- Security (audit trails, user access hierarchy, passwords)

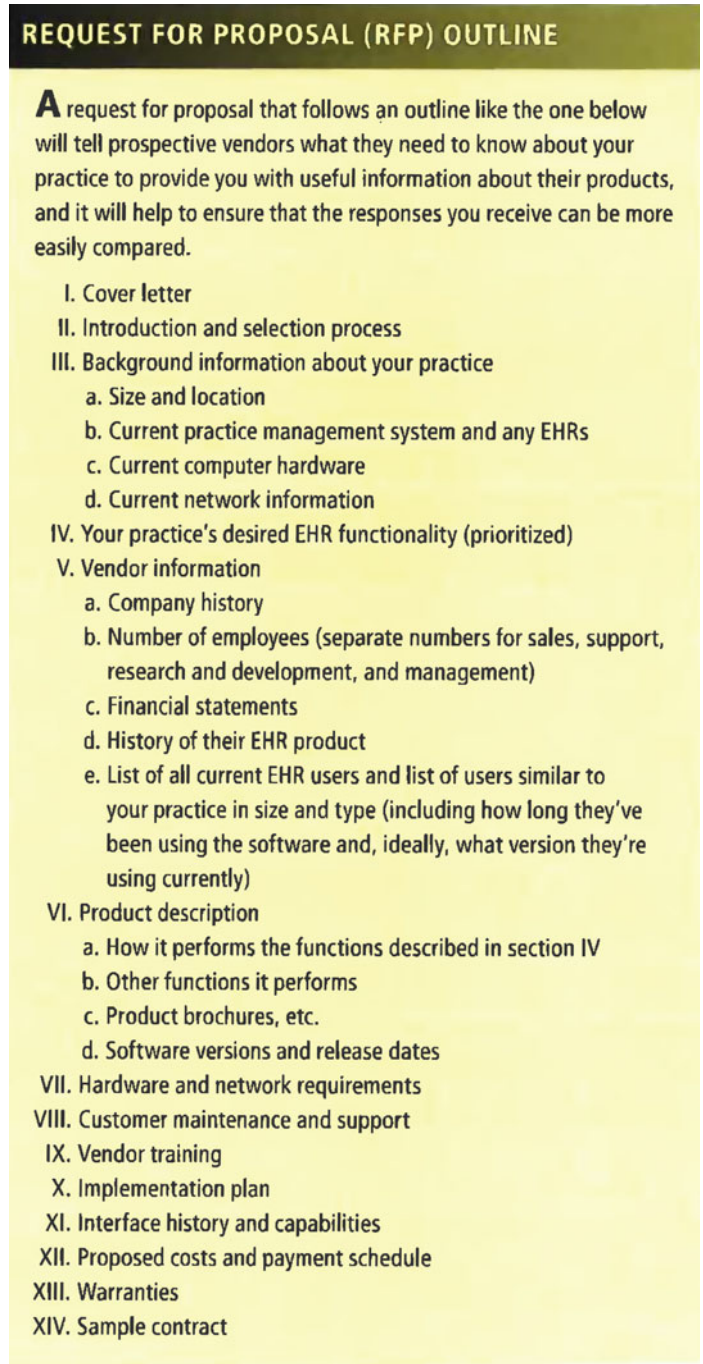
Fig. 2 Specification of EHR functionality (From: Adler [4]. Request for reprint submitted)

patient measures data via an approved registry (the American Board of Family Medicine (ABFM) has operated an approved registry since the program's inception; details available at the ABFM website, www.theabfm.org [8]). Beginning in 2015, physicians who do not participate in the PQRS will begin to experience adjustments (decrements) in their Medicare part B payments.

As noted, the HITECH Act also implemented incentives for adopting EHR technology. This incentive can total as much as nearly $44,000 but varies depending on when the professional enters the program [9] (Table 1). Additionally, the incentives differ depending on whether the professional chooses to participate via Medicare part B or Medicaid billings. To qualify for these incentives, physicians must use certified EHRs [10] and demonstrate meaningful use of these tools [6]. Generally, qualifying for meaningful use requires that the professional demonstrate and/or attest to the ability to perform particular operations in the EHR (e.g., computerized submission of prescriptions to pharmacies and collection and submission of quality measure data.) The Centers for Medicare and Medicaid Services (CMS) have issued frequent changes and updates to the regulations, so eligible professionals (physicians) should consult the CMS website/s for up-to-date information [6].

Although family physicians have adopted EHR systems at an increasing rate [11], many users continue to find frustrations with their systems [12]. Users find the systems cumbersome to use, difficult to navigate, and distracting in the

Fig. 3 Outline for a request for proposals (From: Adler [4]. Request for reprint submitted)



REQUEST FOR PROPOSAL (RFP) OUTLINE

A request for proposal that follows an outline like the one below will tell prospective vendors what they need to know about your practice to provide you with useful information about their products, and it will help to ensure that the responses you receive can be more easily compared.

I. Cover letter
II. Introduction and selection process
III. Background information about your practice
  a. Size and location
  b. Current practice management system and any EHRs
  c. Current computer hardware
  d. Current network information
IV. Your practice's desired EHR functionality (prioritized)
V. Vendor information
  a. Company history
  b. Number of employees (separate numbers for sales, support, research and development, and management)
  c. Financial statements
  d. History of their EHR product
  e. List of all current EHR users and list of users similar to your practice in size and type (including how long they've been using the software and, ideally, what version they're using currently)
VI. Product description
  a. How it performs the functions described in section IV
  b. Other functions it performs
  c. Product brochures, etc.
  d. Software versions and release dates
VII. Hardware and network requirements
VIII. Customer maintenance and support
IX. Vendor training
X. Implementation plan
XI. Interface history and capabilities
XII. Proposed costs and payment schedule
XIII. Warranties
XIV. Sample contract

physician-patient interaction [12]. Additionally, family physicians express disappointment that the systems neither save time nor generally improve care quality. To address these concerns, the American Medical Informatics Association (AMIA) has empaneled the EHR-2020 Task Force [13]. This Task Force embraced four core recommendations: (1) simplify and speed documentation, (2) refocus regulation to stress usability rather than evaluation and management

EHR DEMONSTRATION RATING FORM

Each person who observes vendor demonstrations should complete a form like the one below. The form you use should list the functionality that your selection group decided was most important to your practice. To analyze the results, assign 1 point to strongly disagree, 2 to disagree, 3 to unsure, 4 to agree, and 5 to strongly agree. Calculate average scores for each function and print a summary score sheet for each vendor.

PRODUCT: _____

DATE: _____

EVALUATOR: _____

Please evaluate the product based on all the information you have available at this time. If you need more information, please note that in your comments.

I. FUNCTIONALITY: This product performs the following functions with little user effort:

	Strongly disagree	Disagree	Unsure	Agree	Strongly agree
Results reporting (lab/X-ray)					
Progress/consult notes					
E/M coding					
Telephone message documentation and tasking					
Chart documentation (problem list, medication list, allergies, vital signs, health maintenance, trending lab values, etc.)					
Order entry (lab/X-ray)					
Prescription writer					
Formularies					
E-fax to outside physicians					
Remote access (e.g., to off-site transcription or physician's home)					
Referral management					
Charge capture without manual entry					
E-mail (encrypted)					
Health maintenance alerts					
Medical decision support tools					
Patient education materials					
Security (passwords, audit trails)					

Comments: _____

_____

_____

II. OVERALL EASE OF USE AND FLEXIBILITY

	Strongly disagree	Disagree	Unsure	Agree	Strongly agree
This product allows individual user-specific customization					
This product minimizes user data input					
This product offers multiple note creation options					

Comments: _____

_____

_____

Fig. 4 EHR demo rating form (From: Adler [4]. Request for reprint submitted)

(E&M) coding, (3) increase transparency among EHR vendors by publishing interface application programming interfaces (APIs, tools for linking to the computer programs within EHRs), and (4) foster innovation with the focus of EHRs as an open platform. The Task Force has drawn heavily on recommendations in the report, "A Robust Health Data Infrastructure," published by

VENDOR RATING TOOL

For each EHR product you are considering, assign a ranking from 1 to 5 (with 5 being best) for each of the criteria listed in the functionality and vendor characteristics categories below. Total the rankings for each vendor to determine a combined score for each category, then assign an overall ranking. For the cost section, supply a dollar amount for each criteria listed and then rank each vendor based on your assessment of its total initial and total annual costs. Next, consider the relative importance of the three categories and assign a percentage to each (e.g., functionality = 40 percent, cost = 20 percent and vendor characteristics = 40 percent). Finally, use these percentages to calculate the weighted scores for each vendor.

FUNCTIONALITY	VENDOR 1	VENDOR 2	VENDOR 3	VENDOR 4	VENDOR 5
Quality/presence of features we prioritized (see demo rating summaries)					
Ease of use (e.g., minimizes typing, is intuitive, simple layout)					
Speed (network/hardware configuration, minimizes keystrokes)					
Individual user flexibility • Multiple note creation options (transcribe, voice, template) • Provider can modify/create own templates • Provider can create own macros					
Preloaded templates and patient education					
Combined functionality score (total the rankings for each vendor)					
A Overall functionality ranking					

COST	VENDOR 1	VENDOR 2	VENDOR 3	VENDOR 4	VENDOR 5
Initial hardware and network upgrades					
Initial interfaces					
Initial software					
Total initial cost					
Annual software maintenance (includes upgrades and support)					
Annual interface upgrades					
Total annual cost (excludes initial costs)					
B Overall cost ranking					

VENDOR CHARACTERISTICS	VENDOR 1	VENDOR 2	VENDOR 3	VENDOR 4	VENDOR 5
Training					
Support					
Implementation					
Software upgrades					
Company stability					
Combined vendor characteristics score (total the rankings for each vendor)					
C Overall vendor characteristics ranking					

D Functionality	%
E Cost	%
F Vendor characteristics	%
	should total 100%

OVERALL RANKING	VENDOR 1	VENDOR 2	VENDOR 3	VENDOR 4	VENDOR 5
G Weighted functionality score ((A × D) ÷ 100)					
H Weighted cost score ((B × E) ÷ 100)					
I Weighted vendor characteristics score ((C × F) ÷ 100)					
Weighted overall score (G + H + I)					
Final Ranking					

Fig. 5 Vendor rating form (From: Adler [4]. Request for reprint submitted)

the JASON group of the MITRE Corporation for the Agency for Healthcare Research and Quality (AHRQ) [14]. This report promoted the concept that all EHRs should publish an open API that could facilitate interoperability, and that this "public" API should become a component of the requirements for EHR product certification [15]. This project remains in its early stages but EHR

Table 1 Summary of incentive payments available to eligible providers (EP) based on calendar year (CY)

Maximum incentive payments based on the first CY in which an EP demonstrates meaningful use				
	Maximum incentive payments based on the first CY in which an EP participates in the program			
Calendar year	2011	2012	2013	2014
2011	$18,000			
2012	$12,000	$18,000		
2013	$8,000	$12,000	$15,000	
2014	$4,000	$8,000	$12,000	$12,000
2015	$2,000	$4,000	$8,000	$8,000
2016		$2,000	$4,000	$4,000
Total	***$44,000***	***$44,000***	***$39,000***	***$24,000***

users should follow the group's progress in promoting usability and interoperability of electronic record products.

Clinical Decision Support (CDS) Tools

EHR technology potentially affords user access to a multiplicity of clinical decision aids: point-of-care access to reference material, evidence-based recommendations specific to the diagnosis, reminders, and algorithmic recommendations specific to the patient context all become possible [16]. However, challenges remain in accomplishing widespread adoption of these tools: existing systems have gained mixed acceptance due to interface issues and workflow disruption, patient summaries provide insufficient actionable data, and techniques for integrating multiple guidelines for competing comorbid health states remain elusive [17]. The most straightforward CDS tools consist of disease-specific order sets and templates that present when seeing a patient with a particular diagnosis. To create more complex tools that incorporate patient-specific characteristics and preferences, developers must turn to more sophisticated techniques. Rule-based systems rely on coded logic that uses patient-specific information to tailor recommendations. These systems use a number of different logic coding systems (Arden Syntax, GLIF, GELLO) to integrate guideline recommendations with patient information derived from the EHR database structures [18–20]. These coding environments are not generally accessible to practitioners but rather require working with trained informaticists for implementation.

Online reference services provide information at the point of care to support decision-making at the point of care [21]. A number of subscription services exist in the USA to provide such support: DynaMed® [22], UpToDate® [23], and Epocrates® [24] represent several popular examples. These applications provide reference support such as evidence-based summaries for clinical disorders, formulary information, and drug-drug interactions. The developers have provided apps for the Apple® and Android® smart devices to provide convenient real-time access in the context of patient encounters. These tools promise to improve concordance with clinical guideline recommendations and currency of clinicians' medical knowledge [25, 26].

Standards

Physicians have historically entered clinical data as unstructured free text in paper records. While the free-text approach provides for rich detail and nuance related to the doctor-patient interaction, the lack of standardized terminology limits users' ability to search such record entries for terms and concepts that can be compared across different record systems. A number of standard vocabularies and terminologies have come into use to facilitate extraction of common terms from different clinical systems. SNOMED-CT (Systematized Nomenclature for Medicine-Clinical Terminology) represents a hierarchical vocabulary system consisting of over 400,000 terms [27]. SNOMED-CT provides access to multiple synonyms for a single concept, providing

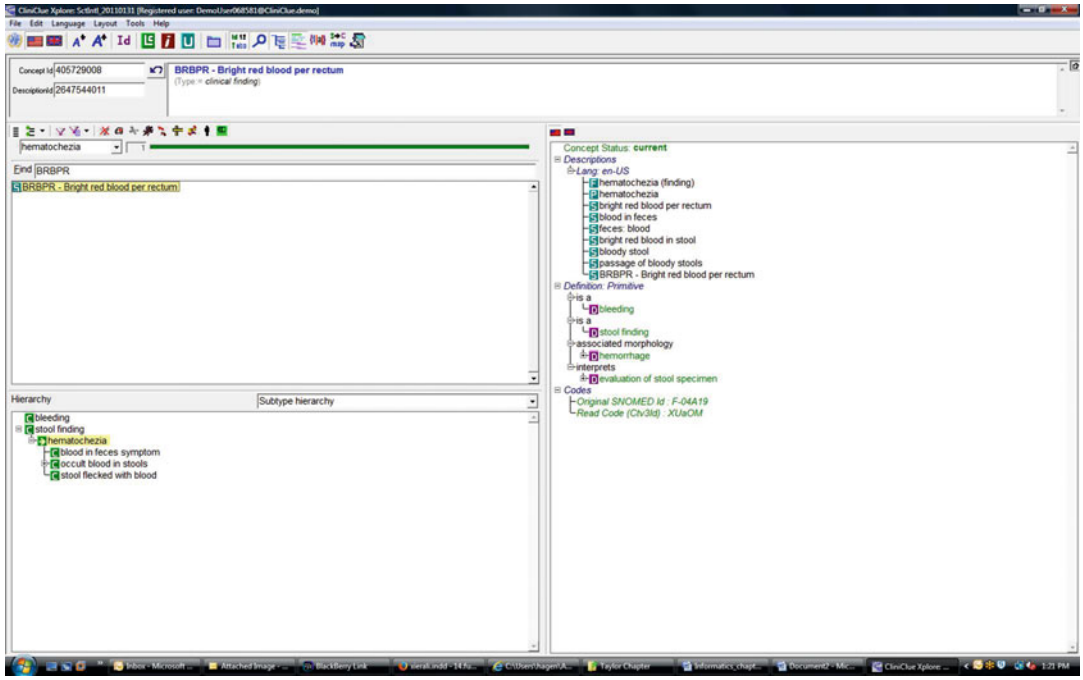


Fig. 6 Example of SNOMED-CT demonstrating the synonyms mapped to "hematochezia" in the terminology

means for mapping to a single standard term multiple different ways of expressing a notion. For example, "rectal bleeding" might appear as "hematochezia" in one user's records, while another user might express rectal bleeding as "bright red blood per rectum" or the abbreviation "BRBPR" (Fig. 6). While no particular terminology has been found to perform perfectly, SNOMED-CT appears to identify primary care terms better than several other options, although at a suboptimal rate [28, 29]. Medical Subject Headings (MeSH) represents a controlled vocabulary used by the National Library of Medicine for categorizing and coding entries in the MEDLINE® and PubMed® literature retrieval services. The Logical Observations, Identifiers, Names and Codes (LOINC®) system provides names and codes for laboratory examinations, vital signs, and radiology studies [30], while RxNORM provides support for mapping among various pharmaceutical terminologies [31]. Fortunately, the Unified Medical Language System (UMLS) represents an additional candidate for standard vocabulary access [32] that includes a number of tools for manipulating and mapping to multiple medical terminologies (most specifically the Metathesaurus, which provides a tool for identifying synonymous terms from systems such as SNOMED-CT®, ICD-10-CM, CPT®, and LOINC®.) These systems as well as other standards will facilitate the interoperability of electronic health records for sharing patient data among various health-care organizations [33].

Patient Portals

The meaningful use requirements discussed earlier include components of "patient engagement," to include patients' access to their clinical records, prescriptions, laboratory data, and messaging with their providers [34]. The various EHR vendors will obviously implement these features differently, but most will provide patients with access to commonly desired functions such as prescription refills, review of medical record

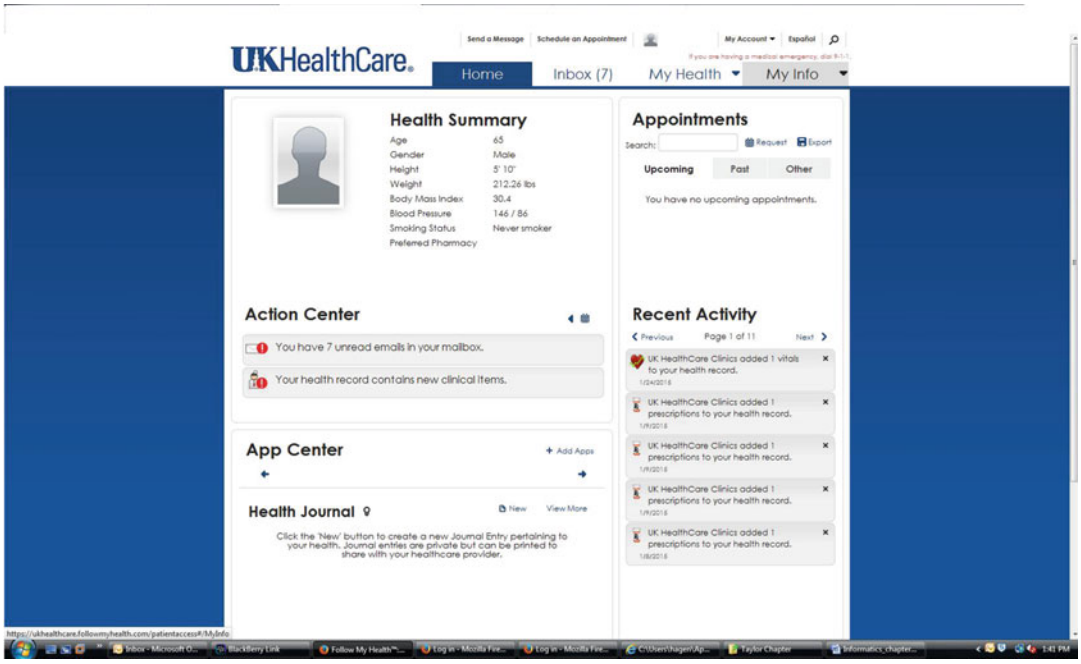

Fig. 7 Example of the "Follow My Health" patient portal provided for patients in the University of Kentucky Healthcare system

information, and secure messaging with their providers [35]. Figure 7 demonstrates one example of such a patient portal interface. Advent of these portals necessitates familiarity with the components of the Health Insurance Portability and Accountability Act (HIPAA), which outlined a number of requirements that providers must observe in managing and sharing patient information. In particular, HIPAA mandates strict requirements for providers' release of "protected health information" and the education of providers regarding these requirements. HIPAA also includes standards for electronic transmission of these data [36].

Telehealth

As broadband access to the Internet and the World Wide Web has expanded, so too has the potential for using health information technology for remote health-care service. Historically, this required dedicated expensive video and audio installations that most users and facilities could not afford. Faster computers and enhanced broadband speeds have made remote access to health services available using a personal computer or tablet device and an Internet connection. Applications include remote interpretation of radiology studies, consultations, and direct patient-physician interaction. These types of remote interactions have raised challenging issues regarding credentialing: is the physician who conducts a consultation with a patient residing in another state practicing in that state without a license? Licensing jurisdictions vary in how they regard these interactions. Most recently, the Federation of State Medical Boards has proposed a reciprocal licensing process that might support these activities [37].

Informatics and Population Health

The increasing pervasiveness of electronic health records affords access to potentially enormous quantities of data for research and identifying patterns of disease. Interoperability among these records can afford efficiencies and eliminate duplication in ways not possible with historical

paper record systems; indeed, one group has estimated that integrated information technology systems could save as much as $78 billion annually in health-care expenditures [38]. Additionally, geographic information systems (GIS) can utilize such data to identify patterns of utilization and patient care access to guide organization of health-care services [39]. Aggregation of data in registries can also identify potential population quality issues that might not appear readily in a single practitioner's experiences [40].

The Learning Health System

Interoperability of health information systems and vast amounts of patient care data provide the opportunity to learn in real time from our daily care activities. The Institute of Medicine (IOM) in 2012 issued its report, "Best Care at Lower Cost. The Path to Continuously Learning Health Care in America," in which the authors identified ten recommendations for enhancing application of the best evidence at the point of care: (1) improve the capacity to capture clinical, care delivery process, and financial data for better care, system improvement, and the generation of new knowledge; (2) streamline and revise research regulations to improve care, promote the capture of clinical data, and generate knowledge; (3) accelerate integration of the best clinical knowledge into care decisions; (4) involve patients and families in decisions regarding health and health care, tailored to their preferences; (5) promote community-clinical partnerships and services aimed at managing and improving health at the community level; (6) improve coordination and communication within and across organizations; (7) continuously improve health-care operations to reduce waste, streamline care delivery, and focus on activities that improve patient health; (8) structure payment to reward continuous learning and improvement in the provision of best care at lower cost; (9) increase transparency on health-care system performance; and (10) expand commitment to the goals of a continuously learning health system [41]. The Learning Health System Initiative has embarked on making these recommendations reality [42, 43].

Clinical Informatics as a Specialty Option

As information systems have become more prevalent and integral to daily practice, the need for trained informaticians has arisen and grown. In 2009, the American Medical Informatics Association developed and published proposed standards for training and certification in a new specialty of clinical informatics [44–46]. The American Board of Medical Specialties (ABMS) approved the new clinical informatics subspecialty in 2011, and two sponsoring boards (the American Board of Preventive Medicine, ABPM, and the American Board of Pathology, ABPath) agreed to serve as sponsoring boards for the new subspecialty certificate. Family physicians can qualify through the ABPM, while pathologists must apply through the ABPath. Two routes exist to qualify to sit for the certification examination: completion of an ABPM-approved fellowship program or documentation of substantial experience in informatics practice. The latter practice experience route will exist for 5 years only, after which completion of an approved fellowship training program will represent the only route to clinical informatics certification. The Accreditation Council for Graduate Medical Education has developed standards and processes for accrediting new and existing informatics training programs [47]. ABPM administered the first examination in 2013, and approximately 80 family physicians succeeded in becoming certified clinical informatics subspecialists [48].

Information technology has revolutionized family physicians' access to tools to both organize their patients' clinical information and support the critical patient care decisions they make day to day. The available systems are at once complex and powerful, but not always user-friendly. The new specialty of clinical informatics provides a route for those who wish to gain additional expertise in both the technical operation and management of these systems. For those who do not want to make such a

formal commitment, good general coverage informatics textbooks [49, 50] can provide more in-depth coverage of this rapidly expanding component of modern family medicine practice.

Introduction

The evaluation and management of work-related health conditions offers the family physician a unique medical challenge that may extend far beyond the confines of a clinic or a hospital. The floors of a lumber mill, the flight deck of a 747, and the dark tunnels of a coal mine are but a few of the environments that can become the concern of the family physician caring for the worker.

From Antiquity to Nanotechnology

The practice of occupational and environmental medicine has its roots in antiquity. Concern for the health of workers has been documented as early as ancient Egypt when Imhotep, considered the grandfather of occupational medicine, described treatment for injuries sustained by pyramid workers. Similar writings are found in ancient Greece, when both Hippocrates and Pliny the Elder wrote on the maladies of miners, horsemen, and metalworkers. Throughout history, many figures have advanced the health of workers. However, it is Bernardino Ramazzini that is considered the "father" of modern occupational medicine. Through his dedication to exploring the ailments of the worker, Ramazzini expanded the breadth and depth of occupational medicine by promoting worksite visits. The toils of his studies resulted in one of the earliest textbooks of occupational medicine, *De Morbis Artificum Diatriba*, which was published in 1700 [1].

Since the time of Ramazzini, there have been many pioneers of the specialty. One more modern contemporary that deserves special attention is Dr. Alice Hamilton. In the early 1900s, Hamilton not only advanced our understanding of the toxicological dangers of work, such as lead, but she also championed the importance of workplace safety. Hamilton's work and accomplishments extend far beyond the care of workers; she was a prominent social activist and also the first female faculty member of Harvard University [2].

Over the last two decades, the most important change in occupational medicine has been a focus on the importance of work. In the past, there was great emphasis in ensuring people were fit for work, leading to the exclusion of disabled persons from the productive work they desired. Moreover, a large part of treating work-related injury and disease was removal from work on medical grounds. Although this may be still necessary in some cases, it is now recognized that work is crucial for health, socialization, and personal identity. Conversely, absence from work is frequently demotivating, demoralizing, and fraught with risks of depression, adverse mood changes, deleterious effects on career progression, and iatrogenically induced prolonged/permanent disability. Poor outcomes have also been demonstrated in occupational injuries compared with similar injuries sustained from sport and recreation. These considerations have led to a revised approach to work injuries. Occupational medicine is now focused on maintaining functional capacity by returning injured workers to productive employment via appropriate work restrictions and case management. It is in this endeavor that occupational medicine finds itself at a frontier within the practice of medicine.

The blossoming concept of work as a healing entity, coupled with the development of novel compounds and industries, such as graphene and nanotechnology, presents ongoing health challenges for workers and occupational medicine providers.

Practice Overview

At the level of the individual patient, occupational and environmental medicine (OEM) focuses on the care of the injured worker, the prevention of workplace injury and illness, and the improvement of worker health and productivity. A division of preventative medicine, OEM is one of the smallest medical specialties recognized by the American Board of Medical Specialties. However, the expertise OEM provides in regard to worker health and population management skills renders it an ever important specialty.

Despite this need, there is a shortage of OEM physicians. Indeed, only 83 physicians achieved board certification in OEM [3]. In addition, with

the number of board-certified occupational medicine specialist in decline, it is anticipated that nearly 1700 OEM physicians will retire in the next 10 years. The result is that there will be a 33 % reduction in specialist numbers [4]. As such, there is a burgeoning practice opportunity for family physicians that are willing to pursue additional training and education in the treatment of workers.

Epidemiology

As the number of specialist OEM physicians declines, the incidence of work-related health conditions continues to be significant. In 2013, there were approximately three million nonfatal workplace injuries and illnesses reported in private industries. More than half of these involved an injury severe enough to require work modifications, job transfer, or time off from work [5]. Private sector laborers, freight/stock/material movers, and heavy/tractor trailer truck drivers reported the greatest number of days off work due to a workplace injury or illness. Persons 45–54 years of age had the highest incidence of injuries, suffering a rate of 119.9 per 10,000 workers. Males had an incidence rate of 119.2 per 10,000, substantially higher than the female rate of 97.0. Some of the most common causes of work injuries across all industries were musculoskeletal disorders (36 %), contact with objects (25 %), same-level falls (17 %), and overexertion (12 %) [6].

While rarely considered during national debates over the financing of medicine, the direct cost associated with work-related health care is tremendous. In 2012, the cost of worker's compensation-related health care was approximately 62 billion dollars, split nearly evenly between medical and indemnity costs [7]. This cost closely approaches the estimated total 2012 US cost associated with the treatment of asthma (75.9 billion), mental disorders (83.6), and cancer (87.5 billion) [8]. Moreover, the true costs of occupational injuries and disease are much larger when indirect costs of lost productivity are included. The loss of productivity exceeds the direct costs of diagnosis, treatment, and indemnity payments (wage replacement while off work) for injured workers. While this data increasingly provides incentives for employers to prevent work-related injury and disease, much of society remains unaware of the cost of injured workers.

Legal Underpinnings and Entities

Given that work is an integral part of the lives many of the patients family physicians will see and work may affect their presentation of illness or injury, a basic understanding of the key regulatory bodies and systems is necessary for successful practice and delivery of care.

Worker's Compensation (WC)

WC is the oldest form of social insurance in the United States and the third largest source of support for disabled workers after Social Security and Medicare. Workers' compensation allows for the provision of monetary compensation for medical and rehabilitation costs and lost wages to certain workers with work-related injuries or disabilities. Before workers' compensation, litigation was usually necessary for full compensation. Workers rendered injured or ill due to a work-related injury or illness bore the full brunt of medical care and lost wages unless employers voluntarily offered compensation. Founded on the principle of providing a compulsory "no-fault" form of insurance for workers injured in the course of employment, employers are held responsible for compensation for work-related injuries and illnesses, regardless of findings of cause, through an insurance mechanism. In this no-fault system, in exchange for certain and prompt compensation, the worker accepts compensation limited to the standard amount specified by each state, whether or not the payment fully covers lost wages, pain, and/or suffering. As such, WC is the exclusive remedy for injured workers.

The first workers' compensation laws were passed in 1911 by nine states, with Hawaii being the last state to do so in 1963. A similar system

had already existed in Europe with Germany being the first to pass these laws in 1884. While WC laws are similar overall, differences can exist between states and federal and private entities. It is important for the family physician to be aware of this and familiar with their local jurisdiction nuances [1].

Occupational Health and Safety Administration

At the turn of the twentieth century, workplace industrial accidents became more publicized and public outrage increased. In the wake of disastrous workplace accidents, such as the Triangle Shirtwaist Factory fire, regulatory agencies and acts, such as the Safety Appliance Act and the United States Bureau of Mines, took form. With the increased industrialization that followed World War II, the incidence of workplace injuries increased dramatically. The dangers of industrialization were compounded by the increasing use of industrial chemical, many of which had unknown health effects. It is estimated that in 1970, there were 14,000 work-related fatalities in the USA.

In 1970, the US government passed the bipartisan Occupational Safety and Health Act (OSH Act), the purpose of which was to create and maintain the safety and health of workers in the USA through training, education, and assistance. Perhaps, the most powerful component of the act is its general duty clause, which states each employer:

> shall furnish to each of his employees employment and a place of employment which are free from recognized hazards that are causing or are likely to cause death or serious physical harm to his employees.

The clause enables the broad protection of workers and workplace safety, even in the absence of specific applicable regulations or standards.

The act led to the establishment of the most recognized government agency pertaining to work safety, the Occupational Health and Safety Administration (OSHA). OSHA, a component of the Department of Labor, is the government's regulatory agency for work safety. Some of the agency's many services include regulatory inspections and enforcement of standards, such as those pertaining to lead and blood-borne pathogens [9].

National Institute of Occupational Safety and Health

The OSH Act also created the National Institute for Occupational Safety and Health (NIOSH) as part of the Centers for Disease Control and Prevention. The purpose of NIOSH is to perform research on worker injury/illness and to make recommendations on workplace safety issues. Examples of NIOSH's research areas include the danger of antineoplastic medications to health-care workers and offshore gas/oil extraction. In addition, NIOSH also funds education, research, and training in occupational health through 18 education centers, 10 agriculture disease-related centers, and 28 training grants. The roles of NIOSH and OSHA are distinct, with OSHA being the regulatory aspect of work safety [10].

Americans with Disabilities Act (ADA)

The purpose of the ADA, first passed into law in 1990 by Senator Tom Harkin of Indiana, is to prevent discrimination against individuals with disabilities in transportation, public accommodations, communications, governmental activities, and employment [11]. The ADA was one of the most important pieces of social legislation in the USA and represented a major change in thinking. A particular impetus to the act was the ongoing exclusion from employment of many Americans with disabilities or a history of disabilities, even when such individuals had improved medically and/or wished to work. The act was amended in 2008 by the Americans with Disabilities Act Amendment Act (ADAAA).

A complete understanding of the nuances of this complicated piece of legislation is beyond the scope of this chapter. However, a basic understanding of ADAAA by the family physician is

important as they may be called upon to opine on the physical capabilities of workers.

First, private employers with greater than 15 employees, state/local governments, employment agencies, and labor unions must provide accommodations for applicants and workers with disabilities as long as such accommodations would not impose undue hardships on the employer. Examples of accommodations include alteration of work schedules and the use of modified equipment. Undue hardship is defined generally as "an action requiring significant difficulty or expense," when taking into account the applicable covered employer's situation.

Second, the act prevents pre-hire inquiries, such as physical examinations, into an applicant's medical status. However, an employer may require a physical examination to determine if an individual can perform the essential functions of a job after an offer of hire has been made and before employment commences. Such examinations must be required of all employees and not on an individual basis. Pertinent records must be kept confidential and separate from employee human resources files.

Family and Medical Leave Act (FMLA)

FMLA was passed into law in 1993. The purpose of this law is to provide employees 12 weeks of unpaid, job-protected leave for qualified medical conditions. In addition, health insurance benefits as part of employment must be continued during such leave. FMLA is applicable to all public agencies, public and private elementary/secondary schools, and employers with greater than 50 employees. To qualify for FMLA, employees must have worked for an employer for 12 months, worked 1,250 h in those 12 months, and worked in a location where the company has greater than 50 employees within a 75 mile radius. Qualifying reasons for leave include the birth/care of a newborn, the initiation of foster care/adoption by the employee, the care of a family member with serious medical conditions, or a serious medical condition of the employee that prevents work [12].

Many family physicians encounter this piece of legislation as a multipage form with a request from patients for physician certification. Satisfactory completion of this documentation will allow appropriate protections for both the patient and employer and efficient execution of this law.

General Approach to the Evaluation of the Worker

The evaluation of the worker requires considerations and elements that extend beyond normal history and physical examination.

The Standard for Documentation

Understandably, the provision of occupational health services occurs in a legal framework. The family physician should assume that any records pertaining to a work-related health condition will be scrutinized by numerous stakeholders, including insurance adjusters, employers, and legal representatives. For example, claims adjusters require detailed information in order to appropriately manage a worker's compensation claim. A failure to provide precise documentation can lead to a loss of appropriate medical treatment covered by workers compensation, costly delays in care, and erroneous assignment of financial/legal responsibilities [13]. As such, attention to detail and accuracy is required throughout occupational health care. It would not be overdramatic to state that if scalpels are the tools of the surgeon, the instruments of the successful occupational health provider are words.

The Systematic Injury History

The majority of occupational health-related treatment by the family physician involves the care of an acutely injured worker. Among the most common work-related injuries seen in primary care clinics involves low back pain, and this complaint can be used to demonstrate the proper documentation of a potentially injurious work event.

Certainly, it would not be sufficient to simply document a "patient injured while lifting at work." Legal needs aside, such a vague description sheds little insight into neither the diagnosis nor avenues for preventing future recurrences. Similar to a forensic investigation, any report of a potentially work-related injury should include the mechanism of injury, the location, the time of the event, and the employees involved in the event. A useful paradigm for recalling these crucial elements is the "4 Ws": what, when, where, and who [14].

Medications and Substances

Outside of the obvious dangers of alcohol and illicit drug use at work, several medications can result in sedation and other dangerous side effects. There has been a massive increase in opioid use in health care [15]. Likewise, there is growing potential for prescription medications, such as opioids, to cause serious and dangerous impairment of workers on the job. Because of this, a detailed description of a worker's medication regimen is required for those who have suffered an acute injury. Special attention should be paid to dosing schedules. A potentially sedating medication, such as cyclobenzaprine (Amrix, Fexmid, Flexeril), may not pose a work safety issue if the employee only works day shifts and the medication is taken in the evening.

An Objective Physical Examination

The physical examination of the worker differs from general primary care in one crucial way: an emphasis on objective evidence. Insurers are conscious of the possibility of fraud, and thus, there is a strong desire to limit liability for nonwork-related conditions. Consequently, insurers place an emphasis on objective indications of pathology. The family physician should note as many objective indications of pathology, such as straight-leg tests and reflexes, as possible during the examination. Indications of nonorganic etiologies should also be noted.

The Occupational History

Understanding the nature of a patient's work is vital for the treatment and management of work-related medical conditions. Many US physicians currently rarely inquire about work activities during clinical encounters [16]. This finding is unfortunate as family physicians are frequently the first physicians to evaluate work-related diseases.

The occupational history need not be an overly tedious and lengthy task [17]. In the case of a simple injury, only a brief history of pertinent facts may suffice. For more complicated diagnoses, such as an occupational infection or chemical injury, more detail may be required. Obtaining the occupational history can be expedited by having patients complete an occupational history questionnaire prior to the clinical visit.

An occupational history begins with obtaining basic information such as job title, employer, work schedule, and general work activities, in particular the activities surrounding the presenting injury or illness in some cases. Special attention should be given to any recent changes at work, such as new equipment/chemicals or alterations in work schedule. It should be noted that a simple description of the current job and tasks is not sufficient when evaluating workers with ailments. Some exposures, such as asbestos, can take several decades to produce health effects. Thus, a review of a patient's entire work history may be necessary in some instances.

Psychosocial Factors

The complicated interplay between work, health, legal entanglements, and worker's compensation demands a careful assessment of psychosocial factors when caring for workers. For example, psychiatric conditions are associated with maladaptive coping mechanisms and delayed recovery from work-related low back pain [18]. Based on such findings, ACOEM guidelines recommend assessing for psychosocial factors, such as work monotony, relationship with supervisors, and job satisfaction [14]. The purpose of inquiring about such stressors is not to discredit the patient or to

imply malingering. Rather, identifying such complications can provide additional treatment options, such as pain counseling or depression treatment, and help to identify and remove otherwise seemingly insurmountable barriers for recovery and return to work [19].

General Approach to the Treatment of the Worker

Communication

Occupational health care can be a challenging endeavor for the family physician. Such emotions are compounded for the patient, many of whom have significant home, work, and financial stressors in addition to the medical condition. Uncertainty, such as with diagnosis and return to work, has been linked to poor recovery and outcomes with work-related care [20]. Unchecked catastrophizing by the worker has been shown to impede improvement [21]. Thus, thorough and clear communication by the physician is of paramount importance. For example, setting return to work dates and educating workers on how to prevent reinjury and recurrence can promote early RTW [22]. Catastrophizing can be mitigated by giving proper context to injuries and diagnostic findings and by positive reinforcement regarding the ability of the worker to perform their job duties. Using modified duty/light duty to progress the worker toward full duty by allowing them to remain in the workplace, surrounded by the culture of work, can help toward successful maintaining of work status and return to work.

Medications

In occupational injuries, the physician is also repeatedly tasked with managing pain. Unfortunately, the increasing use of opioids for the treatment of non-cancer-related pain has led to a greater potential for injured workers to be using impairing medications while at work. This in turn is associated with risks of repeated or new injuries associated with loss of vigilance during work tasks. In the interest of the worker and the public, the family physician treating work-related pain should minimize the use of impairing medications, such as opioids and muscle relaxers. This is especially true for what are called "safety-sensitive" work positions. A systematic review of nearly 22,000 studies by ACOEM found a positive association between opioid use and motor vehicle crashes. Based on this, ACOEM now recommends that workers performing safety-sensitive work, such as commercial driving or crane operations, should not use opioids acutely or chronically [23]. Early use of opioids for the treatment of acute, work-related low back pain has been shown to be associated with prolonged disability, higher medical costs, and prolonged opioid use. Much pain from occupational injuries can be effectively managed with acetaminophen and nonsteroidal anti-inflammatories [24].

Return to Work

It is now apparent that one of the most important ways the family physician can serve the best interest of the worker is with appropriate management of return to work. Many family physicians inappropriately assign time off from work for injured patients. One of the primary reasons for this is a perceived duty to be a patient advocate. Family physicians, like other medical providers, are motivated by a desire to minimize suffering and pain. Thus, when a worker complains of pain at work, removal from work appears to be in the patient's best interest. However, it is the converse that is true. It has been showed repeatedly that work, in safe environments and with proper guidance, is of paramount importance to health. Removal from work is associated not just with financial loss, but also increased mortality from cardiovascular-, respiratory-, violence-, alcohol-, and accident-related etiologies [25]. Likewise, continued work maintains physical and mental conditioning. Thus, it is the return to work as safely and as soon as possible that is almost always in the worker's best interest. This endeavor should be the goal of the family physician's advocacy.

Appropriate return to work can also be adversely affected by the time constraints of the busy family physician's schedule. Time limitations are in turn compounded by a lack of training in return to work by most medical providers outside of occupational medicine. To improve the efficiency of return to work discussions, ACOEM and the American Medical Association (AMA) have created guidance documents for return to work recommendations by primary care physicians [26]. One of the unifying features of the guidelines is the use of a step-based algorithm [27].

The proper use of the algorithms is dependent on having a sound understanding of the definitions of restrictions, limitations, and tolerance [28]. Restrictions are activities that a worker should not perform due to personal risk or risk of hurting others. Limitations are needed when there is a task the worker cannot perform due to their medical condition. Tolerance is the ability of the worker to endure symptoms. It is important to remember that tolerance cannot be determined reliably by medical science. Ultimately, it is the worker that decides to tolerate symptoms that do not cause worse injury or pose a danger to self/others [27].

Removing a worker from work without considering activities the worker can perform within the context of work or even working full duty with the presenting injury is a disservice to the worker and to society as a whole. The family physician should try to gain an understanding of the job tasks and direct the worker/patient accordingly.

Representative Common Occupational Conditions

Injuries

Musculoskeletal injuries represent the bulk of work-related medical conditions encountered by most physicians. In a survey of family physicians between 1997 and 2000, 56 % of work-related care by family physicians involved acute problems, and 48 % involved musculoskeletal chief complaints [29]. In 2013, musculoskeletal disorders accounted for 33 % of nonfatal workplace injuries in all industries. Sprains, strains, and tears were most common, accounting for 38 % of all injuries requiring time off work. The most work-affected body parts were the back (36 %), shoulder (12 %), and knee (12 %). Injuries were most frequent among nursing assistants, laborers, and freight/stock/material movers [4].

Table 1 Common work-related musculoskeletal injuries/conditions seen by family physicians and relevant risk factors

Condition	Potential occupational risk factors	Nonoccupational risk factors
Low back injury [30–32]	Repetitive loading of spine Inadequate rest time at work Awkward lifting Prolonged standing High job demand/stress	Psychiatric disorders Age Smoking
Carpal tunnel syndrome [32–34]	High hand force Prolonged hand force Vibration Repetitive motion	Diabetes Pregnancy Hypothyroidism Genetic predisposition
Rotator cuff tear [32, 35]	Prolonged shoulder flexion Forceful pinching Work above at or above shoulder height Work stress	Age Overhead sports
Slips and falls [36]	Weather Poor lighting Slippery surfaces	Inappropriate footwear Age Fatigue

The treatment of many common industrial injuries is covered elsewhere in this text. Table 1 summarizes a few of the work-related injuries most frequently seen by family physicians and lists their potential risk factors.

Conditions: Infections

Exposure to infectious agents at work is a risk faced by many industries. This risk is especially robust in health-care-related fields, and the family

physician can expect to encounter work-related infectious exposures frequently, even if the provider is not actively providing occupational health-care services. An estimated 5.6 million workers are at risk from blood-borne pathogens. Between 1995 and 2007, there were 30,945 exposure events in the National Healthcare Safety Network. 82 % involved percutaneous injuries and 79 % percent involved blood products. Nurses and providers were the most frequently injured, involved in 72 % of cases [37].

By far, the most concerning health-care work-related infections are HIV, hepatitis B, and hepatitis C. The potential impact of these infections in the health-care workforce is so great; the subject is addressed specifically by the OSHA Bloodborne Pathogen Standard (29 CFR 1910.1030). In an effort to prevent unnecessary transmission of blood-borne pathogens, the CDC provides in-depth and updated postexposure management protocols on their website. Management options can include rapid initiation of antiretrovirals for confirmed HIV exposures and the use of the hepatitis B immunoglobulin/hepatitis B vaccine for hepatitis B exposures. Unfortunately, there is no postexposure treatment for hepatitis C other than monitoring.

While these viruses have remained the primary blood-borne pathogen concerns for health-care workers, there are several other infectious agents not involving blood exposures that can be encountered in the workplace. For example, the incidence of pertussis, measles, and even Ebola has increased in recent years, and the management of work-related outbreaks of these infections can become the responsibility of the family during the care of a community. In addition, classic concerns such as tuberculosis, chicken pox, conjunctivitis, streptococcal pharyngitis, malaria, and typhoid fever can wreak havoc on the worker and workplace. The management of each of these conditions is outside the scope of this chapter, and the reader is directed to the CDC for further direction.

Finally, zoonotic infections can also pose serious risks for workers. Table 2 summarizes some of the zoonotic illness and their associated occupations and settings.

Conditions: Chemical and Environmental Exposures

The EPA's catalog of chemicals used at one time or another in industry exceeds 80,000. Most recently, the EPA estimates that 7,500 chemicals were used by industry in 2012 [40]. Many such chemicals can result in serious health effects, including cancer and death. Similarly, both indoor and outdoor environments can produce symptoms and illness, even in the absence of industrial chemicals. Table 3 summarizes some of the most well-known chemically and environmentally induced health conditions.

The chemical and environmental exposures most likely encountered by the family physician are limited to a few select conditions. The most prevalent are occupational skin diseases, building-related illness, and occupational respiratory conditions.

Latex Allergy

To meet compliance with the Bloodborne Pathogen Standard, which required barrier methods during health-care delivery, the use of latex gloves increased dramatically. This resulted in an increase in immediate hypersensitivity reactions associated with an IgE type I response to naturally occurring rubber from the *Hevea brasiliensis* tree. Those at risk include health-care workers, food handlers, security personnel, and emergency service personnel (i.e., paramedics). Atopy is an independent risk factor. Rates of latex allergy have decreased in recent years with changes in latex processing and the increased use of latex-free gloves [43].

Symptoms from the reaction can range from simple urticaria to life-threatening anaphylaxis. Symptoms typically begin within a few minutes to an hour of contact. Inhaled exposure can occur in the presence of powdered latex. The diagnosis is confirmed by skin prick testing or RAST testing for specific IgE. The primary strategy for management is avoidance [32].

Sick Building Syndrome

Sick building syndrome (SBS) refers to a constellation of general symptoms attributed to indoor

Table 2 Unique occupational infections, symptoms, and associated work and environments

Condition	At risk occupations/environments	History/pearls
Brucellosis	Veterinarians Exposure to fluids and aborted products of conception from infected livestock Consumption of products from infected livestock, such as unpasteurized cheese/milk Laboratory personnel, via aerosolization Slaughterhouse workers Recent international travel	Undulant fever with sweats and malaise Systemic involvement Can be detected via antibodies and treated with antibiotics
Rabies	Animal bites, especially bats Biologists, veterinarians Greenhouse workers	Postexposure treatment can consist of rabies immunoglobulin and four vaccines Consider preexposure prophylaxis in those working with animals, especially in endemic areas abroad
Q fever	Veterinarians Animal caretakers Farm workers, especially those working with sheep, cattle, and goats Living downwind from contaminated farms or farm products (i.e., manure, dust) Laboratory personnel	Caused by *Coxiella burnetii* Exposure is typically through products of conception, fluids, or dust Extremely resistant to environment Widely variant clinic presentation, including flu-like illness, hepatitis, pyrexia of unknown origin, and pneumonia Liver function tests may be elevated in many patients
Scabies	Health-care workers Spread via direct skin to skin contact with infected individuals Higher risk in crowded environments, such as nursing homes or correctional facilities	Caused by human itch mite, *Sarcoptes scabiei* Intense itching and rash Can be spread from an asymptomatic carrier Usually no symptoms for 2–6 weeks
Leptospirosis	Farmers, ranchers, veterinarians, sewer workers, rice farms, laboratory personnel, and loggers Spread in urine of farm animals Higher incidence in tropic regions Exposure occurs via contaminated soils or animal tissue/urine Subsistence farming and urban slums Flooding associated with disease outbreaks	Caused by spirochetes from the genus *Leptospira* Varying clinical presentation, from subclinical to death Usually fever, myalgias, headaches, cough, nausea, and vomiting Look for conjunctival suffusion
Tularemia	Laboratory personnel Farmers Veterinarians Hunters Landscapers Meat handlers Animal or insect bites, especially ticks	Caused by *Francisella tularensis* Ocular and aerosolized exposure also possible Can survive long term in adverse water conditions Nonspecific symptoms, usually a combination of fever, malaise, and anorexia Fever may be intermittent
Rat-bite fever	Laboratory personnel Pet shop workers	Caused mostly by *Streptobacillus moniliformis* Exposure via bites/scratches or fecal contaminated food Clinical course varies depending on infectious agent

References [32, 38, 39]

environments [44] including headache, upper respiratory symptoms, and fatigue. While abnormalities in specific components of indoor air quality (IAQ) can be the cause of such complaints, symptoms are often reported in environments where IAQ is within normal limit, often other than increased carbon dioxide levels, indicative of a mismatch between airflow and human occupancy. Although some consider many instances to be psychogenic, indoor air contaminants below

Table 3 Chemicals/elements and associated health conditions

Chemical/elements	At risk occupations/environments	History/pearls
Asbestos	Construction Shipbuilding Insulators Environmental contamination	Lung cancer Mesothelioma Pathology can develop several years after exposure Malignancy risk significantly increased with smoking
Silica	Sandblasters Concrete/masonry workers Mining	Chronic obstructive pulmonary disorder Scleroderma Increases risk of tuberculosis Unlike coal, causes calcification of hilar lymph nodes
Coal	Coal miners, especially those at the drilling face or with other heavy dust exposures	Lung fibrosis Unlike silicosis, no increase in TB or fungal infections in simple cases
Vinyl chloride	Used to make polyvinyl chloride, which is in turn used to make many plastic products Production of automobile upholstery/parts and housewares	Acutely, causes CNS effects such as dizziness, drowsiness, and headaches Chronic exposure can damage GI system and result in liver cancer
Benzene	Rubber manufacturing Chemical and petroleum production Shoemakers Printers Steel workers Gas station employees	Acutely, can cause dizziness, unconsciousness, and death Chronic exposure can lead to leukemia
Carbon monoxide	Forklift operators Foundry workers Miners Garage attendants Mechanics Firefighters	Headache Tachypnea Cyanosis Syncope Binds strongly to heme O_2-carrying sites, decreasing available O_2 for the body
Hydrogen sulfide	Sanitation workers Farmers Natural gas drilling and refining Workers in confined spaces, especially low-lying, marshy areas with hot weather and little wind	Health effects on concentration (ppm) Symptoms can vary from the smell of rotten eggs, to conjunctivitis and respiratory tract irritation, to immediate collapse with 1–2 breaths at levels of 700–1,000 ppm
Pesticides	Agricultural workers Greenhouse workers Pesticide handlers (i.e., crop dusters, chemical manufacturers)	Wide variety of health effects, depending on type of pesticide involved Must consider pesticide toxicity, exposure, and absorption together when evaluating cases Workers covered by the Agricultural Worker Protection Standard
Lead	Inhalation of lead fumes during burning and sintering Lead reclamation (i.e., battery recycling) Glassmakers, pottery workers Military and law enforcement Munition workers Welders	Lassitude Malnutrition Gingival lead line Encephalopathy Paralysis of wrist and ankles Renal failure
Cadmium	Smelting/refining Manufacturing/construction Plating processes Battery production Dietary intake: shellfish, meat by products, liver, food stored in cadmium-glazed containers	Renal failure Chemical pneumonitis Lung cancer Osteomalacia Japanese rice paddies irrigated with cadmium-contaminated water resulted in an epidemic of osteoporosis in the 1940s Tobacco leaves concentrate cadmium, leading to chronic exposure in smokers

References [41, 42]

the irritation threshold concentration can cause symptoms, especially those with low odor thresholds.

Several factors can contribute to indoor air quality detriments. Environmental elements to consider when assessing SBS include building ventilation rates, temperature and temperature fluctuations, humidity, chemicals (i.e., formaldehyde and ozone), and odors. Personal factors, such as atopy and contact lens use, and psychosocial factors have linked to SBS.

As SBS can involve significant anxiety, clear and open communication is important to effective management. Initial evaluation begins with an interview of affected employees and a work site walk-through. Following the initial investigation, management options can include improvement of ventilation rates, temporary removal from work environments, measures of environmental parameters by an industrial hygienist, cleaning of ventilation systems, and reengineering.

Mold

Of all the naturally occurring environmental contaminants, none seems to invoke as much fear as mold. Mold spores are omnipresent in the environment and reproduce in the presence of moisture. The most common types include *Penicillium*, *Aspergillus*, *Cladosporium*, and *Alternaria*. Molds can cause specific conditions including allergic asthma, but there is little evidence to support fears that airborne mycotoxins produce specific illnesses [45]. Similar to SBS, the evaluation of potential mold-related health conditions begins with an interview of the worker and an evaluation of the work environment that focuses on abnormal indoor moisture.

Remediation of mold and dampness in buildings may improve symptom and consists primarily of removing the source of moisture and visible mold contamination [46]. Such cleaning could require intermittent, temporary relocation of employees. In all circumstances, clear communication with patients and the workforce is of paramount importance.

Specific Types of Occupational Examinations

As a branch of preventative medicine, one of the goals of occupational medicine is the prevention of injury and illness in the workplace. To fulfill this objective, the family physician may be asked to perform a variety of preventative and regulatory examinations for workers.

Posthire, Preplacement Examinations

ADA prevents employers from discriminating against applicants on the basis of disabilities. However, this protection from discrimination must be balanced with ensuring optimum safety of employees and the public. Typically performed at the request of an employer, the purpose of the posthire, preplacement examination is to ensure that an employee can perform the essential functions of a job safely.

To ensure proper screening, it is important that the family physician have an adequate description of the employee's job duties and requirements. While this information could be obtained from the employee, a more reliable source would be a full job analysis document provided by the employer. Job analyses describe the duties and physical requirements of a work position.

Fit for Duty, Return to Work Examinations

Fit for duty examinations are sometimes necessary when an employee has been off of work for an extended period of time. Similar to preplacement examinations, the purpose of the FFD examination is to ensure an employee can still perform the essential functions of their job. An example where such an examination would be necessary is in the case of an employee who recently underwent a knee replacement and is hoping to return to work as a carpet layer.

Again, it is important that the family physician acquire adequate information to assess the employee's current medical status and work requirements when performing such assessments. In particular, the family physician must ensure that the patient does not pose a safety risk due to changes in medications.

Some family physicians are uncomfortable in providing fitness for duty assessments, especially when the results are not to the workers' desire. In such confusing scenarios, rather than contributing unnecessary risk to the patient, other workers, or the public, we suggest that family physicians seek the assistance of their occupational medicine colleagues.

Commercial Driver Medical Examinations

In 2013, there were 4,405 fatal occupational injuries [47]. Two out of five of these fatalities were transportation-related events. Of the 1,740 transportation-related fatalities, three out of five involved motorized land vehicles. With such data, ensuring the safety of commercial drivers and public roads is one of the most important concerns of occupational medicine and also one of the most common avenues for family physicians to provide occupational health care.

To obtain a commercial driver license, the driver must successfully meet the medical and physical requirements described by 29 CFR Part 391.41. This federal regulation provides in-depth information on medical requirements, such as blood pressure limits, and disqualifying medical conditions, such as epilepsy. Until recently, commercial driver medical certification examinations could be performed by a variety of medical providers. Unfortunately, due to a lack of standardized training for examiners, there was varying adherence to federal regulations and guidelines. To remedy this, the Federal Motor Carrier Association has required that after May 2014, all commercial driver examinations be performed by certified commercial driver examiners [48]. Certified commercial driver medical examiners receive standardized training and must pass a certification examination. This move has reduced the number of available examiners and provides family physicians a both important and lucrative occupational health opportunity.

Comprehensive Occupational Health Programs

Many corporations and public sector organizations offer multifaceted programs designed to protect and improve the health of their employees. These programs include components such as health promotion, disability management, international health and travel medicine, benefit design, and workforce data analysis. These programs offer fascinating opportunities to improve health and medical outcomes for a defined population. With additional training, the family physician can assist with such programs.

Problems Related to Physical Agents

Christopher S. McGuire and J. Brian Lanier

Contents

Heat

Environmental heat injury to humans involves a spectrum of disorders. Ranging from mild to severe, these include heat cramps, heat syncope, heat exhaustion, and exertional heat stroke.

Nonathletic heat injuries occur most often in the elderly, especially those in summer heat waves who live without air conditioning. For example, an August 2003 heat wave in Europe resulted in 14,800 deaths (**Arguard**). During this time period one hospital in France experienced 83 admissions, with a 65 % death rate (**Arguard**). Use of antihypertensives and residing in an institution were associated with worse outcomes. Most survivors had a reduced functional status and were not able to be discharged to independent living.

Athletes are another group of individuals who are susceptible to heat injuries. It is estimated that more than 9,000 high school athletes are treated for exertional heat injuries each year, most occurring during the start of the academic year (Kerr2). High school football players are especially vulnerable, as they have the highest rate and absolute numbers of heat injuries (kerr2). Between 1995 and 2010, 35 football players died from heat injuries (Kerr2). Exertional heat injuries can be prevented through a gradual acclimatization to the heat. The National Athletic Trainers Association publishes guidelines for a heat acclimatization process (Casa). Hallmarks include limiting practice times, early practices with helmet only,

DOI 10.1007/978-1-4939-0779-3_53-1

and mandatory breaks between practice sessions in a cool environment.

Sudden cardiac death in athletes participating in endurance sports has been a concern. However, a recent analysis of runners demonstrated that serious heat injuries were ten times more common than cardiac arrhythmias (Yankelson). Additionally, hyponatremia must be in the differential diagnosis for a collapsed athlete. In a 9 h endurance event, it only takes approximately 2.2 l of excess fluid for a 50 kg female to decrease her plasma sodium concentration to 120 mEq/L (Armstrong). An on-site sodium concentration analyzer can be helpful in the evaluation of a collapsed athlete with a near-normal temperature (Wen).

There is no established method for evaluating a return to sports for an athlete that has suffered a heat injury. The Israeli Defence Force has developed a protocol where a soldier walks on a treadmill in a hot (40 °C), humid (40 % RH) room with continuous rectal temperature monitoring (Johnson). A case report of an endurance athlete who had two serious heat-related incidents demonstrated that cycling in a heated room with continuous gastrointestinal temperate and heart rate monitoring could improve heat tolerance. He was then allowed to return to racing and completed several more races in extreme heat stress without incident. Both of these methods are probably not practical for most primary care providers.

Most studies report submersion in ice water as the most effective treatment (Lipman). Natural sources of water can be used, such as rivers, lakes, or the ocean. Care should be taken that the head is kept above the water and that the patient is never left alone. However this is not always practical, and the next best option is removing any clothing or equipment (football helmet, bullet-proof vest, etc.), dousing the patient with cold water, and creating a wind source to facilitate convective cooling, such as a fan. Moving the person to shade also helps but mostly when temperatures are less than 20 °C (68 °F).

The following table is taken from the Wilderness Medical Society Practice guidelines (Lipman):

Severity of Heat-Related Illness	Diagnosis	Treatment
Mild	Heat cramps	Oral isotonic or hypertonic fluid replacement
	Heat edema	Extremity elevation Compression stockings
Moderate	Heat syncope	Removal from heat source Passive cooling Oral isotonic or hypertonic fluid hydration
	Heat exhaustion	Removal from heat source Evaporative and convective cooling Oral or intravenous isotonic or hypertonic fluid hydration
Severe	Heat stroke	Remove from heat source Supportive care of airway, breathing, circulation Cold-water immersion Evaporative and convective cooling Intravenous hydration Evacuation

Cold

Approximately 700 people a year die in the USA from hypothermia (Petrone). Men between the ages of 30 and 49 years are the most commonly affected. Medical conditions such as malnutrition, hypoglycemia, and dementia can predispose individuals to cold injuries. However, the single most common cause is alcohol intoxication.

Mild hypothermia is defined as a core body temperature of greater than 32 °C. The initial management can be accomplished by passive rewarming. This includes removing wet clothing, applying insulating clothing, and moving into a protected area with warm, moist air (Petrone).

The next step is active rewarming. This can be accomplished by submersion in warm water or a forced air rewarming system, such as a Bear Hugger (3 M™ Bair Hugger™ therapy, St. Paul,

Minnesota, USA). The last step is active internal warming. This involves body cavity lavage techniques or extracorporeal rewarming. Infusing warm saline is not an effective technique, as the relative heat transfer from a 1–2 kg amount of warm fluid into a 60–80 kg cold person is small.

Frostbite

Frostbite and nonfreezing cold injuries (NFCI) were once mainly a military health problem; however, with increasing interest in outdoor activities, the incidence in the general population is increasing (Imray). The mainstay of treatment is rapid rewarming. As with hypothermia, the main predisposing factor is alcohol consumption.

NFCI occurs when tissues are exposed to a prolonged cold, wet environment at temperatures above freezing. Most cases occur in the feet and lower legs, with occasional upper extremity involvement. There is rarely any tissue destruction; however, the sequela can be as severe as frostbite. The hallmark of NFCI is a sensory neuropathy that can result in severe pain, edema, and hyperhidrosis. Some individuals are unable to continue to work outside in cold temperatures, which can affect their occupational career as well as recreational opportunities. Prevention remains the key, with encouragement to change into dry socks and/or gloves as well as airing feet several times a day.

The chance of frostbite and NFCI is more correlated with duration of exposure rather than absolute temperature (**Valnicek**). Most often the hands and feet are affected (90 %), but the face, perineum (from sitting on metal seats), and penis (underdressing while running) can be affected.

The pathophysiology of cold injury consists of four phases, the "prefreeze phase," "freeze-thaw phase," "vascular stasis phase," and "progressive or late ischemic phrase." Skin sensation is lost around 10 °C. This induces vasoconstriction. The vascular supply vasodilates in approximately 5–10 min cycles in an attempt to save the extremities. If the temperature falls below 0 °C, eventually ice crystals will form in the extracellular fluid and progress to endothelial damage. The final phase involves thrombosis, ischemia, necrosis, and gangrene.

The extent of tissue damage after injury is difficult to predict based on initial presentation or exam. However, favorable signs include intact sensation, normal skin color, and clear fluid in blisters (Imray). Traditionally, a 3–6 week wait was necessary to determine the full extent of damage prior to surgery. Triple-phase bone scanning may allow an early diagnosis of viability and assist the physician and patient with prognosis.

Prehospital care of frostbite and NFCI involves warming the core by moving out of the wind into shelter and drinking warm fluids. The next step is removing any wet clothing and placing the affected areas in a dry, warm area, such as a companion's axilla. Do not rub the extremity. Aspirin (81 mg) and ibuprofen (800 mg) may help through antiplatelet and antiprostaglandin effects. Tissue that is rewarmed and refrozen almost always becomes necrotic, therefore the decision to rewarm by submersion in warm liquids must include an evacuation plan. The patient should not walk on rewarmed feet (Imray).

The initial hospital management consists of correction of hypothermia, rewarming in a 37–40 °C whirlpool, antibiotics, antitetanus prophylaxis, and ibuprofen. Vasodilators (iloprost, pentoxifylline, and buflomedil) and tPA have been used with some success.

Radiation

Medical imaging is a significant source of man-made radiation [21]. Most of that radiation is due to computed tomography (CT) scans. Plain radiographs use doses of radiation that are approximately 100 times lower. The use of CT has increased dramatically since its introduction in the 1970s (Brenner). This is especially true for children, who represent about 11 % of CT scans (Brenner). There is good evidence from atomic bomb survivors as well as radiation workers that a dose of radiation equivalent to two to three CT scans results in an increased risk of cancer. The evidence is very convincing for children (Brenner).

Many physicians underestimate the risks of radiation from CT. A study noted that 53 % of radiologists and 91 % of emergency room physicians did not believe CT increased the lifetime risk of cancer (Lee). The cancers most correlated to radiation exposure are lung and leukemia (Brenner Radiology 232:735).

The most effective way to reduce the cancer risk from CT is to order fewer studies. It is estimated that approximately one third of all CT scans are not medically necessary. For example, the American College of Radiology recommends no imaging for an uncomplicated headache and no imaging for a suspected pulmonary embolism without a high pretest probability (including a positive d-dimer). Additionally, ultrasound should be the first choice for imaging evaluation of children with appendicitis (choosing wisely.org)

Exposure to radon gas is the second leading cause of lung cancer, behind smoking (BMJ 330:223). There are approximately 21,000 lung cancer deaths each year in the USA attributed to radon (Lantz). Radon is a radioactive, colorless, odorless gas that is naturally released from the ground and can build to toxic concentrations inside many homes. Basements are particularly vulnerable. The average radon level outdoors is 0.4 picoCuries per liter of air (pCi/L) and 1.3 pCI/L inside houses in the USA. The US Environmental Protection Agency limit is 4.0 pCi/L. At that level it is estimated that the lifetime risk of radon-induced lung cancer for never smokers is 7 per 1,000 exposed and 62 per 1,000 exposed smokers. Many public health authorities recommend screening homes with readily available screening kits. Remediation is effective and relatively inexpensive.

Ultraviolet light

Ultraviolet light (UVL) exposure is linked to melanoma and nonmelanoma (squamous and basal cell) skin cancers (IARC working group). These are the most prevalent cancers in the USA. This UVL exposure can occur in the form of excessive natural sun exposure as well as indoor tanning. The risk of cutaneous melanoma is increased by 75 % with artificial tanning use before the age of 30 (IARC2).

However, multiple studies have shown an inverse correlation between sun exposure and overall cancer rates (Bendik, Grober, Grant1, Grant2, Grant3). This is possibly due to a link between Vitamin D deficiency and cancer. Approximately 90 % of vitamin D is produced from skin exposure to sunlight. The benefits of sun exposure in reasonable doses may outweigh the risks.

Electrical Injury

In the USA there are approximately 50 fatal nonoccupational electrocutions per year (CPSC data) and approximately 50 lightning deaths per year (national weather service). However, there are many nonfatal injuries that can result in significant morbidity (Wesner). In general, electrical injury produces more injury to bone, nerve, or muscle than thermal injury does.

Electrical injuries cause the immediate effects of thermal burns, cardiac arrhythmias, seizures, as well as nerve deficits. The initial management includes removing the person from the source of injury (without electrocuting the rescuers) and providing basic life support. Long-term sequelae include neurological injury at the site of entry of the current resulting in chronic pain or other neuropathic sensations. The mechanism of action of injury is not completely known. Central nervous system injuries have also been reported, with a presentation similar to traumatic brain injury. Patients present with difficulty with verbal memory, attention, as well as behavioral changes. This can be present after even minor electrical injuries (Wesner).

Noise

Exposure to excessive sound pressure levels (noise) is the leading cause of preventable hearing loss (Basner). Nonoccupational sound sources include social (amplified music, recreational firearm use, etc.) as well as environmental (living

near airports, subways, etc.). The mechanism of hearing loss is destruction of auditory sensory cells in the cochlea. There is no known cure.

Long-term effects include hearing loss that can interfere with speech understanding as well as tinnitus. Tinnitus usually occurs with an acute or chronic noise exposure. Their association is likely due to similar pathophysiological pathways.

Many youth are exposed to loud noise, mostly due to amplified music. One survey reported over 50 % (mean age 19 years) experiencing temporary tinnitus as the result of noise exposure at a concert or club (Katbamna). Personal headphone use has also dramatically increased. The reported prevalence of listening to music through headphones has increased from 19.8 % in 1988–1994 to 34.8 % in 2005–2006 (Henderson). However, other studies have reported no increased rates of noise-induced hearing loss in 12–19-year-olds from the 1988–1992 to 2005–2006 time periods (Henderson).

There are also nonauditory health effects from noise exposure (Basner). The major effect is on sleep quality. Even levels as low as 33 dB have been shown to activate the autonomic system. Additionally, long-term exposure to noise is implicated in hypertension, ischemic heart disease, and stroke (Basner)

Carbon Monoxide

Carbon monoxide (CO) is a poisonous, odorless, tasteless gas. The most common exposure in the community is due to inefficiently burning hydrocarbons. Examples are internal combustion engines and home heating systems. CO molecules readily combine with hemoglobin to form carboxyhemoglobin and reduce the oxygen-carrying capacity of blood. Additionally, CO directly poisons mitochondria and is implicated in oxidative stress of cells (Guzman)

There are approximately 430 non-fire-related carbon monoxide deaths per year. Additionally it is estimated there are 25,000 hospitalizations due to CO exposure. Treatment with 100 % oxygen is indicated.

Blood carboxyhemoglobin levels can be directly measured through most blood gas analysis machines. Baseline levels in smokers are higher than nonsmokers. Sometimes carboxyhemoglobin levels do not correlate with exposure. Most pulse oximeters cannot reliably distinguish between carboxy and oxyhemoglobin and will be falsely elevated in CO poisoning (Guzman).

The initial treatment for CO poisoning is 100 % oxygen via nonrebreather mask as well as supportive care. The patient may have cardiac ischemia as well as arrhythmias. Severe poisoning can result in metabolic derangements. Treatment with hyperbaric oxygen (via a dive chamber) is controversial but may benefit severely intoxicated patients. CO poisoning in pregnancy is a unique problem, as it is difficult to assess oxygenation status of the fetus and fetal hemoglobin has a higher affinity for carbon monoxide than adult. Pregnant women may uniquely benefit from hyperbaric oxygen.

CO poisoning is easily prevented by correctly installing furnace venting, and running internal combustion engines in well-ventilated areas. Inexpensive home carbon monoxide alarms are available.

Most CO poisoning victims recover without sequela. There is some description of a delayed-onset neurological sequela. This can involve long-term neurocognitive effects as well as depression and anxiety. Many of these symptoms can last 12 months or longer (Guzman).

Pediatric carbon monoxide exposure can have different effects than on adults. Often children do not report any headache and present with seizures or perturbations in consciousness (Cho). Children have a lower rate of delayed neurological sequelae than adults, 2–10 % versus 10–40 % (Cho). Additionally, there are few guidelines for the use of hyperbaric oxygen in children.

Bites and stings account for a small but significant number of patients seen in the primary care setting. Family physicians can provide the patient, family, and community with anticipatory guidance regarding common hazards and appropriate care if a bite or sting does occur.

Mammalian Bites

Most mammalian bites are from dogs or cats. Children are the most frequent victims of dog bites [1]. Most of the dogs involved are known to the victim and were considered friendly prior to the biting episode. Injuries inflicted by cats tend to involve the hand and upper limb.

Clinical Presentation

Significant dog bites tend to be lacerations, often with crushing or tearing of tissue. Bites are most often sustained on the extremities, head, and neck. In children, dog bites may penetrate the skull. Because of their needle-like teeth, cat and rodent bites are usually puncture wounds, often involving tendons or joint spaces. A multitude of organisms reside in the mouths of all higher primates. For this reason, these bites are notoriously predisposed to infection. Human bite wounds most commonly result from conflict or contact sports. Potentially, the most serious human bite wound is the "clenched-fist" injury. This injury is sustained when the victim strikes an adversary in the mouth with a clenched fist and suffers a laceration inflicted by the other's teeth. Microorganisms may be inoculated into the deep tissues of the hand, resulting in a devastating infection.

Diagnosis

All bites are examined meticulously for foreign bodies and devitalized tissue. Radiographs are considered if there is the possibility of fracture or a retained foreign body. The medical record should include information regarding the site, depth, and circumstances of the biting episode, as well as a sketch of the injury.

A clenched-fist injury should be examined after reproducing the position of the hand when the injury occurred. Otherwise, penetration of the wound into the deep tissues of the hand may not be appreciated.

Management

All mammalian bites should undergo copious irrigation with sterile saline. A 19-gauge or larger needle on a syringe is often used to generate a high-pressure stream. Careful debridement of all devitalized tissue is necessary (see chapter "▶ Patient Centered Medical Home"). Further management depends on classifying the wound as high risk or low risk for infection. There is general agreement that high-risk bites are those involving the hands or feet, injuries older than 6–12 h, deep puncture wounds, crush injuries, human bites, cat bites, and bites sustained by elderly or immunocompromised individuals. Bites involving deep structures such as bones, joints, or tendons are also at high risk of infection. Individuals with high-risk bites should have their wounds debrided, packed, and reevaluated in 72 h to consider delayed primary closure. Prophylactic antibiotics should be administered. In practice, many bites otherwise considered high risk are primarily repaired if functional or cosmetic considerations strongly warrant it. Deep puncture wounds, bites of the hand, and wounds that present late should never be closed primarily [2]. Bite wounds involving the deep tissues of the hand should be surgically debrided, packed, immobilized in the position of function, and elevated. These injuries require intravenous antibiotic therapy. Low-risk wounds may be sutured immediately; antibiotic prophylaxis is not required. Cultures of an uninfected wound are not useful.

Human bites may transmit hepatitis B and C as well as herpes simplex virus. Prophylaxis against hepatitis B may be achieved by administering hepatitis B immune globulin (HBIG) 0.06 mL/kg and hepatitis B vaccine. The potential for

human immunodeficiency virus (HIV) transmission by human bites is thought to be low, although there are case reports of transmission by this route [3–5]. The need for tetanus and rabies vaccination should be assessed.

Prophylactic Antibiotics

Patients with high-risk wounds should receive a 3–5-day course of prophylactic antibiotics. Amoxicillin-clavulanate 875/125 mg bid is an appealing agent for prophylaxis of human and animal bite wounds. Its spectrum of activity includes *Pasteurella multocida*, *Staphylococcus aureus*, streptococci, *Eikenella corrodens*, and β-lactamase-producing oral anaerobes. Penicillin-allergic patients may receive cefuroxime 500 mg bid or doxycycline 100 mg bid.

Established Infections

For established infections, empiric treatment with ampicillin-sulbactam 1.5–3.0 g IV q6h, cefoxitin 1 g IV every 6–8 h, or ertapenem 1 g IV every 24 h is recommended [6].

For patients with a definite penicillin allergy, alternatives include clindamycin 600 mg IV every 6 h plus a fluoroquinolone such as ciprofloxacin 400 mg IV every 12 h.

Rabies Prophylaxis

Rabies is a nearly uniformly fatal condition once symptoms begin to manifest. Therefore, a high index of suspicion for this infection must be maintained after any mammalian bite. Bats and other wild mammals are currently the major source of rabies in the United States. Assessment of risk involves a thorough history and physical examination. A break in the skin from the teeth or claws of an infected animal or contact with saliva on mucous membranes or broken skin constitutes exposure. The decision to apply prophylaxis is then guided by the specific situation and animal species. In general, bats, skunks, raccoons, woodchucks, foxes, and other wild carnivores should be regarded as rabid and immunoprophylaxis administered. If the animal is captured, it should be killed immediately and the head sent under refrigeration to an appropriately equipped laboratory for fluorescent antibody examination. If the test is negative, the vaccination series may be discontinued. Domestic dogs, cats, and ferrets that are otherwise healthy should be confined and observed for a period of 10 days. If they remain asymptomatic, prophylaxis is unnecessary. The management of all other exposures, from either wild or domestic mammals, should be decided after consultation with the local health department.

Early, thorough wound cleansing is necessary to reduce the viral inoculum. Wounds are flushed with soap and water. Suturing the wound is avoided if possible. Human rabies immune globulin (HRIG) is administered in a dose of 20 U/kg body weight to both adults and children. This dose should not be exceeded, as passive antibody may interfere with response to the active vaccine. Half of the dose is infiltrated around the wound, if feasible, and the rest given intramuscularly in the gluteal area. Active immunization is accomplished by human diploid cell vaccine (HDCV) or rabies vaccine adsorbed (RVA), the first dose given simultaneously with HRIg with repeat doses on days 3, 7, 14, and 28. The active vaccine is administered intramuscularly in the deltoid. In infants it is given in the anterolateral thigh [7].

Prevention

The role of education in the prevention of these injuries cannot be overemphasized. Dog bites are reported to be among the top 12 causes of nonfatal injury in the United States [1]. Situations reported to be potentially dangerous include approaching dogs immediately after entering their territory, waking a dog from sleep, and teasing or playing with a dog until it becomes overexcited [8]. Male dogs and dogs that have not been neutered are more likely to bite [1, 9].

Family and Community Issues

Most dog bites are preventable. Parents should be counseled never to leave a child alone with a dog, and children should be taught never to approach an unfamiliar dog. They should also be warned of the danger of startling animals. Children should learn to recognize signs of distress in familiar animals and be warned not to disturb them when they are exhibiting this behavior.

Spider Bites

In North America, two species of spider account for most medical problems after bites. The brown recluse spider (*Loxosceles reclusa)* is found primarily in the south-central regions of the United States but may be transported anywhere. It is a small (1–2 cm) tan to dark brown spider with a violin- shaped pattern on the back. It produces a venom containing sphingomyelinase D, which causes endothelial swelling, platelet aggregation, and thrombosis. The black widow spider (*Lactrodectus mactans*) has a shiny black color with a red hourglass-shaped marking on the ventral abdomen. Black widow venom contains α-latrotoxin, a potent neurotoxin.

Clinical Presentation

Brown recluse spider bites are painless or only mildly painful. Within 2–8 h, though, severe local pain may occur. An erythematous or cyanotic macule ("volcano lesion") may appear at the site of the bite often followed by a deep necrotic ulcer, which may take months to heal. Systemic absorption of toxin may lead to fever, malaise, vomiting, skin rash, and jaundice. Hemolysis and disseminated intravascular coagulation (DIC) may occur. Desquamation of the extremities, petechiae, and skin rashes may appear as late as 3 weeks after the bite [10].

Black widow spider bites are often painless, but 20 min to several hours later, localized pain, cramps, and fasciculations may occur. Progression to pain and rigidity in the abdomen, shoulders, and back often follows. Autonomic signs such as nausea, vomiting, fever, dizziness, hypertension, and sialorrhea may occur.

Diagnosis

Often the diagnosis of a spider bite is made presumptively by the victim. One study found that 90 % of suspected spider bites were actually bites from other insects or manifestations of disease states [11]. For this reason, it has been suggested that in the absence of conclusive evidence as to the identity of the culprit, such bites be labeled "arthropod bite, vector unknown" in the medical record [12].

Management

For most spider bites, wound care, ensuring current tetanus immunization status, and monitoring for infection are the only interventions required. Local symptoms are controlled through the use of ice, analgesics, and antihistamines.

Severe systemic symptoms due to brown recluse spider bites may require treatment with enteral or parenteral corticosteroids. Based on studies on rabbits, brown recluse envenomations that only have local effects do not respond to treatment with steroids, antihistamines, or hyperbaric oxygen therapy [13].

If available, specific antivenin (Antivenin, Merck, West Point, PA) may be the management option of choice for all significant envenomations due to black widow spiders [14–16] (Table 1). Parenteral narcotics, intravenous diazepam, or methocarbamol are useful for muscle cramps, as are prolonged hot baths.

Prevention

Clearing away debris, plugging openings into houses, wearing gloves and long pants, using insecticides, and avoiding heavily infested areas are the major preventive steps that can be taken to avoid bites.

Table 1 Antivenins

Antivenin	Indication	Dosage
Antivenin (Crotalidae) (BTG International) Polyvalent	Pit viper envenomation	See text
Antivenin *(Micrurus fulvius)* (Wyeth Laboratories)	Coral snake envenomation	Asymptomatic: 3–5 vials Symptomatic: 6–10 or more vials
Antivenin *(Latrodectus mactans)* (Merck)	Black widow spider envenomation	1–2 vials 1M (IV in severe cases)
Scorpion antivenin (available through Arizona State University[a])	Bark scorpion envenomation	1–2 vials IV

[a]Not FDA-approved. Available to Arizona physicians only

Hymenoptera Stings

Stings by bees, wasps, hornets, and ants are common in most climates. Their shared manifestation is the production of localized dermal wheal and flare reactions. Full-blown anaphylaxis occurs in a subset of individuals. Domestic honeybees are relatively nonaggressive in defense of their colony. In contrast, Africanized bees ("killer bees"), endemic to parts of Arizona, Texas, and New Mexico, engage in massive stinging attacks that are often fatal. Fire ants are endemic to many southern states, and their bites are sustained by a large proportion of the population in infested areas each year.

Clinical Presentation

Wheal and flare dermal lesions are the most common presentation. The fire ant often makes a series of stings, leading to a characteristic semicircular pattern of sterile pustular lesions. Systemic toxicity may develop in the adult if more than approximately 50 bee stings are sustained simultaneously. Generalized edema, dizziness, weakness, and vomiting may be followed by DIC, rhabdomyolysis, and acute tubular necrosis.

Management

The lesion is examined for the presence of a stinger. If one is present, it is promptly removed. Squeezing the venom sac is avoided.

Applying ice to the lesion reduces pain. Topical steroid preparations and oral antihistamines may be used for local reactions. Calamine lotion and cool, moist dressings are useful. Treatment of massive envenomation is identical to that for anaphylaxis, and it may be difficult to differentiate between the two conditions.

Prevention

Individuals at risk should avoid perfumes and brightly colored clothing while outdoors. People who clear vegetation and discarded junk are at increased risk of being stung. Individuals with a history of anaphylaxis after stings should be offered desensitizing immunotherapy. They should also carry an anaphylaxis self-treatment kit (Ana-Kit or EpiPen injectors).

Snakebite

There are two families of poisonous snakes in the United States. Elapidae, or coral snakes, are found in the South. Brightly colored with black, red, and yellow rings, they produce a neurotoxic venom. They rarely bite humans. Crotalidae, or pit vipers, which include rattlesnakes, cottonmouths, and copperheads, are distinguished by heat-sensing organs, or "pits," in the area between the eye and the nostril. Crotalid toxin primarily causes hemolysis, hemorrhage, and local soft tissue damage, although a few Mojave rattlesnakes produce a neurotoxic venom [10].

Clinical Presentation

Patients presenting after snakebite may display extreme anxiety, and it is important not to mistake it as evidence of envenomation. Local tissue changes include pain, edema, bullae, and

ecchymosis. DIC and acute renal failure may occur. Coral snake envenomation may result in bulbar and respiratory paralysis.

Diagnosis

All patients who have sustained a venomous snakebite should undergo a complete evaluation regardless of the initial presentation, as effects can occur unpredictably for up to 12 h after the bite. In addition to the history and physical examination, a complete blood count, DIC screen, creatine phosphokinase assay, electrocardiogram, and urinalysis are recommended and may be repeated at intervals. Serial circumferential measurements of the affected extremity should be performed to monitor swelling. Consideration should be given to prophylactic endotracheal intubation in patients having sustained a bite of the face or head [10].

Management

Once an initial evaluation is done, contact should be made with the state poison control center to discuss the type of snake, location of bite, and signs and symptoms that the patient is having. Poison control can act as an important resource for discussion of administration of antivenin as well as other aspects of management. Intensive supportive care is often indicated. Antivenin is the only specific treatment available (Table 1). Its use for crotalid snakebites is recommended only if there is clinical evidence of envenomation [10]. Clinical assessment of the snakebite severity guides the amount of antivenin administered. Several objective scoring systems are in use [17, 18]. For minimal envenomations, up to 10 vials of antivenin are used and for moderate envenomation 10–20 vials [10]. The antivenin for crotalids (rattlesnake, copperheads, and water moccasin/cottonmouth) is Crotalidae polyvalent immune Fab (ovine) and is reconstituted in 10 mL of saline for each vial and diluted in 250 mL of saline to infuse. Start with 4–6 vials in and run the IV infusion over 60 min, proceeding slowly over the first 10 min at a 25–50-mL/h rate with careful observation for any allergic reaction. If no allergic reaction occurs, increase infusion rate to the full 250 mL/h until completion. Give an additional 4–6 vials followed by 2 vials every 6 h for 18 h for 14–18 vials total as indicated [19]. For severe cases, 20 or more vials of antivenin may be necessary. In children these doses may have to be increased by as much as 50 %. Specific antivenin should be administered to anyone sustaining a bite from a coral snake, regardless of initial presentation, as symptoms may progress rapidly once they appear. Antivenin administration is associated with anaphylaxis and serum sickness in a significant percentage of patients.

Prevention

Prevention is practiced by avoiding infested areas and high-risk behaviors, such as turning over logs and stones in the wild. Boots and long trousers provide significant protection from snakebite. Carrying a light while walking at night is an effective snake repellent.

Other Arthropods

Many other arthropods, including mosquitoes and ticks, target humans among their hosts. In the United States, mosquitoes transmit a number of arboviral encephalitides. Tick-borne diseases include Lyme disease, typhus, babesiosis, Rocky Mountain spotted fever, and ehrlichiosis (see chapter "▶ Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome"). Scorpions native to the United States are not significantly toxic except for the bark scorpion (*Centruroides exilicauda)* endemic to Arizona and New Mexico.

Clinical Presentation

The most common presentation of a tick bite is the discovery of an attached tick. Ticks have a barbed feeding organ, or hypostome, through which they

suck blood. This feeding mechanism is buried under the skin of the host, making removal of the tick difficult. Patients may also present with sequelae of a tick bite, such as erythema migrans. Rarely, injection of a neurotoxin by a female *Dermacentor andersoni* or *Dermacentor variabilis* tick results in a rapidly ascending motor paralysis known as "tick paralysis."

Most scorpion stings result in localized pain and swelling only. Systemic toxicity presents with localized numbness and paresthesias, followed by nausea, vomiting, dyspnea, and sialorrhea. Hypertension, involuntary motor activity, and seizures may occur.

Diagnosis

Ticks may attach anywhere but are often found at the hairline or on the scalp. Tick bites may induce persistent granulomas or ulcers at the site of attachment. Tick paralysis often presents with flaccid paralysis. Bulbar paralysis and respiratory depression may occur. Cerebrospinal fluid examination is unremarkable.

Management

An attached tick is removed by grasping it as close to the host's skin as possible with tweezers or protected fingers. Steady traction should be applied to detach the tick. Pulling too hard decapitates it and leaves the mouth parts embedded in the skin. Tick paralysis resolves spontaneously after removal of the tick.

Patients who display evidence of systemic toxicity from scorpion stings require supportive care. Beta-blockers are used for management of severe hypertension. Specific antivenin is available for severe envenomations.

Prevention

Protective clothing should be worn when traveling in infested areas to avoid tick and mosquito bites. Individuals at risk should be counseled to carry out a visual inspection of the entire body twice daily to detect and remove any attached ticks. An insect repellent containing diethyltoluamide (DEET) should be applied to all exposed skin. Permethrin 0.5 % spray (Nix, Elimite) applied to clothing provides further protection. There is hope for a Lyme disease vaccine in the near future. A previous vaccine, LYMErix, was withdrawn from the market voluntarily in 2002 [20].

Marine Animal Stings

In the United States, stingrays and coelenterates (sea anemones, jellyfish, corals) cause most of the significant human envenomations.

Clinical Presentation

Most commonly, the victim steps on a stingray hidden under the sand and is envenomated by a spine on the dorsum of the creature's tail. Stingray venom contains serotonin and proteolytic enzymes. The victim often experiences immediate pain and swelling of the affected extremity. Nausea, vomiting, weakness, diaphoresis, cramps, and dyspnea may occur.

Coelenterates have thousands of stinging organs called nematocysts on their tentacles. Contact with these organs triggers the sting, which penetrates the skin and releases toxin.

Diagnosis

Wounds inflicted by stingrays are often jagged and edematous. Pieces of the dorsal spine may be embedded in the wound or surrounding tissue.

Coelenterate stings present with a stinging or burning sensation involving the affected area. Erythema and papules appear in a linear distribution. Systemic symptoms include headache, nausea, muscle pain, spasm, and tachycardia. Massive envenomations have led to death.

Management

After soaking the stingray-induced wound in hot (45 °C) water for up to 90 min to deactivate the toxin, the wound is carefully irrigated and debrided. It is then packed and reevaluated at 72 h for delayed primary closure. Tetanus vaccination status is assessed and updated if necessary.

Soaking areas affected by coelenterate stings in hot, uncomfortable (not scalding) water for 5–10 min every 15 min up to 2 h helps deactivate toxins [13]. Any adherent tentacles are removed with gloved hands, and the affected areas may be shaved with a razor or sharp knife to remove any remaining nematocysts. A steroid-containing cream may be applied.

Prevention

Individuals should consider wearing sandals or shoes when wading in areas where stingrays or coelenterates are found. Stingrays and other marine animals must be avoided, even when apparently lifeless.

More than 2.2 million poison exposures were reported to United States poison centers in 2012 [1]a at least 88 % of which were by intentional or accidental ingestion. This chapter provides primary care clinicians with sufficient information to diagnose and comprehensively manage common oral poisonings associated with significant morbidity and mortality. Ingestions of acetaminophen, cyclic antidepressants, aspirin/salicylates, and benzodiazepines are discussed.

General Treatment Measures

When presented with a patient who has ingested toxic amounts of a substance, gastric decontamination should be considered if the ingested substance is highly toxic or if the amounts ingested are sufficient to cause harm to the patient. Activated charcoal is the most effective method of gastrointestinal decontamination and is used with or without gastric emptying. When indicated, gastric emptying by lavage is generally preferable to ipecac-induced emesis. However, gastric emptying should not be routinely used in all cases of toxic ingestion. The doses of these treatments are described in Table 1, with additional information provided in the following discussion.

Activated Charcoal

Indications

Administration of activated charcoal is the most effective method used to prevent absorption of ingested drugs and chemicals from the gastrointestinal (GI) tract. It is not effective for treating ingestions of corrosive agents, cyanide, iron, ethanol, ethylene glycol, methanol, lead, lithium, or organic solvents. Multiple dosing has been shown to be effective for ingestions of theophylline, phenobarbital, carbamazepine, dapsone, and quinine. It is possibly effective for ingestions of salicylates, tricyclic antidepressants, digoxin, digitoxin, piroxicam, phenytoin, dextropropoxyphene, disopyramide, nadolol, phenylbutazone, and sotalol [2]. Dosing information is outlined in Table 1. If a patient is to receive ipecac, activated charcoal should be withheld until ipecac-induced vomiting has stopped (usually 1–2 h after the last ipecac dose). Activated charcoal should never be given before ipecac therapy. Absolute contraindications to the use of activated charcoal include patients with an unprotected airway, intestinal obstruction, or a dysfunctional gastrointestinal tract.

Dosing and Administration

The initial dose of activated charcoal is usually about 5–10 times the amount of ingested substance or 1–2 g/kg (Table 1). This protocol results in adult doses of 50–100 g of activated charcoal and pediatric doses of 10–25 g. Multiple-dose therapy is usually administered until the patient passes a charcoal stool. A level measuring tablespoon contains about 5–6 g of activated charcoal. Activated charcoal is commercially available as a powder to be mixed with water or a ready-made suspension with or without the cathartic sorbitol. Although cathartics were once recommended, they are no longer considered the standard of practice; they may be used with multiple dosing if the patient has not produced a stool after two to three doses of charcoal. The powder form is mixed with tap water to form a slurry (which contains 15–120 g of ingredient depending on the strength); the slurry must be shaken vigorously, as charcoal does not mix well in water. This process can be avoided by using a ready-made suspension containing 25–50 g in 120–240-mL containers. The poor taste of the slurry or suspension can be improved by using the cherry-flavored products or by adding small amounts of fruit juice or chocolate; milk products should be avoided because they decrease the adsorptive properties of the activated charcoal.

Cathartics

Cathartics can be used in combination with activated charcoal to decrease GI transit time and further decrease toxin absorption. Sorbitol and

Table 1 Dosing and administration of ipecac and charcoal

Treatment	Age (years)	Dose (mL)	Frequency	Comments
Ipecac	0.5–1 1–12 >12	5–10 15 30	Repeat in 20–30 min if first dose is unsuccessful [give with 0.5 glass (<1 year) to 1 glass (>1 year) of water]	Do not give >2 h after ingestion; *do* not give after charcoal; do not use *ipecac fluid extract*
Activated charcoal (Liqui-Char, charco aid, actidose)	All	1–2 g/kg (initial dose)	Single dose (most substances); repeat (1 g/kg q4h) until charcoal stool: for theophylline, phenobarbital, carbamazepine, dapsone, and quinine	If ipecac is used, should wait until ipecac-induced emesis stops (usually 1–2 h after last dose of ipecac); use cathartic with first dose

magnesium citrate (or sulfate) are considered the cathartics of choice; irritant cathartics such as cascara, senna, phenolphthalein, and bisacodyl are not recommended. Sorbitol (adults and children receive 4 mL/kg of a 35 % solution) is the treatment of choice because it works faster than the magnesium salts. Magnesium citrate (adult dose 200 mL, children's dose 5 mL/kg) is an alternative. Cathartics may be administered after the first dose of activated charcoal but should not be repeated when multiple doses of activated charcoal are used.

Gastric Lavage

Indications

Gastric lavage is the preferred method for gastric emptying in patients with potentially life-threatening ingestions treated in emergency room settings [3]. Lavage is most effective if performed within 1 h of the toxic ingestion.

Contraindications

Patients who have ingested acidic or alkaline substances are not considered candidates for gastric lavage. Lavage should not be used in patients who have ingested low-viscosity hydrocarbons (kerosene, gasoline, paint thinner), strychnine, or acids or alkalis because of the potential of aspiration. However, lavage is indicated for ingested aromatic or halogenated hydrocarbons and hydrocarbons containing pesticides, camphor, or heavy metals. Risk of hemorrhage or gastrointestinal perforation should also be considered prior to lavage. The passing of a lavage tube may induce vomiting or retching, which may result in aspiration of the hydrocarbon substance. Aspiration can be prevented by endotracheal intubation with a cuffed tube to protect the trachea prior to gastric lavage.

Administration

Conscious patients should drink a glass of water before the gastric tube is passed. Remove all foreign materials (e.g., dentures) from the patient's mouth prior to inserting the gastric tube. A large-diameter orogastric hose [36–40 French (F)] is used for adults and 1 of 24–28 F in children. After confirming tube placement, remove the stomach contents using an irrigating syringe. When the stomach contents have been removed and sent to the laboratory for toxicologic examination, begin lavage by administering 100–300-mL aliquots of fluid (warm water or 0.45 % saline) until the lavage return is continuously clear for at least 2 L or a total of 10–20 L has been administered. At the conclusion of the lavage, activated charcoal 1 mg/kg is administered (followed by a cathartic, if used).

Ipecac

Indications

Ipecac syrup has traditionally been used for acute oral drug overdose and oral poisonings managed at home [4]. If possible, individuals attempting to manage an acute poisoning at home should contact a regional poison control center or an emergency facility prior to the administration of ipecac. The potential for serious toxicity and inability to be seen at a health care facility within 1 h of ingestion may be justifications for its use. However, the mean recovery of ingested substances is 28 % (range 25–50 %) if given within 1 h of ingestion, and ipecac appears to add no benefit compared to activated charcoal alone in terms of clinical deterioration and hospital admission. Furthermore, the American Academy of Pediatrics has recommended against the use of ipecac in the home setting [4]. If ipecac is used, it is most effective if emesis is induced within 1 h after a toxic ingestion; emesis after 1 h may recover less than 20 % of the ingested substance. Emesis usually occurs within 30 min, with the emetic effects lasting for up to 2 h. If the first dose is not successful, administer a second dose within 30 min of the first dose (maximum is two doses). If the second dose is not successful, begin administration of activated charcoal if it is applicable to the ingested substance (see Table 1 for dosing and frequency). Once the patient vomits, save the emesis contents for analysis. If emesis occurs and a decision is made to administer activated charcoal, the charcoal must be given after the cessation of vomiting.

Contraindications

Ipecac should not be used in patients who have ingested acids or alkalis because of the potential of aspiration. The use of ipecac in patients ingesting hydrocarbons is usually not recommended (same exceptions as with gastric lavage). Ipecac syrup should not be confused with ipecac fluid extract, which is 14 times more potent than ipecac syrup. Ipecac should not be used in patients with an impaired sensorium or seizures, those who lack a gag reflex, infants younger than 6 months of age, when gagging where vagal stimulation may cause bradycardia (patients taking calcium channel blockers, beta-blockers, clonidine, digitalis), those with coagulation defects, or following ingestion of substances that cause rapid changes in sensorium.

Adverse Effects

When ipecac syrup is used in the recommended doses, patients experience common adverse effects such as vomiting, diarrhea, and drowsiness. Other complications such as Mallory–Weiss tears, aspiration, and bradycardia have occurred.

Acetaminophen

Acetaminophen overdoses account for large numbers of patients seen in emergency rooms and primary care physician offices. Data from the 1999 Annual Report of the American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS) documented more than 104,400 ingestions of acetaminophen-containing medications that necessitated poison control center contacts in 1999 [1]. Children under the age of 6 years accounted for 38 % of these exposures; about 39 % of the poisoned were age 20 years or older. There were 177 deaths for all ages among those who took acetaminophen and combination products.

Pharmacokinetics

Acetaminophen (APAP) is rapidly and completely absorbed from the GI tract following ingestion of a therapeutic dose. Peak plasma levels occur approximately 0.5–1.0 h after ingestion of therapeutic amounts of immediate-release products but may be delayed 2–4 h after large ingestions. Peak levels may occur even later after ingestion of toxic amounts of extended-release products (e.g.,

Tylenol Arthritis Extended Relief caplets) or products containing diphenhydramine which slow gastric motility (Tylenol PM Extra-Strength) [5, 6]. Once absorbed, acetaminophen is distributed throughout the body water. Protein binding is less than 50 %.

Acetaminophen is metabolized in the liver (96 %) with only 2–4 % excreted unchanged in the urine [7]. Metabolism of therapeutic doses via glucuronidation and sulfation results in the formation of benign metabolites (90–95 %). Oxidation through the cytochrome P-450 enzyme system (CYP 3A4 and CYP 2E1) results in the formation of the toxic metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI) (5–10 %). NAPQI is rapidly conjugated with glutathione to form a nontoxic metabolite. The metabolites are excreted in the urine along with the small amount of unchanged drug.

Acetaminophen metabolism in children younger than 6 years of age appears to differ from that in older children and adults, as evidenced by lower levels of hepatotoxicity with toxic plasma levels from single doses. Although young children have more CYP 3A4 enzyme than adults and may form more NAPQI, they have a greater activity of glutathione replacement and can eliminate NAPQI more readily [8]. Once approximately 70 % of glutathione stores are depleted, levels of NAPQI increase, resulting in hepatocyte destruction. Acetylcysteine (Mucomyst), the treatment of choice for toxic acetaminophen ingestions, exerts its protective effect by replacing the depleted glutathione stores and increasing acetaminophen metabolism through benign pathways.

Several risk factors result in increased NAPQI formation and hepatotoxicity, the first being large ingestions of APAP. "Toxic" doses are considered to be >7.5 g in adults and >150 mg/kg in children. However, supratherapeutic doses (>50–75 mg/kg/day) for 1–5 days in children have been shown to cause hepatotoxicity and death. This occurs more often in children ≤2 years of age who have not eaten for a prolonged period. This also can occur in a febrile child with viral gastroenteritis who is not eating and has received several doses of APAP to lower the fever. Parents using adult-strength APAP products instead of the child products may further increase this risk [9].

Risk factors seen in adults include malnutrition, long-term use of acetaminophen, and chronic alcohol consumption, which also deplete glutathione stores. Medications that induce the CYP 3A4 enzyme (carbamazepine, phenobarbital, phenytoin, rifampin) will further increase the formation of NAPQI. All risk factors must be considered in the prevention and treatment of APAP poisoning.

Clinical Presentation

The clinical course of acetaminophen toxicity consists of four stages [10]. Stage 1 is seen within the first 24 h after ingestion, and in older children and adults, it consists of nausea, vomiting, diaphoresis, and malaise. Children under 6 years of age seem to vomit earlier and at lower serum acetaminophen levels. Hepatic enzymes are usually not elevated unless there are other causes of hepatic dysfunction. Severe symptoms including coma indicate extremely large ingestions or co-ingestants.

Stage 2 occurs 24–48 h after ingestion and is characterized by the appearance of laboratory abnormalities indicating hepatic damage and necrosis. The aspartate transaminase [AST, serum glutamic-oxaloacetic transaminase (SGOT)], alanine transaminase [ALT, serum glutamic-pyruvic transaminase (SGPT)], and bilirubin levels begin to rise; with severe toxicity the prothrombin time (PT) is increased. The nausea, vomiting, diaphoresis, and malaise encountered during stage 1 typically subside, although complaints of right upper quadrant pain may be encountered.

Stage 3 is seen 3–4 days after ingestion and reflects maximal hepatic damage. Nausea, vomiting, and malaise reappear and with severe poisonings may be accompanied by jaundice, confusion, somnolence, and coma. Renal, pancreatic, and cardiac damage may also occur. Peak AST, ALT, bilirubin, and PT values occur during this stage. Although AST levels over 1000 IU/L are diagnostic for acetaminophen-induced

hepatotoxicity, levels as high as 30,000 IU/L may be found with severe poisonings. Bilirubin levels exceeding 4 mg/dL, and PT values more than 2.2 times control are indicative of serious hepatotoxicity.

Stage 4 occurs in survivors 7–8 days after ingestion and represents resolution of the hepatic damage. Clinical signs of hepatic dysfunction and enzyme abnormalities have nearly or completely resolved. Permanent hepatic damage is infrequent.

Infrequently, patients suffer hepatic damage following ingestion of "nontoxic" amounts of acetaminophen (see section "Pharmacokinetics") and may present initially at any stage of toxicity. Abnormally high hepatic transaminase levels for the clinical situation are often seen. At risk are those who regularly drink large amounts of alcohol, take acetaminophen long term, are malnourished, or take other drugs that affect hepatic metabolism.

Despite the potential for hepatotoxicity, fewer than 1 % of adult patients develop fulminant hepatic failure, and it is almost never seen in children under 6 years of age. In fact, hepatic abnormalities are seen in fewer than 5 % of children under 6 years of age who have toxic plasma acetaminophen levels.

Diagnosis

The patient's history of medication ingestion is often inaccurate and may omit co-ingestants. The absence of specific clinical signs and symptoms can also be misleading, particularly early in stage 2 when laboratory findings that indicate hepatic damage are minimal and the clinical symptoms seen in stage 1 are abating. A high level of suspicion is helpful particularly in those who are malnourished, consume alcohol on a chronic basis, and are on CYP 3A4 enzyme-inducing medications.

Therefore, plasma acetaminophen levels should be obtained 4 h (possibly at 2 h if ingestion of a liquid with APAP only) or longer after ingestion from all patients with known or suspected acetaminophen overdoses. Acetaminophen levels should also be obtained for *all* ingestions undertaken as a suicide attempt given the risk of co-ingestion of various substances including acetaminophen. The plasma level is then plotted on the Rumack–Matthew nomogram (Fig. 1) and a decision made regarding the need for treatment.

Management

Treatment of acetaminophen poisoning embodies three principles: preventing absorption of ingested acetaminophen from the GI tract, appropriate use of the antidote *N*-acetylcysteine (NAC), and supportive care. Preventing absorption from the GI tract is described under "General Treatment Measures." Activated charcoal should be given in most cases of acute poisoning, within 1 h of acetaminophen ingestion for best results and preferably at least 1 h before NAC administration. Untreated patients seen within 1 h of ingestion are candidates for gastric lavage. The value of emptying the stomach with ipecac is doubtful, and aggressive use of ipecac may cause prolonged vomiting, thereby expelling the oral NAC as well. If a patient has consumed ipecac, activated charcoal should be given not less than 1.0–1.5 h after ipecac administration (and only if vomiting has stopped) because of the risk of aspiration.

Plasma acetaminophen concentrations should be measured 4 h or more after ingestion in all patients. A full course of NAC treatment is indicated for initial levels in the "possible risk" or higher ranges on the Rumack-Matthew nomogram (Fig. 1) regardless of the type of acetaminophen ingested (immediate- or extended-release products). If the concentration is below the possible risk level and the ingested acetaminophen is known to be an immediate-release product, further evaluation and treatment are unnecessary. If the type of acetaminophen ingested is unknown or includes an extended-release product, it is recommended that a second acetaminophen level be determined 4–6 h after the first level. If the second level is higher than the first level or is close to the possible risk level on the nomogram, it is prudent to measure additional acetaminophen levels every 2 h until the levels stabilize or

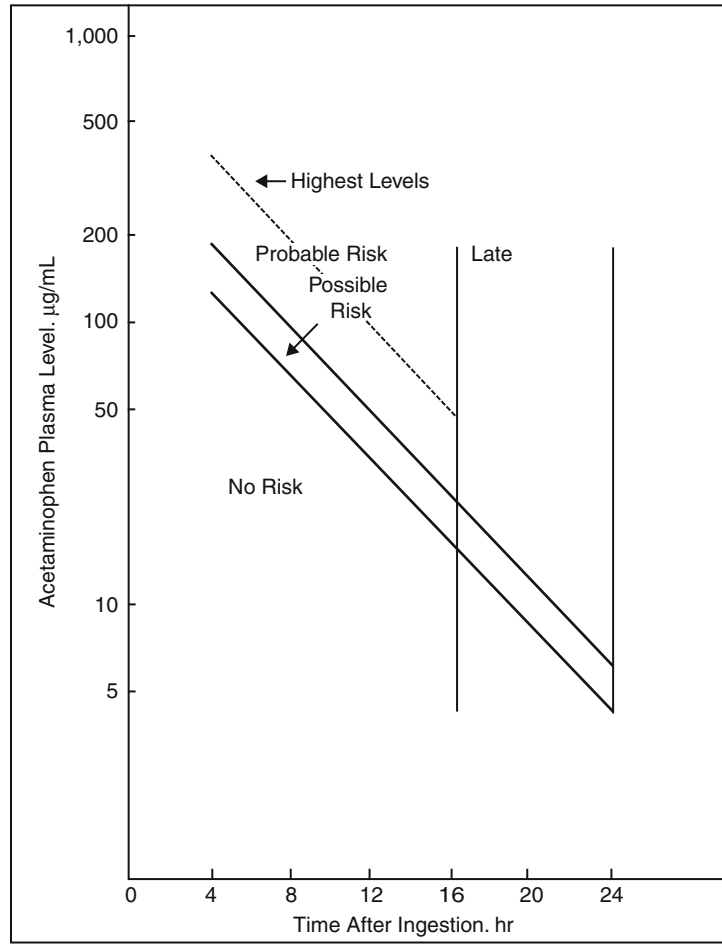

Fig. 1 Rumack–Matthew nomogram (From Rumack et al. [10], with permission)

decline. A full course of NAC treatment should be given if a repeat concentration is in the possible risk or higher ranges on the nomogram. If the concentration remains below the possible risk level, treatment is not indicated.

For optimal therapeutic effect, NAC should be given within 8 h of the toxic ingestion (simultaneously with activated charcoal if necessary to achieve treatment during this period) [11]. If serum levels are not immediately available 8–16 h after ingestion, NAC is given empirically. If the initial and repeat (when indicated) serum concentrations return at nontoxic levels, the NAC may be discontinued in most cases. Possible exceptions include patients at risk for hepatic damage at normal or slightly elevated serum concentrations, including those who regularly drink large amounts of alcohol and those who are severely malnourished. NAC therapy may be effective up to 36 h or more after ingestion, particularly in patients with fulminant hepatic failure [7, 12].

N-acetylcysteine is given orally in a loading dose of 140 mg/kg, followed by 70 mg/kg every 4 h for 17 additional doses. Although activated charcoal adsorbs NAC in vitro, it appears to have a small effect on NAC in vivo, and there are no data showing that activated charcoal inhibits the antidotal efficacy of NAC. Therefore, most information supports the immediate use of activated charcoal with administration of NAC 1 h afterward. If the patient vomits within 1 h of administration of any dose, the dose is repeated. NAC has an odor similar to that of rotten eggs and can be diluted in fruit juices or carbonated beverages to a concentration of approximately 5 % to prevent

nausea and vomiting. Placement of a nasogastric tube may be necessary in cases of refractory vomiting.

Intravenous NAC has been used extensively for treatment of acetaminophen poisoning in Great Britain and Canada, but it is not approved for use in the United States. Intravenous regimens commonly used include a 20-h regimen with a loading dose of 150 mg/kg over 15 min followed by 50 mg/kg over 4 h, then 100 mg/kg over the next 16 h, or a 48-h regimen with a loading dose of 140 mg/kg followed by 70 mg/kg every 4 h for 12 doses [7, 13]. Intravenous administration of oral NAC through millipore filters has been described for situations when intravenous preparations of NAC are not available [14].

Supportive care is often necessary after gastrointestinal decontamination and administering NAC. AST, ALT, bilirubin, PT, complete blood count (CBC), and creatinine values are followed daily until improvement is noted. Treatment for hepatic insufficiency is initiated as indicated.

Cyclic Antidepressants

The 1999 AAPCC TESS identified antidepressants as the poison category associated with the second largest number of deaths that year, after analgesics. Antidepressant poisonings were responsible for the third highest percentage of deaths among categorical exposures, following only stimulants/street drugs and cardiovascular drugs [1]. Cyclic antidepressants (CAs) accounted for only 20 % of antidepressant exposures, but 67 % of deaths. Conversely, selective serotonin reuptake inhibitors (SSRIs) represented 41 % of exposures and 14 % of deaths. The SSRIs are as efficacious as CAs for treatment of depression and are considered first-line therapies for social anxiety disorder, obsessive–compulsive disorder, and panic disorder [15–18]. Despite their low safety profile, CAs continue to be indicated in selected patients for a variety of conditions, including depression, enuresis, and chronic pain (Table 2) (see chapters "▶ Selected Problems of Infancy and Childhood", "▶ Anxiety Disorders," and "▶ Care of the Difficult Patient").

Table 2 Cyclic antidepressants

Generic name	Brand name
Tricyclics	
Amitriptyline	Elavil
	Endep
Amoxapine	Asendin
Clomipramine	Anafranil
Desipramine	Norpramin
Doxepin	Adapin
	Sinequan
Imipramine	Tofranil
Nortriptyline	Pamelor
Protriptyline	Vivactil
Trimipramine	Surmontil
Tetracyclic	
Maprotiline	Ludiomil
Selective serotonin reuptake inhibitors (SSRIs)	
Fluoxetine	Prozac
Paroxetine	Paxil
Sertraline	Zoloft
Fluvoxamine	Luvox
Citalopram	Celexa
Escitalopram	Lexapro

Pharmacokinetics

Cyclic antidepressants are rapidly and completely absorbed when therapeutic amounts are ingested, with peak plasma levels occurring 2–6 h after therapeutic doses. In overdose situations, the severe anticholinergic effects of the CAs result in delayed gastric emptying. Once absorbed, CAs are highly protein bound to plasma proteins (>90 %) and tissue proteins [19]. The remaining unbound compounds readily accumulate in various body tissues (myocardium, liver, brain) at 5–30 times the plasma concentration. The fraction of unbound drug increases as the plasma pH decreases, allowing the antidepressants to accumulate in the tissues and produce toxic effects.

Metabolism of CAs occurs primarily in the liver (90–95 %) and results in the formation of active and inactive metabolites. Metabolites are excreted in the urine and stool. Less than 5 % of CAs or their active metabolites are excreted unchanged. Because of enterohepatic

recirculation and variations in metabolism, the normal half-life for therapeutic doses of CAs ranges from 18 to 36 h. With overdoses the combination of delayed gastric emptying and enterohepatic recirculation leads to increased serum concentrations of CA with half-lives prolonged to >80 h. Plasma drug levels also vary greatly regardless of the dose ingested.

Metabolism of CAs may be affected by patient age and concurrent medications. Consequently, elderly patients typically have a prolonged CA half-life, whereas the converse occurs in children. CA half-lives are shortened by co-ingestions of ethanol, barbiturates, lithium, and tobacco and are prolonged by steroids, oral contraceptives, and phenothiazines, and benzodiazepines.

The SSRIs are almost exclusively eliminated by hepatic metabolism, with all SSRIs (except paroxetine) having active metabolites contributing to serotonergic activity. SSRIs can inhibit hepatic enzymes CYP 3A4 and CYP 2D6 increasing the serum concentrations of several medications (alprazolam, tricyclic antidepressants, propoxyphene, venlafaxine, trazodone) that can further increase toxicity in overdose situations [20].

Clinical Presentation

Overdoses of CAs affect the parasympathetic, cardiovascular, and central nervous systems. Clinical signs and symptoms are the result of several pharmacologic actions including neurotransmitter reuptake inhibition of norepinephrine, dopamine, and serotonin, α-adrenergic blockade, anticholinergic effects, and blockade of myocardial fast sodium channels producing the quinidine-like effect on the myocardium [21]. The signs and symptoms of CA overdose are summarized in Table 3, with most fatal overdoses resulting from cardiac complications. CA overdose should be suspected in any patient (child or adult) who presents with signs of anticholinergic poisoning, seizures, coma, hypotension, respiratory depression, or arrhythmias [22].

Signs and symptoms of an overdose are variable and may change rapidly. Findings resulting from the anticholinergic effects (dilated pupils, dry mouth, hyperpyrexia, blurred vision, CNS excitability) are typically the first to appear. Depending on the time since ingestion, however, patients may present as asymptomatic, have mild to moderate anticholinergic effects, or exhibit signs of severe toxicity including seizures, coma, arrhythmias, and cardiac arrest. Symptoms rapidly progress, with seizures and ventricular

Adult respiratory distress syndrome
Renal tubular acidosis
Metabolic acidosis

RBBB right bundle branch block, *AV* atrioventricular

arrhythmias typically occurring within 6 h after ingestion [23].

Sinus tachycardia is frequently present with serious CA overdoses but is a nonspecific finding. A limb-lead electrocardiographic (ECG) QRS interval of more than 0.10 s is more specific and is considered a sign of potentially serious toxicity [21, 23]. A rightward shift in the terminal 40-millisecond QRS frontal plane axis and R wave $\geq$3 mm in lead AVR are also commonly associated with CA toxicity and considered to be a more significant predictor for seizures or dysrhythmias [21, 24].

Cyclic antidepressants have a low therapeutic index (median toxic dose divided by median effective dose). Whereas doses of 1–4 mg/kg may be therapeutic, overdoses as small as 20 mg/kg may be fatal. For example, ingestion of four 100-mg tablets could be fatal if ingested by a 20-kg child, and ingestion of a 2-week supply of 100 mg tablets can be fatal for an adult.

Overdoses of SSRIs are considered much less lethal than CA and the actual fatality rate due to SSRIs overdose alone is not clear due to the effects of co-ingestants in many patients. The toxic effects of SSRI overdose stem from the effects of excess serotonin (5-hydroxytryptamine, 5-HT) on multiple receptors. Stimulation of 5-HT_1, 5-HT_2, and 5-HT_3 receptors, as well as the resulting inhibition of dopamine release, produces many of the symptoms seen in toxic situations [20].

Patients can experience minor symptoms such as drowsiness, nausea, vomiting, and/or tremors when ingesting doses 50–75 times the normal daily dose of SSRIs. Higher doses (150 times the normal daily dose) can result in severe toxicity or death. Patients may experience "serotonin syndrome" if they present with three or more of the following: mental status changes, diaphoresis, myoclonus, diarrhea, fever, hyperreflexia, tremor, or incoordination. Patients can also experience tachycardia, QT prolongation, and seizures. Many patients experiencing toxicity have co-ingested ethanol, benzodiazepines, or serotonergic agents (dextromethorphan, tricyclic antidepressants) [15, 20].

Diagnosis

A comprehensive history and physical examination (Table 3) should alert the clinician to the possibility of CA overdose. The diagnosis can be confirmed by blood or urine screens for the presence of CAs or SSRIs. Although plasma levels are useful for confirming the diagnosis, they are of little help in predicting serious toxicity.

Co-ingestions of other drugs and the presence of preexisting heart disease must be considered when evaluating patients for CA or SSRI overdose. Each may complicate the clinical presentation and result in a delay in diagnosis.

Management

Treatment of CA poisoning embodies four general principles: preventing absorption of ingested CA from the GI tract, supportive (especially circulatory and respiratory) care, seizure management, and control of arrhythmias. Absorption from the GI tract should be prevented via gastric lavage and use of activated charcoal, as described above (see section "General Treatment Measures"). Ipecac is contraindicated because vomiting may delay charcoal administration or cause aspiration of vomitus in patients with rapidly changing sensoriums.

Asymptomatic patients without signs of CA overdose and with QRS intervals of less than 0.10 s, no QT prolongation, and no deviation of the terminal portion of the QRS (R wave $<$3 mm in AVR) may be transferred for psychiatric management after being closely observed in the emergency room for a minimum of 6 h. Patients showing initial signs and symptoms of CA toxicity and patients with QRS or QT prolongation or deviation of the R wave in AVR should be admitted to the intensive care unit (ICU) and monitored until signs and symptoms of toxicity (including ECG abnormalities) resolve. Patients with refractory or prolonged signs of toxicity should remain in the ICU until 24 h after resolution of all toxic manifestations.

Aggressive supportive care is essential for managing CA poisoning. Patients with depressed

mental status should be evaluated for other possible etiologies. Where appropriate, the patient is intubated with a cuffed endotracheal tube to secure the airway and prevent impending respiratory failure or aspiration. Intravenous access should be established and isotonic fluids administered to correct hypotension and restore effective blood volume. If signs of cardiotoxicity are present (QRS $\geq$0.10 s, R in AVR $\geq$3 mm, QT prolongation, right bundle branch block, wide-complex tachycardia), intravenous $NaHCO_3$ boluses of 1–2 mEq/kg given over 1–2 min can be used until signs of cardiotoxicity and the hypotension improve. An infusion of 150 mEq of $NaHCO_3$ in 1 L of 5 % dextrose in water is then given to maintain an arterial pH of 7.45–7.55 [25]. Patients unable to tolerate large amounts of intravenous sodium may be treated with mechanical ventilation, although this is not as effective as $NaHCO_3$ administration.

Hypotension refractory to crystalloid and sodium bicarbonate therapy may be treated with vasopressors such as norepinephrine or dopamine [25, 26]. Dopamine may be less effective than norepinephrine in treating refractory hypotension from CA overdoses when given at the usual doses, but use at a high dosage (up to 30 μg/kg/min) may improve the response rate in resistant cases. Dobutamine can be used to treat hypotension associated with myocardial depression but causes hypotension in some patients.

Seizures may be treated immediately with intravenous diazepam (Valium) 0.15 mg/kg at 15–20-min intervals until seizures are controlled or to a total dose of 30–40 mg. This regimen is followed by treatment with an anticonvulsant with a longer half-life, such as phenobarbital. Although recommended as second-line therapy, phenobarbital can cause respiratory depression and acidosis and must be used with caution [27]. Phenytoin (Dilantin) should be avoided because of potential cardiotoxicity. Although physostigmine has been advocated for the treatment of anticholinergic CNS effects, it has considerable cardiac and CNS toxicity and should not be used in CA overdoses.

Arrhythmias induced by CAs are treated by sodium bicarbonate therapy and alkalinization of the plasma to pH 7.45–7.55, the use of antiarrhythmics, and cardioversion when necessary. If serious ventricular arrhythmias persist following alkalinization and other supportive measures, lidocaine is the initial drug of choice [25, 28] (see chapter "▶ Ocular Trauma"). The use of class IA (quinidine, procainamide, disopyramide) and IC (flecainide, encainide, propafenone) antiarrhythmic agents is contraindicated because they also inhibit the myocardial fast sodium channels and worsen the cardiotoxicity.

Treatment of SSRI intoxication includes gastric decontamination (activated charcoal) and supportive care for seizures or cardiovascular manifestations as necessary. Treatment for serotonin syndrome includes supportive therapy, cooling blankets, ice packs or ice water enemas, and the use of dantrolene and cyproheptadine in a manner similar to that used in treating neuroleptic malignant syndrome.

Aspirin/Salicylates

Poisoning by ingestion of oral salicylate-containing medications remains a serious problem in the United States. According to US poison control center data, there were more than 16,300 exposures to aspirin and combination products containing aspirin that necessitated poison control center contacts in 1999 [1]. Approximately 28 % of exposures were in children younger than 6 years of age, 32 % in those 6–19 years, and 40 % in adults older than 19 years. There were 51 deaths in all categories of exposure. By 2012 [1]a, the numbers changed significantly. No deaths were reported by salicylates in children younger than 6 years of age. In the remaining groups, age 6–12 years, there was only 1 reported death by salicylate poisoning out of 7 fatal exposures. In the age range 13–19 years, there were 3 fatal salicylate poisonings out of 45 reported fatalities.

Pharmacokinetics

Salicylates are rapidly absorbed from the stomach, jejunum, and small intestine. Peak plasma salicylate concentrations are achieved 0.5–2.0 h after ingestion of immediate-release preparations and usually 4–6 h or more after ingestion of extended-release enteric-coated tablets [29]. With large ingestions, absorption and subsequent peak plasma levels may be delayed as much as 8–12 h because of decreased gastric emptying. In addition, large ingestions are often absorbed more slowly because clumps of aspirin tablets form concretions in the stomach resulting in salicylate in the stomach long after ingestion. Consequently, peak levels may occur 24 h or more after ingestion of large amounts of extended-release tablets.

