of 5.3 % or 49 per 100,000 per year.
- An increase of just one primary care physician yields 1.44 fewer deaths per 10,000 persons.
- Adults with a primary care physician rather than some other specialist had 33 % lower costs of care and were 19 % less likely to die (after adjusting for demographic and health characteristics).

Despite the demonstrated benefits of primary care, the supply of primary care physicians in general and family physicians in particular remains very low (see Fig. 5), creating a difficult barrier to improving the performance of healthcare in the USA.

Role of the PCMH in the Health System

As the PCMH model has continued to develop, the healthcare system has seen its value and the concept has begun to be incorporated into other arenas.

One instance of this is the role of the medical home in Accountable Care Organizations (ACOs) [13]. The Centers for Medicare and Medicaid Services (CMS) define ACOs as "groups of doctors, hospitals, and other health care providers, who come together voluntarily to give coordinated high quality care to their Medicare patients" whose goal is "…to ensure that patients, especially the chronically ill, get the right care at the right time, while avoiding unnecessary duplication of services and preventing medical errors." [14] This purpose of improving quality of care, improving outcomes, improving efficiency, and reducing health costs for defined populations bears a striking resemblance to the purposes of the medical home. CMS requires ACOs to maintain a strong network of primary care providers,

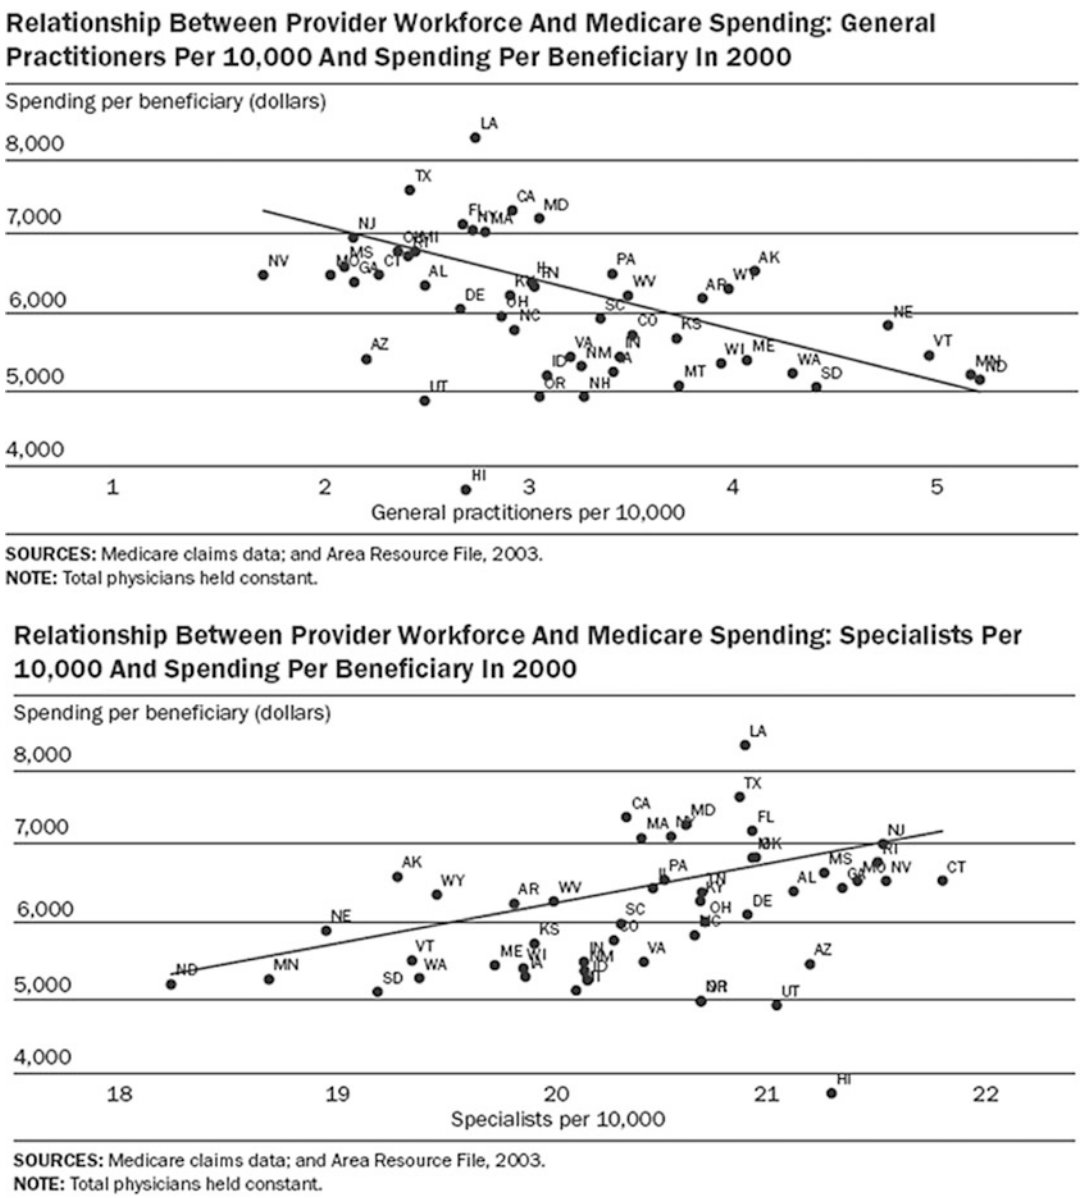

Fig. 3 The cost of care decreases as the supply of generalists per 10,000 population increases, and the cost of care increases as the supply of specialists per 10,000 population increases

but not specifically medical homes. However, it has been suggested that ACO performance can be improved through application of medical home methods along with innovative payment models in which all participating clinicians are rewarded for improving care delivery and health outcomes, and patients are rewarded for making healthy choices. In so doing, all of the benefits of the medical home would be extended throughout the ACO's population. CMS data suggest that this approach has at least initially resulted in improved cost-effectiveness of care and received shared savings.

Another proposed role for the medical home is in the "medical neighborhood" [15]. Like the medical home, this is a concept for which there

Relationship Between Provider Workforce And Quality: General Practitioners Per 10,000 And Quality Rank In 2000

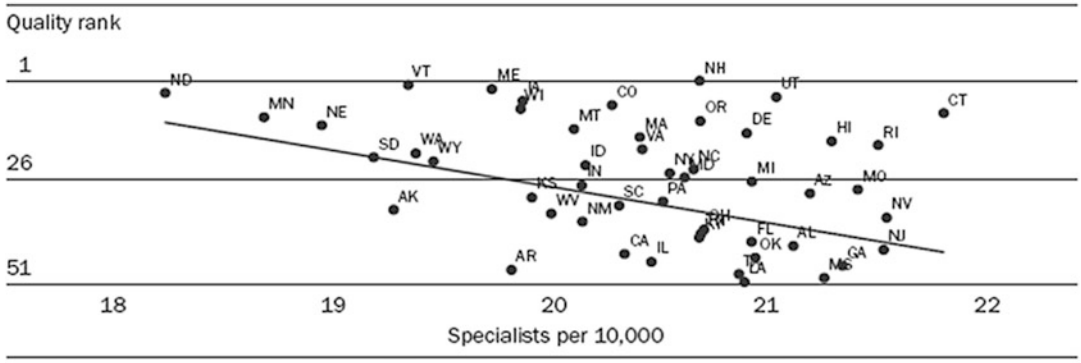
NOTES: For quality ranking, smaller values equal higher quality. Total physicians held constant.

Relationship Between Provider Workforce And Quality: Specialists Per 10,000 And Quality Rank In 2000



SOURCES: Medicare claims data; and Area Resource File, 2003.
NOTES: For quality ranking, smaller values equal higher quality. Total physicians held constant.

Fig. 4 The quality of care increases as the supply of generalists per 10,000 population increases, and the quality of care diminishes as the supply of specialists per 10,000 population increases

is no universal definition, but it has been described by the Agency for Healthcare Research and Quality (AHRQ) as "a PCMH and the constellation of other clinicians providing health care services to patients within it, along with community and social service organizations and State and local public health agencies." The "neighborhood" includes all forms of ambulatory care, diagnostic services, pharmacy, acute and post-acute care facilities, community/social services, and state/local public health entities, with the medical home serving as the central point of contact for the patient and the primary coordinator of the patient's care across various neighbors. AHRQ's outcome statement says, "The intended outcomes of a high-functioning medical neighborhood include improved patient outcomes; patient safety; patient experience; and possibly lower costs through reduced duplication of services, increased delivery of preventive services, and more evidence-based patient care (resulting in fewer readmissions, polypharmacy issues, and adverse events, for example)."