Following absorption of therapeutic doses, aspirin is rapidly hydrolyzed to salicylic acid, and both compounds are highly protein bound (80–90 %) to albumin. Distribution throughout body fluids is extensive and largely dependent on the amount of salicylate ingested and the pH of the body fluids. The amount of pharmacologically active free salicylate increases as salicylate levels increase above the therapeutic range.

Free salicylate exists in either ionized or nonionized form, the nonionized form being able to readily diffuse into body tissues. Decreased body fluid or tissue pH results in increased relative amounts of the nonionized salicylate, allowing greater tissue penetration. Consequently, large overdoses (with greater amounts of free salicylate) in conditions associated with metabolic acidosis (dehydration, chronic or large salicylate overdoses, sepsis) often result in large tissue and CNS concentrations and hence greater toxicity. Also, alkalinizing the urine increases the concentration of ionized form in the urine, thereby reducing the amount of salicylate that is reabsorbed.

After therapeutic doses, salicylic acid is eliminated unchanged in the urine (5–10 %) or as one of five metabolites (90–95 %). At higher doses metabolic pathways are saturated, resulting in exponential increases in plasma salicylate levels. For example, an increase in daily aspirin dose from 65 to 100 mg/kg increases the serum concentration 300 % [30].

Clinical Presentation

The actions of salicylates that account for most of the signs and symptoms seen with poisonings include the following: (1) direct stimulation of the CNS respiratory center, producing respiratory alkalosis and initial compensatory renal excretion of HCO_3; (2) uncoupling of oxidative phosphorylation with increased catabolism, increased oxygen utilization, and increased CO_2 production, an action that can result in metabolic acidosis and hyperpyrexia (tissue glycolysis and utilization of glucose are also increased); (3) inhibition of Krebs cycle dehydrogenases, leading to increased amounts of pyruvic acid and lactic acid; (4) stimulation of gluconeogenesis; (5) increased lipolysis and lipid metabolism with formation of ketones, acetoacetic acid, β-hydroxybutyric acid, and acetone; (6) inhibition of aminotransferases, resulting in increased plasma amino acids and aminoaciduria; (7) irritation of the gastric mucosa and stimulation of the chemoreceptor trigger zone, with subsequent nausea and vomiting; and (8) altered coagulation and hemostasis via cyclooxygenase inhibition and decreased platelet aggregation, increased capillary fragility, thrombocytopenia, and hypoprothrombinemia.

The predominant clinical effects of salicylate poisoning can be grouped into two general categories: acid–base and fluid–electrolyte abnormalities. Approximate guidelines correlating the amount of salicylate ingested to the symptoms produced are as follows:

<150 mg/kg – minimal symptoms
150–300 mg/kg – moderate symptoms
300–500 mg/kg – severe symptoms
>500 mg/kg – potentially fatal

Minimal symptoms include mild to moderate hyperpnea, sometimes with lethargy. Moderate symptoms are characterized by severe hyperpnea and CNS signs including lethargy, excitability, or

both. Severe symptoms include severe hyperpnea, semicoma, coma, and convulsions [31].

Signs and symptoms, which usually begin within 3–8 h of ingestion, include nausea and vomiting, hyperpnea, and respiratory alkalosis. The respiratory alkalosis typically persists but is accompanied by progressive metabolic acidosis as the severity and duration of the poisoning increases. Additional findings may include tinnitus, disorientation, and hyperpyrexia. Cumulative GI, renal, pulmonary, and skin losses of fluids can be massive and may result in hypovolemia, oliguria, and renal failure. Hypernatremia, hyponatremia, and hypokalemia are frequently seen. Initial hyperglycemia may be followed by hypoglycemia caused by depletion of tissue glucose stores. Signs of CNS hypoglycemia, including lethargy, coma, and seizures, may occur despite normal plasma glucose levels [32]. Unexpected bleeding and hepatotoxicity are uncommon.

The progression of signs and symptoms is increased in young children, with large ingestions, with illnesses that include dehydration, and with chronic exposures. Also, use of therapeutic doses of salicylates for conditions accompanied by dehydration and acidosis may result in greater tissue (i.e., CNS) concentrations and increased morbidity and mortality, despite relatively low blood salicylate concentrations.

The clinical presentation of patients with chronic salicylate intoxication may differ from that of patients with acute intoxication. Potential differences include a more gradual onset of symptoms, an advanced stage of intoxication at initial presentation, and a predominance of neurologic symptoms particularly in the elderly [33]. Neurologic findings may include confusion, agitation, stupor, paranoia, and bizarre behavior. Chronic salicylism has been misdiagnosed as sepsis, alcohol withdrawal, myocardial infarction, organic psychosis, and dementia.

Salicylate-induced noncardiogenic pulmonary edema and the adult respiratory distress syndrome are complications of salicylate ingestion, particularly chronic ingestions [34]. Risk factors include increased age, cigarette smoking, and concurrent medical illnesses. Chronic salicylate intoxication has also been associated with development of a pseudosepsis syndrome characterized by hyperthermia, leukocytosis, hypotension with decreased systemic vascular resistance, and multiple organ failure [35].

Diagnosis

A history of salicylate ingestion helps confirm the clinical impression, but documentation of toxic serum salicylate levels is essential for establishing the diagnosis. The Done nomogram (Fig. 2) is used to assess the significance of serum salicylate levels following acute ingestions [31]. Blood salicylate levels should be determined 6 h or more after the acute ingestion. By plotting the serum level at a given time after ingestion, it is possible to predict the severity of the poisoning and the expected symptoms. This nomogram is most useful for acute ingestions and may underestimate the severity of poisonings after chronic exposures, in patients with illnesses accompanied by dehydration and acidosis, in cases of ingestion of enteric-coated or sustained-release products, and in those with indeterminate times of ingestion. Therefore serial serum salicylate levels every 1–2 h after the initial salicylate level have been recommended until levels decline and the patient's condition stabilizes [36].

Management

Treatment of salicylate poisoning encompasses three principles: preventing absorption of ingested salicylate from the GI tract; treating any fluid, electrolyte, or metabolic derangements; and enhancing elimination of salicylate from the body. Careful monitoring of the acid–base status, including prevention of worsening acidosis (respiratory or metabolic), is essential. Preventing absorption from the GI tract (described under "General Treatment Measures") includes emesis and/or gastric lavage (depending on the necessity for gastric emptying) and administering activated charcoal to increase elimination.

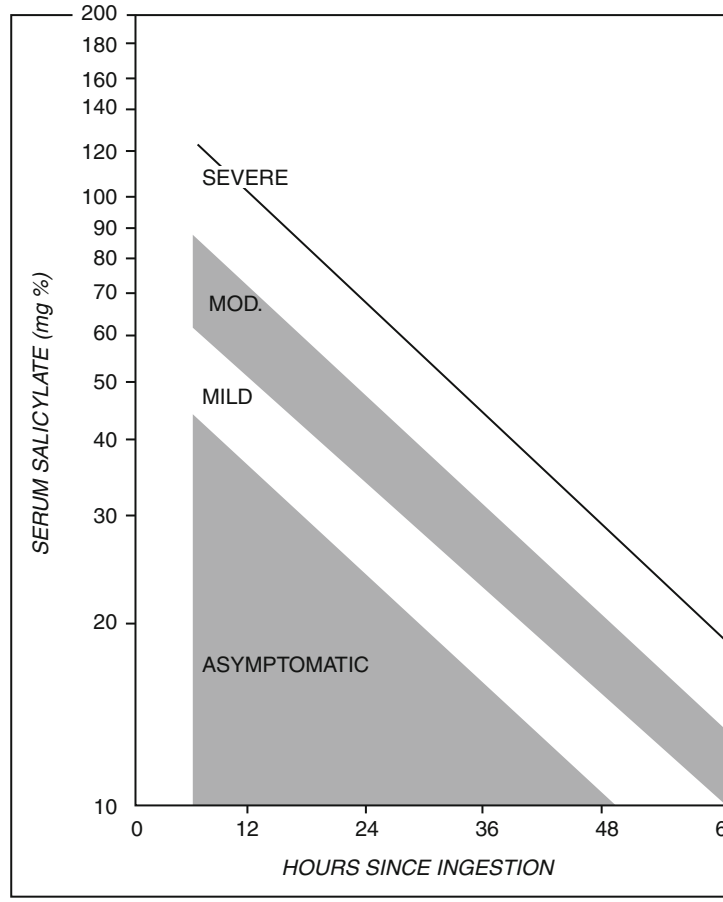

Fig. 2 Done nomogram (From Done AK. Pediatrics 1960;26:800–7, with permission)

Fluid resuscitation is initially directed toward restoring an effective blood volume. If hypotension is present, an isotonic solution should be given intravenously until the patient is no longer orthostatic. If hyperglycemia is not a problem, the solution should contain at least 5 % dextrose. If dextrose is not desired, normal saline or a mixture of 0.45 % NaCl with one ampule of sodium bicarbonate (total 50 mEq $NaHCO_3$) at 10–15 mL/kg/h for 1–2 h may be used, depending on the presence and degree of acidosis. Subsequent fluid management is directed toward alkalinizing the urine, preventing CNS hypoglycemia, and treating electrolyte and fluid abnormalities.

An effective alkaline diuresis (urine pH >7.5) to enhance salicylate excretion should be attempted once the patient is no longer orthostatic and urine output has been established. Superiority of a single method to achieve this has not been established. An initial bolus of $NaHCO_3$, 2 mEq/kg intravenously, followed by an infusion of 1000 cm^3 of dextrose 5 % in water (D_5W) plus three ampules of $NaHCO_3$ (50 mEq $NaHCO_3$/ampule) at 1.5–2 times maintenance rate has been effective. Potassium should be added to the IV as needed for potassium levels below 4.0 mEq/L. Frequent monitoring of serum electrolytes and glucose is essential. The urine pH should be checked hourly until stable at >7.5. Arterial blood gases should be monitored 2–4 h into treatment to ensure the blood pH is *no more than* 7.5. Alkalinization can be discontinued when the serum salicylate level is within the therapeutic range.

Hemodialysis is indicated for unresponsive or worsening acidosis, acute and chronic poisonings with salicylate levels of >100 mg/dL and 40–60 mg/dL, respectively, renal or hepatic

Table 4 Commonly prescribed benzodiazepines

Generic name	Brand name
Alprazolam	Xanax
Chlordiazepoxide	Librium
Clonazepam	Klonopin
Clorazepate dipotassium	Tranxene
Diazepam	Valium
Estazolam	ProSom
Flurazepam	Dalmane
Lorazepam	Ativan
Midazolam	Versed
Oxazepam	Serax
Quazepam	Doral
Temazepam	Restoril
Triazolam	Halcion

failure, noncardiac pulmonary edema, and persistent, severe CNS symptoms [31, 36]. Additional supportive care may be necessary depending on the severity of the poisoning and the patient's response to therapy.

Benzodiazepines

Benzodiazepines are widely prescribed for a variety of conditions, including acute anxiety, convulsions, neuromuscular disorders, panic attacks, insomnia, alcohol withdrawal, and induction of anesthesia. They are commonly used in inpatient and outpatient settings to produce conscious sedation for minor surgical procedures. US Poison Control Center data from 2012 indicate that benzodiazepines accounted for 46 % of all sedative deaths (51 of 110 total deaths) [1]a. Because this information does not include poisonings seen in other health care facilities, it is likely that the total number of benzodiazepine overdoses in the United States was considerably greater. Commonly used benzodiazepines are listed in Table 4.

Pharmacokinetics

Most benzodiazepines are rapidly and completely absorbed following an oral dose. Peak plasma levels occur 0.5–3.0 h after ingestion of therapeutic doses but may be delayed after large overdoses or when co-ingested with alcohol or antacids. Once absorbed, benzodiazepines are extensively bound to serum proteins (70–99 %), with the unbound drug being the active form. Conditions associated with hypoalbuminemia (e.g., cirrhosis) result in a greater proportion of unbound drug and may cause an increased frequency of side effects.

Benzodiazepines have a large volume of distribution in the body, with concentrations in the brain, liver, and spleen being greater than unbound drug concentrations in the blood. The duration of action depends on the rate and extent of tissue distribution (lipid solubility) as well as the rate of elimination.

Benzodiazepines are metabolized in the liver primarily by the CYP 3A4 enzyme pathway and to a minor extent the CYP 2C9 pathway resulting in the formation of active and inactive metabolites. Depending on the benzodiazepine ingested, metabolism may be prolonged by advanced age, cirrhosis, and the coadministration of various medications. These include macrolide antibiotics (clarithromycin, erythromycin), calcium channel blockers (diltiazem, verapamil), antifungal agents (fluconazole, itraconazole, ketoconazole), antidepressants (fluoxetine, fluvoxamine, nefazodone), protease inhibitors, and omeprazole. In addition, concomitant ingestion of grapefruit juice and acute alcohol ingestion can increase benzodiazepine serum concentrations [37, 38]. Although differences exist among benzodiazepines, excretion of metabolites and small amounts of unchanged drug (<1 % of the total dose) occurs primarily in the urine.

Clinical Presentation

Benzodiazepines exert their clinical effects by increasing neurotransmission in γ-aminobutyric (GABA)ergic synapses in the CNS. Specific benzodiazepine receptors, associated with GABAergic pathways, are found predominantly in the cerebral cortex, limbic structures, and cerebellum [39, 40]. Because the major CNS inhibitory effect is mediated via GABAergic pathways, benzodiazepine stimulation causes several physiologic effects, including sedation,

anxiolysis, striated muscle relaxation, and anterograde amnesia.

Benzodiazepines have a high margin of safety, and overdoses usually produce only mild to moderate signs of toxicity, including ataxia, dysarthria, drowsiness, and lethargy. However, severe overdoses can cause coma, hypotension, hypothermia, and respiratory distress requiring endotracheal intubation and assisted ventilation or, in select cases, administration of flumazenil [41, 42]. Such complications are rare in benzodiazepine-only ingestions but occur much more frequently with co-ingestions of other drugs that cause CNS depression (especially alcohol) (see chapter "▶ Athletic Injuries"). CNS depression is worsened in the elderly, in those taking large amounts, in patients with chronic diseases, and in those taking medications that impair hepatic benzodiazepine metabolism. Deaths caused by benzodiazepine-only overdoses are rare.

Diagnosis

A complete history and physical examination are important for determining the diagnosis and type of ingested medication. The diagnosis should be confirmed in all patients by blood or urine screens for the presence of benzodiazepines. It is important to screen routinely for the presence of co-ingestants, particularly in comatose patients. Quantitative determinations of blood benzodiazepine levels are not useful for the management of benzodiazepine overdoses because blood concentrations do not correlate well with clinical manifestations [43, 44].

Management

Treatment of benzodiazepine overdoses consists of patient stabilization, preventing absorption of ingested benzodiazepines from the GI tract, and supportive care including airway support and mechanical ventilation when necessary. Administration of the antidote flumazenil may be useful in selected patients, but is not recommended for routine use in patients with possible mixed drug overdoses or unknown medical histories [45, 46]. Preventing absorption from the GI tract is described above (see section "General Treatment Measures").

Patients are initially assessed for complications from CNS depression. Vital signs are evaluated and the adequacy of the airway and respiratory status ensured. Patients with respiratory depression and hypoxia or hypoventilation are intubated and placed on mechanical ventilation. Comatose patients and others with severe overdoses are examined for evidence of aspiration, hypotension, and hypothermia. Once stabilized, selected patients with benzodiazepine overdose (documented by drug screen or reliable history) who are comatose or have severe CNS depression may be treated with flumazenil (Romazicon). Flumazenil should be avoided in patients suspected of co-ingesting cyclic antidepressants, those with a history of benzodiazepine dependence, or those with a history of seizure disorders treated with benzodiazepines [46–48]. The risks of lethal dysrhythmias, benzodiazepine withdrawal, or seizures outweigh the potential benefits of treatment in these cases.

Flumazenil is a competitive inhibitor of CNS benzodiazepine receptor sites and reverses benzodiazepine-induced CNS depression. Recommended doses for benzodiazepine overdoses in adults are 0.2 mg IV over 30 s; if no response, give 0.3 mg IV over 30 s. Additional doses of 0.5 mg may be given at 1-min intervals as needed up to a total dose of 3 mg. Patients occasionally require a total dose of 5 mg for optimal response, but the requirement for higher dosages may indicate CNS depression due to the presence of co-ingestants [49]. Comatose patients typically awaken within minutes of intravenous administration. The duration of action is approximately 1 h (it may be shorter) and is related to the doses of benzodiazepine ingested and flumazenil administered [39]. Resedation may be observed in cases with prolonged CNS depression and can be treated with repeat 0.2 mg IV boluses (given over 30–60 s) as required, to no more than 3 mg in 1 h. Patients who fail to respond to a maximum dose of flumazenil (5 mg within 5 min) should be

evaluated for co-ingestants and other causes of CNS depression. Flumazenil is not approved for treatment of overdoses in children. For reversal of conscious sedation in children, 0.01 mg/kg (up to 0.2 mg) may be given intravenously over 15 s. If there is no response after 45 s, 0.01 mg/kg (up to 0.2 mg) may be given every 60 s (up to four doses) as needed to a maximum total dose of 0.05 mg/kg (or 1.0 mg, whichever is lower).

The stomach may be evacuated by gastric lavage (regardless of flumazenil administration) if the time since ingestion is less than 1 h, particularly in mixed drug ingestions. Activated charcoal should be administered in most cases and is effective when used as the sole treatment. The use of ipecac should be avoided.

Forced diuresis or efforts to remove the drugs by "cleansing" the vascular compartment (hemodialysis and hemoperfusion) are ineffective and are not indicated for management of overdoses. Antibiotics and corticosteroids are not used except for specific indications.

Supportive care is provided as needed. Hypotension can be managed with crystalloid solutions initially and vasopressors thereafter, as indicated. Treatment of poisoning by co-ingestants is targeted to the specific overdose agents.

Care of Acute Lacerations

Brian Frank*, Carl Rasmussen, Jade Koide and Katherine Marshall
Family Medicine, Oregon Health & Science University, Portland, OR, USA

Introduction

A laceration is a traumatic disruption of the epidermal/dermal junction. Treatment of acute lacerations typically requires mechanical support to approximate disrupted skin layers. Assessment of lacerations should include consideration of infection risk, evaluation of nearby vital structures for damage (e.g., nerves, blood vessels, tendons, etc.), and choice of closure technique to maximize functional and cosmetic outcomes.

Skin Anatomy and Wound Healing

Skin anatomy and the phases of wound healing are important concepts for laceration repair. All skin has a keratinized epidermis with a single, basal layer of regenerative cells. Deep under this is a collagen-rich dermis overlying subcutaneous fat and muscle. The dermal layer provides the majority of skin's strength. Figure 1 represents normal skin and subcutaneous tissue anatomy.

Wound Closure

Closure of acute lacerations is called "primary closure" or "closure by primary intent." Suturing remains the most common form of primary closure; however, alternative methods (e.g., wound closure tapes, staples, and tissue adhesives) may also be used. Secondary closure or "healing by secondary intent" describes wounds left open to heal by granulation. Tertiary closure refers to delayed primary closure. Most lacerations are repaired by primary closure.

Wound healing occurs in three phases: inflammatory, proliferative, and maturation. The inflammatory phase begins at the time of injury and lasts roughly 5 days. Once hemostasis occurs, macrophages and neutrophils remove foreign material and devitalized tissue. There is no gain in wound strength during this time. The proliferative phase occurs between days 6 and 14, during which time fibroblasts initiate collagen synthesis. By the end of this phase, disorganized collagen bundles are present but wound strength is poor [1]. Primary closure provides reinforcement during the first two phases of healing. Starting at 2 weeks after injury, the maturation phase involves remodeling of collagen bundle creation of the fibrotic scar. Everting skin edges (discussed below) help prevent inversion of the scar as it contracts. The healing process restores skin strength to approximately 80 % of normal [2].

DOI 10.1007/978-1-4939-0779-3_56-2

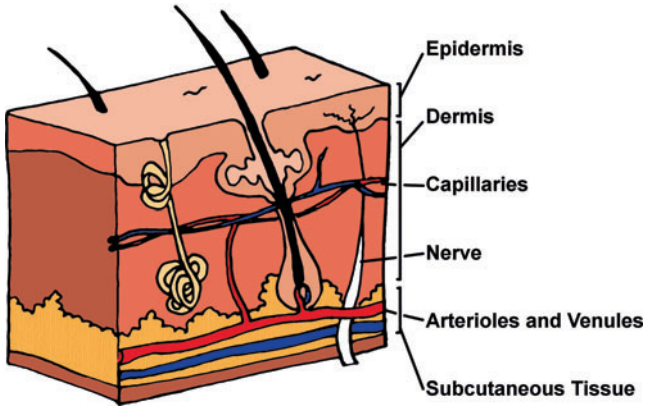

Fig. 1 Normal skin anatomy

Indications/Contraindications to Primary Closure

There is debate over how soon after injury a laceration must be repaired to optimize healing. Infection rate does not increase with delayed repair; however, rate of healing appears slowed after 19 h [3, 4]. Grossly contaminated wounds, wounds that appear infected, and those with significant devitalized tissue such as crush injuries are at high risk for infection. These injuries should be left opened and evaluated for tertiary closure in 72 h [5]. If the wound remains uninfected, delayed primary closure can occur at that time; otherwise, the wound should heal by secondary intent. If delayed repair is not an option, wound edges should be loosely approximated with interrupted sutures to allow for drainage. The decision to repair a wound depends on the skill and comfort level of the individual provider; the following injuries should prompt consideration of specialty referral: [6]

- Deep hand or foot wounds
- Full-thickness eyelid, lip, or ear lacerations
- Nerve, artery, bone, or joint involvement
- Penetrating wounds of unknown depth
- Severe crush injuries
- Severely contaminated wounds requiring drainage
- Cosmetic outcome of significant importance

Anesthesia

Local Anesthesia

Topical Anesthesia

For patient comfort, it is preferable to anesthetize wounds prior to inspection and cleansing. Several routes of administration exist. Topical agents consist of one or more anesthetics with or without a vasoconstrictor (e.g., lidocaine/epinephrine/tetracaine). To apply, a cotton ball soaked with the topical agent is placed over the wound and covered with an occlusive dressing. Application is painless and wound margins are not distorted with application. Anesthetic effect is achieved gradually. Topical agents are absorbed through subepidermal and mucosal tissue. Larger injuries may absorb a volume of anesthetic in excess of the recommended dose; caution should be used. Topical agents are a good choice for pediatric populations

DOI 10.1007/978-1-4939-0779-3_56-2

and can be used alone or as an adjunct to injectable agents. Once the wound is anesthetized, distraction with toys or games helps minimize the patient's anxiety.

Injectable Anesthesia

Injectable anesthetics achieve effect more quickly than topical agents but are more painful. The discomfort can be reduced by buffering the anesthetic with sterile sodium bicarbonate at a 10:1 ratio, injecting through the open wound to avoid nerve endings and infiltrating slowly with the smallest-gauge needle possible [5]. Partially withdrawing the needle and changing the angle prior to advancing ("fanning") decreases the number of injection sites. Allergies to injectable anesthesia are rare; still, patients should be asked about these prior to administration. Despite long-standing beliefs to the contrary, agents containing epinephrine do not increase the risk of necrosis in areas with end arterioles such as fingers and toes; in fact, the use of vasoconstrictors improves hemostasis and can reduce the need for tourniquets [7–9].

Injectable anesthetics can be administered by direct infiltration of the wound ("local" anesthesia), infiltration around the wound (a "field block"), or by proximal infiltration of a nerve that supplies the injured area ("nerve block"). Local anesthesia is used for simple lacerations on the face, trunk, and extremities. Field blocks (Fig. 2) are most useful for injuries where maintenance of architecture is crucial (e.g., lacerations of the ear). Nerve blocks require smaller volumes of anesthetic and last longer than local or field blocks though anesthetic effect takes longer. Additionally, they can anesthetize large areas with a single injection, a property helpful for managing large or diffuse areas of injury supplied by a common nerve. Nerve blocks require a careful review of anatomy and, due to the caliber of the targeted nerve, have an increased risk of prolonged paresthesia. The digital block pictured below is one of the most common nerve blocks and illustrates the general technique required (Fig. 3).

Procedural Sedation

In patients with significant anxiety or who are otherwise unable to tolerate wound repair with local anesthetic, systemic sedation with anxiolytics, analgesics, and/or sedative hypnotics is an alternative. Several terms are used to describe this practice. This text will use the term "procedural sedation and analgesia" (PSA). PSA can be safely utilized by family physicians so long as they are familiar with, and capable of managing, the potential complications associated with the medications required. The goal of PSA in laceration repair is to facilitate patient tolerance of the procedure without compromising

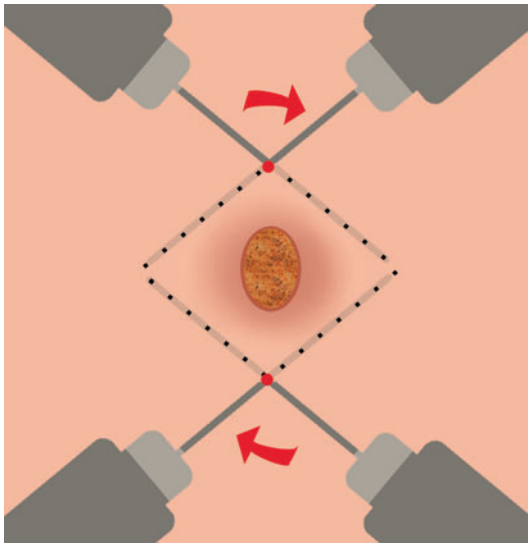

Fig. 2 Injectable anesthesia by field block

DOI 10.1007/978-1-4939-0779-3_56-2

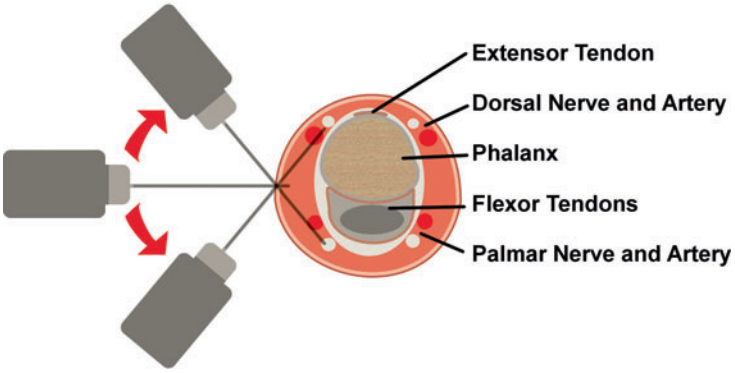

Fig. 3 Digital nerve block

oxygenation or other cardiorespiratory functions. Often patients will maintain the ability to respond to verbal cues; however, occasionally a deeper level of sedation may be required. Many institutions have protocols for PSA; providers are encouraged to consult these if available.

Prior to initiating PSA, patients or their guardians should be informed of the risks of the procedure; the most significant of these are respiratory depression, apnea, hypotension, laryngospasm, vomiting and aspiration; however, other drug-specific effects exist (see Table 1). At a minimum, documentation of verbal consent is recommended. A thorough history and physical exam (including past medical history and review of allergies and medications) is strongly recommended to alert physicians to underlying conditions that may complicate PSA. The physical exam should include assessment of the patient's airway to alert physicians to potential complications should advanced respiratory support be required. While aspiration is a feared complication, delay of PSA based on timing of last oral intake is not necessary [10].

Unplanned complications should be anticipated and appropriate equipment available. Broadly, these should include supplies for additional intravenous access, basic and advanced airway management (including suction), pharmacological antagonists (naloxone and flumazenil), and medications for arrhythmias or other cardiovascular complications. The patient should be placed on supplemental oxygen. Blood pressure and heart rate should be assessed at 5 min intervals and oximetry should be continuous [11]. Capnography, if available, can detect hypoventilation and apnea earlier than pulse oximetry [10]. These data should be recorded and reported to the physician contemporaneous to the procedure. Monitoring should commence prior to sedation and continue through the recovery period (reference). Minimum personnel requirements are the physician performing the procedure and a nurse to administer medications and keep a written record. There are no specific criteria to guide the optimal duration of monitoring following PSA; however, protocols exist at many institutions. At a minimum, patients should be monitored by a trained member of the team (typically a nurse) until the patient is able to independently maintain oxygenation and airway patency. Most often, some form of monitoring is continued until the patient regains his/her baseline level of consciousness. While monitoring a patient undergoing PSA, personnel should not engage in other activities beyond minor, interruptible tasks [11].

Various medications are used for PSA. The most common of these are listed below (Table 1). All doses given are for intravenous administration. The list of considerations highlights only the most common issues. Providers with additional questions or inexperience with these medications should consider consulting a more complete monograph. Impairment of hepatic or renal function as well as body size and composition (i.e., volume of distribution) can all affect the extent and duration of medication effect. Typically, a sedative or anxiolytic is combined with an opiate analgesic. The American Society of Anesthesiologists recommends intravenous administration of medications for PSA though other routes

DOI 10.1007/978-1-4939-0779-3_56-2

Table 1 Medications for PSA

Medication	Dose (IV route)	Onset	Duration	Considerations
Fentanyl (Sublimaze) *Class: Opiate*	Adult 0.5–2 mcg/kg Geriatric 0.25–1 mcg/kg Peds 0.5–2 mcg/kg	Immediate	30–60 min	Impairs respiratory drive Chest wall rigidity (esp in high doses and in children) Reverse with naloxone (Narcan)
Midazolam (Versed) *Class: Benzodiazepine*	Adult 0.5–1 mg given over 2 min Peds <6 months: 50 mcg/kg 6 months to 6 years: 50–100 mcg/kg 6–12 years: 25–50 mcg/kg	3–5 min	30 min	Can cause paradoxical excitement (up to 10–15 % of patients) Reversed with flumazenil (Romazicon) – flumazenil can cause seizures in patients on chronic benzodiazepine therapy
Ketamine (Ketalar) *Class: Dissociative anesthetic*	Adult 1–4.5 mg/kg Peds 1–2 mg/kg	30 s	5–10 min	Absolute contraindication in children <3 months (relative contraindication 3–12 months) Avoid with ocular globe injury and severe hypertension "Emergence phenomenon"
Etomidate (Amidate)	Adult 0.3–0.6 mg/kg Peds <10 years: Do not use >10 years: 0.3–0.6 mg/kg	60 s	3–5 min	Adrenal suppression
Dexmedetomidine (Precedex)	Adult 1 mcg/kg over 10 min Geriatric 0.5 mcg/kg over 10 min Peds Do not use			Hypotension

of administration may be preferable in certain situations; for example, a small child with a relatively minor laceration may be less anxious with an intranasally administered medication. It should be noted that soothing music and visual distraction have both been shown to decrease the need for sedation with unpleasant procedures in adults and children.

Opiates. Opiate medications act on mu receptors to blunt pain response. They can alter consciousness and depress respiratory drive, increasing the risk of hypoventilation and apnea. Their effects are dose dependent and are potentiated by other sedatives and anesthetic agents. The most commonly used opiate for PSA is fentanyl (Sublimaze), an agent with rapid onset and recovery times. In children and in large bolus doses (50 mcg/kg), chest wall rigidity can occur [12].

Benzodiazepines. Benzodiazepines cause sedation and anxiolysis via interaction with GABA receptors. They do not produce analgesia so are typically administered with an opiate. This combination will potentiate the sedation and respiratory depression typically seen with both agents. Midazolam (Versed) is most often used for PSA due to its rapid metabolism and its amnestic effects.

DOI 10.1007/978-1-4939-0779-3_56-2

Ketamine. Ketamine (Ketalar) is a dissociative anesthetic with relatively little effect on hemodynamic and respiratory function. There is an absolute contraindication to ketamine for children less than 3 months old and a relative contraindication in children 3–12 months of age due to risk of laryngospasm. Because ketamine induces catecholamine release, it is contraindicated in patients with acute ocular globe injuries and those with severe hypertension. The most common adverse effect of ketamine is related to its dissociative properties and is known as an "emergence phenomenon." The term refers to profound disorientation as the medication wears off. It occurs in as many as 20 % of patients and is typically more disturbing to adults than children [13]. Adding midazolam to ketamine does not appear to decrease the anxiety provoked by emergence phenomena. Family members of patients should be educated about the effects of ketamine (nystagmus, vacant staring) and encouraged to minimize visual, auditory, and tactile stimulation during the recovery period.

Etomidate. Etomidate (Amidate) is widely used for sedation due to its minimal effects on hemodynamics. It works via a GABA-mediated mechanism. The main adverse effect of etomidate is a transient suppression of adrenal function. For this reason, it is relatively contraindicated in septic patients.

Dexmedetomidine. The newest anesthetic agent in regular use for procedural sedation is dexmedetomidine (Precedex). A potent alpha-2 agonist, dexmedetomidine has potential to induce hypotension but has almost no effect on respiration [12].

Wound Preparation and Further Assessment

The first step in wound repair is ensuring availability of the proper equipment (Table 1). Once accomplished, attention can be turned to the laceration. Now anesthetized, the wound should be inspected for debris and other foreign bodies; damage to deeper tissues; or damage to vessels, nerves, or tendons and specialty referral considered as needed. Once this is complete, irrigation is used to wash away debris or foreign matter and dilutes the bacterial concentration present in the wound. Tap water and sterile saline have equivalent rates of postrepair wound infection, the former being more cost effective [14]. Warmed irrigation solution is less painful. A 60 mL syringe with an 18-gauge angiocatheter supplies adequate pressure without damaging tissue [5]. Commercial splash shields protect against body fluid exposure. The optimal volume of irrigation fluid has not been adequately reported; however, most sources recommend a minimum of 250 mL [15]. Visible foreign matter remaining after irrigation should be removed with sterile forceps, using caution with removal of foreign bodies located near vessels, nerves, or tendons. Wrapping a gloved finger with petroleum-embedded gauze can help the physician remove debris or greasy contaminants remaining in the wound after irrigation. Povidone-iodine, hydrogen peroxide, alcohol-based, or other chemical solutions may be used for cleaning skin surrounding the wound but should not be applied within the wound or approximating skin edges. These solutions are toxic to underlying tissue and impede wound healing. Hair surrounding the wound should be clipped but *not* shaved to avoid wound contamination. Shaving is associated with increased rates of infection [15].

Radiographs are recommended for wounds sustained from glass or metal fragments. Plastic and wood are not radiopaque, so advanced imaging should be considered if the presence of these materials is suspected.

Suture Characteristics

The most common sutures used for percutaneous closure are made from nonabsorbable, synthetic polymers such as nylon and polypropylene in a single filament. These produce less tissue reactivity than

DOI 10.1007/978-1-4939-0779-3_56-2

Table 2 Equipment checklist

Patient consent form
Ruler (for billing/coding)
Anesthetic
Irrigation: 60 ml syringe, tap water, splash device
Sterile field & surgical preparation: fenestrated drape, sterile drape, povidone-iodine or chlorhexidine gluconate, alcohol swabs
Sterile gloves (not needed in uncomplicated closure) [31]
Suture
Needle driver
Pickups with teeth (less traumatic than blunt pickups)

Table 3 Suture characteristics

	Suture	Advantages	Disadvantages	Tissue reactivity
Absorbable	Catgut (plain)	Inexpensive	Low tensile strength and retention (7–10 days), high tissue reaction	High
	Chromic gut	Inexpensive	Moderate tensile strength, retention, and tissue reaction	Moderate
	Polyglactic acid (Vicryl)	Braided, coated, easy handling, mild tissue reaction		Low
	Polyglycolic acid (Dexon)	Good tensile and knot strength, low tissue reaction	Difficult to handle	Low
Non-absorbable	Silk	Moderate tensile strength	Moderate tissue reaction	Moderate
	Nylon (Ethilon, Dermalon)	Low tissue reaction	Difficult to handle, need many knots	Low
	Polypropylene (Prolene, SurgiPro)	Permanent, minimal tissue reaction	Needs extra knots	Low
	Braided polyester (Mersilene, Ethiflex)		Greater infection risk relative to monofilament	Low

natural fibers such as silk and pose decreased risk of infection compared to braided material [16, 17]. In contrast, absorbable sutures are used to reinforce the dermis and provide hemostasis. Synthetic materials are less inflammatory than "gut" sutures made from animal connective tissue and thus are preferred (Table 2) [16, 17].

A suture's thickness is inversely proportional to the number on its package (e.g., 3-0 suture is thicker than 4-0 suture). To optimize cosmetic results, providers should choose the finest suture that will provide sufficient structural support. Generally, lacerations on the trunk are repaired with 3-0 or 4-0 suture, extremities and scalp with 4-0 or 5-0, and face with 5-0 or 6-0 [15]. In nearly all cases, a 3/8 curvature of circle on a reverse cutting needle is sufficient for laceration repair. It is easier to maneuver in small areas than a ½ curvature and slides through skin better than a tapered needle (Table 3).

Wound Closure: Principles and Techniques

After cleansing, the wound is draped with a sterile drape or sterile towels to create a clean field. Devitalized tissue should be debrided and wound edges trimmed so they are perpendicular to the skin

DOI 10.1007/978-1-4939-0779-3_56-2

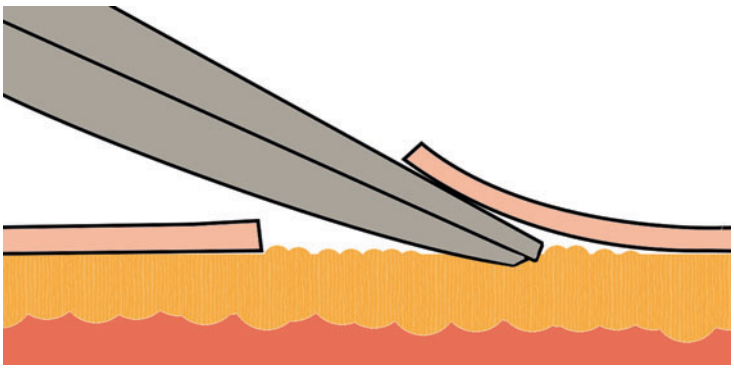

Fig. 4 Undermining wound edges, sagittal view

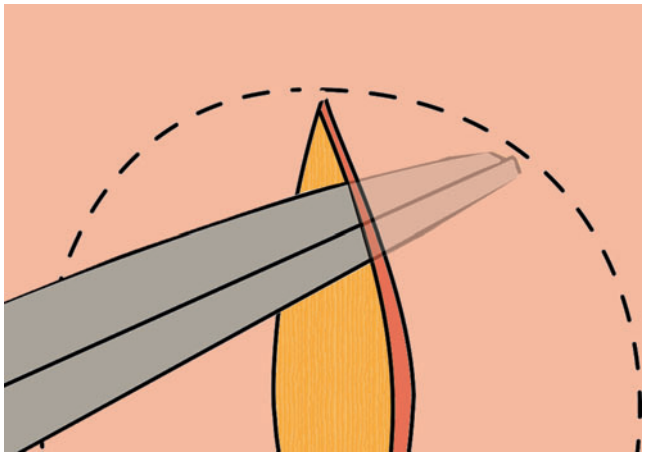

Fig. 5 Undermining wound edges

surface with slight undermining to promote eversion of wound edges (Fig. 4). Undermining permits greater mobility of the skin surface by releasing subcutaneous attachments. A scalpel or pair of sharp scissors is used to make cuts of equal depth, keeping in mind that shallower cuts pose a greater risk of compromising tissue perfusion. Greater tension occurs at the center of the wound, so this area requires the widest undermining (Fig. 5) [18].

Various suturing techniques are discussed below. The fundamental goals for all are as follows:

1. *Hemostasis*: Brisk bleeding should be controlled prior to closing a wound. If direct pressure is insufficient, electrocautery or ligation of bleeding vessels with absorbable sutures may be required. Care should be taken not to cauterize the epithelium, as this will increase scarring. Attempts to cauterize capillaries may compromise blood supply and is generally unnecessary, as capillary bleeding should stop with wound closure.
2. *Elimination of Dead Space:* Fluid accumulation between or within tissue planes can impair healing and act as a nidus for infection. Deep absorbable sutures are used to close this so-called dead space. If deep sutures are insufficient, temporary drains (latex tubing or gauze wicks) are used until the space closes or drainage stops.
3. *Approximation of Tissue Layers:* Sutures should approximate corresponding tissue types with enough pressure to slightly evert wound edges. This ensures that keratinized epithelium does not impair healing and decreases the risk of fibrotic contraction causing a noticeable defect. Tension on wound

DOI 10.1007/978-1-4939-0779-3_56-2

edges should be minimized with undermining and the use of appropriate suture technique. Sutures under high tension can compromise circulation.

Simple Interrupted Closure

Simple lacerations are most commonly repaired with the simple interrupted closure. Individual sutures are placed in parallel to one another at regular intervals along the laceration to provide multiple points of tissue support. The first stitch should bisect the wound perpendicularly to facilitate a symmetric repair. Using a needle driver, the point of the needle enters the skin perpendicular to the surface and penetrates halfway through the dermis. Following the curve of the needle, the needle driver is turned 90°. The needle exits one side of the laceration and enters the other at the same depth, and the needle driver is again turned 90°. The exit point should be directly across the wound edge from the entry point. Both points should be equidistant from the wound edge. The stitch should be as wide as it is deep (Fig. 6). Using an instrument tie (Fig. 7), the suture is tied tightly enough to approximate and evert wound edges but not enough to indent the epidermis. Subsequent sutures are placed in parallel (Fig. 7).

Simple Running Closure

A simple running closure can be completed quickly, an advantage in emergency situations (Fig. 8). It is useful for long, low-tension wounds but should be avoided in high-tension wounds due to the risk of circulatory compromise. Interrupted rather than running sutures should be used if infection risk is high to allow for selective removal of individual sutures to promote drainage without the risk of dehiscence.

Intradermal Running Closure

The term "subcuticular" refers to placement of the suture below the stratum corneum. A more apt term for this stitch is "intradermal." Intradermal sutures are accomplished by driving the needle back and forth across the laceration in parallel to the skin layers, using the dermis as an anchor. An intradermal running closure should be considered when cosmetic outcome is important, such as for facial wounds, as this method creates minimal scarring [19–21]. Intradermal sutures provide less tissue support than percutaneous sutures so should be reserved for linear, shallow wounds under minimal tension (Fig. 9).

Buried knots are used to anchor absorbable intradermal sutures (Fig. 10). If nonabsorbable sutures are used, the skin is entered approximately 1 cm from the apex. Several techniques are used to complete an intradermal repair. The simplest of these is shown below (Fig. 11). Both "tails" are secured in place by adhesive strips. Once initial wound strength has occurred (typically 5–7 days), the suture is removed by gently pulling one end against countertraction.

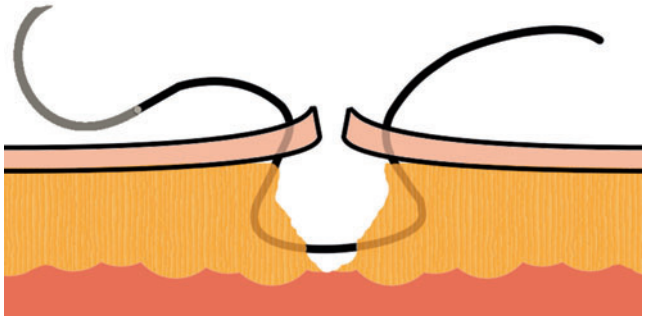

Fig. 6 Simple interrupted, sagittal view

DOI 10.1007/978-1-4939-0779-3_56-2

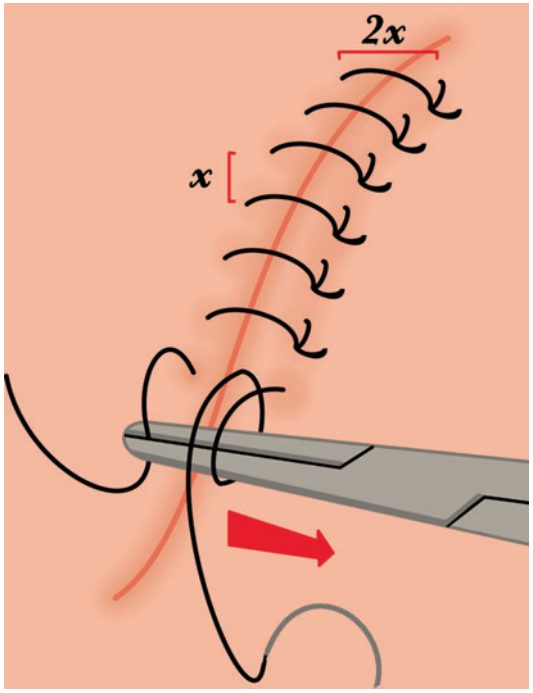

Fig. 7 Suture spacing of simple interrupted closure

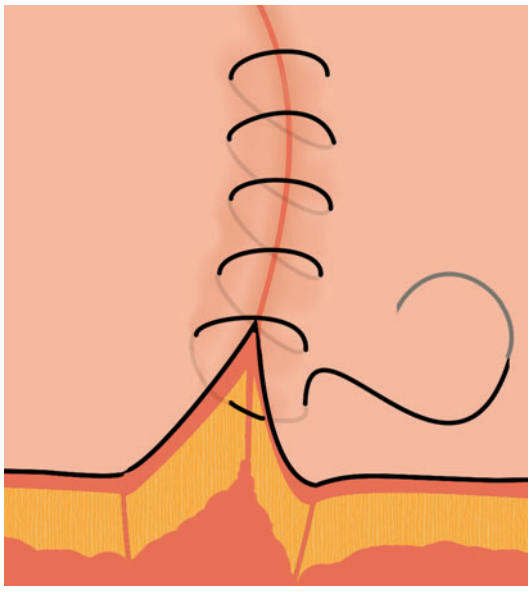

Fig. 8 Simple running closure. Symmetric "baseball stitches" are placed with a single suture and the ends are knotted. The width and depth of each bite should be equal

Two-Layer Closure

High-tension wounds and those with significant dead space require intradermal sutures to approximate underlying tissue. A simple interrupted stitch can then approximate this skin surface under lower tension (Fig. 12).

DOI 10.1007/978-1-4939-0779-3_56-2

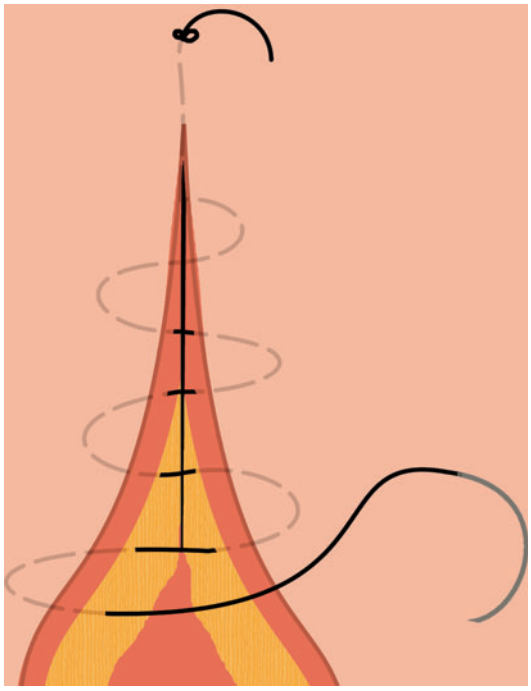

Fig. 9 Intradermal running closure. The wound is entered and exited through its apices. Horizontal "zig-zagging" passes are made with symmetric bites at the dermal-epidermal junction

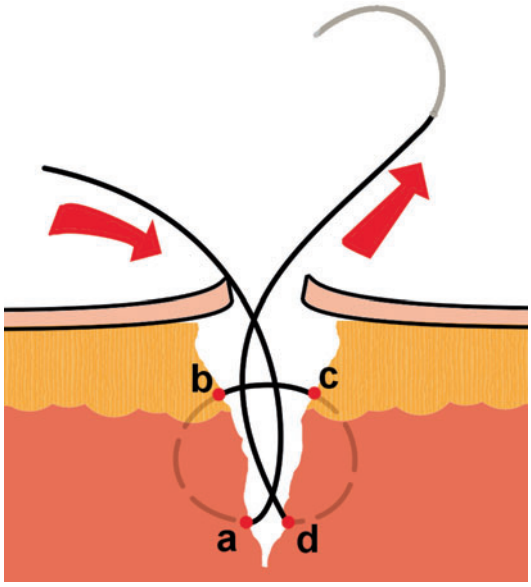

Fig. 10 Deep suture with buried knot. The suture enters the wound edge deep and, following the curve of the needle, exits superficially (still below the dermal-epidermal junction). This throw is reversed on the opposite wound edge and tied off, leaving a "buried" knot

Horizontal Mattress Suture

This suture technique should be considered for closure of gaping or high-tension wounds where intradermal sutures cannot be placed (such as palms or soles) because it spreads tension across the skin surface (Fig. 13). For this reason, horizontal mattress sutures are useful in areas with fragile skin [6].

DOI 10.1007/978-1-4939-0779-3_56-2

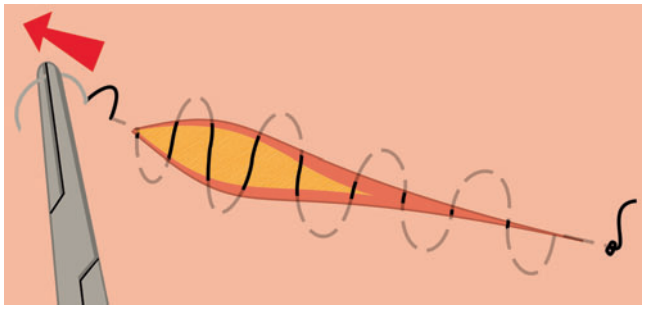

Fig. 11 Completion of intradermal closure. The needle exits the skin approximately 1 cm from the apex and the tail secured by adhesive strip

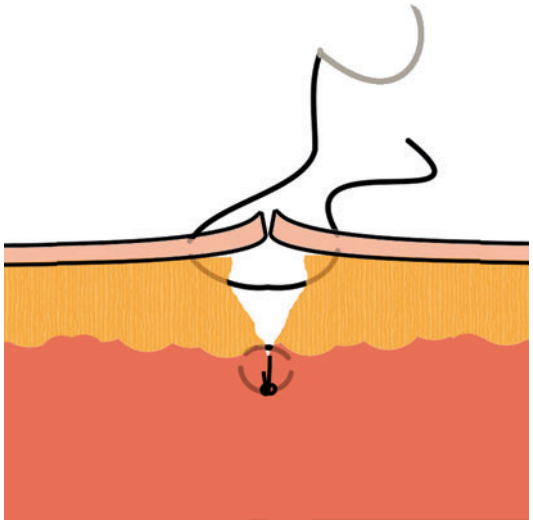

Fig. 12 Two-layer closure. A buried suture placed deep to a simple interrupted stitch. Note the area of undermining just below the epidermis

Vertical Mattress Suture

Like the horizontal mattress, this suture is useful in high-tension wounds. It is particularly good for injuries where skin eversion would otherwise be difficult (Fig. 14) [6].

Half-Buried Mattress Suture

Half-buried mattress sutures, (a.k.a. "corner stitches") are used to close stellate or triangular lacerations without impairing blood flow [6]. Two variations of this technique are illustrated below (Figs. 15 and 16):

Dog-Ear Repair

Wound edges of unequal length (e.g., an arcuate laceration) often result in excess tissue on the longer edge at the end of the repair. Figure 17a–c demonstrates a technique for removing these "dog ears" to improve cosmetic outcomes.

DOI 10.1007/978-1-4939-0779-3_56-2

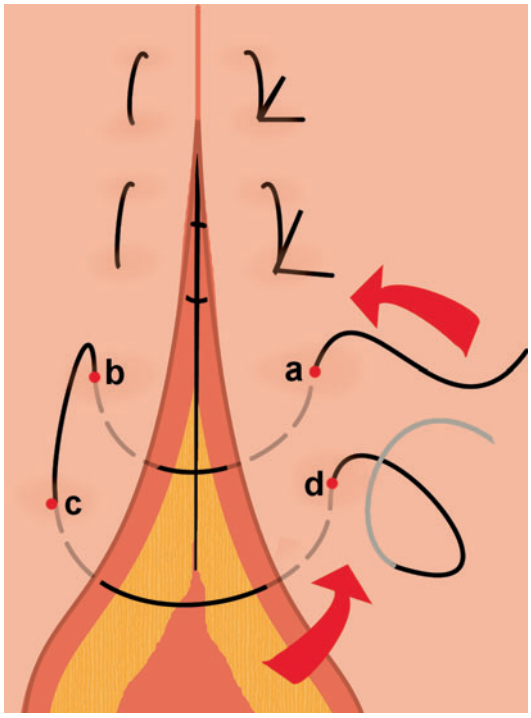

Fig. 13 Horizontal mattress sutu.re. The needle enters 0.5–1 cm from the wound edge, passes deep into the wound and exits symmetrically at the opposite side. The needle reenters and is passed in parallel to the first suture and exits the skin. The knot is then tied in parallel with the wound

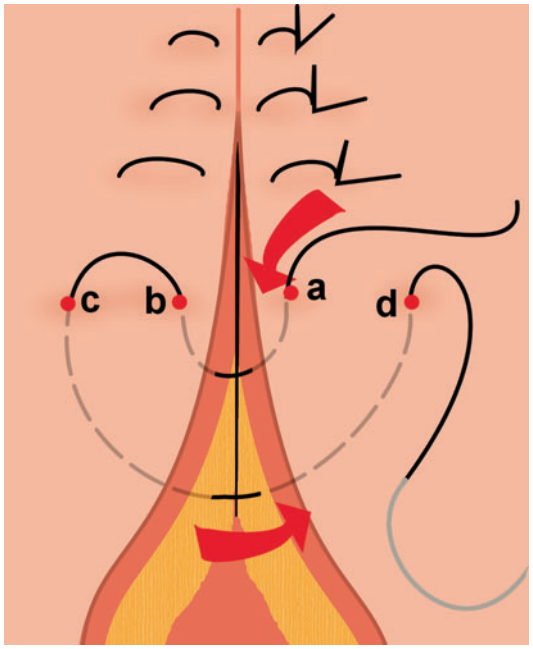

Fig. 14 Vertical mattress suture. The needle enters 0.5–1 cm from the wound edge, passes shallow and exits symmetrically at the opposite side. The needle then reenters laterally on the same side, enters deep into the wound under the previous suture and exits directly lateral to the initial entrance site. The knot is tied perpendicularly with the wound

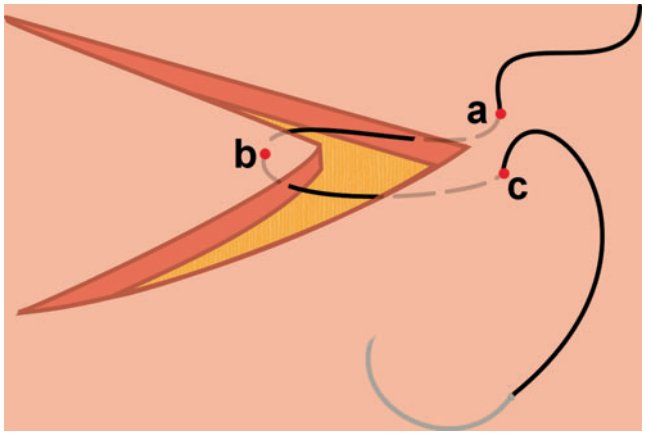

Fig. 15 V-flap repair

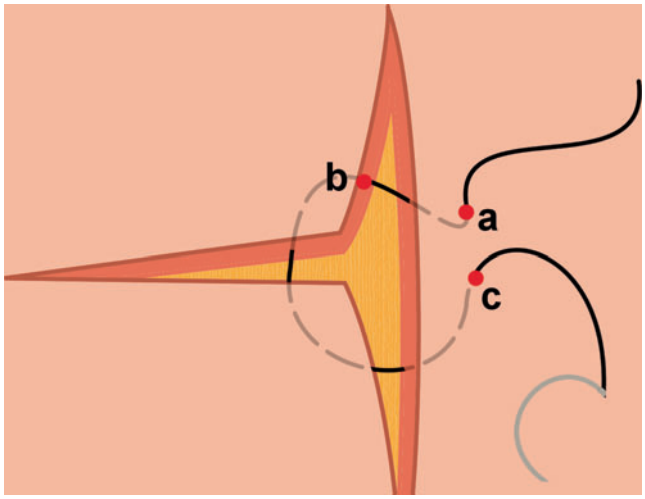

Fig. 16 T-laceration repair

Alternatives to Sutures

Sutures are not always indicated for minor lacerations. Most alternative means of wound closure take less time than suturing, and many are less painful and invasive; however, not all provide satisfactory outcomes when compared to suturing. Alternative wound closures fall into one of two categories: tissue adhesives and percutaneous staples.

Tissue Adhesives

The most commonly used tissue adhesives are derivatives of commercially available cyanoacrylate glues (e.g., "Krazy Glue®" or "Super Glue®") but are less histotoxic. Adhesives are sold in liquid form and come in a variety of applicators, all with the same function. Wound edges are approximated, and adhesive is applied in a thin layer and allowed to polymerize. Typically, three coats are applied creating a waterproof, antimicrobial barrier. For linear, low-tension, traumatic lacerations, cosmetic outcomes between adhesives and sutures are comparable, as are rates of infection though there is greater chance of dehiscence with adhesives [22, 23]. Sutures are more appropriate to repair infected, heavily

DOI 10.1007/978-1-4939-0779-3_56-2

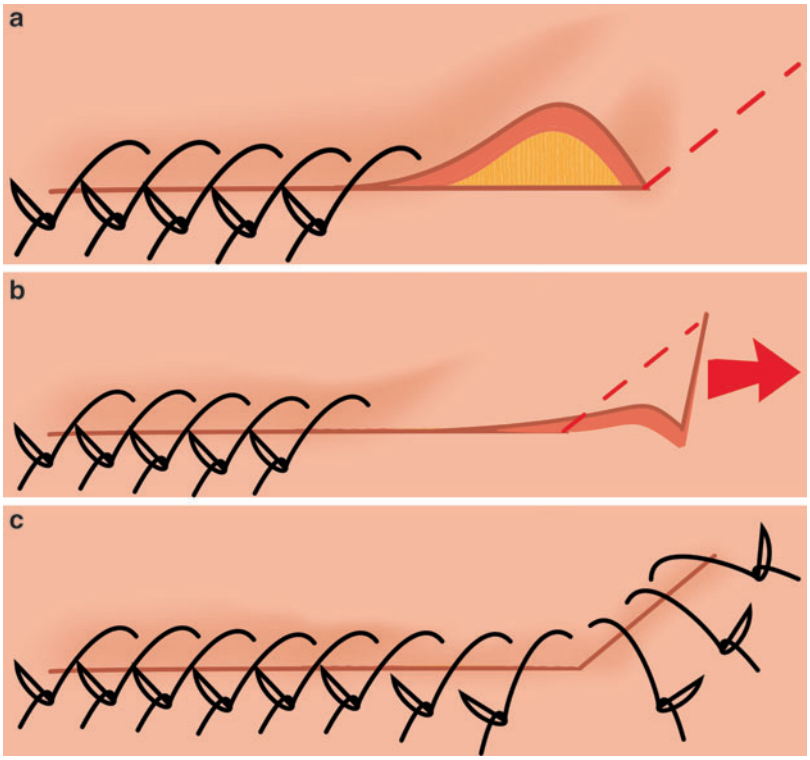

Fig. 17 Dog-ear repair 1–3. (**a**) Incise along the bulging dog ear to free the skin. (**b**) Pull freed skin edge and excise excess skin. (**c**) Close the new incision to allow skin to lie evenly

contaminated, or devitalized wounds as well as those crossing mucocutaneous junctions and joint lines. Proper application of tissue adhesives requires the following:

- Wounds should be clean, dry, and hemostatic. (Areas with high moisture such as the groin and axillae should be avoided.)
- Edges should be closely approximated and in areas with minimal tension. Intradermal sutures may be used to reduce wound tension.
- Wounds should be parallel with the floor to prevent adhesive runoff.

For scalp lacerations, the use of hair apposition (applying adhesive to the wound and then twisting together hair from opposite sides of the wound edge) provides better cosmetic outcomes than suturing with decreased pain and healing times [24]. Use of adhesives on complex lacerations (e.g., stellate, jagged edges, devitalized tissue, contaminated) is not appropriate. Care should be taken to avoid introducing adhesive into the wound as this will delay healing and may cause inflammation. Adhesive runoff into crevices or mucous membranes (especially eyes) is to be prevented. Petroleum-based products degrade adhesives, risking dehiscence. The advantages of adhesives over sutures include shortened procedure duration and decreased procedural pain.

Staples

Like tissue adhesives, staples require comparatively less time to apply than sutures. Unlike tissue adhesives, staples provide adequate support to wound edges in high-tension areas and are an appropriate alternative for more complex lacerations. Infection rates favor the use of staples, even in contaminated wounds [25, 26]. Due to concerns for poor cosmetic outcome, staples have not been compared to sutures

DOI 10.1007/978-1-4939-0779-3_56-2

for facial lacerations and are generally contraindicated as such; however, healing time and cosmetic outcomes with staples in comparison to sutures appear to be statistically similar for lacerations elsewhere on the body [25, 26]. Staples are safe in magnetic resonance imaging (MRI); however, they may cause interference with images in MRI and computed tomography (CT) studies. Timing of removal is the same as for sutures but requires the use of a surgical staple remover.

Adhesive Strips

Adhesive strips (typically a porous tape reinforced with polyester fibers) are most suitable for maintaining wound edge approximation after the removal of sutures in wounds that have not completely healed. They can also be used for small lacerations with very low skin tension in areas that are relatively hairless and will not become wet. Other applications are unsuitable.

Antibiotics

As a general rule, prophylactic antibiotics do not decrease rates of infection and should not be used [27]. In certain high-risk situations, however, antibiotic prophylaxis is warranted. These situations are

- Patients with immunocompromise
- Wounds exposing fractured bone ends, joint spaces, tendons, or cartilage
- Wounds in which gross contamination cannot be removed
- Puncture wounds (due to inability for adequate irrigation)
- Crush injuries with extensive devitalized tissue
- Bite wounds
- Wounds in the mouth
- Wounds occurring >18 h prior to presentation [27]

Prophylactic antibiotics should target the most likely contaminating organisms. For most wounds, a first-generation cephalosporin provides sufficient coverage. Coverage for methicillin-resistant staphylococcus aureus (MRSA) should be considered but is not generally necessary unless the patient has a personal history of or close contact with MRSA infection. Patients with oral wounds should receive penicillin. There is a range of potential contaminants arising from specific exposures that should be considered including exposure to farm animals or marine environments and bite wounds. Specific treatments for these scenarios are discussed elsewhere [27]. Topical triple-antibiotic ointment appears to decrease infection rates in contaminated wounds compared with white petrolatum; however, these differences are not seen with sterile or clean wounds [28]. Tetanus prophylaxis should be considered as outlined in the table below (Table 4).

Wound Care and Follow-Up

After the wound has been appropriately repaired, every effort should be taken to ensure that patients understand all instructions for wound care, monitoring for complications and, if indicated, dose, route, and timing of antibiotics. Patients should be advised to watch for signs of infection such as cloudy (purulent) drainage, increasing redness around the wound, unexpected pain, red streaks leading from the wound toward the trunk, fever, or increasing swelling of the wound >24 h after repair.

DOI 10.1007/978-1-4939-0779-3_56-2

Table 4 Tetanus prophylaxis

	Clean, minor wounds		All other wounds	
Vaccination history	Td[a]	TIG	Td	TIG
Unknown or <3 doses	Yes	No	Yes	Yes
>3 doses	No[b]	No	No[c]	No

[a]Can use TdaP if patient is >10 years old and has not previously received TdaP
[b]Yes if >10 years since last dose
[c]Yes if >5 years since last dose

Epithelialization is not complete until after 48 h although infection from contaminants decreases significantly by 12 h post closure. The standard recommendation is to keep wounds dry and covered for the first 24 h; however, shorter times are not clearly contraindicated [29].

Wounds heal better in moist environments [29]. Patients with clean wounds closed with sutures should be advised to apply a thin layer of white petrolatum several times per day to maintain moisture. Those with contaminated wounds should do the same with triple-antibiotic ointment. Wounds closed with adhesives should not be covered in petrolatum as this may hasten breakdown of the adhesive. Application of hydrogen peroxide, iodine, or topical astringents should be discouraged as they can impair healing.

The decision of how long sutures remain in place before removal needs to balance risk of scarring with risk of wound dehiscence. There is sufficient tensile strength in a sutured wound at 7 days following a repair to safely remove sutures from most locations. Sutures in areas under higher tension (e.g., soles of feet, extensor surfaces) should stay in place for up to 14 days while those in cosmetically sensitive areas under low tension (i.e., face) should be removed after 5 days to minimize scarring. Once sutures have been removed, adhesive strips can be applied to assist with wound edge approximation [3].

Pain tolerance varies widely among individuals; however, over-the-counter analgesics should provide adequate pain control for most simple lacerations. Lacerations associated with crush injuries or with exposure of bones, tendons, joints, or nerves may require short-term opiate analgesics. The judicious use of these agents is at the prescriber's discretion, and risk for chemical dependence or abuse should be evaluated at the time of medication prescribing.

Coding and Billing

Laceration repairs are billed as simple, intermediate, or complex. Wounds may be closed with sutures, staples, or tissue adhesive. The use of adhesive strips alone does not qualify as a laceration repair. Simple repairs require standard debridement ("cleaning the skin until normal tissue is viewed") and no more than a single-layer closure. Intermediate wounds either require two layers of closure (subcutaneous, but not fascial, and epidermal) or, for single-layer closures, require extensive cleaning or removal of particulate contaminants. Complex wounds require "more than layered closure; scar revision, debridement (e.g., traumatic lacerations or avulsions), extensive undermining, stents, or retention sutures may be required. Necessary preparation includes creation of a defect for repairs (e.g., excision of a scar requiring a complex repair) or the debridement of complicated lacerations or avulsions."[30] In addition to these criteria, wounds are categorized by length (cm) and area of the body of the laceration. A complete list of CPT codes is beyond the scope of this chapter, but the following general categories may be useful (Table 5):

DOI 10.1007/978-1-4939-0779-3_56-2

Table 5 General coding for wound care

Simple wounds	CPT 12001-12021
Intermediate wounds	CPT 12031-12057
Complex wounds	CPT 13100-13160
Wound debridement	CPT 11010-11044

What do drowning, barotrauma, burns, swallowed foreign bodies, and fishhook removals have in common? They are all conditions that an astute family physician should be prepared to manage. Injuries as a whole represent the fifth leading cause of death in the USA by the Centers for Disease Control (CDC) [1]. The most common causes of injury deaths are listed in Table 1.

Many of the topics covered in this chapter may present as an impromptu emergency which a family physician may encounter while working in an emergency room (ER), urgent care clinic, or even off duty. Being familiar with these injuries illustrates how a family physician is often expected to be a "jack-of-all-trades."

Drowning and Submersion Injury

General Principles

Definition/Background

Drowning and its many associated terms have been a source of confusion in the past, and in recent years there has been an effort to be more precise in the medical use of these terms. A submersion injury is a nonspecific term that encompasses any medical sequelae related to being submersed in a liquid medium. The terms near drowning, wet drowning, or dry drowning are often misused, can be misleading, and should be avoided. Improper use of these terms also leads to difficulty collecting epidemiologic data for

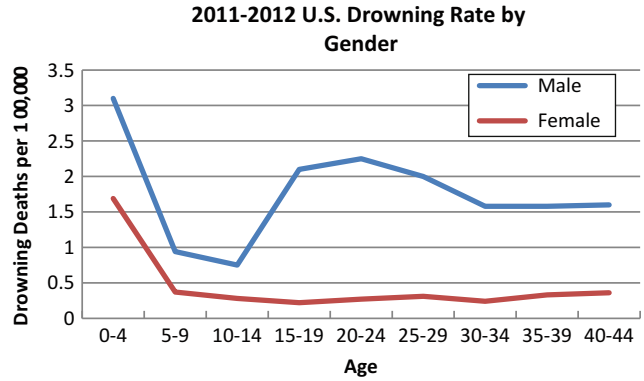

Fig. 1 US drowning death rates by age and gender, 2011–2012 [4]

studies. The World Health Organization (WHO) has clearly defined drowning as, "the process of experiencing respiratory impairment from submersion/immersion in liquid. Furthermore, drowning outcomes should be classified as: death, morbidity, and no morbidity [2]. This will be the definition used in this chapter.

Submersion involves the head being under the surface of a liquid, whereas an individual may also drown while immersed (head out) in choppy or turbulent liquid. Drowning victims suffer respiratory failure due to aspiration of water into the lungs or vocal cord spasm creating airway obstruction. Both of these pathophysiologic causes of drowning lead to secondary cardiac arrest and death if the drowning process is not arrested. While water is by far the most common medium to cause drowning, curious readers are encouraged to research the London Beer Flood and the Boston Molasses Disaster as examples of other fatal liquids.

Epidemiology

Drowning is a leading cause of unintentional death worldwide and is especially prevalent in children who are at the highest risk of drowning [3]. Females have much lower rates of drowning compared to age-matched males. Males have a bimodal drowning risk that sees a second spike in drowning at puberty and persists well into the 30s indicating that the risk-taking behavior of young adult males (what might be called the "show-off" stage of male life) contributes to increased drowning rates (See Fig. 1).

Approach to the Patient

History

The diagnosis of drowning is not difficult given the circumstances under which these patients present. A drowning victim will present acutely with respiratory complaints. Key historical questions

to ask include: how long were they submersed, what were they submersed in, what resuscitation has been done prior to their arrival, and what was the temperature of the water? Inquire about symptoms of shortness of breath, chest pain, and cough.

Physical Exam

The primary survey in a drowning patient follows the basic life support (BLS) and advanced cardiac life support (ACLS) guidance discussed below. Once the patient has been resuscitated and stabilizes, the physical exam should focus on the airway and lungs as these are the most affected by drowning. Crackles, rales, and wheezing may be heard as the lungs often have residual edema and atelectasis due to loss of surfactant. Consider C-spine injury and immobilization if the drowning victim was in a river with white water or if they dove into shallow water. Temperature is important as many drowning victims are also hypothermic due to conductive heat loss in the water. Additionally, a cold-water drowning victim can be resuscitated after extended periods of hypoxia because of decreased metabolic and oxygen requirements in hypothermia.

Treatment

First and foremost, a drowning victim needs to be removed from the water. If a patient is actively drowning, it is recommended that bystanders attempt a rescue from land or boat by throwing a flotation device or reaching with a pole or long tree branch [5]. Untrained rescuers put themselves at great risk of drowning themselves if they attempt to rescue a drowning patient.

After a drowning victim is removed from the water, the patient's level of consciousness and breathing needs to be rapidly assessed. A patient that is not breathing can be assumed to have respiratory failure and possibly secondary cardiac arrest. These patients can respond to rescue breaths alone. A drowning patient that is not breathing should have their airway opened and five rescue breaths before addressing circulation [5]. This is a rare exception to the current BLS algorithm which emphasizes circulation and chest compressions over airway and breathing (CAB). An unconscious patient that is breathing and has a pulse can be supported by being placed on their side in the recovery position and given supplemental oxygen, if available, while awaiting transfer to a hospital. The aspiration of fluid into the lungs washes away the surfactant, so patents have difficulty maintaining ventilation and may require positive pressure support to keep the alveoli open.

Evacuation to a hospital for further evaluation and monitoring should be considered in all drowning patients. Delayed respiratory failure and acute respiratory distress syndrome (ARDS) can occur as a result of surfactant loss. The severity of the patient's initial condition as well as their response to treatment will determine the length of time they need to be observed as an inpatient.

Prevention

Prevention of drowning can be accomplished with adequate safety measures. Children are at the highest risk of drowning and should be the focus of prevention. Pools should be isolated with fencing and children should be supervised by an adult that is within arm's reach [6]. Infants and toddlers have heads that are heavy relative to their bodies and should not have access to water in buckets or toilets because they cannot self-extricate if they fall into these head first. Safety around the water should be taught at a young age, and swimming lessons are encouraged when age appropriate, usually around 4 years old according to the American Academy of Pediatrics (AAP) [7]. Alcohol and drug use should be discouraged when around water as this contributes to the increased risk-taking behavior and increase in drowning fatalities seen in young men.

Barotrauma

General Principles

Definition/Background

Barotrauma is caused by the expansion and contraction of gas in confined spaces in and around the body. This property of a gas is driven by Boyle's law which states that at a constant temperature, the volume and pressure of a gas are inversely proportional. This law comes into effect when humans choose to dive underwater (increase barometric pressure) or travel to high altitudes (decrease barometric pressure). Pressure increases the further down a diver goes, causing the volume of gas to shrink. It takes only 10 m (33 ft) in depth underwater to double the barometric pressure of sea level, also referred to as 1 atmosphere absolute (ATA). Going from 1ATA to 2ATA will half the volume of a gas. Conversely, when traveling to high altitude such as in an aircraft, pressure decreases causing gas to expand; however, because water has more mass than air, it takes a much greater change in altitude to cause significant change in gas volumes. The changes in pressure and concordant changes to the volume of air confined in our body are most commonly felt as pressure in the ears [8]. Our bodies can equilibrate this pressure/volume change to some extent; however, when changes occur rapidly, such as a sudden ascent from a scuba dive or a rapid decompression of an aircraft cabin, it can cause severe or, in some cases, fatal injury.

The body has potentially confined gas in the lungs, gastrointestinal (GI) tract, middle ear, and sinuses. Rarely, teeth with a history of dental work can have confined air within a tooth. Expanding on the concepts described above, when a diver ascends from a depth of 10 m (33 ft or 2ATA) to the surface (1ATA), the volume of air in the lungs will double. Rapid expansion of air in the lungs against a closed glottis can cause the most severe forms of barotrauma: pneumothorax, pneumomediastinum, or arterial gas embolism (AGE). For this reason, divers are taught to surface slowly while exhaling. Pneumothorax and pneumomediastinum are both caused by the expansion of gas dissecting into the pleural space or mediastinum, respectively. AGE is caused when the expanding air dissects into the pulmonary capillary beds and introduces air emboli into the circulation. Sudden cardiac arrest may occur in about 5 % of AGE victims due to filling of the cardiac chambers and great vessels with air [8].

The GI tract generally has the capacity to deal with expanding gas, however, rarely; GI gas can cause intestinal rupture, especially in individuals with a history of bariatric or other gastric surgeries [8].

The middle ear is susceptible to both increased and decreased pressure, and "ear squeeze" is the most common form of barotrauma seen in divers [9]. As pressure increases, such as diving deeper underwater, the volume of gas in the middle ear decreases, and divers must Valsalva to force more air into the middle ear and maintain equilibrium. As a diver surfaces, this middle ear gas expands, and the pressure is released through the Eustachian tube. If a diver has swollen Eustachian tubes from an illness or seasonal allergies, it may lead to middle ear injury in the form of blood and engorged tissue behind the tympanic membrane (TM) or TM rupture. TM rupture causes sudden relief of pain; however, it can also cause vertigo, disorientation, and panic which are not ideal when diving. The round window of the inner ear can also rupture secondary to barotrauma; however, this is uncommon [9]. This will present with tinnitus, vertigo, and hearing loss.

The sinuses are also typically able to equilibrate pressure changes; however, in the setting of clogged sinus tracts, trapped air can cause engorgement and hemorrhage of the sinus lining. This can lead to headache and epistaxis.

Lastly, the skin may be affected by dry suits that contain trapped air or scuba masks that a diver fails to equilibrate. Many of these effects can be seen in relatively shallow water as the contraction and expansion of air are most dramatic in the first 10 m (33 ft) of diving.

Forms of barotrauma caused by waves of high and low pressure as seen with explosions and barotrauma due to mechanical ventilation are beyond the scope of this chapter. Additionally, scuba diving problems caused by dissolved

gases, such as decompression sickness (DCS, aka "the bends") and nitrogen narcosis, are not covered in this chapter.

Approach to the Patient

Diagnosis

History

Patients presenting with barotrauma will have a history of recent exposure to scuba diving or, less commonly, high altitude with rapid decompression. Ask the patient how deep and how long they were down, how much diving they have been doing in the past few days, and how quickly they came up. Ask when the symptoms developed, on the descent or the ascent. Identify if they were doing scuba with compressed air or just breath holding. Identify where their symptoms are. Evaluate for symptoms of chest pain, shortness of breath, pleuritic pain, ear pain, bruising, skin crepitus, or epistaxis. Also, inquire about headache or focal neurologic findings. Gather a full medical history being sure to document any pulmonary disease, scarring, or previous diving injury as these can increase the risk of pulmonary barotrauma.

Physical Examination

A patient with suspected barotrauma has certain areas that must be examined. Look at the face and identify if there is any evidence of mask squeeze, which will be evident as ecchymosis on the face in the distribution of a diving mask. Examine the ears for blood or fluid in the middle ear, dilated vessels in the TM, TM rupture, or small capillary rupture within the TM that have the appearance of red petechiae. Check the patient's hearing using the whisper test. Palpate the patient's frontal, maxillary, and ethmoid sinus regions for pain. Check cranial nerves, and perform a gross sensation, motor, and reflex exam to identify any focal neurologic findings. Auscultate the lungs listening of decreased lung sounds that could indicate a pneumothorax. Do a full abdominal exam, especially in patients with a history of abdominal surgeries.

Laboratory and Imaging

In patients with suspected pulmonary barotrauma, obtain PA/LAT chest radiographs to identify pneumothorax or pneumomediastinum. Portable ultrasound is also a validated modality for detecting pneumothorax. Brain imaging with MRI is indicated in patients with suspected AGE; however, it should not delay treatment. Formal audiology testing should be considered for suspected middle or inner ear injury to document any hearing loss.

Treatment

Treatment for barotrauma is based on the affected area. For skin barotrauma such as "mask squeeze," no specific treatment is necessary, and symptoms will resolve with time. For middle ear barotrauma, patients benefit from oral and nasal decongestants to establish normal Eustachian tube function as well as analgesia as needed. As long as no infection develops, TM rupture secondary to middle ear barotrauma will heal without complication [10]. Subspecialty consultation should be considered in patients with suspected inner ear barotrauma. Sinus barotrauma is treated with oral and nasal decongestants and pain medication as needed. GI barotrauma with perforation requires surgical evaluation.

Pulmonary barotrauma to include pneumomediastinum, pneumothorax, and AGE is managed as an emergency and should be transported without delay to an emergency room, preferably at a facility with a hyperbaric chamber. These conditions should be managed using the BLS and ACLS algorithms. The Divers Alert Network (DAN) at +1-919-684-9111 provides an international emergency hotline 24 h a day to provide first aid recommendations, evacuation assistance, and referral to the nearest hyperbaric chamber. These patients need to be monitored frequently paying close attention to respiratory status and pulse oximetry. The patent should be placed on 100 % oxygen by mask if available in the prehospital setting. Administration of 100 % oxygen has the intended purpose of hastening extra-alveolar gas resorption and minimizing ischemia caused by gas emboli [10]. A pneumothorax can

progress to a tension pneumothorax manifested by hypotension, distended neck veins, and tracheal deviation away from the involved side. This medical emergency should be treated with urgent needle decompression of the affected side. This is accomplished using a large bore (16 gauge) needle of at least 3 in. in length inserted at the midclavicular line in the second intercostal space. Tension pneumothorax patients will eventually need a thoracostomy tube inserted once they are at the appropriate level of care. Cases of AGE should be treated in a hyperbaric chamber as soon as possible to repressurize the patient and attempt to shrink gas emboli while the body resorbs them. Hyperbaric treatment should still be sought even if a delay in care occurs as case reports have shown improvement in patients with cerebral gas emboli as far out as 60 h [11]. Hyperbaric treatments follow the Navy treatment tables and can be repeated as necessary.

Prevention

Individuals should undergo a physical exam and clearance by a licensed provider before participating in scuba diving in order to screen for pulmonary disease such as chronic obstructive pulmonary disease (COPD) which increases the risk for pulmonary barotrauma. Prevention of barotrauma in divers can be accomplished by descending and ascending in a gradual controlled manner. A diver may need to stop changing depth to equilibrate pressure in the middle ear using a Valsalva technique as well as equilibrating the pressure within the face mask. When ascending, divers need to be sure to exhale slowly to prevent pulmonary barotrauma.

Burns

General Principles

Definition/Background

Every family physician will see patients with burns at some point in their career, and most burns may be managed on an outpatient basis. The intent of this chapter is to provide a basic understanding of burns and some clinical pearls to identify patients that can be managed in clinic and those that should see a burn specialist.

Burn terminology has changed over the years, and they are now classified as superficial, partial, or deep. Nearly everyone has experienced a mild superficial burn at some point after being exposed to the sun for too long or touching a hot stove on accident. These burns involve the epidermis and can be extremely painful. Usually, they are self-resolving with minimal risk for complication, and lotion or aloe vera can be used to treat symptoms. The remainder of this section will cover the more severe partial- and full-thickness burns that will require more extensive medical care and knowledge.

Partial-Thickness Burns

The depth of involvement for a partial-thickness burn extends through the epidermis and some of the dermis. As the name suggests, it does not extend through the dermis into the subcutaneous layers. The partial-thickness burn is often further subdivided into superficial and deep partial-thickness burns. However, in this author's opinion and experience, subdividing partial-thickness burns is pedantic, and burn specialists are much more concerned with a primary care doctor's ability to differentiate between partial- and full-thickness burns. Partial-thickness burns will still have sensation on exam and are incredibly painful. The pain can be viewed as a good thing (for the provider) because it is one of the main clinical differentiators to use when diagnosing a burn as partial thickness. Partial-thickness burns will often present with large friable bullae and blistering with surrounding erythematous, moist, weeping skin; however, blisters may be absent at initial presentation and develop later.

Full-Thickness Burns

Full-thickness burns extend through the entire dermis and may involve deeper layers such as subcutaneous fat, muscle, tendon, or bone. Signs of full-thickness burns include lack of pain or sensation and a leathery or charred appearance. The patient will also likely have some areas of

partial-thickness burns around the areas of full-thickness burning.

Approach to the Patient

A detailed history of the injury needs to be taken when a burn patient initially presents. Pertinent things to ask are what caused the burn (thermal, flash, grease, chemical), when it occurred, was there a fire that may have caused airway involvement or CO poisoning, and what the patient has done to treat the burn so far.

Physical Examination

Burns should be managed as a trauma patient with a primary survey to evaluate for life threats followed by a secondary survey that includes a head to toe evaluation. The burn areas need to be exposed and the full extent of the burn documented. A major step is determining the percent of total body surface area (%TBSA) involved as this will play a part in referring the patient to the appropriate level of burn care. Document the shape of the burn in cases involving children and consider child abuse. Suspicious patterns seen in child abuse include isolated lower body burns or circumferential burn to an extremity suggesting immersion into hot water, burns in the shape of an iron or curling iron, or scarring from previous burns.

The burn needs to be identified as thermal or chemical as a chemical burn requires neutralization as well as proper protection for the provider. Additionally, an astute provider will need to consider compartment syndrome that can develop under full-thickness burns as a result of eschar formation and resultant loss of skin elasticity. If there is any concern for compartment syndrome, a family physician should obtain an urgent referral for surgical evaluation as these patients may require escharotomy.

Determination of Percent Total Body Surface Area (%TBSA)

Only partial- and full-thickness burns should be included in the estimation of %TBSA involved. The two classic teachings to help a provider determine %TBSA are the rule of nines and the 1 % hand rule. The rule of nines divides the body into sections that are roughly 9 % TBSA as seen in Fig. 2. Keep in mind that the rule of nines is not as accurate with children and infants due to their larger proportioned head and relatively smaller limbs. The easier – and this author's preferred – method to determine %TBSA is the 1 % hand rule. The palmar surface of the patient's hand represents roughly 1 % TBSA for that patient. The patient can usually hold their hand close to the involved area to help to estimate the %TBSA. For burns involving most of the body, measure the unaffected area and subtract this from 100 to get %TBSA. This rule holds true in children as well.

The area involved needs to be addressed because a small localized full-thickness burn from a dropped crack pipe is not as concerning as a partial-thickness burn that extends over joints of the hand or involves the face (although cigarettes or crack pipes are concerning for different reasons). Most burn centers provide guidance on who should be referred for evaluation based on both %TBSA and location of the burn.

Treatment

Partial-Thickness Burn

The main principles for initially managing partial-thickness burns involve pain control, determination of %TBSA involved, prevention of infection, and fluid resuscitation as needed. Adequate pain control generally necessitates judicious narcotic medication and will need to be titrated to effect depending on the patient, location, and extent of the burn. Patients with extensive partial-thickness burns may need a patient controlled analgesia (PCA) to help manage their pain. Cold sterile water irrigation can be used to clean the wound once pain is controlled as cold water may reduce the depth of the burn and improve the cosmetic outcome [12]. Blisters larger than 6 mm are likely to rupture on their own and should be debrided to prevent infection and mechanical pressure on underlying tissue. Evidence suggests blisters less than 6 mm can be left intact [13]. Topical silver sulfadiazine (SSD, Silvadene) has historically

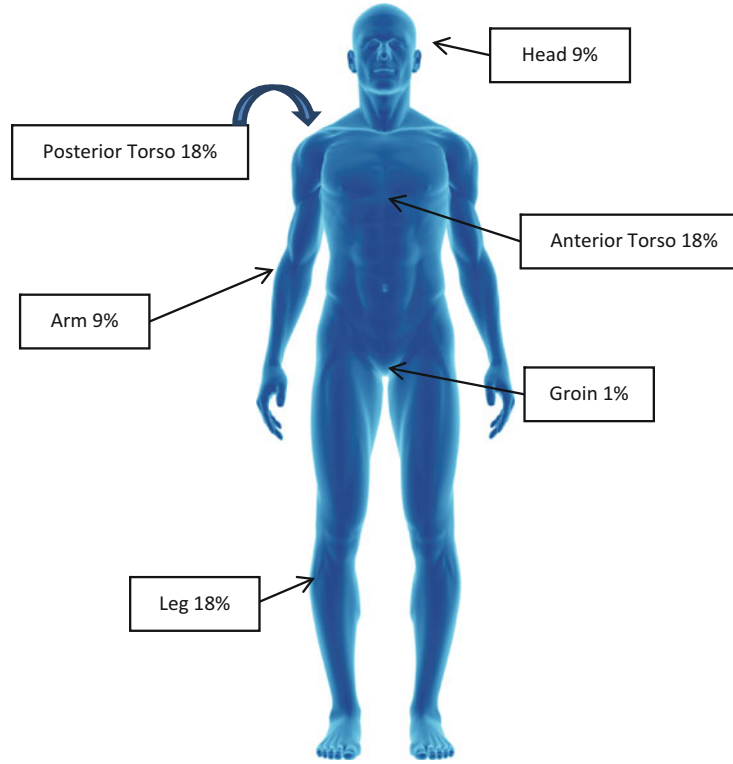

Fig. 2 Rule of nines to estimate %TBSA of partial- and full-thickness burns (Image created with adaptation of Microsoft Office© clip art)

been used for its antibiotic properties and to promote healing; however, a recent Cochrane review suggests higher infection rates and longer hospital stays with SSD when compared with newer synthetic or biosynthetic burn dressings or skin substitutes, of which there are numerous commercial brands [14]. SSD also requires more frequent painful dressing changes when compared to the newer occlusive dressings and as such is typically used as a last resort.

Full-Thickness Burn

Management of full-thickness burns should not be left solely to the family physician except in rare circumstances. These patients are best served by seeing a burn specialist and surgeon early in their course for possible debridement with skin grafting. The family physician will need to facilitate a consult to a burn specialist, establish pain management, document the involved area, initiate fluid resuscitation, prevent infection, and monitor for complications. Patients with large full-thickness burns will need continuous reassessment for shock and compartment syndrome while awaiting transfer to a burn center. Systemic antibiotics have not been shown to prevent infection or mortality and are currently not recommended for prophylaxis [14].

Fluid Resuscitation

Burn patients may require fluid resuscitation depending on the extent of their burns. The Parkland and modified Brooke formulas have historically been used; however, studies have indicated that these formulas lead to over-resuscitation and potentially increase morbidity and mortality [15]. More recently, burn centers and the US Army has started using the "rule of 10" to simplify fluid resuscitation. In this validated formula, the % TBSA is rounded to the nearest 10 and multiplied by 10 to give the initial fluid rate in milliliters per hour (ml/h) for an adult weighing between 40 and 80 kg. An additional 100 ml/h of fluids is recommended for every 10 kg over 80 kg the patient weighs [16]. The best marker of adequate

fluid resuscitation is urine output with a goal of at least 0.5 ml/kg/h.

Prevention

Prevention of burns can be accomplished with education and counseling. Parents should be warned of a child's increased risk of burns and encouraged to use extra precaution when cooking or handling hot liquids around infants and children. Adolescent-age children should be supervised when around fireworks, gasoline, or open fires. Alcohol and drug use should be avoided when near open fires. Proper precautions should always be practiced when near explosive gases such as propane. Smoke detectors should be checked at least annually [12].

Swallowed Foreign Body

General Principles

Definition/Background

Ingestions of foreign bodies are most common in children who have an affinity for putting objects in their mouths. Adults with foreign body ingestion are usually food related or a self-inflicted injury. Most ingested foreign bodies pass spontaneously; however, an estimated 10–20 % of ingested foreign bodies require endoscopic procedure and less than 1 % requires an operation [17]. Swallowed foreign bodies can be classified as blunt (coin, battery), sharp (needles, bones, razors), food bolus, or caustic/toxic (battery).

Ingestion of a foreign body may cause pain and possible airway involvement, and in severe cases, it can involve esophageal or gastrointestinal perforation. Evidence suggests that up to 50 % of cases are asymptomatic in children and as such require a high level of suspicion [18]. Small batteries can cause perforation of the intestinal lumen due to their corrosive effect on mucous membranes. Magnets, especially rare-earth magnets known as buckyballs, can present a problem when more than one is swallowed. These strong magnets can reposition bowel and cause pressure necrosis through up to six layers of bowel wall, often requiring laparotomy to remove the magnets and repair damaged bowel [19].

Approach to the Patient

Diagnosis

History

Foreign body ingestion should be ruled out when evaluating a child with sudden onset of vomiting or wheezing. Keeping in mind that half of these cases can be asymptomatic, a high level of suspicion should be maintained when evaluating children with decreased appetite; vague abdominal, chest, or throat pain; failure to thrive; drooling; cough; irritability; or gagging [18]. Caretakers should be questioned about the possibility of foreign body ingestion, being sure to ask about batteries, coins, or magnets that a child may have had access to. Adults with foreign body ingestions can generally provide a reliable history of what and when the ingestion occurred unless they are intoxicated or have psychiatric illness, in which case they should be approached the same as a pediatric patient.

Physical Examination

Examination should include vital signs to evaluate respiratory rate, pulse oximetry, pulse, and temperature. Tachycardia and fever can indicate potential complications of foreign body ingestion such as perforation. The oropharynx should be examined for any visible evidence of the foreign body. A standard physical exam of the neck, heart, lungs, and abdomen should be completed.

Laboratory and Imaging

Radiographs including anterior-posterior and lateral views of the neck, chest, and abdomen are the initial studies of choice to evaluate for radiopaque foreign bodies as well as evaluate for free air in the setting of perforation. CT scanning may be more sensitive for foreign bodies with one study reporting 100 % sensitivity for foreign bodies including radiolucent fish bones [20]. Contrast studies such as a barium swallow are not

Table 2 Endoscopic management of ingested foreign bodies (Source: adapted from Ikenberry et al. [21])

Endoscopic management of ingested foreign bodies
Emergent
Airway involvement
Esophageal obstruction
Esophageal battery or sharp object
Urgent
Blunt objects in the esophagus
Incomplete esophageal obstruction
Sharp foreign bodies in the stomach or duodenum
Magnets
Nonurgent
Coin in the esophagus >24 h
Objects in the stomach >2.5 cm
Batteries in the stomach >48 h

recommended due to the risk of perforation, the risk of aspiration, and the potential to make endoscopy more challenging [21]. Unfortunately, not all foreign bodies are radiopaque, and if the level of suspicion is high enough with persistent symptoms, endoscopy should be undertaken for both diagnosis and treatment.

Treatment

The treatment of ingested foreign bodies depends on the location of the object, the type of object, and the presence of any complications. Observation is a reasonable option in some cases if the patient is asymptomatic and the object has passed the esophagus. If the object is still in the oropharynx, an attempt to remove it with Magill forceps should be attempted. Recommendations for endoscopic retrieval of the foreign body are outlined in Table 2. In rural or austere settings, providers have successfully removed esophageal foreign bodies, typically coins or blunt objects, by passing a Foley catheter down the esophagus, filling the bulb distal to the object, and pulling the object out in a retrograde direction. This does carry a risk of airway obstruction and should only be used as a last resort. Similarly, a bougie can be used to push a blunt object from the esophagus into the stomach as 90 % of objects that make it to the stomach pass spontaneously [18]. Both of these techniques are contraindicated if the foreign body is sharp. If the object is beyond the reach of endoscopy, it should be followed with serial radiographs daily for sharp objects and weekly for blunt objects [18]. Symptoms of perforation such as fever, tachycardia, distended abdomen, free air on radiography, and/or peritoneal signs should prompt surgical consult. Patients presenting following ingestion of illicit drugs packaged into balloons should be observed as inpatients for obstruction as endoscopic removal is contraindicated for fear of rupturing the package and causing an overdose [17].

Prevention

Parents should be educated at well-child visits to keep small items, batteries, magnets, and coins out of the reach of small children.

Fishhook Removal

General Principles

Fishhooks are intended to catch fish; however, many fishermen/women have been accidentally snagged. This may present in an urgent care setting, or a family physician may be called upon to help at the scene of the injury. The hand is the most commonly affected area followed by the head and face [22]. The difficulty in removing a fishhook is due to the barb that is designed to prevent a fish from getting off the hook once it has been set (Fig. 3). When dealing with imbedded fishhooks, there are four proposed techniques for removal, each with their own risks. Hooks imbedded in the eye require urgent consultation to specialized care and should not be removed by untrained individuals. To date, there have been no head-to-head comparisons between the methods described below.

Common to all methods for fishhook removal is the need for aseptic technique and local anesthesia. Infiltration of lidocaine 1 % using a 25 gauge needle around the involved area or in a digital block works well to achieve adequate

Fig. 3 Common fishhooks. The hook on the *left* is a treble hook. Note the barbs at the head of each hook. The far-*right* hook has a very small barb that might allow for retrograde pull removal

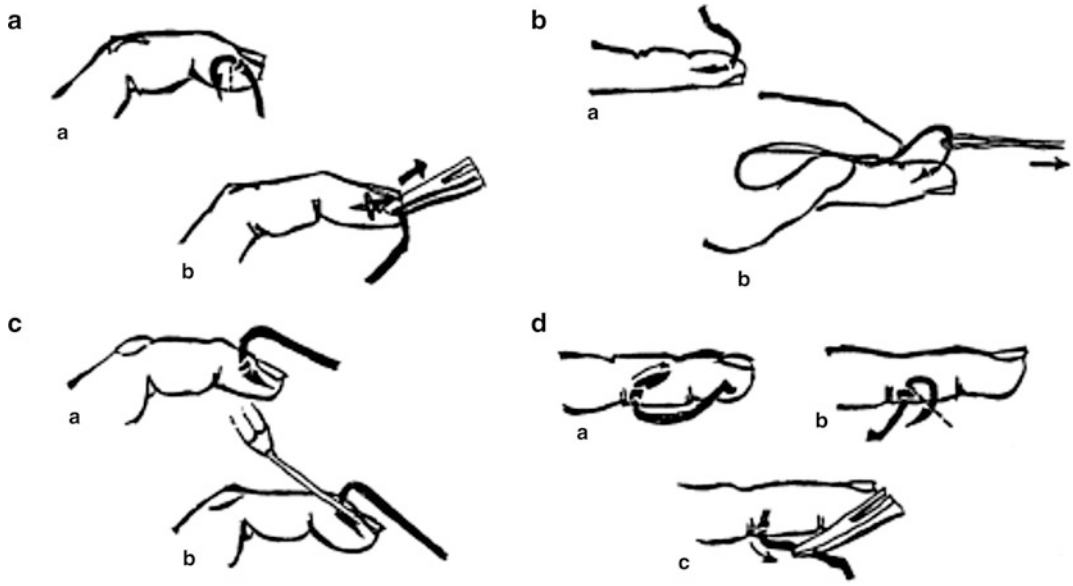

Fig. 4 Fishhook removal. (**a**) Simple retrograde pull. (**b**) String-yank technique. (**c**) Needle-cover technique. (**d**) Push and cut technique (Source: David et al. [24]. With kind permission of Springer Science and Business Media)

anesthesia. Chlorhexidine or iodine-based scrubs around the entry point are reasonable choices to clean the area prior to the procedure [23]. In austere environments, normal saline or clean tap water irrigation would be acceptable methods for cleaning and prepping the area. After the hook is removed, the puncture wound should be washed thoroughly.

Treatment

The patient's tetanus immunity status needs to be determined and appropriate prophylaxis administered after removal of the hook. Antibiotics with activity against *Aeromonas hydrophila*, such as an oral fluoroquinolone, should be given prophylactically to all deep wounds [22].

Fig. 5 Needle-cover technique. Note the hook is grasped with pliers and the needle enters at same location as the hook. This is an 18 gauge needle. No pigs were harmed in the making of this image

Removal

Retrograde pull. Barbless hooks exist and can simply be removed by pulling straight out of the skin along the path of entry (Fig. 4). Additionally, hooks that are not fully set or that are very superficial can be removed using this technique. Use hemostats or needle-nose pliers to ensure positive control of the fishhook while performing this technique. This method can cause local tissue damage and is not suitable for deeply embedded hooks, hooks that are near neurovascular structures, or hooks with large or multiple barbs.

Hook depression and string pull. This technique attempts to disengage the barb by depressing the hook while simultaneously pulling the hook out using a string. The string needs to be strong enough that it will not break, and it works best if the string is wrapped around the hook at least once if not more depending on the diameter of the string. High weighted fishing line, umbilical tape, iodoform packing tape, and shoe string are examples of string that can be used. Ensure a solid grip on the string with one hand, and with the other hand, depress the eye of the hook down toward the skin. Then give a firm pull to the string in a retrograde direction to pull the hook out the way it entered the skin. This technique can cause some local tissue damage as it pulls the hook out and as such is best suited for superficial hooks that are not near nerves or vessels. Additionally, this method requires two hands and cannot be performed by an individual on themselves. Ensure eye protection is worn while attempting this method.

Needle cover. An 18 gauge needle can be utilized to cover the barb of a hook and allow it to be removed in a retrograde manner along the path of entry (Fig. 5). The needle is inserted into the skin at the site where the hook has entered and blindly follows the hook to its barb. Once the barb has been covered by the lumen of the needle, it allows the hook to be withdrawn. This technique is not ideal for deeply set hooks or hooks with large barbs.

Advance and cut. The advance and cut technique is felt to have the best initial success rate and is best suited for deeply set hooks. The downside is the additional trauma it causes. The hook is controlled with pliers or a hemostat and advanced in a direction that brings the point and barb of the hook through the skin at a different location. Once through the skin, the barb may be broken off with the pliers or the hook can be cut proximal to the barb (Fig. 6). Simply back the hook out the path of entry after removing the barb. A variation of this method involving an incision and direct visualization of the advancing hook has been used for a deep hook near the ulnar nerve and muscles of the hand [22]. This is the only technique likely to work when dealing with a hook that has multiple barbs along its shaft. In this situation, the hook is advanced and the end opposite the barb is cut close to the skin, and the hook is advanced all the way through the skin without attempting to

Fig. 6 Advance and cut technique. Note the barb has been advanced through the skin and the hook will be cut proximally to the barb. No pigs were harmed in the making of this image

reverse the direction of the hook. Take note that eye protection should be worn while cutting the hook, and don't underestimate the force required to cut a hook. Powerful pliers are needed for cutting even small fishhooks.

Prevention

Eye protection, long sleeve clothing, and gloves may provide some protection from fishhook injuries.

DOI 10.1007/978-1-4939-0779-3_58-1

Introduction

Family medicine encompasses a wide range of disease processes that can benefit from regular physical activity. In addition, the specialty serves a population that can span from elite athletes to a sedentary desk worker and from a geriatric speed walker to a peewee football player. As such it is important to understand how the diagnosis, management, and approach to these patients and their varying disease processes differ in the setting of exercise. This chapter examines in some detail medical conditions such as asthma, hypertension, diabetes, anemia, and various skin diseases in the setting of athletes, as well as the unique features of physical activity and the special populations of women, pediatrics, and geriatrics.

Physical Activity Guidelines

Regular exercise has been shown to decrease the risk of many chronic diseases as well as improve control of the same. Data over the last several decades clearly support the benefit of regular physical activity on improving obesity, cardiovascular disease, metabolic syndrome, bone health, and mental health. The most recent guidelines in regard to physical activity are from the Department of Health and Human Services (HHS) who reviewed national and international data relating to physical activity and health and published the 2008 Physical Activity Guidelines for Americans. In it they recommend the average adult engage in at least 150 minute a week of moderate-intensity (brisk walking) or 75 minute a week of vigorous-intensity (light jogging) exercise. This should occur in 10 minute increments and preferably spread over the course of the week [1]. They also encourage muscle strengthening of all major muscle groups two times per week [1].

Approach to the Athlete as a Patient

Exercise Physiology

Physical activity puts stress on the body that is important to understand when approaching patients that are athletes. There are two forms of exercise, anaerobic and aerobic. Anaerobic consists of short sprints and resistance training, in order to promote strength, speed, and power. Aerobic involves longer endurance training and requires more oxygen to maintain. Both forms are dependent on the ability to deliver oxygen effectively, and there are several adaptations to the cardiac, respiratory, and hematological systems that occur to optimize performance. In addition, regular exercise results in physiological adaptations of the heart that are important to understand when managing athletes.

Physical activity increases the body's metabolic demand for oxygen and energy sources. In order to meet these demands, the heart must increase cardiac output with an increase in heart rate and stroke volume. Systolic blood pressure increases with increased work, and blood is shunted from splenic and GI organs to the muscular system. In order to meet the almost exclusively aerobic metabolism of the heart, increased coronary artery perfusion is necessary and is accomplished from an increase in perfusion pressure and coronary vasodilation. Exercise also stimulates the sympathetic nervous system which results in a release of catecholamines to further increase coronary perfusion.

With regular activity, these changes that occur acutely during exercise will result in long-term changes of the cardiovascular system. Specific changes in the heart are referred to as the "athlete's heart." These changes consist of increased left ventricular mass, increased left ventricular wall thickness, and increase in left ventricular end-diastolic volume [2, 3]. Over the last decade, echocardiogram-based studies have also shown an increase of size in the interseptal and posterior walls of the heart as well as larger ventricular diameter [2, 3]. For reasons that are not completely understood, well-trained athletes

have reduced sympathetic activity and increased parasympathetic activity resulting in baseline bradycardia. Cumulatively, these changes ultimately allow for higher stroke volumes at a lower heart rate [2].

The need for rapid exchange of oxygen and carbon dioxide during exercise results in an increase in tidal volume followed by increased respiratory rate to improve ventilation. Over time with regular physical activity, the respiratory system can adapt with an increase in maximal voluntary ventilation. Other minor changes can occur over time, but adaptations here are less than in the cardiovascular system, and it is thought that the limitations in exercise secondary to a healthy respiratory system are small [2, 3].

Oxygen delivery can also be affected by the hematologic system and the body's ability to carry and deliver oxygen to the working tissues. Red blood cells (RBC) contribute to oxygen delivery via three important mechanisms. (1) They are a source of nitric oxide which causes vasodilation and increases blood flow to tissue. (2) As the oxygen-carrying cell of the body, an increase in the number of RBC will enhance oxygen delivery. (3) The viscosity of blood, which is partially affected by RBC membranes and their deformability, affects the velocity of blood through the microvasculature. This is still a relatively new area in research, but it is thought that the sequelae of exercise – dehydration, lactate production, and hypoxia – impair blood viscosity during actual episodes of exercise, ultimately resulting in a decrease of whole blood viscosity in the resting athlete and supporting tissue oxygenation [4]. Anemia and sickle cell are examples of conditions that will be addressed where this oxygen delivery can be affected.

In addition to cardiac and respiratory changes, understanding the metabolic demands on a patient is important, especially when managing disease processes such as diabetes that can affect the ability to manage fuel. The main fuel source during exercise is lipid and carbohydrate breakdown from adenosine triphosphate (ATP) and glucose within the muscle. Because of this, there is an insulin-independent uptake and utilization of glucose during exercise, which can help improve overall glycemic control. Under the control of glucagon, epinephrine, and cortisol, fuel utilization will eventually shift to plasma-free fatty acids and blood glucose outside the muscle. In diabetic patients, this metabolic process can be affected due to their inability to properly regulate glucose levels.

Chronic Disease

Medical Problems

Asthma

This common medical condition affects an estimated 8 % of the American population [5]. Symptoms including wheezing, shortness of breath, and cough are a consequence of airway hypersensitivity to various triggers resulting in bronchial spasm and inflammation. When exercise has been identified as a trigger for chronic asthmatics, it is often referred to as exercise-induced asthma (EIA). Without a diagnosis of underlying asthma, transient airway constriction during activity and secondary airway hyperresponsiveness is more appropriately classified as exercise-induced bronchospasm (EIB). The mainstay of therapy includes inhaled beta-agonist, inhaled steroids, and masts cells stabilizers. Primary care providers should be aware of which sports are associated with higher prevalence of asthma and asthma-like symptoms, identify triggers for athletes, and provide an asthma action plan (AAP) and rescue inhalers for all asthmatics for practices and games.

There are a few theories on the pathophysiology of EIB, most of which relate to the exchange of temperature and water that occurs during exercise at the bronchial epithelial level. These changes trigger an increase in cell inflammatory mediators. Additionally, exercise triggers bronchoconstriction in a healthy patient. Athletes with EIB have been shown to have increased levels of nitric oxide and expression of mast cell genes leading to further bronchoconstriction [6].

Breathlessness, cough, wheeze, chest tightness, and excessive mucus production within the first 5–15 minute of exercise with resolution 1 h following cessation of activity are consistent with

EIB. However, these symptoms cannot solely be relied upon for definitive diagnosis; additional pulmonary testing and clinical examination are necessary. Spirometry may be used to assess these patients, but there are a few inherent characteristics of athletes that can make this difficult. Notably, forced expiratory volume (FEV) may be increased above the normal range in more conditioned athletes. Additionally, when exercise is truly the trigger, simple spirometry is not enough to induce bronchoconstriction. Patients may require additional bronco-provocation testing to elicit airway restriction occurring secondary to exercise.

To diagnose EIB, athletes need to have a $\geq$10 % decline in their FEV1 values measured pre- and postexercise (known as an exercise challenge test). Methacholine challenge testing is often used in athletes exhibiting EIB symptoms with equivocal exercise challenge testing. Patients with EIB will require lower amounts of methacholine before showing an impact in FEV1. The eucapnic voluntary hyperventilation test is the gold standard set by the International Olympic Committee. Dry gas containing carbon dioxide, oxygen, and nitrogen is inhaled at a rate of 85 % maximum voluntary ventilation. FEV1 measurements are made and a decline of $\geq$ 20 % indicates EIB [7].

Various environmental factors including location of training, ambient temperature, humidity, and air quality contribute greatly to the onset and perpetuation of bronchoconstriction in the athlete. Two sports disproportionally affected include swimming and cold-weather athletes. Thirty percent of athletes in winter sports such as figure skating and skiing are thought to have EIB secondary to the inhalation of cold, dry air [6]. Swimmers have exhibited incidence of EIB six times greater than nonathletes and spring/summertime athletes, likely as a result of the chlorine exposure [8].

Patients with allergen-induced asthma suffer compounded risks in periods of high pollen count during seasonal and perennial pollination. Importantly, up to 40 % of patients suffering from allergic rhinitis will present similar upper respiratory symptoms to asthmatics while exercising being asymptomatic at rest [9].

Management of EIB/EIA symptoms begins with prevention when possible. Correctly identifying symptoms of allergic rhinitis and treating with a combination of intranasal corticosteroids and antihistamines reduces the concomitant effect in chronic asthmatics. Recommend an indoor sport when possible. For winter athletes, breathing through a scarf can help. Educate the patient on proper warm-up including 15 minute moderate warm-up period followed by a 15 minute rest period which can induce a refractory period. Pharmacologic intervention should be considered with failure of conservative measures. First line is use of a short-acting beta-agonist 15 minute prior to exercise. Daily inhaled corticosteroids (ICS), leukotriene antagonists, or mast cell-stabilizing agents are second line [9, 10]. Long-acting beta-agonists are not as effective and should be used only in conjunction with ICS [11]. Education on use of medications for reversal of EIA when an exacerbation occurs with short-acting beta-agonists continues to be the standard of care.

Cardiac

Hypertrophic cardiomyopathy (HCM) represents the most common genetic cardiovascular disorder, with an estimated prevalence of 1:500 of the general population. Common symptoms include shortness of breath (particularly with exertion), chest pain, palpitations, orthostasis, presyncope, and syncope. Although many patients remain asymptomatic with a benign natural history, sudden cardiac death can be the first manifestation in otherwise asymptomatic young people. HCM has been positively identified in well over a third of cases (36 %) of SCD in athletes under the age of 30 and cited as a possible cause in another 8 %. Symptoms vary widely between individuals, even those in the same family. Despite being a relatively common inherited cardiac disorder, this condition can be hard to differentiate from the enlargement of the heart that can occur with elite athletes. As such, differentiating between HCM and physiologic nonpathologic left ventricular (LV) hypertrophy associated with extensive training ("athlete's heart") can be difficult. Distinction

of this disease has important implications since identification of cardiovascular diseases associated with sudden death may be the basis for disqualification from competition to minimize risk.

Identification of this disorder falls to the family medicine physician using specific criteria and disease-specific questions noted during the patient reported history and pre-participation physical exam. Major risk factors include prior cardiac arrest, unexplained syncope, a family history of SCD, left ventricular wall thickness $\geq$30 mm, an abnormal BP response to exercise (at high exertion peripheral pulses withdraw and systolic blood pressure decreases), and history of nonsustained spontaneous ventricular tachycardia [12]. Some examples of disease-specific questions are:

1. Has anyone in your family died suddenly for unexplained reasons before age 50?
2. Have you ever experienced chest pressure or pain while exercising?
3. Have you ever been diagnosed with a heart murmur?
4. Have you ever had cardiac imaging done?
5. Have you ever passed out or nearly passed out *during* or *after* exercise?

The physical exam for HCM has been an insensitive screening tool for sole identification. This is in part due to most patients with HCM presenting with a nonobstructive disease and unremarkable cardiac exam [13]. Patients presenting with left ventricular outflow tract obstruction most commonly exhibit a late-systolic ejection murmur best appreciated at the left sternal border. This murmur commonly radiates to the aortic and mitral posts, typically heard best when the patient stands or performs the Valsalva maneuver which decreases preload to the heart.

If HCM is suspected based on patient history, physical exam, or a combination of the two, referral to a cardiologist is indicated. In office EKG should be considered for those athletes suspect of cardiac dysfunction. Advanced imaging of cardiac function by echocardiogram is the convention for diagnosis of HCM, which is exhibited by asymmetric LV wall hypertrophy (wall thickness $\geq$13 mm) without chamber dilation. Mild concentric LV hypertrophy (13–14 mm) may be present in healthy individuals who exercise strenuously and indicative for "athlete's heart" [14]. Anterior septum thickening and abnormal systolic motion of the mitral valve may be evident as well. Following identification, disease management is tailored around disease symptoms, risk, and complications becoming largely empiric as no large-scale studies for the medical management of HCM exist to date.

Diabetes

Diabetes is a common disease that affects 30 million people in America. It has been well established that regular physical activity can help decrease the risk of developing diabetes as well as serve to improve glycemic control.

The Diabetes Prevention Program, a large randomized controlled trial focusing on type 2 diabetes treatment through lifestyle modification, found that interventions producing weight loss through improved dietary intake and physical activity decreased the risk of diabetes by 58 % [15, 16]. Their recommendation for exercise modeled that of the Department of Health and Humans Services of 150 minute of physical activity a week consisting of brisk walking distributed over three separate sessions with at least 10 minute per session [15, 16]. With the increased risk for coronary artery disease in the diabetic population, it is important to consider cardiac screening in these patients; however, the benefits of regular exercise far outweigh the cardiac risks.

In the type 1 diabetic, there are three considerations when participating in athletics. First, as previously mentioned, exercise lowers blood glucose independent of insulin, which puts the patient at risk for hypoglycemic events. Second, on the other hand, exercise stimulates the sympathetic nervous system and release of stress hormones such as cortisol and epinephrine and can result in hyperglycemia. This, coupled with the possibility of low insulin levels prior to starting exercise, puts the type 1 diabetic at increased risk of ketogenesis. The final concern for these athletes is delayed hypoglycemia. Tissue insulin sensitivity is increased for 7–11 h post exercise. If carbohydrates are not replaced, the athlete is at risk for

hypoglycemic events for up to 12 h after finishing exercise [17, 18].

Several recommendations can be made to type 1 diabetics to avoid these complications. Adjustments to carbohydrate intake rather than insulin dosing are associated with fewer exercise-related complications [17, 18]. Athletes should check their blood sugar prior to exercise and supplement with a high-carbohydrate snack if less than 150 prior to exercise [18]. For endurance athletes, training sessions longer than 1 h should consider carbohydrate supplementation [17, 18]. All athletes should have a postexercise snack in order to combat the delayed hypoglycemia risk as well as frequent blood sugar checks every few hours in that postexercise period [17].

The insulin pump is becoming a more widely accepted tool for managing type 1 diabetes. In athletes well versed in managing their pump, this is a good way to minimize glycemic fluctuation. It can also be titrated to allow for regular exercise sessions.

Hematological Disease

Anemia

As discussed above, in exercise physiology, the blood and its ability to transport oxygen are an important part of an athlete's performance ability. There is a phenomenon known as "sports anemia" most common in endurance athletes. This refers to the dilutional pseudoanemia that results from plasma expansion. Repetitive long workouts resulting in a hemoconcentration from dehydration result in an overshoot of plasma expansion postexercise and ultimately up to 1.5 g/dL below normal Hgb levels [19]. This should not be high on the differential for nonendurance athletes, but the diagnosis can be tested by stopping workouts. The athlete's Hgb should normalize within 5 days [19]. It is an adaptive response and ultimately does not need to be corrected.

Much like the general population, iron deficiency is the most common form of anemia seen in athletes. The rate of occurrence is no different than the general population. It can occur in up to 20 % of menstruating females and 6 % and 4 % of postmenopausal women and male athletes, respectively [19]. Etiology includes the same as those in the general population – GI bleeding, NSAID use, and menstruation in females. Other sport-specific causes such as hematuria, foot-strike destruction, and iron loss from sweating have been described in the sports literature, but should be low on the differential and diagnoses of exclusion [19]. Iron deficiency anemia should be worked up and treated similarly to iron deficiency anemia in the general population (chapter ?).

In athletes there does appear to be an increase in nonanemic iron deficiency. When ferritin, a predictor of iron stores, is used as an indicator for anemia in studies, there is consistently a difference of anemia in athletes, especially endurance athletes [20]. The utility of replacing iron in these athletes is controversial. A recent review of 17 studies argued that iron supplementation to achieve normal ferritin levels did statistically improve aerobic capacity [20]. Given the controversial nature of this therapy, athletes thought to fall into this category should be referred to a sports specialist for evaluation and management.

Macrocytic and hemolytic anemia in the athlete have similar etiologies and treatment to that of the general population. The phenomenon of foot-strike anemia (also thought to be a cause of microcytic anemia), mentioned above, is a rare and often clinically insignificant disorder that results in endurance athletes from repetitive heel strike, muscle use, or cardiac valve turbulence [21]. It rarely requires treatment.

Hemoglobinopathies

Thalassemia results from the deletion or mutation of genes responsible for the alpha and beta chains that make up hemoglobin. Anywhere from one to four of the chains can be affected and range from asymptomatic to death in utero. Sickle cell trait (SCT) occurs when an individual is heterozygous

for sickle hemoglobin. Under normal physiological conditions, this is typically benign and easily controlled. However, in the athletic population, heat, high altitude, and intense training can put these individuals at increased risks of medical complications such as splenic infarction, hematuria, exertional rhabdomyolysis, and sudden death.

In 2010–2011 the NCAA started to require all Division 1 athletes know their sickle cell status or sign a waiver, thus bringing sickle cell trait to the forefront of several considerations during a pre-participation physical. There is much discussion as to whether this screening should expand outside Division 1 and whether it should be targeted at specific high-risk sports (football and basketball) and populations (African, Mediterranean, and Middle Eastern) [22]. Regardless, athletes with known sickle cell trait should be made aware of the risks. Appropriate precautions should be taken. The athlete should be conscientious of staying well hydrated and tapering workouts to not overexert themselves, especially in hot and high-altitude conditions.

Bleeding Disorders

Von Willebrand's disease, hemophilias, and immune thrombocytopenia are common bleeding disorders that are often discovered in childhood; thus, they can present in the young athlete. The etiology, prevalence, work-up, and management do not vary significantly from the general population. However, once diagnosed, appropriate modifications need to be made in the athletic population. Type of exercise and sport should be tailored to the athlete's interest. Swimming, bicycling, skating, and weight training are good sports to recommend. Avoidance of contact sports should be emphasized along with the use of protective equipment. These diseases do not preclude someone from participation, but it is important to ensure appropriate education is done with the patient.

Skin

Tinea Corporis Gladiatorum

Tinea corporis gladiatorum (TC) is a fungal rash caused by *Trichophyton tonsurans* most often seen in contact sports, especially wrestling. Studies have estimated it to be prevalent anywhere from 24 % to 77 % of individuals in wrestling [23]. It is transmitted by skin to surface contact and has been thought to be transmitted by asymptomatic tinea capitis.

TC presents as well-defined, erythematous, scaling plaques most commonly on the head, neck, and upper extremities. It often is not as ring shaped as typical tinea corporis. Diagnosis can be done via a KOH prep and presence of hyphae, but is more often simply clinical.

Treatment can be either topical or oral. Topical application of clotrimazole twice daily or oral fluconazole 200 mg weekly is a recommended treatment. One small study suggested that application of oral antifungals weekly has resolution of positive cultures 1 week earlier than topical [23]. The most important aspect of treatment, however, is prevention. It is recommended to keep these athletes out of practice for 2 weeks of treatment. Discourage sharing of equipment among the athletes and encourage frequent cleaning of personal equipment.

Tinea Pedis

Another common fungal infection among all athletes is tinea pedis caused by *T. rubrum* and *T. mentagrophytes*. Walking barefoot on communal floors, wearing occlusive footwear, sweating excessively, and poor circulation can all predispose these athletes to this infection. Similarly to tinea corporis, the diagnosis can be made clinically or by KOH prep.

Over-the-counter antifungals are a reasonable first line for treatment followed by prescription topical antifungals. These should be applied twice daily for 2–4 weeks. If the rash is still resistant, then oral agents such as terbinafine

(250 mg daily for 2–6 weeks) or itraconazole (200 mg daily for 2–12 weeks) should be tried.

Staphylococcus and *Streptococcus*

Staphylococcus and *Streptococcus* can cause two common rashes among athletes: impetigo and folliculitis. These are most common in contact sports such as rugby, football, and wrestlers.

Impetigo is due to localized, superficial infections with these bacteria. Well-defined, erythematous, yellow, crusted plaques are characteristic of presentation.

Folliculitis occurs when these bacteria infect the athlete's follicles. The hair follicles become red and inflamed and can have pustule drainage. The rash tends to be itchy and if deeper also painful.

Mupirocin can be used, but with extensive rash, treatment with penicillin or cephalosporin is recommended for a week [23]. The athlete should be kept out of their contact sport for 5 days [23]. In team sports with multiple infections, it is important to consider the possibility of nasal carrying of *Staphylococcus*. Mupirocin ointment applied to both nares twice daily for 1 week should clear *Staphylococcus* carriage for about 6 months [23].

Nail Dystrophies

Trauma and pressure to the nail plate and periungual area can result in sport-specific changes that often look similar to onychomycosis so it is important to be aware of these nail dystrophies.

Runners develop jogger's toe from repetitive thrusting of the toe into the shoe that result in a subungual hematoma. Furthermore, the toenail can become thickened, ridged, and discolored from this repetitive trauma. Sports with quick stops and starts such as racquet sports and basketball can result in similar destruction of the nail bed.

There is typically no need for treatment and the nail can be watched for changes that would indicate fungal infection or melanoma. However, occasionally the patient is having too much pain from these nail changes to effectively participate. In these instances, if there is a clear subungual hematoma, then treatment by drilling a hole through the nail bed is advised [23]. If there is no clear hematoma, but there is evidence of nail bed changes, completely removing the nail is a reasonable treatment option [23].

Talon Noir/Mogul's Palm

Talon noir and Mogul's palm are black macules that result from intraepidermal bleeding as a result of shearing forces. Talon noir occurs on the soles and is most commonly seen in basketball players [23]. Mogul's palm occurs on the hands of skiers from repetitive pole planting. They often can be confused with melanoma. If there is suspicion for melanoma, a biopsy should be done; otherwise paring down the lesion with a surgical blade can remove the old hemorrhage [23].