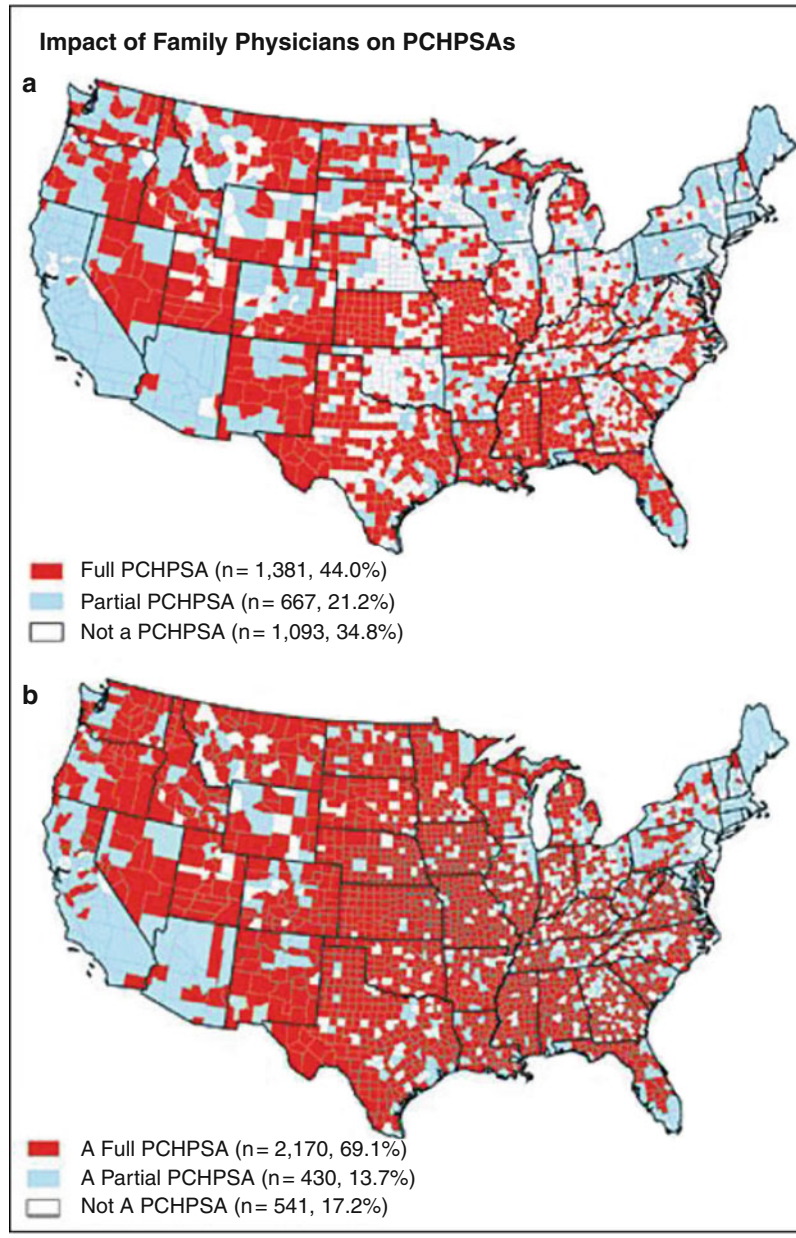


Fig. 5 Map A demonstrates counties designated as Primary Care Health Personnel Shortage Areas (*PCHPSA*); Map B demonstrates counties that would be designated as PCHPSA if family physicians did not practice in those counties

Results and Evidence

The medical home model has been implemented nationwide by a growing number of clinical practices and clinics of all sizes, state and federal agencies, health plans, and employers. As the number of medical homes has expanded, the pool of data assessing outcomes is growing [16–22]. And while the areas impacted vary among medical homes, the general trend has been a demonstration of value added by this model for patients of all ages and in a variety of settings.

An evaluation of aggregated outcomes from 28 peer-reviewed studies, state government program evaluations, and industry reports during

2013–2014 revealed that 24 found improvements in utilization, 17 found improvements in cost, 11 found improvements in quality, 10 found improvements in access, and 8 found improvements in satisfaction.

Examples of outcomes documented by various peer-reviewed articles and industry reports include 31–50 % fewer urgent care and emergency room (ER) visits, 21–53 % fewer hospital admissions, 15–50 % fewer hospital readmissions, 15–40 % fewer inpatient stays, 21 % reduction in inpatient services, 65 % reduction in specialist utilization, 18–65 % improvements in medication management, 31 % increase in self-management of blood sugar, 18 % lower healthcare claims costs, 7 % lower cumulative total spending, and appointment wait time reduced from 26 days to 1 day.

Public statements in support of the medical home have come from the President of the USA, Senators from both parties, the National Academy for State Health Policy, patient and consumer groups, health quality organizations, physicians and providers, purchasers, health plans, pharmaceutical firms, and various think tanks.

Certification, Recognition, and Accreditation

The release and widespread acceptance of the Joint Principles of the Patient-Centered Medical Home in 2007 launched a primary care redesign movement across the country. In view of this, the need for establishing entities offering medical home recognition or accreditation was recognized. In response to this need, AAFP, AAP, ACP, and AOA developed the following "Guidelines for Patient-Centered Medical Home Recognition and Accreditation Programs" [23] to act as a standard for this process, specifying that all Patient-Centered Medical Home Recognition or Accreditation Programs should:

- Incorporate the Joint Principles of the patient-centered medical home
- Address the complete scope of primary care services
- Ensure the incorporation of patient- and family-centered care emphasizing engagement of patients and their caregivers
- Engage multiple stakeholders in the development and implementation of the program
- Align standards, elements, characteristics, and/or measures with meaningful use requirements
- Identify essential standards, elements, and characteristics
- Address the core concept of continuous improvement that is central to the PCMH model
- Allow for innovative ideas
- Care coordination within the medical neighborhood
- Clearly identify PCMH recognition or accreditation requirements for training programs
- Ensure transparency in program structure and scoring
- Apply reasonable documentation/data collection requirements
- Conduct evaluations of the program's effectiveness and implement improvements over time

Accreditation is not required to become a medical home, but some individual entities mandate completion of an accreditation or recognition program for their purposes. Therefore it is important to determine whether such a requirement exists when an agreement is being considered between the practice and another entity – e.g., ACO, payment incentive program, federal grant, and major practice payer agreements.

At the time of this writing, four separate certifying agencies exist – the National Committee for Quality Assurance (NCQA), URAC (formerly the Utilization Review Accreditation Commission), the Joint Commission, and Accreditation Association for Ambulatory Health Care (AAAHC). Each has its own characteristics and methods for applying the features of the medical home, but all comply with the "Guidelines for Patient-Centered Medical Home Recognition and Accreditation Programs." Additional recognition and accrediting agencies may be established as time passes.

Fig. 6 A few resources that provide information, tools, practice, self-assessment, and help with implementation

Practice Transformation

The transformation of a practice to a medical home is not without its challenges [24–26]. It is a gradual and tedious process that requires patience, diligence, tenacity, cooperation, commitment, and effective communication between the practice and the patient, among members of the practice, and between the practice and the community. There are many helpful resources available that provide information, tools, practice, self-assessment, and help with implementation. A few of these resources are listed in Fig. 6.

In Context

The medical home may or may not be "the" solution, but at a minimum it is certainly a worthy effort to reverse negative trends in medicine and at least something to build on. Many practices have reported that the valuable benefits from this process have been well worth the effort.

During transformation, however, caution must be exercised to not be distracted from the primary focus – the patient. In spite of the medical home's mantra of "patient-centeredness," physicians and practices are at risk of becoming so focused on all of the elements and metrics that they can and sometimes do lose sight of the most precious of treasures in primary care – the relationship between the patient and the physician. Every step of the way, the relationship should be assessed to make sure it is preserved and healthy. No aspect of the medical home should ever be allowed to take priority over that relationship.

Chronology: The Evolution of Family Medicine as a Specialty in the United States

Robert B. Taylor[a]* and Paul Paulman[b]
[a]Oregon Health & Science University, Portland, OR, USA
[b]Department of Family Medicine, University of Nebraska College of Medicine, Omaha, NE, USA

Year	Event	Significance
1900	At least 80 % of American physicians were general practitioners: one general practitioner for every 600 persons	General practice was the predominant model of medical care
1910	Publication of the *Flexner Report* by the Carnegie Foundation, with cooperation of the American Medical Association (AMA)	Prompted changes in methods and quality of medical education: premedical education, biomedical research, and postgraduate training
1940	General practitioners (GPs) comprised 76 % of private physicians:	Decline of generalism paralleled the rise of specialty practice
	1950 – 62 % of physicians were general practitioners	
	1960 – 45 % of physicians were general practitioners	
	1970 – 21 % of physicians were general practitioners	
1941	General Practice Certifying Board proposed in AMA House of Delegates	First call for a certifying board for general practitioners; not passed
1946	Section on General Practice of the AMA organized	An early organization of general practitioners with nationwide representation
1947	American Academy of General Practice (AAGP) founded by a small group (no more than 150) of general practitioners meeting in Atlantic City, New Jersey	First major medical organization to require continuing medical education as a condition of membership
1950	First residency training programs in general practice established	Signified need for postgraduate generalist training beyond the internship year
	Publication of journal *GP*	First scientific journal for GPs
1958	Family Health Foundation of America incorporated	Early funding for conferences on generalist education
1960	American Board of General Practice formed	First successful effort to obtain general practice board status
1964	19 % of US medical graduates entered general practice	Continued decline in numbers of general practitioners
	American Board of Family Practice Advisory Group formed	Developed objectives for the American Board of Family Practice (see 1969)
1965	National Family Health Conference sponsored by Family Health Foundation of America	Studied unmet needs of Americans for comprehensive health care, what practitioner can meet this need and how he or she can best be trained
1966	Report of Citizens' Commission on Graduate Medical Education: *The Graduate Education* of *Physicians* (Millis Commission Report)	Identified fragmentation in health care and proposed concept of a “primary physician”
	Report of the Ad Hoc Committee on Education for Family Practice of the Council on Medical Education: *Meeting the Challenge* of *Family Practice* (Willard Commission Report)	Recommended training of a “family physician”

(*continued*)

DOI 10.1007/978-1-4939-0779-3_50-1

Year	Event	Significance
1967	Formation of Society of Teachers of Family Medicine (STFM)	First organization of family medicine educators
1969	STFM published *Family Medicine Times* (*FMT*)	First publication (newsletter) for family medicine educators
	American Board of Family Practice (ABFP) founded	Organized as official certifying board for the new specialty
	Recognition of family practice as a specialty on February 6, 1969, based upon approval of the Liaison Committee for specialty boards	The 20th American medical specialty
	Fifteen approved family practice residencies in the USA	Model graduate training programs established
1970	First examination by ABFP	Successful candidates sitting for 1970 and 1971 examinations became Charter Diplomates
1971	American Academy of General Practice changed its name to American Academy of Family Physicians (AAFP)	The academy recognized shift in emphasis to family practice
1972	AAFP fellowships first awarded	Recognized "interest and participation in special educational programs designed to enhance professional competence and the quality of health care provided to the people of America"
	First meeting of North American Primary Care Research Group (NAPCRG)	Forum for presentation of family practice research results
	WONCA (World Organization of Family Doctors) formed	Worldwide organization begins with member organizations in 18 countries
1973	Publication of *Family Practice* (Conn, Rakel, Johnson, editors)	First major family practice textbook
.	First National Conference of Family Practice Residents and Student Members	First national meeting of family practice trainees
1974	*Journal* of *Family Practice* began publication	First family practice peer-reviewed journal
	Medical students and residents gain seats in AAFP Congress of Delegates	First major specialty to recognize medical student and resident delegates
1975	Residency Assistance Program (RAP) initiated	Family medicine educators develop guidelines and offer consultation to family practice residency training programs
	STFM Foundation formed	The charitable arm of STFM established
1976	First recertification examination by ABFP	First recertification examination by any medical specialty
	Publication of the Virginia Study in the Journal of Family Practice	First major report of doctor-patient contacts in family practice
1977	Doctors Ought to Care (DOC) founded	Championed positive health strategies for the clinic, classroom, and community
1978	Publication of *Family Medicine: Principles and Practice,* 1st edition (Taylor, editor; Buckingham, Donatelle, Jacott, Rosen, associate editors)	First edition of the second major family practice textbook
	Practice eligible route to ABFP certification expired	Candidates for the ABFP certification examination subsequently must have satisfactorily completed a 3-year approved family practice residency
	Association of Departments of Family Medicine (ADFM) established	First organization of family medicine academic units
1979	End of first decade as a specialty: Residency training programs: 364 FP residents in training: 6531 Members of AAFP: 43,956 Diplomates of ABFP: 22,246	Continuing growth of the specialty
	Family Medicine Teacher established	Official journal of STFM