Special Populations

For a family physician, the patient population ranges across all age groups and both genders. As such, it is important to highlight some of the specific considerations for athletes in these groups.

Women

There are gender-specific benefits to exercise that the family physician should know. Weight-bearing activity can increase bone mineral density and decrease the risks of fracture in postmenopausal women [24]. In the past 10 years, a few studies have shown regular exercise to decrease prolactin and progesterone resulting in a decrease in fatigue and improved concentration as well as improvement of premenstrual symptoms of low back pain, pelvic pain, anxiety, and depression [25, 29].

On the other side, as female participation in sports has increased, a set of health problems unique to female athletes has emerged. In 1992 the American College of Sports Medicine first described the female athlete triad as disordered eating, amenorrhea, and osteoporosis. This definition was updated in 2007 to include dysfunction related to energy availability, menstrual function, and bone mineral density. A recent meta-analysis suggested that the prevalence of all three components among female athletes was small (1–15.9 %); however, the prevalence of one or two components ranges from 16 % to 60 % and 2.7 % to 27 %, respectively [26]. Low energy availability can be the result of disordered eating in the form of anorexia or bulimia as well as inadvertent decrease in energy intake or failure to increase caloric intake to match the athlete's training program [27]. This low energy availability coupled with the physical and mental stress of training can lead to menstrual irregularity [27]. Finally, this low energy state results in the decrease in insulin growth factor and hypoestrogen leading to low bone mineral density [27].

Currently, there is no ideal screening tool for the female athlete triad, but if an athlete is found to have one component, it is important to screen for the other two. Treatment should be multidisciplinary and include a physician, dietitian, and often a mental health professional. The focus of treatment is to improve energy balance through improved intake and controlled output in the athlete's training program [27, 28]. Other treatments can include pharmacological therapies such as SSRIs and hormone replacement but should be left to the management of specialists.

Pregnancy is another common area in which questions relating to exercise can arise for the family physician. A meta-analysis of recent studies looking at exercise in pregnancy outlines the many benefits of staying physically active during pregnancy and include [30, 31]:

1. Lower risk of gestational diabetes
2. Enhanced sleep
3. Reduced bone density loss
4. Reduced physical discomfort
5. Maintenance of appropriate weight
6. Improved mental health
7. Lower birth weights despite increased gestational ages
8. Higher apgar scores

The recommendations from the 2009 American College of Obstetricians and Gynecologists in regard to exercise during pregnancy are as follows [31]:

1. Achieve regular moderate exercise at 30 minute or more most days of the week.
2. Avoid exercises requiring the supine position after 12 weeks gestation due to increase risk of obstruction of venous return.
3. Avoid activities that carry with them a risk of abdominal trauma.
4. Avoid physical activity above 6,000 ft.

They also note in these recommendations that there are no reports of hyperthermia being associated with teratogenicity although avoiding extreme overheating is recommended. Additionally, there is no published evidence on the effects of strenuous training, so these athletes should be monitored closely [31].

In summary, women who were previously healthy prior to pregnancy can continue with their training programs during pregnancy. They can restart their training programs when they feel ready, some as early as 1 week [31]. Women with significant cardiac or respiratory disease or complications to the pregnancy should be monitored carefully during exercise [31].

Elderly

The age definition of "elderly" can vary depending on the sport and required skill set. For sports requiring endurance and flexibility, separate age categories can start as early as 19 years. For those demanding a specific skill set, age categories often start at 50 years. For the general public, geriatric classification starts at age 65 with 65–75 being young old, 75–85 being middle old, and very old being those over age

85 [32]. The health benefits of physical activity in reducing cardiovascular events, diabetes, and improving bone health continue through the lifetime, and as such elderly patients should be encouraged to continue to be physically active. In addition, the elderly specifically experience the benefits of better balance and improved cognition allowing them to maintain independence [32]. However, it is important to understand some of the physiologic changes that occur and should be considered when treating elderly athletes.

As a person ages, cardiovascular function declines resulting in a decrease in maximal heart rate, impaired compliance in diastole, incomplete emptying in systole, and reduced inotropic response to sympathetic input [33]. This can affect the elderly's activity tolerance level as well as put them at increased risk for arrhythmias and heart failure. The other major physiologic change in the elderly is sarcopenia – or a decrease in muscle mass, strength, and endurance – which can lead to a decline in functional ability and flexibility putting the elderly at an increased risk of injury and falls [24, 33].

In order to maximize the benefits of exercise and limit the risks of adverse outcomes, the American College of Sports Medicine along with the American Heart Association has set forth the following recommendations for physical activity [34]:

1. Minimum of 150 minute of moderate intensity or 60 minute of vigorous physical activity per week
2. No more than 10 % increase in volume or intensity at a given session
3. Resistance training with 10–15 repetitions of 8–10 exercises that train major muscle groups twice per week
4. Flexibility exercises 10 minute twice a week with 10–30 s of 3–4 repetitions per static stretch
5. Balance activities twice per week

Pediatrics

In 2012 the CDC estimated that 18 % of children 6–11 years old and 21 % of adolescents aged 12–19 fit into the obese category. As such it has become a public health concern to encourage children and adolescents to participate in physical activity in a healthy and beneficial way. On the other hand, there has been a significant increase of participation in team sports in this population. As a family physician, it is important to be aware of some of the medical considerations for this younger population as well as the recommendations for appropriate physical activity.

For the average patient in this population, the Physical Activity Guidelines for Americans set for the following recommendations in 2012:

1. Participate in 60 minute or more of moderate to vigorous intensity aerobic physical activity daily.
2. Resistance training on three nonconsecutive days. This can be part of the 60 minute of daily activity and includes activities such as tug-of-war, rope climbing, or push-ups.

The benefits of following these recommendations include healthy body composition, increased development of bone mass, improved self-esteem, and decrease in anxiety and depression [35].

Several medical conditions such as asthma, exercise-induced asthma, hypertrophic cardiomyopathy and sudden death, type 1 diabetes, and sickle cell anemia are often more prevalent in the pediatric population and have been addressed previously.

Hypertension in the pediatric population is defined by a blood pressure that is >5 mmHg above the 99th percentile for age, gender, and height. These athletes should avoid power lifting and body building until successfully treated [36].

Mononucleosis is a common virus in the adolescent population. One of the sequelae of this virus is an enlarged spleen. Children known to be affected with mononucleosis and having an acutely enlarged spleen should be kept from contact sports until resolution of the enlarged spleen [36]. According to the AMSSM consensus

on mononucleosis and athletic participation, players can return to sport 3 weeks from day of diagnosis [37].

Congenital abnormalities also become a consideration in this population. For example, athletes with Down syndrome or juvenile rheumatoid arthritis need to be assessed for atlantoaxial instability and likely should be kept from certain contact sports such as football, basketball, and wrestling [36]. Athletes with cystic fibrosis should be assessed for the functional capabilities and cleared for sports based on these considerations [36].

Musculoskeletal concerns account for up to 30 % of patient encounters within family medicine. Youth sport participation continues to increase nationwide with over 30 million youth and teens participating [1]. High school athletics alone accounts for over two million injuries, half a million physician visits, and 30,000 hospitalizations annually [2]. Growing sports specializations within adolescents has led to an increase in overuse injuries; accounting for half of all adolescent injuries [1]. Adults are not immune to athletic injuries, as weekend warriors suffer numerous injuries. Weekend warriors commonly suffer ankle injuries, knee injuries, dislocations, and overuse injuries in attempts to stay active.

Injuries result after an insult to bone or soft tissue structure (muscle, ligament, or tendon) and produce disruption in the normal anatomy. Acute injuries are usually secondary to some form of trauma while chronic injuries are usually the result of overuse with or without associated biomechanical deficiencies. Prior injuries to a joint that did not undergo appropriate rehabilitation can also lead to increased risk to further injury. A majority of sports-related injuries occur to the axial skeleton; however, mild traumatic injuries to the brain, i.e., concussions, are becoming a growing concern within our society with over 300,000 sports-related concussions occurring annually [3]. This chapter will discuss both general treatment options and treatment for specific athletic injuries.

General Injury Management

The initial management of sports-related injuries involves decreasing inflammation, pain control, and stabilization of surrounding tissues to prevent additional injury to the area. Inflammation can be reduced with rest, ice, compression, and elevation (RICE). Nonsteroidal anti-inflammatory drugs (NSAIDs) can also be of use in the reduction of inflammation and pain control. Pain control can be accomplished with immobilization, NSAIDs, acetaminophen, muscle relaxants, or opioids. Opioids should be reserved for dislocation and fracture pain control. Imaging of the injured area is usually required in order to fully assess the injury.

Imaging modalities include x-rays, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound (US). Imaging will alert the provider if anatomical alignment needs to be obtained through reduction of the affected joint or bone. After initial management with immobilization, most patients require some form of physical therapy to address underlying muscle flexibility, muscle strength, and biomechanical deficiencies. Unfortunately, some injuries are not to be managed conservatively as discussed above. Referral to a sports medicine physician or orthopedic surgeon is sometimes required for more definitive treatment.

General Fracture Management

A large percentage of nonoperative fractures can be managed by family physicians. Understanding the patient's entire medical picture allows the provider to identify risk factors for impaired fracture healing. Physical examination on initial visit should assess for neurovascular complications and associated soft tissue injuries. Specific anatomic findings and examination findings will be addressed later in this chapter. All fractures need to be visualized on at least two different views on plain films to ensure appropriate anatomical alignment. If clinical suspicion for a fracture is high but plain films are negative, additional imaging with bone scans, CT, or MRI could be warranted. All fractures should be assessed for closed/open status, displacement, angulation, direction of fracture line, and presence of multiple fracture segments in order to provide appropriate care.

The healing of fractures occurs over a several-month period; understanding this process is necessary to appropriately treat fractures. The initial inflammatory phase occurs almost immediately after injury through recruitment of inflammatory cells and formation of a hematoma. Osteoblastic cells are recruited and responsible for the initial remodeling of the injury site. Within the first 2–3 weeks, a soft callous is formed, signifying the arrival of osteoclastic cells. By week 6–8 post injury, a hard callus replaces the soft callus, signifying clinical union. Final bone strength and radiographic resolution occur 3–6 months after injury. Multiple factors can inhibit the above healing process. Smoking, diabetes, and chronic oral steroid usage are common problems managed by primary care providers that inhibit bone healing. NSAID usage, especially during the first 2–3 weeks of healing, can inhibit the recruitment of inflammatory cells and the initiation of the healing process. Judicious usage of NSAIDs is advised in all fractures, with focus of pain control with acetaminophen and opioids if needed.

Immobilization via splinting or casting throughout healing is critical. Any fracture that has significant displacement or angulation requires reduction prior to immobilization. Post reduction images and neurovascular examination are essential. Surgery is indicated if misalignment or neurovascular complications are present or if reduction cannot be maintained. If clinical suspicion for fracture is high but radiographs are negative, immobilize as if a fracture is visualized and reevaluate the patient in 1–2 weeks with additional imaging. Splinting should always occur for the first 3–5 days after initial injury. Circumferential casting can be applied after this time period for a more permanent immobilization solution. Casting a patient during the acute inflammation process can lead to significant morbidity through compartment syndrome or improper cast fitting after swelling resolution. Appropriate cast care instructions should be given to patients. Specific treatment management of common fractures will be addressed later in this chapter. *Fracture Management for Primary Care* [4] and *Handbook of Fractures* [5] are both excellent resources for primary care providers who provide fracture care.

Concussion

History

Concussions result from either direct trauma or application to indirect forces to the face, head, or neck. Patients can complain about a diverse group of symptoms: headaches, balance disturbances, retrograde amnesia, nausea, photophobia, phonophobia, visual tracking issues, slowed

cognition, mood changes, sleep disorders, concentration issues, confusion, and dizziness. Although once thought to be required for diagnosis, loss of consciousness can occur but is not required. Symptoms classically begin immediately after the injury, but delayed presentation of symptoms for up to 72 h can occur. Most individuals will have resolution of symptoms within 10 days; however pediatric and adolescent patients may have prolonged symptoms [6, 7].

Physical Exam

Sideline evaluation of patient should include complete neurological examination and cognitive evaluation. The SCAT3 and Child SCAT3 assessment tools [8, 9] are free resources to assist in initial and follow-up evaluation of concussed individuals. In the acute setting, it is important to evaluate for associated cervical spine injuries. Acute changes in neurologic status, personality changes, or acute worsening of headache should signify the need for additional evaluation at higher levels of care such as the emergency room. Follow-up evaluations should focus on patient's cognitive status, balance testing, and neurological evaluation (reflex testing, rapid alternating eye movements, visual tracking, etc.).

Imaging

Routine imaging after a concussion is no longer indicated. If initial evaluation findings are concerning for an intracranial bleed, a CT scan is indicated [6, 7]. Imaging of the cervical spine is indicated if associated injury is suspected.

Management

Acute management of concussed patients involves immediate removal from competition and close monitoring. Concussed athletes should be reevaluated throughout the rest of the game and afterwards. Suspected concussed athletes should never be allowed to return to competition the day of injury [6–8]. Concussion grading is no longer used and should not be applied to management decisions. The current hallmark of the management is physical and cognitive rest until symptom resolution. Cognitive rest includes removal from classroom activities if needed. A transition process back to full academic participation including extended deadlines on assignment, extended test taking time, and transition from active listener to active learner in the classroom should be utilized [10]. Most sport medicine providers employ a graded return to play physical activity/sports once the patient is symptom free [6, 7]. Computer-based cognitive testing can be used as an adjunct in helping determine when a patient has returned to his or her baseline. Some school districts now obtain baseline neurocognitive testing in the contact sport athletes to help in this, but current evidence is conflicting on the reliability of baseline testing [11].

Symptomatic care for headaches should not include NSAIDs for the first 48 h after injury. Physical therapy for concurrent neck soft tissue injuries can help alleviate tension-type headaches. A patient with prolonged symptoms should be treated with a multidisciplinary approach (pharmacologic, speech therapy, vestibular rehabilitation, physical therapy, and optometry/ophthalmology) [12]. In patients with prolonged symptom, light aerobic exercise should be encouraged as long as it does not worsen their current symptoms [12].

Acute Back Pain

History

Acute low back pain is defined as pain that has been occurring for less than 3 months time. The most important tool in its evaluation is a thorough history and physical. History should focus on associated red flag symptoms such as trauma, fever, chills, new onset or worsening bowel or bladder incontinence, saddle anesthesia, age greater than 50, and new motor or sensory deficits [13]. Movements that worsen symptoms such as hyperextension should be noted in youth athletes,

especially weight lifters, cheerleaders, and gymnasts.

Physical Examination

A standard musculoskeletal exam evaluating range of motion, areas of tenderness to palpation, hamstring and hip flexor flexibility, and lower extremity nerve root examination should be completed. The location of tenderness on palpation will assist the provider in determining if symptoms are secondary to bony or muscular pathology. Flexibility testing of the hamstrings and hip flexors can assist in determining underlying biomechanical causes for the patient's pain. Special tests are often used to evaluate for sciatica and possible spondylolysis. The straight leg raise is often used to evaluate for radicular symptoms (sciatica). While the straight leg raise does have high sensitivity, it exhibits poor specificity. Palpable step offs, loss of normal lumbar spine lordosis, tight hamstrings, pain with single leg lumbar extension, and vertical position of the patient's sacrum are diagnostic clues in identifying acute spondylolysis [14].

Imaging

In the absence of any red flag findings, no imaging is indicated. If other signs or symptoms of fracture are present, then x-ray is the initial imaging of choice.

Treatment

Patient education is the foundation of treatment of acute low back pain. Often, no definitive cause is identified; education on the natural course of acute low back pain and encouragement of continued physical activity should occur [15]. Conservative treatments with NSAIDs or acetaminophen are options for pain control. If muscle spasms are appreciated on examination, a short course of muscle relaxants should help symptoms; however, the patient should be advised of muscle relaxant's side effect profile and dosing precautions prior to initiating therapy. Opioids should be reserved for severe pain that has not responded to more conservative treatment options. Failure of pain control with opioids should cause a reevaluation of possible causes of the patient's symptoms. Home exercises, osteopathic manipulation therapy, and formal physical therapy are additional management options [13, 15].

Rotator Cuff Injuries

History

Patients will often present with nocturnal pain occurring when lying on the affected shoulder. Accompanying pain and/or weakness when raising the arm over shoulder-height is also characteristic. While some rotator cuff injuries occur from an acute injury, most result from cumulative microtrauma.

Physical Exam

Inspection can reveal scapular dyskinesia and/or muscle atrophy of the supraspinatus or infraspinatus. Palpation of the lateral shoulder over the subdeltoid bursa and rotator cuff insertions can elicit pain. Active range of motion will be decreased compared to passive range of motion. Special tests have been developed to test specific rotator cuff muscles. Jobe's "Empty Can" Test evaluates the supraspinatus integrity. In this test, a downward force is applied to a humerus that has been abducted to 90°, forward flexed 30°, and pronated till the thumb is pointed down. Both the teres minor and infraspinatus are tested with resisted external rotation with the arms at the patient's side and elbow flexed to 90°. Subscapularis strength can be assessed with the "Belly Press." The patient is instructed to place their palm on their umbilicus and resist the examiner from pulling his/her hand off their abdomen [16, 17].

Imaging

Radiographs consisting of three views of the shoulder (AP, axillary, and scapular Y) should be obtained. These views assess the shoulder for joint degeneration, fractures, positioning of humeral head in relation to rest of shoulder joint, and soft tissue calcifications. A finding such as a "high riding humerus" is suspicious for a rotator cuff tear. If a detailed evaluation of rotator cuff anatomy is desired, a MRI should be considered.

Management

Acute full-thickness rotator cuff tears should be referred to an orthopedic for surgical management. Physical therapy is the cornerstone of conservative management. Rehabilitation exercises focus on restoring shoulder range of motion, correcting shoulder biomechanics through rotator cuff strengthening and scapular stabilization, and correcting poor static and dynamic posture [17]. NSAIDS and activity modification such as limiting overhead activities can complement the rehabilitation process. Cortisone injections are a commonly used option to decrease inflammation, but judicious use is advised. The benefit of decreased inflammation must be balanced against potential articular cartilage and rotator cuff damage from the components of the injection [18]. As with all musculoskeletal injections, emphasis should be placed on appropriate rehabilitation in conjunction with the injection.

Shoulder Instability

History

The term shoulder instability can be used to describe an acute dislocation or subluxation along with chronic instability leading to recurrent subluxations. The overwhelming majority of shoulder dislocations occur in the anterior direction. Patients will often describe some type of force being applied to their upper arm while it is abducted and externally rotated. Posterior dislocations occur approximately 5 % of the time and are associated with electrocutions or seizures. Chronic shoulder instability can be the result of prior dislocations or nontraumatic repetitive microtrauma. This is often seen in athletes with repetitive overhead motions such as swimmers, baseball pitchers, and volleyball players. With acute dislocations, the patient will describe a popping sensation with subsequent pain and obvious gross deformity. In athletes with chronic instability, the patient will often describe pain and feeling of shoulder instability with certain overhead movements. Overhead throwing athletes will also express a feeling of decreased throwing/hitting velocity. Associated soft tissue trauma to structures such as the labrum and rotator cuff are known complications.

Physical Examination

Gross shoulder deformity will be present with both types of dislocations. Positioning of the patient's arms will be different with an anterior injury (slight abduction and external rotation) versus a posterior injury (adduction and internal rotation). Apprehension with movement will be universal. It is imperative to assess integrity of the axillary nerve; impaired function heralds more urgency in reduction. Testing sensory distribution over the patient's deltoid can easily assess axillary nerve function.

In chronic instability, determining the direction of instability (anterior, posterior, inferior, or multidirectional) is needed so appropriate treatment options can be discussed with the patient. Joint laxity testing can be completed with any number of the following test: apprehension test, relocations test, sulcus sign, load and shift, and jerk test. Testing for associated labrum pathology should also be completed. Multiple examination techniques have been described and include dynamic sheer, passive distraction, biceps load, and O'Brien's [16, 17].

Imaging

Standard shoulder radiograph (AP, lateral, scapular Y) should be ordered with all shoulder traumas. Radiographs allow visualization of the direction of dislocation and associated fractures such as a Hill-Sachs or bony Bankart lesion.

Treatment

Reduction of the dislocated shoulder should be completed as soon as possible. Delayed treatment will allow the patient's shoulder musculature to spasm to the point where conscious sedation may be required to complete the reduction. Techniques for anterior shoulder reductions can be broken down into two broad categories: traction and leverage. Traction options include Hippocratic technique, Stimson technique, and scapular manipulation technique; Kocher's technique and Milch's technique are the two main leverage techniques. Stimson's method is a relatively nontraumatic technique that is easy to complete field side [19]. The patient should lie prone on an exam table or bench with the affected arm. Gentle downward traction is applied in order to facilitate the relaxation of muscles and spontaneous reduction [19]. Relocation of a posterior dislocation is done with patient supine. Traction is applied to the affected arm while forward pressure is applied to the humerus [16]. After reduction, the patient should then be immobilized in a sling for 2–4 weeks with early physical therapy. Positioning (internal rotation versus external rotation) of the arm during immobilization remains controversial [16, 19]. Surgical consultation for discussion of operative treatment options should be considered in a young athlete after his or her initial dislocation; risk of recurrent dislocation is approximately 90 % if initial event occurs prior to the age of 20 [16, 19].

Aggressive physical therapy with strengthening of the rotator cuff and scapular stabilizing muscle remains the mainstay to chronic instability. Bracing options are available but often limit the patient's range of motion too excessively. Surgical options are available for unidirectional anterior or posterior instability if conservative measures fail. Operative results for multidirectional instability have not mirrored those of unidirectional instability but can be discussed if the patient fails conservative management [16].

Biceps Tendon Rupture

History

Rupture can occur at three locations: long head origin within the labrum, short head origin on the acromion, and common distal insertion; the majority of ruptures occur at the insertion of the long head. The most common mechanism of injury involves the elbow being forcibly flexed against resistance. Tears can also occur after prolonged wear and tear to the tendon; most often, these patients will have an associated history of chronic shoulder pain and impingement on the affected side. With an acute rupture, the patient may describe an audible pop followed by gross deformity in the anterior arm with associated ecchymosis.

Physical Examination

With a proximal rupture, patients will be tender over the anterior shoulder along with associated swelling and ecchymosis. Flexing of the elbow will often show a "Popeye deformity" where the bicep will be more prominent over the middle of the humerus compared to the unaffected side. A small decrease in resisted elbow flexion and supination may be observed as well [17]. Distal bicep tendon rupture will present with swelling and ecchymosis over the antecubital fossa along with a lack of musculature over the distal humerus. A noticeable decrease in strength will be noted with Speed's and Yergason's test [20].

Imaging

Shoulder films or elbow films should be ordered depending on the site of tendon rupture to

evaluate for any associated bone injury. Distal tendon injuries should be further evaluated with MRI. Given the long tendon's origin within the labrum, patients with proximal injuries and associated shoulder pain/instability should undergo MRI arthrogram of the shoulder to identity any associated labrum injuries.

Treatment

Proximal bicep ruptures should be referred to physical therapy. If an associated labrum injury is found and the patient does not respond to physical therapy, referral to an orthopedic surgeon should be made. Referral to orthopedics should not be delayed for distal biceps rupture as definitive treatment is surgical and significant morbidity can be seen with delayed operative management [20].

Lateral Epicondylitis "Tennis Elbow"

History

Patients will regularly present with pain in the lateral elbow and upper forearm. The pain often begins after a recent increase in physical activities that require repetitive wrist extension and supination. Common inciting activities include weightlifting and racquet sports such as tennis, badminton, squash, or racquetball. Patients may also complain of decreased grip strength.

Physical Exam

Palpation will elicit point tenderness at lateral epicondyle and along the distal extensor carpi radialis brevis (ECRB) tendon. Resisted wrist extension, wrist supination, and third-digit extension will be painful. Decreased grip strength versus the unaffected side may be present also. Sensory exam should be normal. Radiation of pain from the lateral epicondyle into the proximal forearm and associated weakness with the above resisted testing should raise suspicion of an alternative diagnosis such as radial tunnel syndrome [21].

Imaging

Plain films of the elbow can evaluate for fracture, tendon calcification, osteochondral defects, or radial head arthritis. Ultrasound can help identify chronic tendinosis within the origin of the ECRB.

Management

The vast majority of lateral epicondylitis cases can be managed nonsurgically. Activity modification is a key component of treatment. Decreasing or stopping the instigating motions or modifying equipment such as using a wider grip on a tennis racquet can assist in managing symptoms. Physical therapy, NSAIDs, steroid injections, and counter load braces have been the mainstay of conservative treatment [20, 22]. Increasing evidence shows that prolonged lateral epicondylitis (greater than 4–6 months) is a tendinosis instead of tendinitis, thus calling into question the usage of NSAIDs and steroid injections in its management [21]. New treatment techniques such as dry needling, prolotherapy, topical nitroglycerin patches, and platelet-rich plasma (PRP) are emerging as treatment options [21]. Recalcitrant cases (greater than 18 months of symptoms without response) can be referred to orthopedics for possible operative debridement [22].

Scaphoid Fracture

History

The most common mechanism of injury involves a fall onto an outstretched hand (FOOSH injury). Patients describe pain along the radial aspect of the wrist, usually within the anatomic snuffbox. Wrist pain can be worsened with radial and ulnar deviation and with gripping activities.

Physical Exam

Swelling may be present over the anatomic snuffbox. Pain is reproducible with palpation of the anatomic snuffbox. Wrist active range of motion can be fairly normal but pain is reproducible at the extremes of wrist range of motion, especially with radial and ulnar deviation. Loading of the thumb's carpometacarpal joint will also elicit pain. Watson's test should be completed to evaluate for scapholunate dissociation. The assessment of median nerve function is needed to exclude associated injury.

Imaging

Initial imaging should include four views of the wrist: clinched fist PA, scaphoid, lateral, and oblique views. The scaphoid view puts the wrist in ulnar deviation and allows better visualization of the proximal scaphoid. The clinched fist view evaluates for scapholunate dissociation, with greater than 4 mm of space between the scaphoid and lunate being abnormal. If there is concern for scapholunate disassociation on initial films, a comparison view of the contralateral wrist should be obtained for comparison.

Management

Management depends on location of the scaphoid fracture given the bone's tenuous retrograde blood supply. Indications for orthopedic referral include greater than 1 millimeter (mm) of displacement, fracture comminution, scapholunate angle greater than 60°, scapholunate disassociation, and greater than 10° of angulation [23]. Successful healing with nonoperative treatment occurs in 100 % of distal third and tuberosity fractures, 80–90 % of waist fractures, but only 60–70 % of proximal fractures [23]. Early consultation with orthopedic surgery should be strongly considered in proximal third fractures because of significant morbidity from malunion, nonunion, and/or avascular necrosis (AVN) [24].

If the decision is made to treat the patient nonoperatively, the exact type of cast (short arm thumb spica versus long arm thumb spica) for the initial immobilization depends on fracture type. For each type, repeat imaging should be obtained every 2–3 weeks until radiographic union is observed. Nondisplaced distal fractures require 6–8 weeks for healing. Patients should be immobilized in a short arm thumb spica cast for 4–6 weeks. Additional time may be required if clinical union is prolonged. Middle third and distal third fractures should be immobilized with a long arm thumb spica cast for 6 weeks followed by a short arm thumb spica cast for an additional 6 weeks. Healing times for middle third/waist fracture range from 8 to 12 weeks, while proximal fracture healing usually requires 12–24 weeks. Due to the prolonged immobilization times required for most scaphoid fractures, patients will likely benefit from formal physical or occupational therapy to expedite a safe return to work or sports [23–25].

Patients will often present after a FOOSH injury but their initial imaging will be negative. If a scaphoid fracture is suspected, the patient should be immobilized in a short arm thumb spica splint or cast for 2 weeks with repeat films in 2 weeks time. If follow-up plain films are still negative, additional imaging with CT or MRI is indicated if clinical suspicion for a scaphoid fracture remains. Due to prolonged immobilization time, patients will likely benefit from formal physical or occupational therapy to expedite a safe return to work or sports.

Mallet Finger

History

The mechanism of injury occurs when the distal interphalangeal (DIP) joint that is being extended is suddenly forced into a flexed position. This commonly occurs when the patient is preparing to catch a ball.

Physical Exam

With the practitioner stabilizing the proximal interphalangeal (PIP) joint, the patient will be unable to fully extend his or her DIP joint. Providers should assess passive range of motion of the DIP as well. As with all finger injuries, the assessment of associated joint collateral ligaments, finger alignment, and possible rotational deformity should be assessed.

Imaging

A lateral x-ray view of the affected finger will identify bony avulsion and subluxation of DIP joint or be normal with a tendon avulsion injury.

Management

The majority of mallet finger injury can be managed conservatively. Indications for surgical referral include inability to adequately reduce the avulsed fragment, inability to obtain full passive extension of the DIP, and greater than 30 % of the articular surface of the DIP being involved [26, 27]. Conservative treatment consists of splinting DIP in full extension for 6 continuous weeks. Flexing of the DIP at any time, even with splint changes, will cause the 6-week clock to start over. After the initial 6-week period of splinting, an additional 6-week period of nocturnal and activity splinting should be completed. Multiple different splints are available for the treatment of mallet finger; a Cochrane Review concluded that no splint type was superior, but stressed the need for the splint to be robust enough for daily wear [28].

Jersey Finger

History

Forceful extension when trying to flex the DIP joint can be experienced by an athlete getting his or her finger caught in a jersey or when rock climbing. Seventy five percent of injuries involve the fourth digit.

Physical Exam

A patient will commonly present with pain along the palmar aspect of the DIP and the involved finger held in slight extension relative to the other. Although the patient may be able to weakly flex the DIP, it will be dramatically weaker than their unaffected fingers. It is imperative to isolate the DIP during testing to isolate the flexor digitorum profundus. Finger alignment and rotation should also be assessed [26].

Imaging

PA and lateral view radiographs of the involved finger can identify avulsed bony fragments or fractures.

Management

All jersey fingers require urgent referral to orthopedic surgery. Delay in referral can lead to flexor digitorum profundus retraction and subsequent surgical complications. The involved finger should be splinted in a flexor tendon splint and referred to an orthopedic surgeon as soon as possible [26].

Iliotibial Band Syndrome (ITBS)

History

ITBS is an overuse injury commonly seen in runners or cyclist. The patient can complain of pain anywhere along the IT band but most commonly will complain of lateral thigh or lateral knee pain. Proximal pain usually refers to over the greater trochanter of the hip, while distal pain localizes over the lateral femoral condyle or Gerdy's tubercle. The pain can usually be localized and reproduced with palpation. Often, the

patient has increased their training significantly in terms of mileage per week or intensity. Runners and bikers are especially prone to IT band problems due to the repetitive flexion and extension at the knee.

Physical Exam

Inspection of lower extremity anatomy can help determine if a person is predisposed to IT symptoms. Anterior pelvic tilt, genu varum, and excessive foot pronation leave the patient susceptible to chronic IT band irritation. Gait analysis may reveal a Trendelenburg gait – an indication of hip abductor weakness. Ober's test reveals IT band tightness, and the patient usually has a limitation of hip abduction. Additionally, these patients often have tight hamstrings [29].

Imaging

If pain is located distally, anterior-posterior, lateral, and sunrise radiographic views of the knee can reveal arthritic changes within the knee or patellar mal-alignment.

Management

Treatment of ITBS should focus on correcting underlying biomechanical causes of symptoms. Weakness in hip abductors, specifically gluteus medius, should be addressed; additionally, hip flexor, short hip external rotator, and hamstring flexibility and strength should be maximized. Excess foot pronation should be treated with shoe inserts. Appropriate weaning/breaking in of insoles should be discussed with patients. Activity modification including reduction in training mileage and/or intensity assists with initial symptom management. Changing training to a non-weight-bearing activity such as swimming or elliptical can help keep a patient motivated throughout their rehabilitation process while also curtailing the inflammatory process. Ice massage over Gerdy's tubercle and cross-frictional massage of the ITB are useful adjacent therapies. The patient will need to gradually return to activity as re-irritation of the IT band is very common. Once the patient is back to normal weight-bearing activities, it would be wise to incorporate a maintenance rehabilitation exercise program into their weekly workouts to prevent reoccurrence of symptoms [29].

Patella Dislocation

History

Significant pain and swelling are the most common complaints associated with patella dislocations. Common mechanisms of injuries include playing sports or dancing where repetitive knee valgus and lower leg internal rotation occur within a closed kinetic chain. Injuries may be from an acute event or from repetitive microtrauma. The dislocation resolves spontaneously with knee extension and the patients will often present post spontaneous reduction. History and complaint of recurrent sensation of patellar subluxation are the only other significant clinical clues.

Physical Exam

After an acute injury, a large knee effusion will be present. Significant hemarthrosis increases the chance that an osteochondral injury occurred [30]. An obvious deformity will be seen if relocation has not occurred. If relocation has recurred, the medial retinaculum and lateral femoral condyle are often tender to palpation. A positive patellar apprehension test will be noted, and laxity in patella movement will also be observed.

Imaging

Standard three-view knee films should be obtained to assess for fractures. If the exam does not ensure intact knee ligaments, then an MRI may be needed to look for associated ligamentous

or meniscal injury. MRI is indicated after an acute injury with significant hemarthrosis.

Management

In the event that the patella has not been relocated, reduction should be completed. To reduce the patella, flex the hip and apply a medial force to the patella while fully extending the knee. Immobilization of the knee in full extension for 3–6 weeks should occur after reduction. Controversy exists on surgical versus conservative management on primary traumatic patellar dislocation. Recent research does not show benefit to operative management after an initial traumatic injury. Palpable defects of the parapatellar ligament structures, recurrent subluxation on initial examination, and findings of osteochondral lesion on imaging are indications for referral to orthopedic surgery. Physical therapy can assist the patient in regaining full range of motion and address underlying quadriceps weakness to prevent recurrent dislocations or subluxations. Knee braces with patellar sleeves or lateral J brace can assist athletes in regaining confidence in their knee; however, there is a lack of evidence supporting this practice. After the first dislocation, patients have approximately a 50 % chance of recurrence. Patients with recurrent dislocations should be evaluated by an orthopedist [30].

Knee Ligament Sprain/Tears

History

The knee consists of four major ligaments; each has its own injury history and associated exam findings.

Anterior cruciate ligament (ACL): The ACL runs from its origin on the posteromedial aspect of the lateral femoral condyle to its insertion on the intercondylar tibial eminence (CJSM article); its main function is to prevent anterior translation of the tibia. ACL injuries most commonly occur without contact and occur with a sudden change in direction or pivot such as skiers and soccer players. This mechanism can occur with hyperflexion or hyperextension of the knee as well as when initiating or landing a jump. In contact sports such as football, injury of the ACL can occur in association with MCL and medial meniscus injuries, "unhappy triad," after a valgus force is applied to a planted foot. The patient may report a "pop" sensation followed by significant swelling. Delayed presenters complain of a feeling of instability or "giving way" of the knee. Female athletes are at a higher risk for ACL injuries compared to male athletes secondary to an increased Q angle and quad/hamstring muscle imbalance and decreased knee and hip flexion with landing and hormone status [32].

Posterior cruciate ligament (PCL): The PCL runs from the posterior tibia to its insertion on the anteromedial aspect of the medial femoral condyle; the main function of the PCL is to prevent posterior translation of the tibia. PCL mechanism of injury is hyperextension from a posterior force or hyperflexion with plantar flexion of the ankle. The classic mechanism of injury is a dashboard injury of the knee during a motor vehicle accident. The most common complaint from the patient is instability of the knee.

Medial collateral ligament (MCL): MCL injury is a result of a lateral force to the knee that creates a valgus stress. Patient's will complain occasionally of instability but will most often complain of swelling and pain along the medial joint line.

Lateral collateral ligament (LCL): LCL injury is uncommon, but when it does occur is often associated with a PCL injury. Excessive anteromedial knee force when the knee is fully extended can stress the LCL. Patients will sometime complain of lateral leg numbness and weakness with ankle dorsiflexion secondary to associated perineal nerve injury.

Physical Exam

ACL: Examination for potential ACL injury is best done immediately after the suspected injury before subsequent hemarthrosis and muscle guarding limit your examination. Significant

knee effusion will occur within hours of injury. The most accurate diagnostic test of an ACL injury is the Lachman test with a sensitivity of 85 % and specificity of 94 % [33]. Anterior drawer test is not as reliable and can be falsely positive secondary to a PCL injury. Meniscal integrity should also be checked as significant ACL tears have associated meniscus tears.

PCL: Examination will show an effusion and tenderness within the popliteal fossa. Posterior drawer is the assessment of choice. If posterior drawer test is positive, Dial's test should be completed to evaluate for posterolateral corner (PLC) injury. Positive MCL/LCL testing at full extension is also suggestive of a PCL injury.

MCL/LCL: Assess for laxity in these ligaments with the knee in full extension and at 30° of flexion with varus and valgus stress testing. Generally, these patients have less swelling and instability, rather complain of pain over the ligament, and have an appropriate mechanism of injury.

Imaging

X-rays should be obtained to assess for fractures. MRI is indicated in suspected ligament or meniscal tears.

Management

ACL: Initial management includes rest, ice, compression, and elevation (RICE) along with crutch and brace usage. Weight bearing should be avoided early on as ACL is often associated with significant bone contusions. A range of motion exercises should be started as soon as pain allows. Referral to orthopedics for discussion of operative should be made but is not emergent as surgery is often delayed 3–6 weeks to allow resolution of hemarthrosis.

PCL: Surgical management is deferred unless other associated injuries such as a posterolateral corner injury occurred. Early range of motion and quadriceps strengthening should be encouraged for grade 1 and 2 injuries. Grade 3 injuries respond to immobilization in knee brace for a few weeks followed by formal physical for 3–4 months. Surgical referral should occur if the patient fails conservative management [31].

MCL/LCL: Initial management includes RICE and physical therapy. Grade 3 injuries should be evaluated by an orthopedist, as they are often associated with other soft tissue injuries such as meniscal, PCL, or PLC injuries.

Meniscus Tear

History

A meniscus tear occurs from a traumatic forceful twisting or hyperflexion of the knee. Meniscal injuries are also associated with other traumatic injuries such as ACL and PLC injuries. Patients may complain of mechanical symptoms such as their knee locking or buckling. Swelling after an acute injury presents 48–72 h after the trauma; however, most meniscus injuries are secondary to chronic microtrauma and will have minimal swelling.

Physical Exam

Joint line tenderness is the most common finding on examination. Specialized tests including McMurray test, Apley's Compression test, and Thessaly test can assist in diagnosis.

Imaging

Knee x-rays should be obtained to assess for associated fracture especially in the acute setting. If surgical intervention is being considered, then an MRI is warranted as it is 93 % sensitive and 95 % specific for evaluation of meniscal tears [34].

Management

Rest, ice, activity modification, and physical therapy will treat most chronic meniscal injuries. Steroid injections can be considered to assist in pain

management during physical therapy. Failure to progress with physical therapy and chronic tears that cause true mechanical symptoms should be referred to orthopedics for discussion of operative management. Acute traumatic meniscus injuries often require operative management.

Achilles Tendon Rupture

History

With Achilles tendon rupture, a patient will complain of a sudden pop or snap sensation in their posterior ankle followed by significant pain. Basketball players describe the sensation of someone stepping on their heel.

Physical Exam

Significant ecchymosis will be present over the posterior lower leg. A palpable defect may be palpated over the distal Achilles tendon. Thompson test is the diagnostic test of choice. To complete the test, the patient is placed in the prone position, the knee flexed to 90°, and the gastrocnemius is squeezed. In a negative test (no full substance tear) the patient's foot will plantar flex. With a partial tear, the Thompson test may be positive or negative [35].

Imaging

MRI is the imaging modality of choice. MSK ultrasound is another imaging option.

Management

Initial management includes splinting with a posterior splint with the ankle in plantar flexion. All patients need referral to orthopedic surgery for discussion of definitive management.

Achilles Tendinopathy

History

As with other tendon injuries discussed in this chapter, injuries can range from an acute inflammatory process (tendinitis) to a chronic injury with dysfunctional tendon healing (tendinosis). Patients will complain of pain in their distal Achilles at its insertion at the calcaneus or 3–5 cm proximal to the insertion [36]. Pain often worsens with sudden acceleration, jumping, prolonged walking/jogging, or with calf stretches. A history of recent change in exercise intensity or style of training will sometimes be expressed as well.

Physical Exam

Little to no swelling will be seen on exam. A patient will be tender to palpation along the distal Achilles tendon. Occasionally, nodules will be palpated over the distal Achilles as well. Limited ankle dorsiflexion will be noted secondary to tight gastrocnemius/soleus complex. Pes planus can also be seen on exam.

Imaging

No imaging is indicated, as this is a clinical diagnosis. If the clinician is concerned about a possible partial tendon tear, MRI can be considered.

Management

Treatment depends on the location of symptoms. Initial management includes RICE and activity modification. Heel lifts should be added to the patient's shoes along with ensuring the underlying pes planus is addressed with appropriate orthotics. Very good evidence exists for the treatment of mid-substance tendinopathy with intense eccentric rehabilitation programs. Unfortunately, insertional tendinopathy is more difficult to treat. Eccentric rehabilitation protocols can be

attempted but have not been as successful as with mid-substance disease. If the patient fails to demonstrate any improvement with conservative treatment and a short course of therapy, immobilization in a walking boot with heel lift is often needed for 4–6 weeks prior to reinitiating eccentric rehabilitation. Steroid injections should be avoided in the management of Achilles tendinopathy given the associated increase in tendon rupture [35, 36].

Ankle Sprains

History

Ankle sprains can be broken down into lateral, medial, or syndesmotic "high ankle" sprains. Lateral injuries occur when a plantar-flexed ankle is inverted. Inversion injuries will most commonly damage the anterior talofibular ligament (ATFL). This type of injury is common in basketball, soccer, or football. Medial ankle injuries are not common and involve eversion of a plantar-flexed foot. This mechanism leads to injury to the deltoid ligament and will often lead to lateral malleolus fractures. High ankle sprains occur when a hyper dorsiflexed ankle is forcibly externally rotated. This type most commonly occurs in football and will damage the anterior interior tibiofibular ligament (AITFL). Disruption of the AITFL can lead to disruption of dense connective tissue between the tibia and fibula, i.e., syndesmosis. For all the types of injuries, the patient will often complain of immediate pain, swelling, ecchymosis, and difficulty with ambulation.

Physical Exam

On inspection of the ankle, significant ecchymosis and effusion will often be present with all types of ankle injuries. Limited ankle range of motion will also be seen. Palpation should occur over the bony landmarks of the Ottawa ankle rules; these landmarks include the posterior aspect of the distal one third of the distal lateral malleolus, posterior aspect of the distal one third of the medial malleolus, navicular bone, and base of fifth metatarsal. Palpation over the main ligaments of the ankle (ATFL, AITFL, calcaneofibular ligament (CFL), posterior talofibular ligament (PTFL), and the deltoid ligament). Tenderness over the ATFL is often found on lateral ankle injuries.

Several special tests exist for the ankle. The anterior drawer test and the talar tilt test can be used to assist the diagnosis of lateral ankle sprains. For high ankle sprains, the external rotation test, tenderness over the AITF, and the squeeze test should be done to confirm diagnosis.

Imaging

Initial examination in an ankle injury should include evaluation of the ankle for the need to obtain an x-ray. This can be done using the Ottawa ankle rules which help to reduce the number of unnecessary x-rays by 30–40 % [37]. The Ottawa ankle rules have been validated for a patient as young as age 5 and demonstrate almost 100 % sensitivity [38]. X-rays are indicated if any of the following five physical exam findings are present:

- Inability to bear weight for four steps immediately after the injury or in the exam room
- Bony tenderness over posterior aspect of the medial malleolus
- Bony tenderness over posterior aspect of the lateral malleolus
- Bony tenderness over base of the fifth metatarsal head
- Bony tenderness over the navicular

Standard plain films of the ankle should include AP, lateral, and mortise views. The mortise view is essential to evaluate ankle joint stability in syndesmotic injuries and lateral malleolus fractures. Providers should consider obtaining additional plains of the proximal tibia and fibula on high ankle sprain patients with a positive squeeze test to evaluation for a possible Maisonneuve fracture of the proximal fibula.

Management

Grade 1 and 2 lateral and medial ankle sprains should be treated with rest and ice. A range of motion exercises or formal physical therapy should be initiated within the first 48 h. These injuries will typically heal in 1–4 weeks. Grade 3 injuries may require 5–7 days in a CAM boot until full weight bearing is tolerated. In the rehabilitation period following, a semirigid or lace-up brace should be worn. Grade 3 injuries can take 5–8 weeks to heal and require up to 6 months for full rehabilitation [37, 38]. Significant medial ankle injuries can take several months to fully rehabilitate. Surgical referrals to orthopedics should be reserved for chronic pain, chronic instability, and inability to return back to previous functional level after an appropriate rehabilitation course. Consideration should be made for athletes to wear a lace-up ankle brace with Fig. 8 straps after returning to competition [37, 38].

High ankles sprains require additional immobilization compared to lateral sprains. Immobilization in a walking boot for 3–4 weeks with progressive increase in weight bearing is often needed. Formal physical therapy should begin immediately after injury. Return to athletics can take anywhere from 4 to 8 weeks depending on severity of injury. Providers must ensure that the patient's plain films did not demonstrate a widened mortise, as this indicates an unstable ankle joint and will require surgical fixation.

Proximal Fifth Metatarsal Fracture

History

A patient will either describe an acute injury from an inversion injury or blunt trauma or a history of dull pain with sudden increase in pain. The most common mechanism of injury is adduction of the foot while in plantar flexion. This can occur from a direct force to the lateral side of the foot and/or landing on the side of the foot after stumbling. A good history is imperative as acute fractures and stress fracture that evolved into occult injuries require different durations of treatment.

Physical Exam

Weight bearing will often be difficult. Patients will generally have pain over the lateral border of the forefoot, exaggerated with weight bearing. Resisted foot eversion will increase pain. Point tenderness at the site of the fracture will be present.

Imaging

Standard AP, lateral, and oblique radiographs of the foot are usually sufficient. If fracture is identified on ankle films, a dedicated foot series needs to be completed as well. CT or MRI should be considered in the setting of delayed healing or nonunion.

Management

Treatment depends on the fracture location. Proximal fifth metatarsal fractures are subdivided into zone 1, zone 2, and zone 3 injuries. Zone 1 injuries are avulsion injuries that occur at the styloid. Zone 2 fractures occur at the metaphyseal-diaphyseal junction, while zone 3 fractures occur in the proximal diaphysis [39].

Zone 1 fractures occur in a well-vascularized region and heal without difficulty with conservative management. Treatment focuses on allowing patient to ambulate without pain. Treatment options include a hard-soled shoe or a CAM walking boot for 3–4 weeks. Zone 2 injuries are also known as Jones fractures. Malunion and nonunion complications can occur with both operative and nonoperative management, approximately 20 % with each [40]. Conservative management includes 6 weeks of non-weight bearing in a short leg cast followed by 6 weeks in a weight-bearing short leg cast. After 12 weeks of immobilization, the patient can be transitioned into a CAM walking boot or lace-up ankle brace depending on radiographic and clinical healing. Lack of radiographic healing at 12 weeks should raise concern for malunion, and the patient should be referred to orthopedics for discussion of

operative management. For elite competitive athletes, initial treatment with surgical screw fixation followed by 6 weeks of weight bearing in a short leg cast is another option; however, this method does not remove the risk of malunion and nonunion. The treatment for zone 3 fractures is the same as zone 2; however, more prolonged immobilization may be required for chronic stress injuries that evolved into occult fractures. Total healing times of 18–24 weeks is not unheard of in this type of injury. As with zone 2 injuries, regular radiographic monitoring is needed to evaluate for healing complications.

General Principles

Epidemiology

In 2014 more than one-third of adults (78.6 million) in the United States of America (USA) were obese with annual costs for obesity estimated at $147 billion in 2008 US dollars [1]. The overall prevalence of obesity in the USA doubled between 1994 and 2014, and the prevalence of extreme obesity rose from 3.9 % to 6.6 % between 2000 and 2010 [2]. Childhood obesity has more than tripled in the last 40 years from 5 % between 1963 and 1970 to 17 % in 2003–2004, although the rate has stabilized in children in the last decade [1, 3]. Obesity rose from a prevalence no greater than 14 % in any state in 1990 to no state having a prevalence less than 20 % in 2010, with the national average at 34.9 % [4] (Fig. 1). This rapid increase has led to an alarm of an "obesity epidemic." In 2013 the American Medical Association initiated designation of obesity as a disease "requiring a range of medical interventions to advance obesity treatment and prevention" and "help change the way the medical community tackles this complex issue" [5].

Racial and socioeconomic disparity in obesity rates is clearly evident in children, adolescents, and adults. Among US adults, non-Hispanic blacks have the highest age-adjusted rate of obesity (47.8 %), followed by Hispanics (42.5 %), non-Hispanic whites (32.6 %), and non-Hispanic Asians (10.8 %) with a similar racial trends in

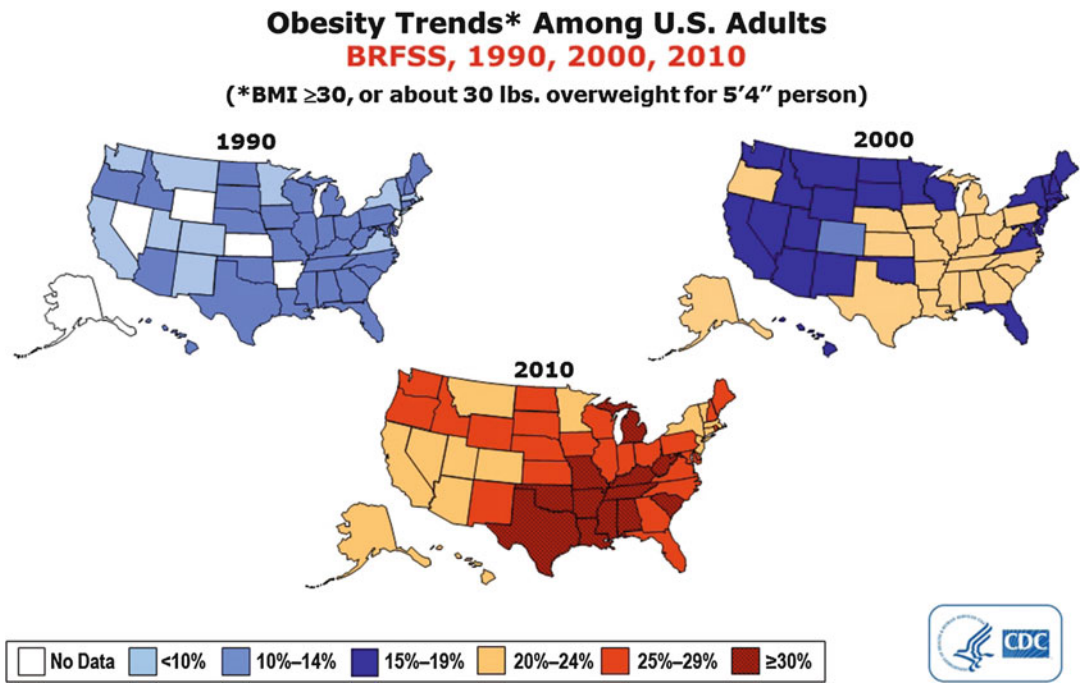

Fig. 1 Prevalence of obesity (BMI $\geq$ 30 kg/m^2) among US adults ages from 1990 to 2010 [4]. CDC's Obesity Prevalence maps, available at: http://www.cdc.gov/obesity/data/prevalence-maps.html. Abbreviations: *BMI* body mass index

children and adolescents except that Hispanic youth have a greater incidence of obesity than non-Hispanic black youth (22.4 % vs. 20.2 %) [1]. Income and educational status have both been associated with trends in obesity, but the specific effects vary between races and gender. These medical disparities highlight the need for individualized treatment plans that factor in cultural and social realities.

Effects

Obesity has long been known to be associated with or increase the risk of developing many of the most common chronic diseases (see Table 1) and has been shown to increase risks of both cardiovascular disease (CVD) mortality and all-cause mortality [6].

The converse is also true in that even a modest weight loss of 3–5 % has been found to improve outcomes for some cardiovascular risk factors including progression of diabetes and hypertension, with larger weight loss resulting in greater benefits [6].

Definition

Obesity is a disease condition of excess body fat that may put a person at health risk [1, 7], but in reality percentage body fat is a difficult thing to measure. Thus, worldwide the definition of obesity is based on body mass index (BMI). Population studies have consistently shown that when BMI is viewed as a continuous variable, all-cause mortality steadily increases above a BMI of 22 kg/m^2, and recent guidelines support the current cut points for defining overweight and obesity [3, 8]. BMI is calculated by dividing a patient's weight in kilograms by their height in meters squared (kg/m^2). Simple web-based calculators and apps are widely available, and most

EMRs are now configured to automatically calculate BMI from the height and weight values.

In adults, obesity is diagnosed in those with a BMI over 30. Overweight and obesity are subdivided as follows: BMI 25–29.9 (overweight), BMI 30–34.9 (class I obese), BMI 35–39.9 (class II obese), and BMI > 40 (class III obese or "extreme obesity") [6]. In children, obesity is based on BMI percentile in reference to CDC growth charts. High BMI in children has been found to predict future adiposity, morbidity, and death leading to recommended diagnostic terminology of children being "overweight" when their BMI is between 85th and 94th percentiles and "obese" when their BMI is at or above the 95th percentile [3].

Etiology

Obesity is the result of a chronic imbalance between energy intake and energy expenditure leading to the storage of excess energy as fat, primarily in white adipose tissue [8]. However, the underlying reasons for this imbalance are multifactorial and complex and include genetic makeup, cultural beliefs, environment, habits, physical activity, dietary intake, and occupation [7, 8]. Contrary to social stigmatization, evidence supports that obesity is not simply a problem of the lack of willpower or self-control, but stems from a disordered regulation of appetite and energy metabolism associated with a variety of comorbid illnesses [7].

Weight homeostasis involves a complex and redundant neurobiological system with signaling primarily between the central nervous system,

adipose tissue, and the gastrointestinal (GI) system to regulate metabolic rate and drive eating behavior [8]. Recent research has focused on peripheral signaling hormones that seem to promote satiety or decreased food intake in hopes of designing therapies to combat obesity or assist with weight maintenance. Anorexigenic hormones secreted from the GI system (cholecystokinin (CCK), pancreatic polypeptide, peptide tyrosine-tyrosine (PYY), glucagon-like peptide-1 (GLP-1), and oxyntomodulin) and adipokines (leptin, adiponectin) produced by white adipose tissue are potential candidates. Research has uncovered that most markers of satiety are reduced and most measures of appetite enhanced in patients who have lost weight, which partly explains the difficulty patients experience in sustaining weight loss [8].

Yet, while "nature" plays a clear role, "nurture" is also at work. The demographics in western societies have shifted over the last half century from that of a largely rural population frequently involved in manual labor to a heavily urban demographic with more sedentary lifestyles. Compounding this are vast changes in food – both in quantity and in kind. Highly processed foods have become widely available and some of the lowest costing foods are calorie dense and contain high levels of fat, sugar, and salts.

Diagnosis

History

Obesity is overwhelmingly a primary process: imbalance of caloric intake to caloric expenditure. As noted, there are myriad reasons for this imbalance, but elucidation of individual factors can be an intensely sensitive topic. Review of a patient's weight trajectory plotted over time, typical caloric intake, and typical physical activity can be used to guide initial work-up of obesity and subsequent office-based recommendations. Further insights can be gleaned when the patient annotates significant life occurrences (i.e., employment changes, tobacco cessation, end in a relationship, etc.) on the weight trajectory timeline. Ideally, patients complete oral intake diaries recording all beverages, meals, snacks – anything a patient puts in their mouth – as well as daily physical activity including the time.

As obesity usually derives from a primary etiology, work-up for secondary causes of obesity in adults should be based on specific symptoms or risk factors coupled with a physician's index of suspicion. Medications should be reviewed for potential obesogenic medications as some common drug classes are clearly associated with weight gain including atypical antipsychotics, anti-depression medications, and diabetic medications. History should ensure there is no comorbid psychiatric illness leading to weight gain such as eating disorders, depression, or body dysmorphia, and in women a detailed menstrual history should be obtained to evaluate for polycystic ovarian syndrome.

Physical Exam

Appropriate height and weight are paramount in children and adults alike. Additional screening of waist circumference in adults with a BMI between 25 and 35 may be undertaken as such individuals have an elevated CVD-related and overall mortality if their waist circumference is $>$102 cm (~40 in.) for males and 88 cm (~35 in.) for females [6]. Measuring waist circumference when BMI is greater than 35 is generally not indicated as such patients can be expected to have increased waist sizes. Physicians should also have a keen eye for physical markers associated with the uncommon causes of secondary obesity including acanthosis nigricans, goiter, moon faces, buffalo hump, central obesity, striae, and hirsutism.

Additional Testing

Most lab testing is geared toward evaluating for comorbidities of obesity rather than ruling out causes. Screening for impaired fasting glucose or frank diabetes (fasting glucose), nonalcoholic fatty liver changes (AST/ALT), and dyslipidemia to complete cardiovascular risk assessment (lipid

panel) is appropriate at least biannually starting at age 10 [3]. While thyroid disease is associated with obesity, TSH is of limited benefit even in adults and is not recommended as a screening test in the pediatric population. In the pediatric population, lab tests ought be performed only in those with short stature (<5th percentile), developmental delays, dysmorphic features, or who have clear signs or symptoms of underlying endocrine abnormalities especially as cortisol, and TSH levels are often elevated in children with obesity [9].

Treatment Plan

In 2013, a seminal Guideline for Management of Overweight and Obesity in Adults was authored collaboratively between the American College of Cardiology (ACC), the American Heart Association (AHA), and The Obesity Society (TOS) and includes an evidence-based treatment algorithm with recommendations on the management of patients with overweight and obesity. After diagnosis of obesity, or overweight with comorbidities, physicians are encouraged to assess for patient willingness to change. Once patients are committed to weight loss, a "high-intensity comprehensive lifestyle intervention" becomes the cornerstone of therapy – with or without adjunct use of pharmacotherapy or surgery [6]. Such an intervention is defined as being greater than or equal to 14 face-to-face sessions in a 6 month time frame and includes three principle components: a moderately reduced calorie diet, an increased physical activity program, and the use of behavioral strategies to better comply with the diet and exercise programs [6].

Dietary Management of Overweight and Obese Patients

In today's targeted consumer-based market, new diets appear almost every season claiming to be more effective than their predecessors. Certain diet plans focus on altering macronutrients, while others emphasize creating a negative energy balance through cutting overall calories. Combination plans combine diet type (i.e., low carbs) with behavior interventions, such as group meetings, calorie counting, or food journals. Patients often want quick results which are often impractical, lead to treatment failures, and cause patient dissatisfaction.

Recent meta-analysis of 48 original RCTs showed overweight and obese adults randomized to any popular diet or meal replacement plan lost significant weight at 6-month and 12-month intervals (approx. 8 and 7 kg, respectively), on any low-carbohydrate or low-fat diet [10]. Thus, the landmark 2013 guidelines by the ACC/AHA/TOS encourage physicians to recommend a weight-loss diet based on patient adherence rather than the diet type [6]. A daily energy deficit of greater than 500 kcal can usually be accomplished with 1,200–1,500 kcal/day for women and 1,500–1,800 kcal/day for men, but very low-calorie diets (800 kcal/day) should be confined to patients within a medical care setting where close medical monitoring and high-intensity lifestyle interventions are available [6].

There may be benefits to a diet beyond weight loss, and dietary composition may affect cardiovascular biomarkers (triglycerides, HDL cholesterol, glucose, and insulin) [11], whether through loss of adipose tissue or an independent mechanism. Data published over the last decade touted that Mediterranean-type diets – those rich in nuts, whole grains, vegetables, poultry, and fish instead of red meats – may help patients achieve better glucose or insulin control. However, a 2014 systematic review showed no difference between diet types (low carbohydrate vs. isoenergetic balanced) in overweight and obese adults when it came to preventing or reducing cardiovascular risk factors (blood pressure, lipids, and fasting blood glucose) [12].

Exercise

Patients often resort to increased physical activity and binge exercise as a weight-loss tool, but data shows that these measures only result in modest weight loss, even over the long term. Moderate

intensity aerobic exercise programs have been shown to net participants 1.7 kg (3.7 lbs) weight loss versus controls over 12 months, and exercise also increases weight loss in those dieting by an additional 1.1 kg (2.4 lbs) [13]. Exercise of any intensity can improve cardiovascular outcomes and metabolic profiles, but results vary for each patient and activity. Similar to recommending a diet, family physicians should encourage patients to partake in activities of moderate intensity that are enjoyable and those to which the patients will adhere.

Pharmacological Management of Obesity

There are several pharmacological agents approved by the Food and Drug Administration (FDA) for use in the short- (<12 weeks) and long-term (>52 weeks) management of obesity. Such agents have various targets and mechanisms of action and include two new medications approved by the FDA in 2012. Physicians should view medications as adjunctive therapy to other interventions, started when initial management strategies including diet, exercise, and intensive behavior therapy fail to yield clinical results. Weight-loss drugs have a long and tarnished history, with many drug recalls and associated adverse events, especially increased cardiovascular risks. Pharmacotherapy should be discussed with patients as early as at the first encounter, including various options, side effects, and any associated adverse events. As with any other therapeutic interventions, physicians need to monitor compliance, respond to treatment, and manage expectations carefully. Significant weight loss can take over a year, and most patients will regain some weight after an initial period of response.

Pharmacotherapy alone is not more effective than diet and exercise; however, when used as adjuvant therapy, physicians and patients can expect to see significant results over the long term. Table 2 summarizes agents currently approved by the FDA for weight loss, along with dosing info, weight-loss results, and most commonly reported adverse events.

Surgical Management of Obesity

Surgical treatment for obesity has been around since the 1950s when it was incidentally discovered that procedures resulting in restriction, size limitation, or malabsorption syndromes of the gut (i.e., gastric and bowel resections) led to postoperative weight loss over both the short and long term. These surgeries were initially considered too risky for obesity management due to high rates of complications and significant morbidity and mortality. The field was transformed in 1991 after the NIH Consensus Conference concluded that vertical banded gastroplasty and Roux-en-Y gastric bypass procedures were safe and effective treatment options for morbidly obese patients (BMI > 40 or BMI > 35 with comorbidities present) [23]. The consensus statement, along with the rise of laparoscopy in the early 1990s, led to standardization and advent of safer techniques.

Clinical evidence demonstrates that surgical treatment of obesity results in greater weight loss than any other conventional pharmacological treatment or lifestyle modifications, including diet, exercise, and intensive behavior therapy [24]. The Swedish Obese Subjects (SOS) study showed long-term mortality was lower in the surgical group (>10 year) [25], and several large randomized trials have shown superior efficacy of bariatric procedures for treating T2DM and inducing remission at 2 years [3]. Observational data has shown improvement in quality of life and a decrease in the incidence of diabetes and certain types of cancer [26].

A 2013 meta-analysis directly comparing bariatric surgery with nonsurgical treatments (lifestyle modifications including diet, exercise, and various pharmacotherapy) for obesity concluded that surgical treatment leads to greater body weight loss and higher remission rates of T2DM and metabolic syndrome [27]. This review included 11 trials and looked at the most commonly used open and laparoscopic techniques: Roux-en-Y gastric bypass (RYGB), adjustable gastric banding (AGB), sleeve gastrectomy (SG), biliopancreatic diversion, or biliopancreatic diversion with duodenal switch. Most common adverse events were anemia (iron deficiency) and reoperations [27]. For the best

Table 2 FDA-approved pharmacotherapy for obesity management

	DRUG[(FDA Approval)] *TRADE NAME*	PHARMACOLOGY / DOSING	TOTAL (PLACEBO SUBTRACTED) WEIGHT LOSS & EFFECTS	SIDE EFFECTS[A]
Long-Term (>52 wks)	**Lorcaserin** (2012) *Belviq ©*	Selective 5-HT2C receptor agonist 10mg PO BID	4.5% (3%) after 1 year[14,15] Decrease in BP[16] Decrease in LDL & HgbA1C Appetite suppression	Headache[17] Nausea Fatigue Dizziness URI/Nasopharyngitis Cardiovascular Risk? [B]
	Naltrexone-bupropion SR (2014) *Contrave ©*	Opioid receptor antagonist; DA/NE reuptake inhibitor 8/90 mg ER titrated up to 2 tabs PO BID	6.5% (4.6%) after 1 year[18,19] Reduced food intake Decreased visceral fat and waist size	Nausea Headache Constipation Sleep disturbance Anxiety
	Orlistat (1999) *Xenical ©* *Alli © (OTC - 2007)*	Lipase inhibitor 120mg PO TID (RX) 60mg PO TID (OTC)	11% (5%) after 1 year 6.9% (2.8%) after 4 years[14] Decrease in LDL cholesterol & HgbA1C Prevention of Type II DM (37% RR reduction)	Flatus with discharge[17] Oily spotting Fecal urgency/incontinence Steatorrhea Fat-soluble vitamins deficiency **Approved for use in adolescents**
	Phentermine/Topiramate ER (2012) *Qsymia ©*	Sympathomimetic / anti-epileptic; exact MOA unknown High Dose: 15mg/92mg ER PO QAM Low Dose: 7.5/46mg ER PO QAM	10.9% (9.3%) at 56 weeks for High Dose[20] 5.1% (3.5%) at 56 weeks (Low Dose) Decrease Systolic & Diastolic BP Decrease in LDL and triglycerides	Paresthesia[19,20] Dry mouth Constipation Dysgeusia Insomnia Mood & cognition related events were reported more frequently in High-Dose treatment group
Short-Term	**Phentermine** (1959) *Adipex-P ©; Fastin ©; others*	Appetite suppression via sympathomimetic action 15mg - 37.5mg PO ONCE DAILY	Paucity of long term trial data to establish weight-loss compared to baseline	*CNS:* insomnia, elevation in heart rate, dry mouth, taste alterations, dizziness, tremors, headache, anxiety, and restlessness *GI:* diarrhea, constipation, and vomiting
Novel Agents	**GLP1-Receptor Agonist** *Liraglutide © - approved for T2DM*	Appetite suppression via GLP1-R agonism *Dose ranges in Phase II / III trials* 1.8mg to 3mg PO ONCE DAILY	8% (5.4%) after 1 year[16] Improvement in plasma glucose[16] Decrease in systolic BP Decrease in triglyceride concentration	Nausea[16] Vomiting Constipation Diarrhea Headache Unclear association with pancreatitis
	Peripheral MetAP2 Inhibitors *Beloranib © (Phase III)*	Peripheral inhibition of angiogenesis in adipose tissue; stimulates energy expenditure, fat utilization, and lipid excretion[21] 0.9 mg/m2 IV TWICE WEEKLY for 4 weeks	3.5% (2.9%) after 4 weeks[21] Appetite suppression[21] Decrease in Triglyceride concentration Decrease in CRP levels	Headache; infusion site injury; nausea; diarrhea

A) In order of frequency reported in randomized trials.
B) Valvulopathy-rates, as seen on echocardiography, were similar in treatment and placebo group at 1 year but FDA has requested a post-approval trial to see long term cardiovascular effects.[16,22]

[a]In order of frequency reported in randomized trials
[b]Valvulopathy rates, as seen on echocardiography, were similar in treatment and placebo group at 1 year, but FDA has requested a post-approval trial to see long-term cardiovascular effects [16, 22]

outcomes, it is recommended that patients be sent to specialty hospitals that perform high volumes of bariatric cases annually.

RYGB has a greater cardiovascular mortality risk reduction and leads to much greater weight loss compared to AGB at 2 years but has a higher risk of short-term (30 days) complications [28]. Some high-volume bariatric surgery centers are able to achieve similar weight loss at 2 years following either ABG or RYGB [P24]. AGB may appear to have a lower rate of short-term risk, but the procedure has a rate of band removal as high as 50 % due to "failure to achieve or maintain clinically significant weight loss; band malfunction, slippage, or erosion; or patient intolerance of the gastric restriction" [29].

Although SG is fast becoming one of the most common bariatric procedures [30], there is limited long-term outcomes data; ongoing trials are expected to yield results in the near future on long-term outcomes data [24]. A Cochrane Review© published in 2014 showed similar

weight-loss results (based on BMI at 2-year follow-up) after either SG or RYGB [28]. Endoscopic techniques are a novel treatment option in the past few years, but again there is a paucity of outcomes data at this time. Endoscopic sleeve gastroplasty (ESG), which aims to reduce gastric volume via placement of full-thickness sutures, showed weight loss of 30 % in 10 patients at 6 months, with no significant adverse events [31].

A big challenge for the primary care physician is deciding when to refer a patient to a surgeon for this invasive and life-altering treatment. As with any other surgical treatment, patients need to be made aware of all the risks and benefits and both short- and long-term complications. There is limited long-term data on aspects of bariatric surgery not related to weight loss, including mental health and reproductive outcomes, or for long-term management of complications due to weight loss [15]. Patients having undergone bariatric surgery are advised long-term follow-up and ongoing nutrition and lifestyle management to monitor for any nutritional deficiencies [29].

Prevention

In obesity, an ounce of prevention may well be worth more than a pound of cure given the clinical realities experienced by those trying to lose and maintain weight loss, not to mention the potential risks of medication or bariatric surgery. A focus on promoting healthy weight in those who are normal weight or overweight may be a more profitable strategy, especially when focusing on children. Family physicians can leverage their understanding of the familial realities in helping individual patients and their families arrive at healthful lifestyle measures that will prevent obesity. Consistent evidence supports family physicians recommending limiting consumption of sugary beverages, limiting screen time (2 h max in children over age 2), limiting eating out, limiting portion size, promoting regular consumption of breakfast, and promoting eating family meals together [3].

Care of the Difficult Patient

Mark Ryan*
Department of Family Medicine and Population Health, Virginia Commonwealth University School of Medicine, Richmond, VA, USA

General Principles

Definition/Background

Although the chapter title and some of the references included here will use the phrases "difficult patient" or "frustrating patient" – or even "hateful patient" – it should be made clear that this is not the author's preferred term. Any doctor/patient interaction by definition involves at least two parties, both of whom have personalities, preconceptions, and prior experiences that are incorporated into current interactions. Difficulties in physician/patient interactions also incorporate patient, physician, and healthcare system factors [1]. For these reasons, phrases such as difficult or challenging patient interactions are preferred.

Epidemiology

Family medicine physicians in the United States account for more than 214 million office visits yearly [2]. It is estimated that 15–37 % of physicians' patients can be described as frustrating or difficult [3, 4]. It is clear, then, that in any given year, family physicians will encounter a large number of patients with whom they will have difficult, frustrating, or challenging interactions.

Approach to the Patient

To discuss difficult patient interactions, it is important to first discuss the characteristics of a therapeutic doctor/patient relationship. According to the AMA's *Journal of Ethics*, "a patient-physician relationship is generally formed when a physician affirmatively acts in a patient's case by examining, diagnosing, treating or agreeing to do so." Once a physician agrees to take on this role, the physician then owes that patient a duty to continue to treat them or to properly end the relationship [5]. Physicians are expected to provide their expertise via their sapiential authority (their medical training and competence), their moral authority (their concern for and obligation to the patient), and their charismatic-empathic authority (their emotional connection and care for their patients) [6]. Physicians must approach patients with inclusion, characterized by personal engagement, and availability, an openness to learn about others' experiences [7].

From the patient perspective, patients want physicians to help orient them to visits, to assess their understanding and preferences, and to engage in meaningful discussions [8]. Patients identified physician communication, respect for the patient, sympathy, empathy, patient-centeredness, and shared decision-making as important elements that were sought in doctor/patient interactions [9].

The value of effective doctor/patient relationships includes improved trust, commitment and adherence to care recommendations [10], and effective relationships result in improved healthcare outcomes including biomedical markers, behavioral outcomes, and improved communication between physicians and patients [11, 12].

DOI 10.1007/978-1-4939-0779-3_61-1

Although "difficult patients" will differ in their specifics, there are common characteristics. "Frustrating patients" report higher rates of somatic symptoms, rate their own health status poorly, and are more often diagnosed with somatization or generalized anxiety disorder than "satisfying" or "typical" patients, even though those patients' physicians did not identify any differences in the severity of underlying health issues [3]. Patients who were described as "difficult" were also found to be more likely to screen positive for mental illness and to be diagnosed with specific psychiatric disorders such as multisomatoform disorders, generalized anxiety or panic disorder, dysthymia or depression, and alcohol dependence. "Difficult" patients were more likely to list a larger number of active symptoms and to be diagnosed with functional illnesses such as irritable bowel or fibromyalgia while not showing any difference in "organic" illnesses such as diabetes, hypertension, cardiac disease, etc. "Difficult" patients were also more likely to report high levels of impairment of disability than "not-difficult" patients [4]. Patients who were part of difficult encounters demonstrated lower functional status. Increased numbers of patient concerns, symptoms, or symptom severity were more likely to result in a patient being described as "difficult" [13].

Family medicine physicians have identified difficult patients as those who have behavioral problems (violent, aggressive, rude, lying, demanding, exploitative), patients who present with repetitive symptoms that never improve or who have multiple complaints, and those patients with psychiatric illnesses [14]. Physicians have further identified patient behaviors that characterize difficult encounters, including insisting on an unnecessary medication, showing dissatisfaction with care provided, etc. [15]. In one study in a resident clinic, poor social support on the part of patients was also associated with problematic doctor/patient relationships [16]. Physicians were also more likely to report difficult patient encounters when patient behaviors and medical problems were opposed to physicians' personalities and approaches to care [17].

Diagnosis

In 1978, Groves identified four types of "difficult" (or, as described in the article, "hateful") patients and characterized them as noted below [18]. Although the language is inappropriate in today's patient-centered approach to care, the categories still have value and may serve as archetypes to facilitate initial approaches to caring for these patients. A reevaluation of this model updated for the twenty-first century [19] highlights the fact that these four general categories are still relevant today. The update notes that illness and disease can be considered a direct threat to the patient's wholes and integrity, and this threat causes individuals to turn to behaviors or coping mechanisms that may not be beneficial of effective.

- Dependent "clingers": characterized by "repeated, perfervid, incarcerating cries" for care and reassurance, and "their self-perception of bottomless need and their perception of the physician as inexhaustible" which lead to fatigue and frustration.
- Entitled "demanders": "use intimidation, devaluation, and guilt-induction to place the doctor in the role of the inexhaustible supply depot," but that this approach generates from a concern for abandonment and "an effort to preserve the integrity of the self" when confronted by illness or potential harm.
- Manipulative "help rejecters": need significant amounts of physician attention, but rather than expecting or demanding to get better they appear to doubt that any care offered will make a difference, and if one symptom is resolved, other symptoms are likely to replace it. These patients are described as having a "need/fear dilemma": they have needs that they seek to address, but fear either being abandoned or overwhelmed. This was clarified in 2006 [19] by noting that in this case patient's goal is the relationship with the physician as opposed to a cure.

DOI 10.1007/978-1-4939-0779-3_61-1

- Self-destructive "deniers": these patients are described as continuing behaviors that actively contradict or undercut physicians' attempts to help them, and that they have "given up hope of ever having needs met."

In a small study, Schafer and Nowlis noted that patients described as difficult by physicians were more likely having personality disorders than control patients, and that physicians were often unaware of these diagnoses [20]. The four categories of difficult patients listed above parallel definitions and diagnoses of personality disorders, especially those in clusters B and C. Given the fact that personality disorders are enduring, pervasive, and inflexible [21], patients with these characteristics will likely demonstrate persistent challenges in physician/patient interactions and will tend to use those approaches with each healthcare visit – allowing identification, categorization, and approaches to care as described later.

Levinson et al. categorized seven specific patient-driven themes/frustrations that contribute to difficult interactions:

1. Lack of trust or agreement
2. Lack of adherence to recommended plans of care
3. Too many problems, especially when combined with a lack of adequate time to address each of them
4. Feeling distressed (angry, overwhelmed, etc.) after patient visits
5. Demanding or controlling patients/families (different from patient-centered care and the idea of shared decision-making)
6. Lack of understanding due to the use of medical jargon or lack of language proficiency
7. Special problems that are difficult to address, such as substance abuse, chronic pain, etc. [22]

It is notable that each of these categories of frustrations does not result from a unilateral patient-side fault. There is a bilateral obligation on the part of patients and physicians to ensure proper and meaningful communication is part of the visit and that shared decision-making is a focus of each visit.

Physician characteristics such as age, ethnicity, and number of years in practice have not consistently been associated with an increase likelihood of experiencing difficult doctor/patient interactions. However, physicians with poorer psychosocial attitudes were more likely to experience difficult patient encounters, and communication defined as "psychosocial" (as opposed to biomedical) was more likely to be associated with patient and physician satisfaction [13]. Physicians working in health maintenance organizations (HMOs), as opposed to private practice, and primary care physicians have indicated higher levels of frustration [22]. Although fewer physicians work in HMOs than in the late twentieth century, this observation is still important and could carry over to physicians working as health system employees and who face similar administrative pressures and lower levels of personal control over their practice than would be the case in private practice. Physicians who reported a high frequency of difficult interactions were more likely to report feeling burned out and less likely to be satisfied with their jobs [15]. In a study that evaluated the characteristics of physicians who worked with "heartsink" patients – patients who created a sense of impotence or helplessness in their physicians – it was noted that physicians were more likely to report they worked with "heartsink" patients if they had "more than the usual workload" [23]. Finally, younger physicians, those who work longer hours, and those physicians whose patient panels include high numbers of those with substance abuse or challenging psychosocial backgrounds were more likely to report that they had a high number of "difficult" patients [24].

In addition to physicians' own assessment of issues that are likely to increase the risk of difficult patient interactions, patients have identified that they have lower trust in their physicians if their physician is not answering questions in ways that they can understand, if physicians are not taking time to answer

DOI 10.1007/978-1-4939-0779-3_61-1

questions, or if physicians are not giving enough medical information [25]. This lower level of trust made patients consider changing physicians and would likely present a risk for difficult or challenging doctor/patient encounters: if therapeutic relationships are at the heart of the work done by family physicians, then any experience or perception that reduces trust in that physician will interfere with this core principle.

The relationship between a high number of difficult patient interactions and reported high stress/low job satisfaction seems evident, but it is difficult to separate cause from result. Physicians working with large numbers of "heartsink" patients may report increased burnout, but that burnout may predispose physicians to more challenging interactions.

Difficult physician/patient interactions are not solely due to physicians or patients. Rather, they result from interplay of different elements. These elements include patient and physician factors as described above, but other elements must also be considered [26]. The illness itself and the health system in which patients access care play important roles in the creation of a difficult interaction. Difficult relationships may occur when physicians and/or patients do not feel that interventions are successful or effective; when patients/physicians are not flexible or adaptable in terms of addressing diversity of thought, experiences, or preferences; or when patients/physicians have misaligned expectations about goals and anticipated outcomes of care [27].

Treatment

In family medicine, it is important to consider that a patient's illness can be defined by predisposing factors, precipitating factors, and perpetuating factors [28]. This model may be used to consider how to approach a difficult patient/physician interaction. The predisposing factors would include the patient and physician factors listed earlier; the precipitating factors may be a particularly difficult interaction, a sudden stress experienced by the patient, or puzzling symptom that is hard to explain; and the perpetuating factors would be a lack of trust, poor communication between the parties, or mismatched goals of care. With this in mind, we need to consider what can be done to address predisposing factors in advance of the visit, how to recognize a precipitating factor when one occurs and how to limit the precipitating factors we can control, and how to reflect after a visit on what factors might be perpetuating the problem. This last step includes how to ensure physicians are taking care of themselves in order to sustain the resilience needed to work with challenging patients.

Before the visit: Strong physician job satisfaction, appropriate physician workload, and training in communication skills and in counseling are associated with a reduction in physician perceptions of patients as being difficult or frustrating, while working with complicated patients with multiple medical problems or in time-restricted settings increases physician frustrations. Postgraduate training in communication and point-of-care counseling interventions, reduced number of patients seen by physicians, and/or increased time provided for patient visits may be beneficial. Training in active listening may help physicians better care for patients by incorporating patients' concerns into encounters. Encouraging ongoing doctor/patient relationships allows a stable dyad to address various ongoing medical issues without feeling obligated to address all of them at any one time.

Enhanced training and education of individual physicians can address some of these issues, but others will require reevaluation of the current practice environment. Fee-for-service payment models result in family physicians being encouraged to see more patients in any given amount of time and are at risk of perpetuating those factors that physicians have identified as making patient interactions more difficult. In comparison, models of patient care such as patient-centered medical homes or direct primary care may allow for lower volumes of care and longer visits for complicated patients and may increase job satisfaction and physician perception of control. These factors, in turn, may help enhance physician

DOI 10.1007/978-1-4939-0779-3_61-1

resilience and reduce the frequency of challenging or frustrating interactions. Addressing time pressures and encouraging physicians and patients to talk about concerns and shared approaches to diagnosis, evaluation, and treatment will improve patient experiences and help reduce the level of frustration felt within the relationship.

In the exam room: During office visits with frustrating or difficult patients, there are useful approaches to identifying which patients may need more attention and to working effectively with patients who generally present challenges to the physician. It has been suggested that a physician's own frustration with a patient might be a marker for which patients may benefit from mental health evaluation and care and that using Kleinman's explanatory model [29] may help enhance communication between physician and patient [3], especially if there are discordant views of the patient's health status.

Active listening, an approach in which physicians move beyond facilitation skills to become aware of cues in patients' comments or behaviors that suggest underlying concerns, may help physicians better elicit the patient's perspective on their illness. Patients may present their perspective via direct statements, expressions of feelings, or concerns about an illness, repeating certain ideas or concerns about an illness, or via behaviors such as reluctance to accept recommendations, interrupting the physician, "by the way" statements as a visit closes, etc. [30]. By recognizing these cues, physicians can seek to better understand patient concerns they may not have fully addressed and will be able to refocus their energy in those areas and can rephrase their conversations with patients to encourage further discussion and disclosure.

Providing patients with diagnoses, prognostic information, etc. is associated with fewer ongoing concerns or continued symptoms and with improvement in symptoms after medical visits, and "difficult" patients were less likely to have received such information and more likely to describe unmet expectations [31]. This suggests that using the patient's explanatory model to frame the discussion of a patient's illness (including functional illnesses) may help align a physician's diagnosis and plan of care with a patient's expectations from a given office visit. Enhanced diagnosis and treatment of mental illness, increased psychosocial awareness and improved communication on the part of physicians, and standardized approaches to manage somatization may help reduce the difficulty of physician/patient interactions [13].

Building out of the four "hateful" patients he described [18], Groves suggested approaches for caring for difficult patients, including setting firm guidelines to doctor/patient interactions, refocusing patients' demands for any and all available interventions or evaluations toward those that will actually provide benefits, noting that treatment may not be curative but that it may help address symptoms, and working to provide the best care possible under the circumstances. In each of these situations, it is important to ensure that specific underlying issues of mental illness have been considered and evaluated, while recognizing that a lack of insight on the part of the patient might limit the effectiveness of such evaluations and interventions. Personality disorders are best approached with techniques such as motivational interviewing and shared problem-solving with the patient [21]. Physicians can approach "difficult" patients using empathy to try and understand the patient's concerns and circumstances, listening with patience and without judgment, setting clear guidelines for patient encounters, and using referrals and specialists judiciously and appropriately [14].

At any point a physician may notice that there is tension or discomfort in a patient interaction, it is important to assess what has happened and to consider the appropriate approach to remedy the situation. This process includes recognizing and acknowledging that tension has developed, assessing the source and the nature of the difficulty, and using a problem-solving approach that aims to preserve the relationship as well as addressing the medical needs while not losing sight of compassion or the importance of appropriate boundaries [27]. This stepwise approach may help avoid conflict and tension and may minimize the experience of difficult interactions between patients and physicians.

One approach to difficult clinical encounters summarizes many of these considerations. The CALMER approach (Table 1) provides six steps family physicians can use during difficult patient interactions and

DOI 10.1007/978-1-4939-0779-3_61-1

Table 1 The CALMER approach

C: Catalyst for Change	Identify where patients are in the stages of change model, and assess their readiness to advance to the next stage
A: Alter Thoughts to Change Feelings	Identify the thoughts patients generate, remember not to take anything personally, and consider how to move forward without feeling angry
L: Listen and Then Make a Diagnosis	Listen to patients, and watch for nonverbal cues in order to accurately interpret information before making a diagnosis/decision
M: Make an Agreement	Share decision making with the patient
E: Education and Follow-Up	Work on a treatment plan the patient has agreed to, provide information to make it successful, and then plan the next visit
R: Reach Out and Discuss Feelings	Following the visit, reflect by yourself and with others regarding the events and the encounter

Pomm et al. [32]

focuses on physician responses to difficult encounters while seeing to preserve the relationship [32]. Experienced physicians have also noted that challenging medical encounters could be salvaged (or encouraged) through physician/patient collaboration and the appropriate use of power and empathy in the encounter [17].

After the visit and physician self-care: Mindfulness techniques can be an important aspect of addressing difficult clinical encounters. Relatively simple interventions such as centered breathing techniques or reflection on important events at the end of a clinic day are easily put into action [33].

An important element of working with patients is empathy, in which physicians attempt to understand to identify with another person's situation. Empathy can enhance a physician's flexibility, ability to work within a patient's frame of reference and to maintain a professional relationship without developing negative reactions to difficult interactions. "[T]hrough patience and tolerance, the physician may get a sense of where the patient is coming from and why the patient has resorted to negative response patterns." Empathy can be fostered by recognizing one's emotions in the moment of an event, reflecting on negative emotions in themselves and in their patients, focusing on the emotional content in patients' histories, being aware of patients' behaviors and nonverbal cues to encourage and enhance communication, and accepting patients' feedback (even if it is negative feedback) as a way to improve their performance while allowing the patient to open up about their concerns and worries [34].

Physicians must also be aware of the risk of countertransference, in which they may develop feelings toward patients based on the physician's own prior experiences and life circumstances. Just as patients engage in transference (where they project experiences from their lives onto the doctor/patient interaction), physicians may project onto patients via countertransference and must be mindful of this reaction and of the patient factors that trigger it [19].

Balint groups have been suggested as a way to help physicians sustain their engagement with patients with whom they may have difficult interactions or relationships. The work of Michael and Enid Balint defined what a therapeutic relationship should look like: a shared commitment to investigating ultimate causes of both the current illnesses as well as the patients' reaction to them, as well as the importance of taking the whole picture into account and acknowledging the patient's concerns as a key element of the illness, and the physician's role in helping the patient move forward [35]. The goal of Balint groups is to evaluate difficult patient interactions and encounters and to help physicians reach a deeper understanding of the patient's perspective of the illness, the relationship, and the current situation. Balint groups for general practitioners have been effective in enhancing physicians' sense of competence in working with patients and in better understanding difficult relationships, in strengthening professional identity, in helping identify skills used in the group that are also effective in patient encounters (active listening,

DOI 10.1007/978-1-4939-0779-3_61-1

Table 2 BREATHE OUT

Before the encounter:	
B	List at least one **B**ias/assumption that you have about this patient
R **E**	**RE**flect upon why you identify this patient as "difficult"
A	List one thing you would like to **A**ccomplish today
T **H**	**TH**ink about one question you'd like to address today that would enable you to further explore your assumptions, including a patient-centered social history review
E	Stop before you **E**nter the patient room and take three deep breaths in through your nose and out through your mouth
After the encounter:	
O	Reflect on the **O**utcome of the encounter. From the patient's perspective, what was their agenda? From the physician perspective, did you accomplish your agenda?
U	Did you learn anything **U**nexpected?
T	List one thing you look forward to addressing if you were to run into this patient **T**omorrow

etc.), and in promoting endurance and satisfaction [36]. Balint groups may be important tools in enhancing physician effectiveness and caring, avoiding burnout, and improving professional satisfaction.

Another approach to assess individual performance after difficult encounters is through use of a Critical Practice Audit. As presented by Stephen Brookfield [37], the Critical Practice Audit allows physicians to consider critical events in a preceding week, assumptions they made (and that patients may have made) that contributed to the situation being challenging, what other perspectives should have been considered during the event, and how a situation may have been handled differently.

The importance of preparing for challenging patient encounters before the office visit and in reflecting and evaluating the outcomes after the visit have been evaluated by using the BREATHE OUT process. BREATHE OUT is a brief tool that involves physician and team preparation before difficult patients are seen in clinic and provides for a structured, reflective review following the encounter (Table 2). In a randomized trial, using BREATHE OUT improved physician satisfaction with challenging patient visits [38].

Finally, other interventions that can be pursued outside of the clinic include familiarizing oneself with community resources, scheduling patients appropriately to allow longer time for more complicated patients, and ensuring continuity of care [1].

Family and Community Issues

While patients described as "difficult" demonstrated increased use of healthcare services [4], Grove suggested that difficult patient interactions could risk harm to patients by fracturing the necessary therapeutic doctor/patient relationship via inappropriate confrontation with the patient or attempts to avoid or exclude patients from the healthcare system [18]. Using the 10-item version of Difficult Doctor-Patient Relationship Questionnaire (DDPRQ-10), physicians reported difficult patients to be frustrating, time consuming, and manipulative and reported that they felt communication was difficult and were ill at ease and lacked enthusiasm for caring for these patients in the future [4]. Given the definition of a therapeutic doctor/patient relationship, it is clear to see that when patients are identified as challenging, it will be more difficult for their physicians to form effective relationships with them. "Difficult" patients are also less likely to be satisfied with their healthcare and to seek more medical visits and interventions [13], suggesting that finding effective ways to work with challenging patients can lower healthcare utilization

DOI 10.1007/978-1-4939-0779-3_61-1

and prevent complications associated with healthcare. Physicians reporting a high number of difficult interactions were also more likely to indicate that they had engaged in suboptimal patient care practices in the past year and more likely to expect future errors in their practice [15]. Though this trend did not reach statistical significance in the study cited, it does raise the concern that a physician facing a high number of difficult patient interactions could cause inadvertent harm despite best intentions.

Closing

The nature of medical care, especially family medicine, is that we will see many patients and we will all face patient encounters that are difficult and challenging. By being aware of patient factors that increase the risk of these interactions and physician and system factors that may precipitate or perpetuate challenging relationships, family physicians can take active roles in our patients' healing while also enhancing our own skills in working in these difficult circumstances and working toward the goal of changing systems to benefit our patients.

General Principles

Background

Fatigue is a common complaint in the primary care setting, with reported prevalence ranging from 5 % to 10 % [1]. With such a broad differential to consider, determining the cause of fatigue and helping the patient to find the appropriate treatment can be a daunting task. Similarly, chronic fatigue syndrome (CFS), a syndrome which arises in the setting of numerous biological, psychological, and social factors, can pose a diagnostic and treatment dilemma for the family physician.

Although fatigue has been described since the beginning of written history, it was not until 1896 that Beard first coined the term *neurasthenia*, a condition resulting from the depletion of the energy of the central nervous system [2]. Over time, various terms have been use to describe similar illnesses, with various etiologies proposed, ranging from environmental changes associated with modern living to immunological and postinfectious, including Epstein Barr virus infection [2]. Fatigue in most patients is multifactorial, and the diagnosis of chronic fatigue syndrome is one of exclusion. It is thought to arise from a combination of genetic, neurological, immunological, and social factors, without one specific etiology. In this chapter, the evaluation of fatigue will be reviewed as well as the approach to diagnosis and treatment for CFS.

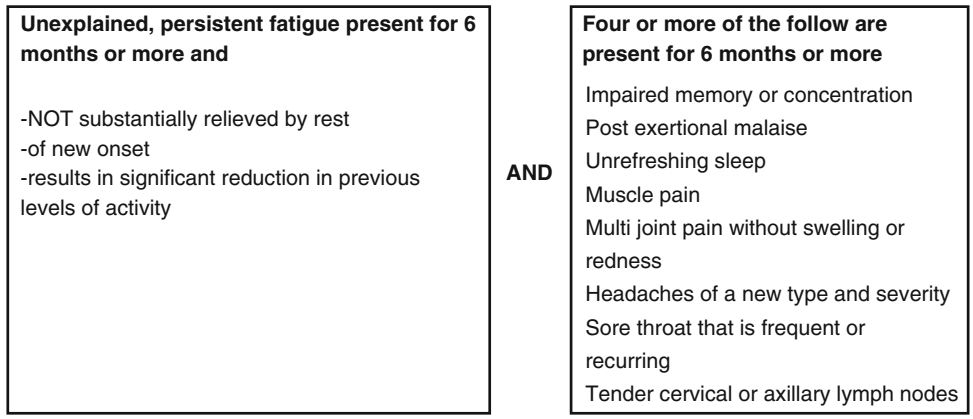

Fig. 1 CDC criteria for diagnosing chronic fatigue syndrome [4]

Epidemiology

While fatigue is a commonly reported symptom in the primary care setting, CFS is far less common. The prevalence of CFS has been noted to be similar across many different cultures and countries but does vary between studies. Epidemiological studies of two US cities demonstrated rates between 0.23 % and 0.42 % [2, 3]. CFS is more common in adults than children and also more common in women and minorities [3]. Special considerations for diagnosis and treatment of CFS in these populations are discussed later in this chapter.

Approach to the Patient

Diagnosis

The differential diagnosis of fatigue encompasses many medical and psychiatric conditions including metabolic, infectious, sleep disorders, depression, and malignancy, just to name a few. When fatigue is present for more than 6 months and no laboratory or physical abnormalities are found, the diagnosis of CFS can be considered.

The diagnosis of CFS is one of exclusion, requiring the family physician to rule out other conditions that can present with similar symptoms. Diagnostic criteria published by the CDC in 1994 offer a framework upon which to evaluate patients with long-standing fatigue [4]. These criteria, which were initially developed for the purposes of defining a specific population for research, are also helpful to the family physician considering the diagnosis of CFS (Fig. 1).

History

In addition to assessing for the above symptoms, a detailed history should focus on the time course of the fatigue, the patient's social history including drug and alcohol use, and current use of medications and supplements [4]. It is also important to consider the medical and psychosocial context within which the fatigue developed as well as prior history of trauma and the social support system of the patient [5]. These components of the history are important, not only for making an initial diagnosis but also for designing a treatment plan tailored to the patient's individual needs and available resources.

Physical Examination

Physical examination of the patient with fatigue should be focused on assessing for underlying infection, inflammatory conditions, and metabolic disorders in addition to gaining an overall sense of the patient's well-being and function.

Complete blood count with differential
Basic Metabolic Panel
Calcium
Phosphorous
Liver function tests (including AST, ALT, alkaline phosphatase)
Albumin
Total Protein
ANA
Rheumatoid Factor
TSH and Free T4
Ferritin (especially in children and adolescents)
UA for protein, blood and glucose
Testing for gluten sensitivity

Fig. 2 Tests to consider in evaluating for underlying causes of fatigue [4, 6]

Laboratory Testing and Imaging

When evaluating the cause of fatigue, prior to considering CFS as the potential diagnosis, it is important to first look for other underlying causes of fatigue. Not all tests listed in this chapter are indicated for all patients. Laboratory testing should be directed at the patient's symptoms and clinical presentation. For example, testing for viral or bacterial infections is not indicated unless the history and/or physical exam indicates an infection may be present [6] (Fig. 2).

If the above indicated laboratory testing is within normal limits and no other underlying medical or psychiatric conditions can explain the patient's fatigue, the diagnosis of CFS should be considered. If the patient does not meet all of the criteria for CFS but no other etiology has been determined the diagnosis of idiopathic chronic fatigue or a CFS-like illness can be made [4].

Treatment

Patient perception lies at the heart of treatment of CFS. Predictors of improvement in symptoms were not related to disease severity or chronicity of the patient's fatigue in one British study but rather the patient's attitudes and beliefs surrounding the illness [7]. For example, patients who participated in support groups had a lower treatment response than those who did not, largely because the group patients tended to participate in reinforced certain illness beliefs as well as exercise avoidance [7]. The two treatments for CFS with the best evidence are cognitive behavioral therapy (CBT) and graded exercise therapy (GET). Both are thought to have an impact on the patient's beliefs about fatigue and their own limitations secondary to their fatigue. A change in patient beliefs surrounding fatigue as well as improving patient's sense of empowerment and self-efficacy whether by CBT or GET is likely to be beneficial for a patient CFS.

CBT

Cognitive behavioral therapy (CBT) has been demonstrated in several studies as more effective than usual care or other psychological treatments including relaxation, counseling, and relaxation/support, though the data on the long-term effects of this are inconclusive [8]. More research is needed into whether CBT or CBT in combination with other therapies such as graded exercise is most optimal, as well as the acceptability of CBT among patients with CFS [8]. Given its demonstrated benefit, at least in the short term, it would be reasonable to offer CBT as a treatment modality to a patient with CFS regardless of the duration or severity of symptoms. CBT can also be directed at other problematic symptoms experienced by patients with CFS, such as chronic pain, depression, and poor sleep.

Graded Exercise Therapy

Graded exercise therapy (GET) has been demonstrated to be beneficial for patients with CFS [5, 6]. GET is thought to work synergistically with CBT because it provides a practical context for the cognitive restructuring around fatigue that effective CBT encourages [9]. In one review of 12 studies of GET and CFS, it was determined that in

order to obtain maximum benefit from GET, patients should be encouraged to focus on a time-contingent approach, rather than symptom-contingent approach, as well as to engage in aerobic exercise as determined by an individually derived target heart rate [9]. Patients can also engage in a home exercise program of 5–15 min per session five times per week and gradually progress to up to 30 min. [9] Given the sensitivity of many patients with CFS to exertion, activity undertaken by patients with this diagnosis should be closely supervised by a medical professional, in order to prevent overexertion and worsening of fatigue.

Medication

Pharmacotherapy, including nutritional supplements, outside of the use of medication for specifically diagnosed comorbidities, has not been shown to be beneficial in CFS [5, 6, 10]. In one Australian study, patients with CFS reported taking a wide variety of prescribed medications such as sedatives and antidepressants in addition to over-the-counter supplements in an effort to gain relief from their symptoms. [10] Patients with CFS are often very sensitive to medication, and this in addition to the side effect profiles of many of these medications make them a less desirable treatment option for patients with CFS. On the other hand it is crucial to treat comorbid conditions, particularly those that have an effect on the patient's level of functioning. While the addition of an antidepressant or other medication in the absence of a diagnosis of a comorbid condition such as major depression has not been demonstrated to be helpful, when the diagnosis of depression is made, it is an important part of the patient's overall medical care [11].

Referrals

Specialist involvement in the care of patients with fatigue should focus on the treatment of comorbid conditions and underlying causes as determined by history, laboratory workup, or physical exam. Additionally, rheumatology consult can be considered. It is important to remember, however, that the family physician plays a particularly important role in the care of patients with CFS, because coordinated care is central to the improvement in symptoms [6].

Patient Education and Activation

Patient education and involvement are central to the treatment of CFS. The patient's perception of fatigue and of their own self-efficacy play a large role in determining their response to treatment of any kind; patient engagement and activation is absolutely critical to success [3].

CFS in Children

Although CFS is thought to be less prevalent in children and adolescents than in adults, a wide range of prevalence of CFS in adolescents is thought to be between 0.11 and 1.29 % found in Dutch, US, and British populations [12]. As in adult populations, the diagnosis of CFS in children and adolescents is one of exclusion, and a detailed history and physical along with any indicated laboratory tests is indicated. In addition to the tests recommended for adults, serum ferritin should be strongly considered in children and adolescents presenting with fatigue. Two thirds of adolescents responded to CBT in one study after 6 months of treatment, and this treatment effect was sustained at 2–3 year follow-up [12]. Making a prompt diagnosis and getting children and adolescents into the appropriate treatment is of the utmost importance, as these determine the prognosis for the child's recovery [12].

CFS in Elderly Adults

Fatigue is a prevalent concern in the elderly with some estimates of prevalence greater than 70 % [13]. While fatigue does tend to occur with normal aging, it is important to rule out underlying

conditions that may result in fatigue. It is estimated that up to two third of elderly patients presenting with fatigue will have a cause found on history, physical and/or laboratory evaluation [13]. The same diagnostic criteria for CFS apply to the elderly as to the general adult population, but special attention should be paid to ruling out psychiatric and neurological conditions, including depression and dementia. In addition to this special care should be taken in elderly patient populations to assure appropriate social support, especially if the diagnosis of CFS is made.

CFS in Underrepresented Minority Populations

The prevalence of CFS is thought to be higher in minority groups, but the diagnosis in these patient populations can be more difficult if the family physician is not aware of the social and cultural context within which the patient presents [3]. One study in the UK looked at why the diagnosis is made less frequently in black and minority ethnic groups when compared to groups of white patients [14]. Their findings suggest that there was a lack of awareness of CFS among this patient population, lack of access to primary care, as well as incorrect assumptions and beliefs among physicians. They cited higher turnover of primary care physicians in inner city practices as well as lack of training in cultural sensitivity as contributing to this problem. They point to the importance of an ongoing relationship with a primary care physician as an important aspect of obtaining the correct diagnosis and providing quality care for this patient population [14].

Family and Community Issues

CFS can produce both community economic hardship through the loss of occupational productivity but also family hardship in a family for whom one member is not able to fully participate in its day-to-day operation. Focusing on function and helping patients work with their families to improve their understanding of their illness and address their fatigue is one way in which family physicians can help patients to participate more fully both at home and at work.

Conclusion

Fatigue is a symptom that is commonly reported to the family physician, and CFS is an illness which helps family physicians conceptualize and treat fatigue for which no clear etiology can be found. Patients complaining of fatigue should have a thorough history, physical examination, and laboratory workup as outlined above. The diagnosis of CFS should be considered in any patient with fatigue for greater than 6 months and associated symptoms as outlined in the diagnostic criteria created by the CDC. The workup of fatigue varies depending on the patient population and presenting complaints. It is important to evaluate fatigue in the context of the patients' social situation, emotional well-being, and ability to act with self-efficacy as these are all important things to be addressed if interventions are to be successful. Coordination of care and a strong therapeutic alliance predict success in the treatment of CFS.

General Principles

Definition/Background

We each spend 1/3 of our lives in the reversible state of perceptual isolation that we call sleep. Unsurprisingly, disruptions and disorders of this primary physiologic state can lead to declines in quality of life, diminished waking performance, more frequent illness, as well as increases in disease morbidity and mortality. The spectrum of sleep disorders mirrors the clinical population of patients seen in a family medicine practice with most patients with sleep disturbance receiving their medical care in the primary care setting [1]. Despite a high prevalence of sleep disorders, sleep complains are under-addressed by physicians. Recently, high-quality epidemiologic studies have documented the importance of the diagnosis and treatment of sleep disorders in primary care practice in reducing morbidity and mortality, improving comorbid disease processes, and improving patient quality of life [2, 3].

Classification

Sleep Disorders: The Clinical Spectrum

Sleep diagnoses range include those presenting primarily based on patient complaint (e.g., the insomnias) as well as those with strong negative affects morbidity and mortality yet affects on waking performance that may be more difficult

for the patient to understand and describe (e.g., sleep apnea). The primary sleep diagnoses are divided into six categories: insomnias, sleep-related breathing disorders, hypersomnias, circadian-rhythm sleep disturbance, parasomnias, and sleep-related movement disorders. Sleep disturbance is often secondary, associated with almost all chronic diseases that result in physical or mental discomfort for the patient, and incorporated into most psychiatric disorders as a diagnostic criteria. Pregnancy and menopause, increasing age, and stress induce insomnia and sleep disruption. Pediatric sleep disorders are common.

The Insomnias

Background

Insomnia is a primary care problem. Thirty percent of the general population report symptoms of sleep disruption, and in the primary care clinic more than 50 % of patients have sleep complaints [4]. Diagnostically, over 40 % of American adults occasionally struggle with insomnia, and 11–14 % of the population have an ongoing problem with chronic insomnia [5]. Those most at risk include women and older adults. The insomnias include the complaint of difficulty with sleep initiation, duration, consolidation, or quality, associated with daytime functional impairment. The daytime functional impairment in insomnia includes fatigue, impaired memory or concentration, mood disturbance, daytime sleepiness, reduced motivation or energy, tension, headaches, or gastrointestinal symptoms. In adults, chronic insomnia is associated with impaired social and vocational function and reduced quality of life and in severe cases may be associated with an increased risk of traffic and work site accidents as well as psychiatric disorders. In pediatrics, insomnia is particularly a problem around the age of two when the child first attempts to sleep independently of parents [6].

Individuals with chronic insomnia consistently report lower values of quality of life particularly on somatic/physical scales. Chronic insomniacs have an increased risk of depression and anxiety. Sleepless individuals are more likely to be obese. Chronic insomnia is also associated with increased pain in rheumatic disease with the degree of insomnia on any given night being a predictor of pain intensity the following day [7]. The cost and health-care utilization data calculated for insomnia includes annual direct costs in the United States which include $1.97 billion for medications and 11.96 billion for health-care services. Indirect costs include decreased productivity, higher accident rate, increased absenteeism, and increased comorbidity with total annual cost estimates ranging from $30 to $107.5 billion [8].

Diagnosis

Diagnosing insomnia can be a complex task as the origin of a patient's insomnia is often multifactorial. Life stressors, concomitant illness, family, and social structure can precipitate symptomatic insomnia. The family medicine physician, who often has a more complete knowledge of these factors than the subspecialist, is in an ideal position to define the cause of the sleep–wake disturbance in a patient with insomnia. The diagnosis of the insomnias is primarily based on a sleep history. Evidence-based criteria for the evaluation and treatment of insomnia are summarized in Tables 1, 2, and 3 [9].

Treatment

Insomnia responds well to cognitive behavioral therapies (including sleep hygiene, sleep restriction, and behavioral approaches to treating conditioned insomnia). Physical exam contributes little to the diagnosis or evaluation of insomnia. The newer GABA-specific site hypnotic medications have high efficacy, low toxicity, and minimal addictive potential. For patients with persistent insomnia, chronic use with the newer hypnotics can be justified and is indicated if medication use leads to improvement in waking performance. These newer hypnotic agents are less likely to have deleterious side effects than most OTC treatments for insomnia [11].

Table 1 Evidence-based symptom and diagnostic correlates for chronic insomnia

Chronic insomnia leads to poorer self-rated quality of life	A	Multiple large retrospective cohort studies
Chronic insomnia leads to increased health-care cost for affected patients	A	Multiple large retrospective cohort studies
Chronic insomnia predisposes an individual to mood disorder/depression	B	Large retrospective cohort study, longitudinal prospective study
Chronic insomnia is associated with decreased work productivity and increased time missed from work and/or school	B	Multiple small retrospective studies with consistent findings
Chronic insomnia leads to drug and alcohol abuse	C	Significant associated variables in adult and adolescent populations
Chronic insomnia leads to obesity	C	Small retrospective studies
Chronic insomnia is associated with an increase in automobile accidents	C	Retrospective review
Chronic insomnia is associated with an increase in mortality in geriatric patients	C	One large retrospective study
Chronic insomnia is associated with increased pain complaints in chronic pain patients	C	Retrospective review

Table 2 Evidence-based recommendations for the diagnosis and treatment of insomnia

The evaluation of chronic insomnia does not require polysomnographic evaluation except when associated with other sleep-associated diseases such as OSA or PLMD	B	Consensus guidelines, usual practice, disease-oriented evidence, prospective diagnostic cohort study
Drug treatment of chronic insomnia leads to improvements in associated sleep states and daytime performance	B	Retrospective cohort and case control studies with good follow-up
Drug treatment of chronic insomnia with newer medications can be maintained long term without loss of efficacy and without negative effects	B	Large prospective study (drug company)
Behavioral treatment of chronic insomnia leads to improvements in associated sleep states and daytime performance	C	Consensus guidelines, usual practice

Adapted and updated table from Pagel and Pegram [9]
Strength of recommendation based on Ebel et al. [10]

The Sleep-Associated Breathing Disorders

Background

Obstructive sleep apnea (OSA) is one of the most physiologically disruptive and dangerous of the sleep diagnoses. Recent epidemiological studies demonstrate that OSA has a strong association with pulmonary, cardiac, endocrine, and cognitive disease [12]. In patients with OSA, continued breathing effort occurs despite obstruction of the airway resulting in inadequate ventilation. OSA is more common among men, those who snore, are overweight, have high blood pressure, or physical abnormalities in their upper airways. Worldwide, more than 700 million individuals now have a BMI $>$ 30 and meet criteria for obesity [9]. This level of obesity and an increasingly aging population have resulted in a situation in which we are currently experiencing an epidemic of this physiologically dangerous diagnosis. The symptoms of OSA include persistent snoring (80 %), daytime sleepiness (22–32 %), and apneas observed by bed partners or caregivers (in adults, the report of observed apnea often indicates the present of severe apnea). OSA is present at high frequency (24–34 %) in the adult primary care clinic population and must be suspected in any patients with comorbid diagnoses known to be associated with apnea [12] (Table 4).

Table 3 Evidence-based criteria for sleep testing

Attended split night attended polysomnography indications		
(a) The diagnosis of sleep-related breathing disorders	A	Standard of care
(b) Positive airway pressure titration	A	Standard of care
(c) Pre- and postoperative evaluation of patients having surgery for obstructive sleep apnea	A	Standard of care
(d) Evaluation of patients being treated for OSA with persistent symptoms	A	High-quality cohort studies
(e) Patients with systolic or diastolic heart failure not responding to optimal medical management	A	Prospective diagnostic cohort studies
(f) Diagnosing restless leg syndrome/periodic limb movement disorder	C	Disease-oriented evidence
(g) Diagnosing insomnia in patients not responding to behavioral or medical therapy	C	Consensus guidelines
Treatment with PAP systems leads to reduced symptoms of sleepiness, increased quality of life, and lower blood pressure	A	Meta-analysis of retrospective cohort studies (standard of care)
Nonattended limited HST for the diagnosis of sleep-related breathing disorders	B	Retrospective cohort and case control studies with good follow-up (developing as standard of care)
Autotitrating PAP for treating obstructive sleep apnea	B	Case control studies with good follow-up
Multiple sleep latency testing indications (a) Assessing daytime sleepiness (b) Diagnosing narcolepsy	B	Meta- analysis, usual practice, usual practice, and disease-oriented evidence

Adapted table from Pagel and Pegram [9]

Adult OSA has a clear association of daytime cognitive impairment (i.e., daytime sleepiness) that leads to a significant increase in motor vehicular accidents in untreated patients [13]. Recent epidemiological studies have cross-matched sleep apnea evaluation with long-term prospective cardiovascular risk, pointing out the consistent and strong association between OSA and essential hypertension, increased mortality, congestive heart failure (both right and left sided), myocardial infarction, and cerebral vascular accidents [12]. Recent studies have emphasized the clinical significance of the association between atrial fibrillation and untreated OSA [14]. OSA can contribute to insulin resistance and metabolic syndrome [15] (Table 5).

Table 4 Clinical diagnoses associated with OSA including the approximate % of adult patients in each category with apnea–hypopnea index (AHI) > 5.0 events per hour

Obesity – 40–75 %
Morbid obesity >80 %
Excessive daytime sleepiness – 60–80 %
Hypertension – 40–80 %
Myocardial infarction (CAD) – 60–70 %
Cerebral vascular accident – 60–70 %
Atrial fibrillation – 60–80 %
Chronic pain treated with opiates – 70–80 %
Congestive failure (right and left sided) – 70–80 %
Metabolic syndrome – 80 %
Diabetes – 40–60 %
Posttraumatic stress disorder – 60–95 %

Diagnosis and Treatment

OSA most often requires polysomnography (PSG) testing for diagnosis and treatment. PSG is the recording of multiple physiological signals during sleep including channels of electroencephalography (EEG), electrooculogram (EOG), and chin electromyogram (EMG) that are required for sleep staging as well as recordings of respiratory effort, airflow, pulse oximetry, snoring, sleep position, ECG, leg EMG, and video monitoring. Additional channels are sometimes utilized including end-tidal or transcutaneous CO_2 and additional EEG channels if potential nocturnal seizure disorders are being evaluated. The clinical indications for PGG are summarized in Table 3.

OSA is most often treated with devices that act as a pulmonary splint keeping the airway open during sleep by utilizing positive airway pressure

Table 5 Evidence-based associations of obstructive sleep apnea (OSA)

Adult OSA	Obesity	A – consistent systemic meta-analyses
	Cognitive impairment (daytime sleepiness)	A – consistent systemic meta-analyses
	Motor vehicular accidents	A – consistent systemic meta-analyses
	Hypertension	A– cross-sectional analysis of prospective cohort studies, consistent systemic meta-analyses
	Increased mortality	B – retrospective cohort studies
	Congestive heart failure (right and left sided)	B – cross-sectional analysis of prospective cohort studies, inconsistent systemic meta-analyses
	Coronary artery disease	B – cross-sectional analysis of prospective cohort studies, retrospective diagnostic cohort study
	Cerebral vascular accidents	B – cross-sectional analysis of prospective cohort studies, retrospective cohort study
	Metabolic syndrome	B – cross-sectional analysis of prospective cohort studies, retrospective cohort studies
	Atrial fibrillation	B – multiple retrospective cohort studies and treatment follow-up studies
	Diabetes	C – retrospective cohort studies
	Other cardiac arrhythmias	C – case series, usual practice
Pediatric OSA	Poor school performance	B – multiple retrospective cohort studies
	Enuresis	C – retrospective cohort studies
	Failure to thrive	C – case series, usual practice
	Learning disability	C – retrospective cohort studies
	Obesity	C – retrospective cohort studies
	Attention deficit/ hyperactivity disorder	C – inconsistent retrospective cohort studies

Adapted table from Pagel and Pegram [9]
Strength of recommendation based on Ebel et al. [10]

(PAP). This treatment is well tolerated by most OSA patients with few side effects and documented reductions in morbidity, hospitalization, and health-care utilization [16]. In evaluating OSA, a split night protocol is often utilized in which a therapeutic treatment or "titration" portion of the PSG is added after a period of diagnostic sleep time. A PSG interpretation should include data as to sleep architecture, respiratory parameters (number and index of apneas [episodes of complete respiratory cessation], hypopneas [episodes of reduced respiratory drive and hypoxia], and respiratory-related arousals), periodic limb movements, a description of any parasomnia or seizure activity, EKG abnormalities, and the results and appropriate setting of any treatment attempted during the night of study.

Sleep laboratory testing can be expensive, and alternative approaches are now often utilized. OSA is now commonly initially evaluated using home screening tests (HSTs), an approach that has been shown to be particularly useful in younger patients without comorbid diagnoses [17]. These studies have limitations. They cannot determine whether the patient is actually asleep during the recording, and in patients with insomnia and those with ongoing psychiatric problems, the number of respiratory events (apneas and hypopneas) per hour will be lower than actually present due to the large amount of recording time that will be in wake. Periodic limb movements and arousals from events such as parasomnias are not recorded by HSTs. Most home screeners differentiate poorly between obstructive and central apneas. Central sleep apnea (CSA) includes nonobstructive apneas in which respiratory efforts do not occur. CSA is present most often in patients with a history of CHF; post-ICU patients; those with a history of significant cardiovascular, pulmonary, or CNS disease; development abnormalities; opiate use; the extreme elderly; and those living at elevations above 6500 ft [18, 19]. Treatment includes oxygen or systems that incorporated backup rates in addition to PAP.

By coupling HST with autotitration treatment, patients with OSA can avoid any form of full PSG testing. Autotitrating pap systems are tolerated well by some patients; however, these systems

have minimal diagnostic capacity and can report inappropriate settings for misdiagnosed patients and patients with central apnea and/or nasal congestion or mouth leaks on pap therapy [20].

The pathophysiology and clinical presentation differ for pediatric OSA. In pediatric patients, OSA is most clearly associated with tonsillar hypertrophy. OSA can contribute to poor school performance [21]. Studies also support the association of pediatric OSA with failure to thrive, obesity, enuresis, attention deficit/hyperactivity disorder, and learning disability. The treatment of pediatric OSA is most often surgical – (T&A).

Excessive Daytime Sleepiness (Other Hypersomnias)

The National Health and Safety Administration (NHTSA) in 1999 estimated that 1.5 % of police-reported crashes and 4 % of all traffic crash fatalities involved drowsiness and fatigue as principal causes. Beyond the personal and social loss associated with these accidents, the cost of untreated daytime sleepiness was estimated at $12.5 billion based on workplace loss and loss of productivity [22]. The most common causes of daytime sleepiness are sleep deprivation and the use of prescription and nonprescription agents as well as drugs of abuse that induce daytime sleepiness (daytime sleepiness is among the most common of medication side effects) [23]. The next most common cause is untreated OSA. The other sleep disorders that induce daytime sleepiness occur at a much lower frequency. The hypersomnias generally require both PSG and multiple sleep latency testing (MSLT) for diagnostic evaluation and assessment of daytime sleepiness. The MSLT includes four to five opportunities to nap in the sleep laboratory after a full-night PSG with EEG, EOG, and EMG monitored, so that sleep and REMS onset can be determined. MSLT reports should include average or mean latency to sleep and the number of sleep onset REMS periods recorded (a diagnostic criteria for narcolepsy). Narcolepsy is the most common of the neurological diseases inducing severe daytime sleepiness, present in 1-2/1000 of the general population. Medications that are used in somnolent patients to induce alertness include the amphetamines (medications with high abuse potential) and newer alerting agents (e.g., modafinil) that have a lower potential for abuse and negative side effects.

Circadian-Rhythm Sleep Disorders

The biological clock for sleeping is based in part on the circadian rhythm of sleep and wake propensity. Chronic sleep disturbance can result from disruptions in this system or from misalignments between an individual's circadian rhythm and the 24-h social or physical environment. Delayed sleep-phase syndrome in which individuals go to bed and rise later than the general population is symptomatic in 7–16 % of adolescents. Shift work disrupts normal sleep patterns for approx 20 % of the population. At least 10 % of individuals evaluated in sleep laboratories for chronic insomnia have a definite circadian component to their disorder [8]. Melatonin is the photoneuroendocrine transducer that conveys information controlling sleep–wake cycles and circadian rhythms in the central nervous system (CNS). Low doses coupled with bright-light therapy are useful in treating these disorders [24]. Jet lag and shift work disorders can also be effectively treated with repetitive short-term use of sedative/hypnotics [25].

Parasomnias

Parasomnias are undesirable physical events or experiences that occur during entry into sleep, within sleep, or during arousals from sleep. Parasomnias encompass sleep-related movements, autonomic motor system functioning, behaviors, perceptions, emotions, and dreaming – sleep-related behaviors and experiences in which the sleeper has no conscious deliberate control. Parasomnias become clinical diagnoses when associated with sleep disruption, nocturnal injuries, waking psychosocial effects, and adverse health effects. Parasomnias are classified based on sleep stage of origin. Recurrent nightmares (the most common of the parasomnias) occur in

15–40 % of normal adolescents. Recurrent, disturbing nightmares are the most common symptom of posttraumatic stress disorder (PTSD). REM behavior disorder (RBD) in which individuals lose the motor block that usually prevents the acting out of dreams is most common in late-middle-age males and in patients with progressive neurological disease (e.g., Parkinson's disease). RBD occurs in 0.38–0.5 % of the population [1]. The arousal disorders of somnambulism (sleep walking), night terrors, and confusional arousals are reported by 4 % of pediatric patients. Enuresis is present in 15–20 % of 5-year-old children declining to 1–2 % in young adulthood.

Sleep-Related Movement Disorders

More than 12 million people in this country experience unpleasant, tingling, creeping feelings in their legs during sleep or inactivity as a symptom of a disorder called restless legs syndrome. This disorder causes an uncontrollable urge to move and to relieve the sensations in the legs. Sleep is often disrupted by periodic limb movements occurring in the extremities during sleep that can be detected by PSG. Low dosages of dopamine precursors and dopamine receptor agonists at bedtime have been demonstrated to be efficacious in these disorders [26].

The Family Physician and Sleep Medicine

Up to 90 % of adult patients visiting their primary care physician on any given day are experiencing sleep-related symptoms, and at least 1/3 are likely to have OSA. Currently, despite the known increases in morbidity and mortality associated with this diagnosis, only 2–4 % of the individuals likely to have OSA have been tested. Approximately 14 % of the general population suffer from chronic insomnia. Payers, concerned with the potential cost of evaluating and treating this large number of patients, are pushing sleep medicine diagnosis and treatment into the primary care setting where family physicians and physician extenders are expected to make correct diagnoses and monitor appropriate treatment. While sleep medicine consultation for difficult patients is available in many communities, the same standard of care is expected even when diagnosis is limited by screening questionnaires with low sensitivity and efficacy, diagnostic tests with debatable sensitivity, and treatment approaches with limited efficacy.

Currently, few primary care physicians address sleep complaints or screen for OSA. Questionnaires can be an excellent tool for obtaining information about sleep disorders, but even when sleep complaint questionnaires are highlighted on patient charts, patients at high risk for are infrequently evaluated. Studies from outside the USA indicate the potential for primary care sleep medicine. In Queensland and New South Wales, Australia, when family doctors were asked to conduct limited HSTs in their patients with BMI > 30, type 2 diabetes, treated hypertension, and ischemic heart disease, 71 % were found to meet at least minimal criteria for OSA (apnea–hypopnea index (AHI) > 5.0) and 16 % were found to have severe OSA (AHI > 30) [18]. Primary care physicians with limited training in sleep medicine were shown to provide a level of care for patients with suspected OSA in South Australia comparable to that provided in the University sleep medicine center in Adelaide [27].

There are a huge number of patients with sleep-associated diagnoses affecting their mortality and morbidity. The current care system has been able to diagnose and treat OSA for only a small percentage of the affected individuals. Sleep-associated diagnoses negatively affect the medical and psychiatric disorders most often seen in family medicine: hypertension, obesity, cardiovascular disease, arrhythmias, mood disorder/depression, and anxiety. The associated personal and medical costs of untreated sleep disorders are staggering. Associated daytime sleepiness negatively affects driving and work performance and when untreated contributes to a large number of motor vehicular accidents, injuries, and deaths. Sleep medicine care is migrating from the sleep laboratory into the primary care office where the HST is beginning to be incorporated becoming a

clinical test as commonly utilized as the EKG and pulmonary function test.

The overwhelming majority of individuals that suffer from disorders of sleep and wakefulness are undiagnosed and untreated. Primary care physicians have access to this large grouping of at-risk patients as well as training and experience in the full extent of medical and psychiatric illness affecting patients with sleep disorders. Family physicians often have close relationships with their patients and an awareness and understanding of the biopsychosocial context. These are advantages that the primary care physician has over the specialist in the diagnosis and management of patients with sleep disorders.

Prevention

Sleep disorders are extremely common yet rarely addressed in most primary care practices. A spectrum of poor sleep hygiene practices can contribute to insomnia, especially in high-risk populations such as adolescents and the elderly. Sleep apnea is a primary risk factor for some of the most common chronic illnesses addressed in primary care practice. Due to the significant morbidity and mortality associated with the diagnosis and the difficulty in making the diagnosis using screening tests, the family physician needs to have a high sensitivity to OSA as a potential diagnosis.

Family and Community Issues

Sleep disorders, including the common diagnoses of OSA and insomnia, are commonly found in family members based on both genetic and social factors. Daytime sleepiness in pediatric age groupings is clearly associated with poor school performance. In adults daytime sleepiness whether based on OSA, sedating medication use, sleep disruption, or neurological disease is associated with a significantly higher level of motor vehicular and work-related accidents. This is a particular problem for shift workers and those who must drive for a living.

DOI 10.1007/978-1-4939-0779-3_64-1

As part of comprehensive care family physicians are often asked to perform presurgical assessments. Over 50 million procedures are performed yearly, each with varying degrees of risk [1]. These preinterventional assessments weigh the risks inherent in the surgical intervention along with the preexisting medical state of the patient undergoing the proposed procedure. It is necessary to get a whole picture of the patient in order to address these risks and determine if they outweigh the benefits of surgery. One of the most important components of the preoperative evaluation is communication with the surgical team. That is just as important as communicating to the patient how to prepare for surgery and after surgery. This chapter will not address emergency situations, i.e., exploratory laparotomy due to trauma, as they do not always allow enough time for a full assessment which could end up delaying life-saving treatment. It will, however, address the process of preoperative risk stratification. Recommendations derived from current guidelines will be presented to help prevent adverse outcomes such as postoperative deep vein thrombosis.

History

The preoperative medical history serves as the foundation of the preoperative evaluation. The data collected guides the clinician in identifying patient risk factors, which may lead to downstream complications from the planned surgical

Table 1 Risk factors for perioperative adverse events

Glaucoma
Anesthesia complication
Cardiovascular disease
Pulmonary disease
Thromboembolic disease
Coagulopathy
TIA or stroke
Seizure
Blood transfusion
Blood borne infections
Oral history
Functional capacity
Tobacco/alcohol
Steroid use

procedure if not addressed. The preoperative medical history begins with detailing the planned surgical procedure, including listing the referring surgeon's name, procedure type, indication, and date of the procedure. In addition to including a comprehensive past medical and surgical history, the physician must ask about factors which may lead to adverse events during or following surgery (Table 1). For example, the physician must ask about a personal or family history of reaction to anesthesia, such as malignant hyperthermia. Additionally, general anesthesia can trigger acute angle closure glaucoma, so it is important to obtain information about personal history of glaucoma [2].

A complete history of any cardiovascular disease is particularly important in determining the patient's risk for cardiac complications. For individuals with history of chest pain, myocardial infarction, congestive heart failure, or arrhythmia, include relevant test results, treatment plans, and procedures (i.e., stress test, catheterization, and coronary artery bypass grafting). Similarly, history of pulmonary disease such as asthma, chronic obstructive pulmonary disease, and obstructive sleep apnea should include degree of disease severity and management. Any individual with active unstable or severe cardiac or pulmonary disease should be referred for additional testing and consultation prior to proceeding with elective, nonemergent surgery.

History of thromboembolism, such as DVT or PE, and coagulopathy must be clarified prior to surgery as these patients are at increased risk for both hemorrhage and thrombosis in the perioperative and postoperative periods, respectively. The patient's blood type, if known, should also be included, along with any documented history of transfusion reaction.

Even with adoption of universal precautions, a history of blood-borne and other chronic infectious diseases can pose an increased risk to the surgical team. As such, it is important to include history of hepatitis or HIV. Additionally, one must evaluate any recent or current acute infection to ensure that they have resolved prior to the surgery. This is especially important in pediatric, geriatric, and immunosuppressed patients and may require referral to a specialist in severe or complex cases.

A complete list of all prescriptions and over-the-counter medications as well as other supplements and herbal agents should be documented. A plan of action for each of these medications must be developed to inform patients what they can take prior to and after surgery. Particular attention must be given to any significant steroid use over the past 2 years, as these patients are at increased risk of perioperative iatrogenic hypothalamic-pituitary-adrenal axis suppression and may require stress dosing. This will be described in detail later in this chapter. All patients should also be questioned about alcohol, tobacco, and drug use.

The patient's functional status has a major bearing on operative risk. Functional status can be quantified in Metabolic Equivalents of Tasks (MET). One MET is equivalent to the resting metabolic rate. Patients capable of four METs of activity, equivalent to walking four blocks or climbing two flights of stairs, generally have sufficient physiological reserve to tolerate most surgical procedures [3].

Because patients with untreated obstructive sleep apnea (OSA) are at increased risk from surgical procedures, careful attention must be given to identifying undiagnosed or untreated patients. Multiple sleep apnea questionnaires have been developed to help streamline this process; they are generally associated with higher

Table 2 STOP-BANG screening tool for obstructive sleep apnea

S = Snoring. *Do you snore loudly* (*loud enough to be heard through closed doors*)?
T = Tiredness. *Do you often feel tired, fatigued or sleepy during the daytime*?
O = Observed apnea. *Has anyone observed you stop breathing during your sleep*?
P = Pressure. *Do you have or are you being treated for high blood pressure*?
B = BMI >35 kg/m^2
A = Age >50 year
N = Neck circumference >40 cm
G = Male gender

High risk of OSA: ≥3 of the above
Low risk: <3 of the above

sensitivity than specificity aimed at screening for patients who require additional testing. The STOP-BANG questionnaire has been validated to a sensitivity of >90 % when using 3 as the cutoff point (Table 2) [4].

Consider additional workup for patients at high risk of OSA with overnight polysomnography if surgery is not urgent. For patients with known sleep apnea, the clinician should review previous sleep study and document their CPAP or BIPAP settings, type of mask used and oxygen level (if any is being used), as well as their level of adherence.

Physical Examination

A comprehensive physical examination should always be completed starting with the vital signs, and then working in a head-to-toe fashion as usual. For the anesthesiologist, information about a deviated nasal septum, loose teeth, dentures, and the patient's ability to open his or her mouth is relevant to intubation procedures. Tongue and tonsil size and neck circumference, in addition to other nasopharyngeal structures, are also relevant for sleep apnea evaluation. The physician should carefully evaluate the cardiovascular and pulmonary systems. The blood pressure, heart rate, heart rhythm, presence of significant murmurs, and added sounds (particularly an S_3) should be noted. Evaluate for signs of congestive heart failure (rales, jugular venous distension, edema). Assess thoracic expansion and diaphragmatic excursion. Listen for wheezing or rhonchi, which may identify the presence and severity of emphysema, asthma, or chronic obstructive lung disease. As patients with rheumatoid arthritis and Down syndrome are at higher risk of atlantoaxial joint injury during intubation due to underlying instability, test range of motion and consider obtaining cervical spine radiographs. A mini-cognitive examination should be included for all elderly patients prior to surgery, because there is a risk for postanesthesia delirium in this patient population.

Preoperative Testing

Routine laboratory testing in previously healthy patients yields low positive predictive value on the outcome of a surgical intervention [5, 6]. Abnormal laboratory values are not a common cause of canceling or postponing a surgical procedure. Therefore, there are no required "routine" labs before surgery [7]. If laboratory tests are performed they should be tailored to the patient's medical history and physical exam findings. In some instances physicians will decide to order labs during a preoperative evaluation as that may be the only time a patient seeks care.

Despite the evidence listed above, some surgical centers still require a panel of laboratory tests to be completed preoperatively for all patients. For patients with preexisting conditions such as diabetes and renal insufficiency, it makes sense to check current renal function. This can be extended to patients on antihypertensive medications. Complete blood counts should be obtained in patients with a history of anemia and in the elderly. Coagulation tests are important in patients with a history of bruising and/or taking anticoagulation medication. Test all women of reproductive age for pregnancy, as it is unreliable to use results solely from a questionnaire.

Electrocardiograms should not be performed routinely in previously healthy patients undergoing low-risk surgical procedures [6] but should be

done in patients who will have vascular procedures. Patients over the age of 45 should have an ECG performed as there may be a higher change of electrical abnormalities [8, 9]. ECG should also be performed in patients with any prior cardiac history. Test results up to 4 months prior to surgery can be used as there is unlikely to be significant change unless there is a change in the baseline health status of the patient [10].

Assessment

Patient's Preoperative Risk Based on Type of Surgery

One element of the preoperative evaluation is determining the risk level of the surgical intervention being proposed. Not all surgeries carry the same risk of adverse medical outcomes. The family physician should have a general sense of the risk a surgery poses to a patient apart from the patient's own health status. This will be another factor in determining the extensiveness of the evaluation, whether further workup is warranted, and if the surgical intervention is in the best interest of the patient versus no intervention.

Examples of high-risk surgery include vascular, neurosurgery, prolonged surgery, and coronary artery bypass graft surgery. These surgeries carry a reported cardiac risk of greater than or equal to 5 %. Also in this category are trauma and emergency surgeries yet in these situations time does not allow for a full evaluation and benefit tends to outweigh the immediate risk of death without surgery.

Moderate-risk surgeries carry a reported cardiac risk less than or equal to 5 %. These include abdominal surgery, orthopedic, urogynecologic, peripheral vascular surgeries, cancer staging procedures, and prostate surgery as examples. Surgeries with a reported cardiac risk of less than 1 % are considered low risk. Some of them are performed in ambulatory surgical centers ("same day surgery"). Cataract surgery, endoscopy, breast biopsy, podiatry procedures, vasectomy, and appendectomy are examples (Table 3) [11].

Table 3 Surgical procedure risk

High risk (reported cardiac risk ≥5 %)
Coronary artery bypass graft surgery
Pneumonectomy
Trauma surgery
Neurosurgery
Major vascular procedure
Ruptured abdominal viscus
Emergency surgery
Anticipated prolonged surgery, with hemodynamic instability
Moderate risk (reported cardiac risk usually ≤5 %)
Abdominal surgery (open cholecystectomy, colon resection, etc.)
Orthopedic surgery
Urogynecologic surgery (prostatectomy, hysterectomy, cesarean section)
Splenectomy
Peripheral vascular procedures (endarterectomy, femoral-popliteal bypass)
Prostate surgery
Low risk (generally <1 %)
Cataract surgery
Podiatry procedures
Endoscopy and biopsy
Breast biopsy
Mastectomy
Herniorrhaphy
Vasectomy
Appendectomy
Dermatologic procedures

Preoperative Risk Based on Comorbidities

The preoperative risk is even more greatly influenced by a patient's intrinsic risk factors, such as medical comorbidities and low functional capacity. Numerous risk stratification tools have been developed to help assess cardiovascular risk. Of the most widely used indices, the Revised Cardiac Risk Index (RCRI) (Table 4) is a validated tool that incorporates procedural risk with medical comorbidities, including history of ischemic heart disease, heart failure, CVA, diabetes, and renal failure, to generate a level of risk for major cardiac complications from surgery [12].

Table 4 Goldman revised cardiac risk index

Each risk factors is assigned 1 point		
• High-risk surgery (intraperitoneal, intrathoracic, suprainguinal, vascular)		
• History of ischemic heart disease (ECG with pathological Q waves, angina, nitrate use, prior MI, positive stress test)		
• History of heart failure		
• History of CVA or TIA		
• Preoperative insulin use		
• Preoperative serum creatinine >2.0 mg/dl		
# of risk factors	Risk class	% Major cardiac complications (95 % confidence interval)
0	I	0.4 (0.05–1.5)
1	II	0.9 (0.3–2.1)
2	III	6 .6 (3.9–10.3)
3 or more	IV	11 (5.8–18.4)

Patients with an RCRI score of two or more are considered to be at higher risk of postoperative myocardial infarction, pulmonary edema, ventricular fibrillation, or cardiac arrest and should undergo additional cardiac risk stratification.

More recently, the American College of Surgeons National Surgical Quality Improvement (NSQIP) database was utilized to identify five predictors of myocardial infarction or cardiac arrest up to 30 days after surgery: age, type of surgery, functional status, elevated creatinine (>1.5 mg/dl), and American Society of Anesthesiologist class (*Class I*, patient is completely healthy; *Class II*, patient has mild systemic disease; *Class III*, patient has severe systemic disease that is not incapacitating; *Class IV*, patient has incapacitating disease that is a constant threat to life; and *Class V*, a moribund patient who is not expected to live for 24 h, with or without the surgery). These predictors were incorporated into an interactive online risk calculator (http://www.surgicalriskcalculator.com/miorcardiacarrest) for easy point of care use [13]. The NSQIP risk calculator outperformed the RCRI; however, risk for pulmonary edema and complete heart block are not assessed in the former. Therefore, the two provide additive prognostic value which helps guide clinical management [14].

Role of Beta-Blockers in the Perioperative Period

Beta-blockers have been long theorized to be beneficial in the perioperative period in reducing risk of cardiac ischemia through helping to decrease myocardial oxygen demand by slowing the heart rate and prolonging the time for diastolic filling of the heart. However, due to complications from bradycardia and hypotension, such as cerebral ischemia, the routine use of beta-blockers in the perioperative period is not recommended. Patients already taking beta-blockers should continue taking them when undergoing surgery. Additionally, patients who have a high cardiac risk for ischemia (two or more risk factors) and will undergo a high-risk surgery may benefit from being started on a beta-blocker [14]. Available evidence suggests that beta-blockers should be started several days before elective surgery (up to 30 days), with the dose titrated to achieve a resting heart rate of about 60 beats per min [14, 15].

Role of Corticosteroids in the Pre/Perioperative Period

Physiological level of cortisol secreted from the adrenal gland is approximately 8–10 mg/day and increases to approximately 50 mg/day of cortisol during a minor surgery or illness [16]. Patients who are currently taking corticosteroids may be at risk of hypothalamic-pituitary-adrenal axis insufficiency when faced with the stress of surgery. However, recent literature supports that the majority of patients do not need glucocorticoid supplementation. Patients must first be placed in one of three categories dependent on their length and amount of exogenous steroid use: those who do not requiring supplementation, those who do, and those in between the first two categories.

Patients not requiring supplementation include those who have been taking any dose of glucocorticoid for less than 3 weeks [17], those using morning prednisone ≤5 mg/day or its equivalent for any period of time [18], and patients treated with less than 10 mg of prednisone or its equivalent every other day. These patients can safely

continue their glucocorticoid regimen postoperatively. As with all postoperative patients, they should be monitored for hemodynamic stability.

Patients who would benefit from stress dose steroids include those taking 20 mg/day of prednisone or its equivalent for more than 3 weeks [19] and patients on steroids with Cushing's syndrome. Patients taking evening steroid doses or who took doses which could suppress adrenal function within the past year may require further testing (e.g., ACTH stimulation testing, serum cortisol levels, etc.).

If a patient falls under the category of requiring stress dose steroids, the amount of glucocorticoid dosing is dependent on the type of surgery and whether it produces minor or major stress. Minor surgeries or procedures using local anesthetic do not require anything more than the patient taking his/her usual steroid regimen. Moderate surgical stress (e.g., joint replacement) would include in addition to the patient's usual dose intravenous administration of hydrocortisone 50 mg before the procedure and 25 mg every 8 h for 24 h. For major surgical stress (e.g., esophagogastrectomy, total proctocolectomy, open heart surgery), take usual morning steroid dose. Give 100 mg of intravenous hydrocortisone before induction of anesthesia, and 50 mg every 8 h for 24 h. Taper dose by half per day to maintenance level [20, 21].

Sleep Apnea

Patients with sleep apnea are at higher risk of respiratory and cardiac complications and intensive care requirement following surgery involving sedation, analgesics, and anesthesia [22]. A patient's sleep apnea risk can be calculated using one of the various sleep apnea screening tools available, such as the STOP-BANG discussed previously in this chapter. Any patient with a high screening tool score (i.e., STOP-BANG of three or more) should undergo additional testing with overnight polysomnography [4]. Additionally any patient with known sleep apnea that is not following the recommended treatment plan (i.e., CPAP or BiPAP) should also be referred to a sleep specialist prior to surgical clearance [22].

Deep Venous Thrombosis

All surgical patients are at risk for developing deep venous thrombosis (DVT). This risk is increased for elderly patients, the obese, cigarette smokers, cancer patients, patients who are having long procedures, those with previous venous disease, and those with a history of congestive heart failure. The risk of developing a postoperative DVT depends on the type of surgical procedure and the presence of risk factors. The optimal modality for DVT prophylaxis is controversial. Low molecular weight heparin (LMWH), e.g., enoxaparin (40 mg/day or 30 mg q12h), significantly reduces the incidence of DVT and pulmonary embolism in patients undergoing general surgical procedures, such as urological or gynecological surgery, surgery for elective hip or knee replacement or hip fracture, and other orthopedic procedures including trauma surgery. LMWH in doses of 40 mg per day or 30 mg every 12 h significantly reduces the incidence of postoperative DVT [23].

Low molecular weight heparin is expensive and not without side effects (thrombocytopenia, bleeding). Dosing of LMWH must be adjusted according to creatinine clearance for those with known renal insufficiency. Elderly patients should be carefully monitored for bleeding complications. LMWH prophylaxis is not recommended for patients who are to have neurosurgical procedures or spinal anesthesia, because of an increased risk of bleeding that may compromise neurological functioning. Neurosurgical patients or patients undergoing spinal cord surgical procedures should have prophylaxis with intermittent compression or elastic stockings, as there is decreased risk for hemorrhagic complications. A decision to institute pharmacological prophylaxis should be made by the neurosurgeon.

The optimal duration of DVT prophylaxis is controversial. Some would recommend that LMWH or warfarin be continued for 6 weeks to 2 months after surgery. At a minimum DVT prophylaxis should be continued until the patient is ambulatory for functional distances.

Medications

In general, most medications can be continued up to the day of surgery. Monoamine oxidase inhibitors interfere with autonomic function and may cause perioperative hypertension and/or hypotension. These agents may prolong neuromuscular blockade, inhibit hepatic enzymes, and prolong the action of narcotic drugs. If possible, the medication is discontinued a few weeks before surgery. Beta-blockers and clonidine should be continued until the day of surgery, as there is a possibility of postwithdrawal rebound hypertension. The surgeon should order antibiotic prophylaxis, the class depending on the type of surgery and most likely organisms encountered in that region of the body.

Management of anticoagulants may be problematic during the perioperative period. For patients taking warfarin, the risk of discontinuing anticoagulation must be assessed. For patients with metallic heart valves, warfarin discontinuation is risky, although continuing warfarin up to the time of surgery is contraindicated. If it is reasonable to discontinue the warfarin, it is stopped at least 3 days before surgery and then reinstituted after surgery and the patient treated with intravenous heparin. The heparin infusion is stopped 6 h before surgery, and warfarin is reinstituted after surgery. Alternatively, low molecular weight heparin (LMWH) may be used in doses of ~1 mg/h every 12 h adjusted to renal function for 3 days prior to surgery with the last dose administered 12 h prior to the operation. LMWH or warfarin may then be reinstituted after surgery. Aspirin, which irreversibly inhibits cyclooxygenase and affects platelet adhesiveness, should be discontinued 7 days before surgery. Other nonsteroidal and nonsalicylate products may be continued up to surgery.

There is weak evidence to support routine antibiotic prophylaxis for bacterial endocarditis. This is a major update to the 1997 AHA guidelines done in 2007 and again in 2014 [24, 25]. Patients who are at risk for bacterial endocarditis (patients with prosthetic heart valves, previous endocarditis, and congenital cardiac malformations among others) should receive prophylactic antibiotic coverage. Bacterial endocarditis prophylaxis is recommended for cardiac conditions that are high (prosthetic valves) or intermediate risk (mitral valve prolapse with regurgitation), for developing endocarditis, and for procedures that may result in bacteremia.

Sex, sexuality, and sexual function are often topics that patients want to discuss with their primary care provider [1–4]. The overall prevalence of patients with sexual concerns is estimated at 30 % for men and 30–40 % for women both in the USA and abroad [1–3]. Sexual health is defined by the World Health Organization as a "state of physical, emotional, mental and social well-being in relation to sexuality; it is not merely the absence of disease, dysfunction or infirmity. Sexual health requires a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences" [6, 7].

Evaluating patients with concerns about their sexual health is important and should be patient centered [1–3, 5, 6]. Most sexual concerns are easily treated within primary care without need for referral [1–3, 6, 8].

Definition of Sexual Dysfunction

The criteria for sexual dysfunction differ depending on which consensus committee or professional organization is defining the dysfunction. In this chapter, the definitions used for sexual dysfunction are based on the Diagnostic and Statistical Manual (DSM) of Mental Disorders published by the American Psychiatric Association. The newest version of the DSM, the fifth revision (DSM-5 2013), revealed major changes to the definitions of sexual dysfunction [6, 9, 10].

Table 1 Risk factors for sexual dysfunction [1, 2, 5, 6, 13–17, 25]

Age[a] Medical conditions: Atherosclerotic risk factors[a]: Obesity (ED) Diabetes[a] Hypertension Hypercholesterolemia Coronary artery disease[a] Peripheral vascular disease[a] Stroke [a]	Neurologic disease: Degenerative disease[a] Spinal cord injury[a] Parkinson's Dermatologic conditions: Psoriasis Lichen sclerosus Genitourinary disease STI, HIV disease Pain with sex Surgical conditions: Genitourinary[a] Pelvic[a] Spinal[a] Vascular Trauma Injury Psychological: Depression[a] Bipolar Sleep disorders Anxiety Trauma Psychotic disorders	Substance use: Tobacco (ED)[a] Alcoholism[a] Drugs: Cocaine (ED)[a] Marijuana Methamphetamine (ED) Heroin (ED) Anabolic steroids Social interpersonal: Stress: Work Financial Relational Sexual trauma[a] and violence Social-cultural beliefs Religious beliefs Low educational level Unrealistic expectations Influence of media (Internet)	Body image Eating disorder ego-dystonic Sexuality Gender dysphoria Women: Obstetrical complications Postpartum period Breastfeeding Vaginal prolapse PCOS Menopause[a] Men (ED): Pudendal nerve neuropathy long-distance cycling Sedentary lifestyle
Endocrinopathies: Thyroid disorders[a] Hypogonadism[a] Pituitary dysfunction Adrenal dysfunction Hypothalamic dysfunction Rheumatologic disease Chronic renal failure Cirrhosis COPD Cancer treatments: Chemotherapy[a] Radiation[a]			

[a]Causes with a greater prevalence of sexual dysfunction
Condition associated with erectile dysfunction (ED)

Two new categories were developed in the DSM-5: female sexual interest/arousal disorder and genitopelvic pain/penetration disorder. Female sexual interest/arousal disorder in the DSM-5 would have included hypoactive sexual desire and arousal disorders in the DSM-IV-TR. And genitopelvic pain/penetration disorders in the DSM-5 would have included dyspareunia and vaginismus in the DSM-IV-TR. Female orgasmic disorder remains as a distinct category, and sexual aversion disorder was removed as it is seldom used as a diagnosis and there is little research to support the diagnosis. In men, the definition for premature ejaculation was further clarified to include ejaculation within one minute of penile entry. Male orgasmic disorder was renamed delayed ejaculation disorder, and male hypoactive sexual desire disorder became a distinct category for men. Erectile dysfunction remained the same [6, 9–11].

Approach to the Patient with Sexual Concerns

Much of the information that is relevant to sexual (dys)function is information collected in a thorough history and physical (H&P), such as past medical and surgical histories (including obstetrical history in women), psychosocial history, medications, family history, and a review of systems [1, 2, 5, 8, 12–15].

The history will reveal much of the information needed to make a diagnosis of sexual dysfunction and its etiology. The goal of history taking for sexual dysfunction should be to determine if there are any medical or psychiatric conditions that are known to cause sexual dysfunction (Table 1). Other important aspects of the history are any medication side effects, including herbals, supplements and over-the-counter medications (Table 2).

Table 2 Medications with sexual side effects [1, 16, 18, 20, 25–27, 32]

Global sexual dysfunction (SD):	**Women desire only**:	**Men global SD**:
SSRIs[a]`(50 % paroxetine worst)	Trazodone	Ketoconazole
Antiandrogens	Venlafaxine	Spironolactone (gynecomastia)
Women global SD:	Statins	**Erectile dysfunction**
TCAs	Beta-blockers	Antipsychotics[a]
Barbiturates	Spironolactone	Antidepressants[a]
Lithium[a]	Methyldopa	Venlafaxine
Affect desire and arousal:	Danazol	Benzodiazepines
Benzodiazepines	GnRH agonists	Beta-blockers[a]
Clonidine	Contraceptives	Thiazide diuretics
Tamoxifen	Histamine 2 blockers	Opiates
GnRH analogues	Promotility agents	Antiretroviral
Ultralight contraceptive pills	Indomethacin	Histamine 2 blockers (cimetidine)
Aromatase inhibitors	Ketoconazole	TCA
Chemotherapeutic agents	Phenytoin	Phenytoin
Affect desire and orgasm:	**Arousal only**:	Phenobarbital
Antipsychotics[a]	Anticholinergics	Lithium
Amphetamines	Antihistamines	Bromocriptine
Narcotics		Levodopa
Digoxin		Gemfibrozil
		Methotrexate
		5-Alpha reductase inhibitors
		Corticosteroids

[a]Most commonly has sexual side effects

Sexual History Taking

The initial question many providers ask in the sexual history varies in syntax; however, the content is the same: "When you are sexually active, is it with men, women, or both." Typically providers ask about sexually transmitted infection (STI) risk and/or contraceptive management as appropriate depending on the patient's needs [1, 3, 12].

There are a number of validated questionnaires for sexual functioning. The brief sexual symptom checklist (BSSC), a self-reported questionnaire for men and women, is easily adapted to primary care. This tool can easily be administered prior to the visit or with the provider. The BSSC quickly allows the provider to hone in on areas of sexual functioning that are troubling their patients and follows the DSM criteria for sexual dysfunction [1–3, 5, 14].

The BSSC begins with asking about satisfaction with sexual functioning. If the patient feels that they *do not* have any issues with their sexual functioning, it is appropriate to stop asking questions about this topic. The BSSC continues with questions about the duration of the dissatisfaction with the patient's sexual functioning and then hones in on interest in sex, pain with sex, how distressing the problem is, and whether the patient would like to discuss the problem with their provider. It also specifically asks women about genital sensation, vaginal dryness, and trouble achieving orgasm. In men, it asks about problems with getting or maintaining an erection, whether the patient ejaculates too early or has delayed ejaculation or none at all with or without orgasm, and finally if the penis has an abnormal curvature when erect [1–3, 5, 8, 14].

Physical Exam

The history should guide the physical exam and may or may not uncover the specific root cause of the sexual dysfunction. The cardiovascular exam

should look for risk factors associated with atherosclerotic disease and cardiovascular disease. This includes body mass index (BMI), blood pressure, peripheral pulses, lower extremity changes associated with peripheral vascular disease such as skin changes, lack of hair, and/or claudication as well as edema. The focus of the neurological exam is to assess for peripheral neuropathy, spinal cord disease, or trauma. The musculoskeletal exam should focus on mobility and ability to participate in sexual activity. Patients should be assessed for thyroid disorders by palpating the thyroid [1, 2, 5, 12, 14, 15, 17].

The genital exam in all patients should assess for normal genital development, secondary sex characteristics, and any signs of anal-genital infection. Lack of pubic hair can be a sign of low androgen levels in women and low testosterone in men. In females, the breast exam can reveal the presence of galactorrhea. In addition, the female patient should be assessed for vulvar abnormalities, evidence of vaginal atrophy, trauma/surgical repair such as episiotomy repair, and STIs. The clitoris should be inspected for abnormalities, included tethering as seen in lichen sclerosus [4]. A speculum and bimanual exam may reveal a cystocele, rectocele and/or uterine or anal prolapse, pelvic muscle tone both hyper- and hypotonicity associated with dyspareunia, as well as vaginismus and evidence of endometriosis such as a fixed, retroverted uterus [1, 2, 5, 14]. In men, the exam should focus on any abnormalities or infections; the testes should be assessed for size, atrophy, varicoceles, and epididymitis. And the patient should be asked about erections, abnormal curvature, or disorders of the foreskin such as phimosis. The rectal exam should be used to assess for tone and in men for any signs of prostatic disease [2, 5, 8, 12, 15].

Labs and Other Testing

Laboratory testing should be directed by the H&P to look for specific medical conditions associated with sexual dysfunction. Any patient with a complaint of sexual dysfunction should be screened for diabetes with a glucose and if elevated a hemoglobinA1c, atherosclerotic disease with a lipid panel, and for endocrine disease with a thyroid stimulating hormone (TSH). In men with erectile dysfunction or hypoactive sexual desire, a total testosterone level should be drawn, ideally a morning level. Imaging should be directed by H&P [1, 2, 5, 12, 15, 17].

Approach to Diagnosing Sexual Dysfunction

According to the DSM-5, in order for the diagnosis of any type of sexual dysfunction disorder to be made, the condition must be present for at least 6 months. Within every disorder, it is important to ascertain if the sexual dysfunction is lifelong (primary) v. acquired (secondary) and situational v. generalized and the amount of distress it causes to the patient defined as mild, moderate, or severe [1, 9, 10, 18].

When diagnosing sexual dysfunction, it is critical to determine if the etiology is related to a root cause such as an underlying medical condition (s) or a psychosocial issue (See Table 1). The typical pattern of a medical cause is an older patient with gradual onset of symptoms (unless related to surgery or trauma), generalized dysfunction, consistent or progressive symptoms, normal desire, and underlying comorbidities [2, 5]. The typical pattern of a psychosocial cause is a younger patient with acute onset of symptoms in a specific situation with intermittent symptoms and decreased desire with absent or minimal underlying medical conditions [2, 5].

It is important to note that more than one type of sexual dysfunction can exist. For example, men may have both hypoactive sexual desire disorder with delayed ejaculation and erectile dysfunction, and women may have both hypoactive sexual desire with delayed orgasm and anorgasmia [1, 2, 5, 12, 14, 17].

The DSM-5 states that if sexual dysfunction exists in the absence of a secondary cause, then a true primary disorder exists. If the cause of sexual dysfunction is thought to be secondary to an illness or psychosocial condition, *treatment must be medically maximized* (Tables 1, 2, 3, and 4).

Table 3 Medical treatment of sexual dysfunction in women [1, 14, 16, 20, 28, 29]

Female sexual interest/ arousal disorder	1. Postmenopausal women and post-oopherectomy with desire disorder: testosterone (not FDA approved in women), studies show 300 mcg/day patch. Studies show consistent improvement and least side effects at 300 mcgs. Debate over dosing as this is superphysiologic. Some use of testosterone gel (this has not been studied but allows for lower dosing~1/5 to 1/10 of the dose for men). Treat for 3–6-month trial. Measure baseline testosterone and after 3–6 weeks of initial treatment. If ongoing, check levels q 6 months. If no benefit at 6 months, discontinue. There is no efficacy and safety data after 24 months. Recommend initial evaluation with endocrinology or OB/GYN as off-label use and comanagement. Suggest monitoring liver function and lipids. Intrinsa 300 mcg/day (testosterone patch available in Europe). Side effects: hirsutism (associated with dose, women not more likely to stop due to hair growth, acne (<10 %), virilization rare, lower dose mild), cv risk (risk not established)
	2. Postmenopausal women with vaginal atrophy can be treated with vaginal estrogen (tablets, gels, cream, and rings equally effective) and sexual lubricants. Lowest effective dose should be used. Duration of treatment has not been established. Usual treatment is daily dosing for several weeks and then enough use to maintain effect
	3. Small studies with women with both arousal and desire disorders showed improvement of genital sensation and satisfaction with foreplay and intercourse with sildenafil (Viagra) 25–100 mg daily
Female orgasmic disorder	1. Testosterone for hypogonadism. Doses above
	2. Add bupropion SR 150–300 mg daily (higher dose better)
	3. Phosphodiesterase inhibitors (PDE5I) limited studies and mixed results and most no improvement. One small study showed improvement in orgasmic dysfunction in women on SSRIs and sildenafil
Genitopelvic pain/ penetration disorder	1. Maximize medical treatment of underlying disorder
	2. Vaginismus: Botox may improve symptoms (not well studied)
	3. Vulvodynia: overnight lidocaine ointment, amitriptyline, gabapentin (Neurontin), pregabalin (Lyrica), duloxetine (Cymbalta)

Treating Sexual Dysfunction: General Principles

The well-person exam is an excellent time to speak to patients and educate them about their sexual health and functioning. For some patients, it is helpful to discuss normal anatomy. Providers will often have the female patient look at their anatomy with a mirror. And in the case of men explaining normal responses and functions such as nocturnal emission. Also it is important to emphasize the breadth of a person's sexuality, like normalizing masturbation and in some cases same-sex attraction [1, 8, 12, 14, 16, 17, 19].

In patients diagnosed with sexual dysfunction, it is important to address habits such as tobacco use, excessive alcohol use, and illicit drug use as they are well known to contribute to sexual dysfunction [12, 14, 15, 18]. Poor sleep due to an underlying physical or mental health issue affects multiple areas of functioning as does stress at work or in the patients relationship [1, 12, 14, 15, 17]. Being overweight can affect body image and obesity is associated with erectile dysfunction [12, 15, 18]. Patients should be encouraged to be physically active, as exercise is associated with increased sex drive and better sexual functioning [12, 15, 18].

Pointing out treatable underlying causes of sexual dysfunction is an excellent way to activate patients by using motivational interviewing. For men with ED who smoke, this may be the hook to engage them in behavioral change. Providers should discuss sexual side effects of medications with patients prior to starting them and as part of follow-up once initiated. Adjustments to medications can be made either by changing class, dosing, or adding adjunctive therapies [1, 12, 14, 16, 18].

Therapy is a critical aspect of treatment for sexual dysfunction. Individual therapy can address a number of concerns for sexual dysfunction, including patients with a history of interpersonal violence in past or current relationships

Table 4 Treatment of sexual dysfunction in men [8, 12, 15, 17–19, 23, 24, 30]

Male hypoactive sexual desire disorder	Testosterone for hypogonadism: depo-testosterone (T) 200–250 mg every two weeks
	Transdermal testosterone (closer to circadian levels)
	Patch applied to the arm, back, or upper buttocks alternate sites and avoid sun-exposed area as can cause skin irritation (multiple formulations) Testosterone gel applied daily to clean dry skin over the shoulders, upper arms, or abdomen
	Wash hands after gel use. [a]In T replacement monitor CBC, LFTS, PSA
	Bupropion 150 mg–300 mg daily
Premature ejaculation	SSRIs
	Fluoxetine (Prozac) 20–40 mg/day
	Citalopram (Celexa) 20–40 mg/day
	Paroxetine (Paxil) 10–40 mg/day[a] 20 mg on demand 3–4 h before sex
	Sertraline (Zoloft) 50–200 mg/day[a] 50 mg on demand 4–8 h before sex
	Tricyclic antidepressants (TCAs)
	Clomipramine 12.5–50 mg daily[a] 25 mg on demand 4–24 h before sex
Delayed ejaculation	Almost always related to underlying cause. Also includes retrograde ejaculation
ED: first line	Phosphodiesterase inhibitors (PDE5I) (see Table 4) [a] require periodic monitoring for efficacy, side effects, and change in medical conditions, including new medications
Second line	Medicated urethral system for erection (MUSE) (alprostadil). Self-administered. Primary care with comanagement with urologist. Needs plastic ring around penis and scrotum to maintain erection. Ring should not be in place for more than 30 minutes. Penile and scrotal pain common side effects. First dose in office due to low risk of hypotension and syncope. Female partners may report vaginal discomfort after ejaculation
Third line	Intracavernous injection therapy. Self-administered. Referral to urology.
Other	Vacuum constriction device. Primary care. Effective, low cost. Needs plastic ring around penis and scrotum to maintain erection. Ring should not be in place for more than 30 min. Caution in patients on anticoagulation and antiplatelet therapies
Other	Herbals: not recommended by AUA
	Yohimbine: meta-analysis which shows efficacy of yohimbine over placebo. Dosing is daily but exact dosing unclear from studies
	Korean red ginseng: two small studies outside the USA. Small sample sizes. Viable alternative. Before invasive measures, dose is 900–1000 mg tid
	Pine bark extract (Pycnogenol) may improve ED. Limited data
	Maca extract may improve ED. Limited data
	ED dietary supplements: Warning by FDA may have active PDE5I ingredients with the same precautions

and/or sexual abuse. Refugees who have experienced sexual violence and torture should be referred appropriately. Modalities like cognitive behavioral therapy (CBT) can explore negative patterns of thinking about sex and sexual function and reduce anxiety associated with sexual (dys) function. Couples therapy can explore specific concerns in the relationship, such as communication issues. Sex therapy can explore the dynamics in the relationship or in the individuals that is preventing the couple from sharing an erotic life together. Sensate focus is used to establish communication between partners that begins with non-sensual touch and progresses to sexual intercourse. Sensate focus is easily learned by primary care physicians and is within the domain of primary care [1, 8, 12–14, 16, 17].

Diagnosing and Treating Sexual Dysfunction in Women

Decreased desire and arousal are the most common sexual complaints in women. Up to 46 % of women experience disordered desire and up to 21 % disordered arousal with increasing

prevalence in women as they age. Orgasmic dysfunction is most associated with medication side effects and is common in primary care with a prevalence of 5–42 % and a prevalence of 4–7 % in the general population. Pain with intercourse often has an underlying cause and is frequently seen in the primary care setting with a prevalence of up to 46 % in primary care and 3–18 % in the general population [1, 14]. There is a paucity of high-quality research on medical treatments for sexual dysfunction in women. There is more research on sexual dysfunction in men, specifically erectile dysfunction [1, 14, 32].

Female sexual interest/arousal disorder is diagnosed if the patient lacks or has significantly reduced sexual interest and/or arousal. Specific criteria for the disorder include no or minimal interest in sexual activity, no or minimal sexual/erotic thoughts or fantasies, lack of arousal or response to erotic cues either externally or internally, decreased sexual activity and/or not interested in sex even when initiated by a partner, minimal sexual excitement and/or pleasure during sexual activity in almost all or all sexual encounters, and/or minimal arousal or sensations genitally or otherwise with sexual activity [9].

In younger women, it is recommended that the provider focus on psychosocial concerns like relationship issues, underlying medical or psychiatric disorders, and medication side effects, such as selective serotonin release and reuptake inhibitors (SSRIs) and oral contraception pills (OCPs) [14]. As women age, interest in sex, sexual activity, and frequency does often decline. The same follows for women (and men) in relationships over time and as such may not be distressing to the patient [1, 3, 4]. In postmenopausal women, vaginal atrophy and lubrication issues are common (see Table 3 for treatment details) [1, 14]. Education about masturbation is important. Using adjunctive aids, such as the Eros clitoral device, which is FDA approved, can improve arousal through direct stimulation [1, 14, 20]. Transdermal testosterone is the most studied hormone replacement therapy. Results are promising with some caveats. Most studies are in postmenopausal women. In one study, three women developed breast cancer taking testosterone and estrogen, prompting the FDA to not approve transdermal testosterone due to lack of long-term safety data. However, in this study, the increase was considered insignificant [14, 21, 28]. Bupropion has been shown to improve symptoms of sexual functioning in women; higher doses show better response. However, the studies have small numbers of patients and inconsistent methodologies [1, 14, 21]. In postmenopausal women diagnosed with both interest and arousal disorders, there is a small study that showed women had improved genital sensation and satisfaction with foreplay or intercourse with sildenafil (Viagra) [1, 21]. (see Table 3 for dosing and more detail).

In women with **orgasmic disorder**, most or all of the patient's sexual activity must either have absent, infrequent, or delayed orgasms or markedly reduced intensity of orgasm [9].

Anorgasmia is frequently a medication side effect, particularly with psychiatric medications (SSRIs are infamous for causing delayed orgasm or no orgasm and decreasing sexual desire). Secondary causes are typically related to underlying neurologic causes, such as neuropathy (diabetes), prior trauma, and/or surgery. Women who have male partners with ED and/or premature ejaculation may have difficulty reaching orgasm [1, 4, 16]. Behavioral interventions include direct masturbation and sexual positions that focus on maximize clitoral stimulation (coital alignment) [1, 14, 16]. Medications include bupropion as a possibility for improvement of anorgasmia, although there are few studies with small sample sizes [1, 14] (see Table 3 for more detail).

Women with **genitopelvic pain/penetration disorder** must have persistent or recurrent vaginal or pelvic pain with vaginal penetration or intercourse; marked fear of the pain before, during, or after penetration; and marked hypertonicity of the pelvic floor muscles during penetration [9].

Specific treatments for pain and penetration disorders are directed by underlying cause. Treat to the type of pain: superficial (vulvodynia, dermatologic disease, STI, vaginismus) v. deep (endometriosis, postsurgical/obstetrical complications, bladder, uterine, ovarian, and intestinal disease) [14]. And consider other etiologies, such as

Table 5 Phosphodiesterase inhibitors (PDE5I) [15, 18, 30]

PDE5I	Dosing	Side effects
Sildenafil (Viagra) Short acting: Tmax 1 h, ½ life 4 h	Range 25–100 mg/dose Starting dose 50 mg Take ½–4 h(s) before sex	Class effects High-fat meal can delay absorption Use lower dose if managing side effects from other medications
Vardenafil (Levitra) Short acting: Tmax 1 h, ½ life 4 h	Range 2.5–20 mg/dose Starting dose 10 mg Can take 2.5–5 mg daily or 10 mg prior to sexual intercourse Take ½–4 h(s) before sex	Class effects QT prolongation[a] High-fat meal can delay absorption Use lower dose if managing side effects from other medications
Tadalafil (Cialis) Long acting: Tmax 2 h, ½ life 18 h	Range 2.5–20 mg/dose Starting dose 10 mg Can take 2.5–5 mg daily or 10 mg prior to sexual intercourse Take ½–12 h(s) before sex	Class effects Back pain Use lower dose if managing side effects from other medications
Class effects: Precautions	Side effects	Complications
Renal and liver disease require dose adjustment Use with caution in: >65 years old Liver failure Renal Insufficiency BP<90/50 Uncontrolled hypertension (BP>170/100) Congestive heart failure Recent MI or stroke or arrhythmia (last 3–6 months) Unstable angina Retinitis Pigmentosa **Contraindicated with nitrate therapy*****	Most common: Headache (10–15 %) Facial flushing (5–10 %) Nasal congestion (5–10 %) Dyspepsia (rare) Can lower Blood pressure (rare) Back pain worse with Cialis	HIV protease inhibitor interactions Use with alpha-blockers can cause hypotension **Interactions with multiple medications Sudden loss of vision is a rare side effect. Known to cause non-arteritic anterior optic neuropathy (NAION) (RF for NAION are 50+, cardiovascular disease, DM, HTN, tobacco use) (counsel patients to stop PDE5I if loss of vision and seek care immediately)** Sudden hearing loss with or without tinnitus, vertigo, dizziness[a] Acute myocardial infarctions no nitro 24–48 h if on PDE5I**

vaginal atrophy or neuropathy [1, 14]. Behavioral techniques include non-penetrating pleasuring techniques and biofeedback [1, 14].

In the case of vulvodynia, vaginal hygiene is important. Patients should only wash with water and wear 100 % cotton underwear during the day and none at night. Acupuncture may decrease pain. Lidocaine 2 % gel or lidocaine 5 % ointment on a moist cotton ball placed into the vestibule at bedtime can alleviate pain. Transcutaneous electrical nerve stimulation (TENS) may help women with vestibulodynia. Tricyclic antidepressants (TCAs) and anticonvulsants are considered first-line therapy (See Table 3). In both vulvodynia and vaginismus, a referral to a specialized physical therapist maybe helpful [1, 14, 22]. Ospemifene (Osphena) is a new selective estrogen receptor modulator (SERM), which has been FDA approved for moderate to severe dyspareunia secondary to vulvar and vaginal atrophy in postmenopausal women. Efficacy data is limited [31].

Diagnosing and Treating Sexual Dysfunction in Men

In primary care, erectile dysfunction is a common sexual complaint. In men age 40–50, the prevalence is 2 % and at age 60–70 this increases to 40–50 %. At first intercourse, fear of ED is 20 % and actual erectile dysfunction that hinders penetration is 8 % [9, 12]. Male hypoactive sexual desire increases as men age with a prevalence of 6 % in men age 18–24 to 41 % in men age 66–74. Prevalence of true premature ejaculation based on the new definition of ejaculation within one minute of vaginal penetration is 1–3 %. However, prevalence of premature ejaculation with the prior definition of prematurity, not including a specific time was 20–30 %,making this a common complaint that causes significant distress in men [22, 24]. Delayed ejaculation is most often associated with medication side effects and substances, such as SSRIs [9] (See Table 4).

Men with **erectile dysfunction** have significant difficulty in getting and maintaining an erection and/or have significant lessening of the quality of the erection in most or all instances of sexual activity [9]. The abridged International Index of Erectile Function 5-item Questionnaire is a brief questionnaire that classifies erectile dysfunction on a scale of mild to severe and can be easily used in primary care [12, 18]. It is important to note that ED itself is a predictor of vascular disease in men. Providers should consider screening men with diagnosed ED for peripheral vascular disease and cardiovascular disease [12, 18]. In addition, questions about nocturnal erections, AM erections, and quality of erections with masturbation are important when distinguishing between a psychosocial etiology and an underlying organic cause [12, 18].

Phosphodiesterase inhibitors (PDE5I) are first-line therapy for ED. They are most effective in the cases of antidepressant side effects, diabetes mellitus, and spinal cord injury [12, 15, 18]. Patient reported treatment failure should be evaluated for new underlying medical conditions, hormonal abnormalities, food and medication interactions, timing and frequency of dosing, alcohol use or other substances, relationship concerns, and adequate sexual stimulation [15]. If patients with ED are identified as having hypogonadism, they should be supplemented with testosterone and Initially comanaged with an endocrinologist (see Tables 4 and 5 for details of treatment). Surgical options are considered last resort [12, 18].

Men with **hypoactive sexual desire disorder** have consistent lack of sexual or erotic thoughts, fantasies, or desire for sexual activity [9]. This disorder is most commonly related to aging and poor medical condition. Other risk factors include medication side effects, mental illness, stress, low erotic thoughts, and history of sexual abuse [17, 21]. Hypogonadism can be a cause of erectile dysfunction as well as hypoactive arousal disorder. Other endocrine etiologies such as elevated prolactin should be investigated by MRI for pituitary adenoma and are treated with bromocriptine and if necessary surgery. These two disorders may be comanaged with an endocrinologist. Bupropion may improve symptoms of sexual functioning and desire in men as in women [1, 17, 18].

In **premature ejaculation,** ask the patient if they ejaculate within 1 min of vaginal penetration most or all the time and if this is before the patient would have liked to ejaculate (i.e., distress). It is important to note that premature ejaculation may occur in instances of non-vaginal intercourse. The DSM-5 makes the point of stating that specific duration criteria have not been established for non-vaginal penetration [9]. In the case of patients that do not meet criteria for premature ejaculation, yet have significant distress, it is recommended that they receive reassurance, education, and psychotherapy if indicated and be counseled on pause techniques with masturbation, such as the "pinch and squeeze" to delay ejaculation [8, 19].

Patients with acquired premature ejaculation should use pause techniques and psychotherapy as first line followed by medications. Patients with lifelong premature ejaculation should start with both treatment modalities [8, 19]. Condoms can decrease sensitivity [8, 19].

The American Urological Association (AUA) recommends offering patients topical treatment or

SSRIs as first-line therapy depending on physician judgment and patient preference [23]. Topical anesthetics such as EMLA cream (lidocaine 2.5 %/prilocaine 2.5 %) can be used 20–30 min before intercourse. The EMLA may result in numbness of the vaginal walls and allergies to any "caine" products for either partner are a contraindication to topical treatment [23, 24]. Antidepressants (SSRIs and TCAs) with delayed ejaculation as a side effect may be used daily or "on demand" prior to intercourse (see Table 4). SSRIs are better tolerated and are safer [19]. Both the International Society of Sexual Medicine and the AUA have evidence-based guidelines with slightly different dosing. The AUA recommends men under 18 and those with a history of bipolar disorder not be prescribed these medications [8, 23, 24]. Some smaller studies are suggesting that combination of SSRIs and PDE5Is may be a recommended treatment in the future [24]. There is limited evidence that surgical procedures work for premature ejaculation [8, 23, 24].

PDE5s can be used in premature ejaculation with signs of erectile dysfunction as first-line therapy according to the ISSM. There is conflicting evidence about the use of PDE5I in men with normal erectile dysfunction, as well as concerns about priapism [8, 23, 24].

With **delayed ejaculation,** it is important to ask patients if they have significant difficulty with delayed, infrequent, or absent ejaculation [9]. The most common etiology is medication side effect (see Table 2). The treatment for delayed ejaculation is determining the cause as this is rarely a primary disorder [9]. Patients with delayed ejaculation or absence of ejaculation, and at risk for retrograde ejaculation should be evaluated for this condition [18].

In the case of **substance-/medication-induced sexual dysfunction,** there must be a temporal association between the substance/medicine (either initiation or withdrawal) and the dysfunction with no other explanation. With substance-induced sexual dysfunction, cessation is the only treatment. With medications, adjustments can be made (see Table 2). There is little research that provides high-quality evidence about treatments for sexual dysfunction secondary to antidepressants. In men, the recommendation is to use PDE5Is and in women the addition of bupropion (300 mg) at higher doses is the most studied. Other less studied options are waiting for drug tolerance (e.g., SSRIs usually 6 months), taking a drug holiday, adding bupropion to an SSRI regimen, or switching to medications with fewer sexual side effects (bupropion or mirtazapine) [1, 14, 27, 32].

Referrals

Most diagnoses of sexual dysfunction can easily be made in the domain of primary care and referral made to mental health providers for supportive therapy as well as specialized physical therapists. Indications for specialized referral are treatment failures, cases requiring surgical intervention, and patient request. Patients with complex endocrinopathies (adrenal, pituitary, hypothalamic), vascular and neurologic disease, or chronic persistent mental illness can be comanaged or referred depending on provider comfort and patient preference [2, 8, 18].

Care of the Alcoholic Patient

Herbert L. Muncie*
Department of Family Medicine, Louisiana State University School of Medicine, New Orleans, LA, USA

Overview

Alcohol, as an intoxicant, has been a part of human civilization for millennia. Alcohol's intoxicating effect appears to be due to the altering of cell membrane's action potentials, specifically modulating the activity of gamma aminobutyric acid (GABA) and *N*-methyl-D-aspartate (NMDA) channels. Enhancing GABA's inhibitory effect leads to a global decrease of membrane potentials. NMDA , an excitatory neurotransmitter, is blocked in the presence of ethyl alcohol. Acutely, this results in an anxiolytic effect and lowers inhibitions. Higher blood alcohol concentrations (BAC) lead to slurred speech, confusion, and motor impairment. Levels above 300 mg/dL (0.3 g/dL) can cause stupor, coma, respiratory depression, and finally death.

Alcohol use disorder (AUD) is an intersection of multiple variables affecting all social and ethnic groups. Genetic predisposition, social variables, family issues, and comorbid medical/psychological diagnoses factor into the development of AUD [1].

Alcohol abuse causes cirrhosis and contributes to the development of cancers of the head, neck, and digestive tract. Excess alcohol intake causes or exacerbates hypertension, cardiomyopathies, stroke, and dementia. Pancreatitis and pneumonia can be the result of alcohol misuse as can an array of psychiatric disorders and other substance abuse disorders.

Prevalence

During their lifetime, 20 % of men and 10 % of women will have an AUD [2]. The risk of alcohol dependence is 12.5 % over a patient's lifetime [3].

Adolescents and young adults have more binge drinking, defined as males drinking five or more drinks (four for women) at any one time. Patients exposed to alcohol at a young age are more likely to develop problematic drinking or other substance abuse problems [4].

The elderly are not immune to AUD with 2–4 % suffering from alcohol abuse. In the older patient, more neurologic and physiologic impairment occurs at a lower BAC. Care should be taken when prescribing medications that can be potentiated with alcohol use, such as sedative-hypnotics [5].

Screening

The United Stated Preventative Services Task Force (USPSTF) recommends screening adults aged 18 years or older for alcohol misuse and providing persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce alcohol misuse [6]. For patients between the ages of 12–17 the USPSTF believes the evidence is insufficient to assess the balance of benefits and harms of screening by a primary care physician.

*Email: hmunci@lsuhsc.edu

DOI 10.1007/978-1-4939-0779-3_66-1

Alcohol use during pregnancy is one of the leading causes of preventable birth defects and developmental disabilities. The physician should screen for alcohol use at every prenatal visit. Screening benefits the mother, the fetus and society. Because there is no safe level of alcohol consumption during pregnancy, abstinence is recommended.

The USPSTF recommends three tools for screening adults for alcohol misuse in the primary care setting; the Alcohol Use Disorders Identification Test (AUDIT) available at http://www.integration.samhsa.gov/AUDIT_screener_for_alcohol.pdf, the abbreviated AUDIT-Consumption (AUDIT-C) and the single-question method. AUDIT has ten questions and takes between 2 and 5 min to administer. The first three questions ask about the patient's consumption pattern. Questions 4–6 quantify the patient's tolerance or dependence on alcohol. The last four questions deal with alcohol-related problems the patient has experienced. A score of 8 or more has a high sensitivity and specificity for hazardous and harmful alcohol use.

The AUDIT-C is comprised of the first 3 AUDIT questions and is scored from 0 to 12 points. Administering it takes between 1 and 2 min. A score of 5 or more for men (four or more for women) is considered high risk for excessive and problematic alcohol use.

The Single-question method has the benefit of taking less than 1 min to administer. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) recommends this question, "How many times in the past year have you had 5 [for men] or 4 [for women and adults older than 65 years] or more drinks in a day?" A positive response warrants further investigation.

The CAGE questionnaire can be used for adolescents and adults. The four questions are: (1) Have you ever felt you should **CUT DOWN** on your drinking? (2) Have people **ANNOYED** you by criticizing your drinking? (3) Have you ever felt bad or **GUILTY** about your drinking? (4) Have you ever had an **EYE OPENER** or a drink in the morning to steady your nerves or to get rid of a hangover? A positive answer to two or more questions is sensitive and specific for AUD.

The CRAFFT questionnaire was designed for the adolescent patient [4]. The questions are: Have you ever ridden in a **CAR** driven by someone (including yourself) who was "high" or had been using alcohol or drugs? Do you ever use alcohol or drugs to **RELAX**, feel better about yourself, or fit in? Do you ever use alcohol or drugs while you are by yourself, **ALONE**? Do you ever **FORGET** things you did while using alcohol or drugs? Do your family or **FRIENDS** ever tell you that you should cut down on your drinking or drug use? Have you ever gotten into **TROUBLE** while you were using alcohol or drugs?

Diagnosis

AUD diagnosis is a collection of physical and behavioral symptoms. The main features are alcohol craving, tolerance, and withdrawal. The diagnostic criteria are listed in The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) (Table 1).

According to the DSM-5, remission of AUD is divided into three categories. Early remission is when no criteria (except for craving or strong desire) have been met for at least 3 months but less than 1 year. Sustained remission is achieved when no criteria (except for craving, or strong desire) have been met for 1 year or longer. And remission in a controlled environment is a special circumstance used when a patient's access to alcohol is outside of their control.

DOI 10.1007/978-1-4939-0779-3_66-1

Table 1 Definition of alcohol use disorder [52]

DSM-5[a]	
A problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by **at least two** of the following, occurring within a 12-month period	
Alcohol is taken in larger amounts or over a longer period than was intended	Important social, occupational, or recreational activities are given up or reduced because of alcohol use
There is a persistent desire or unsuccessful efforts to cut down or control alcohol use	Recurrent alcohol use in situation in which it is physically hazardous
A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects	Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol
Craving, or a strong desire or urge to use alcohol	Tolerance, as defined by either of the following: 1. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect 2. A markedly diminished effect with continued use of the same amount of alcohol
Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home	Withdrawal, as manifested by either of the following: 1. The characteristic withdrawal syndrome for alcohol 2. Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms
Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol	

[a]*Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition

Treatment of Alcohol Use Disorder

The physician's attitude toward the patient is an important aspect of AUD treatment. Alcoholism is a particularly stigmatized mental disorder [7]. These patients provoke more social rejection and negative emotions and are deemed responsible for their condition [7].

Patients with AUD feel embarrassed and deeply vulnerable regarding their prior consequences of alcohol abuse. However, patients who screen positive for alcohol abuse show motivation to change, especially as the severity of alcohol misuse increases. To assist the patient through this difficult time, the physician should be nonjudgmental in their approach. Focus the discussion on past problems that have occurred and take a supportive role in the patient's current problem indicating treatment can be successful.

Intermittent Abuse or Binge Drinking

For patients with intermittent alcohol abuse or binge drinking, the initial treatment is a brief intervention [8]. Brief interventions can be single or multiple short duration (5–25 min) feedback sessions regarding the patient's alcohol use. The healthcare provider discusses the consequences of the patient's alcohol use (i.e., failed relationships, accidental trauma, family stress, job loss), a safe alcohol intake amount and assesses the patient's readiness for change. The patient is told their drinking is not medically safe and they should reduce their intake [9] (Fig. 1). Patients who drink despite brief interventions are candidates for intensive therapy.

DOI 10.1007/978-1-4939-0779-3_66-1

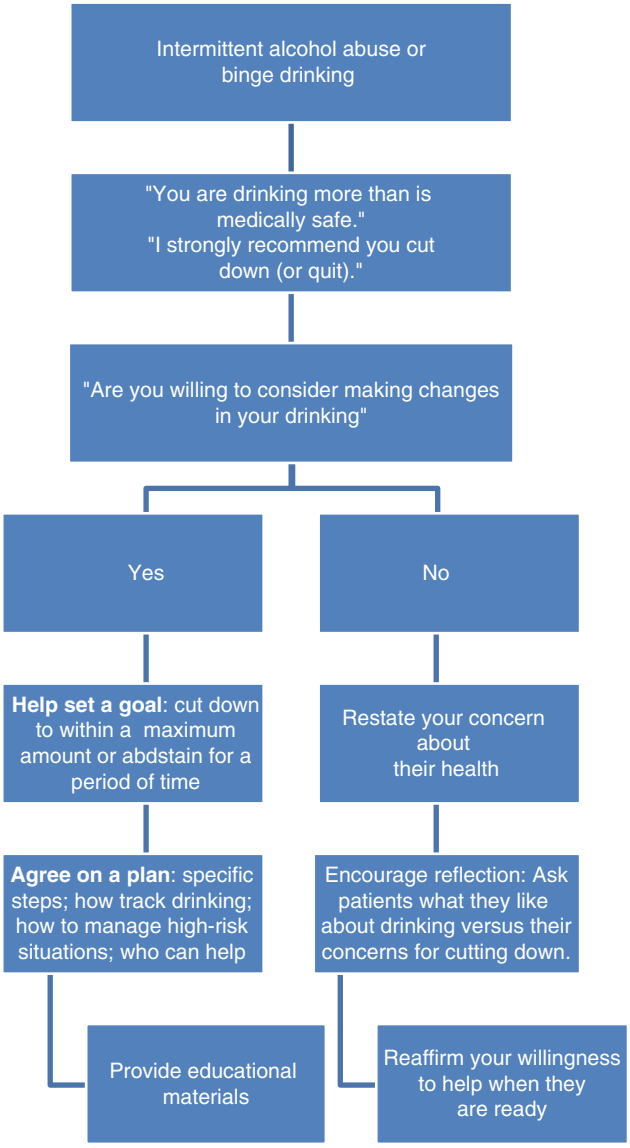

Fig. 1 Brief intervention for intermittent alcohol abuse or bing drinking http://pubs.niaaa.nih.gov/publications/Practitioner/CliniciansGuide2005/clinicians_guide7.htm#top

Chronic Alcohol Abuse and Dependence

Patients with moderate to severe AUD should be confronted about the negative consequences of their alcohol use. Strongly recommend they abstain and ask about their willingness to abstain (Fig. 2). Initial interventions can be cognitive behavioral therapy, 12-step facilitation or motivational-enhancement therapy. Advising patients to cut down or eliminate consumption has been equally effective at reducing alcohol intake.

At a minimum, patients can be referred to interactional group therapy or mutual help programs, such as Alcoholics Anonymous (AA) (See "Long-Term Management of Alcohol Dependence"). The time and location of the local AA meetings can be found during the patient's encounter and the patient encouraged to attend a meeting that day.

DOI 10.1007/978-1-4939-0779-3_66-1

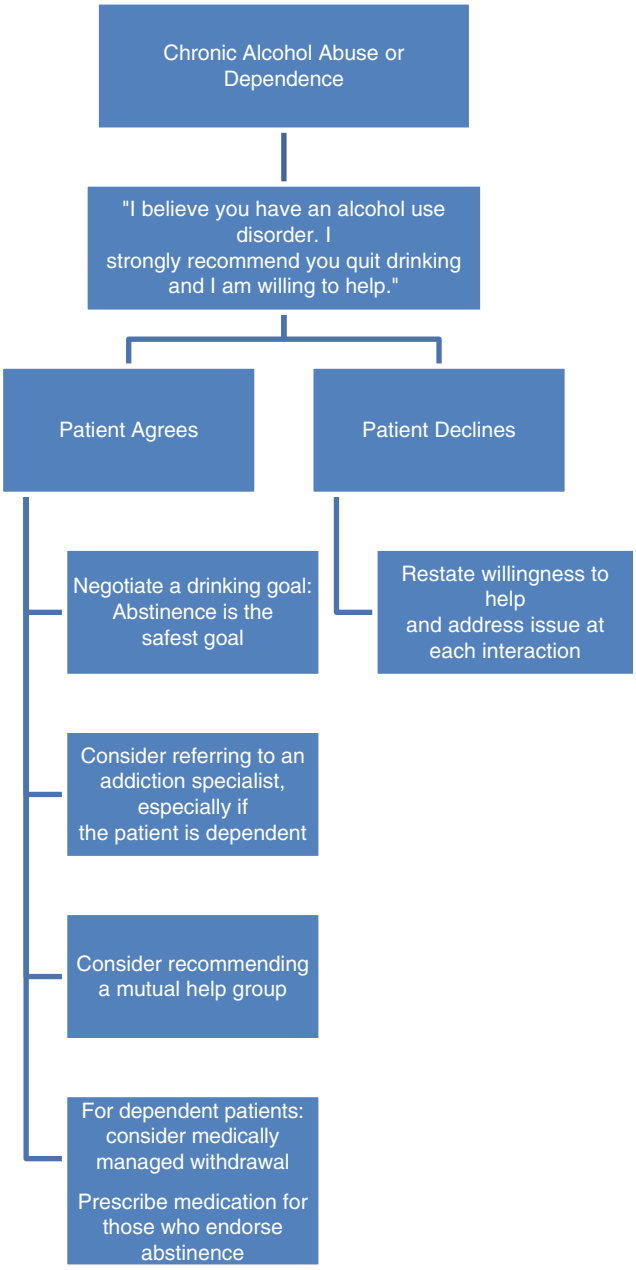

Fig. 2 Confronting chronic alcohol abuse or dependence http://pubs.niaaa.nih.gov/publications/Practitioner/CliniciansGuide2005/clinicians_guide7.htm#top

Alcohol Withdrawal Syndrome

For patients who consume large quantities of alcohol (>20 drinks/week) for a prolonged period of time (>2 weeks) and discontinue intake, approximately 50 % will experience withdrawal symptoms [3]. The symptoms begin 6–24 h after the last alcohol intake or a significant reduction in alcohol intake [10].

Alcohol withdrawal involves the central nervous system, autonomic nervous system, and cognitive function [11]. Alcohol withdrawal syndrome (AWS) is any two of the following: (1) autonomic hyperactivity (sweating, tachycardia); (2) increased hand tremor; (3) insomnia; (4) nausea or vomiting; (5) transient visual, tactile, auditory hallucinations or illusions; (6) psychomotor agitation; (7) anxiety;

DOI 10.1007/978-1-4939-0779-3_66-1

or (8) tonic-clonic seizures [10]. Delirium tremens (DTs), a severe hyperadrenergic state (i.e., hyperthermia, diaphoresis, tachypnea or tachycardia) characterized by disorientation, impaired attention and consciousness with visual and/or auditory hallucinations, can occur with either no treatment or under treatment of AWS [10].

AWS can be viewed in three stages. Stage 1 symptoms are mild anxiety, tremor, insomnia, headache, palpitations, or gastrointestinal disturbances with normal vital signs. Stage 2 symptoms are more intense and associated with abnormal vital signs (i.e., elevated BP or pulse, increased respirations, or increased temperature). Stage 3 includes stage 2 symptoms and either DTs or seizures. Progression to stage 2 or stage 3 can proceed quickly without treatment [12].

AWS severity is assessed using a validated instrument. The instrument often recommended is the Clinical Institute Withdrawal Assessment – A revised (CIWA-Ar) available at http://www.mdcalc.com/ciwa-ar-for-alcohol-withdrawal/ [13]. A CIWA-Ar score of 0–7 points is absent or very mild AWS, 8–15 points is moderate AWS and >15 points is severe AWS [3]. The self-completed Short Alcohol Withdrawal Scale (SAWS) (available at http://www.aafp.org/afp/2013/1101/p589.html) has been validated in the outpatient setting [14]. A SAWS score <12 is mild AWS and ≥12 is moderate AWS.

Treatment of AWS

The AWS treatment goals are to reduce withdrawal symptoms, prevent complications (seizures, DTs, or death), and prepare the patient for long-term abstinence. Adequately and promptly abating AWS symptoms diminishes the severity of future withdrawal episodes and the risk the patient will resume drinking to ameliorate their symptoms [10]. Alcohol withdrawal seizures occur 24–72 h after the last alcohol intake, are typically tonic clonic, and last less than 5 min. Up to one third of patients with an alcohol withdrawal seizure will progress to DTs.

When Is Medically Supervised AWS Treatment Not Necessary?

Patients with no alcohol intake in the preceding 5 days and have not abused other drugs do not require medical treatment. They should not be given medication and any symptoms are related to comorbidities (i.e., anxiety, depression, other drug withdrawal) and not AWS.

Outpatient Treatment of AWS

Outpatient treatment of mild or moderate AWS is safe, effective, and less expensive than inpatient treatment [10]. Treating the patient in an outpatient setting can minimize expenses and allow for less interruption of work and family life. The following conditions preclude outpatient treatment: serious psychiatric conditions (e.g., suicidal, psychosis, etc.), acute illness, severe alcohol withdrawal symptoms, high risk of delirium tremens (DTs), history of withdrawal seizure, long-term intake of large amounts of alcohol, poorly controlled chronic medical conditions (e.g., diabetes, COPD, CHF), lack of a support network [10].

While laboratory tests are not necessary for mild AWS, significant laboratory abnormalities would preclude outpatient treatment. A positive urine drug screen, signifying a co-occurring substance abuse, would prevent outpatient treatment.

And finally, in addition to medical issues that prevent outpatient treatment, the patient must be able to take oral medications, commit to frequent follow-up visits, and have a support person who can stay with them and administer medication [11]. The dispensing of medication requires clinical judgment and creates issues of control, thus caregivers must be informed of their role and be in agreement [10]. Family support can be critical in the success of outpatient treatment. However, family dysfunction or home alcohol consumption triggers can make outpatient treatment success unlikely.

DOI 10.1007/978-1-4939-0779-3_66-1

Inpatient Treatment of AWS

AWS patients could be admitted to the hospital if they are not appropriate for outpatient treatment or if they fail outpatient treatment. AUD patients may be admitted to the hospital for other problems (e.g., pneumonia, pancreatitis, etc.) and experience AWS. When patients are admitted they become accessible to health care professionals for an intervention [15]. If their reason for admission is the consequence of alcohol abuse, it could represent a triggering occurrence which could serve as a catalyst for change in alcohol use [16]. For the nondependent patient, alcohol consumption was reduced if they had more than one brief intervention during their hospital stay [17]. A single screening and brief intervention in the Emergency Room or nonemergency Department hospital setting did not reduce alcohol consumption [18].

Reducing Symptoms

Alcohol withdrawal symptoms are increased with external stimulation. Patients should have a quiet and subdued environment with minimal opportunities for external stimulation. Patients with mild AWS may only require supportive care [10]. Most patients are given medication, particularly if there is any question about their duration of abstinence.

Because AWS patients are often nutritionally depleted, thiamine and folic acid supplementation are given to all patients. Thiamine 100 mg once a day is recommended to reduce the risk of Wernicke's encephalopathy (oculomotor dysfunction, abnormal mentation, and ataxia). Folic acid 1 mg daily is recommended. Intravenous fluids are not beneficial for AWS unless the patient has persistent vomiting or develops DTs.

Preventing Complications

Benzodiazepines (BZD) and anticonvulsants treat alcohol withdrawal symptoms and prevent complications (Table 2). They reduce psychomotor agitation and prevent progression of withdrawal symptoms [19]. They should be administered early in the AWS course. No evidence supports the superiority of any medication in treating AWS.

BZDs can be long-acting (chlordiazepoxide, diazepam) or intermediate-acting (lorzepam, oxazepam). Long-acting BZD may be more efficacious in preventing delirium [20]. They have active metabolites that prolong their sedative and anxiolytic effects [20]. Experts contend that long-acting BZDs provide a smoother withdrawal experience with fewer fluctuations in symptoms; however, intermediate-acting BZD have been used successfully [19]. In patients with hepatic dysfunction, the intermediate-acting agents may be safer because they have no active metabolites. Chlordiazepoxide or oxazepam have less abuse potential, but no data supports their superiority in treating AWS. Because BDZ can cause fatalities when combined with alcohol, they should be prescribed them in small amounts.

Carbamazepine and valproic acid are effective in treating AWS [21]. However, anticonvulsant medication efficacy data is limited and carbamazepine is associated with dizziness, ataxia, diplopia, nausea, and vomiting [22]. Limited evidence supports the use of valproic acid over BZD [23]. Oxcarbazepine was as effective as carbamazepine in treating AWS [24], although one placebo-controlled randomized trial did not support that contention [25]. Gabapentin was effective in treating AWS and reducing drinking during withdrawal [26]. Anticonvulsant medications have reduced abuse liability but they do not prevent withdrawal seizures or DTs.

Alternative AWS Medications: Less Effective

While baclofen was effective in reducing AWS symptoms and may reduce the risk of relapse without a risk of abuse, the overall data is mixed [27]. As adjunctive therapy, beta-blockers and the alpha-adrenergic agonist clonidine are effective in reducing adrenergic symptoms but are not effective in preventing

DOI 10.1007/978-1-4939-0779-3_66-1

Table 2 Medications used to treat AWS

Medication	Typical dosage	Common side effects	Contraindications
Benzodiazepines			
Chlordiazepoxide Diazepam Lorazepam Midazolam (for DTs)	25–50 mg 10 mg 2 mg 1–4 mg (IM/IV)	Sedation, fatigue, respiratory depression, retrograde amnesia, ataxia, dependence and abuse	Hypersensitivity to drug/class ingredient Severe hepatic impairment Avoid abrupt withdrawal
Anticonvulsants			
Carbamazepine Oxcarbazepine Valproic acid Phenobarbital	600–800 mg 450–900 mg 1000–1200 mg 1500–2000 mg/day	Dizziness, ataxia, diplopia, nausea, vomiting	Hypersensitivity to drug/class ingredient, hypersensitivity to TCAs, no MAOI within 14 days, hepatic porphyria, avoid abrupt withdrawal
Beta – blocker			
Atenolol	50 mg if pulse 50–79 100 mg if pulse ≥80	Bradycardia, hypotension, fatigue, dizziness, cold extremities, depression	Hypersensitivity to drug/class ingredient, AV block second or third, uncompensated heart failure, cardiogenic shock, sick sinus syndrome without ICD, untreated pheochromocytoma, avoid abrupt withdrawal
Alpha-adrenergic agonist			
Clonidine	0.2 mg	Hypotension, dry mouth, dizziness, constipation, sedation	Hypersensitivity to drug/class ingredient, avoid abrupt withdrawal

withdrawal seizures [19]. Neither phenothiazines nor barbiturates are recommended for AWS treatment in the outpatient setting [19]. Phenytoin is not effective in the treatment or prevention of withdrawal seizures [11].

Outpatient BZD Dosing Options

BZD are given in a fixed-dose or symptom-triggered schedule. A front-loading or loading-dose schedule is not recommended. The fixed-dose schedule utilizes a specific dosage at specific intervals regardless of the patient's symptoms. Additional medication is given if needed to control symptoms and the dosage reduced if overmedication occurs [10].

The symptom-triggered schedule utilizes medication when the patient has significant symptoms (CIWA-Ar $>$ 9; SAWS $\geq$ 12). This schedule reduced medication use and shortened duration of treatment for inpatients [28]. One trial with a long-acting BZD in ambulatory patients revealed no difference between the fixed-dose and symptom-triggered schedule regarding total BZD dosage, patient satisfaction, or time to relapse [29]. Symptom-triggered schedules rely on the patient and caregiver to rate symptoms and may not be appropriate for some outpatients. A typical fixed-dose and symptom-triggered schedule is suggested (Table 3).

Inpatient Dosing Options

For hospitalized patients, BZDs can be given with a fixed-dose, symptom-triggered, or loading-dose regimen. However, for the hospitalized patient a loading-dose of a long-acting BZD has been found to improve outcomes in AWS [30]. The typical diazepam loading dosage is 20 mg every hour for 3–12 h until symptoms are controlled. Then either the fixed-dose or symptom-triggered outpatient regimen is implemented. Ethanol should not be used to treat AWS.

DOI 10.1007/978-1-4939-0779-3_66-1

Table 3 Fixed dosage and symptom-triggered dosage options to treat AWS [10]

Treatment day	Fixed dosage schedule (orally)	Symptom-triggered schedule (orally) For SAWS $\geq$ 12 or CIWA-Ar $>$ 9
Day 1	Diazepam 10 mg every 6 h Chlordiazepoxide 25–50 mg every 6 h Lorazepam 2 mg every 8 h	Diazepam 10 mg every 4 h Chlordiazepoxide 25–50 mg every 4 h Lorazepam 2 mg every 6 h
Day 2	Diazepam 10 mg every 8 h Chlordiazepoxide 25–50 mg every 8 h Lorazepam 2 mg every 8 h	Diazepam 10 mg every 6 h Chlordiazepoxide 25–50 mg every 6 h Lorazepam 2 mg every 6 h
Day 3	Diazepam 10 mg every 12 h Chlordiazepoxide 25–50 mg every 12 h Lorazepam 1 mg every 8 h	Diazepam 10 mg every 6 h Chlordiazepoxide 25–50 mg every 6 h Lorazepam 1 mg every 8 h
Day 4	Diazepam 10 mg at bedtime Chlordiazepoxide 25–50 mg at bedtime Lorazepam 1 mg every 12 h	Diazepam 10 mg every 12 h Chlordiazepoxide 25–50 mg every 12 h Lorazepam 1 mg every 12 h
Day 5	Diazepam 10 mg at bedtime Chlordiazepoxide 25–50 mg at bedtime Lorazepam 1 mg at bedtime	Diazepam 10 mg every 12 h Chlordiazepoxide 25–50 mg every 6 h Lorazepam 1 mg every 12 h

Monitoring Withdrawal: Outpatient

Most patients are evaluated daily until their symptoms decrease and the medication dosage is reduced. Blood pressure and pulse should be measured at each follow-up visit. If available, an alcohol breath analysis could be done randomly. Reassessment of the AWS severity is done with the same instrument used initially. When the CIWA-Ar is $\leq$8 or SAWS is $<$12, medication can be reduced and eventually discontinued. Alcohol withdrawal symptoms should resolve within 7 days of abstinence. The patient can be discharged to long-term outpatient treatment when symptoms are minimal, no medication is needed, and there has been no alcohol intake for at least 3 days. Patients who have an inadequate response to BZD, miss an outpatient appointment or resume drinking should be referred to an addiction specialist.

Monitoring Withdrawal: Inpatient

For patients admitted to the hospital, the frequency of monitoring is usually every 4–6 h. If possible allow patients to use normal clothes instead of hospital gowns. One advantage of inpatient treatment is the frequent interactions with the nursing staff, who can be supportive during treatment. The patient can be discharged when the AWS symptoms are mild.

Management of DTs

DTs, severe AWS, is associated with an increased risk of death. DTs symptoms begin about 3 days after initial withdrawal symptoms develop [31]. DTs risk factors include sustained heavy drinking, age over 30, more days since last drink, and, most importantly, a prior episode of DTs [10]. Hallucinations, common in DTs and primarily visual, are not dangerous but are distressing to the patient and his or her caregiver.

The treatment of DTs is a medical emergency requiring inpatient care and prompt symptom treatment. The control of agitation is the initial goal and can be achieved with a benzodiazepine (Table 2). The patient's condition determines the route of administration. Most medications will be given intravenously, intermittently, until the symptoms subside. The doses required to control agitation vary dramatically and can be quite large (e.g., $>$2000 mg diazepam in the first 2 days) [3]. Monitoring is more frequent than either outpatient or regular inpatient care, usually every 2 h. Confusion may be reduced by limiting stimulation, good lighting, and environmental cues such as having a clock or calendar visible.

DOI 10.1007/978-1-4939-0779-3_66-1

Physical restraints may be used to protect the patient and staff utilizing the institution's restraint protocol. For patients who do not respond to high doses of a benzodiazepine, propofol (0.3–1.25 mg/kg/h IV) can be administered in the ICU [3]. Another ICU medication is dexmedetomidine (Precedex®) (0.4–0.7 mcg/kg/h IV), an α_2-adrenergic agonist has been administered [32]. Intravenous fluids should be utilized to maintain hydration and to treat electrolyte abnormalities [31].

Long-Term Management of Alcohol Dependence

Due to the chronic and relapsing nature of alcohol dependence, implementing long-term treatment is essential for the maintenance of remission. From 40 % to 60 % of AUD patients relapse within 1 year after entering treatment. Following recovery from alcohol withdrawal, continuing care can be provided in an inpatient or outpatient setting.

Interventions to maintain remission are based on the patient's current clinical status, medical and psychiatric comorbid conditions, level of current use, risk for relapse, motivation for recovery, and personal preferences [33]. The American Society of Addiction Medicine's Patient Placement Criteria (Second Edition) can assist clinicians in determining appropriate levels of care. Levels of care include residential programs, partial hospital programs, intensive outpatient programs, and outpatient care [34].

Levels of Care

Residential care programs are inpatient programs providing housing, peer and professional support, and an alcohol free environment. Examples of residential treatment models include community residential treatment facilities, therapeutic communities, and Oxford house [34].

Therapeutic communities provide comprehensive care and emphasize graduated personal and social responsibility. Appropriate patients tend to be relapse prone, polysubstance abusers, often with psychiatric comorbidities and poor social support. Staff and clients reside together and interact in activities with the goals of assimilation of social norms, development of social skills, and positive impact upon attitudes, perceptions, and behaviors. Typically, stays have ranged from 18 to 24 months with a desired minimum of 90 days.

Oxford House (www.oxfordhouse.org) is a publically supported recovery concept where individuals live together in democratically run, self-supporting residences without addiction counselors. The residential complement ranges from 6 to 15 individuals per house and specific residences may be designated for men, women, or women with children. Treatment interventions are self-selected by the participants.

Partial hospital programs (PHPs) allow for increased flexibility for the patient who wishes to stay at home but needs a higher level of care. Patients participate a minimum of 20 h per week but can be as much as 6 h per day 5–7 days per week. The care includes individual and group counseling, medication management, didactic sessions, and even specialized services such as occupational therapy [34].

Intensive Outpatient Programs (IOP's) are structured similar to PHPs and may be housed in the same facility as a PHP but provide only 10–20 h of treatment per week [34]. **Outpatient care** model utilizes similar services as IOP's but interventions are less frequent (less than 10 h/week) and shorter in duration [34].

Psychosocial and Behavioral Interventions

Interactional Group Psychotherapy or "self-help" groups based on the 12 step program are historically significant but evidence supporting their effectiveness is limited The most well-known adaptation, *Alcoholics Anonymous* (AA), was founded in 1935 and thrives today as a worldwide network [35]. The 12 steps serve as a template for behavioral interventions aimed at maintenance of sobriety and the

DOI 10.1007/978-1-4939-0779-3_66-1

fellowship provides an abstinent social network to replace lost "drinking buddies" [36]. Daily meetings are offered in wide variety of venues and group composition varies by age, gender, and interests of the participants. Common elements include the acknowledgement of individual powerlessness over alcohol and the existence of a higher power, selection of a sober sponsor, and an emphasis on relapse forgiveness. Companion organizations for family support include *Al-Anon* and *Alateen*.

For patients uncomfortable with the spiritual aspect of the model, similar nonreligious programs exist such as *SMART Recovery, Rational Recovery,* and *Save Our Selves.* Though the efficacy of AA has not been sufficiently assessed in randomized controlled trials, experts generally agree that it produces positive outcomes [36–38]. However, a Cochrane review concluded there is a lack of experimental evidence supporting the effectiveness of 12-step programs for alcohol dependence [39].

Group Therapy is a formal continuing care therapy session led by a trained professional. Sessions typically last 90 min and occur one or two times per week. They may occur in a 12 step format where patients report on their progress through the steps and they are given feedback and support, or they utilize an instructional format which utilizes elements of Cognitive Behavioral Therapy (discussed below) or emphasize skills development. The methods are equally efficacious and more cost effective than individual therapy. Advantages include peer influence on sobriety, role modeling of sober behavior, avoidance of social isolation, and reinforcement by example that successful remission is possible [36].

Individual therapy occurs in sessions typically lasting 30–60 min. The frequency and duration of such sessions is dependent on the patient's duration of remission and on continued sobriety. Initially, clinicians may interact with patients three or more times per week. Care is stepped up or down based on the patient's progress [36].

Cognitive Behavioral Therapy (CBT) is a format which identifies triggers for alcohol abuse, develops coping strategies for risky situations, and defines alternative activities to replace those activities which challenge sobriety. Patients are given homework assignments to guide them in determining what leads to alcohol use and in developing responses to avoid relapse. A meta-analysis concluded that CBT was modestly beneficial in maintenance of sobriety [40].

Relapse Prevention is a form of CBT specifically aimed at identifying individual risk factors for relapse and then selecting and rehearsing coping responses for those risks. A meta-analysis demonstrated effectiveness comparable with other psychosocial interventions [41].

Motivational Enhancement Therapy (MET) is based on the premise that responsibility and capacity for change lies within the client. Motivational interviewing techniques include open ended questions and affirmations, reflective listening, summarizing and eliciting "change talk." The therapist emphasizes personal responsibility and together, the therapist and client explore the risks of continued drinking, the benefits of abstinence, the treatment options, and the strategies for relapse avoidance [36].

Combined Behavioral Intervention is a specialized technique that incorporates components of CBT, interactional psychotherapy, and MIT.

Recovering patients benefit from therapy designed for couples and families. **Couples-Based Therapy** engages the client's spouse with improving patient participation and positively influencing the patient's behavior toward sustained abstinence. **Behavioral Marital Therapy** (BMT) addresses issues of marital discord by education in improved communication, conflict recognition and resolution, and engagement of the couple in shared activities. A meta-analysis concluded that behavioral couple's therapy was superior to individual therapy [42].

Pharmacologic Interventions

Less than 10 % of patients with AUD receive medications to assist in maintaining sobriety [43]. Three medications are approved by the Food and Drug Administration for the treatment of alcohol dependence: Naltrexone (oral and injectable), acamprosate, and disulfiram [43, 44]. Acamprosate and oral naltrexone

DOI 10.1007/978-1-4939-0779-3_66-1

are effective in reducing a return to drinking, although no studies demonstrate superiority of one over the other [43] (Table 4).

Naltrexone

Naltrexone, available in oral (*ReVia*) and injectable formulation, has proven efficacy in reduction of alcohol consumption. The oral form (50–100 mg per day) may be started prior to the cessation of drinking. Naltrexone antagonizes various opioid receptors negating the reinforcing effects of alcohol [43]. Common side effects include fatigue, nausea, vomiting, abdominal pain, headache, and dizziness and should be avoided in patients with active liver disease or on opioids. Injectable Naltrexone in depot form (*Vivitrol)* was developed to increase compliance while minimizing side effects. Adverse effects are similar to the oral formulation with the addition of injection site reactions and interstitial or eosinophilic pneumonia [19].

Acamprosate

Acamprosate (*Campral)* is hypothesized to exert effects on both glutamate and GABA, however, its mechanism of action is not clearly elucidated. The usual dosage is 666 mg three times daily after abstinence is achieved. Several meta-analyses support its efficacy in increasing abstinence. However, the *COMBINE* study comparing the efficacy of acamprosate, naltrexone, and placebo found acamprosate to be no more effective than placebo. Though well tolerated, common side effects include, diarrhea, insomnia, anxiety, depression, nausea, and dizziness [43].

Disulfiram

Unlike the other agents, disulfiram (*Antabuse*) does not act at the level of the neurotransmitter. Disulfiram inhibits acetaldehyde dehydrogenase, thus resulting in the accumulation acetaldehyde. Excess acetaldehyde produces a constellation of distasteful symptoms including nausea, vomiting, sweating, headache, dyspnea, flushing, and palpitations thus promoting an aversion to alcohol [43]. Dosages range from 125 to 500 mg daily. A meta-analysis did not find clinically significant benefit of disulfiram over placebo. Noncompliance was a major obstacle in the trials reviewed. A study with supervised medication administration demonstrated superiority of disulfiram over acamprosate and naltrexone in reducing heavy drinking days and average weekly alcohol consumption. Additionally, the time to first drink was increased with witnessed consumption of disulfiram. Once the supervisory component was removed, the benefit dissipated [45].

Other Agents

Topiramate (*Topamax*) is not an FDA approved treatment for alcohol dependence, but has demonstrated moderate effectiveness in the reduction of alcohol use in dependent patients [43]. Mitigation of alcohol consumption is believed to be mediated by effects on glutamate and GABA receptors. A meta-analysis showed decreased consumption of alcohol when compared with placebo. Common side effects include dizziness, somnolence weight loss, fatigue, nervousness, and cognitive dysfunction [43].

Gabapentin (*Neurontin*) has proven efficacy in dosages of 900 or 1800 mg daily versus placebo. Side effects are dizziness and sedation which are dose-dependent [46]. Results were mixed in clinical trials comparing Baclofen with placebo at both low (30–60 mg) and high (150–400) doses. Though generally well tolerated, adverse effects included dizziness, depression, headache, paresthesias, ataxia and insomnia [47]. Selective serotonin reuptake inhibitors (SSRIs) have been found to be effective in the management of alcohol dependence in patients with a comorbid depression diagnosis [48].

Table 4 Medication for long-term treatment of alcohol dependence

Medication	Dose	FDA approved	Mechanism of action	Side effects	Caveats
Naltrexone oral (*ReVia*)	50–100 mg QD	Yes	Opioid antagonist	Dizziness, nausea and vomiting, headache, and transient transaminitis	Avoid in acute hepatitis, hepatic failure or with concurrent opioid use Monitor LFT's Can be started while drinking
Naltrexone injectable (*Vivitrol*)	380 mg q 4 weeks IM	Yes	Opioid antagonist	Dizziness, nausea and vomiting, headaches Anorexia, interstitial or eosinophilic pneumonia, and injections site reactions (cellulitis, induration, hematoma)	Avoid in acute hepatitis, hepatic failure or with concurrent opioid use Monitor LFT's Cannot start until abstinence is established
Nalmefene (*Selincro*)	20–80 mg QD	No	Opioid antagonist	Dizziness, headache, insomnia nausea and vomiting, tachycardia	Increases compliance with treatment
Acamprosate (*Campral)*	666 mg TID	Yes	Glutamate/ GABA receptors/ NDMA receptor	Transient diarrhea Vomiting Nervousness Fatigue	Avoid use in renal failure Cannot start until abstinence is established
Disulfiram (*Antabuse*)	125–500 mg Usually 500 mg for 1–2 weeks then 250 mg QD	Yes	Inhibits acetaldehyde dehydrogenase	Fatigue, headache, rash, hepatitis, psychosis	Avoid alcohol containing products such as mouthwash for at least 2 weeks after stopping Do not use in pregnancy Monitor LFTs Contraindicated in patients with psychosis/severe CAD Effective when administration is supervised Cannot start until abstinence is established
Topiramate (*Topamax*)	50–300 mg Q day	No	Antagonizes glutamate/ GABA receptors agonist	Cognitive dysfunction paresthesias and taste abnormalities, weight loss headache, fatigue, dizziness	Dose must be gradually increased and decreased
Gabapentin (*Neurontin*)	900–1800 mg QD	No	GABA mediated	Sedation at higher doses, dizziness and abuse potential	
Baclofen	30 mg QD High dose 150–400 mg QD	No	GABA receptors agonist	Nausea, vertigo/dizziness, depression, sleepiness, abdominal pain, ataxia, and insomnia	Can be used in patients with liver disease
Selective serotonin reuptake inhibitors	Various	No	Serotonin mediated	Depends upon drug chosen	Use in comorbid depression More effective in late onset alcoholism

Table 5 (continued)

Medication	Dose	FDA indication/	Mechanism of action	Side Effects	Cost	Caveats
Topiramate (*Topamax*)	50–300 mg Q day	No	Antagonizes Glutamate/ GABA receptors agonist	Cognitive dysfunction paresthesias and taste abnormalities, weight loss headache, fatigue, dizziness		Dose must be gradually increased and decreased
Gabapentin (*Neurontin*)	900–1800 mg QD	No	GABA mediated	Sedation at higher doses, dizziness and abuse potential		
Baclofen	30 mg QD High dose 150–400 mg QD	No	GABA receptors agonist	Nausea, vertigo/ dizziness, depression, sleepiness, abdominal pain, ataxia, and insomnia		Can be used in patients with liver disease
Selective serotonin reuptake inhibitors	Various	No	Serotonin mediated	Depends upon drug chosen		Use in comorbid depression More effective in late onset alcoholism
Odansetron	4 mcg/kg BID	No	5 HT3 receptor antagonist	Diarrhea, prolonged QT, headache		Use in early onset alcoholism Avoid use in prolonged QT or with drugs that prolong QT

Other Interventions

Acupuncture has been an accepted adjuvant therapy for many decades. Experts agree that it is most effective when combined with psychosocial and pharmacological interventions [49].

Hypnosis was used to treat addiction in the late nineteenth century with some success. Hypnosis studies are very limited and the numbers of participants small. One study reported a 77 % success rate in 18 clients treated intensively (20 daily sessions) with sustained benefit at 1 year follow up, while another study using audiotapes for self-hypnosis, demonstrated improvement in self-esteem and serenity and a reduction in anger and impulsivity [50].

Intervention for sleep disturbances may benefit patients in maintaining sobriety as some patients use alcohol for its sedative effects. Promotion of good sleep hygiene, bright light therapy and meditation are options (Table 5).

Emerging Interventions

Theoretically, the most successful interventions in the management of alcoholism should be those that are most adaptable and accessible for the needs of a broad spectrum of patients. Recent studies have explored modalities which utilize modern technology to interact and monitor patients following inpatient or intensive outpatient therapy. Technologies such as e-mailing, text messaging, Internet-based social support, Internet-based cognitive behavioral therapy applications, and telephone-based counseling are being used to facilitate maintenance of sobriety. Though some research of Internet- and telephone-based models have proven benefit, further adequately-powered randomized-controlled trials are needed to determine the efficacy of these interventions. Additionally, how these interventions can best be

DOI 10.1007/978-1-4939-0779-3_66-1

incorporated into a comprehensive continuing care model for the long-term management of alcoholism must be explored [51].

Care of the Patient Who Misuses Drugs

Fedoriw Kelly Bossenbroek*
Department of Family Medicine, UNC – Chapel Hill, Chapel Hill, NC, USA

According to the 2013 National Survey on Drug Use and Health (NSDUH), an estimated 24.6 million Americans aged 12 or older were current illicit drug users [1]. This represents nearly 10 % of the population aged 12 and older, and primary care providers encounter these patients on a regular basis. Unfortunately, primary care physicians may not feel well prepared to deal with substance abuse due to lack of training, discomfort with the subject, time constraints, and lack of confidence in available treatments [2]. However, patients with substance use disorder can be well cared for using a chronic disease framework that is familiar to most primary care providers.

General Guidelines

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) no longer separates substance abuse and dependence but groups them together on the continuum of substance use disorder [3]. Patients can be described as having a substance use disorder if they fulfill at least 2 of 11 criteria (Table 1). The disorder can be classified as mild (2–3 criteria), moderate (4–5 criteria), or severe (6 or more criteria). Importantly, patients who are on long-term opioid treatment will likely experience pharmacologic dependence but would not necessarily be considered to have a substance use disorder.

For most patients, substance use disorders are chronic. Unfortunately they are often treated as acute illnesses, but there is evidence that using a chronic disease model may improve outcomes [4]. Screening for substance use, making the diagnosis, offering brief interventions, providing medication management, and knowing when to refer are the essential elements of chronic disease care and apply well to substance use disorders. While referral to addiction specialty services is often indicated, primary care physicians with adequate training and support can offer many of these services for patients.

Screening

The US Preventive Services Task Force has determined that there is insufficient evidence to recommend screening for substance use disorders [5]. Despite the lack of evidence, the American Academy of Family Physicians and the American Psychiatric Association recommend incorporating substance use screening into primary care [6]. The Screening, Brief Intervention, and Referral to Treatment (SBIRT) model is a comprehensive approach that can be used to identify patients with substance use disorders, offering tailored interventions as well as appropriate referrals [7]. The screening tools that are most often used and have been validated for use in primary care are the Drug Abuse Screening Test-10 (DAST-10) and the single-question screening test [8].

The National Institute on Drug Abuse (NIDA) recommends using the single-question screening tool [9]. The single-question screen has a sensitivity for substance abuse disorder of 90–100 % and a

Table 1 Substance use disorder criteria [3]

1. Impaired control
Taking more of the substance that was intended
Inability to cut back or stop using
Spending excessive time obtaining, using or recovering from substance use
Cravings for the substance
2. Social impairment
Failure to fulfill obligations due to use
Recurrent use despite negative consequences to interpersonal relationships
Reducing or eliminating meaningful social activities due to use
3. Risky behavior
Recurrent use in physically dangerous situations
Continued use despite negative physical or psychological consequences caused by the substance
4. Pharmacologic indicators
Tolerance – increasing the amount of substance to reach the desired effect
Withdrawal – physiologic responses to decreasing or stopping the drug

Table 2 Single-question screen [10]

How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?
A positive response is at least once

Table 3 CAGE questionnaire

1. Have you ever felt you should *c*ut down on your drinking?
2. Do people ever *a*nnoy you by criticizing your drinking?

4. Have you ever had a drink first thing in the morning? *E*ye opener

specificity of 74 % [10]. NIDA offers a helpful screening algorithm (www.drugabuse.gov/sites/default/files/pdf/screening_qr.pdf) (Table 2).

Medical professionals often use the CAGE questionnaire to screen for alcohol abuse. CAGE has high test-retest reliability, and it is a valid tool for identifying alcohol abuse in many different settings [11]. CAGE is short and easy to use but is limited in identifying less severe alcohol problems and cannot detect any other form of substance use [11] (Table 3).

Brief Intervention

Brief interventions and counseling patients with substance use disorders can follow the same guidelines as counseling patients with diabetes or other chronic illnesses. Motivational interviewing can be key to approaching patients in a nonjudgmental manner (Table 4). Evidence for brief interventions in an outpatient setting is conflicting. Brief interventions have been shown to decrease drug use [12]. However, the ASPIRE trial failed to show that brief interventions decreased drug use in patients who were identified by screening [13].

DOI 10.1007/978-1-4939-0779-3_67-1

Table 4 Motivational interviewing principles for physicians

Principle/technique	*Rationale*
Resist the righting reflex	Physicians want patients to change or correct unhealthy behaviors. Telling them to do so is a natural reflex, but it can generate resistance in patients. Instead, help them generate their own argument for healthy changes
Understand the patient's motivations	Patients are more likely to change for reasons that they value highly. By eliciting these reasons, physicians can be more effective
Listen to the patient	Physicians need to listen to patients to elicit the best path to behavior change
Empower the patient	Physicians can help patients take an active role in their health care and support self-efficacy
Elicit-provide-elicit	A nonconfrontational approach to advice or information giving that allows the patient to express his or her feelings about change and assists the physician in assessing readiness for change
Decision analysis ("pros and cons")	Physicians can help patients make changes by articulating the advantages and disadvantages of the changes
Reflections	Physicians can identify statements that the patient makes in support of change and reflect them back to the patient, highlighting the patient's reasons for change
Affirmations	Most patients with substance abuse and dependence feel guilt and shame about their drug use, and may lack confidence that they can make changes. Physicians can promote self-efficacy with honest and meaningful affirmations
Less effective approach	*More effective approach*
Physician: "You need to stop using cocaine. It's damaging your heart" Patient: "I don't think it's the cocaine. My friends use cocaine too, and they don't have heart problems"	Physician: "How does it feel when you hear that cocaine may be causing your chest pain?" Patient: "I don't know what to think about it, but it's got me thinking"
Physician: "Now that you are pregnant, you need to stop abusing pain pills for your developing baby" Patient: "I'll do the best I can"	Physician: "Is there anything about your use of pain pills that you are concerned about?" Patient: "Yes, my husband told me he would leave me if I started taking pain pills again"
Physician: "I'm going to refer you to a special program for people with addiction to pain pills" Patient: "I told you already, drug treatment isn't for me"	Physician: "We talked a little about some possible treatment options, but I'm interested in hearing what you think would work for you" Patient: "I won't go to drug treatment, but if there is a medicine I could take that would help me stop, I would do that. Also I used to go to NA, and that seemed to help"
Patient: "I almost didn't come in to see you. I just can't stop using cocaine" Physician: "Did you go to the NA meetings and see a therapist like we discussed?"	Patient: "I almost didn't come in to see you. I just can't stop using cocaine" Physician: "Quitting cocaine is difficult for most people, and I've been impressed by how hard you have worked to cut back"
Physician: "Using cocaine can cause heart attacks. You are putting yourself at risk each time you use, and you need to stop"	**Elicit knowledge and opinions:** Physician: "What do you know about how cocaine affects your health?" Patient: "Well, some people get holes in their noses, but I don't use that much, so I don't think it's affecting me" **Provide tailored information and advice:** Physician: "I'm glad you haven't used enough to have that problem. You might be surprised to know that even small amounts of cocaine increase your risk of heart attack, stroke, and high blood pressure. Sometimes people have heart attacks from using cocaine just one time" **Elicit response and feelings:** Physician: "How does that new information strike you?" Patient: "I don't know. I guess it might be more dangerous than I thought"

(*continued*)

Table 4 (continued)

Principle/technique	*Rationale*
Physician: "Don't you see that your cocaine use is hurting your whole family?" Patient: "What do you know about my family?"	Physician: "What do you like about using cocaine?" Patient: "It lets me forget all the things that are bothering me, and it gives me energy to get things done" Physician: "And what do you not like about cocaine use? What makes you think about stopping?" Patient: "I don't want my kids to see me high, and it's definitely starting to get in the way of work. I'll have to stop someday or it will be hard to keep this job"
Patient: "I don't want to be using cocaine when I'm 80. That would be crazy" Physician: "So why don't you stop?" Patient: "I'm just not ready yet, OK?"	Patient: "I don't want to be using cocaine when I'm 80. That would be crazy" Physician: "You want to stop using cocaine someday" Patient: "Yes, I do. I guess the question is when"
Patient: "I can't believe I relapsed again. It's so frustrating" Physician: "You've just got to get up and try again"	Patient: "I can't believe I relapsed again. It's so frustrating" Physician: "You're frustrated, but the fact that you came back to talk about it tells me that you're determined. You've quit before, and I'm confident you can do it again"

Stimulants: Cocaine and Amphetamines

Cocaine is the second most commonly used illicit substance (marijuana is first) [14]. Although use of cocaine declined during the early 1980s, its misuse increased dramatically in 1985 with the marketing of "crack" cocaine. Crack is a highly addictive form of cocaine readily accessible at a low cost (as inexpensive as $10–$25). Crack cocaine has changed cocaine from a drug of the rich and affluent to a drug anyone can afford (including adolescents and children). In 2013 NSDUH estimated that there were 1.5 million current cocaine users age 12 or older [1] which has declined since the 1990s and early 2000s. However, it is estimated that every day approximately 1,600 Americans try cocaine for the first time [1]. A gram of cocaine typically costs $60–$80 and is almost always "cut" or diluted with lactose, levamisole, mannitol, cornstarch, or other similar substance. Adulterants make up over 50 % of the total volume of cocaine sold [15].

Cocaine hydrochloride is water soluble and can be injected intravenously or inhaled intranasally ("snorted"). Cocaine hydrochloride cannot be smoked because it decomposes. If it is dissolved in ether and distilled, the base form of cocaine (freebase) is reprecipitated, and this substance can be smoked. "Crack" cocaine is produced by dissolving cocaine hydrochloride in sodium bicarbonate and distilling off the water. It then forms "rocks," which can be smoked. The term *crack* comes from the noise the rocks make as they are heated and smoked.

The physiologic effects of amphetamines (including methamphetamine and dextroamphetamine) are very similar to cocaine. However, the "high" from cocaine lasts less than an hour, while amphetamines can last several hours [16]. Amphetamine pills can be crushed and snorted, dissolved in water and injected, or smoked. Pure methamphetamine ("ice" or "glass") is most often smoked in a glass pipe which allows the user to experience immediate effects without the risks of injecting [16]. *Crack* and *crank* are two street terms that are commonly confused. Crank is a street name for methamphetamine that can be taken as pills, injected, or snorted. Crack is freebase cocaine.

DOI 10.1007/978-1-4939-0779-3_67-1

When prescription stimulants are abused, it is often by crushing and snorting or mixing with water and then injecting. Methylphenidate (Ritalin, Adderall) causes a response similar to cocaine when injected. Both substances cause an immediate increase in dopamine, producing the "high" experienced by users.

Effects

Cocaine causes euphoria, talkativeness, increased energy, and increased confidence. The immediate euphoria is quickly followed by a letdown characterized by depression, irritability, restlessness, and a generalized feeling of uneasiness and discomfort. When users start feeling letdown, they use more cocaine, which results in blood levels that cause medical complications and can be lethal. Frequent presenting complaints for patients using cocaine include chest pain, cardiac arrhythmias, new onset seizures, anxiety, chronic sinusitis, headaches, and weight loss. Physical findings suggestive of cocaine use include agitation, dehydration, malnutrition, tachycardia, elevated blood pressure, rhinorrhea, cough, wheeze, and poor dentition.

Agitation is the most common presenting symptom of amphetamine misuse. Hallucinations, suicidal ideation, delusions, and confusion may be present. Cardiac symptoms include chest pain, palpitations, and myocardial infarction. Acute signs of amphetamine intoxication include an elevation in the blood pressure and pulse, dilated pupils, tremor, cardiac arrhythmias, and increased reflexes. The long-term effects of amphetamine abuse include impaired concentration, abrupt mood changes, weight loss, paranoid delusions, and violence.

Acute Medical Treatment

The three primary cardiovascular complications of cocaine abuse are hypertension, myocardial ischemia, and cardiac arrhythmias. Cardiac toxicity can occur with all three routes of administration (intranasal, intravenous, and inhaled). In individuals who are sensitive to cocaine or who have coronary artery disease, cardiac symptoms can occur with relatively low doses of cocaine.

Chest pain is the most common medical problem related to cocaine, but unfortunately it can be difficult to distinguish chest pain from ischemia and myocardial infarction [15, 17]. Patients who present with cocaine-associated chest pain may also have diaphoresis and shortness of breath, but these are not predictive of ischemia [17]. Electrocardiographic (ECG) changes of ischemia are common, but occasionally are not present even with an acute myocardial infarction caused by cocaine. One group estimated that the sensitivity of ECG changes for identifying myocardial infarction was 35 % [17]. It is impossible to clinically differentiate patients with cocaine-induced chest pain and those experiencing a myocardial infarction [17]. In addition, it has been shown that the Thrombolysis in Myocardial Infarction (TIMI) risk score is not clinically useful in this population [17]. Due to the challenges of identifying ischemia in cocaine users, it has been suggested that patients who present with cocaine-associated chest pain who have a normal ECG and negative cardiac biomarkers be observed and followed with serial ECG and troponins [17]. Cocaine misuse should be suspected in any patient under 50 years old who presents with chest pain [15].

Up to 6 % of patients presenting with cocaine-induced chest pain will progress to infarction [17]. The risk of an acute myocardial infarction increases in chronic users but can happen after the initial use as well. During the initial 60 min after cocaine use, the relative risk of myocardial infarction increases almost 24-fold [15]. Even cocaine users who are asymptomatic have been found to have significant myocardial damage [15].

All patients presenting with cocaine-associated chest pain should be treated with aspirin. Both benzodiazepines and nitroglycerine have been shown to relieve chest pain symptoms, although more study is needed to determine if these medications affect cardiovascular outcomes [17]. Historically beta blockers have been avoided in cocaine-associated chest pain due to a fear of inducing unopposed vasoconstriction. While beta blockers are still to be avoided, retrospective studies have not shown an increase in adverse outcomes in patients who were given beta blockers and subsequently had positive cocaine testing [17]. Patients who present with cocaine-associated myocardial infarction should receive

DOI 10.1007/978-1-4939-0779-3_67-1

nitroglycerine, calcium channel blockers, and fibrinolytics when applicable [17]. It is important to note that these recommendations are based on expert opinion due to lack of data [17].

The most common arrhythmia associated with cocaine misuse is tachycardia, but it usually resolves spontaneously as the drug is metabolized or with use of an anxiolytic agent.

Smoking cocaine can cause a cough with black sputum production and dyspnea. Hemoptysis and spontaneous pneumothorax are common in crack addicts. Pulmonary edema (noncardiac) may be an acute hypersensitivity reaction. Asthma can be exacerbated by smoking crack cocaine. Pollutants in crack can also cause bronchitis and tracheitis.

Seizures are common with cocaine misuse. Cocaine decreases the seizure threshold and increases the body temperature, which makes an individual more susceptible to seizures. Intravenous benzodiazepines are the treatment of choice for seizures caused by cocaine.

Serious obstetric complications, including placental abruption, preterm birth, and preeclampsia, are increased in pregnant women who use cocaine [18]. Cocaine easily crosses the placental barrier, and intrauterine exposure can cause fetal demise, growth restriction, and congenital malformations [18]. Newborn infants may demonstrate signs of cocaine withdrawal, including irritability, tremulousness, and poor eating. Women who use cocaine and are pregnant or may become pregnant should be counseled about the potential risks of cocaine use and offered addiction treatment options.

The most common cocaine-induced psychiatric disorders are paranoid delusions and hallucinations which can occur in up to 50 % of cocaine users [19]. Hallucinations called “snow lights” (flashing visual hallucinations) and “coke bugs” (tactile and visual hallucinations) are common with cocaine misuse.

Patients experience withdrawal symptoms when they stop using cocaine. Depression is common after cocaine cessation, and patients frequently experience severe anhedonia that may last several months (antidepressants may help).

Almost all patients who snort cocaine have chronic sinusitis. They may have unilateral inflammation of the nose (cocaine addicts frequently snort in one nostril at a time so only one nostril is inflamed). Chronic rhinitis, perforations of the nasal septum, and abscessed teeth are common in cocaine snorters. Patients who misuse cocaine frequently engage in high-risk sexual behaviors that expose them to sexually transmitted diseases and human immunodeficiency virus (HIV) disease.

Treatment of Addiction/Dependence

Very few pharmacologic interventions have been shown to improve abstinence rates in cocaine users [20]. Current research does not support the use of anticonvulsants, antidepressants including SSRIs, antipsychotics, or dopamine agonists for the treatment of cocaine dependence [20, 21]. There is some limited evidence supporting the use of bupropion, dexamphetamine, and disulfiram as treatment options; however, these require more study before being recommended as therapies used in primary care for cocaine dependence [20].

Opioids

Opioids include both natural opiates such as opium and morphine as well as derivatives and synthetic opioids like heroin and oxycodone. According to the National Survey on Drug Use and Health, 4.8 million Americans have used heroin [1]. In 2011, heroin use was involved in 83 emergency department (ED) visits per 100,000 people [22]. While this number has not changed significantly over the last 10 years, the number of ED visits involving prescription opioids has increased by 153 % over the same time period [22]. In 2013, 4.5 million Americans were considered current users of prescription pain medications for nonmedical reasons [1]. Opioid overdose deaths are also on the rise [23].

DOI 10.1007/978-1-4939-0779-3_67-1

Opioid addiction often begins with taking prescription opioid pills, progresses to crushing the pills to snort or inject, and ends with injecting heroin [24]. The cost of a single dose of heroin varies depending on the location and purity but generally ranges from $10–25. Heroin is often less expensive than buying pills; however, tolerance builds quickly to opioids, and an addict can often spend more than $1200 a month obtaining heroin [25]. In 2006 Americans spent $11 billion on heroin [25].

Opioid pain medications can be crushed to snort or inject although manufacturers are continually developing new ways to prevent this abuse. Heroin is often bought and sold as a white or brown powder that can be snorted, smoked, or injected.

Effects

Initially, opioid users experience euphoria as well as warm flushing and clouded mental thinking. This "rush" is more pronounced with injecting versus other methods. Afterward the user becomes very drowsy which is often referred to as going "on the nod" [26].

Opioids in general can cause shallow breathing, constipation, pruritus, sedation, and nausea. The presenting signs and symptoms of opioid overdose are stupor, miosis, hypotension, bradycardia, and decreased bowel sounds. Frequently needle marks or tracks are present if drugs are being injected. In more severe cases, respiratory depression with apnea and pulmonary edema can occur.

Acute Medical Treatment

Naloxone (Narcan) is the primary treatment for opioid overdose in addition to oxygen supplementation [27]. As a full opioid antagonist, naloxone will reverse all effects of opioids including respiratory depression and analgesic effects. An initial dose of 0.4–0.8 mg can be given intravenously, intramuscularly, or subcutaneously and repeated every 2–3 min up to a total dose of 10 mg. The goal in treatment is to reverse the respiratory depression, not to get the patient awake and alert, which may precipitate an acute withdrawal syndrome. Intravenous naloxone acts almost immediately and will take effect within 1–2 min. The effects of naloxone last between 45 and 90 min and doses often need to be repeated depending on the initial opioid [27]. The effects of heroin can last up to 5 h.

Naloxone has been prescribed for overdose prevention to heroin users and more recently to patients on high-dose opioid pain medications [28]. Auto-injection devices are available (Evzio) as well as intranasal devices (generic).

Opioid withdrawal is not life-threatening although it is very uncomfortable. Symptoms can be managed with clonidine 0.1–0.2 mg orally every 6 h or clonidine transdermal patch 0.1 mg weekly, although the patient should be monitored for hypotension [29]. Benzodiazepines should not be used to control symptoms during opioid withdrawal [30].

Treatment of Dependence/Abuse

Treatment options for opioid dependence include detoxification (withdrawal), agonist maintenance therapy, or antagonist therapy. Detoxification can occur in an outpatient or inpatient treatment facility. For many patients, maintenance therapy with either methadone or buprenorphine is more successful than tapering or detoxification [31, 32].

Medication maintenance therapy can include methadone or buprenorphine. Buprenorphine is often combined with naloxone when used for maintenance therapy (Suboxone, Zubsolv). According to a Cochrane review, buprenorphine in fixed doses of at least 7 mg daily performed as well as fixed doses of methadone in retaining patients in treatment and suppressing illicit opioid use [33].

Methadone treatment for opioid dependence is only available through a regulated Opioid Treatment Program (methadone treatment facility). However, buprenorphine/naloxone can be prescribed in any setting as long as the physician obtains further education and a special licensure from the

DOI 10.1007/978-1-4939-0779-3_67-1

DEA. Prescribing buprenorphine/naloxone in a primary care setting may help improve the health of this underserved population. Primary care physicians are well equipped to provide routine preventative services, targeted screening (HIV, HCV), and chronic illness management. In fact, integrating buprenorphine maintenance treatment in a federally qualified health center has been shown to engage this vulnerable population with primary care, improve health outcomes, and increase preventative services completed [34]. More information can be found at http://buprenorphine.samhsa.gov.

Pregnant women who are opioid dependent may be maintained during pregnancy on methadone or buprenorphine. There is no strong evidence that one medication should be used over the other [35, 36]. In order to avoid neonatal abstinence syndrome, motivated women can slowly taper off opioids during their late second or third trimester without increasing the risk of pregnancy complications [36]. However, it is generally advised that women stay on maintenance medication due to risk of relapse after tapering [35].

The final option for opioid dependence treatment is antagonist therapy with naltrexone (Revia, Vivitrol). Naltrexone is a full opioid antagonist similar to naloxone. Both drugs undergo extensive first-pass metabolism. Naltrexone metabolizes into an active metabolite and can be given orally (Revia) or as a monthly injection (Vivitrol). Naloxone metabolizes into an inactive metabolite and thus is only given as an injection or intranasally for opioid overdose (see above). For highly motivated patients, extended-release injectable naltrexone (Vivitrol) may be a reasonable treatment option [37].

Marijuana

Marijuana is the most commonly used illicit drug in the United States [38]. The National Survey on Drug Use and Health found that 19.8 million people in the United States had used marijuana in the past month [1]. Given the recent legalization and decriminalization of marijuana across the country, this number may increase. In addition, emergency room visits involving the use of synthetic cannabinoids (K2, Spice) have doubled from 2010 to 2011 [39]. Marijuana use can cause dependence and addiction although at lesser rates than other drugs of abuse. Approximately 9 % of marijuana users become dependent as opposed to 15 % of those who try cocaine and 24 % of those who try heroin [40]. This number may seem small, but because the total number of people who try marijuana is much greater than those who try cocaine, the prevalence of marijuana dependence is twice to that of cocaine [40].

Marijuana can be smoked as a cigarette (joint) or through a pipe or bowl (bong). Hashish is a more concentrated form of marijuana that is either pressed into a solid or used as a resin which can be smoked or ingested. Hemp is a low-THC variety of cannabis that is grown to make rope or clothing. The high from marijuana is caused by the activation of cannabinoid receptors by the main active chemical in marijuana, THC (tetrahydrocannabinol). This activation works in the same way as almost all drugs of abuse and activates the reward pathways by releasing dopamine. Users typically feel an initial euphoria followed by sedation [38]. However, some users also experience anxiety and paranoia. Marijuana may be "laced" with other drugs, such as cocaine, phencyclidine (PCP), or other hallucinogens, causing bizarre reactions. Marijuana is highly lipophilic, with a half-life of approximately 3 days. Long-term users can expect daily cough, sexual dysfunction, and loss of motivation [38].

The most common physical signs of marijuana misuse are tachycardia and conjunctival irritation (which may be masked in experienced users by using eye drops). Urine testing is the most effective laboratory method for screening patients suspected of marijuana misuse. In daily misusers, urine toxicology screens may remain positive for several weeks. After a single misuse episode, the urine test is positive for 3–4 days.

Treatment for marijuana dependence typically consists of cognitive behavioral therapy and motivational enhancement therapy [40]. Marijuana withdrawal syndrome is similar to nicotine withdrawal, and

DOI 10.1007/978-1-4939-0779-3_67-1

patients experience irritability, sleep disturbances, and depression [40]. Most pharmacotherapy research has targeted the withdrawal symptoms with the most promising therapy being synthetic THC [40].

1. Effects
2. Acute medical treatment
3. Treatment of addiction/dependence

Hypnotics and Anxiolytics

Both hypnotics and anxiolytics are commonly prescribed in primary care practices. Hypnotics are medications prescribed for insomnia and include zolpidem and zaleplon (Ambien and Sonata). Anxiolytics typically refer to benzodiazepines (BZDs). BZDs can be short acting (alprazolam, lorazepam) or long acting (clonazepam, diazepam). From 1969 to 1982, diazepam was the most commonly prescribed drug in the United States [41]. However, since that time, the prolific prescribing of BZDs has been called into question given the high rate of abuse, dependence, and adverse events associated with this class of medications. Short-term use of BZDs is known to impair learning and memory as well as increase the risk of accidents and injuries [41]. Long-term use is less well studied but has also been associated with cognitive decline and may be a risk factor for dementia [41, 42]. The sedative effects of hypnotics and BZDs are increased when used in combination with alcohol or other sedatives. In fact, as much as 80 % of unintentional overdose deaths that involve opioids also involve BZDs [43]. Concomitant prescription of opioids and BZDs is common, and opioid abusers will often use BZDs to prolong and enhance the opioid high [41, 43].

Withdrawal can occur after just 6–8 weeks of chronic use of BZD or hypnotics [44]. In addition, many patients will experience rebound of their original symptoms when stopping BZDs [45]. Mild withdrawal symptoms can include anxiety and nightmares and severe withdrawal can be life-threatening (see Table 5). In order to avoid withdrawal, BZDs should be slowly tapered over 2–4 months. For chronic users, tapering can be accomplished by decreasing the dose by 10 % per week [44]. Cognitive behavioral therapy has been shown to assist patients who are discontinuing BZDs [44]. Care should be taken not to prescribe BZDs or hypnotics to patients with a history of BZD abuse as the risk of relapse is high. These patients should also be cautioned against alcohol use.

Hallucinogens

Hallucinogens are defined as drugs that produce visual, auditory, tactile, and in some cases olfactory hallucinations. Lysergic acid diethylamide (LSD) is the most potent, most common hallucinogen. It is referred to as acid, dots, cubes, window pane, or blotter. LSD can cause bizarre behavior that begins within an hour after ingestion, peaks in about 3–4 h, and lasts up to 12 h. Tolerance develops quickly to LSD and users must increase their dosage to have the same effect. Hallucinogens are particularly dangerous because their effects are highly unpredictable. Paranoia, depression, anxiety, acute psychosis, combative behavior, and panic attacks are associated with “bad trips.” On physical examination, patients have pronounced pupillary dilation, tachycardia, sweating, and fever. Death can result from cardiovascular compromise due to hypertension or can be self-inflicted due to impaired judgment [19]. Patients diagnosed with LSD intoxication need to be carefully screened for other problems such as hypoglycemia, head trauma, drug withdrawal, electrolyte abnormalities, endocrine disease, central nervous system (CNS) infection, hypoxia, and toxic reactions to other street or prescription drugs. The preferred treatment

DOI 10.1007/978-1-4939-0779-3_67-1

Table 5 BZD withdrawal symptoms [41, 45]

Headache	Catatonia
Muscle aches	

for an acute intoxication is "talking down" the patient whereby patients are reassured that their symptoms are drug induced and they will resolve [19]. In severe cases, haloperidol or a benzodiazepine can be used [19]. Patients may have chronic effects from LSD that include flashbacks, psychoses, depressive reactions, and chronic personality changes. Other hallucinogens include MDMA (ecstasy, molly), mescaline (from peyote cactus), and psilocybin (from some mushrooms).

Physical dependence does not develop to hallucinogens. In addition, psychological dependence is rare likely due to the lack of reliable euphoria [19].

Inhalants

Up to 20 % of children in middle school and high school have misused inhaled substances [46]. The popularity of inhalants in this age group is likely because they are easy to obtain legally and very inexpensive. Frequently abused inhalants include gasoline, airplane glue, aerosol whipped cream, cleaning agents, Freon, rubber cement, and lighter fluid. At a low dose, inhaling these agents can cause euphoria, light-headedness, and a state of excitation. At higher doses, users can experience fearfulness and auditory and visual hallucinations [19]. Users may also exhibit nystagmus, nausea and vomiting, abdominal pain, and psychomotor retardation [19]. Inhalants are sniffed, "bagged" (inhaling the substance from a plastic or paper bag), and "huffed" (inhaling the vapors by holding a piece of cloth soaked in the volatile substance against the mouth and nose).

Inhalants are rapidly absorbed into the bloodstream, are highly lipid soluble, and produce central nervous system depression. Tolerance can develop although withdrawal is typically mild [19]. In the emergency room, solvent misuse frequently can be mistaken for acute psychiatric problems because of the altered mental state and hallucinations. Death can result from respiratory depression, cardiac arrhythmias, or asphyxiation. Chronic abuse may cause brain atrophy, permanent hepatic and renal damage, and bone marrow toxicity [19].