(*continued*)

DOI 10.1007/978-1-4939-0779-3_50-1

Year	Event	Significance
1980	Graduate Medical Education National Advisory Committee (GMENAC) report published	"Near balance" of general practitioners/family physicians vs. need was predicted for 1990; no change recommended for family practice residencies
1981	*Family Medicine Teacher* became *Family Medicine*	Society's publication becomes an academic peer-reviewed journal
	Family Practice Research Journal began publication	Third peer-reviewed journal in family practice
1982	Report of the Study Group on Family Medicine Research: *Meeting the Challenge* of *Research in Family Medicine*	Documented past achievements and current status; indicated future directions in family medicine research
1983	Publication of *Family Medicine: Principles and Practice,* 2nd edition (Taylor, editor; Buckingham, Donatelle, Jacott, Rosen, associate editors)	Principles and practice of discipline integrated as "Family Medicine Content"
1984	Conjoint meeting of STFM and NAPCRG	First joint assembly of family medicine educators and researchers
	Keystone I Conference held at Keystone, Colorado	A time for family practice leaders to meditate and reflect
1985	Liaison Committee on Medical Education (LCME) report *Functions and Structure of* a *Medical School* called for predoctoral training "necessary to enter graduate medical education programs in family medicine. . ."	Official recognition of need for medical schools to present family medicine knowledge, skills, attitudes, and behaviors
	FM student interest groups established at US medical schools	Emphasis on recruitment of medical students to careers in family practice
1986	Family Practice redefined by AAFP and ABFP	New definition affirms independence from other specialties
	More than 20,000 physicians were graduates of 3-year family practice residencies	Record number of residency-trained family physicians
	"Michigan lawsuit" won in United States Supreme Court after 10-year battle	Successful challenge of a Medicare statute that discriminated against family physicians on basis of different fees for the same procedure
1987	First Leadership Skills Development Conference held by the AAFP	Emphasis on enhancing the skills of family physician leaders
1988	*Journal of the American Board of Family Practice* began publication	Fourth US peer-reviewed journal in the specialty
	More than half of all AAFP members were certified by ABFP (26,500 ABFP diplomates)	Most general practitioners had become board-certified family physicians
	Keystone II Conference held in Keystone, Colorado	FP leaders meet to reflect and plan for the future
	First examination for Certificate of Added Qualifications (CAQ) in Geriatric Medicine	Joint venture of American Board of Family Practice and American Board of Internal Medicine
	Publication of *Family Medicine: Principles and Practice,* 3rd edition. (Taylor, editor; Buckingham, Donatelle, Johnson, Scherger, associate editors)	Core problems and procedures in family medicine identified
1989	Anniversary of 20 years as a specialty: 384 residency training programs 7,392 FP residents in training	Family medicine entered third decade as residency-trained physicians began to assume leadership roles
	New active members of AAFP required to be residency-trained family physicians	Affirmed the distinction between family physicians vs. general practitioners and others
	Association of Family Practice Residency Directors (AFPRD) formed	First organization of directors of family practice residency programs
1990	President George Bush signed into law Medicare Physician Payment Reform based on Resource-Based Relative Value Scale (RBRVS)	Projected Medicare payment to be based on resource costs integral to providing a service
	AMA adopted policy that every US medical school should have a family practice department	Recognition of need for medical student exposure to family medicine content and family physician role models

(*continued*)

DOI 10.1007/978-1-4939-0779-3_50-1

Year	Event	Significance
1991	AMA resolved "to develop recommendations for adequate reimbursement of primary care physicians, improved recruitment of medical school graduates, and training a sufficient number of primary care physicians to meet projected national needs"	Evidence of AMA support of family practice and primary care
1992	Medicare physician payment reform began	Beginning phase-in of Medicare fee schedule, eliminating specialty differentials
	Council on Graduate Medical Education (COGME) recommended that half of all medical school graduates enter primary care careers	Recognition that medical schools must meet healthcare needs of the nation
	Archives of Family Practice began publication	American Medical Association affirmed value of family medicine research through support of a new specialty journal
1993	First examination for CAQ in Sports Medicine for primary care physicians	Joint venture of the American Boards of Family Practice, Emergency Medicine, Internal Medicine, and Pediatrics
	Liaison Committee on Medical Education document, *Functions and Structure of* a *Medical School,* changed to read: "Clinical education programs involving patients should include disciplines such as family medicine, internal medicine, obstetrics and gynecology, pediatrics, psychiatry, and surgery"	Family medicine achieved parity with other specialties in requirements for the medical school curriculum
	Number of family practice residencies exceeded 400	New residencies included inner city, rural, and health maintenance organization
1994	Publication of *Family Medicine: Principles and Practice,* 4th edition (Taylor, editor; David, Johnson, Phillips, Scherger, associate editors)	Emphasis on core problems in clinical family medicine
	End of practice pathway to CAQ in Geriatric Medicine	Candidates must complete formal accredited geriatric fellowship program
1995	American Boards of Family Practice and Internal Medicine called for educational resource sharing and collaborative training	Indicated trend for family physicians to teach our knowledge and skills to other specialists
1996	Publication of *Fundamentals of Family Medicine* (Taylor, editor; David, Johnson, Phillips, Scherger, associate editors)	First predoctoral clerkship textbook based on health problems of a single extended family
	Alaska's first graduate medical education program was a family practice residency	Family practice became the first specialty to have residency programs established in all 50 states
1997	Fiftieth anniversary of the AAGP/AAFP	Fifty years since 1947 founding of AAGP in Kansas City Missouri
	Revised Program Requirements for Residency Education in Family Practice	Changes reflect the evolution of the discipline by no longer defining training elements as derivatives of other specialties and emphasizing the role of family physicians as teachers
	Graduates of US family practice residency programs top 50,000	AAFP annual survey confirms that 50,002 physicians have graduated from FP residencies since the 1960s

(*continued*)

DOI 10.1007/978-1-4939-0779-3_50-1

Year	Event	Significance
1998	Publication of *Family Medicine: Principles and Practice,* 5th edition (Taylor, editor; David, Johnson, Phillips, Scherger, associate editors)	Expanded emphasis on clinical problems in generalist health care
	AAFP Research Initiative begun	AAFP commits $7.7 million to support family practice research
	Center for Policy Studies in Family Practice and Primary Care begun in Washington, DC	AAFP initiative intended to bring a family practice and primary care perspective to national health policy deliberations
1999	Anniversary of 30 years as a specialty: Residency training programs: 474 FP residents in training: 10,632 Graduates of FP residency programs: 56,859	Family medicine continues to prosper as it enters the new millennium
	AAFP begins national practice-based network for primary care research	The network's mission will be to "conduct, support, promote, and advocate primary care research in practice-based settings that (1) addresses questions of importance to the discipline of family medicine and (2) improves the healthcare delivery to and health status of patients, their families, and communities"
	Practice pathway to CAQ in Sports Medicine ends	One-year sports medicine fellowship required for eligibility
2000	112 departments of family medicine in US medical schools	Continued success of family practice at the beginning of the new millennium
	476 US family practice residency programs	
	61,000 board-certified family physicians	
	Keystone III Conference held in Colorado Springs, Colorado	A forum for family physicians to share ideas and advance the specialty
2001	Certificate of Added Qualifications in Adolescent Medicine begun	Collaborative effort of ABFP, the American Board of Pediatrics, and the American Board of Internal Medicine
2002	Thirtieth anniversary of the founding of WONCA, which comprises 58 member organizations in 53 countries	World organization of family doctors has total membership exceeding 150,000 general practitioners/family physicians
2003	*Annals* of *Family Medicine* begins publication	New research journal cosponsored by the AAFP, ABFP, AFPRD, NAPCRG, ADFM, and STFM
	Publication of *Family Medicine: Principles and Practice,* 6th edition (Taylor, editor; David, Fields, Phillips, Scherger, associate editors)	Emphasis on evidence-based health care and patient/community-centered practice in the new millennium
2004	AAFP-WONCA combined meeting in Orlando, Florida, USA	Largest meeting in the history of family and general physicians worldwide
2005	American Board of Family Practice changes its name to the American Board of Family Medicine (ABFM)	A new name for the specialty, and the *family practitioner* became the family *physician*
2006	*Preparing the Personal Physician for Practice (P4)* project developed	Fourteen family medicine residency programs to put training innovations into practice
2007	Joint Principles of the Patient-Centered Medical Home developed and endorsed by the major primary care physician associations	A healthcare setting that facilitates partnerships between individual patients and their personal physicians, and when appropriate, the patient's family
2008	The World Health Organization (WHO) publishes *The World Health Report 2008*	Report titled *Primary Health Care: Now More Than Ever* calls for renewal of primary health care as a response to the issues created by globalization
2009	Family medicine celebrates its 40th anniversary as a specialty	Four decades since the specialty was created in 1969

(*continued*)