Signs of inhalant abuse include stains on clothing, unexplained burns, and the odor of solvents on the patient's clothing or breath [19]. Supportive care for acute inhalant toxicity usually allows symptoms to clear within 4–6 h and cardiac monitoring is often necessary.

Tobacco and alcohol use are discussed in other chapters.

Patients in Recovery

Little has been written about the care of patients after they recover from drug or alcohol addiction. Because many medical problems resolve as patients abstain from illicit drugs and alcohol, it is reasonable to wait a few months before treating less severe medical problems. Patients in recovery should be asked

DOI 10.1007/978-1-4939-0779-3_67-1

about their continued abstinence from drugs and alcohol. If family members are present, ask them how the patient is doing. Positive support of patients, even if they have relapsed, is imperative.

Any medication has the potential to cause a relapse, especially mood-altering medications. Prescription medications can cause a relapse by lowering patients' resistance or by patients becoming addicted to the prescribed medication. The following guidelines are for patients with a history of substance use disorder: [47]

1. Whenever possible, use nonpharmacologic treatments. Encourage patients to exercise, meditate, and change their diet; use acupuncture or biofeedback before prescribing medications.
2. Avoid benzodiazepines and narcotics.
3. Be cautious about prescribing "cue stimuli" medications, such as inhalants in former intranasal cocaine addicts.
4. Choose medications with side effects that may be beneficial, such as beta-blocking drugs to treat hypertension because they decrease anxiety, which is common during early recovery.
5. Beware of increased drug sensitivity secondary to damage caused by patients' previous drug and alcohol misuse. Patients need a thorough evaluation focusing on specific complications from their previous addiction. Injection drug users must be assessed for hepatitis and HIV disease.
6. Before prescribing medications, wait for normal resolution of medical problems associated with withdrawal and early recovery, such as hypertension, depression, hyperglycemia, and tachycardia.
7. Anticipate the normal changes (insomnia, anxiety, depression, and some sexual dysfunction) that occur during recovery and counsel patients about them so the patients are less likely to be concerned or to seek medications (Tables 6 and 7).

Table 6 Resources for patients and providers (adapted from [6])

Resource	Description	Appropriate referrals
Alcoholics Anonymous: aa.org Dual Recovery Anonymous: draonline.org SMART Recovery: smartrecovery.org Women for Sobriety: womenforsobriety.org	Free group sessions that are led by a peer and typically based on a 12-step model	Any patient with past or current substance abuse
Inpatient detoxification (medically supervised withdrawal)	Intensive, onsite care where patients are continuously monitored and treated throughout their withdrawal, sometimes for days or weeks	Patients who experience a serious withdrawal syndrome or have significant psychiatric comorbidities
Outpatient detoxification	May include counseling sessions, pharmacologic management	Stable patients without serious withdrawal
Residential treatment	Structured, monitored live-in program that may last for several months	Patients with more severe addictions, significant comorbidities who are in need of a safe living environment or at high risk of relapse
Maintenance treatment	Typically for opioid addiction. Methadone or buprenorphine prescribed by licensed providers in the outpatient setting	Patients with opioid dependence who are relatively stable but have high risk of relapse

Care of the Patient with Chronic Pain

Kelly Bossenbroek Fedoriw

Contents

Definition and Scope of Chronic Pain

Chronic pain is pain that persists beyond the typical healing time of 3–6 months. The Institute of Medicine estimates that 100 million people in the United States suffer from chronic noncancer pain (CNCP) which is more than the number of people with diabetes, coronary heart disease, stroke, and cancer combined [1]. The annual health care costs for patients with CNCP are estimated at $635 billion (in 2010 dollars), but despite the high prevalence, CNCP remains undertreated [2].

Paralleling the incidence of CNCP, prescriptions for opioid pain medications have skyrocketed over the past 15 years, with approximately 259 million opioid prescriptions written by providers in 2012 [3]. This increase in prescriptions has been associated with an alarming increase in accidental overdose deaths involving prescription opioids but shown to have little impact on effectively reducing pain [3, 2].

Patients with CNCP frequently are seen in primary care offices where their treatment is often coordinated by a family physician. While these patients and their pain can often be seen as challenging to manage, using a stepwise approach and collaborative care model can safely and successfully mitigate pain and improve function.

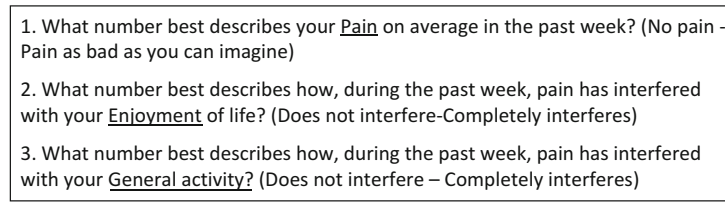

Fig. 1 Pain, enjoyment, and general activity (Scale 1–10) [7]

Treating Acute Pain

Acute pain tends to have an easily identifiable cause and typically resolves when the inciting injury heals. Nonopioid medications should be considered first line for acute pain [4]. However, when opioids are indicated for an acute injury, providers must discuss the risks of treatment as well as the expectations for healing and engage the patient in mutual decision-making. The transition from acute pain to chronic pain is not always obvious. Providers can easily find themselves refilling opioid prescriptions long after the acute injury should have healed and without having discussed the risks of long-term opioids with patients.

Patient Assessment

Every patient in pain requires a thorough initial history and physical exam to assess pain characteristics including location, intensity, quality, duration, and relieving and exacerbating factors. Previous investigations and treatments tried will help guide treatment options and social history; substance use history and any psychiatric comorbidities need to be explored as well [5, 6]. Categorizing the type of chronic pain will help determine possible treatment options.

A functional assessment is essential for patients in chronic pain [6]. Tools for use in primary care include the Pain, Enjoyment, and General Activity questionnaire (see Fig. 1) and the Physical Functional Ability Questionnaire by the Institute for Clinical Systems Improvement. The goal of therapy for chronic pain is to improve function and quality of life as well as control pain. Patients should be aware of these goals, and function should be tracked over time.

In addition to assessing the patient, providers must set expectations for pain management at the first visit. Chronic pain by definition is a chronic disease and must be managed similarly to other chronic diseases. Many patients will require multiple modalities, self-management skills, and more than one medication trial to achieve improvement in their function.

Types of Pain and Treatment Options

Pain can be classified as nociceptive or neuropathic. Nociceptive pain is caused by tissue injury and includes inflammatory, muscular, and mechanical pain. Neuropathic pain is caused by damage to or dysfunction of the central or peripheral nervous system. Importantly, the categories are not mutually exclusive, and patients can be affected by both types of pain. However, classification of mechanism for a given patient can be helpful in guiding therapy [5].

Inflammatory pain – Arthritis, surgery, and infection are potential causes of inflammatory pain. Hallmarks on physical exam are edema, heat, erythema, and pain at the site of an injury. Treatment typically involves NSAIDS, corticosteroids, or immune-modulating agents to control the inflammation.

Muscular pain – Muscle soft tissue pain typically occurs after an injury and involves pain in one or more areas of muscle, loss of range of motion, as well as tenderness over the affected muscle groups. Myofascial pain is a common cause of chronic pain and is best managed by physical therapy and restoring muscle balance and not medication [5]. Trigger point injections or acupuncture may be useful.

Mechanical pain – Mechanical pain is often caused by compression due to a cyst or tumor,

fracture, degeneration, or dislocation. Pain is aggravated by activity and can be relieved by rest [5]. Most chronic neck pain and visceral pain fall into this category. Chronic low back pain can also be in this category but is often multifactorial. Treatment may be surgical in the case of cysts, fractures, and impingement.

Neuropathic pain – Common examples of neuropathic pain include diabetic neuropathy, postherpetic neuralgia, carpal tunnel, multiple sclerosis, and poststroke pain. Neuropathic pain is often described as "shooting" or "stabbing" but can also present as numbness, tingling, and increased sensitivity to benign touch (allodynia) [5]. Neuropathic pain is less responsive to opioid analgesics [8]. Treatment options for neuropathic pain are numerous and can be divided into two categories: disease-specific treatments such as improved glucose control for diabetic neuropathy or surgery for nerve decompression and symptom management. First-line treatment options for symptom management include anticonvulsants, tricyclic antidepressants (TCAs), and serotonin-norepinephrine reuptake inhibitors (SNRIs) [5].

Chronic Pain Treatment Algorithm

See Refs. [5, 6, 8] (Fig. 3, Table 1)

Muscle Relaxants

Little evidence exists to support the use of muscle relaxants such as cyclobenzaprine (Flexeril) and tizanidine (Zanaflex) for chronic low back pain [5, 9]. Carisoprodol (Soma) is structurally similar to alprazolam, has little utility in the management of chronic pain and can be habit forming [5]. If used chronically, muscle relaxants cause central relaxation and may carry the risk of physical dependence [9]. Baclofen is a commonly used antispasmodic agent which may improve neuropathic pain and may be less habit forming than muscle relaxants [9, 5].

Multiple Modalities

Treatment plans for chronic noncancer pain must include more than just medications. Exercise therapy is recommended for chronic low back pain as well as other types of chronic pain and can reduce functional limitations [5]. Patients with CNCP are often deconditioned due to inactivity, and providers should recommend gradually increasing general activity levels as well as formal exercise [5]. In addition, massage has been shown to reduce for chronic pain due to low back pain, knee osteoarthritis, and fibromyalgia [5].

Psychotherapy is an additional treatment modality for patients with CNCP. Psychotherapy focuses on improving the patient's quality of life, social functioning, and mood rather than decreasing the level of pain [11]. Cognitive-behavioral therapy (CBT) and mindfulness-based stress reduction are two psychological interventions that therapists can use to teach patients how to manage their pain and engage in a full life despite their pain. Unfortunately many patients struggle with the cost of these services, but mindfulness and diaphragmatic breathing are methods that can also be taught in primary care settings. Providers can also utilize modified CBT techniques when working with patients (see Fig. 2).

Surgical interventions are sometimes warranted but are beyond the scope of this chapter (Table 2).

Opioid Trial Algorithm

See Refs. [4–6, 12, 13] (Fig. 4)

Indications/Contraindications and Risks of Opioids

Guidelines have been developed to help clinicians safely and effectively treat CNCP with opioids [6, 13–15]. However, many of the recommendations are based on limited data. Most trials involving CNCP are short (<3 months) and evaluate pain scores and not patient function [14]. While the

Table 1 Selected analgesics [8–10]

Drug name	Usual dose	Maximum dose	Comments
Acetaminophen (Tylenol, others)	500–1,000 mg po q6-8 h	3,000 mg/day	Recommended for noninflammatory osteoarthritis. May require maximum dose for 1 week for chronic pain trial. Avoid with chronic alcoholism. Monitor OTC medications for risk of accidental overdose
NSAID			
Ibuprofen (Motrin, others)	400–800 mg po q4–6 h	3,200 mg/day	NSAIDs in recommended doses usually provide superior analgesia compared with aspirin, but do not produce the same analgesic effect in all patients. Major adverse effects are: 1. Elevated blood pressure especially in the elderly and in conjunction with beta-blockers or angiotensin-converting enzyme inhibitors 2. Fluid retention in patients with congestive heart failure 3. Acute renal failure or renal insufficiency 4. Drowsiness and confusion 5. Reversible inhibition of platelet aggregation 6. Anaphylaxis in aspirin-sensitive patients 7. Peptic ulcer disease, regardless of mode of administration, especially in the first month of therapy Adding a proton pump inhibitor, H2-receptor antagonist or misoprostol may decrease GI toxicity Use with caution and for the shortest time possible in the elderly
Naproxen (Naprosyn)	500 mg po q12h	1,000 mg/day	
Indomethacin (Indocin)	25–50 mg po q8h or SR–75 mg po q12h	200 mg/day	
Ketoralac (Toradol, others)	10 mg po q4–6 h	40 mg/day	
	Pts <65 years: 30 mg IM/IV q6h	120 mg/day	
	Pts ≥65 years: 15 mg IM/IV q6h	60 mg/day 60 mg/day	
Diclofenac (Cataflam, Voltaren)	50 mg po q8h or SR-75 mg po q12h	200 mg/day	
Meloxicam (Mobic)	7.5–15 mg daily	15 mg/day	May be more selective for COX-2 at low dose (7.5 mg)
Nabumetone (Relafen)	500–750 mg po q8-12 h	2,000 mg/day	
Celecoxib (Celebrex)	200 mg po q12h	400 mg/day	Selective COX-2 inhibitors and NSAIDs have demonstrated decreased gastrointestinal complications compared with nonselective NSAIDs. They do not inhibit platelet aggregation Less effective than full doses of ibuprofen or naproxen Less effective treatment for acute pain
TCA			Analgesia achieved at lower dose (20–100 mg/day) than antidepressant dose (150–300 mg/day). Contraindications include heart failure, ischemic heart disease and arrhythmias. Side effects include confusion, urinary retention, orthostatic hypotension, dry mouth, drowsiness, nightmares Use cautiously in patients at risk for suicide or accidental overdose due to potential for lethal cardiotoxicity Nortriptyline and desipramine are better tolerated than amitriptyline and imipramine
Nortriptyline (Pamelor)	10–100 mg qHS	300 mg/day	
Desipramine (Norpramin)	50–150 mg daily	150 mg/day	
SNRI			Taper over 2 weeks to discontinue. Better tolerated than TCA Common SE of HA and nausea
Venlafaxine (Effexor)	75–150 mg po daily	225 mg	
Milnacipran (Savella)	50 mg po BID	200 mg/day	
Duloxetine (Cymbalta)	60 mg daily	60 mg/day	Specifically approved for diabetic neuropathy, fibromyalgia, chronic low back pain. No known cardiovascular risk. Nausea is a common side effect
Anticonvulsant			Typically used for neuropathic pain and chronic headaches. Can be added to TCA. Similar efficacy to TCA

(*continued*)

Table 1 (continued)

Drug name	Usual dose	Maximum dose	Comments
Gabapentin (Neurontin)	600–1,200 mg TID	3,600 mg/day	Start at 100–300 mg qHS and titrate to effective dose. Common side effects include dizziness, fatigue, impaired concentration, and peripheral edema. Reduce dose in renal impairment
Pregabalin (Lyrica)	75–300 mg po BID	600 mg/day	FDA approved for fibromyalgia. May have anxiolytic benefits
Carbamazepine (Tegretol)	200–400 mg BID	1,200 mg/day	Effective for trigeminal neuralgia, painful diabetic neuropathy and postherpetic neuralgia
Oxcarbazepine (Trileptal)	300–600 mg po BID	1,200 mg/day	May have fewer side effects than carbamazepine
Topical Agent			
Lidocaine patch (Lidoderm)	1–3 patches for 12 h per day	3 patches/day	Approved for postherpetic neuralgia. Minimal evidence to support other use
Diclofenac (Voltaren gel)	2–4g topical q6-8 h	32 g/day	Topical NSAID with low risk of systemic side effects

OTC over the counter, *COX* cyclooxygenase, *NSAID* nonsteroidal antiinflammatory drug, *SR* sustained release, *TCA* tricyclic antidepressant, *SNRI* serotonin-norepinephrine reuptake inhibitor

Encourage your patient to take an active role in their pain management

Tell your patient that you believe the pain is real and you will work together to manage it

Do not let pain dictate activity or appointments. Schedule regular visits and medications at regular intervals instead of as needed

Fig. 2 Cognitive behavioral techniques [5]

risk of overdose death with high-dose opioids has been well established, there are no high-quality controlled trials that evaluate the effectiveness of opioid therapy for longer than 1 year [14].

There is no evidence in favor of one opioid over another for the treatment of CNCP [14, 15]. Opioid selection is primarily based on cost, side effects, and patient comorbidities. Specifically, there is no compelling evidence to prescribe a long-acting medication accompanied by a short-acting medication for "break-through pain" [15]. Patients who are well controlled and functional on a short-acting medication four times a day do not necessarily need the addition of a long-acting medication.

Methadone deserves specific mention due to the unique risks associated with chronic methadone use [16]. Methadone should be a medication of last resort given the significant risk of QTc prolongation and long, variable half-life which can make titration difficult. Patients who require a trial of methadone can be started at 2.5 mg orally every 8 h. Dosage increases should occur no more frequently than once a week [15]. The starting dose of methadone, even in a patient on high doses of other opioids, should not be higher than 30–40 mg per day [15]. The QTc interval should be monitored with electrocardiograms prior to starting methadone, after 1 month, and yearly while therapy continues. Providers should avoid the use of other medications that prolong QTc and increase monitoring if necessary. Methadone should not be used to treat break-through pain or on an as-needed basis [15].

Given the well-established risks of opioids high-dose therapy, in particular, should be reconsidered. Not surprisingly, limiting dosage is associated with decreased number of overdose deaths [13]. Multiple guidelines support opioid dosage limits, but there is inconsistency over specific threshold recommendations [14]. Patients who do not experience a response to low-dose opioids (up to 40 mg morphine equivalent dose (MED)) or moderate doses (40–90 mg MED) are unlikely to respond to higher doses [13]. Patients

Table 2 Selected opioid analgesics [8, 9]

Drug name	Usual adult starting dose	Duration of action	Comments
Don't use Meperidine (Demerol) due to toxic metabolite			
Many opioids are available in multiple formulations: immediate release, sustained release or extended release formulations. This will affect the starting dosage as well as the dosing interval			
Codeine	15–60 mg po q4h	4 h	Avoid in children
Fentanyl (Duragesic)	Depends on previous opioid dosage[a]	72 h/patch	Warn patients that exposing the patch to heat can increase release of fentanyl and increase risk of respiratory depression Keep away from children. Exposure to patch can be fatal CYP3A4 inhibitors (eg ketoconazole, clarithromycin) can dangerously increase serum fentanyl levels
Hydrocodone (Norco)	5–10 mg po q4-6 h	4 h	
Hydromorphone (Dilaudid)	2 mg po q6-8 h	4–6 h	
Methadone (Dolophine)	2.5–10 mg po q8-12 h	8–12 h	Monitor the initial titration period carefully as the half-life is variable (up to 5 days). Serious arrhythmias can occur and are dose dependent
Morphine (MS Contin)	10–30 mg po q4h (IR)	4 h (IR)	Use with caution in patients with renal impairment.
	15–30 mg po q8-12 h (ER)	8-12 h (ER)	
Oxycodone (Roxicodone, Oxycontin)	5–15 mg po q4-6 h (IR)	4–6 h (IR)	1.5 times as potent as oral morphine
	10 mg po q12 (ER)	12 h (ER)	
Oxymorphone (Opana)	5–15 mg po q4-6 h (IR) 10 mg po q12 (ER)	4–6 h (IR) 12 h (ER)	3 times as potent as oral morphine
Tapentadol (Nucynta)	50–100 mg po q4-6 h (IR) 50 mg po q12 (ER)	4–6 h (IR) 12 h (ER)	Less potent than morphine but fewer GI side effects
Tramadol (Ultram)	50–100 mg po q4-6 h (IR) 100 mg po q24 (ER)	4–6 h (IR) 24 h (ER)	Maximum dose is 400 mg/day (IR) and 300 mg/day (ER)

OTC over the counter, COX cyclooxygenase, NSAID nonsteroidal antiinflammatory drug, SR sustained release, TCA tricyclic antidepressant, IR immediate release, ER extended release
[a]Not recommended for opioid naïve patients

requiring high doses (>100 mg MED) should be re-evaluated for the cause of their pain, and providers should consider more frequent monitoring, evaluation of adherence to the treatment plan, and consider referral to pain specialists [13, 15].

Mitigating Risks

In addition to establishing a diagnosis, patients should be stratified according to risk. Mitigating the hazards of opioid misuse and addiction requires routine and ongoing risk assessment. Multiple patient screening tools are available,

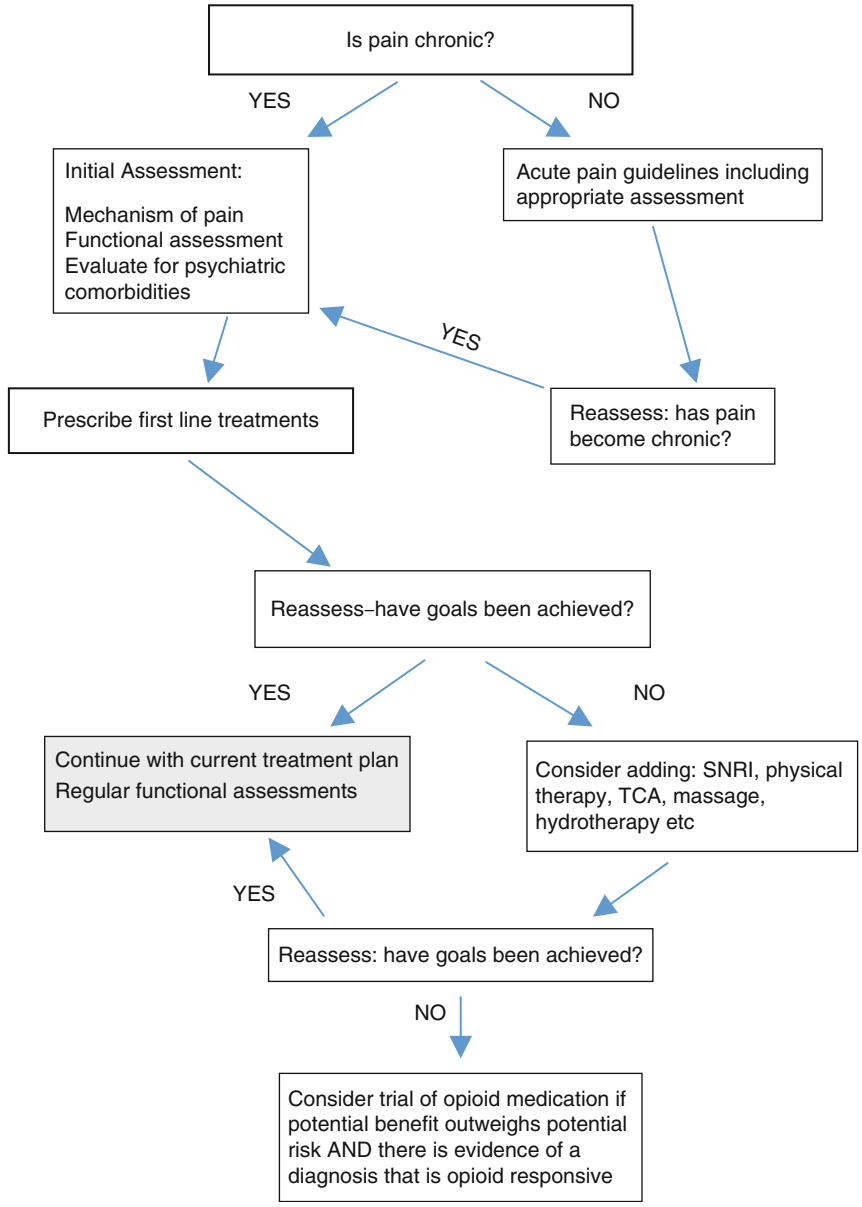

Fig. 3 *SNRI*, Serotonin-norepinephrine reuptake inhibitor, *TCA*, Tricyclic Antidepressant

but unfortunately the effectiveness of these tools is not well studied [14]. However, this should not preclude screening patients. Tools that are often used include the Opioid Risk Tool, Addiction Behaviors Checklist, and the Screener and Opioid Assessment for Patients with Pain [6]. Categorizing patients into high, moderate, or low risk groups can help guide management. High-risk patients and those with significant psychiatric comorbidities or history of drug abuse should be managed only by providers experienced with this population, and comanagement with psychiatry or an addiction specialist is strzongly recommended [15].

Patients must give informed consent prior to starting an opioid trial. Providers should plan for

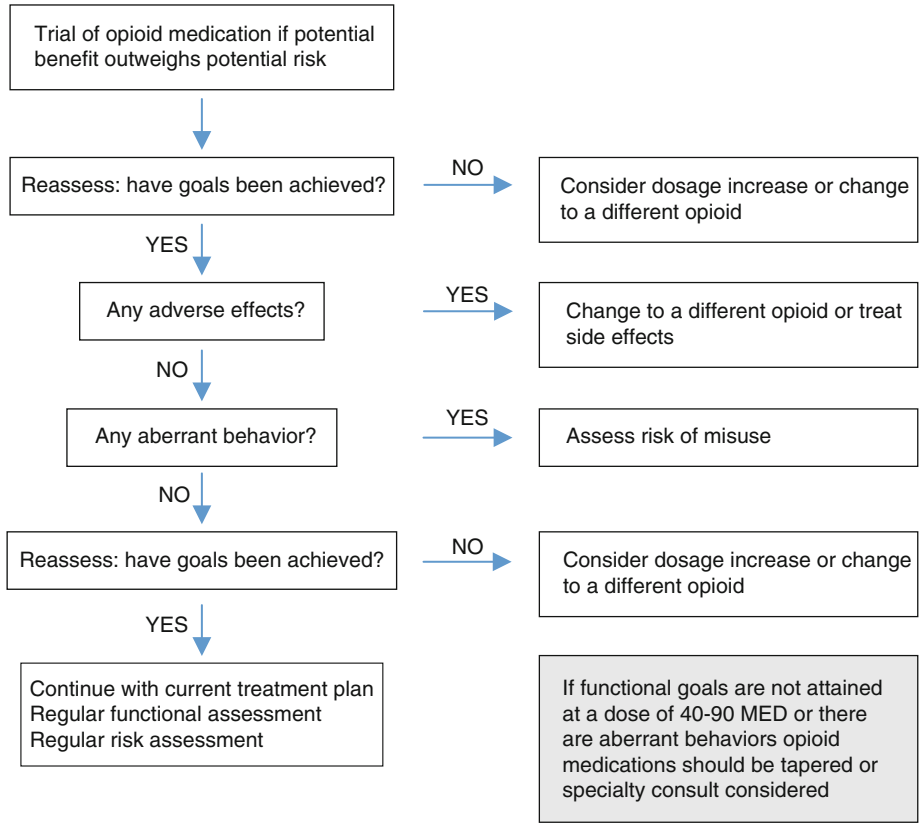

Fig. 4 MED = Morphine equivalent dose

the common adverse effects of opioids at the start of treatment. Even patients on short-term opioids should be warned about constipation and prescribed a stool softener. Chronic opioid users do not develop tolerance to constipation and may also require a stimulant laxative. Nausea is common and typically resolves with time, however antihistamines or metoclopramide will also relieve symptoms [17]. Cognitive impairment or sedation is a major risk when starting or increasing medications or when taken with other sedating substances including benzodiazepines and alcohol. Patients should be instructed not to drive at any time when they feel impaired [15]. The risk of respiratory depression and death is much higher when a patient's dose is increased or when combined with other drugs such as benzodiazepines. A discussion of the risks of physical dependence and withdrawal is also necessary.

Patients and providers should establish reasonable expectations at the start of an opioid trial. Total pain relief with opioids is not realistic. The average benefit on a 10 point pain scale is 2–3 points [15]. A successful opioid trial typically results in a 30 % reduction in pain or a 30 % improvement in function [13].

Documenting informed consent and expectations is crucial and can be accomplished using treatment agreements (pain contracts). There is some evidence that treatment agreements may improve compliance [13]. Using these agreements, providers can also discuss expectations of random urine drug testing, pill counts, replacement of lost/stolen prescriptions and counsel to avoid excessive amounts of alcohol.

Prescription monitoring programs are active in at least 48 states and can reduce doctor shopping and prescription drug abuse [13, 14]

Unfortunately these programs are grossly underutilized [13, 14].

Every patient on chronic opioid therapy should have periodic urine drug screening (UDS) [13]. The frequency of testing can be based on the patient's overall risk of misuse. Using these screens is important, however the interpretation of results is not always straightforward. Results should be considered in the context of patient behavior and overall compliance [15]. Unexpected positive results should be confirmed by more specific means, and a discussion with the laboratory may be helpful to determine concentrations necessary for a positive result when the prescribed opioid is not present. Furthermore, numerous assays and platforms for UDS are available, each with variable test characteristics not equivalent across all drug classes. Not infrequently, pseudoephedrine may result in a false-positive amphetamine screen, while testing positive for cocaine is far more specific.

Discontinuation of Opioids

If patients are not progressing toward established treatment goals, show repeated aberrant behaviors, or are suffering intolerable adverse effects, discontinuation of therapy should be considered [15]. A conservative opioid taper, with weekly decreases of 10 % of the original dose, is usually well tolerated although more aggressive decreases are possible [13]. While not life threatening, opioid withdrawal can be unpleasant, and symptoms can be managed with clonidine 0.1–0.2 mg orally every 6 h or by transdermal patch at 0.1 mg weekly. Patients on clonidine should be monitored for hypotension [13]. Benzodiazepines should not be used to control symptoms during tapering [6]. Patients who are abusing the medication or noncompliant with the taper schedule should be referred for detoxification [13].

All patients with aberrant behavior should be offered addiction resources [15]. Office-based treatment with buprenorphine/naloxone may be appropriate for patients with opioid dependence. This treatment is an alternative to methadone maintenance and can be offered by primary care providers after obtaining further education and a special licensure from the DEA. More information can be found at http://buprenorphine.samhsa.gov.

Chronic Disease Model

Chronic noncancer pain is complex and following current treatment guidelines requires significant clinical resources. However, this is not unlike other chronic illnesses. Using a chronic care model within primary care has clearly improved the care of patients with chronic illnesses such as diabetes, congestive heart failure, and asthma [18]. Chronic noncancer pain must be approached in the same manner. A comprehensive approach that includes risk assessment, treatment agreement, patient self-management, and care coordination can improve adherence to guidelines, pain disability, and pain intensity [19].

Care of the Dying Patient

Franklin J. Berkey

Contents

General Principles

Definition/Background

In contrast to the numerous maladies described elsewhere in this textbook, successful care of the dying patient is not measured in terms of convalescence but rather in achievement of a "good death." While the circumstances of death among the seriously ill in US hospitals are well defined – a high prevalence of pain and frequency of invasive procedures – the characteristics of a "good death" vary between patient, family, and provider [1, 2]. Frequently cited characteristics of a "good death" include control of severe pain, reduction of stress and anxiety, provider compassion, and the perceived knowledge and expertise of the physician [3]. However, patients with terminal conditions often report a sense of abandonment by their primary provider [4]. Increased end-of-life education among family physicians is critical in shifting patient deaths out of the hospital and into the comforts of home in effort to improve end-of-life care [5].

Hospice

There are more than 5,800 hospice programs in the USA today providing end-of-life care to an estimated 1.5 million patients. While cancer diagnosis previously accounted for the majority of the hospice referrals, current data reflects a broad

Source: [13]

array of terminal diagnoses. In 2013, 63.5 % of hospice admissions were for noncancer diagnosis, with dementia (15.2 %), heart disease (13.4 %), and lung disease (9.9 %) leading the list of noncancer hospice admissions [6].

Centers for Medicare and Medicaid Services (CMS) certified programs must provide core services including a physician medical director, hospice nurse, social worker, and counselors for bereavement, dietary, and spiritual needs. Additional services include physical therapy, occupational therapy, speech pathology, home aide services, and volunteer services. All recommendations from the interdisciplinary team are forwarded to the patient's primary physician, as the hospice concept aims to support the patient's personal physician as the primary provider.

Hospice eligibility guidelines vary by diagnosis, but all require a prognosis of 6 months or less as certified by two physicians. Hospice patients are certified for two initial 90-day periods, after which recertification must take place every 60 days. Recertification periods are unlimited, as long as the patient's prognosis, judged by their terminal diagnosis and progression of symptoms, continues to be 6 months or less from the date of recertification.

Surprising to many, hospice patients often live longer than similar patients not enrolled in hospice. One study found that hospice patients with CHF lived on average 81 days longer than disease-matched patients not in hospice, and similar results were noted with lung (39 days), colon (33 days), and pancreatic cancer (21 days). [7] Researchers theorize the difference in life span is due to a combination of factors, including avoidance of side effects related to aggressive treatments, the increased monitoring and symptom management provided in hospice, and the interdisciplinary focus on the patient's emotional needs and well-being.

End-of-Life Patient Communication

Effective communication is the initial step in providing end-of-life care. However, physicians avoid end-of-life conversations for fear of making patients depressed, taking away hope, and shortening life span with hospice involvement [8].

Table 2 Functional assessment staging (FAST)

Score	Characteristics
1	No difficulties
2	Subjective forgetfulness
3	Decreased job functioning and organizational capacity
4	Difficulty with complex task (personal finances, planning dinner)
5	Requires assistance with activities of daily living (ADLs)
6	(**A**) Unable to dress without help (**B**) Unable to bathe properly (**C**) Inability to self-toilet (**D**) Urinary incontinence (**E**) Fecal incontinence
7	(**A**) Speaks $\leq$ 6 intelligible different words in the course of an average day (**B**) Speech limited to the use of a single intelligible word (**C**) Cannot ambulate (**D**) Cannot sit up without assistance (**E**) Cannot smile (**F**) Cannot hold up head independently

Source: [15]
Note: A patient must fulfill criteria in successive order. For example, a patient who is incontinent of bowel and bladder, cannot ambulate (due to a recent hip fracture), and speaks 20 words is scored 6E (not 7C)

End-of-life discussions are associated with less aggressive medical care, earlier hospice referral, improved quality of life, and better bereavement adjustment [9].

The SPIKES Protocol provides a six-step plan to deliver bad news to a patient [10]. The protocol guides the provider in the four critical objectives in delivering bad news: gathering information from the patient and assessing understanding, delivering the medical information, providing support, and developing a follow-up plan.

(**S**) **Setting**: Provide a quiet place for the discussion, minimize interruptions, and involve significant others. Sit, do not stand.

(**P**) **Perception**: Determine what the patient already knows, and his/her perception of their illness. "*When you first felt the lump in your breast*, *how serious did you think it was*?"

(**I**) **Invitation**: Determine how much the patient would like to know and seek permission to provide the new information. "*Is it OK if I share the results of the biopsy with you now*?"

(**K**) **Knowledge**: Share the bad news, providing the information in small amounts, using plain language and checking frequently for understanding. Preface the news with a warning. "*Unfortunately*, *I have some bad news to tell you today*."

(**E**) **Empathy**: Acknowledge and address emotions as they arise; provide empathy. "*I see this news comes as quite a shock to you*."

(**S**) **Strategy**: Address questions, determine next step, and plan follow-up. "*I will see you again in five days*, *but please call if a question comes to mind*."

Prognosis at End of Life

Physicians tend to be overly optimistic when estimating survival [11]. Physician optimism, combined with patient self-deception, is an explanation for why in a survey of nearly 1200 patients with metastatic colorectal and lung cancer, 81 % and 69 % of the patients, respectively, believed their therapy was likely to provide a "cure" [12]. Contrary to popular belief, an accurate prognosis does not eliminate a patient's hope but rather may help a patient make better informed decisions that allow for an improved quality of life.

While determining survival time is difficult, there are tools to aid the family physician. For malignancies, established survival statistics for each stage of a cancer provide a starting point. The Palliative Performance Scale (PPS) (Table 1), a validated scale assessing overall functioning of a terminally ill patient, can assist the physician in refining the prognosis and determining hospice eligibility [14]. While incurable malignancies tend to follow a predictable course, diseases related to end-stage organ failure follow a more erratic and less predictable course.

The Functional Assessment Staging Scale (FAST) is a tool to stage dementia and determine hospice eligibility (Table 2). While patients with mild to moderate dementia often require substantial care, hospice-appropriate dementia patients have a FAST score of at least 7C and one or more of the following comorbid predictors: aspiration pneumonia, pyelonephritis, septicemia, multiple stage three to four decubiti, and fever despite antibiotics. Similar to end-stage organ disease, there is great variability among dementia patients, and the aforementioned criteria have limitations in predicting a 6-month prognosis.

End-of-Life Pain Management

Dr. Cicely Saunders, founder of the modern hospice movement, developed the concept of total pain to describe the suffering experienced by patients and their family. The four major components of total pain – physical pain, social pain, psychological pain, and spiritual pain – are interrelated, and often the sum is greater than the individual components. Successful end-of-life pain management is dependent on attention to all four components, with recruitment of social workers, spiritual leaders, and other allied professions often needed.

Physical Pain

The World Health Organization cancer pain ladder provides a starting point for the treatment of end-of-life pain. The ladder employs a three-step approach, starting with nonopioids such as acetaminophen and ibuprofen (step 1), progressing to weak opioids such as codeine (step 2), and finally strong opioids such as morphine (step 3). However, effective management of end-of-life pain will frequently require a starting point other than step 1 and accelerated progression through the steps. While acetaminophen is an appropriate first step for mild to moderate pain, its use as an adjunct to higher doses of opioids is limited [16]. Nonsteroidal anti-inflammatory drugs (NSAIDs) are also useful as an initial step, and particularly useful as an adjunct to opioids in patients with metastatic bone lesions [17].

Effective pain control with opioid medications is best achieved with a combination of scheduled long-acting opioids in combination with short-acting "rescue" doses. For opioid-naïve patients, the starting dose is usually 5–10 mg of morphine equivalent every 4 hours. Unlike pain management in the nonterminal patient, end-of-life pain management often requires quick titration. A patient's use of short-acting pain medication is calculated over the first 24 h, and then converted to a long-acting form. Thereafter, breakthrough dosing should start at 10–15 % of the new scheduled daily long-acting dose of the same opioid, usually provided every 2–4 h. As a general rule, the need for four or more "rescue" doses in a 24-h period warrants an increase in the long-acting dose. Also, "rescue" doses should be given prior to potentially pain-provoking procedures and daily activities (wound care, dressing change, bed repositioning, bathing).

Methadone, due to its low cost, high bioavailability, and effectiveness at treating neuropathic pain, is frequently used in end-of-life care. It is also useful in patients with renal impairment, as 60 % of its elimination is nonrenal (primarily fecal). Titration is difficult, drug interactions are numerous, and consultation with a palliative care pharmacist is recommended.

While uncommon in hospice and palliative care, opioid toxicity presents as increased drowsiness, confusion, and hallucinations. The side effects often reverse with holding subsequent doses. If naloxone (Narcan) is required, a modified dose for end-of-life patients avoids an abrupt

pain "rebound." In this circumstance, a dilute solution obtained by mixing 0.4 mg naloxone in 10 ml of normal saline is delivered by slow IV push 1 ml every 4–5 min until the side effect resolves. Myoclonus, a rare side effect that can be seen at any dose of opioid, is best handled with opioid rotation. In opioid rotation, a morphine-equivalent dose is calculated, reduced by 20–30 % to account for incomplete cross-tolerance, and then started in place of the original opioid. Consultation with a palliative care pharmacist is often required.

Neuropathic Pain

There are several adjunctive therapies for treating neuropathic pain. Tramadol (Ultram), due to its action on serotonin and norepinephrine, provides relief of neuropathic pain, as well as improvement in sleep and performance status [18]. Tricyclic antidepressants (TCAs) are effective in treating neuropathic pain [19]. Dosed at bedtime, TCAs are also useful as a sleep aide. Most evidence supporting TCAs is in noncancer patients, and full response may take up to 1 month. Gabapentin (Neurontin), titrated over 3–5 days, is also an effective adjunct to opioid therapy for neuropathic pain [20]. Ultimately, a combination of medications may be needed, with titration of each medication dependent on side effects.

Bone Pain

Metastatic bone pain is common in end-of-life care, particularly in patients with breast and prostate cancer. NSAIDs are effective alone and in combination with opioids in treating pain due to skeletal metastasis. Dexamethasone (Decadron) has been shown to reduce pain associated with bony metastasis and may be favorable compared to other steroids due to less fluid retention. Steroids are also effective in treating anorexia, weakness, headache, and nausea and vomiting, with an improvement of symptom intensity seen in less than 3 days on average [21]. Bisphosphonates may be useful in patients with widespread bone pain, especially in patients with multiple myeloma and concomitant hypercalcemia [22]. Radiation therapy is a useful palliative intervention for cancer-related bone pain and appropriate for hospice patients.

Grief and Depression

Grief and depression are common among patients and families dealing with a terminal illness. Grief, while it may cause suffering, is considered both adaptive and healthy. Depression is maladaptive and can significantly increase suffering and reports of pain, decrease quality of life, and shorten survival [23]. Depression is highly associated with brain, breast, lung, pancreatic, and oropharyngeal malignancies and less associated with colon and gynecologic tumors [24, 25]. Treatment with both SSRIs and TCAs is effective in depressed patients with terminal illness, although life expectancy may limit usefulness. Both medication classes may also have secondary beneficial effects based on side effects (tricyclic for neuropathic pain and insomnia, for example). Mirtazapine (Remeron), used at night, is also helpful in the treatment of insomnia and anorexia. In patients with prognosis of less than 4–6 weeks, psychostimulants may reduce depressive symptoms within days of commencement [26].

Nausea and Vomiting

Nausea and vomiting are common complaints in the dying patient, especially in those with advanced cancer. Frequently seen as a side effect of chemotherapy, nausea and vomiting are also a result of anxiety, obstruction, and inflammation. In addition to traditional antiemetic agents, benzodiazepines are useful in treating nausea related to anxiety, and haloperidol (Haldol) is helpful in refractory symptoms near the end of life.

Bowel obstruction is frequently associated with ovarian and colon cancers. Nonsurgical treatments include cessation of oral intake, nasal-gastric decompression, octreotide (Sandostatin),

and corticosteroids. Octreotide, which is administered either intravenously or subcutaneously, inhibits the accumulation of intestinal fluid. Dexamethasone, in daily doses between 6 and 16 mg intravenously, has been shown to relieve symptoms associated with bowel obstruction.

Constipation

Constipation is a frequent pain-provoking symptom in end-of-life care. Decreased mobility, dehydration, and opioid medications are all risk factors for constipation. A stool regimen should be implemented as soon as the symptom arises, or with introduction of an opioid medication, whichever comes first. Hospice programs usually institute an algorithm which includes a daily combination of both osmotic and stimulant laxatives which are increased each day that the patient is without a bowel movement. For example, sennoside (Senna) is given 2–4 tabs nightly along with lactulose 30 ml. If a patient does not have a bowel movement on the second day, the sennoside is increased by two tablets (in divided doses), and the lactulose is increased to 30 ml twice daily. If a patient is without a bowel movement on day three, a rectal exam is usually indicated, with subsequent use of enemas and further titration of the laxatives. Higher-than-usual laxative doses are often required in palliative care. There is no evidence to support docusate (Colace) as softening agent in end-of-life care.

Dyspnea

Primary management of the dying patient with moderate to severe dyspnea is achieved with opioids. Etiologies are multiple, including bronchospasm, effusions, thick secretions, and anxiety. In addition to disease-specific treatments, opioids are effective for patients with COPD, CHF, and terminal cancer [27]. Immediate-release morphine, 2.5 mg to 5 mg every 4 hours, is a reasonable starting point in the opioid-naïve patient. Titration, including the use of long-acting opioids, is similar to that for physical pain. Benzodiazepines are a useful adjunct to opioid therapy in relieving dyspnea attributed to anxiety. While evidence supporting the use of supplemental oxygen in nonhypoxic patients reporting dyspnea is anecdotal, oxygen is often trialed in the hospice patient as the usual Medicare qualification guidelines do not apply. Small studies have also demonstrated a symptomatic benefit with the gentle breeze of a low-set fan.

Recommendation for the Final Hours

Signs of active dying include irregular respirations, accumulation of oral secretions, and fever unresponsive to antipyretics. It is generally accepted that dying patients may have a greater awareness than ability to respond, and family is encouraged to talk to the dying. To minimize sacral pressure, the head should be lowered to less than 30° and the patient turned every 60–90 min. Wound care goals are shifted from healing to comfort, and dressing changes are minimized. The use of dark or red-colored sheets may reduce anxiety among bedside visitors when hemorrhage is a concern. Oral care, using an artificial saliva solution, is provided for comfort. A simple home remedy is made of 5 ml salt and 5 ml of baking soda mixed in 1 l of tepid water [28].

Excessive oral secretions (“death rattle”) are treated with oral administration of 1 % atropine eye drops (one to two drops SL every 4 h) or glycopyrrolate (1 mg SL or 0.2–0.4 mg SC/IV every 4 h). Hyoscyamine (Levsin) and scopolamine are also used.

Terminal delirium is defined as an irreversible agitation in the final hours of life. Highly stressful for caregivers and family, it is best managed with benzodiazepines. Lorazepam (Ativan) 1–2 mg elixir is given sublingually every hour as needed. Benzodiazepines, in addition to their anxiolytic effects, also serve as muscle relaxants to decrease contractures and provide prophylaxis for seizure activity, both unsettling symptoms for caregivers and family.

Advanced Directives: Living Wills/ Health Care Proxy/POLST

An essential part of end-of-life care involves advanced care planning. Family physicians, given their familiarity with the patient and family, are optimally positioned to assist with such planning.

Traditionally, advanced directives consisted of living wills, or documents which state a patient's wishes should they develop an irreversible condition that prevents them from making a decision. However, living wills do not translate into actionable medical orders and oftentimes are not readily available and are too vague to interpret. A health care proxy is someone who is familiar with and can make decisions in accordance with a patient's values and beliefs. However, in the event of an emergency, the proxy may not be available to consult, and Emergency Medical Services (EMS) providers cannot always follow the direction of a health care proxy.

In response to the shortcomings noted above, the Physician Orders for Life-Sustaining Treatment (POLST) provides patient wishes that translate into actionable medical orders. Started by a team at the University of Oregon in the late 1990s, POLST forms are currently operational or in development in all but six US states [29]. While traditional advanced directives are designed for all adults and direct future care, POLST orders are for the seriously ill (life expectancy less than 1 year) and reflect current care. Through an informed and shared decision-making process, a health care professional completes the POLST orders (unlike a traditional advanced directive, which is completed by the patient). A POLST document provides orders regarding resuscitation in the event of pulselessness and apnea as well as decisions regarding level of intervention in terms of transport to the hospital, intubation, mechanical ventilation, noninvasive airway support (CPAP/BiPAP), antibiotics, and artificial feeding [30]. In states where POLST or similar programs are implemented, these orders are transferable between facilities as well as being usable in the prehospital setting (EMS).

Palliative Sedation, Physician-Assisted Suicide, and Euthanasia

There are no greater ethical issues in end-of-life care than palliative sedation, physician-assisted suicide, and euthanasia. While the details of these practices are beyond the scope of this chapter, family physicians need a basic understanding of the terms, if only to dispel myths and distinguish these extreme measures from more common and widely accepted symptom-relief modalities.

While the terms are often erroneously interchanged, there is a clear distinction in intent and practice of the three concepts. Palliative sedation is a last resort practice for the very small minority of patients in which traditional palliative measures cannot relieve intolerable suffering. By way of a reduction in consciousness, symptom relief is achieved. In palliative sedation, the intent is symptom relief, which distinguishes it from physician-assisted suicide, in which the intent is to hasten death. This delineation is strengthened by medical studies which demonstrate that palliative sedation does not hasten death [31]. Physician-assisted suicide, legal in Oregon, Washington, Montana, Vermont, and California, is distinguished from euthanasia in that the physician provides the medications for the patient to take by themselves. In euthanasia, which is illegal in the USA, the physician administers the medications to achieve death.

Headache

Anne Walling*
Department of Family and Community Medicine, University of Kansas Medical Center, Wichita, KS, USA

General Principles

Definition and Classification

Headache is a symptom, not a diagnosis. In addition to the "primary" headaches such as migraine, tension-type or cluster, numerous conditions can cause headaches. These secondary headaches can result from systemic conditions as well as pathology in the head and neck. The International Classification of Headaches provides diagnostic criteria for multiple types of headache (Table 1) [1]. "Mixed headaches" with elements of more than one headache category are common. Individuals may also experience more than one type of headache; for example, patients with migraine often also experience tension headaches, and migraine or tension headaches can transform into medication-overuse or chronic daily headache.

Epidemiology and Impact

Two types of headache, tension and migraine, are the second and third most common diseases in the world, exceeded only by dental caries [2]. Multinational studies estimate that over 70 % of men and 86 % of women experience at least one headache per year. In men, the prevalence peaks at about 82 % in the 30–40-year age group. For women, the peak prevalence is higher (93 %) at younger ages (20–30 years) but remains high through middle age. For both sexes, headache prevalence declines with age, but 48 % of men and 62 % of women older than 60 report at least one headache per year [3]. Headache prevalence does not differ significantly by race or ethnicity but is correlated with lower educational and economic levels, lower reported general health, increased use of healthcare services, and increased number of comorbid physical and/or psychiatric conditions [3–5].

For many individuals, headaches are frequent, severe events that disrupt normal activities, impede personal advancement, and strain relationships. In the USA, 15 % of men and 28 % of women report a severe headache in the last 3 months [4]. About one third of the men and half of the women who report headache experienced symptoms at least once per week [3]. In the USA, headache was the principal cause for over 12 million office visits and was the fifth leading cause for emergency department visits in 2009 [4]. Headache patients, especially those with migraine or medication-overuse headaches, report significant negative impact on education and career success, income, personal relationships, and social activities [3–5]. Many patients perceive stigma associated with headache. Only about one third of headache patients believe that others understand and accept the condition, and at least 30 % avoid letting others know about their symptoms [3].

Approach to the Headache Patient

Despite the high prevalence and significant morbidity, the vast majority of headaches are managed without medical advice [6, 7]. Little is known about why some headache patients seek medical advice. Consultation is not correlated with the severity of symptoms [8]. Each headache episode is interpreted by

Paroxysmal hemicranias
Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT)
Probable trigeminal autonomic cephalalgia
Other primary headaches
Stabbing
Cough
Exertional
Sexually related
Hypnic
Thunderclap
Hemicrania continua
New daily persistent headache
Secondary headaches
Associated with
Head and neck trauma
Cranial or cervical vascular disorders
Nonvascular intracranial disorders
Substance use or withdrawal (including medication side effects)
Infection (intracranial and systemic)
Disturbance of homeostasis
Disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structure psychiatric disorder
Cranial neuralgias, central and primary facial pain, and other headaches
Include various neuralgias and facial pain syndromes
Headaches due to external compression or cold
Unclassified or unspecified headaches

the individual in terms of personal experience, family influences, culture, and belief systems. A relatively minor degree of pain may prompt one headache patient to seek emergency care and comprehensive neurologic assessment, whereas another individual may cope with incapacitating symptoms over a prolonged period.

DOI 10.1007/978-1-4939-0779-3_70-1

Consultations for headache are often challenging. The patient may be dissatisfied with previous headache care, have inaccurate information, and/or have unrealistic expectations for management [7, 8]. Physicians frequently identify headache as a "heart-sink" condition, i.e., evokes "an overwhelming mixture of exasperation, defeat, and sometimes plain dislike" [9]. Physician discomfort with headache consultations may be caused or exacerbated by many factors including the subjective nature of symptoms; the recurrent, chronic pattern of most headaches; lack of confidence in treatment strategies; the potential for patients to be dependent or seeking secondary gain; possible iatrogenic complications (particularly overuse of narcotic analgesics); and fear of missing a potentially serious intracranial lesion [10]. Above all, the consultation may be handicapped by perceived or real lack of trust or respect between patient and physician. The effective management of headaches requires the development of a therapeutic alliance based on a mutually agreed plan for management and expectations for outcomes. Most chronic headache conditions are recurrent and cannot be completely cured. Physicians can, however, greatly help patients to understand their condition, develop effective strategies to reduce the number and severity of attacks, and follow healthy lifestyles not skewed by the presence or fear of headache.

With so many potential causes and complicating circumstances, a systematic approach to the headache patient is essential. This can be achieved in four stages:

1. Clarification of the reasons for the consultation
2. Diagnosis of the headache type
3. Negotiation of management
4. Follow-up

Note: A significant headache history is sometimes discovered in a patient presenting for other reasons. The approach to these patients begins with identifying why the patient has not sought medical help for headache symptoms.

Clarification of the Reasons for Consultation

Patient beliefs about headache, the burden of suffering it imposes, and concerns about the prognosis have been identified as the strongest predictors of poor outcomes of care [11]. Reasons for consultation may range from fear of cancer to seeking validation that current use of nonprescription medication is appropriate. The visit may have been precipitated by a change in the coping ability of the patient, family, or coworkers rather than any change in the severity, frequency, or pattern of headache symptoms. Patients may also consult when they learn new information, particularly about a severe illness that presented as headache in a friend, relative, or public person. Advertising campaigns may influence patients to consult physicians to request new treatments for headaches, especially for migraine. Background information from relatives and friends may give useful insights, but disruptive headaches can lead to highly charged situations, and the physician must avoid becoming triangulated between the patient and others. Patients should always be asked why they decided to seek medical advice for their headaches. With good listening and a few directed questions, the background to the consultation can be clarified and the groundwork laid for accurate diagnosis and successful management. This short time is well invested. Improved symptom outcomes as well as patient satisfaction are correlated more strongly with the physician's perceived interest and communication skills than the diagnostic or management strategies employed [8].

DOI 10.1007/978-1-4939-0779-3_70-1

Table 2 Diagnostic criteria for common primary headaches [1]

Headache	Duration	Characteristics	Associated symptoms	Others
Migraine	4–72 h each episode	At least two: Unilateral Pulsating Moderate to severe intensity Aggravated by activity	At least one: Nausea/vomiting Photophobia and phonophobia	No neurologic source for symptoms Multiple subtypes (Table 1) At least five attacks for diagnosis
Cluster	Individual attacks: 15–180 min Cluster episodes: <1–8 attacks/day for 7 days to 1 year or longer with pain-free periods	Unilateral orbital/temporal/supraorbital stabbing Severe to very severe	Restlessness/agitation At least one ipsilateral: Conjunctival injection Lacrimation Nasal congestion Rhinorrhea Facial sweating Miosis Ptosis Eyelid edema	No neurologic source for symptoms At least five attacks for diagnosis Episodic, chronic, or probable forms Related to paroxysmal hemicrania, SUNCT, and other rare syndromes
Tension type	Individual headaches: 30 min to 7 days *Infrequent* <12 days/year *Frequent* 12–180 days/year *Chronic* >15 days/month for >3 months (>180 days/year)	At least two: Pressure/tightness Bilateral Mild to moderate Not aggravated by activity	No nausea/vomiting Photophobia and phonophobia: absent or only one present, not both	No neurologic source for symptoms At least 10 episodes for diagnosis Exclude medication-overuse headache

Diagnosis of the Headache Type

Headaches are classified into four groups of "primary" headaches and multiple types of secondary headache (Table 1) [1]. Diagnosis depends on identifying the typical clinical picture for each headache type (Table 2) and eliminating other possible causes for the patient's symptoms.

The diagnosis is heavily dependent on history, particularly the patient's description of the headache symptoms and pattern. It is not uncommon for a patient to believe he/she is suffering from migraine when the true diagnosis is another type of headache. Research and treatment innovations focus heavily on migraine, but tension headaches are about three times more common in the general population [12], and secondary headaches may also be more common than migraine in patients presenting to family physicians. Intracranial pathology is a rare cause of headaches presenting to family physicians. Studies and expert groups have identified "red flags" for intracranial pathology (Table 3) mainly based on patients in emergency rooms or those consulting neurologists [13–16].

History

Headache diagnosis depends on using the medical history to identify the criteria for a specific type of headache (Table 2). An open-ended approach, such as "Tell me about your headaches," followed by specific questions to elucidate essential features usually indicates which of the diagnostic categories is most probable. Patients should be asked directly what type of headache they believe they have and what causes it. These issues must be addressed during the management even if they are inaccurate. Patients should also be asked about previous investigations and treatments and their current expectations of management. The history should cover the following areas:

DOI 10.1007/978-1-4939-0779-3_70-1

Table 3 Conditions associated with increased odds of significant abnormality on neuroimaging [13–16]

Cluster headache
Abnormal neurological examination
Undefined headache (not meeting criteria for migraine, cluster, or other primary headaches)
Headache with aura or vomiting
Headache exacerbated by exertion or Valsalva maneuver
Sudden onset of new headache especially in patients older than 50 years
Rapidly increasing headache frequency
Headache that wakens from sleep
Patients with cancer, HIV, systemic illness, or other condition increasing vulnerability to intracranial pathology

1. *Characteristics*: nature of pain, location, radiation in head, intensity, exacerbating and relieving factors or techniques, associated symptoms and signs
2. *Pattern*: usual duration and frequency of episodes, precipitating factors, description of a typical episode, change in pattern over time, prodromes and precipitating factors, post-headache symptoms
3. *Personal history*: age at onset; medical history (including medication, alcohol, and substance use) with special emphasis on secondary causes of headache, such as depression or trauma; environmental and occupational exposure history
4. *Investigations and treatments*: previous headache diagnoses and supporting evidence, patient's degree of confidence in these diagnoses, patient's beliefs and concerns about diagnosis and potential treatments, previous treatments and degree of success, side effects of any investigations and treatments, patient preferences for treatment, and current use of prescription and nonprescription medications
5. *Family history*: headache, other conditions, family attitudes to headache
6. *Review of systems*: special focus on "red flag" symptoms and symptoms indicating a neurological, systemic, or head and neck condition that could cause a secondary headache

The headache profile that emerges from the history has a high probability of correctly classifying the headache. It is important to complete the review of systems to uncover additional information, particularly any neurological symptoms and comorbid conditions. Patients should be directly asked for any symptoms of "red flags" indicating potentially serious secondary headaches. Throughout the history, the physician forms a general impression of the patient. Although subjective, this helps in assessing the patient's understanding of the headache and receptiveness to management strategies.

Physical Examination

The physical examination continues the process of confirming a specific diagnosis, ruling out alternative explanations for symptoms, and laying the groundwork for successful management. Unless the consultation coincides with an attack, most migraine, cluster, and other headache patients have no abnormal findings on physical examination. Expert recommendations stress the importance of a thorough, documented neurological examination at baseline that is repeated if necessary as clinical signs may evolve over time [13–15]. If the history suggests a source of secondary headaches, an appropriate targeted examination should be done, e.g., of the head and neck in the case of an adult with sinus symptoms or an older patient with temporal arteritis or cervical osteoarthritis. The time devoted to physical examination is a wise investment, as it documents both positive and negative physical findings, contributes to the therapeutic alliance, and is often itself reassuring and beneficial to the patient.

DOI 10.1007/978-1-4939-0779-3_70-1

Diagnostic Investigations

Current expert guidelines report "insufficient evidence" to support any specific laboratory or neurophysiological testing, including EEG, in headache evaluation (with a few exceptions for rare conditions) [13]. In individual patients, specific laboratory tests may be indicated to confirm a secondary headache diagnosis suggested by the history and physical examination. Nevertheless, tests are often performed to relieve either physician or patient distress and uncertainty. If the patient or family insists on testing, the concerns and motivations of the patient/family should be explored and the potential contributions and limitations of the requested test(s) reviewed. Similarly, the physician experiencing the WHIMS (what *have I* missed syndrome) should review the data and attempt to make a rational decision as to the potential contribution, cost, and risks of additional testing.

Neuroimaging

Most of the debate over the appropriate role of testing involves radiologic investigation, especially computed tomography (CT) and magnetic resonance imaging (MRI). The role of neuroimaging is limited by the rarity of intracranial lesions in patients presenting to family physicians and hence the very low yield of imaging in unselected headache patients. Serious intracranial pathology has been estimated to cause less than 1 % of new headaches presented to primary care physicians [17] and 1–2 % in patients presenting to neurologists [18–20]. A British study estimated the risk of brain tumor in headache patients presenting to family physicians as 0.09 % [10]. Any potential benefit from neuroimaging must be considered in light of radiation exposure (for CT), patient distress, cost, and the implications of false-positive or noncontributory incidental findings. As various imaging modalities have different characteristics, the physician should have a clear concept of the type and location of any suspected intracranial condition in order to select the most appropriate investigation. Non-contrast CT is very sensitive to acute hemorrhage and certain enhancing solid lesions; MRI provides better resolution in the posterior fossa and superior detection of gliosis, infection, posttraumatic changes, and certain tumors [16]. Other imaging modalities may be indicated for specific circumstances [14–17]. Discussions with a radiologist may be useful before ordering tests.

Current guidelines state that neuroimaging is only indicated if "red flag" conditions are present (Table 3) [13–17]. Although neuroimaging should only be used if the patient has a significant risk of a relevant abnormality and the result is likely to change clinical management, it is often considered in patients who are excessively anxious about the cause of their headaches. The few studies on patient anxiety and satisfaction with headache care indicate that the interaction with the physician is by far the most important factor in improving outcomes. Imaging does not significantly reduce anxiety or improve satisfaction with care [8, 10]. One intriguing study of patients with chronic daily headache and high levels of anxiety and depression concluded that the primary benefit of imaging was in reassuring primary care physicians: the patients did not obtain long-term psychological or physical benefit from imaging [21].

Negotiation of Management

As migraine, cluster, tension/stress, and many secondary headaches are chronic conditions, appropriate management goals are:

- Providing effective treatment of individual headache episodes
- Minimizing the number and severity of headache episodes
- Optimizing patient function and self-care
- Minimizing adverse effects of treatment
- Optimizing cost-effective use of resources [13]

DOI 10.1007/978-1-4939-0779-3_70-1

Most headache patients are open to the concept that they carry a vulnerability to headaches and are willing to learn how to manage this tendency. Patients who strongly resist this approach may have dependent personalities, secondary gain from their headaches, and/or have drug-seeking behavior. The complete management plan includes patient education, treatment plans for both prophylaxis and acute management, and follow-up.

Patient education is essential for the patient and family to manage headaches. They must understand the type of headache, treatment options, and likely prognosis. In addition to providing information, the physician must address hidden concerns. Many myths and beliefs are associated with headache and its treatment. Patients can better manage their headaches once these beliefs are addressed [8]. Patients may be embarrassed by their fears; for example, almost all migraine patients have feared cerebral hemorrhage during a severe attack. Patients gather information about headaches and their treatment from a wide variety of sources, including the Internet, news media, and the experience of friends. Reliable websites may be recommended (see Patient Resources), and the patient warned that the Internet accesses a great deal of misleading and potentially alarming or harmful information about headaches.

One aspect of patient education is identifying and managing situations that precipitate or exacerbate headaches. These situations range from avoiding foods that trigger migraine episodes to practicing conflict resolution. Stress is implicated in almost all headaches; even the pain of secondary headaches is less easy to manage in stressful situations. Formal therapies such as relaxation therapy, thermal biofeedback, and cognitive-behavioral therapy can be effective in individual patients. Practical advice can be helpful in building the placebo effect and therapeutic alliance. Physicians gather experiences from many patients and can pass on tips such as Lamaze-type breathing exercises for tension headaches, cold washcloth over the eyes during a migraine attack, and even attempting vigorous exercise to abort migraine, cluster, or tension headaches. Including such information in the overall treatment plan enhances the physician's credibility and reinforces the message that headache management is not solely dependent on medications.

There are few "absolutes" in the pharmacologic treatment of headaches, and the large number of choices can be bewildering to both physicians and patients. Treatment is specific to the type of headache diagnosed (see below). In general, first-line analgesics and symptomatic treatment are effective, and narcotic use should be avoided. A common mistake is to appear tentative about therapy. The exasperated physician who uses phrases such as "We'll try this" may convey the message that the medication is not expected to work. Conversely, conveying that one has used the scientific literature and expert guidelines to select a medication specific to the individual patient is much more likely to succeed.

Follow-Up

With the exception of headaches secondary to acute self-limiting conditions, headache tends to be a recurrent problem. Unless follow-up is well managed, the patient may return only at times of severe symptoms and/or exasperation at treatment failure. This risks emergency visits complicated by hostility and mutual disappointment. Many patients can manage well if given scheduled appointments, particularly if they are combined with the expectation that the patient will come to the consultation well prepared (i.e., with information on the number, pattern, response to treatment, and any other relevant information about headaches since the last visit). Some authors recommend a formal headache diary to help track changes in the headache pattern over time and monitor for adverse effects of treatment. Headache management requires continuous adjustments, a high index of suspicion for the many conditions that have increased prevalence in headache patients, and promoting a healthy lifestyle. Optimizing general health has a positive impact on headache frequency, severity, and ability to cope with symptoms.

DOI 10.1007/978-1-4939-0779-3_70-1

Clinical Types of Headache

Migraine

Migraine-type headaches (Table 2) are estimated to affect approximately 17 % of women and 8 % of men in the USA [6, 22]. The median age at onset is about 24 years [23] and migraine is most prevalent in young adults [6, 22, 23]. Longitudinal studies indicate very high vulnerability to migraine in the general population with over 40 % of women and 18 % of men reporting at least one migraine during their lifetimes. Researchers suggest that the migraine tendency may be very prevalent and that "induction factors" in early adult life determine which individuals develop clinical migraine. Epidemiological studies implicate various possible genetic, hormonal, or social factors in this process [23]. The vast majority of migraine patients have a first-degree relative, often a parent, who also has migraine. Perhaps because of this familiarity with the condition, at least a third of migraine sufferers have never sought medical assistance for the condition [6].

The headache of migraine is severe, usually unilateral, "throbbing," or "pulsating," and aggravated by movement. The pain usually takes 30 min to 3 h to reach maximum intensity, and it may for last several hours. The eye and temple are the most frequent centers of pain, but occipital involvement is common. The typical headache must be accompanied by nausea and/or vomiting plus both photophobia and phonophobia for diagnosis (Table 2). Additional symptoms such as fatigue, vertigo, and allodynia are common. Many migraine patients describe a prodrome in the days before a migraine when they feel irritable, restless, intensely hungry, or excessively fatigued in the "run-up" to an attack. About 20 % of patients experience consistent, specific neurological changes (aura) up to an hour before the onset of migraine headache. The most common forms of aura are visual scotoma, flashing lights, and/or zigzag lines, but a wide variety of other features have been reported such as paresthesia, speech disturbance, and disorders of body perception. The severity, duration, and impact of migraine attacks vary enormously. Some patients are able to continue normal activities whereas others are incapacitated. During attacks, migraine patients avoid movement and sensory stimuli, especially light. Most go to bed in a dark room if possible. They may use pressure and either heat or cold over the areas of maximal pain. The attack usually terminates with sleep. Vomiting appears to shorten attacks, and some patients admit to self-induced vomiting, although this is not widely described in the literature. Many patients report a "hangover" after a migraine, but others experience freedom from symptoms and a sense of mild euphoria.

Diagnosis is based on history. The diagnostic probability is 92 % if four "POUND" symptoms are present – Pulsating or throbbing headache (1 day duration (4–72 h)), Unilateral location, Nausea or vomiting, and Disabling severity. This probability falls to 64 % for three symptoms and 17 % for two or less [24]. Imaging is not indicated in migraine patients who have normal neurological examination and no red flag findings [14–17]. Research shows that imaging identifies significant findings in about 1 % of migraine patients referred to specialist centers and lower levels in patients presenting to primary care [17, 26].

The cause of migraine remains unknown, but research indicates that the process begins as a wave of neuronal depolarization that triggers complex neurochemical, vascular, and other changes resulting in activation of the trigeminovascular system. The symptoms experienced depend on which parts of the system are activated as well as its interconnections with other parts of the brain and nervous system.

The treatment of migraine is based on enabling patients to manage their own condition. A bewildering variety of therapies is available, and management should be individualized. The treatment plan has three aspects: avoidance of precipitants, optimal treatment of attacks, and prophylactic therapy if indicated. Patients and their families can usually identify triggers of migraine attacks. The role of specific foods has probably been exaggerated, although red wine and certain cheeses continue to have significant reputations as migraine triggers. Disturbance in daily routine, particularly missed meals, excessive sleeping, and

DOI 10.1007/978-1-4939-0779-3_70-1

relaxation after periods of stress, are common precipitants of migraine attacks. Some women correlate migraine with the onset of menstruation each month, but the effect of oral contraception and postmenopausal hormone replacement is unpredictable. Migraines commonly disappear during pregnancy.

Patients should be encouraged to recognize their own aura or prodrome, as early treatment is most effective. The multiple medications used for migraine may be categorized into three groups:

1. Symptom control: analgesics, with or without adjunctive antiemetics or sedatives
2. Triptans: serotonin (5-hydroxytryptamine, 5-HT) receptor agonists
3. Ergotamines and other medications

A common problem in migraine treatment is subtherapeutic dosage of medication or failure to absorb medication because of vomiting and gastric stasis. European guidelines include metoclopramide or domperidone (level B recommendation) for antiemetic and mild analgesic effects as well as possibly improving absorption of other medications [25].

The USA and newer European guidelines found strong evidence to support the use of several different medications in acute migraine (Table 4). The choice of medication(s) and route of delivery must be individualized based on the migraine pattern (particularly the likelihood of vomiting), patient factors such as other medical problems, and medication issues including efficacy, speed of onset, side effects, cost, and acceptability. Guidelines stress the balance between effective treatment and avoiding iatrogenic effects from inappropriate medication use [13, 25]. Patients frequently appreciate having more than one agent or combination of agents available, e.g., an analgesic or a triptan to use when they need to "keep going" and a combination of analgesic and sedative for situations when they can "crash." Many patients also report that a specific medication works well for several months but then becomes less effective.

Narcotics have almost no place in migraine therapy. Even in the emergency room situation, adequate analgesia, triptans, injections of antiemetics, or injectable ergotamines are superior to narcotics [26]. The migraine patient who demands narcotics or claims allergies to alternative treatments may be drug seeking. Rarely, patients develop dehydration and "status migrainosus" when the attack lasts several days. These patients may require steroids in addition to fluids and aggressive therapy based on antiemetics plus a triptan or ergotamine.

For most patients, analgesics with or without antiemetics are the first choices for treatment. Some experts advocate triptans as first-line treatment for more severe cases [27]. In studies, triptans are comparable or only marginally more effective than adequate analgesia. They benefit about 60 % of patients who do not respond to NSAIDs [25]. The various triptans appear to be equally effective but vary in speed of onset and duration of action. This allows selection of a specific triptan that matches the patient's typical migraine attack, especially in selecting one with a long half-life for patients who experience slowly developing symptoms that persist over several days or who experience significant rebound headaches. Treatment should be started early in a migraine attack, but triptans are not effective and are reported to be potentially dangerous if taken during aura [25]. Depending on the medication used, up to 40 % of patients experience recurrence of symptoms after initial improvement. This "rebound headache" often responds to a second dose of the initial treatment. Combining an NSAID with a triptan as initial therapy reduces recurrence [25].

If patients find normal life disrupted by the frequency and severity of migraine attacks, prophylactic treatment should be considered. An estimated 38 % of migraine patients could benefit from prophylactic treatment but less than 13 % currently use it [28]. Good efficacy has been demonstrated for several beta-blockers and antiepileptic drugs. Other agents, especially some antidepressants, are probably effective (Table 4). A recent US guideline also found good evidence supporting the herbal therapy petasites (butterbur) with more limited evidence for some NSAIDs, magnesium, feverfew, and riboflavin

DOI 10.1007/978-1-4939-0779-3_70-1

[29]. The dosage at which individual patients benefit must be established by weeks or months of monitoring of frequency and severity of migraine attacks plus any adverse effects. Some behavioral therapies such as thermal biofeedback, relaxation training, and cognitive-behavioral therapy are recommended as preventive interventions and may be combined with prophylactic medications [13, 30]. Patient compliance is crucial to prophylactic therapy. The choice of any prophylactic agent must

	Agent and dose	Comment	Agent and dose (per day)	Comment
Tension				
	Ibuprofen 200–800 mg Ketoprofen 25 mg Aspirin 500–1000 mg Naproxen 375–550 mg Acetaminophen 1000 mg		Amitriptyline 30–75 mg Mirtazapine 30 mg[b] Venlafaxine 150 mg[b]	

Level A recommendations unless otherwise noted

[a]Simple analgesic restricted to 15 days/month: combination analgesics restricted to 10 days/month to prevent medication-overuse headache

[b]Level B recommendation (probably effective)

[c]Triptans restricted to 9 days per month. Significant danger of medication-overuse headache after 12 days/month

Treatment must be of rapid onset. (1) All therapy should be started at first sign of attack, but triptans are not advised during aura. (2) Other symptomatic relief may be added, especially antiemetics and sedative. (3) Encourage patients to find abortive therapy (e.g., caffeine, exercise, cold ± pressure over the site or pain) to use in addition to above. (4) Narcotics are rarely necessary for migraine

5-HT 5-hydroxytryptamine (serotonin), *NSAID* nonsteroidal anti-inflammatory drug

AAFP treatment guidelines are available at http://www.aafp.org/afp/20001115/practice.html

balance potential benefit against issues of compliance, side effects, and cost. Migraine patients can usually be assisted to find regimens that enable them to minimize attacks and deal effectively with those that do occur. They may be comforted by knowing that the condition tends to wane with age and has afflicted a galaxy of famous people.

Cluster Headaches and Other Trigeminal Autonomic Cephalalgias

The updated international classification [1] recognizes that cluster headache is part of an uncommon group of conditions in which activation of the trigeminovascular system is associated with reflex autonomic activation. The three clinical syndromes of cluster headache, paroxysmal hemicranias, and short-lasting unilateral neuralgiform attacks with conjunctival injection and tearing (SUNCT) are characterized by brief, unilateral, severe headache plus cranial autonomic symptoms such as conjunctival injection, lacrimation, nasal congestion or rhinorrhea, facial sweating, miosis, or ptosis [1, 31]. Cluster headache has an estimated prevalence of less than 1 % of adults and is more common in men. The average age at onset is 28–30 years, but it can start at any age and is persistent with 80 % of patients still experiencing attacks 15 years after the initial episode [32].

The headache is severe, unilateral, centered around the eye or temple, and accompanied by lacrimation, rhinorrhea, red eye, and other autonomic signs on the same side as the headache. Symptoms develop rapidly, reach peak intensity within 10–15 min, and last up to 2 h. During the attack, the patient is restless and may be suspected of intoxication, drug-induced behavior, or hysteria. The diagnosis is based on the description of attacks, especially their severity, and is confirmed by the unique time pattern. During a cluster period, which typically lasts 6–12 weeks, the patient experiences attacks at the same time or times of day or night with bizarre regularity. Most patients report one or two cluster periods per year (often in spring and autumn) and are completely free from symptoms at other times. About 10 % of patients develop chronic symptoms, with daily attacks over several years. During a cluster period, drinking alcohol or taking vasodilators almost inevitably precipitates an attack. Cluster headache may be due to a disorder of serotonin metabolism or circadian rhythm (or both), but the cause remains unknown [32, 33].

DOI 10.1007/978-1-4939-0779-3_70-1

Management strategies aim to provide relief from individual attacks and prophylactically to suppress cluster episodes (Table 4). Acute treatment must be of rapid onset and able to be administered by the patient or family. Conventional analgesics do not act quickly enough to provide relief, and all treatments can be difficult to administer to a patient who is restless and distracted with pain. Inhalation of oxygen at least 7 l/min with a non-rebreathing facial mask is effective in about 60 % of cases (level A recommendation). Hyperbaric oxygen appears ineffective [31]. If the patient has no contraindications, subcutaneous sumatriptan (6 mg or less) is reported to be about 75 % effective [31]. Although less evidence is available, triptan nasal sprays (sumatriptan, zolmitriptan) appear to be effective. Recent studies found subcutaneous octreotide (100 ug) effectively terminated cluster attacks [31]. Older treatments including nasal lidocaine and oral or intranasal ergotamine are useful but have not been extensively researched [31].

The mainstay of cluster headache management is to suppress attacks during a cluster period. The first-line agent is verapamil, but patients must be monitored for possible adverse cardiac effects. Steroids may also be effective for short periods. Clinical studies have reported mixed effectiveness for lithium with older studies reporting it to be as effective as verapamil, but newer studies are not confirming this outcome. Other drugs with limited evidence of effectiveness in suppressing cluster include methysergide, topiramate, valproic acid, and melatonin [31]. Prophylactic treatment should be initiated as soon as a cluster period begins and continued for a few days beyond the expected duration of the cluster. Only the previous experience of each patient can be used to judge the duration of therapy. Each patient has a set length for the cluster period as well as a tendency to repeat the same time and symptom pattern of individual headaches. It is particularly important in the age group usually affected by cluster headaches to monitor for potential cardiovascular adverse effects associated with several of the recommended medications for acute and prophylactic use.

Tension-Type Headaches

Tension-type headaches (TTH) are the most common of all headaches and impose the greatest burden on individuals and society. Compared to migraine, direct costs for TTH are 54 % higher and three times as many work days are lost [12]. Most patients have infrequent episodes of TTH that are managed without medical assistance; however, about 10 % of individuals with TTH report headaches at least weekly. The average age of onset of TTH is 25–30 year with the peak prevalence in the 30–39 age group. Women are slightly more impacted than men (sex ration 5:4). Poor general health, problems relaxing, and difficulty sleeping are related to TTH [34].

The classification into acute or chronic is based on frequency of episodes (Tables 1 and 2), but this is more significant than the timing and pattern of the condition. It correlates with the impact on patients and indications for prophylactic therapy. The pathophysiology may also differ. Chronic TTH may result more from chronic central pain mechanisms than the peripheral processes underlying episodic and milder TTH [35].

Although TTH is the most common form of headache seen in family practice, these patients represent a select group of all TTH sufferers. The vast majority of individuals self-manage their TTH symptoms. The pain is classically described as bilateral, pressure, or tightening of mild to moderate intensity. Sometimes described as "featureless," TTH is characterized by the lack of accompanying symptoms that could indicate a migraine, cluster, or secondary headache, especially one due to a neurological disorder [35]. The diagnosis requires a good history, supplemented if necessary by a headache diary, and a negative physical examination with any necessary additional investigations to exclude secondary headache. Careful documentation of analgesic, triptan, or ergotamine intake is essential to rule out medication-overuse headache. As with all headaches, the history must screen for "red flags" and comorbidities. Over 90 % of patient with migraine also have TTH and TTH is a predictor for depression and anxiety [12].

DOI 10.1007/978-1-4939-0779-3_70-1

The treatment of tension headaches can be challenging. Success depends on treating any underlying or associated condition (particularly depression), patient education about TTH, and control of symptoms without creating dependence or other adverse effects. Patients may have already been investigated extensively, and prior medical experiences color expectations and evaluation of management approaches.

Individual episodes of TTH are best managed by first-line analgesics, such as acetaminophen, aspirin, ibuprofen, or another NSAID. Some studies indicate that NSAIDs may be more effective than other analgesics, but no difference in efficacy has been demonstrated among different NSAIDs [35]. The principal potential adverse effects are gastrointestinal bleeding for NSAIDs and liver injury for acetaminophen. To avoid medication-overuse headache, analgesics should not be used on more than 14 days per month [35]. Narcotics and combination drugs, especially those that contain barbiturates or caffeine, should be avoided. Triptans and muscle relaxants do not have good evidence of efficacy in uncomplicated TTH [35].

Prophylactic therapy is appropriate for patients with chronic TTH or those who have disruptive episodic TTH, believe they could benefit, and are willing to adhere to daily therapy. Based on a few studies, the best evidence supports amitriptyline to reduce headache frequency and intensity. A systematic review concluded that mirtazapine was as effective as amitriptyline for chronic TTH [36]. This review found other antidepressants and anticonvulsants to have "unknown effectiveness" and rated botulinum toxin and benzodiazepines as "likely to be ineffective or harmful" [36]. Similarly, cognitive-behavioral therapy and acupuncture were of "unknown effectiveness," and both chiropractic and osteopathic spinal manipulations were "likely to be ineffective or harmful." This review and another review [37] found little evidence to support biofeedback but a larger meta-analysis, and the European guidelines found a positive effect from biofeedback, especially in younger patients and if combined with relaxation training [35, 38]. The European guidelines recommend biofeedback and/or relaxation training for tense patients with TTH and cognitive-behavioral therapy for those with psycho-behavioral issues or affective distress [35].

Outcomes in TTH are often disappointing. Drug efficacy in acute attacks is modest in studies (about 30 % pain-free at two hours) [35]. Long-term studies report that a third of patients with chronic TTH were unchanged after 10 years, with an additional 20 % developing medication-overuse headache. In the same time period, a quarter of patients with episodic TTH converted to chronic forms [39].

Secondary Headaches

Headache is part of the clinical picture of many conditions. Particularly in children, frontal headache is a common accompaniment of fever. In all age groups, almost any condition of the head and neck and several systemic conditions can present as headache. A careful history combined with physical examination and other investigations where appropriate is essential to differentiate secondary from primary headache.

Family physicians face the challenge of not missing the rare but serious intracranial condition, especially brain tumor. The symptoms of an intracranial lesion depend on its type, size, location, and displacement effect on other tissues. No single characteristic headache picture can therefore be given. Suspicion should be raised about headaches of recent onset that appear to become steadily more severe, do not fit any of the primary classifications, and do not respond to first-line treatment. Close follow-up and repeated physical examinations may detect the earliest neurologic abnormalities. A review identified potential predictive features for intracranial abnormality as undefined-type or cluster headaches, the presence of aura or vomiting, headaches exacerbated by exertion or Valsalva maneuver, and any abnormal findings on neurological examination [15]. This concurs with US guidelines that also report increase odds of finding abnormality in patients with rapidly increasing frequency of headache, discoordination, or headache causing wakening from sleep [13]. Even in selected patients, these are weak predictors and the yield from imaging is low [10].

DOI 10.1007/978-1-4939-0779-3_70-1

Medication-Overuse Headache

A growing concern for family physicians is medication-overuse headache (MOH), defined as chronic headache (at least 15 days per month) in patients who have taken excessive headache-related medication for at least 3 months during which time headache symptoms have increased. The headache resolves or returns to the original pattern within 2 months of discontinuing the overused medication [1]. Medication-overuse headache can originate in tension, migraine, or any secondary headache and can result from use of analgesics, triptans, or ergotamines [40]. By some estimates, up to half of patients with chronic headaches suffer from MOH, and MOH is the leading diagnosis of patients attending specialized headache clinics [40, 41]. Medication-overuse headache is more common in women (male/female ratio 1:3.5) and appears to be related to several psychiatric disorders, low coping skills, and dependency-related behavior [41]. Perhaps because of this combination of chronic symptoms and impaired ability to cope, MOH imposes the greatest burden on patients and families of all headaches. Personal annual costs are triple those for migraine and ten times greater than for TTH. Most of this cost was indirect in terms of lost productivity and inability to carry out usual activities [2]. Patients with MOH significantly outscored those with migraine or TTH on all measures of negative life impact and were ten times more likely than migraine patients to report breakdown of relationships due to headache [2].

While the exact mechanism of MOH is unclear, it probably involves central sensitization and dysfunction in pain networks. Biochemical, pharmacological, and imaging studies all provide evidence of reversible central pain system changes induced by medications in vulnerable patients [41].

The patient often has difficulty describing precise characteristics of MOH beyond that it is severe, intractable, and debilitating. The headache and related symptoms may change from day to day. Apart from chronicity and burden, the key features in the history are experience of an established prior headache pattern (usually migraine or TTH or both) and escalating high intake of headache-related medication. It is important to document the quantity and different types of medications used, including nonprescription medications and substances obtained illegally, to get a complete picture of the extent of medication use. Screening for depression, anxiety, or another psychiatric condition may be indicated.

No expert guidelines have been developed for the investigation of MOH. Because the symptoms may be severe, changing, and not related to criteria for one of the primary headaches, physical and neurological examinations are necessary to detect any indicators of secondary headaches, especially intracranial conditions. Many patients report conditions that meet the guidelines for imaging, but decisions to obtain imaging must be individualized. The rate of detection of abnormalities in all "indeterminate" headaches investigated by specialist centers is about 3 %, but no data are available on patients with probable MOH [19].

The treatment of MOH requires withdrawal ("detoxification") and institution of effective treatment for the underlying headache. No clear advantage has been demonstrated with abrupt versus tapered withdrawal for most medications, but guidelines recommend tapered withdrawal for opiates, barbiturates, and benzodiazepines [40]. Withdrawal symptoms such as headache, nausea, restlessness, tachycardia, and anxiety can resolve in 2 days or last several weeks. Withdrawal appears shorter from triptans (average 4 days) than NSAIDs (average 9.5 days). Most patients can be managed in primary care with symptomatic treatment. Some protocols include oral steroids during withdrawal. No significant improvement in outcomes was demonstrated in comparisons of inpatient withdrawal, but it is recommended for patient with significant symptoms and/or comorbidities as well as those withdrawing from opiates, barbiturates, or benzodiazepines [40]. Effective prophylaxis for the underlying headache should be started as soon as possible in MOH. Limited data support topiramate or valproic acid in MOH developing from migraine [40].

Despite good initial results of treatment with about 75 % of patients successfully detoxifying, the relapse rate is about 30 % within 1 year and may be 60 % at 4 years [40, 42]. This does not appear to be

DOI 10.1007/978-1-4939-0779-3_70-1

related to treatment but might be related to male sex, use of analgesics (especially combinations containing codeine), poor quality of life, use of alcohol and/or tobacco, and years of experiencing headache [40].

Specific Headache Syndromes

The international headache classification system describes criteria for several uncommon primary headache syndromes that are often named for their character ("thunderclap," "stabbing") or precipitating event ("cough," "exertional") (Table 1). These syndromes are more common in men and are characterized by the severity of the pain and the potential for confusion with serious intracranial conditions [1]. Despite the sometimes dramatic history, the conditions are generally benign with the exception of thunderclap headache. Physical examination, testing, and neuroimaging may be necessary to confirm the specific diagnosis. Some of these syndromes are very responsive to indomethacin. For others explanation, reassurance, avoidance of precipitants, and symptom control are usually effective.

Epilepsy is a chronic neurological disorder characterized by recurrent seizures. A seizure happens when abnormal electrical activity in the brain causes an involuntary change in body movement or function, sensation, awareness, or behavior. Epilepsy is a chronic seizure disorder.

Epilepsy affects 2.3 million adults [1, 2], and more than 450,000 children 0–17 years old [2] in the United States. About 1 in 26 people will be diagnosed with epilepsy at some point in their lives [3]. Epilepsy each year accounts for $15.5 billion in direct costs (medical) and indirect costs (lost or reduced earnings and productivity). More than one-third of people with epilepsy continue to have seizures despite treatment. Each year, about 200,000 new cases of epilepsy are diagnosed in the United States.

The International League Against Epilepsy redefined Epilepsy in 2014 [4]. Epilepsy is defined as (1) at least two unprovoked (or reflex) seizures occurring >24 h apart; (2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60 %) after two unprovoked seizures, occurring over the next 10 years; (3) diagnosis of an epilepsy syndrome.

Epilepsy is considered resolved for individuals who either had an age-dependent epilepsy syndrome but are now past the applicable age or who have remained seizure free for the last 10 years and off antiseizure medicines for at least the last 5 years indicating that epilepsy is no longer considered to be a lifelong disorder.

Types of Seizures and Epilepsy

The two main types of seizures are generalized and focal. In generailzed seizures there is involvement of both cerebral hemispheres. And in focal seizures the seizure involves one hemisphere or a lobe of a hemisphere. The vast majority of seizures are focal seizures, between 70 % and 80 % in adults (Fig. 1).

Generalized Seizures

Generalized seizures are conceptualized rapidly engaging bilaterally distributed networks involving both hemispheres. Such bilateral networks can include cortical and subcortical structures. On

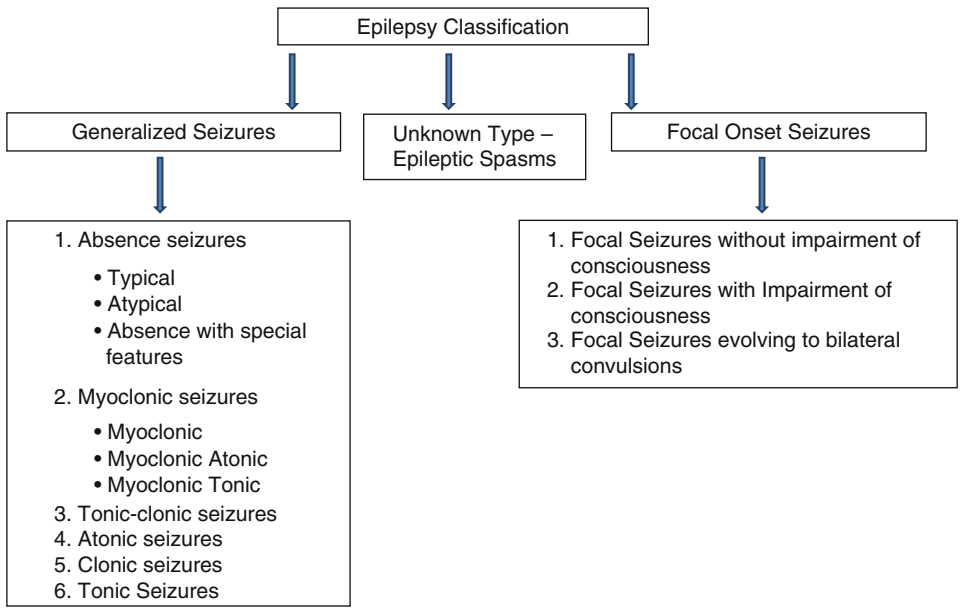

Fig. 1 Classification of Seizures

scalp EEG they seem to be present all over and hence the use of the word *generalized*.

Generalized seizures are further subdivided into tonic-clonic (which is used to describe stiffening of all four extremities in the tonic phase and rhythmic shaking of all extremities in the clonic phase). This was referred to as "Grand Mal." In absence seizures the basic phenomenon is a blank stare; absence seizures can be typical, atypical, or have special features. Other kinds of generalized seizures are myoclonic seizures, clonic seizures, tonic seizure, and atonic seizures (also known as drop attacks).

Focal epileptic seizures are conceptualized as originating within networks limited to one hemisphere. They may be discretely localized or more widely distributed. The focal seizures can be with or without impairment of consciousness and may secondarily generalize.

Clinical Manifestations

Epileptic seizure can have variable clinical manifestations including many types of auras. After each seizure there might be a postictal period the length of which is variable. The first step of diagnosing epilepsy is obtaining a detailed description of the aura (warning before a seizure), ictus (the actual seizure), and postictal phase (immediately after a seizure) from the patient and an observer.

Generalized Seizures

Generalized seizures are thought to arise at some point within the brain and rapidly involved both hemispheres. Different types of generalized seizures have different features which placed them in different categories.

Absence Seizures

Typical Absence Seizure

Absence epilepsy accounts for 10–17 % of all cases of childhood-onset epilepsy, making it the most common form of pediatric epilepsy. The syndrome is characterized by daily frequent brief staring spells, typically beginning at 4–8 years of age, in an otherwise apparently healthy child. The classic electroencephalogram (EEG) displays 3 Hz generalized spike-wave bursts.

Majority of the seizures last between 5 and 20 s. Seizure onset is sudden, and the child becomes motionless with a vacant stare. The eyes may drift upward, and there is slight beating of the eyelids. Typical absence seizures are frequently repeated many times per day with reports to as many as 100 or more per day.

Hyperventilation (for about 2 mins) tends to provoke these seizures and can be used in a clinic setting as a diagnostic tool as well, but caution is advised.

Atypical Absence Seizures

Atypical absence seizures have less abrupt onset and offset, more pronounced changes in tone, variable impairments of consciousness, and tend to last longer than typical absences. They are most likely to occur during drowsiness and are not provoked by hyperventilation or photic stimulation.

Other types of absence seizures include myoclonic absence seizures and eyelid myoclonia with absence seizures.

Generalized Tonic-Clonic (GTC) Seizures

These seizures usually begin with stiffening of muscles in all extremities along with axial and laryngeal muscles which leads to a loud moan also referred to as an "ictal cry." This is referred to as a tonic phase of the seizure. Following this there can be rhythmic jerking of the arms and legs which is referred to as the clonic phase. An aura is usually not present prior to the seizures.

During the seizure there can be tongue bite and/or urinary and fecal incontinence. During the tonic phase the patient is not breathing, and in children it can lead to perioral cyanosis. Rarely during the tonic phase one can fracture the vertebral bodies, and so back pain after a seizure should be carefully evaluated.

When the patient is having a generalized tonic-clonic seizure the area around him or her should be cleared of any sharp or dangerous objects that might cause injury to the patient if they were to bump into the objects. No attempt should be made to insert any foreign objects into the patient's mouth. And while the patient is in the clonic phase no attempt should be made to forcibly hold him down as this can lead to injury

Myoclonic Seizures

Myoclonus is a brief sudden and involuntary contraction of one part of the body or muscle group. This could either be epileptic or nonepileptic. Myoclonus can occur physiologically when patients are falling to sleep. Myoclonic seizures are characterized by brief, sudden, involuntary muscle contractures involving different combinations of head, trunk, and limbs. On EEG the generalized spike wave or polyspike and wave discharges are noted with these myoclonic jerks.

The commonest type of myoclonis epilepsy is juvenile myoclonic epilepsy (JME). This type of epilepsy starts in the teenage years; it is obviously characterized by myoclonic seizures, but in about 80 % of cases they also have GTC seizures. Rarely they can also have absence seizures.

Atonic Seizures

Atonic seizures are characterized by a brief and sudden loss of postural muscle tone which usually results in frequent falls (drop attacks) in these patients. These last a few seconds and usually do not have any postictal confusion..

Focal Seizures

In the past focal seizures were referred to as partial seizures. These were characterized as simple partial and complex partial seizures based on loss of consciousness. However, using the terms *simple* and *complex* was misleading to the patients who could easily misinterpret these connotations as simple being easier to treat or have a better prognosis as compared to complex seizures. Hence the term *focal* is more appropriate in the new classification.

Focal Seizures Without Impairment of Consciousness

Focal seizures can present as motor, sensory, or autonomic seizures. These mostly arise in patients with a structural brain abnormality. For example, a person with a brain tumor in the motor cortex can have rhythmic shaking of his contralateral arm without impairment in consciousness. These can be rather challenging to treat in certain cases and refractory to medications. In the past these were known as simple partial seizures.

Focal Seizures with Impairment of Consciousness

These were previously referred to as complex partial seizures. They usually consist of an aura which is specific and stereotypical. The patient will have a sudden behavioral arrest along with automatism as well in certain cases. Automatisms consist of lip smacking, picking hand movements, swallowing, and chewing. Automatisms are ipsilateral to seizure onset region and can be helpful in lateralizing seizure onset to right or left hemisphere.

Focal Seizures Evolving to Bilateral Convulsive Seizures

These were previously referred to as complex partial seizures with secondary generalization. This term has been now replaced with bilateral convulsive seizures. These usually consist of an aura which is specific in severe typical with spread of the seizure activity to both hemispheres including the motor strip which causes tonic-clonic seizures. These patients tend to have an aura which makes it different from generalized seizures where it might not be present. Also, paying attention to

automatism and forced head deviation can help with lateralization and localization.

Focal seizures are usually referred to by the lobe of the cortex the seizures originate in.

Focal seizures	Clinical characteristics
Temporal lobe seizures	*Aura* – epigastric sensation, déjà vu, abnormal taste or smell, intense anxiety
	Ictus – blank stare, with or without oral automatisms, hand automatisms
	Postictal – confusion and disorientation
Frontal lobe seizures	Usually motor seizures, vocalization (dominant hemispheres) nocturnal seizures, brief in duration, fencing posture, bicycling leg movements, Jacksonian march, forced eye/head deviation
Parietal lobe seizures	Paraesthesias
Occipital lobe seizures	Visual phenomenon

Seizure Syndromes by Age-Group

Neonatal Period
- Benign Familial Neonatal Epilepsy (BFNE)
- Early Myoclonic Epilepsy (EME)
- Ohtahara syndrome

Infancy
- Dravet syndrome
- West syndrome
- Epilepsy of infancy with migrating focal seizures
- Benign infantile epilepsy
- Myoclonic epilepsy of infancy
- Myclonic encephalopathy in non-progressive disorders
- Benign familial infantile epilepsy

Childhood
- Febrile seizures plus
- Panayiotopoulos syndrome
- Benign epilepsy with centro-temporal spikes (BECTS)
- Epilepsy with myoclonic atonic seizures
- Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE)
- Gastaut syndrome
- Epilepsy with myoclonic absence
- Lennox-Gastaut syndrome
- Landau-Kleffner syndrome
- Childhood absence epilepsy
- Epileptic encephalopathy with continuous spike and wave during sleep

Adolescence
- Juvenile absence epilepsy
- Juvenile myoclonic epilepsy
- Progressive myoclonic epilepsies
- Epilepsy with generalized tonic clonic seizures alone
- Autosomal dominant epilepsy with auditory features
- Other familial temporal lobe epilepsies

Less Age Specific
- Reflexive epilepsies
- Familial focal epilepsy with variable foci

Seizures in Neonates and Infants

Benign Familial Neonatal Seizures

These are also known as 3rd day fits. Seizures consist of tonic stiffening, apnea/cyanosis, autonomic signs, face and limb clonus, lasting about 1–3 min. These are associated with a potassium channel abnormality in the KCNQ2 and three channels. Seizures usually last for about 3–6 months and then resolve spontaneously.

Early Infantile Epileptic Encephalopathy (Ohtahara)

Ohtahara syndrome affects newborns, usually within the first 3 months of life (most often within the first 10 days) in the form of epileptic seizures.

More common in males. Infants have primarily tonic seizures but may also experience partial seizures and rarely myoclonic seizures. Ohtahara syndrome is usually caused by metabolic disorders or structural damage in the brain, although the cause or causes for many cases can't be determined. Majority of the cases have cortical malformation. The EEG of infants with Ohtahara syndrome reveals a characteristic pattern of "burst suppression."

Early Myoclonic Encephalopathy

These occur typically within the first 1 month of life. As the name describes myoclonic seizures are the predominant type in this syndrome. Patients usually have a concurrent nonketotic hyperglycinemia. There is progression to tonic spasms as they grow older.

Infantile Spasms

These can be extensor or flexor spasms and typically occur between 4 and 8 months of life. Also known as salaam attacks in the past. It tends to occur in clusters and tends to be at the time of sleep-wake transition. There is sudden flexion or extension of all extremities including the axial musculature which corresponds to an electrodecremental response on EEG. EEG background is high voltage slowing, disorganized pattern with multifocal sharps also referred to as hypsarrhythmia. Most patients have intellectual disability. Treatment includes ACTH and Vigabatrin.

Benign Myoclonic Epilepsy of Infancy

Onset is usually between 4 months to 3 years of age, and patients eventually outgrow this. There is sudden jerking of the extremities along with eyedrops which make it look like infantile spasms. The EEG however shows a generalized spike and polyspike pattern instead of the classical hypsarrhythmia seen in infantile spasms. Also they have a normal development which clearly distinguishes this from infantile spasms. The treatment is Valproate, levetriacetam, or clonazepam.

Seizures in Childhood

Febrile Seizures

These occur between 6 months to 5 years of age. Febrile seizures are convulsions brought on by a fever in infants or small children. During a febrile seizure, a child often loses consciousness and shakes, moving limbs on both sides of the body. There are simple and complex febrile seizures.

Simple Febrile Seizure

Eighty to ninety percent of all febrile seizures are simple febrile seizures. The setting is fever in a child aged 6 months to 5 years. The single seizure is generalized and lasts less than 15 min. The child is neurologically normal. The cause of the fever is always outside the central nervous system.

Complex Febrile Seizures

The seizure duration is greater than 15 min. There are focal seizure manifestations or seizure recurrance within 24 h. Abnormal neurological status of the child and a family history of epilepsy. These seizures have a worse prognosis and have a much higher incidence of subsequent epilepsy.

Occurs in about 3–5 % of the US population with a median age of 18 months. About one third of these patients will have a second febrile seizure (23–42 %). About half of those one third will have a third febrile seizure (7–30 %). Higher recurrence when the age of onset is under 1 year.

Management of Febrile Seizures

1. Lumbar puncture to rule out Infection as indicated clinically
2. CBC, S. Calcium, S. Electrolytes, UA
3. EEG
4. MRI – if prolonged or focal febrile seizure or clinically indicated

Dravet Syndrome or Severe Myoclonic Epilepsy of Infancy (SMEI)

Dravet syndrome appears during the first year of life with frequent febrile seizures and is rare

beyond age 5. Later, other seizure types arise, including myoclonus. Status epilepticus may also occur. Children with Dravet syndrome typically experience poor development of language and motor skills and hyperactivity. There is a genetic cause identified – SCN1A mutation or copy number variant in 80 % of cases. Usually pharmacoresistant. Sodium channel medications can make seizures worse. Treatment with valproate, Topamax, and Stiripentol.

Rolandic Epilepsy or Benign Epilepsy With Centrotemporal Spikes (BECTS)

This is the most common focal epilepsy in childhood with onset between 2 and 13 years of age with a peak around 7–10 years of age. It is mostly bilateral although in some cases can be unilateral. Seizures usually occur during the first part of the night, but 10–20 % of the patients can have daytime seizures as well. Seizures can be sensory or motor consisting of drooling as well as abnormal feeling in the tongue, lips, and gums, or abnormal movements of the tongue, larynx, and pharynx. Rarely they can generalize as well.

EEG shows centrotemporal spikes more during drowsiness and sleep. Carbamazepine and Valproate are useful as initial monotherapy. Treatment beyond the age of 14–16 years is not indicated as BECTS resolves by that age.

Lennox Gastaut Syndrome (LGS)

LGS is characterized by multiple seizure types, mental retardation, and a diffuse slow spike and wave discharge on EEG [5]. LGS is characterized by the patient having multiple seizure types which include aonic, atypical absence, tonic, focal, as well as generalized tonic-clonic seizures. Seizure onset around 3–5 years of age. LGS syndrome patients can have preceding infantile spasms. EEG shows a characteristic slow generalized spike and wave pattern $<$2.5Hz. Treatment options are topiramate, Levetriacetam, lamotrigine, clobazam, and Rufinamide. Vagal nerve stimulation is also an option. Corpus callosotomy and ketogenic diets have also been used.

Landau Kleffner Syndrome

This presents with seizures along with progressive aphasia (apparent word deafness or verbal auditory agnosia) and language regression. The peak onset is around 3–6 years of age and is more common with boys compared to girls. EEG shows continuous generalized spike and wave activity during sleep also known as ESES (electrical status epilepticus of sleep). Typically they have seizures first and then onset of regression. Eventually, seizures tend to resolve more than the regression. Sodium channel AED (PHT, CBZ, PB, OXC) should be avoided in these patients.

Seizures in Adolescence

Juvenile Myoclonic Epilepsy

This is the most common form of generalized epilepsy in the adolescent age-group typically occurring between 12 and 18 years of age. Most of the seizures are upon awakening. They can have myoclonic seizures, absence seizures, and generalized tonic-clonic seizures.

The children will have myoclonic jerks early in the morning, for example, sudden jerking of the hand while brushing teeth or spilling milk while eating cereals. They can have generalized tonic-clonic seizures in 80 % of the cases. These patients are very photosensitive, and video games can offer trigger seizures. EEG shows diffuse 4–6 Hz generalized spike/polyspike and wave pattern. A genetic locus for JME is in chromosome 6p11.

Sodium channel antiepileptic medication should be avoided in these cases as it can make the seizures worse. Levetiracetam, valproic acid, and lamotrigine are better choices for antiepileptic drug therapy. A large number of these patients are well controlled on antiepileptic medications which have to be continued throughout their life.

Management of Seizures

History

It is important to ask the *age of seizure onset* as this information helps in the diagnosis of the type of seizure, as explained in the preceding section.

Next one should inquire about the *seizure risk factors* like perinatal hypoxia, family history of seizures, history of febrile seizures, any head injury with loss of consciousness, and any history of meiningitis or encephalitis. Next it is important to get a description of the seizure from an eyewitness and the patient. The patient should be asked about any warning before the seizure – *Aura*. The eyewitness should be asked about the seizure itself – *Ictus* and then the *post-ictal phase.* Then we need to find out about the duration and frequency of the seizures. All of the above information is critical to making an accurate diagnosis. As temporal lobe seizures last for a minute whereas frontal lobe seizures can last for seconds, temporal lobe seizures usually occur a few times a week whereas frontal lobe seizures can occur several times a day.

Next we need to find out what antiepileptic drugs (AEDs) the patient is taking and also ask about the AEDs that the patient has used in the past. It is important to find out the results of the workup undertaken in the past like CT Head, MRI Brain, EEG, and Video-EEG.

Neurological Exam

A good neurological exam is of critical importance in patients being evaluated for seizures. It is important to note any external signs of trauma; a good cognitive exam is important to see if there is any associated cognitive deficit. Dysmorphic facial features should also be noted as they may be associated with cortical malformations. Head circumference should be measured. Dermatological stigmata can give clues to a neurocutaneous disorder. Deficits on motor, sensory exam can indicate a hemispheric lesion.

Neuroimaging

MRI Brain is the investigation of choice and should be done with and without Gadolinium. We are looking for obvious cortical lesions causing seizures like tumors, stroke, cortical malformation, etc. It should also be done to check for a very common abnormality seen in temporal lobe epilepsy, mesial temporal sclerosis (MTS). In MTS there is unilateral atrophy of the hippocampus involved and increase in the T-2 signal in the hippocampus. CT Head is done in the emergency department essentially to rule out a bleed or other obvious abnormalities.

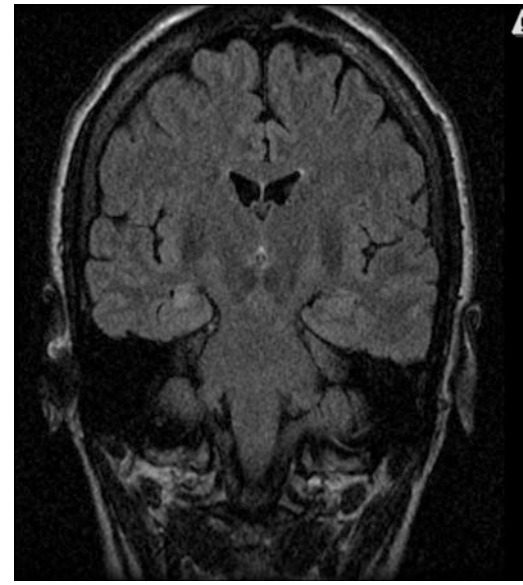

Fig. 2 MRI brain coronal FLAIR – left Mesial Temporal Sclerosis – increased T2 signal

Every seizure patient should get an MRI Brain and an EEG (Figs. 2 and 3).

Electroencephalography (EEG)

EEG is an essential test for all seizure patients. It helps in the diagnosis and classification of seizures. EEG is a graphical representation of the electrical activity of the brain as recorded by electrodes placed on the scalp of the patient. It can show focal epileptic discharges suggestive of focal epilepsy or it can show generalized (diffuse) epileptiform discharges diagnostic of generalized epilepsy. Spikes, sharps, polyspikes, and spike and wave discharges are the epileptic discharges indicating a tendency to have seizures.

A normal EEG does not rule out epilepsy as it is only abnormal in one third of the cases of

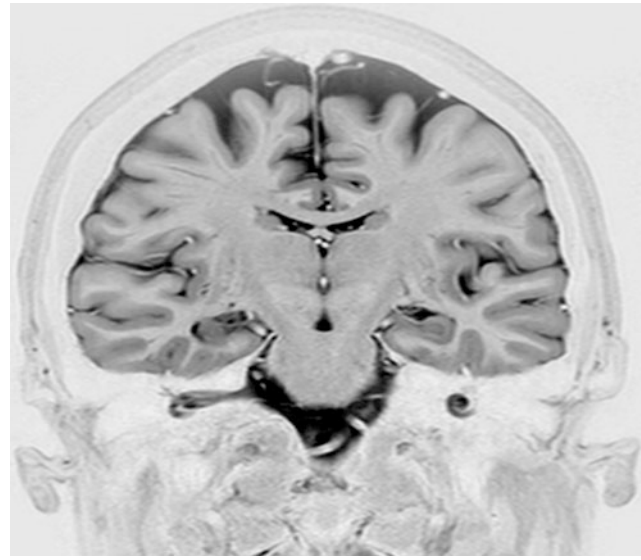

Fig. 3 MRI brain coronal view – left Mesial Temporal Sclerosis – hippocampal atrophy

definite epilepsy. Repeating the EEG does increase the yield in cases of epilepsy (Figs. 4, 5, and 6).

Video-EEG Monitoring

This is an inpatient testing in the Epilepsy Monitoring Unit of the hospital. The patient is hooked up to the EEG and is also being monitored simultaneously on video; they stay from 1 to a few days till the required data is gathered. Video-EEG monitoring is required in specific circumstances. It is an advanced testing done for epilepsy evaluation. It is performed when the physician needs to establish whether the paroxysmal spells represent epileptic seizures. It is also done to establish the type and frequency of seizures. And it represents the initial step in seizure focus localization for epilepsy surgery.

Other Tests

There are certain other tests done for epilepsy particularly for epilepsy surgery. These include a FDG-PET Scan which determines the uptake of radiolabeled glucose by the brain. The epileptic focus is malfunctioning and so does not take up the glucose as well as the other regions. Neuropsychological testing is done to determine the area of the brain that is not functioning optimally. The other tests done include a SPECT scan (measures blood flow) and a MEG scan.

Medical Treatment

Medications are the mainstay for the treatment of epilepsy [6]. Approximately 70 % of epilepsy patients can be treated by antiepileptic drugs (AEDs). There has been an increase in the number of medications available for the treatment of epilepsy in the last two decades.

A good clinical pearl to follow when using all AEDs is "start low and go slow," start at a low dose and titrate up slowly based on clinical response. Drug interactions are an important thing to keep in mind while using AEDs. Hormonal contraceptives can be compromised by the following antiepileptic medications – phenytoin, carbamazepine, phenobarb, Topamax, lamotrigine, and oxcarbazepine (Table 1).

All AEDs may cause suicidal thoughts or actions in a very small number of people, and one should educate the patients about this possibility and monitor them for this. Carbamazepine may worsen seizures in myoclonic epilepsy.

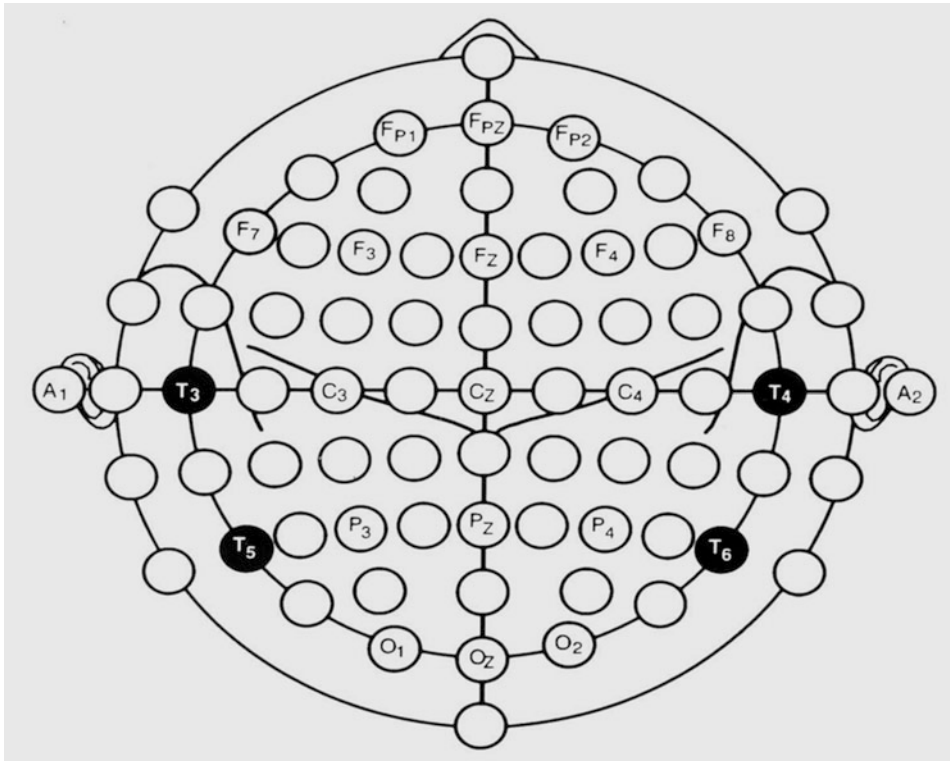

Fig. 4 EEG – recording electrodes

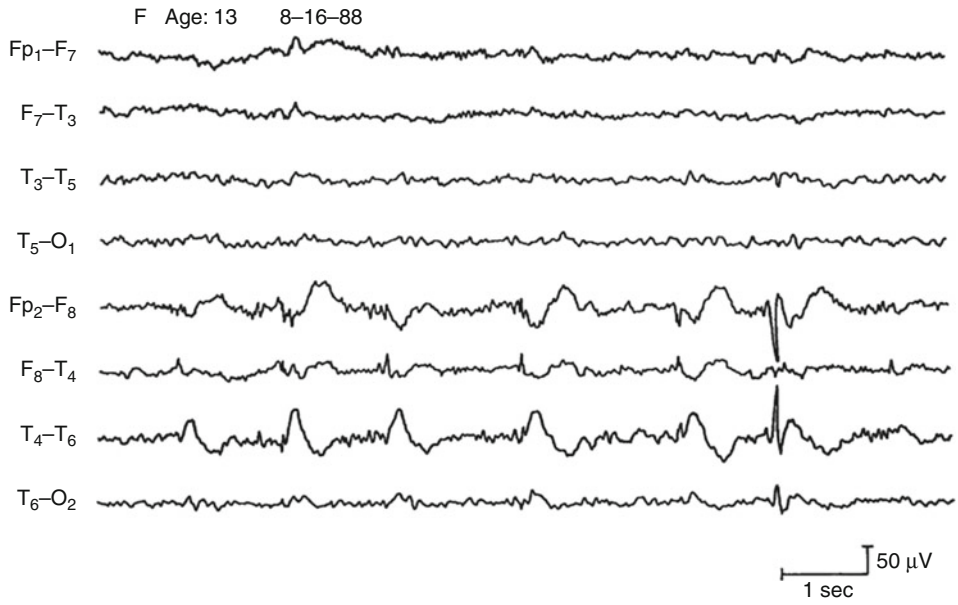

Fig. 5 EEG - Focal epileptiform discharge – right temporal spike

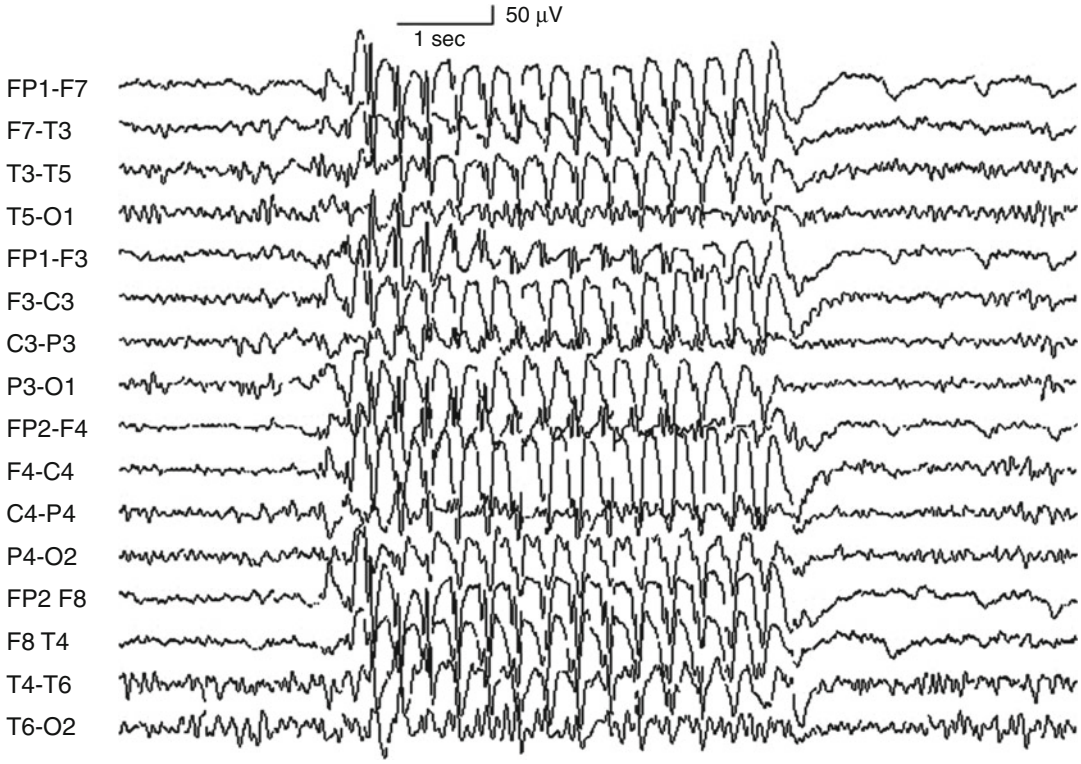

Fig. 6 EEG - Generalized epileptiform discharges – 3 Hz spike and wave discharge

Epilepsy Surgery

When patients do not respond to medications then they are candidates for respective epilepsy surgery if there is localized seizure focus that can be safely resected. Epilepsy surgery is certainly recommended in refractory mesial temporal lobe epilepsy (MTLE) as a randomized study has shown that such patients who underwent surgery (anterior temporal lobectomy) had a 58 % seizure freedom rate as opposed to only a 8 % seizure freedom rate for those treated with further medications.

Vagal Nerve Stimulation

Vagal nerve stimulation is an FDA-approved form of treatment of refractory epilepsy. It is successful in about 40 % of cases, and success is defined as a 50 % reduction in seizures. This device is surgically implanted, and the stimulation parameters can be managed externally by a programming wand and a computer via radiofrequency signals.

Status Epilepticus

Status epilepticus is a life-threatening emergency requiring immediate medical attention and affects 65,000–150,000 people in the United States each year [9]. It is not a disease itself but rather a manifestation of either an underlying primary central nervous system insult or a systemic disorder with secondary effects.

Roughly 55,000 deaths are associated with status annually. There is about 20 % mortality in status epilepticus.

The definition of status epilepticus is having continuous seizure activity for more than 30 min or two or more sequential seizures without recovery of consciousness to baseline. However, with the need for prompt care of patients there is an operational definition that is used for management

Table 1 Antiepileptic medications – summary

Name of antiepileptic medication	Indication	Major side effects	Miscellaneous
Phenytoin	Focal epilepsy, secondary generalization, GTC seizures	Hepatic insufficiency, bone density decrease, rash, ataxia, hirsuitism	Monitor LFTs
Carbamazepine	Focal epilepsy, secondary generalization	Bone marrow depression, hyponatremia, liver insufficiency, rash, ataxia, bone density decrease	Monitor CBC, CMP
Valproate	Generalized eizures, secondarily generalized seizures	Hepatic failure, tremors, hair loss, weight gain, teratogenecity	Monitor LFTs
Phenobarb	Focal seizures	Sedation	Monitor cognitive decline
Oxcarbazepine	Focal seizures	Hyponatremia (more common in elderly), rash	Hyponatremia in the first 3 months
Lamotrigine	Focal seizures, generalized seizures	Rash, including Stevens Johnson and toxic epidermal necrolysis hypersensitivity reactions	Side effects more common with concomitant valproate use and reduced with slow titration
Levetiracetam	Focal and generalized seizures	None	Irritability/behavior change
Topiramate	Focal and generalized seizures	Nephrolithiasis, open angle glaucoma, hypohidrosis in children	Metabolic acidosis, weight loss, language dysfunction
Zonisamide	Focal seizures	Rash, renal calculi, hypohidrosis in children	Irritability, photosensitivity, weight loss
Gabapentin	Focal seizures	None	Weight gain, peripheral edema, behavioral changes in children
Pregabalin	Focal seizures	None	Dizziness, somnolence, dry mouth, edema, blurred vision, weight gain, and peripheral edema
Ethosuximide	Generalized – absence seizures	Allergic reaction-DRESS, Pancytopenia, nausea, abdominal pain, rash	Used only for absence epilepsy
Eslicarbazepine	Focal seizures	Allergic reaction, rash	Dizziness, sleepiness, nausea, headache, double vision, vomiting, feeling tired, problems with coordination, blurred vision, and shakiness
Perampanel	Focal seizures	Serious or life-threatening psychiatric and behavioral adverse reactions including aggression, hostility, irritability, anger, and homicidal ideation and threats have been reported	Dizziness, somnolence, fatigue, irritability, falls, nausea, ataxia, balance disorder, gait disturbance, vertigo and weight gain
Clobazam	In the U.S.A. it is approved for use only as adjunctive treatment of seizures associated with Lennox-Gastaut syndrome	Stevens-Johnson syndrome and toxic epidermal necrolysis	Constipation, somnolence or sedation, pyrexia, lethargy, and drooling
Rufinamide	As adjunctive treatment of seizures associated with Lennox-Gastaut syndrome	Multi-organ hypersensitivity, rufinamide has been known to shorten the QT interval	Headache, dizziness, fatigue, somnolence, and nausea

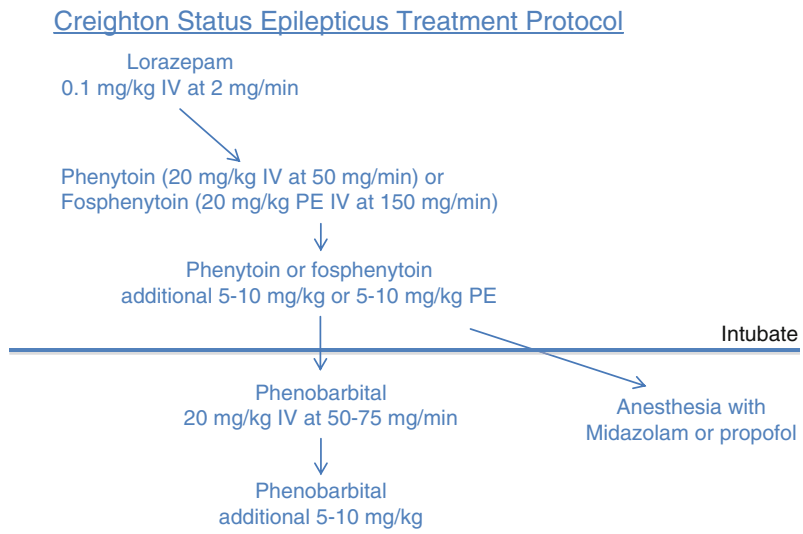

Fig. 7 Creighton Status Epilepticus Treatment Protocol

purposes, which is seizures lasting longer than 5 min are considered to be status epilepticus.