DOI 10.1007/978-1-4939-0779-3_50-1

Year	Event	Significance
2010	The Patient Protection and Affordable Care Act, commonly called the Affordable Care Act (ACA), signed into law	Most comprehensive overhaul of the United States healthcare system since the passage of Medicare and Medicaid in 1965
2011	Family medicine residencies achieve a record 94 % enrollment rate and add 100 new positions to accommodate the applicant demand	Health system changes seen spurring the increased student interest in family medicine as a career
2012	WONCA celebrates its 40th anniversary	Originally founded in 1972 by member organizations in 18 countries, WONCA grows to 97 member organizations in 79 countries, with a total membership in the member organizations of over 200,000 general practitioners/family physicians
2013	ABFM sponsors pilot of program of 4-year residency training programs	New programs to allow more flexibility in family medicine residency training curriculum
	Family Medicine Working Party launches the *Family Medicine for America's Health* initiative	Multiyear strategic program to define the role of the 21st century family physician
2014	AAFP report *Family Physician Workforce Reform* calls for 65 new family medicine training positions yearly over the next 10 years	Proposal calls for adding 4,475 family medicine training positions by 2025, projected to end the shortage of family physicians in the United States
2015	AAFP Foundation begins the Family Medicine Leads Program and sponsors the First Emerging Leader Institute for medical students	New medical student program offers tracks in policy and public health leadership, personal and practice leadership, and philanthropy and mission-driven leadership
2016	Publication of *Family Medicine: Principles and Practice,* 7th edition (P. Paulman, R. Taylor, editors; L. Nasir, A. Paulman, associate editors).	A new editorial team for the book "by family physicians for family physicians," and the first edition published both in digital and print media

Medical Informatics, the Internet, and Telemedicine

Michael D. Hagen

Contents

Information systems and technology have become all-pervasive in the family medicine practice realm: electronic health records (EHRs), digital imaging systems, computerized physician order entry (CPOE) systems, decision support tools, billing, and evaluation and management (E&M) coding systems reside in nearly all family physicians' practices. Indeed, the vast majority of family physicians now use some form of EHR [1]. This chapter will focus on those aspects of clinical informatics most important to family physicians' effective use of information technology.

Electronic Records

Until the latter twentieth century, most physicians relied on paper records to store and maintain summaries of interactions with their patients. While such records served to support the care of individual patients in individual practice contexts, they did not afford efficient data extraction for communication with other providers or conduct of research. The rise of minicomputers and personal computers in the latter twentieth century provided the technical platforms for creation of electronic systems that could record, store, maintain, sort, and communicate information needed for patient care and development of new information [2]. Indeed, family physicians have adopted electronic health records at a steadily increasing pace [1] (Fig. 1).

ELECTRONIC HEALTH RECORD ADOPTION

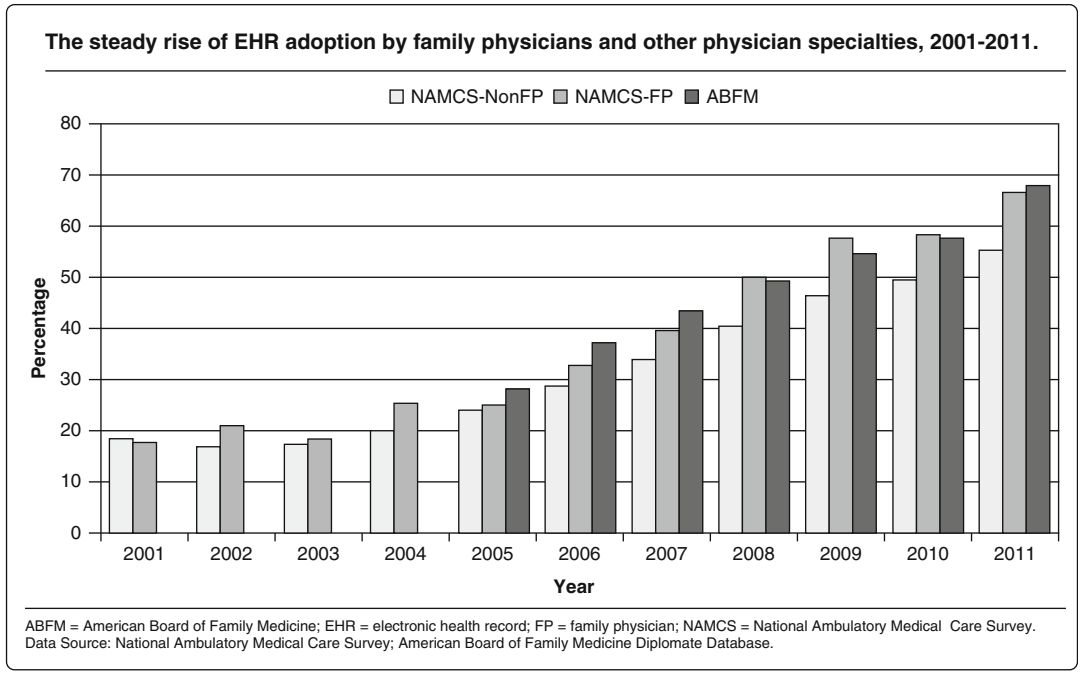

Fig. 1 EHR adoption rate for family physicians and other physician specialties, 2001–2011 (From: Xierali et al. [1]. Request for reprint submitted)