The initial management is like managing any medical emergency; airway, breathing, and circulation need to be attended to. Check for blood sugar; give 50 % glucose and thiamine as indicated. Establish two i/v lines as you should avoid infusing Dilantin through an i/v that has been used to give glucose. Send labs including drug levels and a toxicological screen. Treat hyperthermia, but avoid treating high blood pressure unless there is end organ damage as the blood pressure will come down as you treat status epilepticus.

The drug treatment of status epilepticus follows a protocol. Here we describe our status epilepticus protocol [8]. The drug of choice for initial treatment is Lorazepam [7]. Then the patient is given Phenytoin. After phenytoin there are two options: one is to administer phenobarb and the other to go to anesthetic agents directly. However before any of these two options are exercised the patient must be electively intubated as both these medications will suppress the respiratory drive. These patients must be on continuous EEG monitoring to determine whether the patient has stopped having seizures, as the patient may be in nonconvulsive status epilepticus or after paralyzing the patient for intubation this is the only way we can find out about seizure activity (Fig. 7).

Specific Conditions

Sudden, Unexplained Death in Epilepsy (SUDEP)

Sudden *nexpected* death in epilepsy (SUDEP) is a nonaccidental death in a person with epilepsy, who was otherwise in a usual state of health. On autopsy, no other of cause of death can be found. The death should not be due to status epilepticus, which is a prolonged life-threatening seizure episode.

The rate of SUDEP is approximately 1 death per 1,000 people with epilepsy per year. In people with frequent epileptic seizures that are poorly controlled with medications, the rate is approximately 1 in 150 per year.

The risk factors for SUDEP include the following:

- Having uncontrolled generalized tonic-clonic seizures
- Early age of epilepsy onset or long duration of epilepsy
- Not taking medications as prescribed
- Stopping or changing medications abruptly
- Young adult age (20–40 years old)
- Intellectual disability (IQ $<$ 70)

First Seizure

The risk of recurrence after a first seizure is about 33 % without any testing. If both the MRI Brain and EEG are within normal limits then the risk decreases to about 24 %, and thus we do not start such a patient on chronic antiepileptic medication. If both are abnormal as in the case of a cortical tumor the risk of recurrence is high, and so we do recommend treatment with an antiepileptic medication [10]. When a patient has a second seizure then the risk of the third seizure is over 70 %, and so we then do recommend treatment with antiepileptic medications. And thus the definition of epilepsy is two or more unprovoked seizures.

First Seizure Management

1. History
2. Physical examination
3. Labs – complete blood counts, complete metabolic panel and urine drug screen
4. Rule out mimics
5. Syncope
6. Hyperventilation
7. Panic attack
8. Psychogenic seizure
9. Transient ischemic attack
10. Transient global amnesia
11. Migraine equivalents
12. Imaging – MRI brain with and without contrast (preferable) or CT head with and without contrast
13. EEG – higher yield with sleep deprived EEG

General Principles

Definition/Background

Cerebrovascular disease refers to the group of conditions that lead to neurological deficits secondary to impairment of circulation of blood in the brain. If the brain is deprived of blood flow for longer than a few seconds, brain cells can die causing permanent brain damage leading to neurological deficits. In this chapter we will use the word "stroke" interchangeably with "cerebrovascular disease."

Stroke is the fourth leading cause of death in US adult population; it is also one of the leading causes of disability among US adult population [1, 2]. Each year 795,000 people in USA suffer from stroke resulting in a total of 6.8 million stroke survivors [1]. In 2011, stroke was responsible for 128,932 deaths in the USA, which is 41.4 deaths for every 100,000 people in USA that year [2].

In a report published by Centers for Disease Control and Prevention (CDC), elderly African American individuals with low level of education and residing in southeastern USA were found to have a higher prevalence of stroke when compared to other areas [3]. Behavioral Risk Factor Surveillance System (BRFSS) data from 2012 illustrates prevalence of stroke among different race/ethnicity as follows: 1.8 % in Hispanics, 1.9 % in Asian-Pacific Islanders, 3 % in non-Hispanic whites, 3.8 % in non-Hispanic

blacks, 4.1 % in multiracial people, and 5.8 % in American Indians/Alaska natives [3].

World Health Organization (WHO) reports stroke as the fourth leading cause of deaths among low-income countries, and globally it is the second leading cause of deaths taking toll of 6.7 million people in 2012 alone [4].

Pathogenesis

The mechanisms leading to impairment of circulation of blood in various areas of the brain can be broadly classified into two types: ischemic and hemorrhagic.

Ischemic

Ischemic stroke is caused by inadequate circulation of the blood to the brain and accounts for more than 80 % of all strokes. The aftermath of such inadequate circulation is dependent on the presence of collateral blood vessels, degree of blockage, vasculature of the patient, and blood pressure. If the blood circulation can be restored in time before the affected brain tissue dies, it is called transient ischemic attack (TIA). If the circulation cannot be restored in time, then tissue at the center of ischemia dies, but surrounding tissue with ischemia, also known as penumbra, can still be revived if circulation can be restored promptly. Hence treatment goal is directed toward early re-establishment of the circulation in the affected area.

Etiology of ischemic stroke or TIA can be grouped into three broad categories:

(a) Blockage of intracranial vessel from embolus released from a distant site, for example, embolus from heart in case of arrhythmia or valvular heart disease
(b) Thrombus formation in intracranial blood vessel
(c) Hypoperfusion due to narrowing of major extra/intracranial vessel such as carotid stenosis or hypoperfusion due to cardiac arrest. Such hypoperfusion can lead to a type of ischemia called "watershed ischemia" where the areas of brain in border zone without collateral circulation are affected

Blockage in smaller intracranial arteries can lead to ischemia in a limited brain area leading to specific deficits; such strokes are called lacunar strokes.

Hemorrhagic

This accounts for about 20 % of all strokes. As the name implies, in hemorrhagic stroke there is excess blood in intracranial space due to rupture of blood vessel(s). The possible mechanisms by which hemorrhagic stroke affects neurological function are bleeding impairing perfusion to brain tissue, mass effect due to the hemorrhage, and cytotoxic swelling around the area affected by the stroke.

There are two main subtypes of hemorrhagic stroke: intracerebral hemorrhage (ICH) and subarachnoid hemorrhage (SAH). In ICH blood vessels rupture and bleeding occurs within brain tissue, and in SAH blood vessels rupture and bleeding occurs in subarachnoid space.

Risk Factors

Risk factors in relation to pathogenesis of stroke can be grouped as modifiable, potentially modifiable, and nonmodifiable risk factors [5, 6].

Modifiable risk factors include smoking, poor diet (high portion of red meat, organ meat, eggs, fried foods, salty snacks), physical inactivity, excess alcohol consumption, and illicit drug use [5, 6].

Potentially modifiable risk factors include psychosocial stress, depression, diabetes, dyslipidemia, heart disease, chronic kidney diseases, sleep apnea, obesity, and hypertension [5, 6].

Nonmodifiable risk factors comprise of increasing age, susceptible family history, and genetics [5, 6].

Prevention of Cerebrovascular Disease

Prevention of cerebrovascular disease can be discussed under three broad stages: primary prevention, secondary prevention, and tertiary prevention.

Table 1 Primary prevention strategies for cerebrovascular diseases [5]

Primary prevention of cerebrovascular disease
1. Take family history of stroke and appropriate counseling for risks
2. Non-invasive screening for un-ruptured intracranial aneurysms for: (a) People who have 2 or more than 2 first degree relatives with subarachnoid hemorrhage (SAH) or intracranial aneurysm (b) Similar screening for those with autosomal-dominant polycystic kidney disease (PCKD); or one or more first degree relative(s) with autosomal-dominant PCKD and SAH/intracranial aneurysm (c) Patients with cervical fibromuscular dysplasia
3. Routine physical activity
4. Lifestyle modifications and treatment with statins to reduce risk of atherosclerotic cardiovascular disease (ASCVD)
5. Lifestyle modifications (Diet and exercise) for patients with hypertension
6. Annual screening of blood pressure
7. Appropriate follow ups in patients with hypertension to maintain blood pressure less than 140 systolic and 90 diastolic
8. Maintaining body mass index (BMI) at normal range
9. Close follow up on patients with diabetes to maintain normal blood sugar, normal blood pressure and statin therapy
10. Smoking cessation
11. For patients with atrial fibrillation evaluate the need for oral anticoagulation and treat accordingly
12. Appropriate anticoagulation treatment in patients with valvular heart disease
13. Aspirin and statins should be prescribed in patients with asymptomatic carotid stenosis. For those patients undergoing carotid endarterectomy (CEA), aspirin treatment is recommended preoperatively and postoperatively unless contraindicated
14. Treatment of carotid stenosis if indicated
15. Appropriate referral for patient with sickle cell disease for prevention of stroke
16. Counseling against unhealthy alcohol drinking
17. Address illicit drug abuse
18. Identifying patients with sleep apnea and their appropriate treatment
19. Consider Aspirin 81 mg tablet daily for prevention of stroke in patients whose cardiovascular risk is more than 10 % in 10 years; female with diabetes mellitus; and in patients with chronic kidney disease.

Primary prevention includes measures to prevent development of cerebrovascular disease in those patients who do not have the disease. Table 1 summarizes key components in primary prevention of cerebrovascular disease.

Secondary prevention includes measures in management of patients with cerebrovascular disease. The following sections of this chapter discuss this stage of prevention in more depth.

Tertiary prevention involves the strategy of rehabilitation once patient has had events of cerebrovascular disease. This is discussed later in this chapter.

Approach to Patients with Stroke

The initial important steps in approach to patients with stroke are prompt recognition of signs and symptoms of stroke: initiation of stroke chain, prompt transport of the patient to appropriate center.

American Stroke Association (ASA)'s website has simplified information for public including health care professionals on prompt recognition of symptoms and signs of stroke [7]. One should be concerned for possible stroke if they recognize five symptoms and signs in patients also known as "five suddens": sudden weakness and/or numbness of one part of the body; sudden confusion and trouble communicating; sudden imbalance; sudden unknown cause of severe headache; and sudden vision impairment [7, 8]. Another approach is to remember the acronym "F.A.S.T." which means to recognize ***facial drooping***, ***arm weakness***, ***speech impairment*** as possible stroke symptoms, and if present then it is ***time to call*** for help by calling emergency medical services (EMS) [7, 8]. Only half of the patients who experience a stroke reach the hospital via EMS service; this leads to a longer delay in the stroke treatment and potentially leads to morbidity and mortality [9]. Public awareness can improve this part of the stroke chain by emphasizing a need to promptly call EMS for evaluation of stroke in suspected patients [9].

American Heart Association (AHA) and the ASA recommend stroke chain of survival which starts with early identification of warning signs of stroke and call for help; quick dispatch of EMS; quick transportation and communication to the

hospital; and rapid diagnosis and treatment. The goal of this process is to minimize nervous tissue damage and to maximize recovery of stroke patients.

The principle of management of stroke patients preceding the hospital visit is to provide support to airway, breathing, and circulation as a part of adult cardiovascular life support (ACLS) program [10]. Prehospital measures in patients with suspected stroke are oxygen supplementation, fluid administration in patients with hypotension, and hypoglycemia management if hypoglycemia is present [8, 10]. There is no evidence to support benefit of managing hypertension as prehospital management of stroke [10].

During transportation and upon arrival in a treating center, a thorough past medical history, medication history, and social history have to be gathered without delaying the triage process and urgent treatment. Acquiring the medical history will assist in differentiating the stroke from other potential differential diagnoses such as hypoglycemia, seizure disorder, psychosomatic disorder, migraine, delirium, alcohol and substance abuse, movement disorder, cranial nerve palsy, or central nervous system neoplasm [8, 11].

Examination of airway patency, breathing movements, hemodynamic status, and detailed neurological examination as well as cardiovascular examination (including examination of carotid bruit, distal pulses) and signs of coagulopathy all goes hand in hand while taking history [8, 12]. On a side note, the blood pressure management principles differ between the types of stroke and are discussed in their respective sections later in the chapter. The National Institutes of Health Stroke Scale (NIHSS) is a helpful tool to be used by healthcare professionals to assess patients with stroke symptoms and its severity [2]. NIHSS scale takes into account different patients' status score based on their level of consciousness, answer to orientation, response to commands, gaze, visual fields, facial movement, motor function of arm, motor function of leg, limb ataxia, sensory exam status, language, articulation, and inattention. For details on the scale, please refer to the NIHSS website [2].

Neuroimaging is the cornerstone of management of stroke and helps to classify stroke into ischemic or hemorrhagic category. It is critical to confirm ischemic versus hemorrhagic pathogenesis because the specific management of each type of stroke is different and misdiagnosis can lead to severe consequences. The main modalities of neuroimaging are computed tomography (CT) scan and magnetic resonance imaging (MRI) of the brain.

Before further discussion on the choice of neuroimaging, it may be relevant to discuss guidelines from "Proceedings of a National Symposium on Rapid Identification and Treatment of Acute Stroke in 1996" for any patient with stroke [13]:

(a) Physician evaluation should be done in $\leq$10 min of arrival.
(b) Stroke team should be able to see patient in $\leq$15 min of arrival.
(c) CT evaluation should be initiated in $\leq$25 min of arrival.
(d) CT interpretation should be done in $\leq$45 min of arrival.
(e) Administration of thrombolysis for stroke if indicated should be done in $\leq$60 min.
(f) Admission to appropriate inpatient setting should be done in $\leq$3 h of arrival [13].

With advances in imaging, there are now different options available for neuroimaging. The choice of neuroimaging depends on the availability of the machine/system and the condition of the patient. CT scan is similar to MRI in detecting acute intracranial hemorrhage. The sensitivity of CT and MRI scan of brain is 26 % and 83 % respectively in any acute stroke within the first 24 h of onset of symptoms [14]. Diffusion weighted MRI is found to be more sensitive to detect acute stroke even in subtle cases. MRI also helps to differentiate acute from chronic hemorrhage [14]. Despite these advantages the higher cost of the investigation, unavailability of the machine at all centers, longer duration of procedure, claustrophobia, and various patient factors are limitations of MRI compared to CT scan [8]. Contrast enhanced CT and MRI provides specific information on area of brain damage, but this information was not beneficial in a study

looking at ischemic strokes [15]. Magnetic resonance angiography (MRA) has shown promise in detailing vessels involved in stroke. Computed tomographic angiography (CTA) is more rapid technique than MRA, but effects of radiation and contrast have to be considered.

Besides neuroimaging a workup of stroke includes basic metabolic panel, blood glucose, oxygen saturation monitoring, blood alcohol level, urine drug screen, cardiac enzymes, bleeding profile, electrocardiogram, and cardiac monitoring, [8, 12]. Persistent hyperglycemia has been associated with bad prognosis in all types of stroke, and management should be targeted to maintain normoglycemia as per AHA/ASA guidelines [8, 12, 16].

A comprehensive stroke center is recommended for care of patients with stroke. A comprehensive center is a multidisciplinary team that includes [17–19]

(a) Incorporation of rehabilitation services like occupational therapy, physical therapy, speech therapy, behavioral therapy
(b) Monitoring of common infections like pneumonia or urinary tract infections
(c) Speech therapist service to monitor swallowing function
(d) Appropriate interventions for feeding in patients with dysphagia
(e) Measures for prevention of future strokes
(f) Prevention of pressure sores, deep venous thrombosis (DVT), pulmonary embolism (PE), pneumonia
(g) Avoiding falls
(h) Prevention of peptic ulcers secondary to patient's prolonged intensive care unit stay or hospital stay

Comprehensive care also deals with management of possible aftermath of stroke. Management of complications of stroke needs evaluation by a team comprising of neurologists, interventional neurologists, neurosurgeons, as well as nursing staffs, rehabilitation staffs, and palliative care team trained in stroke care.

The following section in this chapter will give an overview of management based on specific pathogenesis.

Ischemic Strokes and Transient Ischemic Attacks (TIAs)

Transient Ischemic Attacks (TIAs):

TIAs are classically defined as a sudden onset of neurological weakness lasting less than 24 h. With advances in neuroimaging, TIAs are now defined as those ischemic insults where the affected tissue has not reached the stage of infarction making the neurological deficits only transient [20, 21]. However, it is important to state here that 10.5 % of patients with TIAs are found to have stroke within 90 days; this risk is 50-fold higher than patients without TIA sustaining ischemic stroke in similar age-groups [22, 23]. Half of all the strokes that followed TIAs happened within 2 days of the onset of TIAs [23]. Early treatment, however, has been associated with decrease in stroke risk in TIA by 80 % [24]. Therefore, approach to the patient with TIAs should include a thorough evaluation and identifying those groups of patients where the risk of stroke after TIAs is high [21, 23]. Higher risk of stroke after TIAs are observed in patients aged 60 and above, presence of diabetes, symptomatic speech or motor deficits, and in those patients with TIAs lasting more than 10 min [21, 23]. Because of only brief periods of neurological deficit, patients with TIAs usually present at an outpatient setting or urgent care setting instead of emergency centers. Neuroimaging should be obtained within 24 h of onset of symptoms; preferably with an MRI. A noninvasive imaging of cerebral vessels should be done as a part of routine evaluation [8, 21, 23]. There should be low threshold for hospital admission in patients with unreliable outpatient follow-ups for proper evaluation and monitoring [8, 21, 23].

Ischemic Stroke:

Under this heading are those ischemic attacks in brain where the neurological symptoms do not resolve within 24 h of onset and an evidence of infarction can be seen in neuroradiological investigations. Time to intervention from the onset of

symptoms is very critical in pathogenesis, management, and most importantly the outcome of ischemic stroke. Each minute of ischemia leads to death of 1.9 million neurons in the brain [25].

Diffusion weighted MRI is the preferred imaging compared to standard MRI and noncontrast CT scan, as diffusion weighted MRI has higher sensitivity and specificity to detect ischemia within minutes of the occurrence of initial symptoms [26]. In a study by Fiebach et al., sensitivity of detection of infarction with diffusion gated MRI was 91 % compared to 61 % with noncontrast CT scan [27]. Other imaging procedures like CT angiogram, MR angiogram, transcranial Doppler ultrasound, and conventional angiogram can also be utilized based on individual cases to identify intracranial vasculature involved [8]. In addition, extracranial vasculature study like carotid Doppler ultrasound, CT angiogram, MR angiogram, and conventional angiogram are important to find out the etiology of ischemic events. Extracranial vasculature study is useful for clinical decisions for neurology interventions such as carotid endarterectomy, angioplasty, and stenting [8]. Intracranial vasculature studies are vital to decide on procedures like mechanical thrombectomy or intra-arterial fibrinolytic therapy.

Managing Hypertension in Patients with Acute Ischemic Stroke

Thrombolytic treatment is contraindicated in patients with sustained systolic blood pressure (SBP) of more than 185 mmHg and sustained diastolic blood pressure (DBP) of more than 110 mmHg [8]. In such situations, blood pressure should be stabilized below 180 mmHg SBP and below 105 mmHg DBP before, during, and at least 24 h after thrombolysis. If a patient is not a candidate for thrombolysis, then blood pressure may be lowered if SBP is more than 220 mmHg or DBP is more than 120 mmHg. Any antihypertensive treatment has to be targeted to lower blood pressure approximately 15 % of baseline blood pressure during first 24 h after onset of symptoms of ischemic stroke.

Fibrinolysis

Fibrinolytic agents initiate local fibrinolysis/breakdown of the blood clot in the area where cerebral blood circulation has been blocked, resulting in recovery of cerebral circulation.

Eligible candidates for such fibrinolysis are those patients who are 18 years or older in age, who present with measurable neurological deficits within 3 h of onset of symptoms [8]. Indication is now extended from 3 to 4.5 h from onset of symptoms with the exception of patients aged 80 years and above, severe stroke (with NIHSS more than 25), taking oral anticoagulants regardless of INR, and patients with a history of diabetes and prior ischemic stroke. *Extent of ischemia in imaging is not an important factor for initiation of fibrinolytic therapy.*

Following patients are absolutely contraindicated for fibrinolysis treatment:

1. Significant head trauma or stroke within 3 months prior to stroke symptoms
2. Subarachnoid hemorrhage
3. Arterial injury in noncompressible part of the body within a week
4. Prior history of intracranial hemorrhage
5. Intracranial tumor and vascular malformations
6. SBP $>$ 185 mmHg; DBP $>$ 110 mmHg
7. Active internal bleeding
8. High bleeding risks like platelet count $<$ 100,000/mm^3, elevated aPTT $>$40 s, INR $>$1.7, PT $>$15 s, use of anticoagulants, thrombin inhibitors, etc.
9. Hypoglycemia with blood glucose $<$ 50 mg/dl
10. CT scan showing large hypodensity covering more than a third of cerebral hemisphere

CT scan evidence of hypodensity and mass effect when treated with fibrinolytic agent is found to be associated with eightfold higher risk for intracranial hemorrhage [8, 28].

Following situations are relative contraindications, where clinical decision is made on an individual basis [8]:

(a) Pregnancy
(b) Seizure at onset of symptoms
(c) Major surgery or serious trauma within 2 weeks
(d) Urinary tract or gastrointestinal bleeding within 3 weeks
(e) Acute MI within 3 months
(f) Rapidly improving stroke symptoms

Food and Drug Administration (FDA) approved intravenous recombinant tissue plasminogen activator (rTPA) as a fibrinolytic agent for use in acute ischemic stroke in 1996. The treating dose is 0.9 mg/kg (total dose not exceeding 90 mg) over 60 min [29]. The bolus dose is administered as 10 % of the total dose over 1 min.

Patient should be closely monitored in stroke unit or intensive care unit during and throughout the management. Throughout the treatment and monitoring period patient's blood pressure and neurological exam should be assessed every 15 min for first 2 h. Follow-up neuroimaging is done after 24 h of treatment. The treatment should be discontinued if patient exhibits severe headache, if blood pressure rises acutely, or if patients develop nausea, vomiting, and worsening of neurological weakness. Urgent neuroimaging has to be performed in event of such concerning symptoms.

Other Agents

Streptokinase is not recommended anymore due to its higher risks with intracranial hemorrhage [30]. Other newer fibrinolytic agents such as Urokinase, Desmoteplase, Reteplase, Tenecteplase have not been tested extensively [8].

Endovascular treatments are considered only in highly specialized centers and in selected patients. Such treatments include intra-arterial fibrinolysis, mechanical clot/embolus removal procedures, acute angioplasty, and stenting.

Role of thrombin inhibitors in treatment of acute ischemic stroke is not established. Urgent anticoagulation treatment is not recommended for patients of acute ischemic stroke, and their usefulness in patients with internal carotid artery stenosis is not established [8].

Antiplatelet Therapy

Aspirin 325 mg is recommended for patients to take orally within 24–48 h of onset of stroke symptoms. Although role of clopidogrel in secondary prevention of ischemic stroke has been established, its role in treatment of patients with acute ischemic stroke is not well known. Furthermore during an episode of acute ischemic stroke, aspirin-clopidogrel dual therapy increases the risk of bleeding and does not improve the outcome of ischemic events compared to monotherapy alone [8, 31].

Other Considerations

Cardiac monitoring with continuous electrocardiogram should be done as soon as possible after the onset of symptoms and continued throughout the assessment and for at least 24 h upon admission [8]. Volume status should be addressed appropriately by volume replacement if indicated [8]. Hyperthermia if present should be worked up for etiology and addressed appropriately; fever in stroke patient can be a bad prognosis [8, 32]. Protective effects of hypothermia in stroke are not well established [8]. Regarding statins, continuation of statin therapy during hospitalization of patients with acute ischemic stroke is recommended. Specific treatment such as revascularization procedure is considered if there is presence of significant carotid stenosis; anticoagulation strategy is for atrial fibrillation [8].

Complications

Approximately, one fourth of the patients with ischemic stroke will develop complications. The most common complications following an ischemic stroke are (with incidence in parenthesis): brain edema (33 %), intracranial hemorrhage

(10 %), recurrent ischemia (11 %), and seizures (<10 %). Brain edema can increase intracranial pressure leading to further neurological weaknesses and increases the risk of mortality. Such complication from brain swelling usually occurs within 3 days of stroke. Hence, close monitoring of patients is warranted for the first 72 h [33].

After the initial phase of management, another secondary prevention strategy has to be started along with behavioral approaches for risk modifications [34]. This includes addressing key modifiable risk factors, which are control of blood pressure and diabetes mellitus. Smoking cessation has to be reinforced [34]. Other behavioral modifications include addressing excess alcohol consumption, obesity, and physical inactivity [34]. Managing valvular heart disease, cardiac arrhythmias, and addressing symptomatic carotid stenosis are important [34]. With regard to antiplatelet therapy any of the following options are recommended [34]:

(a) Aspirin (50–325 mg daily orally)
(b) Combination of aspirin (25 mg) and extended-release dipyridamole (200 mg) twice daily
(c) Clopidogrel (75 mg daily orally)

Combination of aspirin and clopidogrel has not been found to be beneficial and appears to have higher bleeding risks. In ischemic strokes secondary to carotid stenosis of 55–99 %, treatment with aspirin 325 mg daily orally is recommended [34].

Treatment of sleep apnea in patients with obstructive sleep apnea and ischemic strokes has been shown to improve outcomes [34].

Within the context of secondary prevention it is relevant to discuss the new guidelines on management of cholesterol to prevent atherosclerotic cardiovascular dfisease (ASCVD) published jointly by American Heart Association (AHA) and American College of Cardiology (ACC) in 2013 [35]. ASCVD includes acute coronary syndrome, history of myocardial infarction, angina, peripheral artery disease, stroke, and transient ischemic attack. Four groups of patients are found to benefit from therapy with statins:

(a) Patients with any form of clinical ASCVD
(b) Patients at age 40–75 with LDL-cholesterol at level 190 mg/dl or greater
(c) Patients at 40–75 years of age with diabetes and LDL-C between 70–189 mg/dl
(d) Patients 40–75 years of age without diabetes but whose estimated 10 year ASCVD risk is 7.5 % or greater

Taking the risks of ASCVD in consideration, these groups of patients will benefit from high-intensity statins or moderate-intensity statins in elderly at or more than 75 years of age. The proposed new 10 year ASCVD risk calculator takes into account gender, age, presence or absence of diabetes mellitus, SBP reading, presence or absence of hypertension treatment, smoking status, and total and HDL cholesterol [35].

Intracerebral Hemorrhage (ICH):

One in every ten patients with stroke is due to intracerebral hemorrhage (ICH) [2, 36–38]. Approximately a third of all patients with ICH die within a month; 50 % of all such deaths are within the first 48 h [36, 38]. Compared to ischemic strokes, ICH symptoms progress more rapidly, over minutes to hours. Some of the key symptoms of ICH are sudden headache, nausea, vomiting, elevated blood pressure, altered level of consciousness, and focal neurological deficits [39]. History of intake of medications that predispose to bleeding (like antiplatelet, antithrombotic agents) and other medical conditions that can lead to bleeding (like liver disease) are very important [12].

Prompt recognition of the ICH and its prognostic indicators will guide the management and prompt referral to a tertiary facility if necessary [12]. Volume of ICH and admission Glasgow coma scale (GCS) of the patients are strong prognostic indicators for patients with ICH [37]. High volume of ICH, low GCS, and presence of hydrocephalus are associated with bad prognosis [37, 40]. Another poor prognostic factor after hemorrhagic stroke is presence of fever within the first

3 days of stroke. Fever in the patient with ICH has been associated with supratentorial ICH and ventricular hemorrhage [41]. Low fibrinogen level, cortical location of ICH, and milder extent of neurological deficits are associated with better prognosis [42].

Patients with hemorrhagic stroke are found to be sicker than ischemic stroke patients. They also need close monitoring of intracranial pressure and neurological functions. They also have higher need for neurosurgical interventions [12].

Head CT scan and MRI of the brain are equally good in detecting ICH. Compared to serial MRIs, serial head CT scans are more feasible to monitor blossoming of the intracranial hemorrhage. MRI of the brain is superior in identifying vascular malformations. Cerebral angiography is indicated if there is bleeding in unusual sites like sylvian fissure bleeds, vascular abnormalities, subarachnoid hemorrhage, abnormal calcifications, or if no obvious etiology of hemorrhage can be identified [12]. Timing of angiography has to be weighed against hemodynamic stability of patients; unstable patients may need prompt neurosurgical intervention prior to angiography [12].

The key treatment goals in patients with ICH are to stop the bleeding, to remove the hematoma, and to address problems due to mass effect of the hematoma [12]. Just like in the case of ischemic stroke, the patient's airway patency, breathing motion/movements, and hemodynamic stability have to be addressed before specific management is initiated. If the treating center does not have a neurosurgical service, a timely referral to tertiary center can improve the outcome after a hemorrhagic stroke. Intensive care monitoring is needed throughout the recuperation process. ICU monitoring includes close monitoring of the hemodynamic status, intracranial pressure (ICP), cerebral perfusion pressure (CPP),, neurological status examination, and assessment of seizures [12]. Antiseizure medicines can be used prophylactically especially in patients with lobar hemorrhage. Duration of such prophylaxis should be brief unless there is a change in clinical picture of the patient. Use of recombinant activated factor VII (rVIIa) in patients with hemophilia has been proven to be beneficial, but its use for the treatment of bleeding in patients without coagulopathy has not been well established. The standard goal for blood pressure management in patients with ICH varies according to the patient's baseline blood pressure, history of hypertension, degree of intracranial pressure (ICP), and patient's age among many other variables [12]. Rehabilitation is started as soon as the patient is stable for mobilization.

Managing High Blood Pressure in Patients with ICH

The strategy of addressing high blood pressure differs among patients with ICH and patients with ischemic stroke. The outline of management of high blood pressure in ICH patients is recommended as follows [12]:

(a) If SBP >200 mmHg or mean arterial pressure (MAP)>150 mmHg, aggressive lowering of blood pressure is recommended to decrease risk of more hemorrhage.
(b) If SBP >180 mmHg or MAP >130 mmHg, ICP may be elevated; in such situation ICP monitoring and lowering blood pressure is important to maintain CPP between 60 and 80 mmHg.
(c) If SBP >180 mmHg or MAP >130 mmHg without any evidence of elevated ICP, a gradual blood pressure lowering should be the strategy with target blood pressure of 160/90 mmHg.
(d) In patients with SBP of 150–220 mmHg, the target SBP of 140 is probably safe.

There is high risk of increased ICP in patients with ICH due to multiple mechanisms like mass effect, swelling secondary to ischemia, secondary hemorrhage, and hydrocephalus [43]. Clinically patients with elevated ICP should be monitored closely with the help of tools like NIHSS scale and GCS; patient's ICP and CPP should be monitored in the intensive care unit. ICP lowering strategies used in intensive care units are elevation of head of bed to 30°; drainage of cerebrospinal fluid; osmotic therapy (mannitol, hypertonic

saline), and hyperventilation [12]. In patients with hydrocephalus of worsening neurological symptoms, ventricular drainage of cerebrospinal fluid can be considered [12].

Neurosurgical intervention to remove hematoma is recommended in patients with ICH > 3 cm, with deterioration of clinical situation, brainstem compression signs, or hydrocephalus leading to obstruction of CSF flow [12]. In supratentorial ICH with lobar clot within 1 cm of the surface of brain, evacuation can be considered. The time to craniotomy and evacuation of the clot has to be managed perfectly as there is possible harm due to recurrent bleeding in case of early craniotomy and there is the possibility of minimal benefit in outcome with added risks of surgery with late craniotomy [12].

In patients with ICH and impaired mobility, there is a high risk of development of DVT and PE. Pneumatic compression of legs is recommended for prevention of DVT. Only after cessation of intracranial bleeding, cautious use of anticoagulants as prophylaxis for thromboembolism can be considered, which is usually after 3–4 days of ICH. In cases with high bleeding risk, inferior vena cava (IVC) filter placement is widely used to prevent progression of DVT to PE [12].

The recurrence of ICH depends on the risk factors for ICH. The odds ratio for recurrence of ICH in elderly patients > 65 years of age and male gender are 2.8 and 1.8 times respectively [44]. The odds ratio of ICH recurrence in patients with untreated hypertension and treated hypertension are 3.5 and 1.4 respectively [45]. Relationship between smoking, heavy alcohol use, cocaine use, and ICH are well established, and these risk factors need to be addressed for prevention of ICH and its recurrence [12].

Subarachnoid Hemorrhage (SAH):

Three percent of all stroke is due to SAH [1]. SAH due to rupture of aneurysm is also called aneurysmal SAH (aSAH) and accounts for 85 % of SAH.

Fifteen percent are nonaneurysmal SAH (NASAH) [46]. Nonaneurysmal bleeding causes are often not identified. Some of the causes are perimesencephalic nonaneurysmal hemorrhage and other nonaneurysmal vascular malformations. Perimesencephalic nonaneurysmal bleed has excellent prognosis compared to aneurysmal bleeds [46].

Nonmodifiable risk factors for aSAH are presence of cerebral aneurysms, female gender, history of prior aneurysmal bleed, family history of cerebral aneurysms [16]. Modifiable risk factors for aneurysmal SAH are smoking, hypertension, cocaine use, alcohol abuse [16]. Smoking cessation, cutting down alcohol, treatment of hypertension, and diet rich in vegetables may prevent incidence of SAH [16]. For first-degree relative of patient with familial aneurysmal SAH or history of aneurysmal SAH, a noninvasive test to screen for aneurysms can be considered [16]. Among cerebral aneurysms, those that are large, located at posterior communicating artery (PCA), or the vertebrobasillary system aneurysms are at higher risk of developing aneurysmal SAH [16]. Although aneurysmal size of more than 7 mm size of aneurysm is more prone to develop SAH [47], risk factors like smoking, alcohol, and psychosocial stress can influence the rupture of aneurysm regardless of the size [48, 49].

There is a high risk of early rebleeding of aneurysms, therefore any case of aneurysmal SAH should be closely monitored and re-evaluated after treatment with routine reimaging [16]. Furthermore after discharge, these patients should be followed up closely with regard to minimizing risk factors and behavioral modifications [16].

SAH should be the primary diagnosis of any patient who presents with acute sudden severe headache unless proven otherwise [16]. Most SAH will be diagnosed with a noncontrast head CT. If the initial noncontrast CT scan is inconclusive an evaluation of cerebrospinal fluid after lumbar puncture will help with the diagnosis. Other imaging modalities that can be considered are CT angiography, digital subtraction angiogram (DSA), or brain MRI[16].

Surgical method is the primary mode of management for SAH. For majority of aneurysmal bleeds, the aneurysm should be repaired by surgical clipping or endovascular clipping as soon as possible. Preventing rebleeding is a key issue in the

management of aneurysmal bleed. Most of the rebleeding occurs within 12 h of first bleed [50]. Rebleeding associated with high blood pressure can be prevented by judicious use of antihypertensives. Although there is no established cutoff blood pressure as a treatment goal, AHA/ASA guidelines recommend maintaining the SBP under 160 mmHg based on expert consensus [16]. Limited studies have shown benefits on short-term treatment with antifibrinolytic therapy (tranexamic acid or aminocaproic acid) to reduce rebleeding in patients with high risk of repeat bleed [16, 50].

Cerebral arterial vasospasm leading to delayed cerebral ischemia (DCI) is the primary reason for disability and death after aneurysmal SAH. Controlled studies on SAH management demonstrate no benefit on outcome from traditional hemodynamic augmentation of triple-H therapy (hemodilution, hypervolemia, and hypertensive therapy) [16]. Nimodipine, a calcium channel blocker, has been found to improve outcome in patients with aneurysmal bleed and is therefore recommended in all patients with aneurysmal SAH [51]. The mechanism of action by which the drug prevents DCI is unknown. In a Cochrane review by Dorhout et al., Nimodipine was found to prevent arterial vasospasm and DCI [51]. Hemodynamic stability by maintaining normal volume status of the body is also recommended to prevent DCI [52]. SAH associated hydrocephalus is treated by draining excess cerebrospinal fluid either by lumbar drainage or external ventricular drainage [16].

Prophylactic antiseizure medicine is recommended to prevent seizures after SAH [16].

Rehabilitation in Patients with Cerebrovascular Disease

Cerebrovascular disease is a leading cause of disability in USA. After stroke event, 40 % of patients sustain moderate disability, and about 20 % sustain severe disability affecting their daily life [53]. Organized multidisciplinary rehabilitation program has been proven to improve functional outcome of patients after stroke [28, 53, 54]. Table 2 summarizes key strategies in rehabilitation of patients with stroke.

Table 2 Tertiary prevention strategies for cerebrovascular diseases [19, 53]

Strategies in rehabilitation
1. Use standardized tool like NIHSS for close monitoring of patients
2. Swallowing screening in all patients in order to screen for dysphagia and to prevent aspiration
3. Address nutritional status of the patient to meet calorie and protein needs; use of feeding tube is recommended in case this need can be fulfilled orally
3. Prevention of DVT by appropriate strategies
4. Early mobilization of stroke patients; addressing motor impairment like spasticity
5. Multidisciplinary approach is proven to improve outcome in rehabilitation for stroke patients. This includes physical therapy, occupational therapy, speech therapy and palliative care
6. Strategies to prevent pressure ulcers
7. Address incontinence, urinary retention and constipation issues
8. Falls prevention strategies
9. Screen and manage depression, counsel patients and their families

Contents

Parkinsonism/Parkinson's Disease

Idiopathic Parkinson's disease (IPD) has a prevalence of about 0.3 % in the general population with prevalence increasing to 5 % by age 85. The disease is fairly rare less than 50 years of age. Smoking appears to be a protective factor, with less smokers progressing to IPD [1].

Diagnosis

The diagnosis of IPD rests on the presence of cardinal motor symptoms – distal resting tremor (between 3 and 6 Hz), rigidity, bradykinesia, and atypical onset. In addition to this, a response to levodopa and the absence of atypical symptoms are very suggestive of the disease [2]. Atypical symptoms such as early postural instability (within 3 years of onset), early freezing phenomena, hallucinations (not due to treatment), early cognitive impairment, and paralysis of upward gaze suggest a diagnosis other than IPD. For a patient to have true Parkinsonism, some form of upper body akinesia must be present. Upper extremity rigidity is usually present, and a resting tremor is present in about two-thirds of patients [3]. Given that the prevalence of IPD increases with advanced age, it can often be misdiagnosed since patients may assume that they are just "slowing down."

- **Akinesia:** This is the most disabling feature of IPD and is present in all cases [3], especially in the upper body. It is a compendium of symptoms that involves slowness of movement (bradykinesia), poverty of movement, difficulty initiating movement, decreased ability to initiate movements, and accomplish alternating movements. Poverty of movement involves what is commonly called the "mask facies" or staring. These manifestations are due to the inability to initiate movements. Other common complaints are weakness, fatigue, difficulty buttoning clothes, difficulty swallowing, and a soft voice. Micrographia, or small handwriting, can be a subtle sign of the development of IPD [4].
- **Tremor:** Tremor of IPD is typically a resting tremor and can be distinguished from many other conditions because it often disappears when the tremulous body part is activated. There are times when it is present during activity, but it is typically much more prevalent at rest. The typical resting tremor has a frequency between 3 and 6 Hz, though most are found to be between 4 and 5 Hz [5]. The tremor may begin in a single finger and usually progresses to the classic "pill rolling" tremor of the hand and then often involves the entire limb. With time, other extremities begin to be involved. Additionally, Parkinson's tremor may be found in the lips, tongue, and jaw [6].
- **Rigidity:** Rigidity is increased tonicity of flexor and extensor muscle groups during passive movement of a joint. This symptom is usually only manifest during physical exam and often is not appreciated by the patient. In a similar manner to tremor, it often begins unilaterally and then can progress to other extremities. There are two main types of rigidity: "lead pipe" or "cogwheeling." Lead pipe rigidity refers to smooth tonic resistance throughout passive range of motion. Cogwheel rigidity is thought to be due to tremor superimposed upon rigidity and is characterized by a pattern of resistance and relaxation as the physician moves the extremity through range of motion.
- **Gait Disturbances:** Rigidity, bradykinesia, and tremor often lead to gait disturbances as the disease progresses and the manifestations become much more diffuse. As a patient's stride shortens, their gait becomes more shuffling, and they adopt a stooped posture. Patients often have difficulty initiating ambulation and tend to lean forward involuntarily while taking very quick, short steps – sometimes on the forefoot or toes to avoid falling (festinating gait). A simple clinic test used to detect postural instability is the "pull test." After warning the patient, the examiner can stand behind the patient and pull backward on their upper arms. Those with mild instability will take a step or two backward to regain their balance, while those with severe instability will be forced to fall helplessly into the hands of the examiner. This is helpful for patients and caregivers to understand the serious potential for falls [7].

Differential Diagnosis

IPD is essentially a diagnosis of exclusion. Thus, it is important to rule out other causes of Parkinsonism in patients that are thought to have IPD. The physician should not hesitate to start a patient on anti-Parkinsonism drugs, however. In the end, if the patient fails to respond, alternative diagnoses must be sought.

- **Drug-Induced Parkinsonism:** The second most common cause of Parkinsonism is drug-induced Parkinsonism (DIP). Clinical features of DIP usually include a bilateral and symmetrical Parkinsonism. Bradykinesia and rigidity are often more prominent than in IPD. Clinical features alone cannot be used to differentiate IPD from DIP. When a patient presents with symptoms of Parkinsonism, a careful review of medications should be undertaken to reveal any common causes of DIP. Common offenders include antipsychotics, antiemetics, calcium channel blockers, and drugs that deplete dopamine (see Table 1) [8]. In addition

Table 1 Drugs implicated in drug-induced Parkinsonism

Typical antipsychotics	Chlorpromazine, prochlorperazine, perphenazine, fluphenazine, promethazine, haloperidol, pimozide, sulpiride
Atypical antipsychotic	Risperidone, olanzapine, ziprasidone, aripiprazole, clozapine, quetiapine
Antiemetics	Metoclopramide, levosulpiride, clebopride, domperidone, itopride
Calcium-Channel blocker	Flunarizine, cinnarizine
Dopamine depleters	Reserpine, tetrabenazine
Mood stabilizer	Lithium
Antidepressant	Citalopram, fluoxetine, paroxetine, sertraline
Antiepileptic drugs	Valproic acid, phenytoin

Adapted from table in Ref. [8] with additions from Refs. [7, 9, 10]

to Parkinsonism, these drugs can cause other movement disorders such as tardive dyskinesia (TD), which is a disorder of the face that causes twisting movements of the tongue or smacking of the lips. Abnormal movements of the limbs can also occur with TD. This can persist for years and is sometimes permanent, though with early identification and discontinuation of medications, TD may improve over time [9]. DIP will usually resolve within weeks to months of stopping the offending agent; however, it may persist in 10–50 % of patients. Those with a full and lasting recovery are the only ones that are considered to have a pure DIP. Those patients with persistent Parkinsonism, and sometimes progression after withdrawing the offending agents, probably had a preclinical IPD [8] (Table 1).

- **Cerebrovascular disease:** Infarct to the area of the basal ganglia or brainstem may cause Parkinsonism. Clues that point to this etiology might include abrupt onset of symptoms as well as the presence of risk factors for cerebrovascular disease. If a patient has other neurological complaints such as paralysis, seizures, or numbness, or if focal deficits such as aphasia, abnormal reflexes, and cranial nerve deficits are appreciated, then prompt consideration of and investigation for cerebrovascular disease should be made. Additionally, space occupying lesions such as tumors or abscesses could cause similar symptoms as could hydrocephalus. Patients in whom these are a consideration should undergo advanced imaging with computed tomography (CT) or magnetic resonance imaging (MRI).
- **Inherited disease:** Several inherited disorders can present with Parkinsonism. As such, a thorough family history is important to obtain.
  - Wilson's disease is associated with copper deposition in the liver and basal ganglia. If a patient presents with Parkinsonism under the age of 50, Kayser-Fleischer rings on ocular examination, or abnormal liver function studies, they should undergo further testing for Wilson's disease as this could be effectively treated with chelation [10].
  - Huntington's disease is an inherited disease caused by trinucleotide repeat expansion in an autosomal dominant pattern. However, Huntington's disease presenting with true Parkinsonism is fairly rare because the typical movement is choreiform, which is rapid, involuntary, nonrepetitive, or arrhythmic movements of face, trunk, or limbs https://m.youtube.com/watch?v=VZlUNLJiEhk
- **Dementia:** Patients with Alzheimer's disease often develop some signs of Parkinsonism, though they are usually mild.
  - The second most common cause of neurodegenerative dementia is dementia with Lewy bodies (DLB), which very frequently can be confused for IPD. Characterizations of this disease include visual hallucinations, fluctuating cognition, and Parkinsonism. Patients with IPD often do develop cognitive decline, though it can be distinguished from DLB because those with DLB usually develop the dementia concomitantly or before the development of Parkinsonism. In those with IPD who develop dementia, Parkinsonism is usually present for more

than a year prior to dementia onset. Additionally, hallucinations are inconsistent with IPD [11].

- Another IPD mimic is progressive supranuclear palsy (PSP). It can cause a frontal lobe dementia, although that can take several years to develop. Otherwise, it can be differentiated from IPD by vertical supranuclear palsy with downward gaze. It has a poor prognosis as death occurs at a median of 6 years after onset with progressive decline. It can be difficult to distinguish from IPD as a small percentage of patients may have some initial response to levodopa [12].

Therapy

Unfortunately, there is no cure for IPD. However, drug therapy can be extremely useful in improving quality of life and controlling some of the debilitating symptoms associated with Parkinsonism, and it is the mainstay of treatment for Parkinsonism. Adjuncts to drug therapy include physical therapy, occupational therapy, and counseling which can also help patients and their families cope with the disease. Additionally, a randomized controlled trial has shown improvements in spinal flexibility and physical performance following specific exercise programs aimed at those specific areas (Table 2) [13].

Table 2 Drugs used for treatment of idiopathic Parkinson's disease

Class/Agent	Starting dose	Maximum dose
Dopamine precursor		
Levodopa/carbidopa (Sinemet)	100/25 mg two to four times daily	2000/200 mg/day
Dopamine agonists		
Bromocriptine (Parlodel)	1.25 mg bid	30 mg tid
Pramipexole (Mirapex)	0.125 mg tid	1.5 mg tid
Ropinirole (Requip)	0.25 mg tid	8 mg tid
Rotigotine (Neupro)	2 mg/24 h transdermal patch	6 mg/24 h
Apomorphine	2 mg tid subcutaneous injection	20 mg/day
Monoamine oxidase B (MAO B) inhibitors		
Selegiline (Eldepryl)	2.5 mg bid	5 mg bid
Catechol-O-methyltransferase (COMT) inhibitors		
Entacapone (Comtan)	200 mg/dose	200 mg 8 x/day
Tolcapone (Tasmar)	100 mg tid	200 mg tid
Anticholinergics		
Trihexyphenidyl (Artane)	1 mg qd	10 mg qd
Benztropine (Cogentin)	0.5 mg qd	6 mg qd
Miscellaneous		
Amantadine (Symmetrel)	100–200 mg qd	200 mg

From Refs. [2, 18, 19]

- **Levodopa/Carbidopa:** Levodopa is the most effective treatment for symptomatic treatment of IPD. It especially helps with symptoms of bradykinesia but can also manage tremor and rigidity, though is less likely to help with the postural instability. Levodopa is the immediate precursor to dopamine. It is given with a decarboxylase inhibitor (carbidopa) with the intention of preventing metabolism to dopamine in the periphery, thus increasing its availability and effectiveness in the Central Nervous System (CNS). It should be initiated as soon as symptoms of IPD develop as it can aid in diagnosis (as most other causes of Parkinsonism will not respond to it), improve functional capacity, and actually improve patient survival [14]. When initiating levodopa/carbidopa, dose titration should be accomplished to find a dose that provides maximum benefit while avoiding unwanted side effects as listed in Table 3. The typical dose of levodopa for most patients will end up being between 300 and 600 mg daily. Using adjunctive medications with levodopa/carbidopa can improve patient responsiveness at lower doses and avoid unwanted side effects. As the disease progresses, responsiveness to therapy decreases.

Table 3 Side effects of commonly used medications for treatment of idiopathic Parkinson's disease

Class of medication	Side effects
Dopamine precursors	Common – Nausea, somnolence, dizziness, headache
	Less common – confusion, hallucinations, delusions, agitation, psychosis, orthostatic hypotension, hip fractures (due to elevation in serum homocysteine levels), motor fluctuations
Dopamine agonist	Common – Nausea, vomiting, sleepiness, orthostatic hypotension, confusion, hallucinations, peripheral edema
	Less common – Valvular heart disease, impulse control disorders, dopaminergic dysregulation syndrome
MAO B inhibitors	Nausea, headache, confusion, insomnia
COMT Inhibitors	Dyskinesia, hallucinations, confusion, nausea, orthostatic hypotension, diarrhea, elevated liver enzymes
Anticholinergics	Memory impairment, confusion, hallucinations, dry mouth, blurred vision, constipation, nausea, urinary retention, impaired sweating, tachycardia.
Amantadine	Livedo reticularis (mottled skin), ankle edema, confusion, hallucinations, nightmares

From Refs. [2, 9, 18]

- **Dopamine Agonists:** The most common dopamine agonists used are pramipexole, ropinirole, and bromocriptine. These may delay onset of dyskinesias or wearing off as compared to levodopa alone. However, adverse effects are common with dopamine agonists and may limit their use. Similarly to levodopa, patients should be started at a low dose and titrated slowly with close follow-up for effectiveness and side effects. When adding agonists to levodopa/carbidopa, the dose of levodopa should be titrated downward. Rotigotine is another option of dopamine agonist and may benefit those patients that cannot tolerate oral medications. It is a once daily transdermal patch. Another dopamine agonist on the market is apomorphine, which is an injectable medication that can be used as rescue injections or to treat levodopa-induced motor fluctuations. Prior to initiating its use, however, a challenge test dose must be accomplished to ensure that it is tolerated by the patient as side effects can be severe and include chest pains, severe hypotension, vomiting, and loss of consciousness. Additionally, its use with ondansetron or serotonin receptor agonists is contraindicated as it can worsen side effects [15]. All dopamine agonists must be tapered off slowly when discontinuing as abrupt withdrawal can lead to severe withdrawal symptoms [16].
- **Monoamine Oxidase B (MAO B) Inhibitors:** Selegiline delays catabolism of dopamine allowing it to work longer within the CNS. There has been some discussion on whether selegeline can also offer neuroprotection, though this has not been well established in long-term follow-up studies [17]. It is not as good for monotherapy as either levodopa/carbidopa or dopamine agonists, though if used, may delay the need to start levodopa. If using as an adjunct, the dosage of levodopa should be decreased by about 20 %.
- **Catechol-O-Methyl Transferase (COMT) Inhibitors:** COMT inhibitors are used to block the catabolism of levodopa in the gastrointestinal (GI) tract and periphery. Their effectiveness is similar to that of adding carbidopa to levodopa as it increases levodopa availability in the CNS. They have been shown to reduce motor fluctuations or the wearing-off phenomenon in those patients treated with levodopa. They are ineffective when given alone but have been shown to improve disabling complications of Parkinsonism when given with levodopa [18]. Levodopa dosage should be decreased by about 25 % to decrease dyskinesia and other levodopa-related side effects.
- **Anticholinergics:** Anticholinergics have best effect on the tremor of Parkinsonism and are most useful for those patients that have disabling tremor but are not as bothered by gait disturbance or bradykinesia.

- **Amantadine:** This is an antiviral agent found to have some effectiveness on parkinsonian symptoms. It is most often used early in the disease as an adjunct to levodopa therapy. Its mechanism of action is unknown, but it is thought to possibly increase dopamine release, inhibit dopamine reuptake, and stimulate dopamine receptors [19].

Other therapies exist beyond pharmacological management. In patients that progress to severe IPD that are not responding to typical therapies, other options should be considered. Consultation with neurologists and neurosurgeons is important as patients may undergo continuous apomorphine infusions or deep brain stimulation (DBS). A large randomized control trial showed that in select patients with advanced IPD and motor complications, DBS improved motor functions and motor fluctuations when compared to best medical therapy [20]. Stimulation generally involves the subthalamic nucleus and globus pallidus pars interna with stimulation of the subthalamic nucleus leading to greater reduction in antiparkinson medication doses, though change in motor function was not significantly different [21]. DBS has largely replaced prior surgical options such as thalamotomy and pallidotomy. It is preferred due to its proven efficacy and decreased complications. It is hoped that future research may establish improved treatments with proof of neuroprotective therapy to prevent long-term deterioration and disability.

Tremor: Other Causes

Tremor is an involuntary, rhythmic, oscillatory movement of a body part. It is the most common movement disorder encountered in clinical practice. There is no diagnostic standard to distinguish among common types of tremor, which can make the evaluation challenging. However, establishing the underlying cause is important because prognosis and specific treatment plans vary considerably. History and physical examination can provide a great deal of certainty in diagnosis. The most common tremor in patients presenting to primary care physicians is enhanced physiological tremor, followed by essential tremor and parkinsonian tremor. All tremors are more common in older age [22]. Tremors fit into classification of either action or resting (Table 4).

Table 4 Broad classification of tremor

Tremor type	Description
Action	Occurs with voluntary contraction of muscle Includes
Postural	Occurs when the body part is voluntarily maintained against gravity – includes essential, physiologic, cerebellar, dystonic, and drug-induced tremors
Kinetic	Occurs with any form of voluntary movement – includes classic essential, cerebellar, dystonic, and drug-induced tremors
Intention	Subtype of kinetic tremor amplified as the target is reached – presence of this type of tremor implies a disturbance of the cerebellum or its pathways
Rest	Occurs in a body part that is relaxed and completely supported against gravity – most commonly caused by Parkinsonism, but may also occur in severe essential tremor

Adapted from table from Ref. [22]

Differential Diagnosis

As above, the most common tremor is physiological, with essential tremor being second and Parkinson's tremor third. As Parkinson's was addressed in detail above, it will not be discussed in this section. Other considerations in those with tremor include cerebellar tremor, drug-induced tremor, dystonic tremor, and psychogenic tremor.

- **Essential Tremor (ET):** The most common pathological tremor is essential tremor. In - one-half of cases, it is transmitted in an autosomal dominant fashion, and it affects 0.4–6 % of the population. Careful history reveals that patients with essential tremor have it in early adulthood (or sooner), but most patients do not seek help for it until 70 years of age because of its progressive nature. Despite being sometimes called "benign essential tremor," essential

Table 5 Medications used for essential tremor

Class	Medications that can be used
Beta Blockers	Propranolol, atenolol, sotalol, nadolol, metoprolol
Anticonvulsants	Primidone, gabapentin, topiramate
Benzodiazepines	Alprazolam, clonazepam
Botulinum toxin type A	

tremor often causes severe social embarrassment, and up to 25 % of those afflicted retire early or modify their career path. Essential tremor is an action tremor, usually postural, but kinetic and even sporadic rest tremors have also been described. It is most obvious in the wrists and hands when patients hold their arms in front of themselves (resisting gravity); however, essential tremor can also affect the head, lower extremities, and voice. It is generally bilateral, is present with a variety of tasks, and interferes with activities of daily living. In a series of 200 Italian patients referred to a neurologist for evaluation of tremor, 15 % had uncommon clinical features that included postural, action, rest, orthostatic, and writing tremors, and 10 % had tongue or facial dyskinesia [23]. Diagnostic criteria for ET have not been universally accepted. Persons with essential tremor typically have no other neurological findings; therefore, it is often considered a diagnosis of exclusion. If the tremor responds to a therapeutic trial of alcohol consumption (two drinks per day), the diagnosis of essential tremor is assured [22].

If essential tremor is suspected, it is appropriate to begin pharmacological treatment. Many treatments have shown efficacy and are listed in Table 5. In addition to pharmacology, alcohol has been used for diagnostic and self-treatment purposes as ET will usually improve with alcohol intake. However, because of concerns for dependence and abuse, it should not generally be recommended for treatment purposes.

- **Beta blockers:** Of the beta blockers listed in Table 3, propranolol has been most proven to be effective in treating limb tremor and probably helps with head tremor as well. The effective dosage can be between 60 and 320 mg/day. Side effects include lightheadedness, fatigue, impotence, and bradycardia. The other beta blockers listed in the table have been shown to probably be effective for tremor, but their efficacy has not been established as much as propranolol [24, 25].
- **Anticonvulsants:** Primidone at doses up to 750 mg/day is effective in reducing tremor associated with ET. It should be started at much lower dosage (around 25 mg nightly) and titrated slowly to effectiveness. Side effects include sedation, drowsiness, fatigue, depression, nausea, vomiting, malaise, dizziness, confusion, vertigo, and acute toxic reaction. These are usually more severe at initiation of treatment. The other anticonvulsants listed may be effective but are not as commonly used [24, 25]. Gabapentin usually has fewer side effects than primidone, but topiramate often will have high rates of adverse effects.
- **Benzodiazepines:** Clinical trials have shown that alprazolam reduces tremor when compared to placebo. Mean effective dose for alprazolam was 0.75 mg/day [26]. Data regarding clonazepam is more conflicting, and it may reduce tremor if used.
- **Botulinum Toxin type A:** Botulinum Toxin has some effectiveness in limb tremor and may also reduce head tremor and voice tremor [24].

In those who do not respond well to pharmacological therapy or disease progresses, deep brain stimulation and thalamotomy are options which can be considered and are efficacious [24].

- **Enhanced Physiological Tremor:** A physiological tremor is present in all persons. It is a low-amplitude, high-frequency tremor at rest and during action that is not reported as symptomatic. This tremor can be enhanced by anxiety, stress, and certain medications and metabolic conditions. Patients with a tremor that comes and goes with anxiety, medication use, caffeine intake, or fatigue do not need further testing [22]. Treatment would be to discontinue the exacerbating factor.

Table 6 Medications and substances that may exacerbate tremor

Amiodarone	Hypoglycemic agents
Amphetamines	Lithium
Atorvastatin (Lipitor)	Metoclopramide (Reglan)
Beta-adrenergic agonists (e.g. albuterol)	Methylphenidate (Ritalin)
Caffeine	Terbutaline
Carbamazepine (Tegretol)	Theophylline
Corticosteroids	Thyroid hormones
Cyclosporine (Sandimmune)	Tricyclic antidepressants
Epinephrine	Valproic acid (Depakene)
Fluoxetine (Prozac)	Verapamil
Haloperidol	

From Refs. [22, 24, 25]

- **Drug- and Metabolic-Induced Tremors:** Many medications can cause or exacerbate tremor. Patients with new-onset tremor should have a comprehensive medication review with specific attention to medications started prior to the onset of tremor. Medications prone to inducing or activating tremor are listed in Table 6.

When medication review reveals a possible culprit, trial off of the medication should be attempted.

Metabolic causes of tremor are varied. Initial workup of tremor may include blood testing for hepatic encephalopathy, hypocalcemia, hypoglycemia, hyponatremia, hypomagnesemia, hyperparathyroidism, hyperthyroidism,, and vitamin B12 deficiency [22].

- **Cerebellar Tremor:** The classic cerebellar tremor presents as a disabling, low-frequency, slow intention or postural tremor and is typically caused by multiple sclerosis with cerebellar plaques, stroke, or brainstem tumors. Other neurological signs include dysmetria (overshoot on finger-to-nose testing), dyssynergia (abnormal heel-to-shin testing and/or ataxia), and hypotonia. Presence of these signs should prompt urgent head imaging with CT or MRI [22].
- **Psychogenic Tremor:** Differentiation of organic from psychogenic tremor can be difficult. Features consistent with psychogenic tremor are abrupt onset, spontaneous remission, changing tremor characteristics (can be resting, postural, and action), and extinction with distraction. It usually has a relatively constant frequency. Often, there is an associated stressful life event. Based on clinical experience, the prevalence of psychogenic tremor is thought to be high, but there are no precise estimates [22]. Electrophysiological testing can help with determining the frequency and disappearance with distraction. This can be a challenging diagnosis to make as patients will oftentimes refute it believing that there is another cause of their symptoms [27]. There are no universally accepted treatments for psychogenic tremor, though evidence suggests that psychotherapy, cognitive behavioral therapy, and antidepressant medications may help [28, 29].
- **Dystonic Tremor:** Dystonic tremor is a rare tremor found in 0.03 % of the population. It typically occurs in patients younger than 50 years. The tremor is usually irregular and jerky, and certain hand or arm positions will extinguish the tremor. Other signs of dystonia (e.g., abnormal flexion of the wrists) are usually present [22].

Family/Community Issues

IPD and ET can be very difficult diagnoses to deal with for both patients and their families. As a result, it may be necessary to refer patients to counseling who are feeling depressed. Family

counseling may be considered as well. It is also important for family physicians simply to understand the difficulty that they might be having and show empathy in their interactions.

Disorders of the Peripheral Nervous System

Kirsten Vitrikas*
Family Medicine Residency, David Grant Medical Center, Travis AFB, CA, USA

Background

Disorders of the peripheral nervous system are caused by a variety of diseases, toxins, trauma, and metabolic causes. Neuropathies are estimated to affect 2–8 % of the population with the incidence being higher in older individuals [1]. Depending on the cause a single or multiple nerves may be involved. The most common causes of polyneuropathy are diabetes, alcoholism, fatty liver disease, and malignancy.

In axonal disease typically the more distal ends of the nerves are affected first resulting in the "stocking and glove" distribution seen in diabetic neuropathy. This type of damage will also result in loss of distal reflexes (i.e., ankle jerk) with preserved reflexes elsewhere. Demyelinating neuropathies often have proximal weakness with generalized loss of reflexes. Pain, loss of temperature sensation, and autonomic features suggest involvement of small nerve fibers. Autonomic features include light intolerance (pupillary), postural hypotension (cardiovascular), nocturnal diarrhea (gastrointestinal), impaired sweating (sweat gland), and bladder dysfunction. These symptoms may occur as part of diabetic neuropathy or as a sign of more systemic nerve involvement such as with amyloidosis or autoimmune conditions. Many diseases have mixed involvement of both sensory and motor symptoms.

Compressive neuropathies often result from overuse or mechanical problems. Presentation is more common in the later decades. For all compressive neuropathies except carpal tunnel, initial presentation is usually at ages 55–64 [2]. Carpal tunnel is more likely to present initially in women aged 45–54 years, and radial nerve palsy is more common in men aged 75–84 years [2]. Prevalence rates from a UK study are shown in Table 1.

The duration of development may help provide clues as to the etiology and is divided into categories: acute (<4 weeks), subacute (1–3 months), and chronic (>3 months). Neuropathies that occur acutely tend to be related to vasculitis or Guillain-Barre syndrome [3].

Evaluation

A thorough history and physical should be performed looking for underlying causes and clues to systemic disease. The patient should be questioned about toxin exposures including occupational exposures, prescribed medications, and chemotherapy treatments in addition to nutrition. Careful examination of the neurologic system should involve testing of sensory function including vibration, proprioception, temperature, and pinprick in addition to reflexes. Specific testing may be performed for mononeuropathies such as carpal tunnel syndrome (Tinel's, Phalen's).

Initial laboratory testing to determine causes should include a complete blood count, comprehensive metabolic profile, erythrocyte sedimentation rate, fasting blood glucose or hemoglobin A1C, vitamin B_{12}, and thyroid-stimulating hormone levels [3]. Additional testing based on clinical suspicion may include human immunodeficiency virus (HIV) antibodies, Lyme antibodies, rapid plasma reagin (syphilis), urine and serum protein electrophoresis (paraproteinemias), angiotensin-converting enzyme levels

Table 1 Prevalence of compressive neuropathies

Type	Prevalence	Female: male
Carpal tunnel	2.78 %	3–1
Morton's neuralgia	1.27	2–1
Ulnar neuropathy	0.4	1–1.3
Meralgia paresthetica	0.22	1–1
Radial neuropathy	0.045	1–2

(sarcoidosis), and antinuclear antibodies (vasculitis). In at least 15 % of cases, a cause may not be determined with this initial testing [3]. The etiology in these cases is often autoimmune or hereditary [3]. Lumbar puncture and cerebrospinal fluid (CSF) analysis may also be helpful in diagnosis of Guillain-Barre syndrome or chronic inflammatory demyelinating neuropathy, which usually have notably elevated protein levels.

Electrodiagnostic testing consisting of nerve conduction studies and electromyography (EMG) should be considered if the diagnosis remains unclear after initial evaluation [3]. These studies can help determine if the damage to the nerve is axonal, demyelinating, or mixed. Normal studies decrease the likelihood of the peripheral neuropathy as the cause of symptoms. These studies are not as sensitive for neuropathies of small nerve fibers (pain, temperature, or autonomic functions).

Nerve biopsy is considered when the diagnosis still remains uncertain or when confirmation is needed prior to initiating aggressive treatment (e.g., vasculitis which may require immunosuppressive medications). Sural and superficial peroneal nerves are preferred for biopsy. Epidermal skin biopsy may also be performed in patients who are suspected to have disease of their small nerve fibers [3].

Cranial Neuropathies

Bell's Palsy

Bell's palsy is an acute unilateral facial nerve paralysis of unknown etiology. Patients usually describe an acute onset of unilateral facial weakness. They may have an associated earache in addition to numbness in the distribution of the nerve. Both upper and lower parts of the face are affected which distinguishes this from a central lesion in which only the lower portion of the face is paralyzed. This condition affects 11–40 persons per 100,000 with peak incidence between the ages of 15 and 50 years [4]. Groups at higher risk include pregnant women, diabetics, the elderly, and patients with hypothyroidism [4]. The cause is unknown, though there is evidence that a reactivation of herpes virus, either herpes simplex 1 (HSV-1) or herpes zoster (HZV), is involved. Several other infectious causes have been implicated in addition to autoimmune disease (Hashimoto's), ischemia, and familial syndromes [4]. The symptoms result from inflammation and edema of the facial nerve. Most patients recover within weeks to months.

Laboratory and imaging studies are not routinely needed. They are only recommended when there is concern for Lyme disease, recurrence of symptoms or no improvement after 3 weeks of treatment [5]. Even without treatment approximately 70 % of patients with complete paralysis will recover within 6 months. A Cochrane review showed that corticosteroids had significant benefit in the treatment with faster recovery and improved nerve function when started within 72 h of symptom onset [6]. Conversely antiviral drugs alone have not been shown to benefit recovery [7]. Care should be taken to protect the cornea due to improper lid closure caused by the disease. This may be done with lubricating drops or eye ointment during sleep. In addition, providers may need to provide psychological support to patients with this disfiguring condition [4, 5].

DOI 10.1007/978-1-4939-0779-3_74-1

Trigeminal Neuralgia

Trigeminal neuralgia (tic douloureux) is defined as sudden, usually unilateral brief stabbing, recurrent episodes of pain in the distribution of one or more branches of the trigeminal nerve by the International Association for the Study of Pain [8]. Some authorities further classify the condition as classic (idiopathic) and symptomatic (associated with a structural abnormality) [9]. Routine neuroimaging may identify a cause in up to 15 % of patients [10]. Patients with bilateral symptoms, younger age, and the presence of trigeminal sensory deficits are more likely to have symptomatic trigeminal neuralgia, though there is significant overlap with the classic form [10]. Carbamazepine has been shown effective for treatment in doses ranging from 300 to 2400 mg per day, as has oxcarbazepine at 600–1800 mg per day. Baclofen, lamotrigine, and pimozide have shown effectiveness in single trials [10]. When symptoms are refractory to treatment with medications, surgical therapy may be considered.

Mononeuropathies

Carpal Tunnel Syndrome

Carpal tunnel syndrome arises from compression of the median nerve. Patients complain of paresthesias, pain, and numbness in the distribution of the median nerve. It presents more commonly in women. Risk factors include obesity, diabetes, pregnancy, menopause, ovariectomy, and hysterectomy [11]. The condition can be caused by repetitive strain injury or other conditions causing edema and inflammation of the synovial sheath. Examination may reveal thenar atrophy and reproduction of symptoms with provocative testing such as Tinel's or Phalen's test. The diagnosis is usually made clinically. One may consider nerve conduction studies when the diagnosis is in question or as a predictor of symptom severity and functional status [12].

Treatment is based on severity of symptoms and physical limitations [11]. In pregnant women, the symptoms usually resolve after birth. Conservative treatment may consist of behavior modification, anti-inflammatory medications and analgesics, splinting, physical and occupational therapy, oral corticosteroids, and ultrasound [13]. Additional treatment with local steroid injection may be attempted when conservative measures fail. In patients who fail conservative treatment or have evidence of median nerve denervation, surgery should be considered [13].

Cubital Tunnel Syndrome

Cubital tunnel syndrome is the second most common entrapment neuropathy after carpal tunnel syndrome. Compression of the ulnar nerve causes pain or paresthesias in its distribution involving the fourth and fifth finger and the medial aspect of the elbow. Conservative therapy consists of splinting and activity modification. Steroid injections do not seem to offer benefit over splinting. Surgery may be considered for persistent symptoms; however, there is controversy as to which patients benefit from surgery [14].

Radial Neuropathies

The characteristic feature of radial tunnel syndrome is pain over the lateral proximal forearm with little or no motor weakness. It is difficult to differentiate this syndrome from lateral epicondylitis due to location of the pain; however, the pain from radial tunnel syndrome should be 3–4 cm distal to the lateral epicondyle [15]. Posterior interosseous nerve syndrome results from compression of the same nerve; however, it results in loss of motor function with patients complaining of motor weakness in the first three fingers. The function of the wrist should be preserved in these cases [15]. Initial therapy for both of these conditions should be rest, activity modification, splinting, and anti-inflammatory medications. Particularly for posterior interosseous nerve syndrome, one should consider removal of any masses such as

DOI 10.1007/978-1-4939-0779-3_74-1

lipomas or ganglions that are causative. Injection of steroids may serve therapeutic and diagnostic purposes for radial tunnel syndrome. If there is no improvement after 3 months, surgery should be considered for both conditions [15].

Posture-induced radial neuropathy, popularly known as Saturday night palsy or sleep paralysis, is a result of prolonged compression of the radial nerve and causes a wrist-drop. The most common cause is due to sleeping with the arm over the back of a chair particularly while drunk. Symptoms usually resolve with conservative treatment of splinting and avoidance of provocative activities. Patients with denervation findings on needle EMG and severe initial weakness have a poorer prognosis for long-term recovery [16, 17].

Lumbosacral Neuropathies

Trauma involving the lumbosacral plexus is much less common than that of the brachial plexus; lumbosacral neuropathy may occur perioperatively (especially with lithotomy positioning), with pregnancy and childbirth, or from compression by aortic aneurysms or tumors. Vascular lesions associated with diabetes may produce a proximal multiple mononeuropathy of the plexus.

The clinically important branches of the upper, lumbar portion of the plexus include the lateral femoral cutaneous nerve, obturator nerve, and femoral nerve. The lower, sacral portion of the plexus gives rise to the inferior and superior gluteal nerves and the sciatic nerve; the sciatic nerve branches to form the common peroneal and tibial nerves.

Meralgia Paresthetica

Compression neuropathy of the lateral femoral cutaneous nerve of the thigh may occur where it passes underneath the inguinal ligament or where it pierces the fascia lata. It occurs most frequently in overweight individuals or in diabetics. Compression may also occur as the result of a tight belt compressing the nerve as it passes over the iliac crest. Patients experience increasingly severe numbness, pain, and paresthesias, as well as decreased sensation of the anterolateral thigh; there is no weakness. Tests such as the pelvic compression test and Tinel's sign performed over the nerve as it exits the inguinal ligament region may help solidify the diagnosis. Treatment is generally conservative with avoidance of compression activities, anti-inflammatory medications, and physical therapy [18].

Femoral Neuropathy

The femoral nerve mediates extension of the leg at the knee through innervation of the quadriceps muscle. Its sensory distribution includes the anteromedial aspect of the thigh and the medial aspect of the lower leg and foot. The femoral nerve is commonly affected by diabetic vascular mononeuropathy, surgical positioning, and inguinal hernia, or tumor involving the lumbar plexus may also compress it.

Sciatic Neuropathy

The sciatic nerve arises from the sacral portion of the plexus. It leaves the pelvis through the sciatic notch and passes down the posterior thigh, where it divides into the tibial and peroneal nerves at the level of the popliteal fossa. The sciatic nerve innervates the extensors of the thigh, the hamstrings, and all of the muscles of the lower leg and foot; it also supplies sensation to the perineum, posterior thigh, lateral calf, and foot. Pain and weakness in the distribution of the sciatic nerve are most commonly the result of lumbar disk herniation, although fractures of the pelvis or femur, gunshot wounds to the buttock and thigh, or pelvic tumors may damage the sciatic nerve itself.

DOI 10.1007/978-1-4939-0779-3_74-1

Peroneal Neuropathy

The common peroneal nerve mediates dorsiflexion and eversion of the foot and supplies sensation to the dorsum of the foot and ankle. It is particularly prone to compression at the level of the fibular head, whether due to trauma, sitting cross-legged, improperly applied stirrups at the time of delivery, or an ill-fitting cast. Diabetic, vasculitic, and hereditary neuropathies may also affect the peroneal nerve.

Interdigital Neuralgia

Entrapment neuropathy of the interdigital nerve is a common cause of foot pain. Morton's neuroma, a benign swelling of the nerve, is usually responsible. Unlike metatarsalgia, there is palpable tenderness between the metatarsal heads in the second or third web spaces. Runners, ballet dancers, and women who wear tight shoes and high heels are particularly prone to the development of a neuroma. Conservative measures may be helpful, but surgical resection is often necessary.

Polyneuropathies

Thoracic Outlet Syndrome

Thoracic outlet syndrome (TOS) encompasses several clinical entities. Currently it is categorized as vascular (arterial and venous), neurologic (true/classic and disputed), and neurovascular/combined (traumatic and disputed). Classic and disputed account for the majority of cases. This type most commonly affects the brachial plexus due to either direct trauma or repetitive stress injury. There is a female predominance. True neurologic TOS is a unilateral disorder affecting mainly women due to fibrous bands extending from a cervical rib causing stretching and compression of the proximal lower trunk of the brachial plexus. Traumatic TOS is most commonly caused by a midshaft displaced clavicle fracture.

Patients present with hand weakness, atrophy, and loss of dexterity. They may also have a preceding history of intermittent medial upper extremity and forearm myalgias and paresthesias. Depending on the rami affected patients will report pain from the head, neck, thorax, shoulder (upper plexus; C5–C6) or neck, medial arm, forearm, and fourth and fifth digits (lower plexus; C8–T1). Motor function is affected preferentially with patchy sensory deficits. There may also be vascular symptoms along the forearm and medial arm. Provocative tests such as Adson maneuver, Halstead test, Roos test, and Wright maneuver may be used to potentiate symptoms. Radiographs may be helpful in revealing the presence of a cervical rib or clavicle fractures.

True neurologic TOS should be treated surgically to disrupt the fibrous band and prevent further nerve damage. Disputed TOS is initially treated medically using multiple modalities that include rest, activity restrictions, analgesics, anti-inflammatory medications, and muscle relaxants. Physical therapy modalities are numerous. Surgical therapy for disputed TOS can be considered after 3 months of attempted medical therapy [19].

Brachial Plexus

Brachial plexopathies may be due to any trauma involving the axilla or causing a violent increase in the angle between the shoulder and head, producing stretching or even tearing of various plexus elements. This injury, the cause of the "burner" or "stinger" syndrome seen in football players, results in temporary numbness, paresthesias, and diffuse weakness of the arm and shoulder [20]. Direct extension of apical lung tumors or breast cancer may cause similar symptoms. It is often difficult to distinguish between metastatic brachial plexopathy and late-onset impairment caused by radiation therapy.

Acute idiopathic brachial neuropathy also known as Parsonage-Turner syndrome or neuralgic amyotrophy is a rare disorder characterized by rapidly progressive pain of neck and shoulder followed

DOI 10.1007/978-1-4939-0779-3_74-1

by progressive weakness and hyporeflexia. The etiology is uncertain, but it has been reported in association with surgery, infections, trauma, and vaccination. The condition is generally self-limited with the pain lasting 1–2 weeks. The weakness may develop days to weeks after the onset of other symptoms. Treatment involves control of pain symptoms with anti-inflammatory medications, opiates, and neuroleptics. There may be some role for oral steroids, but further studies are needed to establish efficacy. Once the initial pain has abated, physical therapy plays a role in strengthening the affected muscles; timing depends on the level of denervation of the muscles [21].

Lumbosacral Plexus

Lumbosacral plexitis is a rare condition that presents with acute onset of severe lower extremity pain followed by wasting and weakness of leg muscles. It is usually unilateral, though many patients may develop bilateral symptoms. Sensory loss is variable. Patients typically have weight loss and elevated erythrocyte sedimentation rates. Mass lesions and trauma should be excluded as causes. One must also look for mimics such as diabetes or Lyme disease. Peak incidence is in children and age 40–60 years. There may be an antecedent history of viral illness or vaccination particularly in children. It is considered an autoimmune disorder with biopsies typically showing microvasculitis. This condition can often be mistaken for lumbar radiculopathy because patients will show abnormalities on magnetic resonance imaging of the spine. Those with milder disease should be offered supportive care and physical therapy. For more severe cases, immunomodulatory therapy may be considered. However, due the rarity of the condition, there is little data to support a specific regimen. Patients with milder disease will resolve over weeks to months with pain improving before the weakness. Some will go on to develop a relapse with progressive disability [22].

Infectious Neuropathies

Postherpetic Neuralgia

Herpes zoster results from reactivation of dormant varicella-zoster virus. Patients develop a vesicular rash and pain in a single dermatome. The postherpetic pain results from direct damage to the peripheral nerve. Classically the condition is defined as pain persisting at least 90 days after the appearance of the rash. Approximately 20 % of patients report some pain at 3 months after onset and 15 % report pain at 2 years. Risk factors for development of the condition include older age and greater severity of the prodrome, rash, and pain during the acute phase.

The only effective method of prevention is with vaccination. A live attenuated varicella-zoster vaccine is available for persons 50 years of age and older and has been shown to reduce the incidence of herpes zoster by 51 % and incidence of postherpetic neuralgia by 66 %. While the use of antiviral drugs has been shown to reduce the severity of acute pain and rash in addition to hastening rash resolution with herpes zoster, the trials did not assess the subsequent incidence of postherpetic neuralgia. Addition of steroids to antiviral treatment has not been shown to reduce the incidence of neuralgia.

Topical therapy is considered first line for mild pain, though evidence is equivocal as to its benefit. Lidocaine patches (Lidoderm) 5 % and capsaicin cream 0.075 % (off-label use) or patch (Qutenza) 8 % may prove helpful. Side effects are minimal and mainly related to local reactions. Several studies have shown benefit with use of tricyclic antidepressants (off-label use), gabapentin, and pregabalin [23, 35].

Leprosy

While uncommon in industrialized countries, leprosy remains one of the most common treatable causes of peripheral neuropathy worldwide, particularly in tropical countries. Typically patients present with

DOI 10.1007/978-1-4939-0779-3_74-1

mononeuritis or mononeuritis multiplex. It causes a predominantly axonal neuropathy with more severe symptoms in the lower limbs. There is a subtype of leprosy in which patients have purely neural symptoms without the classic skin lesions. Diagnosis can be difficult in these patients as it predominantly affects small nerve fibers. Biopsy will assist in establishing the diagnosis [24].

Hepatitis C

Hepatitis C may cause several different patterns of peripheral neuropathy: polyneuropathy, mononeuropathy or multiple mononeuropathies, cranial neuropathy, or a combination of polyneuropathy and cranial neuropathy. Biopsies show inflammatory vascular lesions and axonal degeneration supporting an ischemic mechanism rather than a direct role of the virus [24].

Human Immunodeficiency Virus (HIV) Infection

Neuropathy occurs in approximately 35 % of acquired immunodeficiency syndrome (AIDS) cases. The main patterns are multiple neuropathy, acute or chronic inflammatory neuropathy, polyneuropathy, and distal symmetric neuropathy (DSN). Age, use of antiretroviral medications, severity of HIV infection, diabetes, alcohol use, and race are associated with development of distal symmetric neuropathy in particular. The antiretroviral drugs stavudine, didanosine, and zalcitabine have been implicated as causative in some patients. Differentiation of these drugs versus the virus as the cause can be made by withdrawing the potentially offending agent with improvement of symptoms [24]. Early initiation of highly active antiretroviral therapy significantly lowers the risk of developing distal symmetric neuropathy.

Lyme Disease

In the acute phase, patients with Lyme disease frequently present with subacute cranial neuropathies particularly Bell's palsy. Late disease symptoms are more likely to be symmetric sensory polyneuropathies. In areas with endemic Lyme, many authorities recommend checking titers as a potentially treatable cause of peripheral neuropathies.

Acute Inflammatory Demyelinating Polyradiculoneuropathy (Guillain-Barre Syndrome)

Incidence of Guillain-Barre syndrome (GBS) is 1–2 cases per 100,000. Patients present with acute onset of symmetric ascending motor weakness, although a substantial portion of patients have sensory symptoms. Pain presents in 50–60 % and will sometimes precede the weakness. Patients have decreased or absent deep tendon reflexes. Diagnosis is made mainly on clinical presentation [27]. There is suggestion that host factors play a role, though no definitive genetic link has yet been found. *Campylobacter jejuni* gastroenteritis is the most frequently associated antecedent infection though several other infectious etiologies and vaccines have been implicated.

All patients should be hospitalized to monitor respiratory status, and neurological consultation obtained. Treatment with plasmapheresis or intravenous immunoglobulin (IVIG) should be initiated early in the disease course. These treatments are felt to be equally efficacious [28, 29]. Supportive care with invasive ventilation may be necessary. Intensive rehabilitation produces greater functional improvement and reduces disability in the later stages of recovery [27].

DOI 10.1007/978-1-4939-0779-3_74-1

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is a rare acquired immune-mediated progressive or relapsing disorder causing peripheral neuropathic disease of duration more than 2 months. Incidence is reported to be 1.2–7.7 per 100,000 worldwide with a slight male predominance. Clinically patients present with proximal and distal weakness, sensory involvement, and areflexia. Lab testing may be positive for paraproteins such as anti-myelin-associated glycoprotein and anti-ganglioside antibodies. Cerebrospinal fluid protein levels are usually elevated. Patients often spontaneously improve making clinical treatment trials difficult to interpret. IVIG and corticosteroids are considered first-line treatment. Small studies have shown some benefit of other immunomodulating agents [30].

Metabolic Neuropathies

Diabetic Neuropathy

Diabetic neuropathy is the most common polyneuropathy encountered by family physicians. Neuropathy may occasionally be the presenting feature of diabetes, but more commonly it is related to increasing duration and severity of the disease. Therefore good glycemic control is essential in the prevention or delay of this condition.

Diabetic neuropathies encompass the spectrum of peripheral nerve disorders. Classically, patients experience distal symmetric polyneuropathy with predominantly sensory involvement and mild motor signs (stocking and glove pattern). Damage to the small nerve fibers results in sensations of burning or lancing pains particularly on the soles of the feet. Decrease in sensation may be confirmed with testing using a 10 g monofilament. Damage to the large nerve fibers leads to decreased position sense and may progress to sensory ataxia and arthropathy (Charcot joint).

Patients with diabetes also experience a higher frequency of compression and entrapment mononeuropathies than those without the disease. Diabetic amyotrophy is a multiple mononeuropathy involving the lumbosacral plexus or motor fibers of the lower extremity as described above (lumbosacral plexopathies). This condition is felt to be partly ischemic in nature though evidence also suggests immune-mediated etiology.

Some diabetic patients will present with purely autonomic signs and symptoms. Postural hypotension is common, but gastrointestinal (diabetic gastroparesis, intestinal hypomotility, and constipation or diarrhea) and genitourinary (impotence, neurogenic bladder) symptoms may also occur.

For treatment of painful diabetic neuropathy, only duloxetine and pregabalin are FDA approved; however, studies support use of numerous other agents in the treatment of this condition. Venlafaxine, amitriptyline, gabapentin, valproate, and topical capsaicin are other options for treatment. Opioids and tramadol can be considered also. One should consider the potential side effects and interaction with other medications when choosing an agent [31].

Uremic Neuropathy

Neuropathy is a common complication of end-stage kidney disease, typically presenting as a distal symmetric process similar to diabetic neuropathy. Many of these patients also have diabetes making it difficult to determine the etiology of the neuropathy. Autonomic features may be present. Nerves of uremic patients have been shown to exist in a chronically depolarized state with the degree of depolarization corresponding to serum potassium levels [32]. It is thought that maintenance of near normal potassium levels may improve symptoms. Renal transplantation has been shown to rapidly reverse the symptoms of uremic neuropathy.

DOI 10.1007/978-1-4939-0779-3_74-1

Toxin Induced

Toxic neuropathies develop over several weeks to months as a result of continued exposure to various drugs, industrial toxins, or heavy metals. A progressive, symmetric, ascending polyneuropathy is most frequently seen with occupational exposures. The most commonly implicated drugs include antineoplastic agents, particularly cisplatin and vinca alkaloids, antiretroviral drugs (didanosine, zalcitabine, stavudine), as well as isoniazid, dapsone, and amiodarone. Rare cases of arsenic poisoning, either intentional or from insecticide exposure, may cause a delayed-onset progressive polyneuropathy. Chronic lead exposure causes a predominantly motor neuropathy, typically beginning in the upper limbs, with asymmetric radial neuropathy and wrist-drop. A careful review of potential occupational exposures is the key to diagnosis of neuropathy caused by heavy metals and industrial toxins.

Chemotherapy-induced peripheral neuropathy is predominantly a sensory neuropathy, but may have motor and autonomic changes. There is no effective prevention strategy for this condition, and onset generally requires a dose reduction or cessation of the chemotherapeutic agent. The prevalence is 68.1 % in the first month after chemotherapy and falls to 30 % 6 months after chemotherapy [25]. Risk factors for development of chemotherapy-induced peripheral neuropathy are baseline neuropathy, smoking, abnormal creatinine clearance, and specific sensory changes during chemotherapy [25]. Medications used to treat other neuropathic pain conditions have not been shown to be successful with the exception of one study showing improvement after 5 weeks of treatment with duloxetine [26].

Nutritional Neuropathies

Malnutrition may affect all areas of the nervous system. Risk factors for malnutrition include alcoholism, eating disorders, older age, homelessness, and lower socioeconomic status. Absorption of nutrients may be impaired by several conditions including inflammatory bowel disease, fat malabsorption, chronic liver disease, bowel resection, gastric bypass, and celiac disease.

Alcoholic Neuropathy

The polyneuropathy related to chronic alcoholism is clinically indistinguishable from that due to vitamin deficiencies and may be better classified as toxin induced. Alcohol causes deficiencies by replacing more nutritious foods in the diet, by increasing the requirements for B vitamins (which are needed for its metabolism), and perhaps by impairing vitamin absorption. Alcohol may also have a direct toxic effect on peripheral nerves: in a few patients a neuropathy occurs despite an adequate diet. The prognosis for ultimate, but slow, recovery is good for patients who are able to stop drinking and resume a proper diet with multivitamin supplements.

Vitamin B1 (Thiamine) Deficiency

Neuropathy due to thiamine deficiency or beriberi is associated with alcoholism, recurrent vomiting, AIDS, long-term total parenteral nutrition, eating disorders, and bariatric surgery. It is also responsible for Wernicke's encephalopathy and Korsakoff's syndrome. Features include sensory loss, burning pain, or muscle weakness in the toes and feet. If untreated, the neuropathy will ascend. It may also involve the recurrent laryngeal nerve or cranial nerves manifesting with hoarseness and tongue and facial weakness. Thiamine replacement can occur either intravenously or intramuscularly at an initial dose of 100 mg daily. Symptoms may take 3–6 months to resolve [33].

DOI 10.1007/978-1-4939-0779-3_74-1

Vitamin B6 (Pyridoxine) Deficiency and Toxicity

Vitamin B6 can cause neuropathy both in deficiency and excess. Dietary deficiency is rare; however, many medications interfere with B6 metabolism. Culprits include isoniazid, phenelzine, hydralazine, and penicillamine. It may also be seen in alcoholics, patients on dialysis, and pregnant or lactating women due to high metabolic needs. Symptoms of deficiency are numbness, paresthesias, and burning pain in the feet that ascends. Examination will show decreased distal sensation, reduction of deep tendon reflexes, ataxia, and mild distal weakness. Toxicity causes sensory ataxia, areflexia, and impaired cutaneous sensation. Prophylactic doses of pyridoxine 50 mg per day are recommended for those treated with isoniazid or hydralazine and 10–50 mg for those undergoing dialysis [33].

Vitamin B12 Deficiency

Vitamin B12 is found in animal and dairy products and is liberated from food by stomach acid. Persons at risk for B12 deficiency include patients with malabsorption, pernicious anemia, gastrointestinal surgeries, and strict vegan diets. The neuropathy usually presents with sensory symptoms in the feet and may be associated with anemia or normal blood counts. Patients have increased tone, loss of proprioception and vibration, weakness in the corticospinal tract (hip and knee flexors), brisk reflexes, and extensor plantar responses in the toes. Diagnosis is made with serum levels less than 200 pg/mL or in the low normal range up to 400 pg/mL. Measuring serum methylmalonic acid or homocysteine may improve sensitivity. Treatment is with administration of B12 1000 mcg intramuscularly for 5–7 days followed by 1000 mcg monthly or alternatively starting with once weekly injections for 4 weeks followed by monthly. Patients with cobalamin malabsorption may be treated with oral supplements of 1000 mg daily as they will be able to absorb free cobalamin [33].

Vitamin E Deficiency

Vitamin E is a fat-soluble vitamin; therefore deficiency may take 5–10 years to manifest. Symptoms mimic Friedreich's ataxia with ataxia, hyporeflexia, and loss of proprioception and vibration. Diagnosis is made with alpha-tocopherol levels in the serum. Treatment is with oral supplementation of 400 international units twice daily until normalization of levels. Those with malabsorption syndromes may require water-soluble or intramuscular preparations [33].

Copper Deficiency

Copper deficiency can cause both a peripheral neuropathy and myelopathy. It is mainly caused by prior gastric surgery or excessive zinc intake. Patients present with gait difficulty and lower limb paresthesias. Exam will reveal loss of proprioception and vibration in addition to sensory ataxia. There may also be upper motor neuron signs such as bladder dysfunction, brisk knee jerks, and extensor plantar reflexes. MRI may show increased signal in the posterior columns. Serum levels of copper, ceruloplasmin, and urinary excretion of copper will be low in addition to anemia. If deficiency is due to excessive exogenous zinc, this should be discontinued. Replacement with 2 mg of elemental copper three times daily via oral route is preferred [33].

Hereditary Neuropathies

Hereditary neuropathies are estimated to occur in 1 per 10,000 individuals. Due to the slowly progressive, indolent course of these disorders, many patients do not recall other family members being affected and in some cases they do not recognize the abnormalities in themselves. The hereditary neuropathies are typically associated with foot drop, high-arched feet (pes cavus), hammertoe deformities, slowly progressive weakness and wasting of peroneal muscle groups, and a high-stepping, slapping gait. Sensory symptoms are much less prominent.

DOI 10.1007/978-1-4939-0779-3_74-1

The genetics and pathophysiology of numerous hereditary neuropathies have been elucidated; however, just two types of hereditary motor and sensory neuropathies (HMSN I, HMSN II) represent virtually all forms of this disorder. HMSN I, a demyelinating process with onset during the teenage years, constitutes roughly 70 % of the hereditary neuropathies. Nearly all other hereditary neuropathies are HMSNII (formerly called Charcot-Marie-Tooth or peroneal muscle atrophy), a primarily axonal degeneration with secondary demyelination that occurs during the fourth decade of life or later. These two types share an autosomal dominant inheritance; however, many subtypes have been identified with varying inheritance patterns. Specific genetic tests are now available to confirm the diagnosis of many of the hereditary neuropathies [34].

There is no specific treatment for any of these disorders; genetic counseling and education are needed. Patients with this disorder frequently have deformities of the foot that can be managed with physical therapy. Disability varies widely between families. Animal trials have shown promise using ascorbic acid and progesterone antagonists. Clinical studies are ongoing.

Treatment

Appropriate treatment for any underlying diseases should be instituted (e.g., control of glucose, thyroid replacement). Offending toxins or medications should be stopped and nutritional deficiencies corrected. Other disease-specific treatments are addressed above.

Neuroleptic drugs and tricyclic antidepressants have been the mainstay of treatment for neuropathic pain. Patients can be started on amitriptyline, duloxetine, gabapentin, or pregabalin initially [35]. Gabapentin and pregabalin have the best evidence for treatment of painful diabetic neuropathy, postherpetic neuralgia, and central neuropathic pain [36]. Gabapentin and carbamazepine also show efficacy in treatment of pain associated with Guillain-Barre syndrome [37]. Other neuroleptics may have benefit in individual patients. Tramadol may be considered for acute pain, but opioids are not recommended for chronic treatment of neuropathic pain as they have questionable efficacy with deleterious side effects and safety concerns [38].

Meningitis

Background

Meningitis is defined as an acute inflammation of the meninges, which may result in significant morbidity and mortality. Meningitis may be caused by infectious agents (bacteria, viruses, parasites, and fungi) or may arise from a noninfectious etiology (cancer, systemic lupus erythematosus, certain medications, head injury, and brain surgery). When caused by an infectious agent, approximately one in four cases of meningitis is bacterial, with an additional 10 % due to fungus and other non-viral agents. The remainder is due to viruses. In the United States, bacterial meningitis occurs at a rate of 1.38 cases per 100,000 population per year, with a case fatality of approximately 15 %. The causative bacterial agent varies with age. Under 2 months of age, group B streptococcus is the most common bacterial agent, and in those 11–17 years of age, *Neisseria meningitides* is the most common bacterial agent. In all other pediatric age groups and in adults, *Streptococcus pneumonia* is the most common bacterial agent. Viral meningitis is most commonly caused by enteroviruses followed by herpes simplex virus type 2 and varicella zoster virus. The most common causes of fungal meningitis are *Cryptococcus neoformans* and *Cryptococcus gattii* [1].

Presentation

About half (44 %) of adults will have a "textbook" presentation of meningitis, the triad of fever, neck stiffness, and change in mental status. However, the most frequent symptom in adults subsequently found to have meningitis is headache, followed by neck stiffness, fever, and change in mental status. Using a dyad (two of four of the following: headache, fever, neck stiffness, or a change in mental status) increased the positive predictive value to 95 %. Only 4 % of patients subsequently diagnosed with meningitis had one symptom, with 1 % having none of the four symptoms. The clinical presentation of meningitis for children under the age of three is usually more subtle and atypical, may not have any of the four cardinal symptoms, and may present only with irritability and lethargy.

Diagnosis

History

Aside from making the diagnosis, a carefully taken history is important to determine if there are any predisposing or complicating factors. These include infectious illness, immunocompromised state, previous neurosurgical procedure, and immunization status. However, clinical history alone is not sufficient to diagnose meningitis.

Physical Examination

The physical exam for meningitis is focused on finding and documenting neurologic deficits on presentation. In addition to documenting meningeal signs (jolt accentuation of headache, Kernig's and Brudzinski's signs), the physical exam should include an assessment of the rest of the neurologic system including the Glasgow Coma Score. The presence of meningeal irritation is assessed by laying the patient supine and gently flexing the neck forward while examining the neck for rigidity. Kernig's sign is performed with the patient supine and the hip flexed to 90 °. A positive sign is present when extension of the knee from this position elicits resistance or pain in the lower back or posterior thigh. Brudzinski's sign is present with passive neck flexion in a supine position results in flexion of knees and hips. The jolt accentuation of headache is positive if the patient's headache worsens when turning his or her head horizontally 2–3 rotations per second. The sensitivity and specificity for neck stiffness for meningitis are 30 % and 68 %, for Kernig's sign are 5 % and 95 %, and for Brudzinski's sign are 5 % and 95 %, respectively. Since these bedside diagnostic tools have poor sensitivity, further diagnostic testing should not be precluded by the absence of these clinical signs [2].

Cerebrospinal Fluid Examination

Prompt examination of the cerebrospinal fluid (CSF) is required for diagnostic confirmation of meningitis. Imaging for intracranial lesions should be performed prior to lumbar puncture (LP) in patients with altered mentation, focal neurological findings, and papilledema or if there is clinical suspicion of increased cranial pressure. Other relative contraindications to performing a lumbar puncture include local infection at the puncture site, recent administration of anticoagulation within the past hour, and platelet count less than $20 \times 10^3/\mu L$. Videos of how to perform a LP are readily available online.

When possible, opening pressure of the CSF within the spinal canal should be documented. Normal opening CSF pressure is 10–100 mm H_2O in young children, 60–200 mm of H_2O after 8 years of age, and up to 250 mm of H_2O in obese patients. 1–5 ml samples of CSF are normally placed into four tubes, numbered in the order in which they were collected. Tube 1 is used for cell count, tube 2 for protein and glucose, tube 3 for specific tests as indicated (e.g., latex agglutination for bacterial and viral antigens, polymerase chain reaction), and tube 4 for cultures. Normal values are easily obtained from multiple references and may vary with the patient's underlying condition [3].

Laboratory Testing and Imaging

Additional testing should include a complete blood count with differential, complete metabolic panel, and blood culture. Cultures should be obtained from blood as well as other potential sources of infection. Additional imaging performed should be obtained as warranted by clinical suspicion.

Treatment

Antibiotic therapy should be initiated as soon as possible after the diagnosis of meningitis is entertained and should not be delayed to obtain a CSF sample. Antibiotic choice is dependent on age, comorbidities (e.g., immunodeficiency, prior neurosurgical procedures), and situation (e.g., head trauma). For most suspected meningitis cases, an initial broad-spectrum approach such as vancomycin and a third-generation cephalosporin is suggested as an empiric antibiotic regimen with subsequent changes based on culture results. For adults older than 50 years, the regimen should include ampicillin, as well as vancomycin and a third-generation cephalosporin. For infants younger than 1 month, the suggested empiric antibiotic regimen should include ampicillin and cefotaxime or ampicillin and an aminoglycoside. The use of dexamethasone remains controversial. If herpes simplex meningitis is clinically suspected, empiric treatment should include acyclovir. For uncomplicated cases of viral meningitis, no specific antibiotic therapy is necessary.

Course and Prognosis

Without treatment, mortality of patients with bacterial meningitis approaches 100 %. However, even with treatment, the mortality rate for children is 3 % and for adults is 21 %. Hearing loss is seen in 14 % of adult patients and hemiparesis in 7 % of adult patients. Stroke is seen in 3 % of children [4, 5].

Special Considerations

Chronic Meningitis

Chronic meningitis is defined as "irritation and inflammation of the meninges persisting for more than 4 weeks associated with pleocytosis in the cerebrospinal fluid." Chronic meningitis may be caused by persistent infection, allergic inflammatory reaction to an infection, autoimmune disease, or chemical and drug exposure. Clinical presentation is often nonspecific and only becomes similar to that of acute meningitis over time. The approach to diagnosis is necessarily broad, but an accurate and detailed history and physical exam will help to narrow the differential diagnosis. Up to one-third of patients with chronic meningitis will not have a definitive diagnosis even after a thorough and complete investigation [6].

Noninfectious Meningitis

Medications [trimethoprim–sulfamethoxazole (Bactrim), ibuprofen (Motrin), and naproxen (Naprosyn)] and medical procedures (intrathecal injections and neurosurgical procedures) can rarely cause noninfectious meningitis. Brain tumors may cause "chemical" meningitis due to the lipid-induced chemical irritation and may require repeated LPs and careful examination of CSF for diagnosis. Connective tissue diseases and vasculitis syndromes have been reported to be associated with noninfectious meningitis, especially sarcoidosis, systemic lupus erythematosus, and Behçet's disease [7].

Prevention

Vaccines as primary prevention have been successful in greatly reducing the incidence of bacterial meningitis in children and adults – especially since their addition to the childhood vaccine schedule. Vaccines are available for *Haemophilus influenzae* type b, *Neisseria meningitis*, and *Streptococcus pneumonia*. Guideline for chemoprophylaxis for close contacts of individuals diagnosed with bacterial meningitis is available. In addition, universal screening of all pregnant women for group B streptococcal disease with subsequent treatment during labor has caused a marked decline in perinatal group B streptococcal disease [5].

Encephalitis

Background

Encephalitis is the presence of an inflammatory process of the parenchyma of the brain in association with clinical evidence of neurological dysfunction. Encephalitis can be caused by a large variety of pathogens. Of the cases where an etiology was identified, most were viral, followed by bacterial, prion-related, parasitic, and fungal etiologies. In the majority of cases, an etiology will not be identified. In the United States, the most commonly identified etiologies are herpes simplex virus (HSV), West Nile virus, and enteroviruses, followed by other herpesviruses. Exposure can be immediately proximate to the onset of symptoms or delayed such as encephalitis associated with measles, congenital rubella, or HIV. HSV encephalitis can be either acute (33 %) or the result of reactivation of latent infection (66 %).

Presentation

The presentation of encephalitis is very similar to that of meningitis and includes fever, headache, nausea and vomiting, and altered level of consciousness often associated with seizures and focal neurological findings. Other common findings include disorientation, speech disturbances, and behavioral changes. Alterations in mental functions may cause lethargy, drowsiness, confusion, disorientation, and coma.

Diagnosis

History and Physical Exam

As the differential diagnosis of encephalitis is broad, a thorough history and physical exam are necessary to narrow the differential diagnosis list. Helpful questions to ask during history taking to determine the etiology include age, animal contact, immunocompromised states, ingested items, insect contact, occupation, recent sick contacts, recent vaccinations, recreational activities, season, transfusion and transplantation, travel history, and vaccination status. A detailed physical exam with careful attention paid to a careful neurological exam may be helpful in narrowing the differential diagnosis list as certain physical exam findings are associated with specific etiologies (see Table 1).

Laboratory Testing

Cerebrospinal fluid (CSF) analysis is essential to diagnosis in all patients with encephalitis (unless contraindicated) and will typically demonstrate lymphocytic pleocytosis with normal glucose and a modest elevation of protein. CSF should be analyzed for virus-specific IgM antibodies and nucleic acid amplification – especially herpes

Table 1 Findings associated with specific etiologies

Etiology	Findings
Herpes simplex virus	Frontotemporal signs Mucous membrane lesions
Rabies	Psychomotor excitation Bulbar dysfunction and spasm
Creutzfeldt–Jakob disease	Subacute personality changes Dementia with myoclonus

Adapted from Refs [9, 10]

simplex polymerase chain reaction (PCR). Other studies should include complete blood count; tests of renal and hepatic function; coagulation studies and chest radiography; cultures of body fluid specimens; biopsy of specific tissue for cultures, antigen detection, nucleic acid amplification tests, and histopathology examination; serological testing of IgM antibodies; acute- and convalescent-phase serum samples for retrospective diagnosis of an infectious agent; nucleic acid amplification of body fluids outside of the CNS; and peripheral blood smear. Additional diagnostic studies should be performed on the basis of specific epidemiological and clinical clues.

Imaging

Magnetic resonance imaging (MRI) of the brain is the most sensitive neuroimaging test to evaluate patients with encephalitis, although computerized tomography (CT), with and without contrast, should be used in patients if MRI is unavailable, impractical, or cannot be performed. MRI may show characteristic patterns seen with specific agents in patients with encephalitis.

Treatment

All patients with encephalitis should empirically be started on acyclovir (Zovirax) 10 mg/kg (500 mg/m^2 for children <12 years) IV infused over 1 h every 8 h for 14–21 days pending results of diagnostic tests and elimination of the possibility of HSV as a causative agent. Other antimicrobial agents should be started on the basis of specific epidemiological or clinical factors, including appropriate therapy for bacterial meningitis. In patients with clinical and epidemiological clues suggestive of rickettsial or ehrlichial infection during the appropriate season, doxycycline (Vibramycin) 100 mg twice daily for 10–14 days should be added to the empirical regimen. Specific therapy should be tailored based on the results of diagnostic testing.

Course and Prognosis

Morbidity and mortality remain high with encephalitis. Poor prognostic factors include age above 60, reduced Glasgow Coma Score on admission, and, for HSV encephalitis, delay between hospitalization and starting treatment with acyclovir. The mortality rate for encephalitis is dependent on the causative organism ranging from less than 5 % with ehrlichiosis to 33 % with Eastern equine encephalitis virus to 100 % with rabies. In addition, approximately two-thirds of survivors will have significant neuropsychiatric sequelae including memory impairment, personality and behavioral change, dysphagia, and seizures [8–10].

Brain Abscess

Background

Brain abscesses, or focal intracerebral infections consisting of an encapsulated collection of pus caused by bacteria, mycobacteria, fungi, protozoa, or helminths, are most commonly caused by bacteria. *Streptococcus* species is the most common causative agent, followed by *Staphylococcus* species, then gram-negative enteric species. Brain abscesses are rare, with the incidence estimated to be 0.3–1.3 per 100,000 people per year. The incidence is significantly higher in developing countries and in patients who are alcoholic, are immunosuppressed (e.g., acquired immune deficiency syndrome, chemotherapy, biologic drugs), have cyanotic heart conditions, or are severely debilitated by neurological conditions. Brain abscesses most often arise from direct invasion

from a contiguous focus of infection (i.e., otitis, mastoiditis, sinusitis, meningitis, and odontogenic). They can also be secondary to blood-borne pathogens (i.e., pulmonary focus or heart disease) or arise in areas of previous head trauma.

Presentation

An area of damaged brain tissue allows a nidus of infection to occur with subsequent local areas of infarction. Cerebritis follows as the area becomes necrotic and encapsulated within a few weeks. Presentation is dependent on mechanism and pathogen, which includes focal mass expansion, increased intracranial pressure, diffuse destruction, or focal neurological deficit. Clinical signs and symptoms of brain abscesses are varied and commonly include fever, headache, hemiparesis of a cranial nerve, hemiparesis, meningism, altered level of consciousness, seizure, nausea and vomiting, and papilledema.

Diagnosis

Physical Exam

The most common symptoms of brain abscess are headache (69 %), fever (53 %), and focal neurological deficits (48 %). However, as a triad, the three together only occur in 20 % of patients with brain abscesses. A high index of suspicion is required to make the diagnosis, particularly in febrile patients with a history of central nervous system instrumentation.

Laboratory Studies

Laboratory studies, such as blood cultures, complete blood count, and chest radiograph, are commonly performed, but may not provide useful data, as only 28 % of blood cultures were positive in one study. CSF cultures are often sterile, and lumbar puncture is not recommended and may be contraindicated due to increased intracranial pressure.

Neuroimaging

Diagnosis is dependent on neuroimaging. Classically, a hypodense lesion with a contrast-enhancing ring will be seen on computed tomography (CT) of the brain or magnetic resonance imaging (MRI) of the brain. CT of the brain allows for detection, localization, characterization, and is ubiquitous in emergency departments. In addition, CT of the brain can detect hydrocephalus, increased intracranial pressure, edema, and other associated infections. However, CT of the brain has a 6 % false-negative rate. Diagnosis of brain abscess by MRI of the brain is more accurate than CT, but MRI is not as ubiquitous or available as CT and so is less commonly used.

Treatment

Treatment of brain abscess requires a combination of antibiotic treatment, surgical intervention, and eradication of the primary foci. Successful treatment of brain abscesses often requires drainage under CT guidance in addition to antibiotic therapy.

Antibiotic Therapy

Until the abscess can be drained and cultured, empiric antibiotic therapy should consist of broad-spectrum antibiotics that easily cross the blood–brain, and blood–CSF barriers should provide coverage for the most common pathogens. Acceptable antibiotic choices include a third-generation cephalosporin and metronidazole. Vancomycin should be added if there is a history of penetrating trauma or recent neurosurgical procedure. Antibiotic therapy should be tailored for patients with specific immune function defects, transplant recipients, cancer, and on chronic steroid therapy. However, as cultures are often sterile, broad-spectrum antibiotics should be continued for the entire course.

Duration of antimicrobial therapy has been suggested to be 4–6 weeks for a surgically drained abscess, 6–8 weeks for a brain abscess solely treated with antibiotics, and 3–12 months for immunocompromised patients.

Neurosurgical Intervention

Emergent drainage of brain abscesses is indicated as part of the management and to establish the causative pathogen due to the high sterile culture rate. Aspiration has become the preferred method for drainage providing relief from increased intracranial pressure and avoids the possibility of damage to the surrounding brain. However, aspiration often (70 %) requires repeat procedure and can possibly cause iatrogenic puncture of the ventricle and subarachnoid leakage of pus leading to extension of the brain abscess.

Adjunctive Therapy

Steroids are generally avoided except in the perioperative period. They are indicated for reduction of intracranial pressure and avoiding acute brain herniation in those patients that demonstrate signs of meningitis or disproportionate cytotoxic edema posing a life-threatening problem. Steroids should be tapered as rapidly as possible.

Anticonvulsants are commonly used to control seizures and are used as prophylaxis for subsequent seizures after resolution of brain abscesses. Anticonvulsants are recommended to be continued for 5 years after resolution of the brain abscess. However, discontinuing anticonvulsants may be considered if the patient has been seizure-free for 2 years after surgery and no epileptic activity is seen on electroencephalography (EEG). The law regarding driving with a diagnosis of seizure is dependent on the state, but usually requires being seizure-free for 6–12 months prior to resumption of driving.

Course and Prognosis

The mortality rate of brain abscesses has declined by 50 %, from 20 % to 10 % in recent years. Approximately half of patients will have a good outcome, but the other half will either die or have neurological sequelae. Poor prognostic indicators include delayed diagnosis, rapidly progressing disease, coma, multiple lesions, intraventricular rupture, and fungal etiology. Outcomes are worse in the elderly and newborn. Neurological sequelae include focal neurologic deficits, intellectual disability, and postoperative seizures [11–13].

Neurosyphilis

Background

Syphilis is a sexually acquired condition caused by infection with *Treponema pallidum* and is known as the "great imitator" due to its varied presentation. Although syphilis was close to eradication in 2000, in the years between 2005 and 2013, syphilis has increased in annual rate from 2.9 to 5.3 cases per 100,000 population [14].

Presentation

Syphilis is divided into primary infection (ulcer or chancre), secondary infection (skin rash, mucocutaneous lesions, lymphadenopathy), neurologic infection (cranial nerve dysfunction, meningitis, stroke, acute or chronic altered mental status, loss of vibration sense, and auditory or ophthalmic abnormalities), and tertiary infection (cardiac or gummatous lesions). However, neurosyphilis can occur at any stage of infection and has three distinct patterns of occurrence. Asymptomatic neurosyphilis is defined as the presence of cerebrospinal fluid (CSF) abnormalities consistent with neurosyphilis in persons with serological evidence of syphilis and no neurological signs or symptoms. Early symptomatic neurosyphilis involves diffuse inflammation of the meninges and presents similarly to meningitis – headache, photophobia, nausea, vomiting, cranial nerve palsies, and occasionally seizures. Lastly, meningovascular syphilis consists of endarteritis of vessels anywhere in the central nervous system resulting in thrombosis and infarction.

Headache, vertigo, and insomnia often occur early in the course of infection. Dramatic symptoms such as the sudden onset of contralateral hemiparesis, hemianesthesia, homonymous hemianopsia, and aphasia lead to a more rapid diagnosis. Symptoms of syphilis involving the spinal cord include spastic weakness of the legs, sphincter disturbances, sensory loss, and muscle atrophy. Parenchymatous syphilis may manifest as either paretic neurosyphilis ("general paralysis of

the insane") or tabetic neurosyphilis ("tabes dorsalis"). Early symptoms of paretic neurosyphilis include irritability, forgetfulness, personality changes, headaches, and changes to sleep habits, while late symptoms include emotional liability, impaired memory and judgment, disorientation, confusion, delusions, seizures, and other psychiatric symptoms. Tabetic neurosyphilis presents classically as ataxic gait, lightening pains, paresthesias, bladder dysfunction, and failing vision.

Diagnosis

Physical Exam

Depending on the stage and presentation of neurosyphilis, the physical exam may be unremarkable or may be similar to other disease processes. Physical exam findings may include papillary abnormalities (Argyll Robertson pupils), diminished reflexes, impaired vibratory sense and proprioception, ocular palsies, and Charcot joints (progressive degeneration of weight-bearing joints) [15, 16].

Laboratory Studies

The diagnosis of syphilis is made using a combination of serological tests [Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR)], treponemal tests [fluorescent treponemal antibody absorbed (FTA-ABS) or *T. pallidum* passive particle agglutination (TP-PA)], or dark-field examination. Laboratory testing can only be used to support the diagnosis of neurosyphilis, but no single test can be used to diagnose neurosyphilis in all circumstances. The identification of serologic changes in the cerebrospinal fluid (CSF-VDRL) has a high specificity, but low sensitivity. CSF-VDRL can be positive in early syphilis, but is a finding of uncertain significance. CSF can be tested for treponemal antibodies using FTA-ABS. This is more sensitive than CSF-VDRL, but less specific. Therefore, diagnosis of neurosyphilis is a combination of reactive serological test results and a reactive CSF-VDRL, in the presence of signs of CSF inflammation (elevated cell count and protein), with or without clinical manifestations.

Treatment

Antimicrobial Treatment

Penicillin is the preferred drug for treating all stages of syphilis – including in pregnancy. Those with a penicillin allergy should undergo desensitization and be treated with penicillin.

A frequent reaction to the administration of penicillin G at any stage of syphilis is the Jarisch–Herxheimer reaction, which is an acute febrile reaction frequently accompanied by headache, myalgia, and fever. Although this may induce early labor or fetal distress in pregnant women, this should not delay or prevent therapy.

Penicillin G 18–24 million units per day is the preferred dosage and should be administered as 3–4 million units by IV every 4 h or as a continuous infusion for 10–14 days. If compliance is an issue, an alternative regimen is procaine penicillin 2.4 million units once daily and probenecid 500 mg orally four times daily for 10–14 days.

If CSF pleocytosis was present initially on examination, repeat CSF examination should occur every 6 months until the cell count is normal. If cell count or protein is not normal after 2 years, retreatment should be considered.

Special Considerations

Persons who are exposed to syphilis via intimate contact at any stage should be evaluated clinically and serologically. If the exposure was within 90 days preceding the diagnosis of any stage of syphilis – even if the exposed person is seronegative – he or she should be treated presumptively. Persons who are exposed 90 days or more prior to diagnosis of any stage of syphilis in a sex partner should have serologic testing prior to treatment. However, the exposed person should be treated presumptively if serological testing is not available immediately and follow-up is uncertain. In addition, intimate partners of infected patients should be provided presumptive treatment if

Table 2 Distribution of primary brain tumors by histology

Histology	Percentage of total
Meningioma	36.1 %
Glioblastoma	15.4 %
Tumors of the pituitary	15.1 %
Nerve sheath tumors	8.0 %
All other astrocytomas	6.0 %
Lymphomas	2.1 %
Ependymal tumors	1.9 %
Oligodendrogliomas	1.6 %
Embryonal tumors	1.1 %
Oligoastrocytic tumors	0.9 %
All other	11.8 %

Adapted from Ref [18]

they have had sexual contact with the patient within 3 months plus the duration of symptoms for primary syphilis, within 6 months plus duration of symptoms for secondary syphilis, and within 1 year for patients with early latent syphilis [17].

Brain Tumors

Background

Primary brain tumors are rare, accounting for 1.4 % of all new cancer cases with an incidence of 5.42 per 100,000 children aged 0–19 years and 27.9 per 100,000 adults aged 20 years and older. Approximately 34 % of all primary brain tumors are malignant. The most common types of primary brain tumor are malignant glioblastoma and meningioma. In adults, the most common types of primary brain tumor are glioblastoma, meningioma, astrocytoma, and pituitary adenoma, while in children, the most common types of primary brain tumors are tumors of pilocytic astrocytoma, embryonal tumors, and malignant glioma (see Table 2) [18].

Metastatic disease to the CNS is much more common than primary brain tumors occurring up to ten times as often as primary brain tumors. Although primary lung cancers are the most common source of metastatic lesions, melanoma and breast cancer are becoming more frequent. Approximately 80 % of brain metastases occur in the cerebral hemispheres, followed by 15 % in the cerebellum, and 5 % in the brainstem.

Presentation

The presenting signs and symptoms of metastatic brain lesions are similar to other mass lesions and can be separated into focal or generalized symptoms. Focal symptoms are dependent on tumor location. For example, focal symptoms of brain tumors in the frontal lobe include dementia, personality changes, gait disturbance, expressive aphasia, and seizures; in the parietal lobe include receptive aphasia, sensory loss, hemianopia, and spatial disorientation; in the temporal lobe include complex partial or generalized seizure, behavior change, including symptoms of autism, and quadrantanopia; in the occipital lobe include contralateral hemianopia; in the thalamus include contralateral sensory loss, behavior change, and language disorder; in the cerebellum include ataxia, dysmetria, and nystagmus; and in the brainstem include cranial nerve dysfunction, ataxia, papillary abnormalities, nystagmus, hemiparesis, and autonomic dysfunction. Generalized symptoms include headache, memory loss, cognitive changes, motor deficit, language deficit, seizures, personality change, visual problems, changes in consciousness, nausea or vomiting, sensory deficit, and papilledema [19].

Diagnosis

Diagnosis is dependent on appropriate brain imaging followed by histopathology to confirm diagnosis. Acute headaches with red flag symptoms should prompt immediate imaging (See Table 3) [20]. The imaging modality of choice is gadolinium-enhanced magnetic resonance imaging (MRI). For those who cannot have a MRI performed, computed tomography (CT) of the head and spine is acceptable; however, CT does not have as high of a resolution as MRI and is

Table 3 Red flag symptoms that should prompt immediate imaging

Red flag	Differential diagnosis
Headache beginning after 50 years of age	Temporal arteritis, mass lesion
Sudden onset of headache	Subarachnoid hemorrhage, pituitary apoplexy, hemorrhage into a mass lesion or vascular malformation, mass lesion
Headaches increasing in frequency and severity	Mass lesion, subdural hematoma, medication overuse
New-onset headache in a patient with risk factors for HIV infection or cancer	Meningitis (chronic or carcinomatous), brain abscess (including toxoplasmosis), metastasis
Headache with signs of systemic illness (fever, stiff neck, rash)	Meningitis, encephalitis, Lyme disease, systemic infection, collagen vascular disease
Focal neurological signs or symptoms of disease (other than typical aura)	Mass lesion, vascular malformation, stroke, collagen vascular disease
Papilledema	Mass lesion, pseudotumor cerebri, meningitis
Headache subsequent to head trauma	Intracranial hemorrhage, subdural hematoma, epidural hematoma, posttraumatic headache

Adapted from Ref [20]

unable to adequately assess lesions in the posterior fossa and spine.

Treatment

Due to the varied course and symptoms of primary and metastatic brain tumors, prognosis and treatment are highly individualized and are dependent on age and performance status of the patient, proximity to "eloquent" areas of the brain, feasibility of decreasing the mass effect, resectability of the tumor, and time since last surgery for those with recurrent disease. In general, regardless of tumor histology, the best outcome is through a combination of maximal safe resection (stereotactic biopsy, open biopsy, subtotal resection, or complete resection) and radiation therapy (brachytherapy, fractionated external beam radiotherapy, or fractionated stereotactic radiotherapy). Whole brain radiotherapy and stereotactic radiosurgery is often reserved for metastatic disease.

Symptom Treatment

Corticosteroids may be necessary to treat vasogenic edema. Often, corticosteroids need to be tapered slowly, although side effects of long-term use of corticosteroids include cognitive impairment, hypoglycemia, gastrointestinal problems, myopathy, and opportunistic infections. Seizures are common with brain tumors, including after surgery. However, prophylactic use of antiseizure medications is not indicated [21].

Course and Prognosis

Prognosis is dependent on histopathology (oligodendrogliomas have a better prognosis than mixed gliomas, which have a better prognosis than astrocytomas) and tumor grade. Younger age, good initial performance score, and O6-methylguanine methyltransferase (MGMT) gene promoter hypermethylation are associated with a more favorable prognosis [22].

Multiple Sclerosis

Background

Multiple sclerosis (MS) is a disabling demyelinating immune-mediated disease of the central nervous system (CNS) that disproportionately affects women, smokers, persons living at higher latitudes, and persons with a family history of MS. Increased exposure to sunlight and higher 25-hydroxyvitamin D levels confer lower risk. The incidence of MS ranges from 47.2 to 109.5 per 100,000 persons in the United States [23].

Presentation

The clinical presentation of MS is varied and can include symptoms such as depressed mood,

dizziness or vertigo, fatigue, hearing loss and tinnitus, loss of coordination and gait disturbance, pain, sensory disturbances (dysesthesias, numbness, paresthesias), urinary symptoms, visual disturbances (diplopia and oscillopsia), and weakness and can include signs such as ataxia, decreased sensation (pain, vibration, position), decreased strength, hyperreflexia, spasticity, nystagmus, and visual defects (internuclear ophthalmoplegia, optic disk pallor, red color desaturation, or reduced visual acuity) [24, 25].

Diagnosis

History, Physical Exam, and Diagnostic Imaging

The current guideline for diagnosis of multiple sclerosis (MS), the 2010 revisions to the McDonald Criteria, requires a combination of history, physical exam, and diagnostic imaging. An attack is defined as "patient-reported symptoms or objectively observed signs typical of an acute inflammatory demyelinating event in the central nervous system (CNS), current or historical, with duration of at least 24 h, in the absence of fever or infection." The diagnostic criteria for MS based on clinical presentation are listed in Table 4 [26].

Differential Diagnosis

MS has a broad differential diagnosis, and consideration should be given to testing angiotensin-converting enzyme levels, autoantibody titers, *Borrelia* titers, human immunodeficiency virus (HIV) screening, rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL), thyroid-stimulating hormone, and vitamin B12 level.

Treatment

Disease-Modifying Agents

The mainstay of treatment of MS is disease-modifying agents, which slow disease progression, preserve function, and sustain the immune system while suppressing the T-cell autoimmune cascade. Approved disease-modifying agents, which include interferon beta, glatiramer, fingolimod, teriflunomide, dimethyl fumarate, natalizumab, and mitoxantrone, are usually managed by an experienced neurologist.

Exacerbations

Exacerbations are common, affecting over 85 % of patients with MS, and are often caused by infection or stress. Oral corticosteroids are the mainstay of the treatment of exacerbations. However, if there is no response to corticosteroids, plasmapheresis or plasma exchange may be performed.

Symptom-Specific Management

Neurogenic bladder, affecting more than 70 % of patients with MS, may be alleviated with anticholinergic medications for failure-to-store symptoms; limiting evening fluid intake, desmopressin, or injections of onabotulinumtoxinA for nocturia; and clean intermittent catheterization or alpha-adrenergic blockade for failure-to-empty symptoms. Neurogenic bowel, affecting more than 75 % of patients, may present with incontinence, constipation, or both and may require a colostomy if symptoms are intolerable. Sexual dysfunction is common, but often unaddressed. Men may be treated with centrally acting phosphodiesterase-5 inhibitors, although women have no similarly approved medication. Pain will affect approximately 85 % of patients with MS (trigeminal neuralgia and neuropathic pain most commonly). Trigeminal neuralgia may be treated with carbamazepine and baclofen, while neuropathic pain may be treated with tricyclic antidepressants, anticonvulsants, or selective serotonin reuptake inhibitors. Spasticity should be treated with baclofen, although diazepam, gabapentin, or onabotulinumtoxinA may also be helpful. Treatment of fatigue, present in more than 90 % of patients with MS, is multifocal and includes environmental manipulation (controlling heat and humidity levels) and energy conservation measures (napping and use of assistive devices for mobility). Amantadine has been used off-label for the pharmacological management of fatigue, but may cause insomnia and confusion [24].

Table 4 Diagnostic criteria for multiple sclerosis

Clinical presentation	Additional data needed for MS diagnosis
≥2 attacks; objective clinical evidence of ≥2 lesions or objective clinical evidence of one lesion with reasonable historical evidence of a prior attack	None
≥2 attacks; objective clinical evidence of one lesion	Dissemination in space, demonstrated by: ≥1 T2 lesion in at least 2 of 4 MS-typical regions of the CNS Awaiting another clinical attack implicating a different CNS site
One attack; objective clinical evidence of ≥2 lesions	Dissemination in time, demonstrated by: Simultaneous presence of asymptomatic gadolinium-enhancing and non-enhancing lesions at any time A new T2 and/or gadolinium-enhancing lesion (s) on follow-up MRI, irrespective of its timing with reference to a baseline scan Await a second clinical attack
One attack; objective clinical evidence of one lesion (clinically isolated syndrome)	Dissemination in space and time, demonstrated by: For DIS: ≥1 T2 lesion in at least 2 of 4 MS-typical regions of the CNS Await a further clinical attack implicating a different CNS site For DIT: Simultaneous presence of asymptomatic gadolinium-enhancing and non-enhancing lesions at any time A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan Await a second clinical attack
Insidious neurological progression suggestive of MS (PPMS)	One year of disease progression (retrospectively or prospectively determined) plus two of three of the following criteria: 1. Evidence for DIS in the brain based on ≥1 T2 lesion in at least two of four MS-typical regions of the CNS 2. Evidence for DIS in the spinal cord based on ≥2 T2 lesions in the cord 3. Positive CSF (isoelectric focusing evidence of oligoclonal bands and/or elevated IgG index)

Adapted from Ref [26]
MS-typical regions of the CNS include periventricular, juxtacortical, infratentorial, or spinal cord

Course and Prognosis

MS has an extremely varied course, characterized by two broad pathways. Primary-progressive MS is characterized by the invariable progression despite occasional plateaus or temporary minor improvements, with an average time to disability requiring use of a cane to ambulate of 6–21 years. Those diagnosed with relapsing-remitting and secondary-progressive MS tend to have an initial relapsing-remitting disease course, progressing to less prominent relapses and ensuing relentless progression. In these patients, the relapsing-remitting phase lasts for about 20 years prior to the secondary-progressive phase. The introduction of disease-modifying agents has increased

the life span of a patient with MS, but is still approximately a decade shorter than expected from an age-matched general population [25].

The Red Eye

Gemma Kim[a]* and Tae K Kim[b]
[a]Department of Family Medicine, UCRiverside, School of Medicine, Palm Springs, CA, USA
[b]Department of Family and Community Medicine, University of California Riverside School of Medicine, Palm Springs, CA, USA

General Principles

Definition/Background

Red eye is one of the most common ocular conditions that presents in the primary care setting. Most cases are benign; however, some may cause permanent vision loss. Many conditions can be treated by primary care physicians. Therefore, it is important for the provider to be able to determine those cases that require urgent ophthalmic consultation. Most causes of red eye can be diagnosed by taking a detailed patient history and careful eye examination. Obtaining certain elements in the history can aid in determining whether an ophthalmic consultation is required. Key elements in the history include pain, decreased vision, foreign body sensation, photophobia, trauma, use of contact lens, and discharge. The assessment of clinical signs should include the location of the redness (eyelids, conjunctiva, cornea, sclera, and episclera, or intraocular), unilateral or bilateral involvement, associated symptoms (pain, itching, visual decrease or loss), and other ocular (mucopurulent discharge, watering, blepharospasm, lagophthalmus) or systemic (fever, nausea) findings [1]. Equally important is to perform a thorough ophthalmologic examination, including visual acuity, penlight examination, and fundus examination.

Conjunctivitis, whether infectious or noninfectious, is the most common cause of red eye presenting to the primary care setting. Other less common causes include episcleritis, scleritis, iritis, herpes keratitis, trichiasis, and acute angle-closure glaucoma (see Table 1).

Conjunctivitis

Acute conjunctivitis affects approximately six million people annually and consists of approximately 1 % of all primary care visits in the United States [2, 3]. It is estimated that 70 % of all patients with acute conjunctivitis present to primary care and urgent care centers [4]. Conjunctivitis, commonly referred to as pinkeye, is the inflammation of the mucous membrane that lines the inside surface of the eyelids and the outer surface of the eye. The causes of acute conjunctivitis can be divided into infectious (e.g., bacterial, viral, chlamydial) or noninfectious (e.g., allergic, nonallergic/irritants). The most prominent signs consist of generalized conjunctival injection with gritty discomfort, mild photophobia, and variable amounts of discharge with no loss of visual acuity [1]. Generally, viral conjunctivitis and bacterial conjunctivitis are self-limiting conditions, and serious complications are rare. Since there is no specific diagnostic test to differentiate viral from bacterial conjunctivitis, most cases are treated using broad-spectrum antibiotics [5].

Table 1 Differential diagnosis of the red eye

	Etiology	Eye pain	Discharge	Visual acuity	Pupillary changes	Corneal involvement	Intraocular pressure	Immediate referral
Bacterial conjunctivitis	Gram + and gram – organisms	Pain with gritty sensation	Mild to moderate purulent discharge	Unchanged	None	Possible	Normal	No
Viral conjunctivitis	Adenovirus (most common)	Pain with gritty sensation	Watery	Unchanged	None	None	Normal	No
Chlamydial conjunctivitis	*Chlamydia trachomatis*	Irritated	Watery to mucopurulent	Unchanged	None	Corneal scarring with trachoma	Normal	No, unless trachoma is suspected
Allergic conjunctivitis	Environmental allergens	Gritty sensation	Watery	Unchanged	None	None	Normal	No
Episcleritis	Idiopathic, possible association with systemic disease	Mild	Watery	Unchanged	None	None	Normal	No
Scleritis	Associated with systemic disease	Severe, constant piercing pain	Watery	Unchanged	None	None	Normal	Yes
Iritis	Infection or immune-mediated disease	Gradual onset of aching pain	Minimal and watery	Blurred	Constricted and sluggishly reactive to light	Normal	Normal	Yes
Herpes keratitis	Predominately HSV-1	Pain with foreign body sensation	Watery	Blurred	None	Recurrent infections cause reduced corneal sensation	Normal	Yes
Trichiasis	Abnormal positioning of the eyelids	Irritation	Watery	Untreated can cause vision loss	None	Can cause corneal scarring	Normal	No
Acute glaucoma	Narrowing of the ant. chamber	Severe throbbing	Watery	Decreased	Partially dilated, nonreactive	Swelling	Elevated	Yes

DOI 10.1007/978-1-4939-0779-3_76-1

Table 2 Acute bacterial conjunctivitis treatment options

Medication	Dosage form	Adult dosage	Pediatric dosage	Comments
Erythromycin (Ilotycin)	0.5 % ointment	Apply 1 cm ribbon up to 6×/day × 7–10 days	Apply 1 cm ribbon up to 6×/day × 7–10 days	Ointment recommended for children
Trimethoprim-polymyxin B (Polytrim)	10,000 units/ 1 mg/ml sol	1 drop every 3 h × 7–10 days	>2 months: 1 drop every 3 h × 7–10 days	Drops better for adults
Bacitracin-polymyxin B (AK-Poly-Bac, Polycin)	500 units/ 10,000 units/g ointment	Apply 0.25–0.5 in. ribbon every 3–4 h × 7–10 days	Apply 0.25–0.5 in. ribbon every 3–4 h × 7–10 days	Ointment recommended for children
Sulfacetamide (Bleph-10)	10 % ointment 10 % solution	* 0.5 in. ribbon every 3–4 hours and qhs × 7–10 days * 1–2 drops every 2–3 h × 7–10 days	>2 months: * 0.5 in. ribbon every 3–4 hours and qhs × 7–10 days * 1–2 drops every 2–3 h × 7–10 days	Not first line due to potential sulfa allergy
Gentamicin (Garamycin)	0.3 % ointment 0.3 % solution	* 0.5 in. ribbon bid-tid * 1–2 drops every 4 h	>1 month: * 0.5 in. ribbon bid-tid * 1–2 drops every 4 h	May cause ocular burning
Tobramycin (Tobrex)	0.3 % solution	1–2 drops every 4 h	>2 months: 1–2 drops every 4 h	May cause ocular burning
Ciprofloxacin (Ciloxan)	0.3 % solution	1–2 drops every 2 h while awake and then every 4 h × 5 days	>1 year: 1–2 drops every 2 h while awake and then every 4 h × 5 days	Reserved for severe infections or contact lens wearers
Levofloxacin (Iquix, Quixin)	0.5 % solution	1–2 drops every 2 h while awake × 2 days and then every 4 h while awake × 5 days	>1 year: 1–2 drops every 2 h while awake × 2 days and then every 4 h while awake × 5 days	Reserved for severe infections or contact lens wearers
Ofloxacin (Ocuflox)	0.3 % solution	1–2 drops every 2–4 h × 2 days and then 1–2 drops qid × 5 days	>1 year: 1–2 drops every 2–4 h × 2 days and then 1–2 drops qid × 5 days	Reserved for severe infections or contact lens wearers
Gatifloxacin (Zymar, Zymaxid)	0.5 % solution	1 drop every 2 h up to 8×/day × 1 day and then 1 drop bid-qid × 6 days	>1 year: 1 drop every 2 h up to 8×/day × 1 day and then 1 drop bid-qid × 6 days	Reserved for severe infections or contact lens wearers
Moxifloxacin (Vigamox, Moxeza)	0.5 % solution	1 drop tid × 7 days	>1 year: 1 drop tid × 7 days	Reserved for severe infections or contact lens wearers

Bacterial Conjunctivitis

Bacterial conjunctivitis is caused by a wide range of gram-positive and gram-negative organisms; however, gram-positive organisms are more common [6]. *Staphylococcus aureus* is more common in adults, while *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* are more common in children. The incidence of *Haemophilus influenzae* has decreased as more children are immunized. Gram-negative organisms include *Escherichia coli* and

DOI 10.1007/978-1-4939-0779-3_76-1

Pseudomonas species. Hyperacute bacterial conjunctivitis is usually caused by *Neisseria gonorrhoeae* and is considered a sight-threatening infection that requires immediate ophthalmologic evaluation with hospitalization for systemic and topical therapy. It is usually transmitted from the genitalia to the hands and then to the eyes. It is characterized by a profuse purulent discharge present within 12 h of infection [7]. Additional symptoms include redness, lid swelling, and tender preauricular adenopathy. Gram staining of the purulent discharge reveals gram-negative diplococci.

History

Acute bacterial conjunctivitis initially presents with tearing and irritation in one eye but usually spreads to the opposite eye within 2–5 days. It is highly contagious and causes a rapid onset of generalized conjunctival redness, purulent discharge (yellow, white, or green), gritty discomfort, swelling of the eyelid, early morning crusting of the eyelids, and usually no loss of vision. However, one should suspect a gonococcal infection if the patient presents with profuse amounts of purulent discharge associated with a rapid progression of redness, irritation, and pain. *Neisseria gonorrhoeae* confirmed in a child should raise concern for sexual abuse. For *Neisseria meningitides*, one should consider meningitis.

Physical Examination

For acute bacterial conjunctivitis, visual acuity is preserved with normal pupillary reaction and absence of corneal involvement. Additional findings include conjunctival injection and swelling of the eyelid, with mild to moderate purulent discharge. Patients will often describe that their eyelids are stuck together upon wakening due to the mucopurulent discharge. For hyperacute bacterial conjunctivitis, there is chemosis (swelling of the conjunctiva) with possible corneal involvement, pseudomembrane formation, and preauricular lymphadenopathy. Patients will complain of severe pain with copious amounts of purulent discharge and diminished vision.

Laboratory Findings

In most cases of bacterial conjunctivitis, the diagnosis and the identification of the presumed organism are based on history and clinical presentation. Further studies to identify the organism and determine its sensitivity to antibiotics are reserved for more severe cases or those that are unresponsive to initial treatment [8]. If a gonococcal infection is suspected, gram staining will reveal gram-negative diplococci.

Treatment

Most cases of bacterial conjunctivitis if uncomplicated are self-limited regardless of antibiotic therapy [9]. However, antibiotics are indicated for conjunctivitis caused by gonorrhea or chlamydia and in those patients that wear contact lenses [10]. It has also been shown that antibiotics cause earlier reduction of symptoms and therefore can be prescribed. Initial preferred treatment options include erythromycin ophthalmic ointment or trimethoprim-polymyxin B drops (see Table 2). For children or for those whom it is difficult to administer eye medications, ointment is preferred as it still maintains a therapeutic effect although none may have been directly applied to the conjunctiva. Because ointment can blur the vision and cause the eyes to feel sticky, drops are recommended for adults who require clear vision for driving or work. Sulfacetamide ophthalmic drops are not considered first line due to potential allergic reactions. Fluoroquinolones are effective and well tolerated but are usually reserved for more severe infections or contact lens wearers. For those who wear contact lenses, contact lens use should be discontinued, lens case discarded, and lenses disinfected or replaced. Once antibiotics have been completed and the eye has cleared and remains free of discharge for 24 h, contact lens wear may be resumed. Bacterial conjunctivitis that is chronic, resistant to initial antibiotic treatment, or caused by gonorrhea or chlamydia requires immediate referral to an ophthalmologist.

DOI 10.1007/978-1-4939-0779-3_76-1

Viral Conjunctivitis

Viral conjunctivitis is a common, self-limiting condition that is most commonly caused by adenovirus, which consists of 65–90 % of viral conjunctivitis cases [11]. Other viruses which are less likely to spread include herpes simplex virus, varicella zoster virus, picornavirus (enterovirus 70, Coxsackie A24), poxvirus (molluscum contagiosum, vaccinia), and human immunodeficiency virus (HIV). Adenoviruses 8, 19, and 37 are associated with epidemic keratoconjunctivitis, which is highly contagious, while adenoviruses 3 and 7 cause pharyngoconjunctival fever which is characterized by high fevers, sore throat, and preauricular lymphadenopathy [9]. Enterovirus 70 and Coxsackie A24 cause acute hemorrhagic conjunctivitis, which is characterized by the rapid onset of painful conjunctivitis and subconjunctival hemorrhage. Although benign and resolving within 5–7 days, it can cause a polio-like paralysis developing in approximately one in 10,000 patients infected with enterovirus 70 [12]. Conjunctivitis caused by herpes simplex virus is usually unilateral with watery discharge and ipsilateral vesicular facial rash [9]. Herpes zoster virus, commonly known as shingles, can involve the eye when the first and second branches of the trigeminal nerve are involved. Ocular involvement most commonly affects the eyelids (45.8 %) followed by the conjunctiva (41.1 %) [13]. Herpes zoster ophthalmicus represents approximately 10–25 % of all cases of herpes zoster [14].

History

The patient with acute viral conjunctivitis initially presents with a unilateral red eye with watery discharge and itching. Many times, the other eye becomes affected a few days later. Typically there is absence of visual involvement or photophobia. Symptoms are typically mild with spontaneous remission in 1–2 weeks [1]. Pain, photophobia, and subconjunctival hemorrhages may be associated with keratoconjunctivitis or acute hemorrhagic conjunctivitis. Commonly, cases of acute viral conjunctivitis occur during or after an upper respiratory infection or with exposure to a person with an upper respiratory infection as it is highly contagious and spreads through direct contact via contaminated fingers, medical instruments, swimming pool water, or other personal items [5].

Physical Examination

For acute viral conjunctivitis, visual acuity is unaffected with normal pupillary reaction and absence of corneal involvement. Additional findings include follicular injection/erythema and swelling of the eyelid, with watery clear discharge. Keratoconjunctivitis is associated with preauricular lymphadenopathy and possible corneal infiltrates. Pharyngoconjunctivitis can be associated with subconjunctival hemorrhage. Herpes simplex virus causes a unilateral follicular conjunctivitis with an ipsilateral vesicular rash [9]. When involving the eye, herpes zoster can cause vesicular lesions in the distribution of the ophthalmic division of the trigeminal nerve with possible blepharitis, keratitis, uveitis, ophthalmoplegia, or optic neuritis [1]. Molluscum contagiosum usually presents as a unilateral follicular conjunctivitis with umbilicated lesions at the eyelid margin.

Laboratory Findings

Generally, viral conjunctivitis is diagnosed on clinical features alone. Laboratory testing is typically not necessary unless symptoms are severe, chronic, or recurrent infections or in patients who fail to respond with treatment. There are rapid immunochromatographic tests available to diagnose adenoviral infections in the office. In addition, Giemsa staining of conjunctival scrapings can aid in characterizing an inflammatory response. Fluorescein staining may reveal dendrites on the cornea for herpes simplex infections.

DOI 10.1007/978-1-4939-0779-3_76-1

Treatment

As most cases of viral conjunctivitis are self-limiting and there is no effective treatment available, treatment is mostly supportive and can include cold compresses, saline rinse, ocular antihistamines, and artificial tears. These agents treat only the symptoms and not the disease itself. Antiviral medications and topical antibiotics are not indicated. Use of antibiotic eye drops can increase the risk of spreading the infection to the other eye due to contaminated droppers [11]. Treatment for ocular herpetic infections usually consists of a combination of oral antivirals and topical steroids and warrants immediate ophthalmology referral to monitor for sight-threatening corneal involvement. Molluscum treatment options include excision or cryotherapy of the lesions. Patients with molluscum do not need to be isolated from others while symptomatic [9]. If symptoms do not resolve after 7–10 days or if corneal involvement is suspected, referral to ophthalmologist is indicated.

Family and Community Issues

Patients should be counseled that since viral conjunctivitis although self-limiting is highly contagious, it is important to prevent spread by practicing strict handwashing and avoid sharing personal items with those infected. In cases of adenoviral conjunctivitis, the replicating virus is present 10 days after the appearance of symptoms in 95 % of the patients but only in 5 % by day 16 [8]. Due to the high risk of spread, children should be refrained from attending daycare and school for up to 1 week [9].

Chlamydial Conjunctivitis

Chlamydial conjunctivitis is a bacterial infection of the eye caused by *Chlamydia trachomatis*. Chlamydial conjunctivitis can be divided into two types: trachoma and inclusion conjunctivitis. *Chlamydia trachomatis* serotypes A through C cause trachoma and are characterized by a severe follicular reaction which can develop into scarring of the eyelid, conjunctiva, and cornea leading to vision loss. It is the leading infectious cause of blindness worldwide [15]. It is endemic in developing countries with limited resources and is seen only sporadically in the United States. Chlamydial serotypes D through K cause inclusion conjunctivitis, which causes a unilateral chronic follicular conjunctivitis that usually occurs in young adults or neonates (ophthalmia neonatorum) via the birth canal from infected mothers. Chlamydial inclusion conjunctivitis is sexually transmitted from the hand to eye or from the genitalia to eye.

History

Chlamydial conjunctivitis should be suspected in sexually active patients with chronic follicular conjunctivitis that is not responsive to standard antibacterial treatment [16]. There is usually an absence of symptoms from the genital tract; however, males may have symptomatic urethritis and females may have salpingitis or chronic vaginal discharge. Ophthalmia neonatorum, also called neonatal conjunctivitis, usually occurs in the first 4 weeks of life. The incubation period is typically 7 days after delivery but can vary from 5 to 14 days if there was a premature rupture of membranes [17]. Among those neonates with known exposure to chlamydia, 30–50 % will develop conjunctivitis [18].

Physical Examination

The patient usually presents with a red, mildly irritated eye with scant watery discharge to severe mucopurulent discharge with eyelid and conjunctival swelling [18]. A palpable preauricular lymph node may be present on the affected side. Vision is usually not affected and there is usually no history of recent upper respiratory infection. Trachoma causes chronic follicular conjunctivitis that leads to entropion, trichiasis, conjunctival, and corneal scarring causing permanent vision loss.

DOI 10.1007/978-1-4939-0779-3_76-1

Laboratory Findings

Diagnosis is usually made based on history and clinical presentation. However, conjunctival scrapings revealing elementary bodies via direct fluorescent antibody stain or polymerase chain reaction testing on scrapings are diagnostic. Culture of conjunctival scrapings can be performed but may take weeks to grow.

Treatment

For newborns, topical therapy is not indicated as more than 50 % of affected neonates have concurrent lung, nasopharynx, and genital tract infections [10]. Recommended treatment is a systemic course of erythromycin ethylsuccinate (EryPed) 50 mg/kg/day in four divided doses per day for 14 days [19]. To treat inclusion conjunctivitis in adults, a systemic course of oral tetracycline (Sumycin) 250 mg four times per day for 3 weeks, erythromycin stearate (Erythrocin) 250 mg four times per day for 3 weeks, doxycycline 100 mg twice per day for 10 days, or azithromycin 1 g single dose to treat the infection. Topical antibiotics may suppress the ocular symptoms but does not treat the genital disease. Pregnant patients should be treated with erythromycin since tetracyclines can cross the placenta. Sexual partners should also be treated to prevent reinfection and possible coinfection with gonorrhea should be tested.

Allergic Conjunctivitis

Allergic conjunctivitis is a type 1, IgE-mediated hypersensitivity to allergens such as pollen, animal dander, and other environmental allergens [8] and affects up to 40 % of the population in the United States [20]. Seasonal allergic conjunctivitis is the most common form consisting of 90 % of all allergic conjunctivitis in the United States usually worse in the spring and summer [21]. It is often encountered in patients with atopic diseases, such as allergic rhinitis (hay fever), eczema, and asthma [22]. Perennial allergic conjunctivitis is similar to seasonal allergic conjunctivitis but occurs throughout the year and the symptoms tend to be less severe. Other types of ocular allergies include vernal keratoconjunctivitis, atopic keratoconjunctivitis, contact allergy (contact dermatitis), and giant papillary conjunctivitis [23].

History

The hallmark for allergic conjunctivitis is itching along with watery eyes, redness, gritty discomfort, eyelid swelling, and nasal congestion. Vernal keratoconjunctivitis is more common in warmer climates and affects young patients and resolves by age 20. Atopic keratoconjunctivitis is the ocular version of atopic eczema or dermatitis. Contact ocular allergy is caused by contact with an allergen. Giant papillary conjunctivitis is commonly associated with contact lens use or ocular implants.

Physical Examination

Allergic conjunctivitis commonly presents with bilateral dilatation of the conjunctival blood vessels, large cobblestone papillae under the upper lid, conjunctival swelling (chemosis), and watery to mucoid discharge [1]. Redness or conjunctival injection is mild to moderate. Visual acuity is unaffected with normal pupillary reaction and absence of corneal involvement. Vernal keratoconjunctivitis is characterized by the giant papillae found under the upper eyelid. In atopic keratoconjunctivitis, the eyelid skin may have a fine sandpaper-like texture with mild to severe conjunctival injection and chemosis [23]. Giant papillary conjunctivitis may cause giant, medium, or small papillae under the upper lid similar to vernal conjunctivitis [23].

Laboratory Findings

Allergic conjunctivitis is diagnosed based primarily on history and clinical presentation. Giemsa staining of conjunctival scrapings can help characterize the inflammatory response and may reveal eosinophils.

DOI 10.1007/978-1-4939-0779-3_76-1

Allergy testing via direct skin testing or radioallergosorbent test (RAST) is indicated mostly for patients with systemic allergy or may be indicated for some with ocular allergy.

Treatment

Patients with allergic conjunctivitis should be advised to refrain from rubbing their eyes as this causes mast cell degranulation and worsening of their symptoms. Cool compresses may reduce eyelid swelling and use of artificial tears throughout the day may help to clear out potential allergens. Patients should also refrain from wearing contact lenses as allergens have the ability to adhere to the contact lens surface. In addition, avoidance of known allergens may reduce exacerbations. Medical therapies that are topical include antihistamine/vasoconstrictor combination products, antihistamines with mast cell stabilizers, and glucocorticoids, which are reserved for resistant cases and should be used under the supervision of an ophthalmologist. Systemic oral antihistamines, such as loratadine (Claritin), fexofenadine (Allegra), and cetirizine (Zyrtec) are often used for the management of allergies in general; however, topical ocular medications are found to be more effective when ocular symptoms primarily predominate.

Other Causes of Red Eyes

Episcleritis

Episcleritis is a benign inflammatory disease that affects the episclera, which is the thin layer of tissue that is beneath the conjunctiva but is superficial to the sclera. It is usually self-limiting and resolves within 3 weeks. Most cases occur mostly in young to middle-aged females but can affect any age group. The etiology is mainly idiopathic with a minority of cases associated with an underlying systemic disease, such as rheumatoid arthritis, inflammatory bowel disease, vasculitis, and systemic lupus erythematosus [24]. Episcleritis is classified into two types. In the diffuse type, the redness involves the whole episclera, whereas, in the nodular type, the redness involves a smaller contained area.

History

Patients usually present with an abrupt onset of mild eye pain, redness, watery eyes, and mild photophobia. The pain associated with episcleritis is typically mild when compared to the pain experienced with scleritis. The diffuse type of episcleritis may be less painful than the nodular type. Eye involvement may be either localized or diffuse. There is no associated discharge and vision is not affected.

Physical Examination

There is unilateral or bilateral localized or diffuse redness of the episclera. There may be mild pain with palpation. Vision is not affected and there is no edema or thinning of the sclera. A slit-lamp biomicroscope can help visualize any changes in the sclera to differentiate between episcleritis which is benign and scleritis which causes more destructive inflammation. In addition, phenylephrine eye drops can cause transient clearing of the episcleral redness so that a more careful examination of the sclera can be made.

Laboratory Findings

There are no specific laboratory tests for the diagnosis unless a systemic disease is suspected as the cause of the episcleritis. In this case, blood tests, such as rheumatoid factor, antibodies to cyclic citrullinated peptides (anti-CCP), antineutrophil cytoplasmic antibodies (ANCA), and antinuclear antibody testing (ANA), can be drawn targeted to specific inflammatory diseases.

DOI 10.1007/978-1-4939-0779-3_76-1

Treatment

Since episcleritis is self-limiting and does not cause vision loss, the treatment is based on symptom relief. Treatment options include topical lubricants/artificial tears and topical glucocorticoids for severe cases [5]. Topical nonsteroidal anti-inflammatory drugs (NSAIDs) are not indicated and have been shown to have no significant benefit versus placebo [25]. Referral to ophthalmology is recommended to definitively confirm episcleritis versus scleritis and for recurrent or worsening of symptoms.

Scleritis

Scleritis is a painful and destructive inflammatory disease that affects the sclera, which comprises 90 % of the outer coat of the eye. It is associated with an underlying systemic disorder, such as rheumatoid arthritis, Wegener's granulomatosis, and systemic lupus erythematosus, in up to 50 % of patients [26]. The sclera is divided into an anterior and posterior compartment. Inflammation can occur in either compartment but rarely does it affect both. Approximately 90 % of scleritis involves the anterior compartment which can be further subdivided into diffuse, nodular, and necrotizing. Diffuse anterior scleritis is the most common, least severe, and usually does not recur. Nodular anterior scleritis is the second most common and tends to be recurrent. Necrotizing anterior scleritis is the least common, most severe, and more likely to cause ocular complications. Posterior scleritis can also be subdivided into diffuse, nodular, and necrotizing but is more rare and difficult to assess clinically.

History

Patients present with a gradual onset of severe, constant, piercing pain that involves the eye and radiates to the face and periorbital region. Tenderness and redness may affect the entire eye or a more localized area. Because the extraocular muscles insert into the sclera, movement of the eye tends to exacerbate the pain. The pain is usually worse at night or in the early morning hours, causing awakening from sleep. Patients also experience headache, watery eyes, and photophobia.

Physical Examination

Examination reveals a characteristic violet-bluish hue of the globe with scleral edema and vasodilatation of the episcleral plexus and superficial vessels. The globe is usually tender to the touch. Using slit-lamp biomicroscopy, one can visualize inflamed scleral vessels which are adherent to the sclera and cannot be moved with a cotton-tipped applicator, whereas the more superficial vessels of the episclera are movable. Although phenylephrine eye drops cause blanching of the superficial episcleral vessels, the deep vessels are not affected which can aid in the differentiation between scleritis and episcleritis.

Laboratory Findings

Like episcleritis, there are no specific laboratory tests for the diagnosis of scleritis. If history and physical examination indicate a systemic inflammatory condition, specialized serologic tests can be drawn. There are some imaging studies that are useful in the evaluation of scleritis, such as ultrasonography of the orbit which can confirm scleral thickening and CT and magnetic resonance imaging of the orbit which can visualize orbital lesions associated with systemic disease processes.

Treatment

If suspected, immediate referral to ophthalmology is warranted. Two-thirds of patients with scleritis require high-dose corticosteroids or the combination of corticosteroids with an immunosuppressive agent [24]. If an underlying systemic disease is suspected or known, referral to rheumatology may be indicated.

DOI 10.1007/978-1-4939-0779-3_76-1

Iritis

Iritis is the inflammation of the anterior uveal tract, also referred to as anterior uveitis. It can be caused by infection such as from a wound or corneal ulcer, or it can be caused by a systemic immune-mediated disease. Spondyloarthritides, such as ankylosing spondylitis and reactive arthritis (Reiter syndrome), are the most common systemic immune diseases associated with anterior uveitis. Uveitis can occur in up to 37 % of spondyloarthropathy patients, of which most are positive for the human leukocyte antigen (HLA)-B27 allele [27, 28]. Ten to thirty percent of patients with juvenile idiopathic arthritis develop chronic anterior uveitis, and it remains a cause of blindness in childhood [29]. Other associated systemic diseases include sarcoidosis, inflammatory bowel disease, and Behçet's disease.

History

Patients present with a gradual onset of pain (often described as an ache) developing over hours to days with the exception of trauma. Ocular erythema and excessive tearing are commonly present. In addition, photophobia with blurred vision is commonly noted. Iritis can be unilateral, bilateral, or recurrent affecting either eye, dependent on the etiology or associated disease process.

Physical Examination

The eyelids, lashes, and lacrimal ducts are not involved. Conjunctival examination reveals hyperemic injection surrounding the cornea. If discharge is present, it is minimal and watery. The pupil is constricted in the affected eye and is sluggishly reactive to light. Visual acuity may be decreased in the affected eye but extraocular movement is not affected. Both direct and consensual photophobia may be present. With slit-lamp biomicroscopy examination, keratic precipitates (white blood cells) can be visualized in the anterior chamber which is a hallmark of iritis. With severe inflammation, the leukocytes in the anterior chamber can settle and form a hypopyon, which is an accumulation of purulent material that can be visualized without magnification.

Laboratory Findings

Iritis (anterior uveitis) is diagnosed based primarily on history and clinical presentation. Slit-lamp biomicroscopy is required to properly assess the presence of leukocytes or protein accumulation in the aqueous humor within the anterior chamber of the eye. If a systemic immune-mediated disease is suspected from the patient's history and examination, diagnostic testing to confirm the specific diagnosis is warranted.

Treatment

If iritis is suspected, immediate referral to ophthalmology is warranted. Although leukocytes may be present on examination, antibiotics are not indicated. Iritis is a diagnosis of exclusion and can be associated with serious complications, such as band keratopathy, posterior synechiae, intraocular hypertension, glaucoma, cataract formation, and increased risk of herpes keratitis. If an underlying systemic disease is suspected or known, referral to rheumatology may be indicated.

Herpes Keratitis

Herpes keratitis is caused by a recurrent herpes simplex virus (HSV) infection in the cornea. It is very common in humans as both subtypes, HSV-1 and HSV-2, have humans as their only natural host. HSV-1 accounts for most oral, labial, and ocular infections and HSV-2 accounts for most genital infections. However, there is quite a bit of overlap of their distributions. HSV-1 causes over 95 % of ocular HSV infections, excluding neonatal infections [30]. HSV infection is the leading cause of corneal blindness in the United States despite the fact that only a very low percentage of infected individuals develop ocular

DOI 10.1007/978-1-4939-0779-3_76-1

disease. Ocular HSV-1 infections are predominately unilateral; however, up to 12 % of cases involve both eyes in which the infection tends to be more severe and occurs in younger individuals [31].

History

Primary HSV infection typically presents as an acute oropharyngitis type of illness. Following the initial infection, the virus may go into a latent period within any of the divisions of the trigeminal nerve. It is the reactivation of the latent HSV that causes the primary ocular infection. Patients will present with a unilateral blepharoconjunctivitis with a vesicular rash on the eyelids and follicular conjunctivitis. Patients may present with pain, photophobia, foreign body sensation, blurred vision, tearing, and conjunctival redness.

Physical Examination

Examination may reveal mild conjunctival injection with hyperemic injection surrounding the limbus (ciliary flush). After staining of the eye with fluorescein dye, the typical branching corneal ulcer (dendritic ulcer) with terminal bulbs associated with HSV infection may be seen [32]. With resolution of the infection, patients can develop subepithelial scarring and recurrent infections can lead to focal or diffuse reduction in corneal sensation.

Laboratory Findings

The diagnosis of herpes keratitis is mostly based on clinical history and examination. The dendritic lesions are usually pathognomonic for HSV infection. Laboratory confirmation is rarely indicated, and serologic testing is not recommended due to the prevalence of latent disease and the frequency of recurrences. In severe cases or when clinical findings are atypical, ocular scrapings of epithelial lesions can be sent for viral culture, detection of viral antigen, or detection of viral DNA.

Treatment

Treatment of herpes keratitis is dependent on whether the infection is caused by active viral replication or due to an immune response from a prior infection. Regardless, HSV keratitis warrants immediate referral to an ophthalmologist. For most cases, topical corticosteroids are not indicated as it may worsen the infection.

Trichiasis

Trichiasis is an eyelid abnormality in which the eyelashes are misdirected and grow back toward the eye causing irritation of the cornea and conjunctiva. It can be caused from congenital defects, infection, autoimmune conditions, and trauma. If left untreated, permanent scarring of the cornea can occur, leading to vision loss.

History

The history is essential in directing the clinical examination and formulation of the correct diagnosis. Important questions to ask include recent history of a severe eye infection or travel to a developing country where trachoma is commonly seen, history of herpes zoster ophthalmicus, ocular cicatricial pemphigoid (autoimmune disorder), Stevens-Johnson syndrome, eyelid surgery, or trauma.

Physical Examination

The irritation from the eyelashes causes constant eye irritation, pain, redness, excessive tearing, and sensitivity to light.

DOI 10.1007/978-1-4939-0779-3_76-1

Laboratory Findings
There are no specific laboratory tests for the diagnosis of trichiasis. It is primarily based on clinical history and physical examination.

Treatment
For immediate relief, the eyelashes can be plucked out; however, regrowth usually occurs. For more severe cases or for recurrent disease, permanent removal of the affected eyelashes using a radiofrequency device, electrolysis, or cryosurgery can be performed to prevent scarring of the cornea and permanent vision loss. In some cases, corrective eyelid surgery may be indicated.

Acute Closed-Angle Glaucoma
Acute glaucoma is associated with a narrowing of the anterior chamber with obstruction of the aqueous humor from the posterior chamber to the anterior chamber of the eye. This obstruction leads to a rapid increase in intraocular pressure. Acute glaucoma is an ocular emergency and can lead to permanent blindness if left untreated. Primary angle-closure glaucoma is more common in females and those with family history. It is also more prevalent in Eskimos and Southeast Asian populations with a higher risk in individuals over 40 years of age [33]. As people age, the lens of the eye enlarges and pushes the iris forward decreasing the area where the aqueous humor drains thereby increasing the risk for angle-closure glaucoma.

History
Patients present with severe throbbing eye pain, redness, blurred vision, profuse tearing, haloes around lights (due to corneal swelling), nausea, vomiting, and headaches. In acute attacks, it is common for unilateral eye involvement and more severe symptoms. Some may experience intermittent episodes of angle closure and elevated intraocular pressure without a full-blown attack, which is referred to as subacute angle-closure glaucoma. These patients typically are asymptomatic and may experience mildly blurred vision or haloes around lights. These symptoms usually self-resolve once the angle reopens. It is important to review current medications as certain medications can cause drug-induced secondary angle-closure glaucoma.

Physical Examination
Examination requires slit-lamp biomicroscopy which can confirm corneal edema due to the sudden elevation in intraocular pressure. There may also be dilatation of episcleral and conjunctival vessels, shallow anterior chambers, erythema surrounding the iris, and inflammatory cells within the anterior chamber. Tonometry will reveal eye pressures above 21 mmHg and may be as high as 40–80 mmHg. Gonioscopy can be performed to assess the drainage angle of the eye and ophthalmoscopy can be used to assess the optic nerves for any damage or abnormalities.

Laboratory Findings
There are no specific laboratory tests to confirm the diagnosis of acute glaucoma. It is diagnosed based on clinical history and examination via slit-lamp biomicroscopy.

Treatment
If acute angle-closure glaucoma is suspected, immediate referral to an ophthalmologist is indicated to initiate treatment and prevent permanent vision loss. Initially medications are used to decrease intraocular pressure in preparation for laser iridotomy (treatment of choice), which creates holes in the iris so that the

DOI 10.1007/978-1-4939-0779-3_76-1

aqueous humor may drain freely from the posterior chamber to the anterior chamber, thereby reducing intraocular pressures.

Conclusion

There are various causes of red eye and many may be diagnosed based on clinical history and focused examination. In the primary care setting, it is of great importance to be able to determine those cases that require immediate referral to an ophthalmologist. Indications for immediate or emergent referral include unilateral painful red eye that is associated with nausea and vomiting, severe ocular pain or visual loss in association with a red eye, corneal infiltrates or ulcers seen with fluorescein staining, and hypopyon (purulent exudate contained in the anterior chamber of the eye).

DOI 10.1007/978-1-4939-0779-3_77-1

According to a comprehensive survey of eye injuries in the United States published in 2005, 51 % of eye injuries are seen in the emergency room, while 47 % are treated by private practice physicians and in outpatient facilities [1]. Many of these patients will be seen by family physicians; the purpose of this chapter is to assist in correctly diagnosing and managing eye injuries.

In the United States, more than 40,000 eye injuries and 27 % of all pediatric ocular trauma hospital admissions were sports related [2, 3]. In Norwegian and Scottish studies, high percentages of eye injuries were caused by a ball, primarily soccer, and racquet sports [3]. Ninety percent of sports-related eye injuries are preventable with proper protective eyewear [4].

The chapter is divided into red eye, trauma, and burns. Each section covers the history and physical, treatment, and management for the diagnosis.

General Eye Exam

The eye is examined beginning with function, followed by structure, from the outermost to the innermost structures. Screen for vision loss using a Snellen eye chart at 20 ft (or near vision card, if necessary); record vision for each eye. If the patient is unable to use the eye chart, note presence or absence of light perception, hand movements, and ability to count fingers. Then inspect the lids and orbits. If there is significant swelling, palpate to determine the degree of edema or orbit involvement. Next, inspect the sclera and conjunctiva.

If there is a foreign body sensation, evert the upper lids to explore for foreign body. Topical anesthetic may be used. Use a cotton-tipped applicator to remove any foreign bodies from the internal surface of the upper lid. If cotton-tipped applicator is not successful, a sterile needle or eye spud may be used to flick out the foreign body. If there is a penetrating injury, do not attempt to remove a foreign body to avoid extrusion of eye contents.

Using direct ophthalmoscope, inspect the cornea for infiltrate or ulcer. Inspect the anterior chamber for hypopyon (pus) or hyphema (blood). Look for evidence of a penetrating eye injury. Assess the pupil to see if it is irregular in contour, dilated, or fixed. Examine for extrusion of ocular contents. These problems should be referred to ophthalmology on an urgent, same-day basis.

Use your office eye tray to procure the necessary items for fluorescein staining and inspection. The eye tray should include:

- Fluorescein stain strips
- Dropper bottle of sterile saline
- Cobalt blue light or black light
- Ophthalmic antibiotic ointment: erythromycin 0.5 % ointment
- Topical anesthetic: tetracaine hydrochloride 0.5 %, 1 % or proparacaine hydrochloride 0.5 %
- Topical mydriatic to dilate the pupil: phenylephrine 2.5 %,
- Topical cycloplegic, if needed for ciliary spasm: cyclopentolate 1 % (Cyclogyl) or homotropine 5 %
- Combined topical cycloplegic/mydriatic: tropicamide 0.5 %, 1 %
- Pocket-size Snellen chart
- Loupes for examiner to provide magnification

Moisten the strip with a drop of saline or topical anesthetic, pull down the lower lid, and gently touch the strip to the bulbar conjunctiva. Ask the patient to blink and the stain will be distributed over the cornea and conjunctiva. Inspect with magnification for patterns of injury.

Red Eye

The top causes of red eye are (1) conjunctivitis, (2) subconjunctival hemorrhage, and (3) corneal abrasions. Vision is the vital sign of the eye, so all patients should be screened for visual acuity with a hand-held Snellen chart or eye chart. For discussion of conjunctivitis, see chapter "► The Red Eye".

Subconjunctival Hemorrhage

Subconjunctival hemorrhage is painless and may occur spontaneously, after rubbing the eye, or in the setting of Valsalva maneuver, such as persistent coughing or a woman straining in labor. Direct visual inspection of the eye reveals the diagnosis. It is harmless and will resolve spontaneously without treatment within 2 weeks. While subconjunctival hemorrhage is usually benign, if extensive and mechanism of injury is traumatic, consider occult globe rupture [4].

A more concerning cause of red eye is corneal abrasion which usually causes eye irritation and may be accompanied by the presence of a foreign body.

Corneal Abrasions and Foreign Bodies

Corneal abrasions account for approximately 8 % of ocular cases in the primary care setting [5]. Correct diagnosis and early treatment is important. For although these injuries heal quickly, they have the potential to cause scarring and subsequent loss in visual acuity.

History and Physical Exam

Patient may present with eye pain and tearing, sensitivity to light, and foreign body sensation. There may be a history of eye rubbing. Common sources of injury include applying mascara, working with wood or metal, working in a dusty environment, and wearing contact lens. Mechanism of injury is important for the differential diagnosis.

Linear or blocky defects may be due to trauma. Punctate lesions may be associated with infection or ulceration in contact lens wearers. A branching pattern is worrisome for herpes simplex keratitis, which requires urgent, same-day referral to ophthalmology. A scratch pattern of vertical lines suggests foreign body under the upper lid. A pattern of diffuse generalized uptake is consistent with conjunctivitis, viral or bacterial. Figure 1

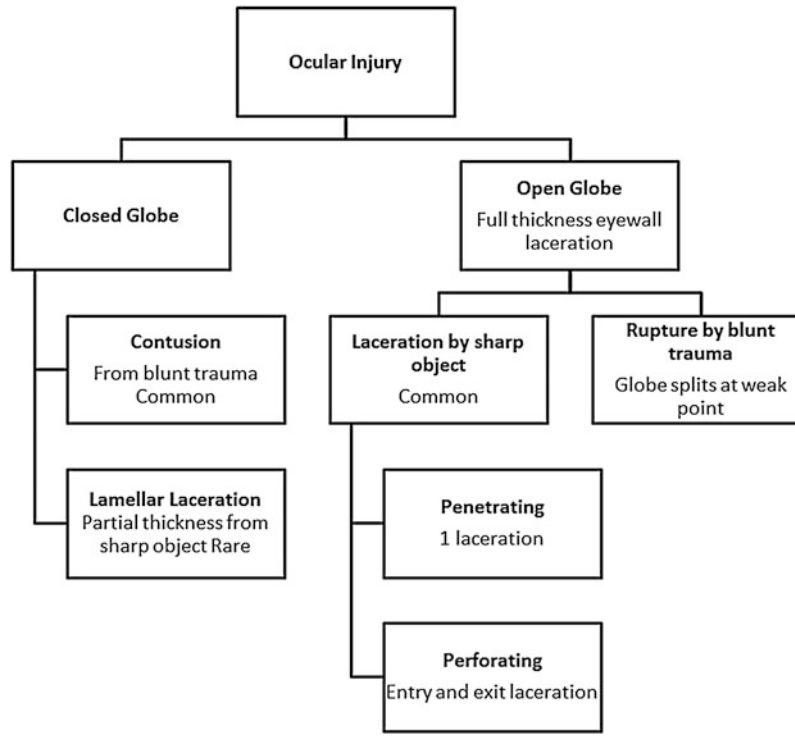

Fig. 1 Evaluation and management of corneal abrasions (Modified from Wipperman [7])

Table 1 Topical ophthalmologic medications for treatment of corneal abrasion

Medication	Dosage	Cost estimate[a] Generic cost (brand cost)
Home treatment		
Topical antibiotics		
Erythromycin 0.5 % ointment	0.5-in. ribbon, four times per day for 3–5 days	$17.86 (NA) for 3.5-g tube
Polymyxin B/trimethoprim (Polytrim) solution	1 drop, four times per day for 3–5 days	$4 ($57.48) for 10 ml eyedropper
Sulfacetamide 10 % (Bleph-10) solution	1–2 drops, four times per day for 3–5 days	$4 ($98.35) for 1 15 ml eyedropper
Antipseudomonal antibiotics		
Ciprofloxacin 0.3 % (Ciloxan) ointment	0.5-in. ribbon, four times per day for 3–5 days	NA ($135.05) for 3.5-g tube
Ciprofloxacin 0.3 % (Ciloxan) solution	1 drop, four times per day for 3–5 days	$10.97 ($100.37) for 5 ml eye dropper
Gentamicin 0.3 % ointment	0.5-in. ribbon, two to three times per day for 3–5 days	$13.56 (NA) for 3.5-g tube
Gentamicin 0.3 % solution	1 drop, four times per day for 3–5 days	$4 (NA) for 5 ml eye dropper
Ofloxacin 0.3 % (Ocuflox) solution	1 drop, four times per day for 3–5 days	$5 ($88.27) for 5 ml eye dropper
Topical NSAIDs		
Diclofenac 0.1 % (Voltaren)	1 drop, four times per day for 2–3 days	$15.64 ($80.20) for 5 ml eye dropper
Ketorolac 0.4 % (Acular LS)	1 drop, four times per day for 2–3 days	$15.00 ($191.09) for 5 ml eye dropper
Office treatment		
Topical cycloplegics[b]		
Cyclopentolate 1 % (Cyclogyl)	1 drop, may repeat in 5 min if needed	$5 ($24) for 2 ml eye dropper
Homatropine 5 %	1 drop, may repeat in 5 min if needed

[b]All Pregnancy Class C

provides a flowchart to assist in the diagnosis and treatment of corneal abrasions.

Treatment and Management

If a corneal abrasion is identified, treatment is targeted to prevent pain and infection. Table 1 provides common medications that can be prescribed for corneal abrasions and foreign bodies. The corneal epithelium grows rapidly and usually uncomplicated abrasions heal in 24–48 h. An abrasion of 4 mm or less with normal vision may not require follow-up as long as symptoms resolve within 24 h. For patients with diminished vision, contact lens wearers, and abrasions greater than 4 mm, arrange for follow-up in 24 h. A review of the literature has reported that patching v. nonpatching plays no significant role in the patient's prognosis [6].

Eyelid Lacerations

History

Patients with eyelid lacerations present with periorbital pain and tearing. Determine the extent of the injury: a partial- or full-thickness defect of the eyelid involves the skin and the subcutaneous

tissue. Superficial lacerations or abrasions may mask a deep laceration or injury to the lacrimal drainage system (e.g., puncta, canaliculi, common canaliculus, lacrimal sac), the orbit, the globe, or the cranial vault.

In accidents or altercations, details of the history will help determine the mechanism of injury and the likelihood of a foreign body [8].

Physical Exam

When examining superficial eyelid lacerations, first rule out a globe injury. Full-thickness lacerations, especially those involving the lid margin, warrant an immediate referral to an ophthalmologist. Do not forcibly open a lid swollen shut by edema or hematoma, as this could express eye contents through a previously undiscovered laceration. Refer to ophthalmology for more complete examination [4].

Complete an ocular examination, including bilateral dilated evaluation of the fundus. Ensure there are no injuries to the globe and optic nerve before attempting eyelid repair. Evert the lid, and use toothed forceps or cotton-tipped applicators to gently pull open one edge of the wound to determine the depth of penetration [4].

Treatment and Management

For superficial eyelid lacerations, use sterile superficial skin closures if only skin is involved.

Globe Injuries

Injury types are classified in a standardized manner using the Birmingham Eye Trauma Terminology criteria [9]. Figure 2 provides a modified BETTS for ocular trauma.

Closed-globe injuries are most commonly caused by blunt trauma. Blunt trauma commonly occurs in sports [3, 4]. The eye wall is not completely penetrated, whereas in open-globe injuries, there is a full-thickness wound.

Closed-Globe Injuries

Closed-globe injuries from blunt trauma most commonly cause contusions. However, when partial thickness wounds of the eye wall (lamellar lacerations) occur, these are usually caused by a sharp object.

The size of the object causing blunt force can determine the type of injury. Objects smaller than the orbital opening (e.g., golf, racquet, and squash balls) cause rapid interior-posterior compression of the globe, dilation of the middle of the globe, and extreme force on internal ocular structures. The lens-iris diaphragm absorbs most of the force. When the highly vascular iris bleeds, red blood cell sediments create a fluid level in the anterior chamber called "hyphema." Objects larger than the orbital opening allow "a pressure release valve," protecting eye structures by fracturing the thin bones at the floor and medial wall of the orbit ("blow out fractures of the orbit") [10].

Hyphema

History and Physical Exam

Patients with hyphema complain of decreased visual acuity and pain. Blood may be grossly visible, appearing black or red [5]. If the pupil in the traumatized eye does not constrict with light exposure, traumatic ocular neuropathy should be suspected. Understanding the mechanism of injury is an important step in determining the extent of damage. Patients' medications should also be examined for anticoagulants or a history of sickle cell disease and coagulopathies [5].

Treatment and Management

The severity of hyphema dictates the management. Hyphemas are graded based on the amount of the anterior chamber which is filled with blood (from Grade 0-microhyphema, which is only visible by slit lamp to Grade IV, which is completely

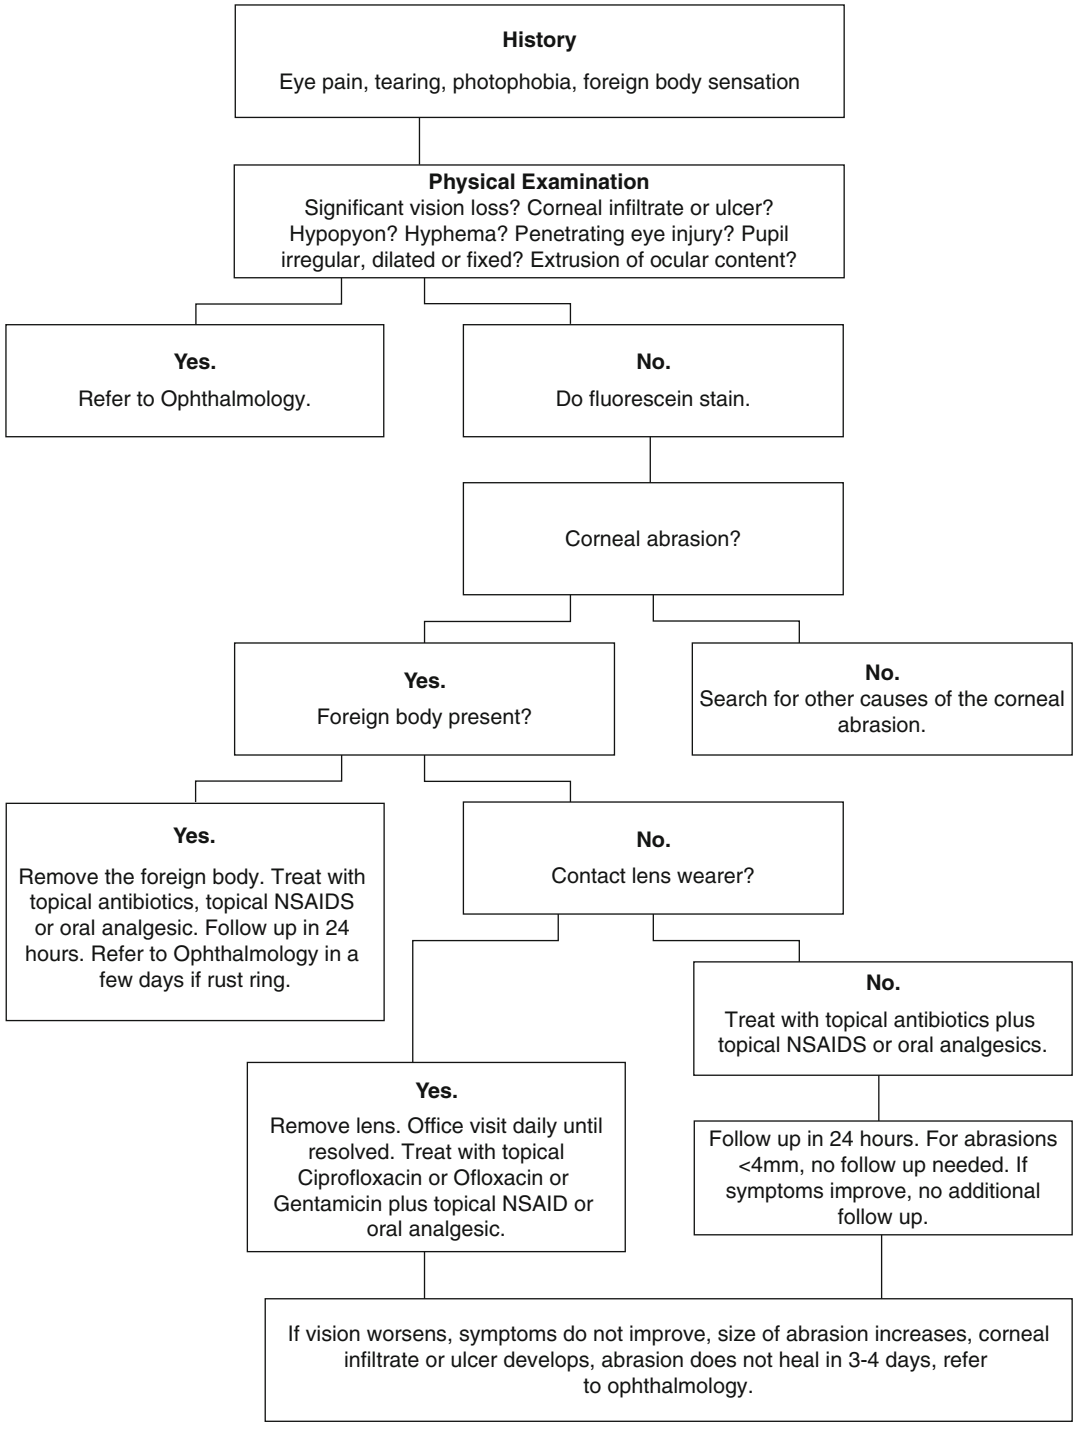

Fig. 2 Modified Birmingham Eye Trauma Terminology system classification for ocular trauma [9]

filled with clotted blood). Use of an eye shield, limited activity, and head elevation are usual for uncomplicated hyphema. Severe hyphemas require a referral to ophthalmology. In a recent review, the benefits of treating hyphemas with corticosteroids or antifibrinolytics were inconclusive [6].

Traumatic Retrobulbar Hemorrhage

History and Physical Exam

Arteries behind the globe can shear with blunt trauma. The bleeding causes the globe to press forward, causing increased intraocular pressure due to resistance from anterior structures. Continued pressure results in optic nerve damage and decreased blood flow in the central retinal artery.

Clinical presentation includes pain, decreased vision, and inability to open the eyelid due to severe swelling. Patient may have massive subconjunctival hemorrhage with no posterior border. Other signs are proptosis, hard eyelids, and a tense orbit that cannot be moved posteriorly on palpation. Extraocular movements are limited; pupillary reaction may be normal, or as damage to the optic nerve progresses, an afferent pupillary defect develops [3, 8].

Treatment and Management

Assessment includes fundoscopic exam and measurement of intraocular pressure. Refer to ophthalmology for medication to decrease intraocular pressure and/or surgery [3, 8].

Blowout Fractures

History and Physical Exam

Double vision with a vertical gaze and pain with vertical eye movement is the classic clinical presentation of an orbital floor blowout fracture. Pain with horizontal eye movement suggests orbital fracture at the medial wall [8]. The sudden increase in intraocular pressure which leads to orbital fracture can damage the trabecular meshwork and cause glaucoma and cataract formation [10]. One-third of these injuries occur during sport participation [11].

Swelling of the eyelids after sneezing or blowing the nose suggests communication between the sinus and the orbit. Other symptoms are sunken eye (enophthalmos which may be obscured by edema), decreased extraocular movements, and tenderness at the rim of the orbit [3, 8]. There may be "orbital emphysema" due to air entering the orbit. Cheek numbness indicates injury to the infraorbital nerve [8].

"Trapdoor" fractures are detected by significant extraocular muscle restriction (usually vertical) on exam. Pediatric patients may not have external swelling or lacerations due to the flexibility of their bones. When children have diplopia, they may close one eye rather than report double vision. In pediatric head trauma, symptoms of nausea, vomiting, bradycardia, and syncope may represent an oculocardiac reflex, rather than concussion [8].

Treatment and Management

Apply cold compresses to reduce edema and advise patient to avoid blowing nose or sneezing. Use an ice pack for 20 min per hour for the first 24–48 h and incline the head at 30° when at rest. If a communication between the sinus and the orbit is suspected, use nasal decongestants (e.g. oxymetazoline nasal spray b.i.d. for 3 days) and antibiotics. Antibiotics are also appropriate for patients who are immunocompromised, and those who have chronic sinusitis or diabetes. Antibiotic choices include cephalexin 250–500 mg p.o. q.i.d., erythromycin 250–500 p.o. q.i.d., or doxycycline 100 mg p.o. b.i.d. for 7 days.

For severe swelling which interferes with examination, consider oral corticosteroids. Concomitant oral antibiotics may be prudent to prevent infection. Consider consultation of neurosurgery. If fracture of the frontal sinus, midface, or mandibles is involved, consider

consultation of otolaryngology or oral maxillofacial surgery [8].

Particularly in pediatric patients, CT of the orbits with fine cuts and attention to the coronal views is critical to detect rectus muscle incarceration or "missing" inferior rectus [8].

Open-Globe Injuries

Open-globe injuries are full-thickness wounds of the eye wall, most commonly caused by trauma from sharp objects. Most open-globe injuries are caused by laceration from a sharp object. Open-globe lacerations are determined to be penetrating (single laceration) or perforating (two lacerations that enter and exit the eye wall).

Injuries caused by sharp objects are more common in males than females 3:1 [9]. Mechanism of injury is often due to high velocity splinters of metal or wood, which can occur during hammering (metal on metal or metal on stone), woodworking, or use of power tools. In the pediatric population, mechanisms of injury include compressed air-powered guns (paint ball and BB guns), fireworks, darts, and bungee cords [2]. Males also predominate in pediatric eye injuries.

History and Physical Exam

Patients commonly complain of a foreign body sensation, pain, and decreased visual acuity.

Globe Rupture

History and Physical Exam

Globe rupture occurs when severe blunt trauma causes the globe to split at the weakest point. Twenty percent are missed on initial presentation [12]. Findings associated with ruptured globe include irregular or oval pupil, hyphema, irregular-shaped iris, laceration with dehiscence of tissue, or leakage of fluid.

Treatment and Management of Open-Globe Injury and Globe Rupture

If open-globe injury or globe rupture is suspected, do not instill topical antibiotics or apply pressure to the eye. Patient should avoid Valsalva maneuver to prevent extrusion of ocular contents. Patients who are nauseated or vomiting should be given antiemetics. To protect against endophthalmitis, administer antibiotics with coverage for staph and strep. Antibiotic options include the oral fluoroquinolones levofloxacin (500 mg every 12 h) or moxifloxacin (400 mg every 12 h) due to excellent vitreous penetration. IV antibiotics vancomycin (1 g every 12 h) or ceftazidime (1 g every 8 h) are good alternatives [13].

After placing a protective eye shield, refer to ophthalmology immediately. CT is used to rule out intraocular foreign body. Surgical repair is recommended within 24 h.

Posterior Segment Injuries

Any of the previous described traumatic mechanisms of injury can result in posterior segment injuries. Posterior segment injuries include vitreous hemorrhage, retinal detachment, and damage to the optic nerve.

Retinal Detachment

History and Physical Exam

The typical presentation of retinal detachment is acute unilateral vision loss with floaters and flashing lights. The neurosensory layer of the retina pulls off the underlying pigment epithelium. This is usually caused by detachment of the vitreous which pulls on the retina and may cause a retinal tear. Rapid diagnosis is helpful since early treatment will minimize permanent vision loss.

Dilated funduscopic exam usually reveals retinal detachment. However, cataracts, corneal scars, or vitreous hemorrhage may obscure the retina. In that case, ultrasound is necessary for diagnosis.

Treatment and Management

Same-day referral to ophthalmology will allow treatment using laser photocoagulation to seal retinal tear, if present, and reattach the retina to the underlying epithelium. Key to prognosis is whether the macula is involved. Ophthalmology follow-up is required since patients are at a high risk for recurrent retinal detachment or detachment of the retina in the other eye [13].

Optic Nerve Injury

History and Physical Exam

Optic nerve injury can be direct (compression from bone, foreign body, edema) or indirect (shearing injury from blunt trauma to the head) [3]. Optic nerve injury is suggested by loss of afferent pupillary reflex and decreased ability to see red in the central field of vision. In the swinging flashlight test, the affected pupil will paradoxically dilate with direct illumination. This is because the light has been removed from the functioning optic nerve in the healthy eye causing dilation of both pupils since the injured optic nerve does not sense the incoming light (Marcus Gunn pupil).

Evaluation should also include dilated eye exam, visual fields, visual acuity, and color vision testing. CT scan of the orbits and head may demonstrate compressive injuries not seen on direct ophthalmoscopy.

Treatment or Management

If optic nerve injury is suspected, refer for same-day ophthalmology consultation and high-dose corticosteroids. Optic nerve injuries may result in permanent visual loss.

Shaken Baby Syndrome

Shaken baby syndrome is a triad of retinal hemorrhage, encephalopathy, and subdural hematomas. The pattern of retinal hemorrhage in shaken baby syndrome is widespread distribution, occurring at multiple depths, and too numerous to count. Any retinal hemorrhage in the setting of unexplained trauma should raise suspicion of inflicted injury [2].

Burns

Chemical Burns

Chemical burns are caused by an number of caustic agents including alkali (e.g., lye, cements, plasters, airbag powder, bleach, ammonia), acids (e.g., battery acid, pool cleaner, vinegar), solvents, detergents, and irritants (e.g., mace). The most common alkali burns involve ammonia, lime, and sodium hydroxide. Alkali burns are twice as common as acid burns and more severe, due to penetration of tissue and precipitation of glycosaminoglycans [10]. Chemical burns are a common cause of ocular trauma in males ages 16–45 as a result of accidents (work and home) or criminal assault [5]. The most common acid burns are hydrochloric acid and sulfuric acid. In the case of a chemical burn, treatment should begin immediately, even before vision testing, unless an open globe is suspected.

Emergency treatment includes copious saline irrigation for at least 20 min. One to 2 l of saline or lactated ringers should be run over the involved eye(s) using the Morgan lens irrigation apparatus. For alkali burns, tap water may be more efficacious in inhibiting elevated intracameral pH than normal saline. Never use acidic solutions to neutralize alkalis or vice versa as acid-base reactions themselves can generate harmful substrates. Irrigation is continued until neutral pH is achieved (i.e., 7–7.4) [8].

History and Physical Exam

With a chemical burn, it is critical to determine the time of exposure, the type of material, the time between exposure and irrigation, the duration and type of irrigation, and whether any eye protection was involved [5].

Table 2 Modified Dua classification for ocular surface burns

Grade	Prognosis	Clinical findings	Conjunctival involvement
I	Very good	0 clock hours of limbal involvement	0 %
II	Good	<3 clock hours of limbal involvement	<30 %
III	Good	Between 3 and 6 clock hours of limbal involvement	30–50 %
IV	Good to guarded	Between 6 and 9 clock hours of limbal involvement	50–75 %
V	Guarded to poor	Between 9 and 12 clock hours of limbal involvement	75–100 %
VI	Very poor	Total limbus involved	Total conjunctival involvement

Modified from Dua et al. [14]

Following emergency treatment, perform a slit-lamp examination with fluorescein staining to identify any corneal or conjunctival ulceration. Eyelid eversion should be performed to identify and remove any foreign bodies. The Dua classification system is helpful when referring patients to ophthalmology [5, 14] (Table 2).

Treatment and Management

Prescribe a topical antibiotic ointment, oral pain medication, and Cycloplegic. If IOP is elevated, acetazolamide 250 mg p.o. q.i.d., acetazolamide 500 mg sequel p.o. b.i.d., or methazolamide 25–50 mg p.o. b.i.d. or t.i.d. may be given. Electrolytes, especially potassium, should be monitored in patients on these medications. Add a topical beta-blocker (e.g., timolol 0.5 % b.i.d.) if additional IOP control is required. Alpha-agonists may be avoided because of their vasoconstrictive properties.

Initially, follow-up is daily, then every few days until the corneal epithelial defect is healed. Topical steroids may be used to reduce inflammation. Monitor for corneal epithelial breakdown, stromal thinning, and infection [8].

Ultraviolet Burns

Radiation injuries, or UV burns, occur as a result of exposure to ultraviolet light in snow skiing, water skiing, and other water sports. For example, snow blindness results from prolonged exposure to UV-B rays reflected from snow.

History and Physical Exam

Patients with UV burns typically present with intense pain, photophobia, and often a delay in symptom onset [4].

A fine punctate staining with fluorescein is characteristic.

Treatment and Management

UV burns are generally treated with a systemic analgesic and topical antibiotic. If epithelial defect is present, refer to an ophthalmologist. Prognosis is excellent following treatment.

Otitis Media and Externa

Gretchen Dickson* and Jennifer Wipperman
KU School of Medicine-Wichita, Wichita, KS, USA

Acute otitis media (AOM), an infection most often caused by *Streptococcus pneumoniae, Haemophilus influenzae*, or *Moraxella catarrhalis,* will affect one in four children by age 10 [1]. Differentiating the infectious AOM from the noninfectious otitis media with effusion (OME) is a critical skill for accurate diagnosis as both conditions demonstrate fluid trapped in the middle ear on physical exam.

Epidemiology

Acute otitis media is a common diagnosis in young children. Each year in the United States, more than 2.2 million episodes of acute otitis media occur [2]. Risk factors for acute otitis media include male gender, Native American ethnicity, having multiple siblings in the home, premature birth, bottle-fed status, tobacco smoke exposure, family history of recurrent AOM, and attendance at an out of home day care [3, 4]. Additionally, children with earlier onset of first episode of AOM may be more likely to have recurrent disease and complications leading to morbidity and mortality [4, 5].

Diagnosis

Acute otitis media is a clinical diagnosis that should be based on history and physical exam findings. The American Academy of Pediatrics published guidelines in 2013 to help clinicians to limit overdiagnosis and subsequent overtreatment of AOM. Bulging of a tympanic membrane with either associated intense erythema or recent onset of ear pain or new onset of otorrhea not explained by otitis externa are common presentations of AOM [6]. Middle ear effusion alone is not sufficient to diagnose acute otitis media as otitis media with effusion (OME) may also present in this manner [6]. The major factor that distinguishes acute otitis media and otitis media with effusion is that OME is not an infectious process and as such there should not be signs of infection such as an erythematous tympanic membrane or otalgia.

Treatment

Treatment for AOM has been controversial in recent years as guidelines designed to promote watchful waiting in lieu of immediate antibiotic therapy often had poor adoption by physicians [7, 8]. Current guidelines published by the American Academy of Pediatrics in 2013 emphasize the need for adequate analgesia for children during an AOM episode and offer clear definitions of children who would be most likely to benefit from observation rather than immediate antibiotic therapy.

Table 1 When to use antibiotics other than amoxicillin for AOM [6, 16]

Special circumstance	Antibiotic choice instead of amoxicillin
Child had amoxicillin in prior 30 days	Amoxicillin-clavulanate (90 mg/kg/day amoxicillin and 6.4 mg/kg/day clavulanate)
Child has concurrent bacterial conjunctivitis	Amoxicillin-clavulanate (90 mg/kg/day amoxicillin and 6.4 mg/kg/day clavulanate)
Child has penicillin allergy	Cefdinir, cefuroxime, cefpodoxime, or ceftriaxone
Child has tympanostomy tubes in place	Topical ciprofloxacin/dexamethasone
Child on amoxicillin not improving in 48–72 h	Amoxicillin-clavulanate (90 mg/kg/day amoxicillin and 6.4 mg/kg/day clavulanate), ceftriaxone, or clindamycin

Analgesia

Acute otitis media is associated with significant pain that may persist for up to 7 days, despite antibiotic therapy [9]. Both oral and topical medication choices exist to alleviate pain associated with AOM. Oral ibuprofen or acetaminophen as well as topical procaine, phenazone, or benzocaine has all been shown to be effective for AOM-related pain [10–12]. Narcotic pain medications, antihistamines, and decongestants are associated with significant side effects that outweigh any potential analgesic benefit for AOM [10, 13]. Other pain relief options may include naturopathic remedies or osteopathic manipulation though randomized controlled trials that demonstrate effectiveness of these options are limited [14, 15].

Antibiotic Therapy

All children older than 6 months with evidence of acute otitis media with otorrhea or who have severe symptoms should receive immediate antibiotic therapy [6]. Severe symptoms include toxic appearance, persistent otalgia for more than 48 h, temperature greater than 39° Celsius in the last 48 h, or uncertain ability to follow-up [6]. Additionally, children less than 2 years of age with bilateral acute otitis media should receive immediate antibiotic therapy [6].

First-line antibiotic treatment for acute otitis media remains amoxicillin 80–90 mg/kg/day [3]. Special circumstances that may necessitate the use of an alternative antibiotic are described in Table 1.

Children less than 2 years of age should be treated for 10 days with antibiotics while older children may be offered a 5–7 day course of therapy [6]. Any child who fails to improve after appropriate antibiotic therapy should be considered a candidate for tympanocentesis and culture of middle ear fluid to guide therapy [6].

Observation

Children who are older than 6 months with unilateral AOM without otorrhea or severe symptoms or children older than 2 years with bilateral AOM without otorrhea or severe symptoms are candidates for observation rather than immediate antibiotic therapy [6]. No child should be offered observation as a treatment option if there is concern that the child will not be able to return for evaluation or obtain antibiotics if they fail to improve in 48–72 h of onset of symptoms [6]. As 78 % of AOM episodes will resolve spontaneously and antibiotic side effects such as rash and diarrhea are common, observation in well-chosen patients is a reasonable option [17, 18].

Surgical Options

Children who have more than three episodes of AOM within a 6-month period or more than four episodes of AOM within a year should be referred for evaluation for tympanostomy tubes [19].

DOI 10.1007/978-1-4939-0779-3_79-1

Complications

Acute otitis media can be associated with significant complications. Hearing loss may be a temporary result of fluid within the middle ear. Unfortunately, fluid may remain for weeks or months following an episode of AOM. Though hearing loss may be frustrating for both child and parents during this time, little evidence exists that speech and language delays result from this hearing loss alone [20–22]. Of note, however, rarely permanent sensorineural hearing loss may occur as a result of AOM.

Balance problems, tympanic membrane perforation, and cholesteatoma may also result from acute otitis media with recurrent episodes increasing risk [23]. Chronic suppurative otitis media, mastoiditis, petrositis, labyrinthitis, meningitis, abscess in the brain or epidural space or thrombosis of the lateral sinus, cavernous sinus, or carotid artery may also result from acute otitis media. Thankfully, these complications are rare. Of note, no studies have demonstrated an increase in meningitis or mastoiditis since implementation of observation guidelines in children [4].

Prevention

Effective prevention strategies would yield large benefits given the prevalence of AOM. While no targeted acute otitis media vaccine exists, introduction of higher-valent pneumococcal vaccines as well as increased influenza vaccination rates have resulted in risk reduction for AOM [24–26]. Supplementation with vitamin D and zinc has been shown to be beneficial only in children with documented nutritional deficiencies [27–30]. Xylitol, a polyol sugar alcohol found in raspberries, has been demonstrated to be effective at preventing acute otitis media though current dosing requirements of administration five times daily make its use limited [31]. Formula-fed infants may benefit from probiotics such as *Lactobacillus rhamnosus* GG and *Bifidobacterium lactis* Bb-12 [32]. However, exclusive breastfeeding may be more beneficial as a risk reduction strategy than probiotic-supplemented formula [3]. In infants, eliminating exposure to passive tobacco smoke and reducing pacifier use after 7 months of life may also lead to reduced incidence of AOM [3].

Otitis Externa

Otitis externa is defined as inflammation of the external auditory canal. It may be classified as acute, lasting less than 6 weeks, or chronic, lasting more that 3 months. Most cases of acute otitis externa (AOE) are infectious, while most cases of chronic otitis externa (COE) are allergic or related to a dermatologic condition.

Epidemiology

AOE is a disease of the young, with 95 % of cases occurring at those aged 18 years or younger [33]. It tends to occur in the summer and in warmer, humid climates. Risk factors include repetitive ear trauma, water exposure, hearing aids, and underlying dermatologic conditions such as eczema or psoriasis.

DOI 10.1007/978-1-4939-0779-3_79-1

Pathophysiology

Trauma to the epithelial lining of the ear canal, lack of cerumen, and disturbance of the normal acidic environment can lead to bacterial or fungal infection causing an inflammatory response. Cerumen protects the ear canal by limiting exposure to moisture, creating a slightly acidic pH and inhibiting bacterial growth through lysozymal activity. Self-cleaning the ear canal, such as with cotton swabs, not only removes cerumen but traumatizes the ear canal, and is a common cause of AOE. Excessive water exposure, such as in swimmers ("swimmer's ear"), can cause maceration and breakdown of the epithelial lining.

Most (98 %) cases of AOE are bacterial [34]. *Pseudomonas aeruginosa* and *Staphylococcus spp.* are most often implicated, and AOE may be a polymicrobial infection. Fungal infection (otomycosis) is uncommon but may be seen after treatment of AOE with topical antibiotics.

Diagnosis

Patients with AOE present with the rapid onset of ear pain, itching, or fullness (Table 1) [35]. Some patients also experience hearing loss, due to obstruction of the ear canal, or jaw pain. On physical exam, tenderness of the pinna or tragus is the hallmark of AOE. Early in its course, the tenderness is often severe and disproportionate to physical exam findings. As AOE progresses, the ear canal may become diffusely edematous and erythematous, with otorrhea that obstructs the tympanic membrane. Regional lymphadenitis or cellulitis of the pinna and surrounding skin may occur.

AOE can lead to inflammation of the tympanic membrane, making distinction between AOE and AOM difficult. Furthermore, AOE and AOM may co-occur and should be treated as separate entities. Pneumatic otoscopy and tympanometry are useful to help differentiate the two. Mobility of the tympanic membrane with pneumatic otoscopy and a normal peaked curve (type A) on tympanometry help rule out a middle ear effusion. In addition, normal tympanometry is indicative of an intact tympanic membrane, which is useful when the tympanic membrane is obstructed by canal edema and debris.

Obtaining cultures for bacteria and fungi is not generally needed for AOE. However, cultures should be obtained in patients with recalcitrant or recurrent cases, frequent topical antibiotic use, or immunocompromised states.

Treatment

Successful management of AOE includes aural toilet, treatment of infection, pain control, and avoiding promoting factors. Removing debris and impacted cerumen will allow topical antibiotics to penetrate the ear more effectively and enhance healing. Additionally, it important to ensure that there are no retained foreign bodies, especially in children. Debris may be cleared using gentle suction or direct visualization with an otoscope and blotting with a cotton swab or ear speculum. Irrigation may be used if the tympanic membrane is intact, but should be avoided in patients who are immunocompromised or with diabetes mellitus as there is an increased risk of malignant otitis externa [36]. Placement of an ear wick facilitates drug delivery if there is significant canal edema.

Topical therapy is the mainstay of treatment for AOE (Table 2). Generally, antiseptic and antibiotic preparations have similar effectiveness, and there is little difference between antibiotic classes [37]. Therefore, treatment should be based on convenience, cost, and potential adverse effects. Acetic acid 2 %

DOI 10.1007/978-1-4939-0779-3_79-1

Table 2 Common topical preparations for acute otitis externa

Component	Brand name	Cost[a]	Dosage	Comments
Acetic Acid 2 % solution	VoSol	$	3–5 drops every 4–6 h	Avoid if TM perforated. May cause local irritation
Acetic acid 2 %/hydrocortisone 1 % solution	VoSol HC	$$$	3–5 drops every 4–6 h	As above
Neomycin/polymyxin B/hydrocortisone solution	Cortisporin	$	3–4 drops every 6–8 h	Avoid if TM perforated
Ciprofloxacin 0.2 % solution	Cetraxal otic	$$	3–4 drops every 12 h	Single-use containers
Ciprofloxacin 0.2 %/hydrocortisone 1 % suspension	Cipro HC	$$$	3–4 drops every 12 h	
Ciprofloxacin 0.3 %/dexamethasone 0.1 % suspension	Ciprodex	$$$	3–4 drops every 12 h	
Ofloxacin 0.3 % solution	Floxin otic	$	10 drops once daily	
Dexamethasone 0.1 % suspension	Maxidex	$$		

[a]Based on generic price if available. Cost information obtained from www.goodrx.com; $ = 0–50 USD, $$ = 50–100 USD, $$$ = >100 USD

(VoSol) is inexpensive and provides similar cure rates to topical antibiotics in mild cases of AOE. However, it may cause local irritation and, due to ototoxicity, should be avoided if the tympanic membrane is not intact.

Topical antibiotics include fluoroquinolone and aminoglycoside preparations, which are effective against *Pseudomonas* and *Staphylococcus spp*. Aminoglycoside preparations are usually inexpensive and well tolerated. However, they require frequent (four times daily) dosing and are ototoxic to the inner ear. Neomycin, which is a found in Cortisporin otic, is a frequent cause of contact dermatitis. Fluoroquinolones are dosed twice daily and are the treatment of choice if the tympanic membrane is not intact or cannot be visualized. However, most fluoroquinolone preparations are more costly. Many topical preparations are available in combination with a steroid, which hastens resolution of pain and itching [38]. Patients should be treated for 7 days. If symptoms are not resolved, drops may be continued until resolution and then continued for 2–3 more days. Systemic antibiotics are not needed in most cases of AOE. Topical antibiotics reach high concentrations in the ear canal and are effective even against resistant bacterial strains. Systemic antibiotics, usually a fluoroquinolone (ciprofloxacin 500 mg twice daily for 7–10 days), are indicated if there is surrounding cellulitis, if canal edema limits penetration of topical antibiotics, or if the patient is immunocompromised.

Patient education on administration of topical preparations is paramount to successful treatment. Drops should be applied with the patient lying on their side with the affected ear up. Application is more successful if another person administers the drops. Enough drops should be instilled until the entire canal is filled, gently pulling the pinna to and fro to eliminate air trapping. Patients should wait 3–5 min before sitting up.

Pain control is achieved with over-the-counter analgesics such as acetaminophen or nonsteroidal anti-inflammatory drugs. Severe cases may require opioid analgesics. Topical benzocaine should be avoided as continued use can mask progression of disease; it is also ototoxic and can cause a contact dermatitis.

DOI 10.1007/978-1-4939-0779-3_79-1

Monitoring

Most patients improve dramatically within 48–72 h and have minimal or no symptoms by 7 days. If there is no improvement within 48 h, or symptoms continue for more than 14 days, patients should be reevaluated. Common causes for treatment failure include inadequate drug delivery, canal obstruction, or misdiagnosis. Referral to an otolaryngologist is indicated if there is lack of expected improvement, inability to remove debris, or suspected malignant otitis externa.

Complications

Infection may extend to surrounding structures, causing chondritis, perichondritis, or facial cellulitis. Over time, patients with chronic infection may develop canal stenosis and conductive hearing loss. Malignant otitis externa is a severe, life-threatening complication of AOE and occurs most often in diabetic adult patients [39]. Infection spreads from the skin of the ear canal to bone of the skull base (osteomyelitis), causing severe pain, canal erythema, edema, and otorrhea. Granulation tissue is often visualized on the floor of the ear canal. Patients may have fever and signs of systemic toxicity. Sedimentation rate is usually significantly elevated, and diagnosis is confirmed with imaging by computed tomography or magnetic resonance imaging. Treatment requires intravenous antibiotics that cover *Pseudomonas* and potentially surgical debridement.

Prevention

Patients with AOE should avoid water immersion for 7–10 days. Patients may place a petroleum jelly-coated cotton ball in the affected ear while bathing. Competitive swimmers may return to play after 2–3 days if pain is resolved and they use well-fitting earplugs. Hearing aids should be avoided until pain has subsided.

To prevent future episodes, moisture retention in the ear canal should be minimized. Acidifying drops, such as acetic acid 2 %, or a hair dryer on the lowest setting, can be used to dry out the ear canal after swimming. Well-fitting earplugs can also limit water exposure. Any trauma to the ear is best avoided, including frequent ear cleaning and poorly fitting hearing aids.

Chronic Otitis Externa

Chronic otitis externa is a common pathway for several disease states and should be considered in the differential diagnosis of AOE (Table 3). Chronic inflammation of the ear canal may be due to allergic contact dermatitis, dermatologic conditions such as psoriasis, or chronic bacterial or fungal infection. Patients usually have more itching than pain. Contact dermatitis causes a maculopapular rash with excoriations on the external ear. Patients with psoriasis and atopic dermatitis may have an eczematous, lichenified appearance to the ear canal and external ear. In seborrheic dermatitis, the ear canal often lacks cerumen and is erythematous with dry, flaky skin. COE may result from chronic otitis media with tympanic membrane perforation, as the drainage causes chronic irritation and infection. In otomycosis, fluffy, cotton-like debris may be seen in the canal, as well as with sprouting hyphae or black dots. Culture for bacteria and fungi is prudent if chronic infection is suspected.

DOI 10.1007/978-1-4939-0779-3_79-1

Table 3 Differential diagnosis of acute otitis externa

Carcinoma of the ear canal
Chronic suppurative otitis media
Contact dermatitis
Eczema or Psoriasis
Furunculosis
Herpes zoster oticus
Malignant otitis externa
Otomycosis
Seborrheic dermatitis

Treatment of COE depends on the cause. For most dermatologic conditions, a medium-to-high-potency topical steroid is effective. Clotrimazole 1 % solution or cream treats most fungal otitis externa. Patients with bacterial infection should be managed as for AOE.

Box 1: Diagnostic Criteria for Acute Otitis Externa

1. Rapid onset (generally within 48 h) in the past 3 weeks
2. Symptoms of ear canal inflammation that include:
   - Otalgia (often severe), itching, or fullness
   - *With or without* hearing loss or jaw pain
3. Signs of ear canal inflammation that include:
   - Tenderness of the tragus, pinna, or both
   - Diffuse ear canal edema, erythema, or both
   - *With or without* otorrhea, regional lymphadenitis, tympanic membrane erythema, or cellulitis of the pinna and adjacent skin

Disorders of the Oral Cavity

Nicholas Galioto* and Erik Egeland
Department of Family Medicine, Broadlawns Medical Center, Des Moines, IA, USA

Healthy People 2020 lists oral health as one of its top nine health indicators [1]. Diseases of the oral cavity can have a significant impact on the overall health of the individual patient. The mouth can provide a window to the body. Disease in the mouth can cause systemic disease such as endocarditis, make chronic disease management such as diabetes more difficult, or provide clues to the timely diagnosis of systemic disease [2].

Caries

Dental caries or tooth decay is the most common infection or chronic disease affecting the mouth [3–5]. Half of US seniors perceive their dental health as poor or very poor, and less than 50 % of people age 2 years and older have had a regular dental check-up in the last 12 months [1]. Fifty percent of children between the ages of 6 and 8 years old have dental caries, and nearly 24 % of adults age 24–64 have untreated dental caries [2–4]. Dental caries develops through the complex interaction of oral microorganisms (*Streptococcus mutans* and lactobacilli), metabolizing dietary sugars into lactic acid creating an acidic environment [2, 4, 5]. This acidic environment leads to demineralization of the tooth's protective enamel coating and subsequent tooth decay. When the subsequent caries or decay penetrates through the full thickness of the enamel to reach the underlying dentin layer, patients will begin to typically experience mild intermittent tooth pain or sensitivity to thermal changes or sugary foods. This process is also known as reversible pulpitis and is treated through the mechanical removal of the decayed area and restoration through the placement of a dental filling [3, 4]. As the demineralization process progresses, areas of dental caries may become brown or black stained making them more visible to the naked eye. If the caries goes untreated, irreversible pulpitis may ensue resulting in severe persistent dental pain despite removal of any inciting stimulus. The patient with irreversible pulpitis will often present with poorly localized pain or even pain referred to the opposite jaw [3, 4]. Once again definitive treatment involves mechanical removal of the decay through either restoration or extraction by a dentist. Insufficient evidence exists in the literature to recommend antibiotic therapy, unless infection has spread to the surrounding soft tissue [3–5].

Dental exams should begin when patients are 1 year of age. However, the most cost-effective intervention for prevention is the public health policy of adding 0.7–1.0 parts per million of fluoride to the municipal water supply [3]. Fluoride's mechanism of action helps to strengthen tooth enamel and also has a bacteriostatic effect. Whether or not local water has been fluoridated, the effectiveness of topical fluoride has been well established. When compared with mouth rinses or gels, fluoridated toothpastes have a similar degree of effectiveness for the prevention of dental caries in children [3]. Parents should introduce toothbrushing with a pea-size amount of low-fluoride toothpaste to children at 2 years of age. In children younger than 2 years, parental brushing without toothpaste is recommended. After the age of six, children can safely use regular fluoridated toothpaste. The use of mouth rinses and gels at home is not recommended for children younger than six years. Toothbrushing with fluoridated toothpaste twice a day after meals is recommended as an effective way to prevent tooth decay on exposed surfaces, and flossing

*Email: ngalioto@broadlawns.org

DOI 10.1007/978-1-4939-0779-3_80-1

daily helps prevent plaque build-up on interdental surfaces. Children and adolescents should also be considered for dental sealants when they are most likely not to be compliant with daily dental hygiene regimes [4]. Sealants are resinous materials that are professionally applied to the biting surfaces of teeth most susceptible to decay (molars and premolars). These sealants create a barrier against acid environments and bacterial penetration. Additionally, dietary changes such as reducing the amount and frequency of foods with high sugar content may further decrease dental caries rates.

Periodontal Diseases

Periodontal disease is an inflammatory response caused mainly by bacterial colonization within the subgingival dental plaque. Though bacterial colonization is an essential component to the development of periodontal disease, certain conditions such as Down's syndrome, Papillion–Lefevre syndrome, diabetes, xerostomia, medications, and smoking may further dispose a patient to periodontal disease [2–3, 5]. Some evidence also suggests that the presence of chronic periodontal disease may exacerbate the progression of certain diseases such as diabetes and cardiovascular disease [3, 5]. Periodontal disease can be divided into gingivitis and periodontitis.

Gingivitis

Gingivitis is characterized by reversible inflammation of the gums. Patients present with erythematous swollen tender gums that bleed with routine brushing or flossing. Halitosis may also be present. Pregnancy or other hormonal changes may increase the prevalence of gingivitis in female patients. Medications such as phenytoin, calcium channel blockers, and cyclosporine can also lead to increased inflammatory or noninflammatory gingival hyperplasia [4]. Care should include removing any offending agents such as medications and tobacco and improved daily oral hygiene. General measures for treating and future prevention include improved oral hygiene with frequent toothbrushing, daily flossing, and use of warm saline or chlorhexidine gluconate 0.12 % rinses [3, 4]. Mouth rinses containing essential oils such as Listerine has been shown to be as effective as chlorhexidine but with less tooth staining [3, 4]. Antibiotics are not necessary unless patient presents with acute necrotizing ulcerative gingivitis also known as Vincent's disease or trench mouth [5]. Trench mouth is caused by anaerobic bacteria (*Treponema*, *Selenomonas*, *Fusobacterium*, and *Prevotella intermedia*) and typically presents in patients whose host defenses are compromised by poor oral hygiene, poor nutrition, or systemic illness. Clinically the gingival tissue is denuded with punched-out crater-like areas of necrosis and is accompanied by pain, fetid breath odor, fever, malaise, and cervical lymphadenopathy. In addition to the general measures for treating gingivitis, patients should be prescribed penicillin VK 500 mg orally every 6 h or metronidazole 500 mg orally twice daily [5]. Patients should be given a 7-day course of either regime depending on patient allergy history and/or prescriber preference.

Periodontitis

If left untreated, chronic gingivitis over a period of months to years progresses to periodontitis. Persistent exposure of the mouth to plaque-associated bacteria leads to a local and systemic inflammatory response. This inflammatory response leads to the destruction of the tooth's underlying supporting tissue and alveolar bone. Clinical presentation may demonstrate deep inflamed painful gums with deep pockets that bleed easily, heavy tooth plaque, receding gums with exposed root, and loose teeth. Proliferation of bacteria within the deep gum pockets can lead to periodontal abscess formation, which in addition to pain and swelling is further characterized by suppurative drainage. The most common organisms implicated in periodontitis are gram-negative bacteria such as *Actinobacillus actinomycetemcomitans*, *Porphyromonas*

DOI 10.1007/978-1-4939-0779-3_80-1

gingivalis, and spirochetes [5]. General measures for treating periodontitis should be aggressive plaque descaling by a dentist, incision and drainage of local abscess, and good oral hygiene practices as outlined in the gingivitis section. Antibiotics are indicated when an abscess spreads to the deeper tissues of the oral cavity causing facial swelling and lymphadenopathy or if generalized periodontitis exists where the patient has multiple loose teeth [3, 4]. Antibiotic regimes include doxycycline 100 mg daily, metronidazole 500 mg orally twice daily, or topical application of metronidazole, doxycycline, or minocycline [2–3, 4]. Periodontitis is a common and serious condition affecting approximately 20 % of all adults and is the leading cause of tooth loss [4]. Besides causing focal oral disease, multiple studies demonstrate an association between periodontitis and cardiovascular disease, worsening diabetes, and increased risk for preterm labor [2, 4]. However, no study has demonstrated whether treating or preventing periodontal disease leads to improved systemic disease outcomes [4].

Candidiasis

Candida species are normal inhabitants of the gastrointestinal tract and present as part of the normal oral flora in sixty percent of healthy adults [2, 4, 6]. Certain local and systemic factors may make certain individuals more susceptible to oral candidal infections. These include infection with human immunodeficiency virus (HIV), diabetes or glucose intolerance, xerostomia, malnutrition, presence of dentures, patients with cancer, medications (broad spectrum antibiotics, inhaled or systemic steroids, chemotherapy), and reduced immunity related to age [2, 4, 6]. Oral candidiasis is common in infants, affecting 1–37 % of newborns [6]. Diagnosis is usually made through a history of risk factors and symptoms. The most common presentation is of painless adherent curd-like white patches along the oral mucosa and/or tongue. These white patches can be partially wiped off using a tongue blade or gauze and diagnosis confirmed either by culture or by preparing a potassium hydroxide slide looking for hyphae. Oral candidiasis may also present as erythema of the oral mucosa especially in denture wearers and/or as angular cheilitis/perleche (painful, erythematous fissures at the corners of the mouth). Common treatments include nystatin suspension 100,000 U/ml four to six times daily, Mycelex (clotrimazole) troches 10 mg five times a day, or fluconazole (Diflucan) 200 mg orally on day one then 100–200 mg daily [3, 4, 6]. Infants should be treated with nystatin suspension 0.5 ml in each cheek, massaging the cheeks to spread throughout the oral cavity. Fluconazole 6 mg/kg orally on day one and 3 mg/kg thereafter may be used as an alternative for resistant cases. All regimes are used for an average of 7–14 days. All pacifiers and bottle nipples should be boiled. In breastfed infants, mother's nipples may be treated if needed, with topical antifungal creams or ointment.

Stomatitis

Characterized by inflammation of the mucosal lining of the mouth, lesions are erythematous, are painful, and can be ulcerated. Most common conditions include hand–foot–mouth disease, herpetic stomatitis, and recurrent aphthous stomatitis/ulcers. Additional causes include herpangina, nicotinic stomatitis, and denture-related stomatitis. Any remaining causes are considered rare and uncommon. The most common forms of stomatitis present with shallow ulcerations less than 1 cm in diameter and resolve spontaneously over 10–14 days [4, 6]. Patients usually present with complaints of burning sensation, localized pain, irritation with certain foods, and intolerance to temperature changes. Recurrent aphthous ulcers or "canker sores" affects 5–21% of the population and etiology remains unclear [6]. Treatment focus is on providing topical relief (see Table 1). Since disease course is generally self-limited, when an ulcer persists beyond

DOI 10.1007/978-1-4939-0779-3_80-1

Table 1 Topical agents for symptom relief of aphthous ulcers

Two percent viscous lidocaine (swish and spit)
Topical steroid (Kenalog) in Orabase three to four times daily
Miracle mouthwash: various combinations in equal parts (swish and spit several times daily)
Maalox or Mylanta, diphenhydramine, 2 % viscous lidocaine
Maalox or Mylanta, diphenhydramine, Carafate
Nystatin, diphenhydramine, hydrocortisone

3 weeks, other causes should be considered. Nutritional deficiencies, such as folate, B_{12}, B_6, or iron, drug reactions, Behcet's disease, Reiter's syndrome, inflammatory bowel disease, celiac sprue, lichen planus, and HIV infection have all been associated with recurrent aphthous ulcers [4, 6, 7]. Additionally, squamous cell cancer may present as a nonhealing or non-resolving ulcer, and biopsy of the ulcer should be considered [4].

Lichen Planus

Lichen planus is a chronic inflammatory condition most likely precipitated by an autoimmune response. Lichen planus affects approximately 1–2 % of the population, more often in those over age forty and a slight predilection in perimenopausal women [4, 6, 8]. In women with oral lichen planus, 25 % of them will also have concomitant involvement of the vulva and vagina [8]. Patients with lichen planus have also showed a greater prevalence for exposure to hepatitis C (HCV), making it appropriate to screen patients with lichen planus for HCV infection [8, 9]. There are four forms of oral lichen planus: reticular, atrophic, bullous, and erosive. The reticular form is the most common and manifests as asymptomatic bilateral white lace striations on the oral mucosa. The atrophic form presents as erythematous atrophic-appearing lesions within the oral mucosa and may be more painful than the reticular form. The bullous form manifests as fluid-filled vesicles, while the erosive form leads to ulcerated erythematous, painful lesions. Patients can often have a burning sensation within their mouth. Management options should start with good oral hygiene and avoiding irritating foods and tobacco products. Medium- to high-potency topical steroids are first-line therapy to treat symptomatic lichen planus [4, 8]. Clobetasol 0.05 % or fluocinonide 0.05 % is applied twice daily to lesions [8]. Topical calcineurin inhibitors such as pimecrolimus 1 % (Elidel) or tacrolimus 0.1 % (Protopic) can be effective for those patients that do not respond to topical steroids [8].

Glossitis

Geographic tongue also known as known as benign migratory glossitis affects 1–14 % of the population and is of unknown etiology [10, 11]. Geographic tongue is characterized by areas of papillary atrophy that appear smooth and are surrounded by raised wavy borders. The regions of atrophy spontaneously resolve and migrate giving the tongue a topographic map appearance. The condition is benign, but some patients may have sensitivity to hot or spicy foods. Treatment includes bland foods and use of topical steroids triamcinolone 0.1 % (Oralone) or antihistamine mouth rinses which also can be used to help reduce tongue sensitivity [10].

In fissured tongue deep groves develop within the tongue usually due to the physiologic deepening of normal tongue fissures secondary to aging. The deeper fissures can lead to food trapping causing inflammation of the tongue and halitosis. Gentle brushing of the tongue is useful in symptomatic patients.

DOI 10.1007/978-1-4939-0779-3_80-1

Down's syndrome, Sjogren syndrome, Melkersson–Rosenthal syndrome, psoriasis, and geographic tongue have all been associated with fissured tongue [10].

Hairy tongue results from the accumulation of keratin on the filiform papillae of the dorsal tongue leading to hypertrophy of the papillae. The hypertrophied papillae tend to resemble elongated hairs. Bacteria and debris get trapped in the elongated hairs causing discoloration of the tongue. Color of the tongue can range from white to tan to black. This condition is most often associated with smoking, poor oral hygiene, and antibiotic use [6, 10, 11]. Most patients are asymptomatic but some may experience halitosis or abnormal taste. Daily debridement with a soft toothbrush or tongue scrapper can remove the keratinized tissue.

Oral hairy leukoplakia is characterized by white hairy-appearing lesions on the lateral borders of the tongue either in a unilateral or bilateral fashion. This condition is associated with Epstein–Barr super infection or immunocompromised condition [10, 11]. In the absence of a known immunocompromised condition, testing for human immunodeficiency virus (HIV) should be considered. Treatment consists of the use of antiviral medications though recurrences are common. Acyclovir (Zovirax) 800 mg orally five times daily or ganciclovir 100 mg orally three times a day for 1–3 weeks may be used [10].

Atrophic glossitis results from the atrophy of the filiform papillae and is also referred to as smooth tongue. The tongue has a smooth glossy appearance with a red or pink background, and the patient will often complain of a painful sensation within the tongue. Atrophic glossitis is most commonly caused by nutritional deficiencies [10]. Nutritional deficiencies of iron, folic acid, riboflavin, niacin, and B_{12} are most often implicated [10]. Other possible etiologies include syphilis, candidal infection, amyloidosis, celiac disease, Sjogren syndrome, protein malnutrition, and xerostomia [9].

Halitosis

Halitosis is an unpleasant or offensive odor emanating from the oral cavity. In approximately 80 % of the cases, halitosis is caused by conditions of the oral cavity [12]. The most likely cause of oral malodor is the accumulation of food debris and bacterial plaque along the teeth and tongue. The oral malodor arises from the microbial degradation of these organic substrates into volatile sulfur-containing gas compounds. Though the majority of cases of halitosis originate in the oral cavity, non-oral etiologies may include infections of the upper or lower respiratory tract, metabolic disturbances, carcinomas, systemic diseases, and medications [12]. Therefore, before halitosis can be managed effectively, an accurate diagnosis must be made. Achieving an accurate diagnosis starts with first determining whether the source of the odor is of an oral or non-oral etiology. One of the simplest ways to distinguish oral from non-oral etiologies is to compare the smell coming from the patient's mouth with that exiting the nose. To perform this sniff test, have the patient tightly hold their lips together and forcibly blow air through the nostrils. Repeat the test with the patient holding their nostrils closed and passively breathing through their mouth. One can then compare the odors emanating from each cavity and further characterize the intensity and quality of the odor. A systemic origin may be suspected in the case where the odor from the mouth and nose are of the same intensity and quality [13].

As noted the majority of cases of halitosis originate from the oral cavity. The oral cavity should be inspected for evidence of gingivitis, periodontal disease, and oral cancers. All of which can produce foul putrid-smelling breath. In patients where a rigorous oral hygiene regime of twice daily brushing, flossing, and professional cleaning does not improve the problem, the tongue especially the posterior region should be suspected [12, 13]. The posterior tongue can be assessed by obtaining a gentle scrapping of the area using a plastic spoon. The spoon can be smelled to compare the odor with the overall mouth odor [14]. Gentle but thorough tongue cleaning using either a tongue scrapper or toothbrush should be added to

DOI 10.1007/978-1-4939-0779-3_80-1

the daily oral hygiene routine. Faulty dental restorations or dentures can be another etiology of bad breath. The odor from dentures may have a somewhat sweet though unpleasant nature and can be more easily identified when the dentures are placed in a sealed plastic bag and smelled after a few minutes [14]. Saliva also affects bad breath. Xerostomia or dry mouth may be a contributor to halitosis secondary to decreased salivary flow and the resultant increased risk for dental infections. A transient odor associated with acute tonsillitis is common especially in children. Tonsillectomy however is rarely indicated for chronic halitosis [12, 14].

Nasal sources are second in frequency to oral etiologies as causes of halitosis [12, 14]. Nasal odor is often indicative of sinus infection, but may also signal an obstruction to normal air flow that could occur with nasal polyps, craniofacial anomalies, or foreign body (especially in small children). Nasal discharge can have a fetid cheesy odor [14]. The lungs are also a source of some odors secondary to infection and/or metabolic disorders. A pulmonary source is suggested when the odor intensity increases during expiration. Lung abscess, necrotic tumors, tuberculosis, and bronchiectasis are all possible infections causing bad breath. Because of the associated pus production and tissue necrosis with these diseases, a putrid foul odor similar to rotting meat is produced [14]. Hepatic failure, renal failure, and diabetes are all systemic diseases that may contribute to or present as halitosis. Hepatic failure or cirrhosis may have a mousy, musty, or rotten egg smell, while the uremia from kidney failure can impart a fishy ammonia-type smell to the breath [14]. Trimethylaminuria is a rare genetic metabolic condition that can also produce a foul fishy odor [12, 13]. Diabetes is best known for its distinct sweet fruity odor [14]. GI causes are rarely implicated, though some sources have reported halitosis as a symptom related to *Helicobacter pylori* (*H.pylori*) infection [11, 12]. Studies investigating the reduction or elimination of halitosis in *H.pylori* patients after antibacterial therapy have not clearly demonstrated that the improvement in symptoms is not just a consequence of the simultaneous eradication of odor-producing oral bacteria [11].

Temporomandibular Disorders

Temporomandibular joint (TMJ) disorders are a constellation of conditions characterized by pain and/or dysfunction of the TMJ and surrounding tissues. Incidence is approximately 15 % in the general population, although a much smaller percentage seeks medical care for their symptoms [16]. TMJ disorders are thought to be three to four times more common in women, with onset of symptoms usually in the first half of life [16, 17]. In most cases, these disorders lack organic pathology, are self-limited, and resolve spontaneously [17]. Patients complain of pain, clicking or popping of the jaw, and occasionally limited range of motion. Pain severity is often poorly correlated with the degree or presence of organic pathology. Examination may reveal tenderness of the TMJ and/or muscles of mastication. Occasionally there is palpable crepitus or audible clicks; however, these findings are also commonly found in asymptomatic individuals as well. The TMJ may be imaged with a panoramic radiograph to screen for organic pathology [17]. More advanced imaging such as ultrasound, CT, or MRI should be ordered based on the findings of the panoramic film. Inter-incisal opening can be serially measured to assess for improvement. Underlying causes of TMJ disorders and treatments options are poorly understood. Behavioral, psychological, and structural factors all appear to contribute to the formation of TMJ disorders. The differential diagnosis of TMJ disorders should include, but is not limited to, osteoarthritis, rheumatoid arthritis, temporal arteritis, and claudication of the masticatory muscles. Oral habits such as frequent gum chewing or bruxism may aggravate or cause inflammation within the joint. Current literature indicates a need for high-quality randomized control trials comparing various treatment options. However, the one concept that all authors emphasize is that patient education be at the forefront of treating nonorganic and chronic TMJ disorders [16–18]. It is important for patients to understand that TMJ is

DOI 10.1007/978-1-4939-0779-3_80-1

generally not related to oral pathology and these disorders are self-limiting and nonprogressive in the absence of any systemic disease. The mainstay and most common dental treatment for TMJ has been dental splinting or interocclusal orthosis. Dental splints work to primarily open the mouth, release muscle tension, and prevent teeth clenching or grinding [17, 18]. Generally most patients perceive the splint to be effective in providing symptomatic improvement. Cognitive behavioral therapy, muscle relaxation techniques, biofeedback, physical therapy, and acupuncture have all shown to be helpful in at least temporarily reducing the pain associated with TMJ [16–18]. Nonsteroidal anti-inflammatory agents are frequently utilized as first-line pain medications. Other medications to be considered include corticosteroids, muscle relaxants, antiepileptics, anxiolytics, and tricyclic antidepressants. Referral for surgical evaluation is rarely indicated in the absence of organic pathology [17, 18].

Oral Cancer

Cancers of the oral cavity and oropharynx are the ninth most common cancer in the United States [19]. African-Americans have a higher incidence than Caucasians, and males have a slight predominance over their female counterparts [19]. Patients are typically over age 40 at time of presentation. Squamous cell carcinomas account for approximately 90 % of all oral cancers [4, 19]. Most commonly these lesions occur on the tongue, floor of the mouth, and vermillion border of the lower lip. The major risk factors for developing oral cancer are tobacco use of any kind and heavy alcohol consumption [2, 4, 19]. Over 75 % of all head and neck cancers are linked to one or both of these risk factors, and there does appear to be a synergistic effect when the two are used concomitantly [4]. Despite decreased smoking rates over recent years, the incidence of oral cancers has continued to rise. This increased incidence of oral cancers is largely explained by the rise in human papillomavirus (HPV)-positive cancers [20]. These cancers tend to occur more frequently in younger Caucasian males and have sexual behavior as the main risk factor [20]. Other potential risk factors for oral cancers include ultraviolet light exposure, history of previous head and neck radiation, HIV, and chronic mechanical irritation from poor fitting dentures or restorations. Overall 5-year survival rate for oral cancer is 50–55 %, but if detected at an early stage, survival rates can approach 90 % [4]. HPV-related oral cancers tend to have better survival rates and lower rates or recurrence [4, 20]. Oral cancers can be subtle and asymptomatic in the early stages and may present as a solitary chronic ulceration, red or white lesion, indurated lump, fissure, or enlarged cervical lymph node. Other concerning symptoms include bleeding, unexplained mouth or ear pain, odynophagia, chronic sore throat, or hoarseness. Oral leukoplakia is the most commonly known premalignant lesion and is defined as a white patch or plaque that cannot be explained by another clinical cause [5, 18]. Similar red lesions are called erythroplakia, and combined red and white lesions are known as speckled leukoplakia or erythroleukoplakia. Erythroplakia and erythroleukoplakia are more likely than leukoplakia to microscopically demonstrate dysplastic or cancerous changes [19]. Any ulcer, white, red, or mixed lesion that is not resolving after removing any irritating precipitant such as tobacco, alcohol, and ill-fitting dental restorations, requires a biopsy to exclude malignancy [4, 19]. Treatment generally involves surgery and/or radiation therapy. Radiation therapy and/or chemotherapy can be used for patients not amenable to surgery or palliation for unresectable tumors. Counseling of patients regarding risk factors (tobacco, alcohol, sun exposure, and sexual habits) and periodic examination of the oral cavity especially in patients over age 40 with risk factors can help to reduce the incidence of oral cancers and increase earlier detection rates [21].

DOI 10.1007/978-1-4939-0779-3_80-1

Other Oral Lesions

Bony Tori

Tori are benign, nonneoplastic bony protuberances that arise from the cortical plate. They are more common along the hard palate of the mouth but can also arise from the floor of the mouth. Those that form along the hard palate are known as palatal torus or torus palatines, while those located along the lingual aspect of the mandible are known as mandibular torus or torus mandibularis. The overall prevalence in the general population is 3 %; palatal tori are three to four times more common than mandible tori [4, 19]. These lesions are thought to be congenital anomalies though they usually do not develop until adulthood. They can be confused for cancerous growths. Bony tori are usually painless and do not cause any symptoms. No management is necessary; unless the tori are interfering with oral function, denture fabrication, or subject to recurrent traumatic ulceration, then surgical removal by an oral surgeon is recommended [4, 19].

Mucocele

Mucoceles are benign fluid-filled sacs which result from disruption of a salivary duct gland secondary to mild local trauma such as biting. Most frequently they occur on the lower lip and are more prevalent in children and young adults [19]. Patients typically present with a pinkish/blue dome-shaped fluctuant papule or nodule. The underlying gelatinous sac can often be felt with palpation. Patients are seldom symptomatic, but often find the lesions irritating because of the recurrent trauma that occurs while eating. Lesions will often resolve on their own due to spontaneous rupture. If the lesion becomes symptomatic it can be excised, which should include the entire cyst to prevent recurrence. Once excised, the specimen should be sent for pathologic examination to rule out neoplastic changes [4, 19]. As with any lesion in the mouth that does not resolve on its own within 3–4 weeks, consideration should be given for further assessment and pathologic examination either by biopsy or excision [4].

Pyogenic Granuloma

A pyogenic granuloma is an erythematous rapidly growing lesion that develops in response to local irritation, trauma, or increased hormone levels related to pregnancy [19]. These lesions may be smooth or lobulated, easily bleed when touched, and are non-painful. Oral pyogenic granulomas vary in size and most often develop along the gingival border, but can be found anywhere within the oral mucosa. Treatment usually involves surgical excision and removing the local source of irritation. Recurrence is uncommon except in pregnancy. Pyogenic granulomas induced by pregnancy associated hormonal changes are more likely to spontaneously resolve following childbirth, and therefore observation alone may be an adequate treatment [19].

Adult Hearing Loss

General Principles

Hearing impairment affects over 28 million people in the United States. It is one of the most common disabilities of the adult population. Although hearing loss becomes more common in the aging population, it can also affect younger adults as a result of environmental exposures. Hearing loss is associated with decreased quality of life and can lead to, in severe cases, cognitive decline and depression [1, 2].

Pathophysiology

There are three different types of hearing loss: (1) conductive hearing loss, (2) sensorineural hearing loss, and (3) mixed conductive and sensorineural hearing loss.

Conductive hearing loss is secondary to anomalies of the outer or middle ear [3]. This may be due to obstruction of the external auditory canal, impairment of the tympanic membrane function, or middle ear pathology [1]. Examples of conditions that cause conductive hearing loss include (but are not limited to) cerumen impaction, foreign body in the auditory canal, otitis externa or media, exostoses or osteomas of the external auditory canal, tympanic membrane perforation, cholesteatoma, Eustachian tube dysfunction, myringosclerosis, otosclerosis, and glomus tumors [4].

Sensorineural hearing loss is due to dysfunction of the inner ear or neural pathways to the auditory cortex. Sensorineural hearing loss usually begins at high frequencies and progresses to lower frequencies [1]. This may occur bilaterally or unilaterally and is more commonly found in adults. Bilateral sensorineural hearing loss most commonly is found in the elderly, referred to as presbycusis [4]. Noise trauma due to exposure to occupational, recreational, and accidental noise also results in sensorineural hearing loss. Prolonged and chronic noise exposure to levels of greater than 85 dB can lead to permanent and irreversible hearing loss [2]. Exposure to ototoxic medications (diuretics, salicylates, aminoglycosides, chemotherapeutics, etc.) can lead to sensorineural hearing loss, which may be temporary and reversible if identified early. Autoimmune hearing loss is characterized by a rapidly progressing bilateral sensorineural hearing loss with poor speech discrimination as well as vertigo and disequilibrium [4]. Infections such as meningitis, herpes, mumps, syphilis, and tuberculosis may also lead to hearing loss [2]. Unilateral sensorineural hearing loss may also occur due to a variety of reasons which include but are not limited to fracture to the temporal bone or other trauma to the inner ear, Meniere's disease, acoustic neuromas, or other cerebellopontine-angle tumors, or it may be considered idiopathic [4]. Certain noise exposures (gunfire) may also cause unilateral hearing loss [2].

Evaluation and Diagnosis

Hearing loss may simply be identified by asking, "Do you have trouble hearing?" Other hearing loss screens exist, such as the "Hearing Handicap Inventory for the Elderly – Screening Version." Positive answers should further be questioned as to duration of hearing loss, if it has been sudden or gradual hearing loss, and whether it is unilateral or bilateral. It is important to ask occupational history as well as history of noise exposure. Further information may be elicited regarding family history of hearing loss, chronic medical problems, medication use and any associated tinnitus, dizziness, or other ear problems [1, 4].

The physical exam should consist of examining the auricle and periauricular tissues. An otoscope may be used to evaluate the external auditory canal for any cerumen or foreign objects. The tympanic membrane should be evaluated for surface anatomy, color, and mobility. The pneumatic bulb will aid in evaluating the tympanic membrane movement and aeration of the middle ear. Finally, evaluate the head, neck, and cranial nerves if clinically indicated [2, 4].

Objective evaluation of hearing is commonly performed by pure tone audiometry. This is a diagnostic test that gives information on hearing loss to include the type and degree of hearing loss at a specific frequency threshold [3]. This test may evaluate hearing from frequencies of 250–8000 Hz [2]. Tympanometry is another simple test performed in the office, which evaluates the mobility of the tympanic membrane and function of the middle ear and Eustachian tube [5].

Treatment

If a concern of hearing loss is identified and proper equipment is not available in the primary care office, specialty referral to audiology and/or otolaryngology is indicated. Counsel on and eliminate environmental noise and ototoxic agents if possible. Intervention is important, not only for hearing improvement but also for social and emotional function, as well as for communication and cognition [1].

In some cases, the only treatment option is hearing amplification. Hearing aids have several models to include those which fit behind the ear or in the canal. Assisted listening devices may be used for those unable to utilize hearing aids. Surgical implants are an option for those with severe cochlear (sensorineural) hearing loss.

Referral to rehabilitation services may help teach patients to use nonverbal clues and vocational modification to ensure safe functioning despite his or her hearing impairment [1, 2].

Prevention

Prevention of some types of hearing loss may be impossible; however, prevention of exposure to ototoxic agents is possible by carefully choosing medications and discontinuing offending agents. Additionally, noise-induced sensorineural hearing loss may be prevented by screening for noise exposure, counseling about proper hearing protection, and avoidance of overexposure [2].

Pediatric Hearing Loss

General Principles

Hearing loss is the most common neurological birth defect and the fourth most common developmental defect in the United States [6, 7]. Pediatric hearing loss can have a profound impact on growth and development of the infant and child to include adversely affecting speech and language development, academic success, visual reception, fine motor skills, and social and emotional development. Early intervention may prevent long-term impacts of pediatric hearing loss [7, 8].

Pathophysiology

Hearing loss in the neonate or child can be classified as congenital or acquired. Of the congenital etiologies, it can be further classified as either (1) syndromic or nonsyndromic or (2) autosomal recessive, autosomal dominant, or X-linked [7]. Of the acquired cases of hearing loss, approximately half are considered environmental and half idiopathic [8]. Environmental risk factors to the neonate include cytomegalovirus, rubella, measles, syphilis, or exposure to alcohol. Other risk factors for neonates and children may include exposure to ototoxic drugs such as aminoglycosides or antineoplastic agents, hypoxic ischemic injury, or hyperbilirubinemia. Ear malformations are considered nonsyndromic genetic or hereditary causes of hearing loss. The most common inner ear malformation is the vestibular aqueduct enlargement [7, 8].

Evaluation and Diagnosis

Newborn hearing screening is mandated in nearly every state in the United States. There are two main screening methods in the United States: the otoacoustic emission (OAE) test and the automated auditory brainstem response (ABR) test. The OAE is largely used as the initial screening for most newborns [6]. It allows for individual ear

testing at any age. It is an effective screen for middle ear pathology and for moderate to severe hearing loss [9]. Passing the OAE demonstrates functioning middle ear; however, it does not test the eighth nerve [7]. Results of this test may be interrupted by middle ear fluid, ear canal debris, or external environmental noise [6]. The ABR test is often used as a follow-up screening exam if the OAE is failed; however, the ABR may be used as an initial screen and is often used as such in the settings of neonates in the intensive care unit. The ABR is considered a superior evaluation of the auditory system and better detects auditory neuropathy. It requires a sleeping or quiet infant as motion can cause artifact [6, 9]. The Joint Committee on Infant Hearing encourages that all neonates undergo hearing screening. If the neonate does not pass, then rescreen and refer for further evaluation by the age of 3 months. Any infant with hearing loss should have intervention by 6 months of age [10, 11].

If the initial newborn screening exams are passed, it is still important to continually evaluate pediatric patients for potential hearing impairment. This may be realized during well exams if developmental milestones are missed, especially speech and language development. It is important to address any parental concerns during these visits. If the neonate has risk factors of hearing impairment, at least one diagnostic audiology assessment should be completed by age 24–30 months. Risk factors are listed in Table 1 [7, 9, 10, 11].

The physical exam should consist of particular attention to head size and symmetry, jaw size and symmetry, facial movement and symmetry, as well as external and middle ear morphology [7]. Signs of the head and neck exam which may be related to hearing loss include malformation of the auricle or ear canal, dimpling or skin tags around the auricle, cleft lip or cleft palate, asymmetric facial structures, microcephaly, or tympanic membrane abnormalities. Many times, the physical exam will be normal [7, 9, 10, 11].

Further imaging and laboratory testing may be indicated. Imaging such as a computed tomography (CT) scan may assess the temporal bone. A magnetic resonance imaging (MRI) may further evaluate the brain and internal auditory canal.

Table 1 Risk factors for infant and child hearing loss [7, 9, 11]

In utero infectious exposures or postnatal infections associated with hearing loss: cytomegalovirus infection, herpes, rubella, syphilis, toxoplasmosis, meningitis
Syndromes associated with progressive hearing loss
Craniofacial abnormalities
Neurodegenerative disorders
Head trauma
Extracorporeal membrane oxygenation (ECMO)
Chemotherapy
Caregiver concern
Family history of hearing loss
Identification of syndromes related to hearing loss
Genetic testing related to hearing loss
Speech and language delay
Neonatal intensive care for greater than 5 days
Exposure to ototoxic medication (gentamycin, tobramycin, loop diuretics, etc.)
Hyperbilirubinemia requiring exchange transfusion
Chronic otitis media with effusion
Excessive noise exposure
Hypoxia requiring respiratory support

Labs may be completed based on history and physical exam findings [7, 9, 10].

Treatment

Any abnormal hearing test requires intervention. Appropriate referrals include those to otolaryngology, audiology, speech and language pathology, and a genetics specialist. Referrals to early intervention programs are essential. Early intervention services should be provided by professionals with expertise in hearing loss, speech and language pathology, and audiology. An ophthalmologic evaluation may also be appropriate if syndromic associations are identified [11].

Tinnitus

General Principles

Tinnitus is the perception of sound within the ears or head without an objective external stimulus. The noise has been described as ringing, buzzing,

Table 2 Risk factors for tinnitus [12, 14]

Hearing loss
Exposure to high levels of recreational and occupational noise
Obesity
Alcohol use
Smoking
Arthritis
Hypertension
Ototoxic drugs: salicylates, quinine, aminoglycoside antibiotics, platinum-based antineoplastic agents
Otologic diseases: otosclerosis, Meniere's disease, vestibular schwannoma (acoustic neuroma)
Anxiety
Depression
Dysfunction of the TMJ
Hyperacusis (loud noise sensitivity)

clicking, pulsations, roaring, hissing, sizzling, music, or voices. Although much of what we understand about tinnitus remains an enigma, it is considered a symptom, not a disease in and of itself. It can have great effect on the quality of life for those who suffer from tinnitus [12, 13].