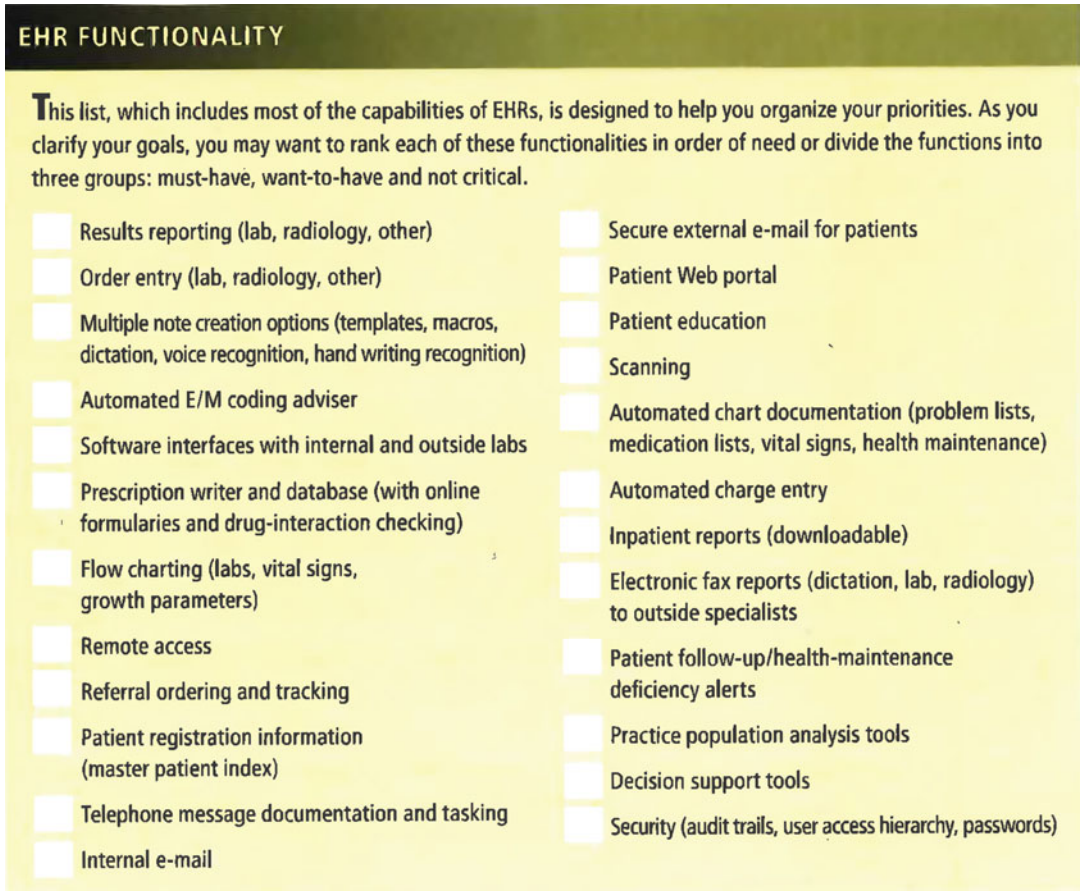
Family physicians face a multitude of options when attempting to select an EHR system appropriate to their particular practice contexts [3]. Costs, knowledge needed to use the system, and technological considerations can all complicate the decision process. Fortunately, tools exist to aid family physicians in making these decisions. The American Academy of Family Physicians (AAFP) has published protocols that family physicians can use to guide them in the selection process [4]. The AAFP describes multiple steps in making a selection: identify the decision-makers in the practice, clarify the goals the practice or organization hopes to accomplish in adopting an EHR, develop a request for proposals (RFP) that reflects your organization's needs, identify the vendors to which one should send the RFP, review the subsequent proposals and narrow the candidates to those that most closely meet your needs, attend demonstrations, seek out other users for their perspectives, rank the candidate vendors, visit sites that have the candidate systems in place, select a finalist, confirm your organization's commitment, and, finally, negotiate a contract (Fig. 2 (Functionality), Fig. 3 (RFP outline), Fig. 4 (Demo form), Fig. 5 (Vendor rating tool) [4]). The multiplicity of EHR vendors requires that family physicians take such a systematic approach to selecting the system that will work best for their practices.

Cost represents a substantial barrier to EHR adoption and maintenance [3]. As a means to promote EHR adoption, the HITECH Act of 2009 (part of the American Recovery and Reinvestment Act, the "stimulus bill") created several incentive programs [5]. These include incentives for meaningful use [6] and for participating in the Physician Quality Reporting System (PQRS) [7].

The PQRS has provided bonus payments for eligible physicians based on a percentage of Medicare part B billings. Participants can submit information either from claims data or by entering



EHR FUNCTIONALITY

This list, which includes most of the capabilities of EHRs, is designed to help you organize your priorities. As you clarify your goals, you may want to rank each of these functionalities in order of need or divide the functions into three groups: must-have, want-to-have and not critical.

- Results reporting (lab, radiology, other)
- Order entry (lab, radiology, other)
- Multiple note creation options (templates, macros, dictation, voice recognition, hand writing recognition)
- Automated E/M coding adviser
- Software interfaces with internal and outside labs
- Prescription writer and database (with online formularies and drug-interaction checking)
- Flow charting (labs, vital signs, growth parameters)
- Remote access
- Referral ordering and tracking
- Patient registration information (master patient index)
- Telephone message documentation and tasking
- Internal e-mail
- Secure external e-mail for patients
- Patient Web portal
- Patient education
- Scanning
- Automated chart documentation (problem lists, medication lists, vital signs, health maintenance)
- Automated charge entry
- Inpatient reports (downloadable)
- Electronic fax reports (dictation, lab, radiology) to outside specialists
- Patient follow-up/health-maintenance deficiency alerts
- Practice population analysis tools