Pathophysiology

There is no clear etiology of tinnitus; however, there are some known risk factors which are outlined in Table 2. Tinnitus is most notable in patients who have been exposed to hazardous levels of industrial, recreational, or military-related noise [12]. Other underlying associations to tinnitus include nerve damage from brain trauma or lesions, inner ear damage, acute ear infections, foreign objects in the ear, allergies, ototoxic medications (aminoglycosides, aspirin, chemotherapeutics), stress, or low serotonin activity [12, 14].

Tinnitus can be characterized in several different ways, but most commonly, it is characterized as either "objective" or "subjective" tinnitus. Objective tinnitus can be heard by the examiner, usually with a stethoscope, and it is generally referred to as "pulsatile" tinnitus. If it synchronized with the heartbeat, it may be considered vascular in origin. If it is not, it may be originating from the middle ear or palatal muscles. Subjective tinnitus, on the other hand, is only heard by the patient. The tinnitus may be chronic or intermittent. It may be heard in one ear, both ears, or centrally within the head. The onset may be abrupt or insidious, and the severity may change with time as well [13, 14].

Evaluation and Diagnosis

There is no current standardized guideline for the evaluation of tinnitus. Although serious pathology leading to tinnitus is rare, it is important to get a complete medical history to understand of any possible underlying causes [12, 13]. Assess the character of the tinnitus: (1) subjective versus objective, (2) location and quality, and (3) distinguish chronicity (chronic is considered at least 6 months duration). Subjective idiopathic tinnitus is the most commonly diagnosed type of tinnitus [12]. There are several questionnaires to evaluate tinnitus to include the "Tinnitus Handicap Inventory" and the "Tinnitus Functional Index" [12]. Evaluate for any associated hearing loss and tympanic membrane dysfunction [13].

If asymmetric tinnitus is associated with asymmetric hearing loss or any other neurological deficits, further investigation and imaging is indicated. Likewise, for any heartbeat-synchronous pulsatile tinnitus, further evaluation with advanced imaging is indicated: this may include but is not limited to CT, MRI, CT angiography, MRI angiography, or ultrasound. If the tinnitus is unilateral and pulsatile or the tinnitus is associated with vertigo, it is recommended that the patient be referred to a specialty provider [12].

Treatment

There have been multiple medications, to include complementary and alternative, studied to evaluate treatment of tinnitus, but none so far have demonstrated statistically significant improvements [12, 13]. There have been medical interventions studied such as transcranial magnetic stimulation, electromagnetic stimulation,

low-level laser therapy, and acupuncture; however, none of these has shown consistent improvement of tinnitus either [12].

Sound therapy or sound maskers, which produce sound to cover the tinnitus, have not shown statistically significant improvement. Sound technologies, such as hearing aids (if the patient has associated hearing loss), may help mask tinnitus by increasing the overall level of ambient sound delivered to the patient. Cochlear implants may also help to mask tinnitus and improve perception of external noise; however, these are only for patients with profound sensorineural hearing loss [12].

Much of the treatment involved for treating tinnitus is truly aimed at treating the comorbid conditions associated with tinnitus such as anxiety, depression, hearing loss, and sleep disorders. Psychological and behavioral interventions are recommended to improve associated distress [12, 13].

Unfortunately, there is no single effective treatment regimen to cure or significantly alleviate tinnitus. It is important to treat or eliminate any underlying risk factors. Any surgical otologic disorders should be evaluated by otolaryngology.

Prevention

Because there is no effective treatment for most cases of tinnitus, the focus should be on prevention of known causes: reduce exposure to ototoxic drugs as well as avoid occupational and recreational loud noises [13].

Salivary Gland Inflammation and Salivary Stones

General Principles

Major salivary glands include the parotid, submandibular, and sublingual glands. Additionally, there are minor salivary glands lining the oral cavity, pharynx, lips, and tongue [15]. Inflammatory conditions of the glands, or sialadenitis, are most common in the major salivary glands. Inflammation may be acute or chronic, and the inflammation occurs due to viral, bacterial, autoimmune, or neoplastic etiologies. These conditions can also lead to salivary stone formation which will further enhance the inflammation in some cases [16].

Pathophysiology

Acute bacterial sialadenitis is most often seen in the parotid gland in medically debilitated patients. Debilitation and dehydration may lead to the stasis of salivary flow which can generate stone precipitation and strictures of the salivary ducts. This environment favors bacterial infection, most commonly from Staphylococcus aureus, Streptococcal species, and Haemophilus influenza [15, 16].

Acute viral sialadenitis is most commonly found in the setting of mumps in children aged four through six. Other viral causes include Cytomegalovirus, Lymphocytic Choriomeningitis virus, Coxsackie virus A, echo virus, and parainfluenza virus type C [16].

Chronic sialadenitis is characterized by repeated episodes of pain and edema. Noninfectious etiologies of chronic sialadenitis include autoimmune diseases, previous irradiation, Sjogren's syndrome, and paucity of salivary flow with resultant stones or salivary duct strictures. Infectious etiologies include Mycobacterium, Toxoplasma, and Actinomyces species [16].

Neoplasms may be benign or malignant. Malignancies of the salivary gland are rare, encompassing only 16 % of all salivary gland neoplasm cases [15].

Evaluation and Diagnosis

Acute bacterial sialadenitis has characteristic clinical findings of salivary gland pain and edema. Mucopurulent material can sometimes be expressed at the orifice of the nearby salivary duct [15, 16].

Acute viral sialadenitis is most commonly due to mumps offending the parotid gland, which is

characterized by parotid edema with symptoms of fever, malaise, myalgias, and headaches in the weeks preceding during the incubation period. Some children can experience recurrent viral sialadenitis. This can last weeks and recur every few months. Viral serology may help to confirm the diagnosis [15].

Chronic sialadenitis has characteristic findings of repeated episodes of pain and edema of the salivary glands. Generally this occurs from little to no salivary flow and due to stones or strictures. It is sometimes possible to palpate the stone along the nearby duct [15].

Neoplasms typically present as painless, asymptomatic, slow-growing masses. Malignant neoplasms may present with findings such as facial paresis, fixation of the mass, and lymphadenopathy. Specialty referral and biopsy is essential for further diagnosis. A CT scan with contrast or MRI may also be used to identify the mass's characteristics [15].

Ultrasound is the primary imaging modality for evaluation of sialadenitis. Ultrasound can help to identify characteristics of the gland as well as to identify any associated stones [16].

Treatment

Acute bacterial sialadenitis is treated by empiric antimicrobial therapy (i.e., Augmentin, etc.). Increasing salivary volume and flow by increasing hydration and utilizing sialagogues is also recommended. Salivary gland massage may also be useful.

Recurrent parotitis of childhood and chronic sialadenitis in adults are treated similarly as in acute cases as outlined above. It generally resolves spontaneously over time. Anti-inflammatory medications may also be considered.

Viral parotitis or mumps treatment is supportive. It is important to hydrate and control the pain as well as promote oral hygiene. Mumps usually resolves spontaneously within weeks [15].

Any stones contributing to acute or chronic sialadenitis may need surgical removal if not easily removed through the duct orifice.

Prevention

Vaccination has reduced the incidence of mumps by 99 %. It is important to promote hydration and use sialagogues for enhancement of saliva production and prevention of stone formation [15].

Xerostomia

General Principles

Xerostomia is the subjective sensation of dry mouth. It is a common condition in the elderly, affecting up to 57 % of those greater than age 65 [17]. Major and minor salivary glands produce the saliva, which is composed of electrolytes, organic compounds, and water. The salivary glands continually change the production of saliva based on flow rate, blood supply with available substances, and stimuli. Saliva aids in digestion, prevents dental caries, and protects mucosal surfaces. Saliva also contributes to the sensation of thirst in times of dehydration [18].

Pathophysiology

Xerostomia can occur with the reduction in the quantity, flow rate, or composition of the saliva produced. In some cases, xerostomia may occur despite normally produced saliva. Xerostomia can adversely affect speaking, chewing, and swallowing. Prolonged dry mouth can lead to tooth decay and reduced quality of life [19]. There are several causes of xerostomia such as dehydration, poor nutritional status, head or neck radiation, chemotherapy, salivary gland aplasia, Sjögren's syndrome, depression, smoking, and a variety of medications, which are listed in Table 3 [17].

Evaluation and Diagnosis

Patients may complain of dry mouth or other symptoms from dry mouth like a burning sensation or difficulty with speech and swallowing. He or she may also note a change in taste.

Table 3 Medications contributing to xerostomia [17]

Anticholeinesterase (ACE) inhibitors
Alpha or beta blockers
Anticholinergics
Antidepressants
Antipsychotics
Anxiolytics
Calcium channel blockers
Diuretics
Muscle relaxants
Sedatives
Antiepileptics
Antiparkinsonisms
Cytotoxics
Antihistamines
Tricyclics

On exam, the mucosal surfaces may be dry and the tongue swollen and dry [17].

Treatment

Treatment is aimed at identifying the offending agent and either eliminating it or treating it. If a medication is identified as causation, then it should be changed or eliminated if possible. It is important to encourage hydration, especially in the elderly and those with poor nutrition. Avoid food and drinks such as alcohol, sugar, and caffeine which may lead to dry mouth or dental caries [17].

Topical treatments, saliva stimulators, and saliva substitutes are also available. Sugar-free chewing gum or candy can promote salivation [17]. Oxygenated glycerol triesters (OGTs) are saliva substitute sprays that have been shown to be effective at improving dry mouth [19]. Medication which may stimulate saliva production includes Pilocarpine or Cevimeline drops [17].

Hoarseness

General Principles

Hoarseness (or dysphonia) is a term used to describe a symptom or sign of altered voice quality [20]. The change in voice may be an alteration in quality, pitch, loudness, or may be described as breathy, strained, rough, or raspy [20, 21]. It is a common problem in the US adult population affecting up to one-third of all adults at some point in time and leads to 2.5 million dollars in lost work cost [20].

Table 4 Etiologies of hoarseness (or dysphonia) in the adult population [21]

Irritants and inflammation	Acute laryngitis: viral, vocal abuse, allergies Chronic laryngitis: smoking, voice abuse, laryngopharyngeal reflux, allergies, inhaled corticosteroids
Neuromuscular	Vocal cord paralysis: injury to recurrent laryngeal nerve, head and neck surgery (especially thyroid surgery), endotracheal intubation, mediastinal or apical immersion of lung cancer Muscle tension dystonia Spasmodic dysphonia (laryngeal dystonia)
Psychiatric	Stress and other psychiatric disorders
Systemic	Parkinson's disease Myasthenia gravis Multiple sclerosis Hypothyroidism Acromegaly Inflammatory arthritis
Neoplasms	Laryngeal papillomatosis Laryngeal leukoplakia Dysplasia or squamous cell carcinoma (risk factors: smoking, alcohol use, chronic reflux)

Pathophysiology

The larynx houses the vocal cords, which are responsible for the production of sound as airflows pass these structures. The larynx extends from the base of the tongue to the trachea and is innervated by the superior and recurrent laryngeal nerves [21].

There is a multitude of etiologies which may cause hoarseness. In general, these etiologies may be from irritants, inflammation, neuromuscular, psychiatric, systemic, or neoplastic disorders [21]. Table 4 outlines details of each of these categories.

Evaluation and Diagnosis

A careful history and physical exam are important to understand the etiology of the patient's hoarseness. Evaluate the onset and duration of voice changes. In the medical history, it is prudent to ask about any recent upper respiratory infections, allergies, or chronic medical problems. Assess for any associated symptoms of gastroesophageal reflux. In the social history, it is important to discuss any environmental exposures, tobacco use, or alcohol use. In addition, vocations in singing, teaching, and of the clergy are more at risk for this condition. Learning of any recent surgeries is also key. Associated symptoms such as cough, dysphagia, or odynophagia is important and may lead to more serious underlying causes of hoarseness [20, 21].

During the physical exam, it is important to assess for rhinorrhea, sneezing, or watery eyes which may suggest a more benign cause such as allergies or viral irritation; however, findings such as lymphadenopathy, stridor, or weight loss may be more concerning for serious etiologies such as malignancies. Stridor may indicate airway obstruction due to mass [21].

Laryngoscopy may be performed at any point in time. Different recommendations exist as to when direct visualization is required ranging from after 2 weeks to after 3 months of persistent hoarseness [20, 21]. The procedure should be done in the primary care office or referred to a specialist who has this capability. Direct visualization of the larynx should be done sooner if there is any suspicion of serious underlying condition. In case of obacco or alcohol use, a neck mass, hemoptysis, dysphagia, odynophagia, neurological symptoms, unexplained weight loss, aspiration of a foreign body, persistent symptoms after surgery or if the hoarseness significantly impairs the quality of life of the patient, then visualization is more urgent [20].

Imaging, such as a CT or MRI, may be used to assess specific pathology; however, it is recommended that direct visualization be performed prior to any imaging [20].

In cases of pediatric hoarseness, it is generally indicated for the patient to be referred to otolaryngology and speech and language pathology early [22].

Treatment

If hoarseness duration is less than 2 weeks (acute), it is more likely to be benign. Reassurance is appropriate but also address and treat any underlying etiologies such as viral infections, allergies, or reflux. If reflux is suspected, a 4 week trial of high-dose PPI for 3–4 months is warranted; however, if there are no other signs of reflux, treatment for such is not recommended. Likewise, antibiotics are usually not indicated in treating hoarseness [20, 21]. If corticosteroids are on the patient's medication list, the clinician may recommend a decrease or alteration in the dose or type of corticosteroid used for 4 weeks. Inhaled fluticasone (Flovent) is the most common offending agent [21]. Oral corticosteroid to treat hoarseness is not recommended [20]. If there is a systemic condition which has a known symptom of hoarseness (such as hypothyroidism), optimize treatment for the condition and reassess after 4 weeks.

If laryngoscopy is completed and no serious pathology is found, it is recommended the patient be referred for vocal hygiene training and voice therapy by a speech and language pathologist [20, 21].

Surgery may be indicated for any findings of benign or malignant masses, glottic insufficiency, or if airway obstruction is a risk [20, 21].

Prevention

The patient should be counseled on avoidance of triggers such as tobacco smoke, environmental irritants or allergens, and vocational abuse of the voice [20].

Epistaxis

General Principles

Epistaxis is a common condition that can affect up to 60 % of the general population [23]. Up to 9 % of the pediatric population experiences recurrent epistaxis. Epistaxis is generally categorized as anterior (more common) or posterior (less

Table 5 Local and systemic causes of epistaxis [23–25]

Local causes	Systemic causes
Trauma	Hypertension
Nose picking	Antiplatelet medications
Foreign objects stuck in nose	Hereditary hemorrhagic telangiectasia
Neoplasms or polyps (nasopharyngeal angiofibroma)	Hemophilia
Rhinitis or sinusitis (chronic, acute, allergic)	Leukemia
Medications (inhaled corticosteroids)	Liver disease
Irritants (occupational exposures, cigarettes, etc.)	Medications (aspirin, anticoagulants, NSAIDS)
Septal perforation	Platelet dysfunction
Vascular malformations or telangiectasia	Thrombocytopenia
Environmental: dry and low humidity	

common but more severe). Anterior epistaxis generates from either Kiesselbach's plexus or the anterior inferior turbinate [24]. Posterior epistaxis results from bleeding of the posterior edge of the nasal septum of the nasopharynx.

Pathophysiology

The etiology of epistaxis can be divided into two general causes: local or systemic. Local causes refer to specific complications to the nasal mucosa. Systemic causes refer to more systemic diseases causing epistaxis to be more likely [23]. See Table 5 for a list of local and systemic causes of epistaxis.

In children, the most common etiology of anterior epistaxis is trauma (usually nose picking). Idiopathic nose bleeding occurring at night is also common in children but is eventually outgrown. Posterior epistaxis in children is most often due to juvenile nasopharyngeal angiofibroma, which is most commonly seen in teenage boys. Similar to adults, systemic disease of childhood may also lead to epistaxis such as (1) vascular anomalies: hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome); (2) hematologic problems (genetic or acquired) such as primary idiopathic thrombocytopenic purpura, leukemia, or aspirin use; or (3) coagulopathies (genetic or acquired) such as von Willenbrand disease, hemophilia, warfarin use, liver diseases leading to coagulopathy, or drug-related thrombocytopenic purpura [25].

Evaluation and Diagnosis

Anterior epistaxis is generally obvious to the examiner, and blood loss is usually not significant. Posterior epistaxis may be associated with a large volume of blood loss but may present insidiously with symptoms such as nausea, hematemesis, hemoptysis, or melena [23]. It is important to identify the likely source of bleeding (anterior or posterior) as well as inquire about the history leading up to the epistaxis episode in order to understand if further workup is necessary. Estimate the volume of blood loss, time of onset, frequency of any prior episodes, any medical comorbidities, acute respiratory infections, use of medications, recreational drug use, and any recent surgery or trauma [24].

The physical exam may be performed with the aid of a vasoconstrictor spray or gauze soaked in a vasoconstrictor. This in combination with an anesthetic may be helpful during the physical exam to successfully identify the source of bleeding [25].

Treatment

Because 90 % of epistaxis cases are anterior, most cases of epistaxis are treated successfully with conservative therapies [24]. Initial treatment consists of pinching the lower portion of the nose against the anterior nasal septum, placing pressure along the ala for several minutes. Cotton-tipped applicators or cotton balls can be used to place pressure against the source of bleeding. These items may be soaked in topical vasoconstrictors or decongestants if needed [23, 24]. It is important to tilt the head forward, not backward, in order to avoid pooling of the blood, which can lead to airway obstruction [23]. If direct pressure is not helpful, silver nitrate sticks or

electrocautery may be applied to the area of bleeding. Apply the cauterization instrument directly to the source of bleeding to avoid any excessive soft tissue damage [25]. Avoid cauterizing bilaterally due to risk of septal necrosis and perforation. If bilateral cauterization is needed, it is optimal to perform cauterization 4–6 weeks apart [24, 25].

If this initial management is unsuccessful, nasal packing may be an effective next step. There are many commercial products or commercial nasal tampons available for nasal packing. The principle is to localize the source and apply packing to stop the site of bleeding. The packing may be left in for several days [23]. If anterior packing is unsuccessful, then one can move to posterior packing, which is a more complex procedure. If this is necessary, specialty consultation and admission to the hospital is recommended due to complexity and risks involved in the procedure. Toxic shock syndrome is a risk in the setting of any type of packing techniques. Antistaphylococcal antibiotic (oral or topical) may be considered as prophylactic therapy [24].

Similar to posterior packing for persistent anterior bleeding, posterior bleeding should be treated in the hospital setting and with specialty consultation. Additional intervention may be indicated such as arterial embolization or arterial ligation [23–25].

In summary, epistaxis, in particular anterior epistaxis, is a common condition that can be treated in the outpatient setting with conservative measures; however, in cases of persistent bleeding or posterior epistaxis, more invasive measures performed with specialty consultation in the hospital may be necessary.

Prevention

If recurrent anterior epistaxis persists, consider underlying etiologies. If underlying pathology is ruled out, various treatments may be helpful in prevention such as humidification of air, application of petroleum jelly to the local area to maintain humidity, or application of antiseptic creams [25, 26].

Foreign Bodies in the Ear and Nose

General Principles

Foreign bodies lodged in the ear and nose is a problem commonly seen in children and patients with mental handicaps [27]. At times, it can be difficult to diagnose as the object placement may not have been observed by the parent or caregiver [28]. Common foreign bodies found in the ear or nose include beads, rubber erasers, toy parts, pebbles, food, marbles, and button batteries [28, 29].

Pathophysiology

Although a foreign body can be found in any portion of the nasal cavity, it is most commonly found in one of two places: below the inferior turbinate or anterior to the middle turbinate [28, 29].

A foreign body within the ear is usually lodged at the point where the external auditory canal narrows into a bony cartilaginous junction. If lodged too far, the tympanic membrane can be damaged [28].

Evaluation and Diagnosis

A nasal cavity foreign body may be asymptomatic; however, it may also present as unilateral, malodorous, mucopurulent nasal discharge. Intermittent epistaxis may also be present. It may cause pain or be painless [29]. If left for a prolonged period of time, it can lead to ulceration or erosion of the mucous membrane.

When evaluating a patient for a nasal foreign body, it is useful to apply a topical vasoconstriction agent to reduce mucosal edema, such as 0.5 % phenylephrine or oxymetazoline [28]. Anesthesia may also be accomplished with a topical spray such as 4 % lidocaine [27]. Anterior rhinoscopy can be performed with the use of a fiberoptic nasopharyngoscope or a zero-degree rigid endoscope [29].

A foreign object in the ear may also be asymptomatic or an incidental finding on exam. Symptoms can include otitis, hearing loss, or a sense of ear fullness [28]. It is important to appropriately

visualize the object in order to decrease trauma. If it is not easily visualized or if ear anesthesia is necessary, it may be necessary to refer to a specialty physician. Topical anesthesia of the ear is generally not successful [27].

Treatment

In most cases, a foreign object in the nose or ear is not an emergency so removal may be delayed if it is not easily achieved in the family physician's office. It is appropriate, then, to refer to an otolaryngologist. In the event a caustic object is present (batteries, etc.) irrigation should not be used, and a referral is urgent [27].

Removal of a nasal cavity foreign object may be completed by several different techniques. Most commonly, if the object is in the anterior passage, it may be graspable with a forceps, curved hooks, cerumen loops, or suction catheter. A balloon tip catheter may be used by lubricating the balloon tip, passing the tip past the foreign body, inflating, and then pulling forward [28]. Of course, asking the patient to blow his/her nose with the opposite nostril occluded is also an option. Positive pressure may be performed on babies by occluding one nostril and blowing air through the mouth [27]. Once the object is removed, it is important to reinspect the nasal cavity for any additional objects or localized trauma. If the object is not successfully removed, it may be necessary to refer to an otolaryngologist.

Removal of a foreign object within the external auditory canal may be performed using similar techniques as mentioned above. Irrigation is another option, which may be helpful for small objects closer to the tympanic membrane [27]. If a live insect is present, it is important that it be killed prior to removal. Alcohol, 2 % lidocaine, or mineral oil may be instilled in the canal. This should be done only if the tympanic membrane is intact. If the object is not easily graspable, however, there are higher rates of complications such as canal lacerations and tympanic membrane damage. In the event of unsuccessful removal, high risk of trauma, or if there is need for anesthesia, specialty referral is recommended [28].

Hypertension

Mallory McClester Brown[a]* and Anthony J. Viera[b]
[a]Department of Family Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA
[b]University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

General Principles

Hypertension is the most commonly seen condition in adult primary care practices. It affects one in three American adults over the age of 18, with women and men being nearly equally affected [1]. Data from the Framingham Heart Study have shown that patients who are normotensive at 55 years old still have a 90 % lifetime risk for developing hypertension [2]. Fortunately, treatment of hypertension reduces the risk of heart failure, stroke, myocardial infarction, chronic kidney disease, and cognitive decline. Left untreated, hypertension may lead to vascular and renal damage, which with time could become treatment resistant [3]. The percentage of people who know they have hypertension, who are treated, and who have controlled blood pressure (BP) has increased. From 2005 to 2010, nearly 82 % of adults with hypertension were aware of their status (up from 75 % in prior years), and approximately 75 % were taking medication. Nearly 53 % of these patients had controlled BP [4, 5].

Men and women between the ages of 55 and 64 are equally likely to have high BP with nearly 52 % of the population affected. Prior to this age, men are more commonly affected, and after these ages, more females are affected. Black women most commonly have hypertension (43 %), with black men following (40 %). Approximately 30 % of white men have high BP whereas 27 % of white women are affected. About 26 % of Mexican American men and women have hypertension [4, 5].

Lifestyle modifications to lower BP include weight loss (if overweight), increased physical activity, alcohol use only in moderation, reduced sodium intake, and the Dietary Approaches to Stop Hypertension (DASH) eating plan [6]. Multiple pharmacological treatments are available including diuretics, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), calcium channel blockers, and beta-blockers. Unfortunately, many patients do not fully adhere to the treatment plan or self-adjust their regimens based on side effects of their medications. Clinicians also have a tendency to tolerate less than adequate BP control and not titrate BP-lowering medications. This clinical inertia plays an important role in suboptimal BP control. Overall, it is the physician's challenge to develop a plan with patients that will effectively control their BP, reduce cardiac risk factors, and manage comorbidities (e.g., diabetes) while minimizing side effects and maintaining quality of life. Treatment and the plan of care should include the patient's needs and preferences [2].

Detection and Diagnosis

The United States Preventive Services Task Force (USPSTF) recommends screening all adults over 18 for hypertension [7]. While the USPSTF previously made no recommendation as to screening interval, the Joint National Committee (JNC)-7 recommended screening adults every 2 years if BP was recorded as less than 120/80 mmHg and every 1 year for systolic BP 120–139 mmHg or diastolic BP 80–90 mmHg [6]. Recently, the USPSTF published recommendations for annual screening for adults 40 years and older

and those at increased risk for high BP. Persons deemed at increased risk include those who have high-normal BP (130–139/85–89 mmHg), are overweight or obese, or are African American. Adults ages 18–39 years with normal BP (<130/85 mmHg) who do not have other risk factors should be rescreened every 3–5 years [8].

The diagnosis of hypertension should be based on at least two separately recorded elevated BP recordings. The finding of an elevated BP at an initial visit should be confirmed at a follow-up visit, preferably with at least two BP recordings separated by at least 1 min each time [9]. In a patient with a single greatly elevated BP reading in the office setting who already has hypertensive-related target organ damage, the diagnosis may be made without follow-up readings. BP should be recorded with the auscultatory or oscillometric method in a standardized fashion. Patients should be seated quietly for at least 5 min in a chair with their feet on the floor and arm supported at heart level. An appropriate-sized cuff (cuff bladder encircling at least 80 % of the arm) should be used to ensure accuracy [6]. Additionally, caffeine and nicotine should not be ingested within the 30 min prior to measurement. Ideally, ambulatory BP monitoring (see subsequent section) should be used to confirm the diagnosis [8], primarily to exclude white-coat hypertension.

BP level can be classified into one of several categories, as shown in Table 1. The BP category into which a patient falls can help guide treatment.

Evaluation

The evaluation of patients with newly diagnosed hypertension has three main goals: (1) assess for comorbid cardiovascular disease (CVD) risk factors, (2) investigate for potential secondary causes of hypertension, and (3) determine if the patient has any target organ damage. These goals can be addressed with a thorough medical history, physical exam, laboratory evaluation, and, if necessary, diagnostic procedures.

Medical History

The provider should ask about previously elevated BP measurements, CVD risk factors (Table 2), symptoms of or diagnosis of secondary causes of hypertension (see below), medication (including supplement) use, and family history of hypertension and cardiovascular disease.

Physical Exam

Each patient diagnosed with hypertension should have a physical exam including more than one BP recording verified with recording in the contralateral arm in both the standing and sitting position. The

Table 3 Drugs that may cause BP elevation

Drug	Common examples
Estrogen	Oral contraceptives, hormone replacement therapy
Herbals	Ephedra, ginseng
Illicit drugs	Amphetamines, cocaine
Non-steroidal anti-inflammatories	Ibuprofen, Naproxen
Psychiatric agents	Fluoxetine (Prozac), Lithium, Tricyclic Agents (TCAs)
Steroids	Prednisone
Sympathomimetics	Over-the-counter nasal decongestants

exam should also include (1) calculation of the body mass index (BMI), (2) evaluation of the optic fundi, (3) exam of the neck including palpation of the thyroid gland and auscultation for carotid bruits, (4) cardiac exam, (5) lung exam, (6) abdominal examination with special attention for enlarged kidneys, masses, abdominal aortic pulsation, and abdominal or renal bruits, (7) examination of the lower extremities for pulses and edema, and (8) a neurological evaluation.

Laboratory Tests and Diagnostic Procedures

Baseline laboratory tests may be helpful for the initial evaluation and are also important before initiating treatment. Recommended tests include serum potassium and sodium levels, blood urea nitrogen, and creatinine level. An electrocardiogram, blood glucose, hematocrit, and fasting lipid panel are also recommended, if not done previously, to help assess overall cardiovascular risk. The ECG also may reveal target organ damage in the form of left ventricular hypertrophy or prior myocardial infarction (Q waves). Optional tests include a TSH level and calcium. Tests such as a chest radiograph or echocardiogram are only recommended if indicated based on findings from history, physical exam, or ECG.

Secondary Causes

Though most cases of hypertension are considered idiopathic or primary, it is important to consider secondary causes of hypertension at the time of diagnosis. Diets high in salt and alcohol can contribute to elevated BP. Many medications can cause elevation of BP as well (Table 3). A trial of potentially offending medications (if possible), or a change in diet, may be warranted before embarking on pharmacological treatment.

The initial history, examination, and laboratory tests on rare occasions may reveal a potential secondary cause of hypertension which can be investigated (Table 4). The most common secondary causes of

DOI 10.1007/978-1-4939-0779-3_82-2

Table 4 Secondary causes of hypertension in adults

Aldosteronism
Atherosclerotic renal artery stenosis
Cushing Syndrome
Fibromuscular dysplasia
Obstructive sleep apnea
Pheochromocytoma
Renal Failure
Renal parenchymal disease
Thyroid dysfunction

hypertension vary by age-group [10]. Among children, renal parenchymal disease and coarctation are most common, while among middle-aged adults, obstructive sleep apnea and aldosteronism are the most common. Further investigation for secondary causes should be completed in a stepwise fashion based on level of suspicion or concern [10].

Management

Benefits of Treatment

In clinical trials, antihypertensive therapy has been associated with reductions in stroke incidence averaging 35–40 %; myocardial infarction, 20–25 %; and heart failure, more than 50 % [11]. These data support the importance of treating patients to not only bring BP down but more importantly to prevent the morbidity and mortality associated with hypertension.

The panel members appointed to the Joint National Committee 8 (JNC 8) recently provided an evidence-based update to BP treatment goals. Per their report, in the general population aged ≥60 years, pharmacological treatment should be initiated to lower BP at systolic BP ≥150 mmHg or diastolic BP ≥90 mmHg and treat to a goal systolic BP <150 mmHg and goal diastolic BP <90 mmHg. This recommendation is made with Grade A (i.e., highest level) evidence. For patients <60 years of age, expert opinion recommendation is to initiate treatment with a systolic BP of ≥140 mmHg and treat to a goal of <140 mmHg, and grade A recommendation is to initiate pharmacological treatment to lower BP at diastolic BP ≥90 mmHg and treat to a goal <90 mmHg. In the population aged ≥18 years with chronic kidney disease (CKD) or diabetes, the recommendation is to initiate pharmacological treatment at systolic BP ≥140 mmHg or diastolic BP ≥90 mmHg and treat to goal <140/90 mmHg [12].

Nonpharmacological Interventions

Lifestyle recommendations should be part of the management plan for all patients with hypertension. These recommendations include the DASH eating plan, reduced sodium intake, exercise, alcohol reduction, and weight loss if overweight (Table 5). For overall cardiovascular disease risk reduction, all patients who smoke should be counseled about smoking cessation and provided assistance modalities.

The DASH eating plan emphasizes intake of vegetables, fruits, and whole grains. Additionally, low-fat dairy products, poultry, fish, legumes, and nuts should be included. Diet should be rich in calcium and potassium. Intake of sweets, sugar-sweetened beverages, and red meats should be limited. Sodium intake should be no more than 2400 mg each day. Research has shown that a DASH eating plan with no more than 1600 mg sodium has effects similar to single-drug therapy [13].

DOI 10.1007/978-1-4939-0779-3_82-2

Table 5 Lifestyle recommendations for hypertension

Recommendation	Description	Approximate systolic BP reduction
DASH eating plan	Diet rich in fruits, vegetables, and low-fat dairy with reduced fat intake	8–14 mmHg
Exercise	Regular aerobic activity at least 30 min per day	4–9 mmHg
Reduced dietary sodium intake	Maximum 2400 mg (ideally 1600 mg) of sodium daily	2–8 mmHg
Moderate alcohol drinking	Maximum 2 oz ethanol per day for men; maximum 1 oz per day for women	2–4 mmHg
Weight loss	Achieve/maintain BMI of 18.5–24.9 kg/m2	5–20 mmHg

Adults with elevated BP should be encouraged to engage in aerobic physical activity to lower BP. The recommendation is to include three to four sessions per week lasting an average of 40 min per session and involving moderate- to vigorous-intensity physical activity [14].

Some research has shown increased BP to be positively correlated to more than 2 oz/day of alcohol. Therefore, it is important to limit alcohol intake [15]. Alcohol should be limited to no more than 1 oz or 30 mL ethanol/day for women and no more than 2 oz (60 mL)/day for men [8].

Pharmacological Treatment

When deciding on pharmacological therapy, the individual patient characteristics including age, race, sex, family history, cardiovascular risk factors, and concomitant disease states should be considered. Additionally, the patient's ability to afford the prescribed therapy as well as their compliance must be taken into account.

In the general nonblack population, including those with diabetes, initial antihypertensive treatment should include a thiazide-type diuretic, calcium channel blocker (CCB), ACE inhibitor, or ARB. In the general black population, including those with diabetes, initial antihypertensive treatment should include a thiazide-type diuretic or CCB. In the population aged $\geq$18 years with CKD, initial (or add-on) antihypertensive treatment should include an ACE inhibitor or ARB to improve kidney outcomes. This recommendation applies to all CKD patients with hypertension regardless of race or diabetes status. Note that an ACE inhibitor and ARB should not be used together [16].

The main objective of hypertension treatment is to attain and maintain goal BP. If goal BP is not reached within a month of treatment, the initial drug dose should be increased or a second drug such as a thiazide-type diuretic, CCB, ACE inhibitor, or ARB should be added. If the goal BP cannot be reached with two agents, a third drug should be added [12] (Fig. 1).

Diuretics

Thiazide-type diuretics (chlorthalidone, hydrochlorothiazide) increase renal excretion of sodium and chloride at the distal segment of the renal tubule, which results in decreased plasma volume, cardiac output, and renal blood flow and increased renin activity. With these agents, potassium excretion is increased while calcium and uric acid elimination is decreased. Because of its greater potency and longer duration, chlorthalidone should be preferred over hydrochlorothiazide, especially when used alone. Potential side effects of all thiazide-type diuretics include hyponatremia, hypokalemia, dizziness, fatigue, muscle cramps, gout attacks, and impotence. Special attention should be paid when starting these agents

DOI 10.1007/978-1-4939-0779-3_82-2

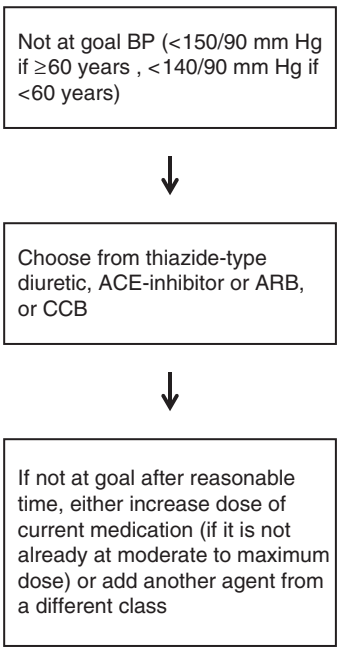

Fig. 1 Evidence-based simplified algorithm for hypertension treatment

in patients with diabetes, elevated cholesterol, or gout as thiazides can worsen each of these conditions. None of these conditions is a contraindication, however.

Loop diuretics and potassium-sparing diuretics can be used as adjunct therapy when thiazide-type diuretics are not sufficient (e.g., in patients with decreased glomerular filtration rate). Loop diuretics (furosemide, torsemide, and bumetanide) inhibit sodium and chloride reabsorption in the proximal and distal tubules and the loop of Henle. Side effects include diarrhea, headache, blurred vision, tinnitus, muscle cramps, fatigue, or weakness. When used in high doses in patients with significant renal disease, ototoxicity may occur.

Potassium-sparing diuretics (spironolactone, triamterene, amiloride) are useful for preventing potassium wastage that occurs with thiazide and loop diuretics. Spironolactone competitively inhibits the uptake of aldosterone at the receptor site in the distal tubule, in turn reducing the effect of aldosterone. This drug is an evidence-based fourth-line medication for resistant hypertension (described below). Main adverse effects to be aware of include gynecomastia and hyperkalemia. Triamterene and amiloride are typically used more specifically to stop potassium loss, and both have side effect profiles similar to the thiazide diuretics [17].

ACE Inhibitors

ACE inhibitors block the conversion of angiotensin I to angiotensin II, resulting in decreased aldosterone production with subsequent increased sodium and water excretion. As a result, renal blood flow is increased, and peripheral resistance decreases. Renin and potassium levels typically increase. Major side effects include cough, angioedema, and the possibility of acute renal failure (in patients with renal artery stenosis). Importantly, this class of medication can cause syncope in patients who are salt or volume depleted. This drug class is teratogenic in the human fetus and should therefore be avoided in pregnancy and in women who may become pregnant.

DOI 10.1007/978-1-4939-0779-3_82-2

ACE inhibitors have little effect on insulin and glucose levels or lipid levels, making them a good choice for most diabetics and patients with hyperlipidemia. ACE inhibitors are a particularly good choice for patients with congestive heart failure, peripheral vascular disease, and renal insufficiency as well.

Angiotensin Receptor Antagonists

ARBs bind to the angiotensin II receptors, blocking the vasoconstrictor and aldosterone-secreting effects of angiotensin II. Aldosterone production decreases while plasma renin and angiotensin II levels rise. There is no notable change in the serum potassium level, renal plasma flow, glomerular filtration rate, heart rate, cholesterol level, or serum glucose.

ARBs are generally well tolerated but can cause hyperkalemia. ARBs are also teratogenic and should be avoided in patients of childbearing age. The major use of ARBs is for patients who cannot tolerate an ACE inhibitor due to cough.

Calcium Channel Blockers

CCBs reduce the influx of calcium across cell membranes in myocardial and smooth muscles. This in turn dilates coronary arteries, as well as peripheral arteries. This dilation reduces total peripheral resistance leading to decreased BP. Structural differences exist between agents in this class, which lead to different adverse effect profiles as well as differences in their effect on cardiac conduction. Verapamil and diltiazem (non-dihydropyridines) work to slow the conduction through the AV node and prolong the effective refractory period in the AV node. The dihydropyridines (e.g., amlodipine, nifedipine) increase cardiac output and have a more profound vasodilatory effect, making them the preferred CCBs for hypertension.

The main noteworthy side effect of dihydropyridine CCBs is peripheral edema, but they can also cause constipation, flushing, and tachycardia. CCBs are contraindicated in patients with heart block, acute myocardial infarction, and cardiogenic shock. CCBs have no effect on glucose metabolism or lipid levels. CCBs are a particularly good choice for patients with migraine headaches, angina, chronic obstructive pulmonary disease or asthma, peripheral vascular disease, renal insufficiency, supraventricular arrhythmias, and diabetes.

Beta-Blockers

Beta-blockers are not indicated for first-line treatment of uncomplicated hypertension but are recommended for patients following a myocardial infarction and for patients with congestive heart failure. Beta-blockers antagonize the effects of sympathetic nerve stimulation or circulating catecholamines at beta-adrenergic receptors, which are widely distributed throughout the body. Beta1-receptors are predominant in the heart (and kidney) while beta 2-receptors are predominant in other organs such as the lung, peripheral blood vessels, and skeletal muscle. In the kidney, the blockade of B1 receptors inhibits the release of renin from the juxtaglomerular cells and thereby reduces the activity of the renin-angiotensin-aldosterone system. In the heart, blockade of B1 receptors in the sinoatrial (SA) node reduces heart rate, and blockade of the B1 receptors in the myocardium decreases contractility. It is likely a combination of these effects that leads to BP reduction. The overall clinical response to beta-blockers is a decreased heart rate, decreased cardiac output, lower blood pressure, decreased renin production, and bronchiolar constriction.

DOI 10.1007/978-1-4939-0779-3_82-2

The side effect profile of beta-blockers depends on their receptor selectivity. In those without intrinsic sympathomimetic activity, the heart rate is slowed, a decrease is seen in cardiac output, and an increase is noted in peripheral vascular resistance. Bronchospasm may also be caused. Typical side effects seen with these agents include fatigue, erectile dysfunction, dyspnea, cold extremities, cough, drowsiness, and dizziness. These agents tend to increase the triglyceride level and decrease the HDL level but have little effect on blood glucose levels. Beta-blockers should not be used in patients with sinus bradycardia, second- or third-degree heart block, cardiogenic shock, cardiac failure, and/or severe COPD/asthma.

Central Acting Drugs

Methyldopa, clonidine, guanfacine, and guanabenz are central alpha-2 agonists. These agents act to decrease dopamine and norepinephrine production in the brain, resulting in decreased sympathetic nervous activity throughout the body. BP declines with the decrease in peripheral resistance. Methyldopa is unique in its adverse effect profile as it can induce autoimmune disorders such as those with positive Coombs and antinuclear antibody (ANA) tests, hemolytic anemia, and hepatic necrosis. The other agents can lead to sedation, dry mouth, and dizziness. Importantly, abrupt clonidine withdrawal can lead to rebound hypertension.

Alpha-Blockers

Alpha-1 receptor blockers, such as prazosin, terazosin, and doxazosin, block the uptake of catecholamines by smooth muscle cells. In the peripheral vasculature, this results in vasodilation. A marked reduction in BP may be noted with the first dose of these drugs; therefore, it is recommended they be started at low doses and slowly titrated upward. Side effects of these agents include dizziness, sedation, nasal congestion, headaches, and postural effects. They have no effect on lipid levels, glucose, exercise tolerance, or electrolytes. These agents are probably best reserved for men with hypertension and comorbid BPH symptoms.

Vasodilators

Hydralazine and minoxidil dilate peripheral arterioles, resulting in a fall in BP. Several other responses simultaneously occur including a sympathetic reflex which leads to increased heart rate, renin and catecholamine release, and venous constriction. The kidneys retain sodium and water. Side effects include tachycardia, flushing, and headache. A beta-blocker and a loop diuretic are usually used with these drugs to minimize side effects. These agents are used mainly for resistant hypertension.

Follow-up and Ongoing Care

After initiating therapy, most patients should be seen monthly until BP control is met. More frequent visits should be utilized for patients with significant comorbidities or with stage 2 hypertension until BP goals are met. Once goals are met, follow-up can be spaced out to every 3–6 months. Laboratory evaluation including serum creatinine and potassium should be obtained at least 1–2 times/year [6].

DOI 10.1007/978-1-4939-0779-3_82-2

Resistant Hypertension

Resistant hypertension occurs when BP remains above goal even with adherence to a combination of at least three optimally dosed antihypertensive agents of different classes. Management of resistant hypertension includes assessing adherence, readdressing lifestyle modifications, working up potential secondary causes, and optimizing drug regimens [17, 18].

It is important to revisit drug adherence in patients with resistant hypertension. Patients may discontinue the use of some agents due to side effects, multiple daily dosing, and/or financial expense. When possible, it is important to simplify the patient's medication regimen. Once-daily dosing and single-pill combinations improve patient's adherence to antihypertensive medications [19]. Discussing side effects with the patient may increase both their understanding of the medication as well as their adherence to the agents. Volume overload can often play a role in resistant hypertension, and for this reason, unless contraindicated, all patients should be treated with a regimen that includes at least one diuretic.

It is also important to ensure accurate BP measurements when investigating resistant hypertension. Careful attention should be paid to measurement technique. Approximately one-third of patients with suspected resistant hypertension will actually have normal BP on ambulatory blood pressure monitoring. Therefore, evaluation of the patient with potentially resistant hypertension should include out-of-office monitoring to rule out white-coat effect [18].

Home and Ambulatory Blood Pressure Monitoring

With ambulatory BP monitoring (ABPM), the patient wears a monitor that is preprogrammed to measure and record the BP multiple times over 24 h. Recent recommendations from the USPSTF state that ABPM should be used to confirm high BP prior to diagnosis and treatment of hypertension, unless immediate therapy is indicated [8]. By providing confirmatory measurements in the ambulatory setting, overdiagnosis and overtreatment can be avoided.

Home blood pressure monitoring (HBPM) also can be useful in confirming the diagnosis of hypertension if done in a systemic way after BP cuff is confirmed to be the appropriate size, correct technique is used, and the device is accurate. HBPM may also improve patient's compliance with treatment and awareness of their control.

Hypertensive Emergency

A hypertensive emergency is described as a severe elevation in BP accompanied by evidence of impending or progressive target organ dysfunction [6]. Clinical manifestations of target organ damage usually involve derangements in the neurological, cardiac, or renal systems. The patient with hypertensive emergency may present with encephalopathy, pulmonary edema, myocardial infarction, or unstable angina.

The most common origin of hypertensive emergency is an abrupt increase in BP in patients with chronic hypertension, most often as a result of medication noncompliance [20]. Hypertensive emergency may be related to medication effect. Examples include withdrawal syndrome from antihypertensives including clonidine and beta-blockers as well as stimulant intoxication with cocaine, methamphetamine, and phencyclidine (PCP). Pheochromocytoma is a rare cause of hypertensive emergency.

Upon presentation, a focused physical exam should include repeated BP recording in both arms. Direct ophthalmoscope exam should be completed with special attention to look for papilledema. A brief neurological examination should be done to assess for focal deficits and to assess for altered mental status. The cardiac and pulmonary examination should be complete with attention to possible arrhythmias and pulmonary edema. Abdominal exam should focus on palpating for abdominal masses and tenderness as well as auscultation for abdominal bruits. Peripheral pulses should be palpated.

DOI 10.1007/978-1-4939-0779-3_82-2

The immediate goal when treating hypertensive emergency is to reduce the systolic BP by 10–15 %, but by no more than 25 %, within the first hour and, if the patient is then stable, to 160/100–110 mmHg over the ensuing 2–6 h [6]. Potential medication choices for treatment include hydralazine, labetalol, methyldopa, and nitroglycerin.

Ischemic Heart Disease

Anthony J. Viera and Ashley Rietz

Contents

General Principles

Ischemic heart disease (IHD) refers to the condition of inadequate blood supply to the myocardium. It is also commonly referred to as coronary heart disease or coronary artery disease. Each year about 600,000 Americans have their first myocardial infarction (MI) with more than 300,000 experiencing a subsequent event [1]. In 2010, the total number of people affected by IHD was estimated to be 17 million [2]. While deaths from IHD have declined since 2000, it remains the leading killer of both men and women [3, 4]. In addition to the loss of life, IHD has a large financial impact. The National Heart, Lung, and Blood Institute estimates a loss of 177 billion dollars in 2010 including loss of productivity [1].

Angina pectoris, or simply angina, refers to the chest pain that occurs when myocardial oxygen supply cannot keep up with demand. Most patients with IHD experience angina. Thus, the evaluation of chest pain is ultimately what leads to the diagnosis in most instances. This chapter will review the diagnosis of IHD when patients present with chest pain, distinguish between the acute coronary syndromes, and describe the management of acute coronary syndrome as well as stable IHD.

Diagnosis

History

The first task when evaluating a patient with chest pain is to quickly establish whether it is secondary to a life-threatening cause such as a myocardial infarction. However, it is important to note that few cases of chest pain seen in the primary care setting are cardiac in nature. Most such patients have musculoskeletal (36 %), esophageal (19 %), or anxiety-related causes (at least 8 %) [5]. These prevalence estimates reinforce the need for confidence in understanding the presentations of IHD.

The clinical history is one of the most important tools in the evaluation of the patient presenting with chest pain. Typical angina is classically described as a sensation of pressure or heaviness located in the center or left side of the chest. It is brought on by exertion and relieved by rest. Its onset is typically not abrupt and lasts for only a few minutes. Angina can be specified further by the level of exertion needed prior to onset. Stable angina typically occurs during strenuous or prolonged typical activity [2]. When the chest pain has two of these criteria, it is classified as atypical angina. Nonanginal chest pain has only one of these clinical features.

It is important to note that "nonanginal" pain does not mean that IHD is not the cause, only that the pain is much less characteristic. With the combination of the type of chest pain (typical angina, atypical angina, nonanginal) and a patient's age and sex, the pretest probability of flow-limiting IHD can be estimated (Table 1) [6].

While these criteria are helpful in estimating the pretest probability of IHD, it is worth noting that in the WISE (Women's Ischemic Syndrome Evaluation) study, women ultimately diagnosed with IHD did not have typical angina 65 % of the time [7]. Additionally, some patients lack the chest discomfort and are thus characterized as having silent ischemia.

Other important symptoms to inquire about include pain radiating to the arm(s) or jaw, epigastric pain, dyspnea, and any association of the pain with nausea, diaphoresis, or syncope [8]. Such clinical features increase the probability of a myocardial infarction in patients presenting with chest pain. Interestingly, pain radiating to both is the clinical feature that has the strongest positive likelihood ratio (approximately 7) for acute MI [9]. Pain that is pleuritic, sharp, or positional tends to lower the likelihood of MI as the etiology [10].

Obtaining a thorough past medical history is extremely valuable when assessing a patient for possible IHD. A history of hypertension, hyperlipidemia, diabetes, and any prior cardiovascular events should be noted.

Acute coronary syndrome (ACS) refers to unstable angina, non-ST segment elevation myocardial infarction (NSTEMI), and ST segment elevation myocardial infarction (STEMI). When angina occurs at rest and lasts more than 20 min or newly occurs with minimal exertion, it is categorized as unstable angina [2]. Additionally, in patients with previously stable angina, a change of chest pain from baseline in terms of increase in frequency, new occurrence with lower levels of activity, or increase in length of symptoms also is deemed unstable angina [11]. The historical features of unstable angina overlap with those of NSTEMI and STEMI. For example, rest angina lasting longer than 20 min is associated with both types of acute MI [11]. For this reason, unstable angina and MI cannot be differentiated by history alone. The use of electrocardiogram and cardiac

Table 1 Estimating pretest probability of ischemic heart disease [6]

	Men			Women		
Age range	Nonanginal	Atypical	Typical	Nonanginal	Atypical	Typical
30–39 years	5.2	21.8	69.7	0.8	4.2	25.8
40–49 years	14.1	46.1	87.3	2.8	13.3	55.2
50–59 years	21.5	58.9	92.0	8.4	32.4	79.4
60–69 years	28.1	67.1	94.3	18.6	54.4	90.6

biomarkers (discussed below) is essential to distinguishing among these clinical entities.

Physical Exam

Generally speaking, the physical exam is not typically helpful in the diagnosis of IHD. The physical exam of the patient presenting with chest pain that may represent underlying IHD begins with an assessment of vital signs. Note the pulse and blood pressure. Significant hypotension may be a manifestation of MI.

A third heart sound or pulmonary crackles on auscultation also would be concerning for possible MI [9]. Tenderness or reproducibility of chest pain on chest wall palpation argues against IHD as a diagnosis but does not necessarily rule it out [10].

Electrocardiogram and Biomarkers

The electrocardiogram (ECG) is a critical component of the evaluation of IHD, whether stable or possible acute coronary syndrome. A pathologic Q wave is indication of prior MI. ECG abnormalities that may indicate myocardial ischemia include changes in the PR segment, the QRS complex, and the ST segment. In the setting of possible ACS, a careful evaluation of ECG changes can assist in estimating time of the event, amount of myocardium at risk, patient prognosis, and appropriate therapeutic strategies. ST segment elevation found on an ECG is the hallmark sign of an acute STEMI [8]. The ECG alone is often insufficient to make the diagnosis of an acute MI, and the sensitivity and specificity of ECG are increased by serial assessments [12]. ECG changes such as ST deviation may be present in other conditions, such as left ventricular hypertrophy, left bundle branch block, or acute pericarditis. Note that in addition to patients diagnosed at the time of presentation of their chest pain, each year an additional 195,000 Americans experience a "silent" MI [1].

Like the ECG, cardiac biomarkers are an important extension of the history and physical examination in the evaluation of the patient with possible ACS. They are not part of the evaluation of patients with stable IHD. Cardiac troponins are biochemical markers of active or recent myocardial damage. Increases in cardiac biomarkers, notably cardiac troponin (I or T) or the MB fraction of creatinine kinase (CKMB), signify myocardial injury leading to necrosis of myocardial cells. However, elevated cardiac biomarkers in and of themselves do not indicate the underlying mechanism of injury and do not differentiate between ischemic or nonischemic causes. There are several clinical conditions that have the potential to result in myocardial injury and cause elevations in cardiac biomarkers, including acute pulmonary embolism, heart failure, end-stage renal disease, and myocarditis [13]. As a result, cardiac biomarker elevations cannot be utilized in isolation to make a diagnosis of MI. The preferred cardiac biomarker is troponin, which has high clinical sensitivity and myocardial tissue specificity [14]. Troponin levels should be measured on initial assessment, within 6 h after the onset of chest pain, and in the 6–12 h time frame after onset of pain. In addition, it is important to understand that elevations in troponin may be seen for up to 14 days after the onset of myocardial necrosis. If troponin concentrations are unavailable, then CKMB should be measured. Ideally, both troponin and CKMB should be obtained during evaluation for ACS due to the different concentrations of these biomarkers over time and the added diagnostic value of serial testing.

Stress Testing and Cardiac Imaging

In the evaluation of a patient with possible stable IHD, the first step before ordering or conducting a stress test is to decide whether it will be helpful. For patients with a low pretest probability (Table 1), a stress test is not diagnostically helpful. The sensitivity and specificity of a standard exercise tolerance test varies depending on the definition of disease (e.g., >70 % stenosis) but in general has a sensitivity of approximately 50–65 % and specificity of approximately 75–85 % [15]. For example, a 36-year-old

woman with atypical chest pain has an estimated pretest probability of 4 %. If an exercise tolerance test is positive, her posttest probability of having IHD is only about 9–10 %, and if the test is negative, her posttest probability of having IHD is about 2 %. The test is most useful for people with a moderate pretest probability, although the testing range spans from 10 to 90 %. For people with a high pretest probability, a negative stress test does not reduce the posttest probability sufficiently. Such patients should be considered for diagnostic coronary angiography (catheterization).

Before embarking on standard exercise tolerance testing, it is also important to know that the patient can exercise sufficiently for the test. An ECG should be obtained prior to ordering the stress test to make sure that there are no baseline ECG abnormalities that will make interpretation of the stress test difficult. Patients with a bundle branch block (especially left) or irregularities in the ST segment (e.g., due to digitalis or strain pattern) are not candidates for standard exercise tolerance testing.

The most common alternative to standard exercise tolerance testing is radionuclide perfusion imaging. It can be accomplished with or without exercise. A radionuclide (e.g., technetium sestamibi) is injected intravenously, and its uptake by the myocardium is compared via imaging during rest and at peak exercise. For patients unable to exercise, adenosine or dipyridamole is used to dilate the coronary arteries and induce a relative difference between stenotic and nonstenotic vessels. Sensitivity and specificity are greater with perfusion testing (approximately 75 % and 85 %, respectively).

Stress echocardiography is another test that can be used to evaluate for possible IHD. Areas of the myocardium that are not perfused will exhibit a wall motion defect. Like radionuclide imaging, stress echocardiography can be performed with or without exercise, the latter method using dobutamine.

Coronary Angiography

Patients with a positive stress test or those with a high pretest probability or for whom the diagnosis remains equivocal should be referred for possible coronary angiography. Coronary angiography is the gold standard for diagnosing coronary artery disease, and depending on the findings, therapeutic interventions can be accomplished simultaneously.

Management

Acute Coronary Syndrome

Initial management of ACS consists of identifying whether a patient should be managed with an early invasive strategy versus an initial conservative strategy. Early risk stratification should take into account a patient's age and medical history, physical exam, ECG, and cardiac biomarker measurements [11]. A risk assessment tool can be used to predict the patient's risk of recurrent ischemia or death following an ACS event. The Thrombolysis in Myocardial Infarction (TIMI) risk score is a scoring system for UA and NSTEMI that incorporates seven variables upon hospital admission and has been validated as a reliable predictor of subsequent ischemic events (Table 2) [11].

For patients presenting with a STEMI with symptom onset within the prior 12 h, reperfusion therapy should be considered [16]. Percutaneous coronary intervention (PCI) is the recommended method of reperfusion when it can be performed with the goal of time from first medical contact to device time of less than or equal to 90 min [16]. If patients are unable to get to a PCI-capable hospital within 120 min of a STEMI, then fibrinolytic therapy should be administered within 30 min of hospital arrival, provided there are no contraindications. The benefit of an early invasive strategy for patients initially presenting with NSTEMI or UA is less certain. A meta-analysis was inconclusive in regard to survival benefit associated with early (typically $<$24 h) versus delayed invasive strategy in patients presenting with NSTEMI [17]. However, early invasive coronary angiography is recommended in NSTEMI/UA patients who have refractory angina or hemodynamic or electrical instability [18]. Early invasive strategy is reasonable for higher-risk NSTEMI/UA

Table 2 The Thrombosis and Myocardial Infarction (TIMI) risk score for UA/NSTEMI [11]

Baseline characteristics	TIMI risk score (points)	Rate of composite endpoint (%)[a]
1 point for each of the following: Age $\geq$ 65 years At least 3 risk factors for IHD[b] Prior coronary stenosis $\geq$ 50 % ST segment deviation At least 2 anginal events in the last 24 h Use of aspirin in the last 7 days Elevated serum cardiac biomarkers[c]	0–1	4.7
	2	8.3
	3	13.2
	4	19.9
	5	26.2
	6–7	40.9

[a]All-cause mortality, new or recurrent MI, or severe recurrent ischemia requiring urgent revascularization through 14 days after randomization
[b]Risk factors include family history of IHD, hypertension, hypercholesterolemia, diabetes, or being a current smoker
[c]CKMB fraction and/or cardiac-specific troponin level

patients previously stabilized who do not have serious comorbidities (e.g., liver or pulmonary failure, cancer) or contraindications to the procedure [18].

Antithrombotic Agents. Antiplatelet therapy is a foundation in the management of ACS because it reduces the risk of thrombosis [18]. Well-established antiplatelet therapies in the management of ACS include aspirin, adenosine diphosphate P2Y12 receptor antagonists, and glycoprotein IIb/IIIa inhibitors. Aspirin should be started as soon as possible after an ACS event with an initial loading dose of 162–325 mg, unless contraindicated. Aspirin should be continued at a dose of 81 mg daily. A P2Y12 antagonist should be added to aspirin for patients with ACS who are medically managed as well as those undergoing PCI [16, 18]. P2Y12 receptor antagonists frequently used in the management of ACS include clopidogrel (Plavix), prasugrel (Effient), and ticagrelor (Brilinta) [19–22]. Triple antiplatelet therapy accomplished by adding GP IIb/IIIa inhibitors has been shown to be efficacious when used during PCI in reducing ischemic complications. However, triple antiplatelet therapy has also been associated with an increased bleeding risk [18].

Anticoagulants. Parenteral anticoagulants (unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), fondaparinux, or bivalirudin) are used in combination with antiplatelet agents during the initial management of ACS. The choice of anticoagulant agent is dependent upon the initial management strategy, and the recommended duration of therapy varies based on the chosen agent [11, 16].

Beta-Blockers. For patients presenting with UA, NSTEMI, or STEMI, oral beta-blocker therapy should be initiated within 24 h of the onset of the event unless the patient has evidence of low-output state, signs of heart failure, increased risk for cardiogenic shock, or other contraindications to therapy [11]. The use of intravenous beta-blockers is reasonable in patients who are hypertensive and do not have contraindications. Beta-blockers decrease cardiac work and reduce myocardial oxygen demand by reducing myocardial contractility, sinus node rate, and AV node conduction velocity. Beta-blocker should be continued in the post-MI setting unless contraindicated or not tolerated. The duration of benefit of long-term oral beta-blocker therapy is uncertain, but many clinicians choose to continue beta-blockers indefinitely. If patients are experiencing side effects from beta-blocker use, it may be reasonable to discontinue therapy at least 1 year after an MI [23]. For patients who are unable to take beta-blockers and experience recurrent ischemia, consideration should be given to starting a nondihydropyridine calcium channel blocker (i.e., verapamil or diltiazem) [11, 16].

Renin-Angiotensin Inhibitors. As long as no contraindications exist, an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) should be initiated within the first 24 h of patients presenting with ACS who have pulmonary congestion, heart failure, STEMI with anterior location, or left ventricular ejection

Table 3 Management of stable ischemic heart disease

	Recommendation	Comment
Aspirin	81 mg daily unless contraindicated	Clopidogrel can be used for patients allergic to aspirin
Blood pressure-lowering medication(s)	Goal BP < 140/90 mmHg for most patients	Beta-blocker recommended as part of regimen for post-MI patients
Cholesterol-lowering medication	Statin therapy	Use at least moderate dose
Smoking cessation	Any patient who smokes should be provided recommendation, counseling, and resources to quit	
Symptom management	Control angina symptoms with beta-blocker, nitrates, and/or calcium channel blocker	Beta-blocker is first line; calcium channel blocker should be long-acting nondihydropyridine or dihydropyridine (avoid nifedipine); long-acting nitrate can be added to help manage chronic angina

fraction (LVEF) $\leq$ 40 % [11, 16]. ACE inhibitors have been shown to reduce mortality in a broad spectrum of patients following MI, including those with and without LV dysfunction [24–29]. Patients with stable CAD who are not medically optimized (i.e., cannot tolerate a beta-blocker or statin), who are not able to be revascularized, and/or who have poorly controlled diabetes have shown mortality benefit with continued treatment with ACE inhibitors [30]. When initiating inhibitors of the renin-angiotensin system, it is important to monitor for adverse effects associated with these agents including hyperkalemia, elevations in serum creatinine, and hypotension.

Statin Therapy. Statin (HmG-CoA reductase inhibitor) therapy is recommended for all patients presenting with ACS who have no contraindications [11, 16]. High-intensity statin therapy following an ACS event was shown to confer an absolute risk reduction of 4 % over 2 years compared with a moderate-intensity statin for the composite endpoint of death from any cause, recurrent MI, UA requiring rehospitalization, revascularization, and stroke [31]. Statin therapy is beneficial following ACS even in patients with baseline low-density lipoprotein cholesterol levels of <70 mg/dL [11, 16]. Recently published American College of Cardiology and American Heart Association Guidelines on treatment of cholesterol recommend high-intensity statins (i.e., $\geq$ atorvastatin 40 mg daily or $\geq$ rosuvastatin 20 mg daily) for high-risk patients, which include patients who have an ACS event [32]. Lower-dose statins can be considered if patients are >75 years old or if patients cannot tolerate high-intensity statins.

Stable Ischemic Heart Disease

Stable ischemic heart disease represents an established pattern of angina, a history of myocardial infarction, or the diagnosis of coronary artery disease on catheterization. The goals of managing stable IHD are to prevent progression of disease and reduce the likelihood of cardiovascular disease events (secondary prevention), ultimately reducing premature mortality. The "ABCs" of management are shown in Table 3.

Antiplatelet Medication. Low-dose aspirin (typically 81 mg) is recommended for all patients for secondary prevention unless it is contraindicated (e.g., allergy) or poorly tolerated [2]. Aspirin inhibits cyclooxygenase, and the resultant reductions in prostaglandin and thromboxane-A prevent platelet aggregation. Numerous studies have demonstrated the benefit of aspirin for secondary prevention.

Blood Pressure Lowering. Control of blood pressure is important in the management of IHD. Recent evidence-based guidelines recommend initiation of treatment for hypertension at blood pressure >140 mmHg systolic and/or >90 mmHg diastolic in patients with diabetes, CKD, or in patients younger than 60 years old without these

comorbidities [33]. These new guidelines support permissive elevation of systolic blood pressure to 150 mmHg prior to initiation of therapy in patients 60 years and older. See the chapter on "▶ Hypertension" for further discussion of BP lowering.

Cholesterol Lowering. The ACC/AHA Lipid Guidelines support use of a high-dose statin in all patients less than 75 years old who will tolerate this treatment [32]. The LDL goals seen in previous guidelines are no longer recommended. Consider at least a moderate-dose statin in patients older than 75 [32]. Statins are the preferred treatment, but for patients who do not tolerate them, a bile acid sequestrant or niacin (or both) are reasonable alternatives. Fibrates can be prescribed for patients with elevated triglycerides.

Smoking Cessation. Patients with IHD should be counseled to make smoking cessation a priority. See the chapter on ▶ Tobacco Cessation for information on strategies and clinical interventions that may help patients become smoke free.

Symptom Control. Options for antianginal therapy include beta-blockers, nitrates, and calcium channel blockers. Beta-blockers are the first-line recommendation for control of angina [2]. By reducing myocardial oxygen demand, they reduce the frequency of chest pain episodes and improve exercise tolerance. In addition to their benefit for symptom control, beta-blockers help prevent reinfarction and reduce mortality in patients who have suffered an MI. When beta-blockers are contraindicated or not effective as monotherapy, a nitrate or calcium channel blocker can be used.

Sublingual nitroglycerin or nitroglycerin spray is provided for relief of acute episodes of IHD-related chest pain. These preparations can also be used a few minutes before activity to prevent effort-induced angina. A long-acting nitrate (e.g., isosorbide mononitrate) can be provided as a supplement to beta-blocker or calcium channel blocker for controlling chronic angina. Nitrate tolerance is minimized by having a nitrate-free interval of about 12 h.

Ranolazine is a newer therapy for angina control. It is a sodium channel blocker that reduces oxygen demand by decreasing tension during ventricular relaxation. The medication can be a useful add-on when angina is not controlled with the above strategies or can be prescribed instead of beta-blockers if beta-blockade is contraindicated or poorly tolerated [2]. Ranolazine can be used in patients with bradycardia or low blood pressure.

Other Recommendations. Lifestyle modifications for all patients include weight loss if overweight, regular physical activity, and an eating plan that is low in saturated fats, trans fats, and cholesterol [2]. Referring a patient to a dietitian may be reasonable.

Coronary Revascularization. When angina cannot be controlled with medical management, referral to a cardiologist for consideration of coronary angiography and potential revascularization is recommended.

The electrical activation of heart muscle follows a precise and organized pathway which ensures that contraction and relaxation occur in an efficient way to support effective circulation. Arrhythmias result from an abnormal electrical activation of the heart which may lead to an abnormal rhythm and rate of the heart cycle. While some arrhythmias are benign and pose no significant cardiovascular compromise, others degrade the mechanical pumping activity and lead to hemodynamic compromise and, in some cases, to collapse and or death.

Arrhythmias are commonly seen in primary care, and many are diagnosed and managed by primary care physicians, either alone or along with a cardiologist. Although more common among the elderly and those with heart disease, they must be considered in the differential diagnosis of all patients presenting with syncope, lightheadedness, palpitations, fatigue, dyspnea on exertion, and shortness of breath. The main goal in evaluating patients is to first assess cardiopulmonary stability and, in life-threatening situations, activate emergency response. In stable patients, the workup focuses on identifying the arrhythmia, its cause, and its effect on cardiac function and on treating it to improve patients' symptoms and reduce morbidity and mortality.

Electrophysiology of the Heart

The heart generates its own electrical impulse, an action potential (AP) transmitted through specialized cells and conductive fibers to activate myocardial cells to contract and relax in a highly coordinated fashion. This determines heart rate and rhythm.

Figure 1 [1] shows a schematic view of the normal electrical conduction system. The AP originates at sinoatrial node (SA), a group of specialized cells in the upper posterior wall of the right atrium. It is transmitted to the atria and to the atrioventricular node (AV), a group of cells in the posterior region of the atrial septum. In the AV node, the impulse is delayed, allowing atrial contraction to occur before the ventricular activation. The AV node transmits the impulse through the bundle of His, fast-conducting fibers in the upper interventricular septum, which splits into two branches, right and left. Then the impulse continues through the Purkinje fibers, which transmit it to all ventricular cells, resulting in ventricular contraction and ejection of blood into the circulation. Although the AV node, bundle of His and Purkinje can act as pacemakers, the SA node has the highest intrinsic rate of depolarization, and it serves as the pacemaker. At rest, the SA node triggers APs at a rate of 60–100 times per minute. In an ECG, this pattern is seen as regular waves known as P, QRS, and T waves, which is normal sinus rhythm (NSR).

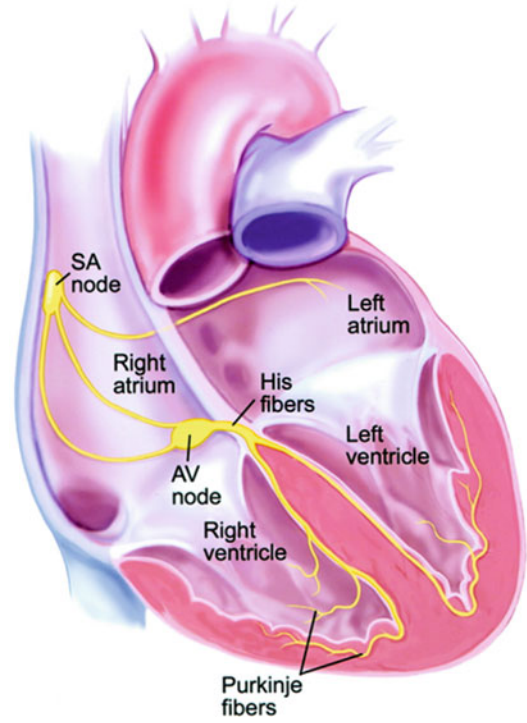

Fig. 1 Diagram of the heart and the electrical conduction system of the heart (From Ref. [1])

At the molecular level, the generation of the AP is due to unstable transmembrane potential caused by a slow sodium leak into the cells, depolarizing the membranes until the threshold is reached that triggers an AP. Cardiac cells have several voltage-gated ion channels, and the in and out flow of Na, K, and Ca ions through these gated channels (fast and slow) play key roles in

generating the AP and repolarizing cell membranes. Through the cycle, cells exhibit absolute and relative refractory periods. Sympathetic and parasympathetic fibers innervate the heart but do not participate in the generation or transmission of electrical activity; they modulate cardiac function.

Three main mechanisms have been identified as the causes of arrhythmias: increased automaticity, triggered activity, and reentry. Reentry is the most common cause of arrhythmias. It occurs when the normal electrical impulse does not dissipate and re-excite cardiac cells after the refractory period.

Arrhythmias are described according to where they originate (in the atria, ventricles, along the multiple sites of the electrical conduction system, or on myocardial cells); according to their effect on heart rate (HR) (fast, tachyarrhythmias, >100 beats per minute, or slow, bradyarrhythmias, <60 beats per minute); and according to their effect on heart rhythm (regular versus irregular patterns). All these characteristics define a unique pattern in the ECG.

Evaluation of Patients with Arrhythmia

History and Physical Exam (H&P)

Although studies have shown poor correlation between symptoms and actual arrhythmias, the H&P helps to identify potential causes, risk factors, and comorbidities. Elements of the history must consider both cardiac and noncardiac causes of arrhythmia. As usual, it must include onset, patient's description of symptoms, duration, aggravating and alleviating factors, severity, and course of symptoms. The review of systems must inquire about shortness of breath, palpitations, dizziness, edema, orthopnea, paroxysmal nocturnal dyspnea, fatigue, lightheadedness, chest pain, syncope, orthostatic hypotension, symptoms of sleep apnea, pedal edema, new medications (prescribed or over the counter), herbal and other supplements, symptoms of thyroid disease, and recent illnesses. The social history provides information about the use of recreational drugs, alcohol, and diet pills as possible causes or contributors. Table 1 presents the most common causes of arrhythmias. Rare conditions such as infiltrative heart diseases, pheochromocytoma, and other endocrine conditions must be considered. All patients must have a complete physical exam (PE), vital signs, and BMI. The cardiovascular exam should include inspection, palpation, percussion, and auscultation of the heart, assessment of heart rate and rhythm, presence of murmurs, carotid bruits, patient's JVD, peripheral pulses, and edema.

Table 1 Most common causes of arrhythmias

Cardiac	Noncardiac
CAD: myocardial ischemia or infarction	Pulmonary disease
Heart failure	COPD, PE, pneumonia
Structural heart disease: congenital or acquired	Cor pulmonale
Dilated cardiomyopathy	Thyroid disease
Ventricular hypertrophy	Drug toxicity
Valvular disease	Antiarrhythmics
Atrial septal defect	Beta agonist inhalers
Ebstein anomaly	Lithium
Epicardial, myocardial, and endocardial diseases: infectious, injury, or drug toxicity	Drugs that increase QT interval
	Electrolyte abnormalities
Iatrogenic	Recreational drugs
Post-cardiac catheterization	Diet pills
Post-cardiac surgery	Collagen vascular disease
Post ablation	Infiltrative disease
Post-ICD placement	Hypothermia

Evaluation of Cardiac Arrhythmia

Because patient symptoms often do not correlate with actual arrhythmias and the H&P cannot characterize the arrhythmia, the first step is to get an ECG. The ECG provides immediate information of the HR and rhythm and changes in P wave, PR interval, QRS complexes, ST segment, and T waves. Since a normal ECG cannot capture a paroxysmal arrhythmia, a Holter monitor (24 h recording) or an event monitor (7–30 days recording) may be required. In some cases, a long-term implantable loop recorder may be necessary [2]. An echocardiogram is also needed to evaluate heart function and assess for possible structural diseases.

Initial blood tests include a complete blood count with differential, a complete metabolic panel, magnesium, phosphate, lipid panel, and TSH. Additional tests may be necessary depending on the patient's H&P and risk factors. These include stress echocardiogram, nuclear perfusion imaging, or cardiac catheterization for ischemia or coronary artery disease, table tilt test for vasovagal syncope, drug screen (if suspected), and urine vanillylmandelic acid and serum metanephrine for evaluation of possible pheochromocytoma.

Treatment Options for Cardiac Arrhythmias

Several options are available to treat arrhythmias. They include cardioversion, drugs with AV nodal suppression, antiarrhythmic drugs acting on different ion channels, radiofrequency ablation, pacemakers, defibrillators, and surgery. Based on best evidence from clinical trials, the most updated knowledge of pharmacology and pathophysiology, the American Heart Association, the American College of Cardiology, the European College of Cardiology, and the Heart Rhythm Society, AHA/ACC/ECC/HRS, have developed guidelines for the evaluation and treatment of arrhythmias [3–8]. These guidelines are frequently revised and updated to include latest knowledge, and they provide a framework for a discussion with patients and their families about treatment options. Therapeutic decisions also must reflect patients' preferences and choices. Prior to initiating specific therapy, it is essential to identify and treat reversible causes of arrhythmias.

Cardioversion

It is the attempt to return the heart rhythm to NSR and can be achieved by an electrical current shock or by drugs. The goal is to override all abnormal electrical activity and synchronize the heart rhythm again. Unless done in an emergency basis, it requires preparation: IV access, continuous cardiac monitoring, sedation and/or anesthesia, resuscitation equipment, proper anticoagulation, normal electrolytes, short fasting, etc.

Electrical cardioversion is accomplished by delivering a direct current electric shock of 50–360 J of energy. Shocks are delivered in synchrony with the R or S wave of the QRS complex to avoid the relative refractory period and minimize triggering of other arrhythmias. One or more shocks may be necessary, starting at the lowest energy. The main indications for cardioversion are unstable or poorly tolerated narrow QRS complex tachycardias (atrial fibrillation AF or flutter) and ventricular tachycardia not responsive to drug therapy.

Pharmacologic cardioversion and maintenance of NSR have been challenging due to limited long-term efficacy of drugs, the risk of triggering ventricular arrhythmias, and their long-term adverse side effects [3]. It is more successful in young patients with healthy hearts who have recently developed an arrhythmia. Most commonly used drugs include ibutilide (Corvert), flecainide (Tambocor), dofetilide (Tikosyn), propafenone (Rythmol) and amiodarone (Cordarone, Nexterone, Pacerone). Contraindications for cardioversion include digitalis toxicity, multifocal atrial tachycardia, and suboptimal anticoagulation.

Antiarrhythmic Drug Therapy

Multiple drugs are available to suppress and treat arrhythmias. Drugs are classified according to their mode of action, although some drugs have more than one effect [9–12]. Table 2 shows drug classification, indications, and contraindications, potential adverse side effects, and their pharmacokinetics. Detailed description of each drug and its pharmacology is beyond the scope of this chapter.

Class I. These drugs block Na channels and therefore act on the depolarization phase of the cardiac AP. They are further subdivided into three subclasses according to their effect on the

Table 2 Antiarrhythmic drugs

Class		Medication Name and MOA	Indications	Contraindications	Side effects (SE)	Half-life and pharmacokinetics
I OR Sodium Channel Blockers	Ia	Quinidine (Qualaquin) different types: Gluconate, sulfate ↓↓ Phase 0 slope	A-Fib, A- flut, VT	HtoD, myasthenia gravis, Immune thrombocytopenia, thrombocytopenic purpura, Digitalis toxicity, complete AV dissociation	QT prolongation, paradoxical pulse in A-Fib/A-flut, bradycardia in SSS, ↓ BP, diarrhea, vertigo, vision changes Warnings: HB without pacemaker Pregnancy risk C Lactation risk L2	6–8 h
		Procainamide[a] ↑ AP duration	VT	HtoD, complete HB, 2nd- or 3rd-degree AVB SLE, torsades de pointes	↓ BP, widened QRS, rash, agranulocytosis, drug-induced lupus Warnings: complete HB, SLE, torsades de pointes Monitor *N*-acetylprocainamide (NAPA) levels Pregnancy risk C Lactation risk L3	3–4 h E: renal Adjust dose if CrCl < 50 ml/ min
		Disopyramide (Norpace) ↑ Effective refractory period	VT	HtoD, cardiogenic shock, congenital prolonged QT, 2nd- or 3rd-degree block	↓ BP, HF, widened QRS, QT prolongation; 1st HB (reduce dose), anticholinergic effects Warnings: 1st- and 2nd-degree HB Pregnancy risk C Lactation risk L2	7–8 h E: renal Adjust dose if CrCl < 40 ml/ min
	Ib	Mexiletine[a] ↓ AP duration	VT	HtoD, cardiogenic shock, 2nd- and 3rd-degree AVB, if no pacemaker is present	Acute liver injury, leukopenia, agranulocytosis, tremor, blurry vision, lethargy, and nausea Warnings: SSS, HB, ↓ BP, HF Pregnancy risk C Lactation risk L2	10–12 h
		Phenytoin (Phenytek, Dilantin) (Rarely used in arrhythmia) ↓ Effective refractory period	VT secondary to digoxin	HtoD or other hydantoins, concomitant use with delavirdine or rilpivirine	Rash, gingival swelling, constipation, N/V, ataxia, slurred speech, SLE, SJS, agranulocytosis, pancytopenia, hepatotoxicity, suicidal thoughts, drug withdrawal seizure	14–22 h E: mostly Liver
		Lidocaine (Xylocaine) ↓ Phase 0 slope	VF, VT	HtoD or to local anesthetics of the amide type	↓ HR, HB, cardiovascular collapse, agitation, anxiety, coma Pregnancy risk B Lactation risk L2	1–2 h E: renal

(*continued*)

Table 2 (continued)

Class		Medication Name and MOA	Indications	Contraindications	Side effects (SE)	Half-life and pharmacokinetics
		Tocainide (Tonocard)	VF, VT	HtoD, 2nd- and 3rd-degree AVB, HF, ↓K, liver and kidney disease	↓ HR, ↓ BP, rash, abdominal pain, ataxia, tremor, vertigo, blurry vision	12 h
	1c	Flecainide (Tambocor) ↓↓↓ Phase 0 slope	PAF, ventricular arrhythmia, PSVT, P-atrial flut	HtoD, RBBB with left hemiblock without pacemaker, 2nd- and 3rd-degree AVB without pacemaker	Palpitation, dyspnea, headache, dizziness, fatigue. Cardiogenic shock, VF, VT, torsades de pointes	20 h prolonged HL in renal impairment
		Propafenone (Rythmol) ↔ AP duration	PSVT and PAF Without Structural Heart disease, VT	HtoD, bradycardia, Brugada syndrome, severe bronchospasm, COPD, cardiogenic shock, HF, electrolyte imbalance, marked hypotension. SSS and AVB without pacemaker	New or worsen arrhythmias, worsen HF, dose-related ↑ in PR, QRS intervals, HB, neutropenia, and/or agranulocytosis. Warnings: bradycardia, shock, prolonged QT interval, CAD Pregnancy risk C Lactation risk L2	5–7 h E: liver Dose adjust with severe liver and kidney disease
ll Beta blockers Most commonly used	B1S: metoprolol (Toprol), atenolol (Tenormin). Esmolol (Brevibloc) Nβ1S: Coreg (carvedilol), Sotalol (Betapace, Sorine, Sotylize) Propranolol (Inderal, Innopran, Hemangeol) ↓SA node automaticity ↓ HR and conduction ↓ chronotropy and inotropy by inhibition of β1 receptor		VT, PVC, VF ST, A-Fib, A-flut, PAT	HtoD, ↓ BP or shock, severe bradycardia, HB >1st degree (unless pacemaker), MI precipitated by cocaine, overt HF with pulmonary edema (start at low dose)	↓ BP, ↓ HR, 1st-degree HB, dizziness, fatigue, rash, diarrhea, dyspnea, bronchospasm, hypoglycemia, seizure	Met: IV 3–4 h PO:7–9 h Aten: 6–9 h Prop: 3–6 h Esm: 9 min Sot: 12 h Carv: 7–10 h

lll K channel blockers	Ibutilide (Corvert)	A-Fib, A-flut	HtoD, HF, prolong QT, ↓ HR, MI, electrolyte abnormalities, liver disease. Not to use with Class 1 or other Class III	↓ HR, HB, prolong QT, VA. Torsades de pointes, CVA, renal failure, pulmonary edema	6 h
	Amiodarone (Pacerone, Cordarone, Nexterone) Delays repolarization (phase III)	Supraventricular arrhythmia, VA	HtoD, severe bradycardia, syncope without pacemaker, severe sinus node dysfunction, 2nd- and 3rd-degree AV blocks (unless with pacemaker). Cardiogenic shock	↓ HR, ↓BP, photodermatitis, optic neuritis, thyroid dysfunction, liver failure, abnormal gait and coordination, anaphylaxis, pseudotumor cerebri, ARDS	Weeks
	Dofetilide (Tikosyn) Prolongs AP phase III	A-Fib, A-flut	HtoD, prolong QT, severe renal impairment, concomitant use of cimetidine, hydrochlorothiazide, ketoconazole, prochlorperazine, verapamil	Prolong QT, VF, torsades de pointes, CP, dizziness, headache	10 h
IV Ca channel blocker	Verapamil (Calan, Covera, Isoptin, Verelan) Diltiazem (Cardizem, Cartia, Dilacor, Dilt-CD, Diltzac, Taztia, Tiazac, Matzim) Block L-type Ca channels Most effective at SA and AVN ↓ HR and conduction	A-Fib, A-flut with RVR	HtoD. Ver: A-Fib, A-flut associated with WPW syndrome. SSS, 2nd- and 3rd-degree AVB without pacemaker, HF with EF < 30% hypotension HtoD. Dilt: all of the above Newborns, acute MI with pulmonary congestion, administration within a few hours of IV β blockers	↓ HR, HB, worsening of HF, ↓BP Warnings: WPW, SSS, HB, other AV nodal blockers Pregnancy risk C Lactation risk L2	Ver: 7 h Dilt: 4–8 h E: liver for both

(*continued*)

Table 2 (continued)

Class	Medication Name and MOA	Indications	Contraindications	Side effects (SE)	Half-life and pharmacokinetics
Miscellaneous	Digoxin (Lanoxin, Lanoxicaps, Digox, Digitek) Inhibits Ca-K ATPase, causing ↑ chronotropic and ↓ inotropic effects	A-Fib, A-flut with RVR, HF	HtoD, VF	Arrhythmias, N/V Warnings: bradycardia, HB, renal Failure, hypokalemia Pregnancy risk C Lactation risk L2	30 h Narrow therapeutic range E: renal
	Adenosine (Adenocard, Adenoscan) ↓ AV node conduction Velocity, ↑ refractory period	PSVT	HtoD, asthma, 2nd and 3rd AVB, symptomatic bradycardia, and SSS without a pacer	AVB, flushing, chest burning due to bronchospasm, brief period of asystole Warnings: HB, wide complex VT Pregnancy risk C Lactation risk probably safe	<10 s
	Dronedarone (Multaq) Combined effects of Classes I–IV	A-Fib or A-flut	HtoD. SSS, 2nd and 3rd AVB without pacemaker, liver, and lung toxicity. HF (New York Class lV or recent decompensation), severe liver impairment and use of CYP3A inhibitors. Prolonged QT > 500 and PR interval > 280 s	Stop Class I or III agents first. HF, HB, bradycardia, QT prolongation Pregnancy risk X Lactation risk unknown	13–19 h

Data presented in this table are from Refs. [9–12]

[a]Medications without brand names in the USA

duration of the AP: shortening it, Class Ia; lengthening it, Class Ib; or no effect, Class Ic.
- Class Ia agents prolong the initial phase of the AP thus delaying depolarization. They also increase the absolute refractory period. They include quinidine (Qualaquin), procainamide, and disopyramide (Norpace).
- Class Ib. These drugs shorten the duration of the AP by increasing repolarization. They include lidocaine (Xylocaine), phenytoin (Phenytek, Dilantin), mexiletine, and tocainide (Tonocard).
- Class Ic. These drugs have no effect on AP duration, but they significantly slow the initial depolarization of the AP and have no effect on refractory period. They include encainide, flecainide, propafenone, moricizine.

Class II. These are β blockers which have antisympathetic activity by blocking β1 adrenergic receptors, slowing HR by delaying conduction at the AV node [11]. Among them are propranolol (Hemangeol, Inderal, InnoPran), esmolol (Brevibloc), timolol, metoprolol (Toprol), atenolol (Tenormin), and bisoprolol (Zebeta).

Class III. These drugs block K channels and prolong repolarization and thus the refractory period of cardiocytes. They are useful in treating reentry arrhythmias. Among them are amiodarone, sotalol (Betapace, Sorine, Sotylize), ibutilide, dofetilide, and dronedarone (Multaq).

Class IV. They are calcium channel blockers (nondihydropyridine) that delay conduction at the AV node, slowing HR. They also inhibit heart contractility and thus are contraindicated in patients with heart failure. They include diltiazem (Cardizem, Cartia, Dilacor, Dilt-CD, Diltia-CD, Taztia, Tiazac, Diltzac, Matzim) and verapamil (Calan, Covera-HS, Isoptin SR, Verelan).

Class V, Miscellaneous. This class includes drugs with different effects from the above classes. They include digoxin (Lanoxin, Lanoxicaps, Digitek, Digox), adenosine, and magnesium
- Digoxin decreases conduction at the AV node, and it increases vagal activity. Its main indication today is in addition to β blockers and calcium channel blockers to slow HR in AF.
- Adenosine (Adenocard, Adenoscan), a purine nucleoside with a half-life of <30 s, transiently blocks the AV node, and it is useful in stopping SVT due to reentry circuits within the AVN, atria, and accessory AV circuits. When used, patients need to be under continuous cardiac monitoring, be warned about transient unpleasant side effects (flushing, metallic taste, lightheadedness, and diaphoresis, lasting <1 min), and resuscitation equipment must be available. Adenosine is as effective as CCB in terminating SVT [13]. It is contraindicated in wide QRS tachycardias, 2nd and 3rd degree AVB without a pacer, sick sinus syndrome without a pacer, decompensated heart failure, hypotension, heart transplant patients, and severe asthma.
- Magnesium sulfate is only effective in the treatment of torsades de points, a deadly form of ventricular fibrillation.

Ablation Therapy

Electrophysiology studies are used to identify, study, and accurately map the foci of arrhythmia. Ablation therapy is then used to destroy abnormal foci and pathways by delivering radiofrequency energy to the target site(s). The injury to heart tissue is thermal and creates scarring, inflammation, and then necrosis. Sometimes the same arrhythmia recurs within days, weeks, or months, and the procedure may need to be repeated. Indications for ablation therapy include AF, WPW syndrome, and preexcitation [4, 6–8].

Pacemakers and Defibrillators

Patients at risk of life-threatening arrhythmias, or when arrhythmias severely compromise their cardiac function, must be referred to a cardiologist for evaluation of pacemaker and/or defibrillator placement. Pacemakers and defibrillators are sophisticated computers which can pace, sense, and respond to arrhythmias by inhibiting and/or stimulating electrical activity in the atria,

ventricles, or both. Pacemakers can also modulate their responses in a graded fashion. Detailed pacemaker settings and function are beyond the scope of this chapter. Several studies have demonstrated their effectiveness in preventing sudden death from arrhythmias [4–6].

The ACC/AHA and the North American Society of Pacing and Electrophysiology recommend the implantation of pacemakers in patients with complete 3rd degree AV block, advanced 2nd degree AVB (block of two or more consecutive P waves), symptomatic Mobitz I or Mobitz II 2nd degree AV block, Mobitz II 2nd degree AV block with a widened QRS or chronic bi-fascicular block, and exercise-induced 2nd or 3rd degree AV block (in the absence of myocardial ischemia). They also recommend biventricular pacing for patients with dilated cardiomyopathy (ischemic and nonischemic), those with an LVEF $<35\%$, those with QRS complexes >0.12 ms, and in patients with New York Heart Failure Class III or IV heart failure, despite optimal medical treatment [4–7].

Patients with implanted pacemakers need to be monitored regularly by cardiology for proper function, programming, and battery life and to monitor patient's clinical symptoms.

Defibrillators deliver unsynchronized electrical shocks to the heart with the aim to stop a lethal arrhythmia and reestablish a viable cardiac rhythm. There are several types of defibrillators: external, transvenous, implantable in the form of a cardioverter-defibrillator (ICD), or as part of a pacemaker. Some have become part of the general public domain, known as automated external defibrillators (AEDs), allowing even the lay public to use them successfully. Today, most defibrillators deliver shocks in a biphasic truncated waveform which is more efficacious while using lower levels of energy to produce defibrillation. Defibrillation is only recommended for ventricular fibrillation and pulseless ventricular tachycardia.

Surgery

Two surgical therapies for atrial fibrillation are available: the surgical disruption of abnormal conduction pathways within the atria, known as Maze procedure, and the obliteration the left atrial appendage (LAA).

In the Maze procedure, incisions are made in the atria to isolate and interrupt reentry circuits while maintaining the physiologic activation of the atria. In another version, incisions are made to create an electrical corridor from the SA to the AV node. The Maze procedure has undergone multiple revisions since its development, and it is considered for patients who need invasive cardiac surgery for other reasons [14].

LAA obliteration is a surgical procedure aimed at reducing the risk of thromboembolic events in patients with AF and possibly avoiding long-term anticoagulation. The rationale for obliteration is based on the observation that $>90\%$ of the thrombus forms in the LAA and is the main source of thromboembolism [15, 16]. It is only recommended for patients undergoing other cardiac surgery, most commonly mitral valve repair [3, 4].

Referral to Cardiologist

Cardiology referral is warranted when patients have complex cardiac disease, cannot tolerate the arrhythmia, need rhythm control, require ablation therapy, may benefit from surgical treatment, or need a pacemaker or defibrillator.

Supraventricular Tachyarryhthmias (SVT)

These arrhythmias originate above the ventricles and involve the atria or the AV node for initiation and propagation. These arrhythmias are due to reentry circuits or accessory pathways, most commonly the AV nodal reentrant tachycardia, the atrioventricular reentrant tachycardia, or the atrial tachycardia. In the absence of other conduction defects, the ECG shows a rapid HR with narrow QRS complexes. Wide QRS complexes indicate additional conduction abnormalities distal to AVN, such as bundle branch block and/or accessory pathways. These arrhythmias are treated as ventricular tachycardias.

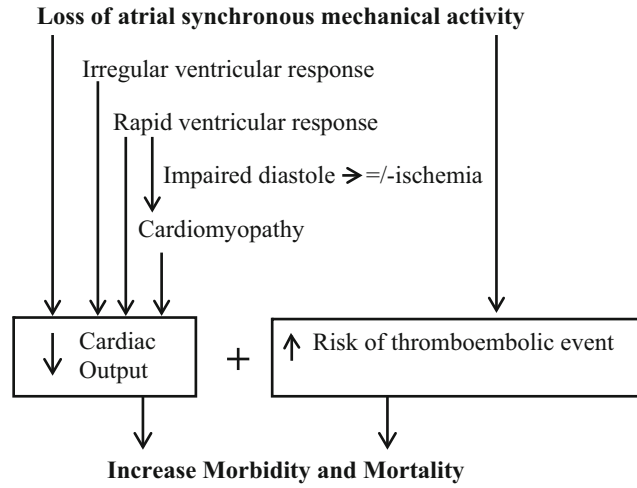

Fig. 2 Clinical implications of atrial fibrillation

Key questions to answer in evaluating SVT are: What is the ventricular response? Does it lead to a narrow or wide QRS? Is the arrhythmia regular or irregular? And, what is the effect on the heart rate and mechanical function? [17].

Atrial Fibrillation (AF)

AF is the most common SVT seen in primary care. In addition to adverse effects on cardiac function, it increases the risk of stroke. AF has been identified as an independent risk factor for death [18, 19]. It worsens heart failure and increases mortality in the setting of myocardial infarct [20, 21]. It causes about 10 % of strokes, and these are more devastating and a major cause of disability. Figure 2 shows the deleterious effect of AF [22].

AF results from uncoordinated atrial activation leading to deterioration of mechanical function. In the ECG, the normal P waves are lost, and irregular impulses reach the AV node and activate the ventricles at an irregular rapid rate, usually between 90 and 170 beats/min. The QRS complex remains narrow unless other conduction abnormalities coexist (Fig. 3). Enhanced automaticity of depolarizing foci and reentry in one or more circuits are responsible.

AF may result from several disease processes with different prognoses and associated morbidities and mortalities. AF in patients younger than 60 with no underlying heart disease is known as lone AF and has good prognosis. AF due to congenital or acquired valvular disease carries the highest risk for stroke. AF due to noncardiac disease such as hyperthyroidism or pulmonary disease is referred as secondary AF, and treating its cause resolves it. AF treatment and prognosis are affected by its duration and persistence. Paroxysmal AF is defined as episodes of self-resolving AF. Persistent AF lasts for >7 days and can still be terminated by cardioversion. Chronic AF is continuous and unresponsive to cardioversion. Paroxysmal and chronic AF carry the same risk for stroke. Persistent AF causes atrial remodeling (anatomical and physiologic changes) which leads to its perpetuation [3].

Patients with AF may be asymptomatic, have vague symptoms, or present with myocardial infarction, a stroke, or complete hemodynamic collapse. The diagnosis requires the typical ECG pattern: loss of P waves, narrow QRS complex with a fast and irregular ventricular response. An event or Holter monitor may be needed to capture the arrhythmia.

The management of AF depends on the patient's clinical presentation. In cases of hemodynamic instability, stroke, or myocardial infarction, emergency evaluation and treatment are warranted, including emergency cardioversion.

The long-term treatment of AF poses three main therapeutic challenges: (1) reverse to NSR by cardioversion or ablation; (2) control the

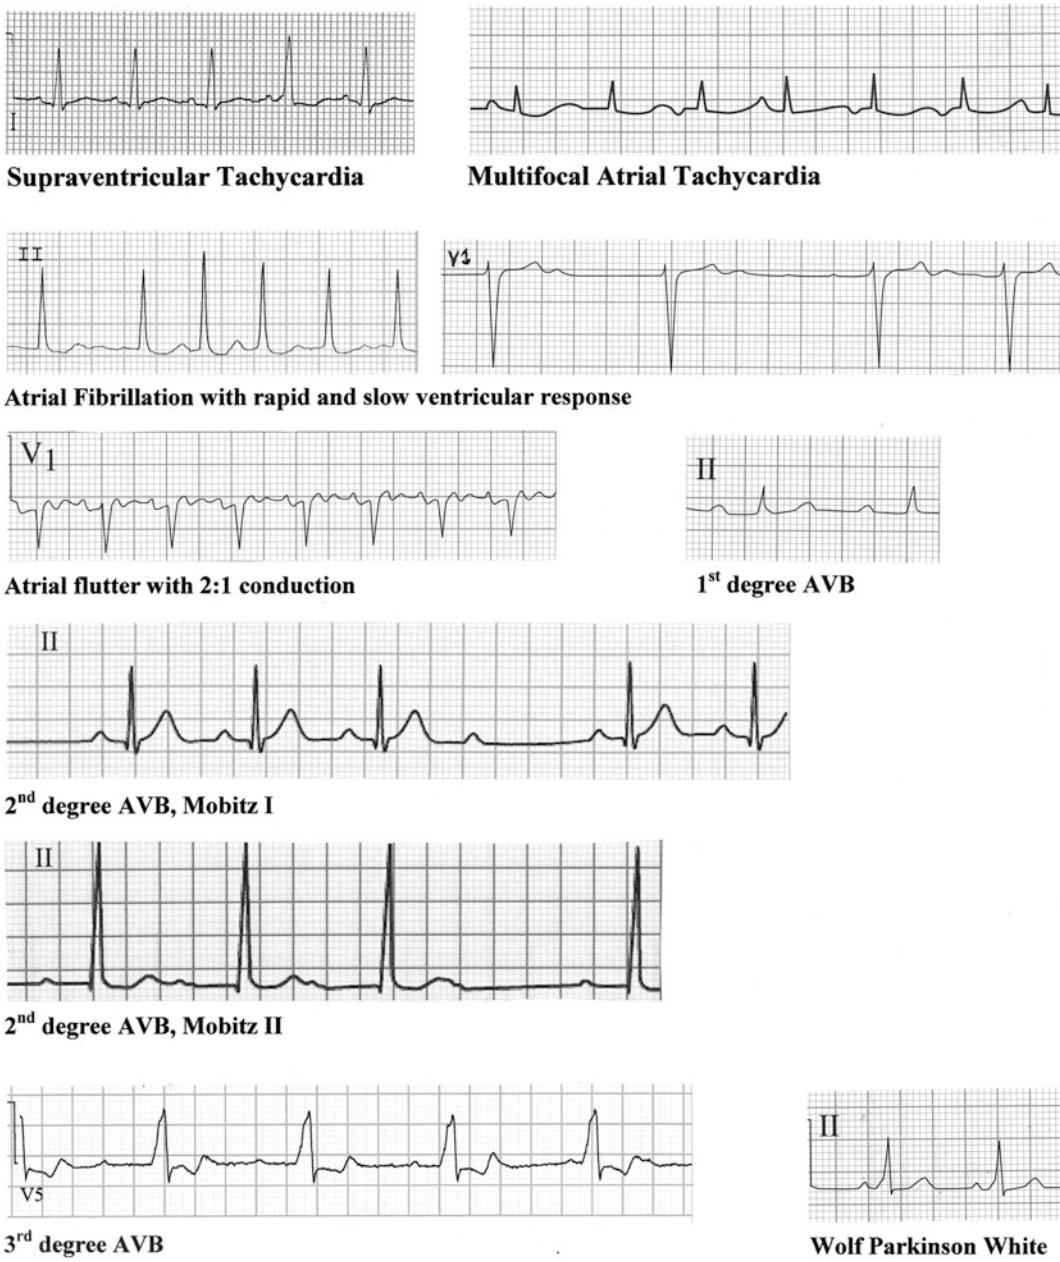

Fig. 3 Most common supraventricular arrhythmias. For each arrhythmia, see discussion in corresponding section

ventricular rate and allow AF to continue; and (3) in either case, start anticoagulation.

Cardioversion can be achieved electrically or pharmacologically. Unless done emergently or if AF is known to be less than 48 h, cardioversion requires 4 weeks of pre- and 3–4 weeks post-anticoagulation. Pharmacologic cardioversion with antiarrhythmic drugs has limited efficacy. Commonly used drugs include flecainide, propafenone, dofetilide, amiodarone, dronedarone, and sotalol. Because they can trigger additional arrhythmias and have long-term adverse side effects, it is suggested to refer or co-manage patients with a cardiologist.

Table 3 CHAD2DS2-VASc Stratification Risk for Stroke

CHA2DS2-VASc	Risk factor score	CHA2DS2-VASc total score	Adjusted stroke rate (percent/year)	Anticoagulation recommendation
Congestive heart failure/ LV dysfunction	1	0	0	No
Hypertension	1	1	1.3	
Age <65 65–75 >75	0 1 2	2	2.2	Unless risk outweighs benefits, recommended Options Warfarin to target INR 2–3 Dabigatran 150 mg bid Rivaroxaban 20 md qd Apixaban 5 mg bid For patients unable or who refuse above choices Aspirin 81–325 mg qd Clopidogrel 75 md qd

Ablation therapy is another way to restore NSR. It is gaining acceptance after the discovery of specific foci that trigger AF. These foci are at or near the pulmonary veins, at the cristae terminalis, and coronary sinus [23]. The ACCF/AHA/HRS AF guidelines recommend it for patients with recurrent AF who are symptomatic but who have no structural heart disease [3].

Most patients are treated with ventricular rate control vs rhythm control [24, 25]. Rate control slows the ventricular response and improves diastolic ventricular filling, reduces myocardial oxygen demand, and improves coronary perfusion and mechanical function. β blockers, metoprolol, esmolol, and propranolol, and nondihydropyridine calcium channel blockers (CCB), diltiazem and verapamil, are used to achieve rate control with a goal of <80 during rest and <110 during exercise. More lenient rate control to a resting heart rate of <110 is reasonable in asymptomatic patients with normal left ventricular function [26]. Digoxin is no longer a first or sole choice, but it can be used in addition to β blockers or CCB [3]. Rhythm control is an option for patients in whom rate control cannot be achieved or who remain symptomatic.

Surgical treatments for AF include left atrial appendage obliteration and the Maze procedure. Both are invasive and are only considered in patients undergoing cardiac surgery for other reasons [14–16].

Anticoagulation significantly reduces the risk of stroke. Several stratification tools to assess both the risk of stroke and risk of bleeding have been developed. Although they have limitations, they are useful in evaluating patients' risks and benefits for long-term anticoagulation.

The widely used CHADS2 acronym score, a validated tool to assess risk of stroke, has been replaced by CHAD2DS2-VASc [27]. Table 3 shows the current risk stratification and recommendations for anticoagulation [3]. Similarly, several tools have been developed to assess the risk of bleeding from anticoagulation. The ATRIA and now preferred HAS-BLED tools are used to assess risk of bleeding [28–31]. Risk factors include anemia, severe renal disease, age, previous bleeding, hypertension, liver disease, labile INR, and drug or alcohol use.

Warfarin (Coumadin, Jantoven) has been the corner stone of anticoagulation, but its use is challenging due to its narrow therapeutic range,

Table 4 Pharmacological properties of approved anticoagulants available for the prevention of thromboembolism in atrial fibrillation

Property mechanism	Warfarin Vitamin K antagonist	Dabigatran Direct thrombin inhibitor	Rivaroxaban Factor Xa inhibitor	Apixaban Factor Xa inhibitor
Dosing	Variable (dose adjusted on the basis of international normalized ratio)	150, 110 mg bid 75 mg bid for creatinine clearance ± 15–30 (USA only) Not recommended if < 15	20 mg daily;15 mg daily for creatinine clearance 15–50, Not recommended if <15	5 mg bid; 2.5 mg bid for patients with > 2 of the following: Creatinine > 133 μm/L, age > 80 years or weight < 60 kg, creatinine clearance± <15: no data available
Oral bioavailability	100 %	3–7 %	60 %	58 %
Time to effect (h)	72–96	1–2	2–4	3–4
Half-life (h)	40	12–17	5–9	8–15
Notable drug numerous interactions		Strong P-glycoprotein inducers		
		Strong P-glycoprotein inhibitors with concomitant kidney dysfunction	Strong P-glycoprotein inhibitors, strong cytochrome P450 inducers and inhibitors	

From Ref. [38]

multiple drug and food interactions, and need for frequent monitoring. The therapeutic goal is an INR between 2 and 3 for patients with non-valvular AF and an INR of 2.5–3.5 for those with valvular AF. Warfarin is more effective than aspirin (Bayer Aspirin, Bufferin, Ecotrin) and clopidogrel (Plavix) alone or in combination, but it carries a higher risk for bleeding. It is estimated that warfarin lowers the risk of thromboembolic events by 68 % while aspirin by 21 % [32–35].

Newer anticoagulants such as direct thrombin inhibitors and factor Xa inhibitors have emerged. As new data is gathered on their effectiveness and safety and their costs decrease, they likely will change anticoagulation practices.

Dabigatran (Pradaxa), a thrombin inhibitor, is as effective as warfarin in preventing stroke and systemic emboli. Rates of major bleeding were similar to those of warfarin, except for fewer intracranial bleeds but increased gastrointestinal bleeds. Caution and adjustment in dosing is needed for patients with kidney disease [36].

Factor Xa inhibitors now available are rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa). As compared to warfarin, rivaroxaban and edoxaban were non-inferior in preventing stroke and systemic thromboembolic events and have the same effect on major and non-major bleeding. Apixaban is superior to warfarin in stroke prevention and has the same bleeding rate as warfarin. Doses need to be adjusted for patient with kidney disease [37, 38].

The main advantages of thrombin and factor Xa inhibitors over warfarin include fixed dosing, no food interactions, fewer drug interactions, and no need for monitoring. Their major drawbacks are high cost, difficulty in reversing their effect in emergency situations, and not FDA approved (as of 2014) for valvular AF, pregnant or lactating patients, and those with advanced kidney disease. Table 4 shows a summary of approved anticoagulants available and their characteristics [37, 38].

Atrial Flutter

Atrial flutter is an organized regular rhythm caused by a reentry circuit around the tricuspid

valve. It is often seen after cardiac surgery or cardiac ablation. AF and atrial flutter can occur back and forth and sometimes coexist, but they are different. In atrial flutter, waves of depolarization activate the atria to contract regularly at about 280–300 times per minute, and if there is a healthy AVN and no AV node blocking drugs, there is a 2:1 conduction resulting in a ventricular rate of about 150 beats per minute (Fig. 3). The preferred treatment for atrial flutter is ablation. Class Ic drugs have not been effective and may be dangerous due to their pro-arrhythmic effects. AV node suppression drugs often change atrial flutter to AF, which may be better tolerated by patients. In the setting of cardiovascular compromise, electrical cardioversion may be necessary using biphasic defibrillator starting at 50 J energy shock.

Atrial or Sinus Tachycardia

Sinus tachycardia (Fig. 3) is in most cases a normal response of the heart to physiologic stressors such hyperthyroidism, dehydration, anemia, hypoxia, etc. A rare type of atrial tachycardia, called inappropriate sinus tachycardia (IST), is diagnosed when all possible causes have been excluded.

Frequent or Premature Atrial Contractions (PACs)

These are not classified as SVT. They generate from a single focus tachycardia but 1:1 P/QRS ratio with a single P wave morphology. When more than one focus triggers the arrhythmia, this is referred as multifocal atrial tachyarrhythmia (MAT). In this case, the heart rate is greater than 100 beats/min, and the EKG has at least three different P wave morphologies with variable PP, PR, and RR intervals (Fig. 3). MAT is seen in heart disease, pulmonary disease, hypokalemia, and hypomagnesemia. When patients have different P wave morphologies and heart rate is <100 beats/min, the condition is referred as wandering pacemaker. Therapy is mostly focused at reversing potential causes, and CCB and BB are used to slow heart rate.

Wolff-Parkinson White (WPW) Syndrome

It occurs when one or more accessory pathways exist bypassing the AVN, allowing the ventricles to activate earlier than normal and resulting in tachyarrhythmia. The ECG shows a short PR interval with a slurring of the initial part of the QRS, making it wider, which is known as "delta wave" and represents preexcitation (Fig. 3). Drugs with AV node suppression effect such as BB, CCB, digoxin, and adenosine are contraindicated. Propafenone, flecainide, sotalol, or amiodarone can be used, but most patients need EPS to identify the accessory pathways and undergo ablation.

Atrioventricular Arrhythmias

Atrioventricular block (AVB) results from an abnormal delay or interruption in the conduction of AP from the atria to the ventricles. This block can occur in the atria, at AVN, and the His-Purkinje fibers, and it can be intermittent, complete or incomplete, and uni-fascicular, bi-fascicular, or tri-fascicular depending on where the lesion is. The severity is described in degrees.

In 1st-degree AVB, the delay conduction is at the AVN, but each AP from the SA reaches the ventricles. The ECC shows a prolonged PR interval, >0.2 s (Fig. 3). Usually this block does not cause significant symptoms, and it does not require treatment. Drugs with nodal suppression effects such as digoxin, nondihydropyridine CCB, and beta blockers can be the culprit.

There are two types of 2nd-degree AVB, known as Mobitz I and II. Mobitz I occurs when the PR intervals progressively increase in length until a QRS is dropped. This phenomenon is also known as Wenckebach (Fig. 3). In Mobitz II, the PR interval remains constant, but not all APs from the SA are transmitted to the ventricles. Thus, the 1:1 P/QRS ratio is lost, and 2:1 or 3:1 conduction patterns appear. In patients with bi-fascicular block, a pacemaker is recommended.

In 3rd-degree AVB, there is complete blockage of conduction between the SA and AV nodes, and the atria and ventricles contract at different rates (Fig. 3). Depending on the ventricular response, the rate may be too slow to sustain appropriate circulation, and in some cases, it can lead to complete heart block. Most patients are symptomatic and require a permanent pacemaker.

Sick Sinus Syndrome (SSS) Also Known as Sinus Node Dysfunction (SND)

SSS describes a bradyarrhythmia caused by a sick SA node unable to be pacemaker, usually as a result of aging or heart disease. The SA node generates AP at a very slow rate leading to severe bradycardia, sinus pauses, and sometimes arrest. As the heart is unable to maintain adequate perfusion, patients experience lightheadedness, pre-syncope, syncope, dyspnea, and angina. Some patients develop brady-tachy syndrome with paroxysmal atrial tachycardia (most commonly AF) in response to the bradycardia. It is crucial to establish a correlation between the arrhythmia and symptoms to make the diagnosis of SSS, and a Holter or an event monitor is required. Treatment is focused at treating reversible causes, such as stopping drugs that suppressed the SA node, correcting electrolyte imbalances, and hypoxia. Drug therapy has not been successful, and most patients require the implantation of a pacemaker. Patients with asymptomatic bradycardia do not need treatment but need close follow-up.

Ventricular Arrhythmias (VAs)

VAs are caused by electrical activation of ventricular cardiac cells without atrial or nodal influences, most commonly triggered by reentry mechanism. Their characteristic ECG pattern shows wide QRS complexes (>120 ms), bizarre shape, no preceding P wave, and large T wave usually of opposite polarity to the QRS complex. They are serious arrhythmias associated with sudden cardiac death especially among patients with underlying cardiac disease and require cardiology referral. VAs are classified according to their frequency, persistence, and effect on ventricular contraction.

Premature Ventricular Contractions (PVCs)

PVCs (Fig. 4) are very common in the general population. Isolated events in patients with healthy hearts do not require treatment. First-line therapy for symptomatic patients is either a β blocker or nondihydropyridine CCB. Some patients may benefit from EPS and catheter ablation if specific foci are identified. PVCs also present in bigeminy, trigeminy, or quadrigeminy patterns when followed by 1, 2, or 3 normal beats, respectively (Fig. 4). Their clinical significance depends on their frequency, complexity, and hemodynamic response.

Ventricular Tachycardia (VT)

It is defined as more than 3 PVCs in a row and HR >100 beats/min. VT is further characterized by duration and morphology [39]. Non-sustained VT lasts for <30 s. Sustained VT lasts >30 s, is symptomatic, and causes hemodynamic instability. VT may have single morphology (single focus) or polymorphic (two or more foci). Polymorphic rhythms are seen in patients with structural and ischemic heart disease, and they are associated with worse prognosis. It is key not to confuse VT with SVT associated with BBB or aberrant conduction.

Sustained VT requires emergent cardioversion and eventual ICD placement. Unstable polymorphic rhythms require defibrillation. Antiarrhythmic drugs (procainamide, amiodarone, and less commonly, lidocaine) can be given to patients with monomorphic, stable, and sustained VT or when VT is refractory to cardioversion. Transvenous pacing may be necessary until a permanent ICD is placed. Patients with VT and ischemic heart disease benefit from β blockers, ACEI or ARB, and aggressive treatment of HF. Class I antiarrhythmic agents are contraindicated post

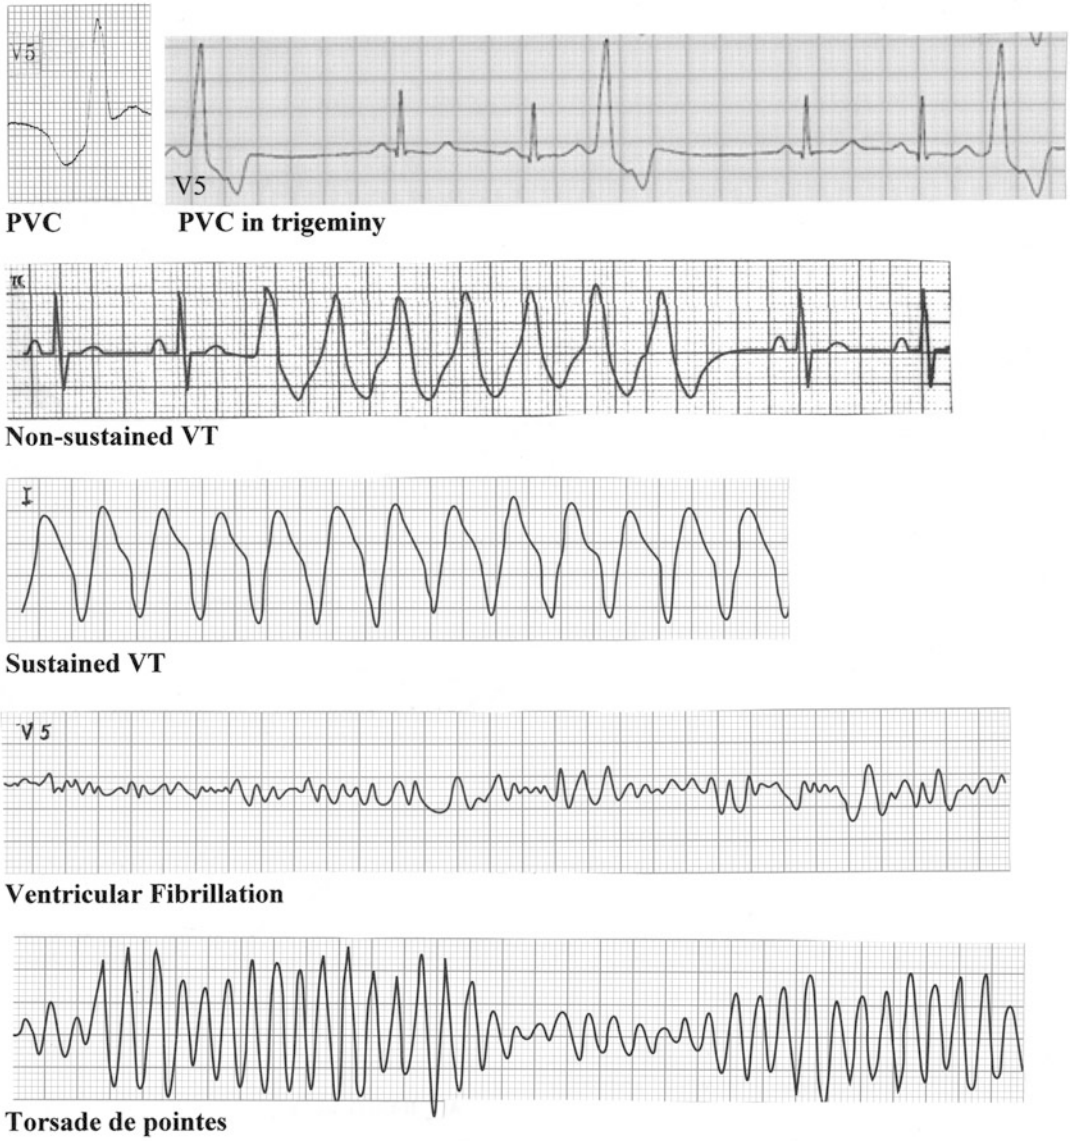

Fig. 4 Most common ventricular arrhythmias. For each arrhythmia, see discussion in corresponding section

MI and in HF. Patients with syncope should have EPS and ablation therapy if indicated.

Ventricular Fibrillation (VF)

This deadly arrhythmia is caused by the activation of multiple foci in the ventricles leading to loss of effective ventricular contraction. The EKG shows chaotic rapid polymorphic QRS complexes (Fig. 4). It requires immediate cardiopulmonary resuscitation and emergent defibrillation.

Torsades de Pointes

It is a rare form of VT characterized by repeated cycles of QRS complex changing in amplitude and twisting along the isoelectric axis, giving a unique pattern in the ECG (Fig. 4). It is associated

with a significant QT prolongation, >600 ms. Although torsades can self-terminate, it can also degenerate into VF. Treatment requires IV magnesium given under continuous cardiac monitoring (even when Mg is normal). Temporary transvenous pacing can be used, with atrial pacing preferred to maintain the atrial filling, except in patients with AVB where ventricular pacing is best. Long-term therapy includes β blockers (except in congenital torsades) and permanent pacing. In refractory cases, an ICD is necessary, and rarely, thoracic sympathectomy is done.

VF and torsades are associated with sudden cardiac death. Since most events occur outside the hospital, recognition by lay persons, activation of the emergency system, immediate CPR, and defibrillation when indicated are key to survival [40, 41]. This has been the reason to install automatic external defibrillators (AED) in public places.

In Summary

Arrhythmias are commonly seen by family physicians in the office. Immediate recognition of arrhythmias causing cardiovascular instability is key to improving patients' survival, sometimes requiring activation of the emergency system. Full evaluation, diagnosis, and treatment are warranted for all patients presenting with an arrhythmia or with suggestive symptoms, despite normal exams and/or EKGs. Reversible causes should be treated as well as comorbidities. Treatment option is tailored to the type of arrhythmia and must reflect a shared decision-making between patients and doctors, based on best available evidence and the patients' preferences.

Introduction

The challenge of valvular disease is in distinguishing the benign nonprogressive disorder from a concerning and potentially dangerous structural disease [1, 2]. The family physician is in a particularly challenging position because we will be addressing these potential concerns at every stage of life and often may be dealing with determining the significance of a new heart sound as an incidental finding. Valvular disease may lead to decreased functional status, permanent structural changes, and increased mortality [3, 4]. Timely diagnosis and appropriate testing and consultation are the goals of the family physician, in order to prevent the negative sequelae of inappropriately addressing valvular disease. Learning maneuvers and understanding the sounds present within the heart facilitate appropriate diagnosis [5].

The Third Heart Sound

The third heart sound S3 occurs after S2; it has a low frequency as such and may be the most difficult heart sound to hear. It has age-dependent indications. In patients under 30 years old, it can be physiologic and not associated with abnormal structure or function. It may be suspicious in patients 30–40 years of age. These patients may have conditions such as thyrotoxicosis, pregnancy, or anemia, which may produce the third heart sound without the presence of heart pathology. An S3 should be considered an indication of pathology in patients 40 or older. In this age group, the S3 often correlates with dysfunction or volume overload in the ventricles [4, 5]. Pathology that leads to the S3 includes ventricular overload such as high output state (pregnancy, thyrotoxicosis, and anemia), valvular regurgitations, or excessive fluid overload. Extensive periods of this diastolic overload may lead to permanent and irreversible ventricular dysfunction.

The Fourth Heart Sound

The fourth heart sound is of low frequency and occurs just prior to S1. The S4 is produced as a result of decreased compliance within the ventricles. As such, the presence of an S4 typically indicates hypertrophy of the ventricles due to pathology such as long-term hypertension, hypertrophic cardiomyopathy, or aortic stenosis. The fourth heart sound is most prominent at the apex and may also be palpable. Although there is some disagreement in whether or not S4 may be heard in the absence of disease, the presence of a clearly audible and palpable S4 has high correlation with pathology. On hearing an S4, reasons for the decreased compliance should be pursued and when possible mitigated or corrected [3–5].

Innocent and Physiologic Murmurs

Heart murmurs are the result of turbulent flow through the structures of the heart. The vast majority of murmurs heard in primary care in children and up to 40 % in adults are innocent or physiological murmurs, meaning no correlation with heart pathology. Innocent murmurs have no cardiac pathology, and physiologic murmurs result from the alteration of flow due to perturbations of physiology, examples being whether in a normal state such as pregnancy or abnormal such as thyrotoxicosis and anemia [3–5].

Characteristics

Murmurs are characterized by their timing in the heart cycle, their auditory volume as noted by their grade (Table 1), and their location and response to maneuvers. Innocent murmurs are always either systolic or continuous and never solely diastolic. Diastolic murmurs are always pathologic until proven otherwise and would likely need referral for further evaluation. Innocent murmurs are generally soft and never greater than grade 3, usually having no radiation [1, 2, 5].

Physical Maneuvers

Exam room maneuvers may alter the qualities of a murmur and may help to define and diagnose innocent versus pathological. Maneuvers that increase afterload are better for ruling out murmurs than ruling in. Methods of increased peripheral resistance, such as the patient gripping something hard, decreases outflow from the heart and thus decreases outflow, physiologic, and innocent murmur volumes [3, 5].

Decreased preload maneuvers decrease venous return to the heart, so murmurs affected by filling, including innocent and physiologic murmurs and outflow, mitral valve, and tricuspid valve murmurs, will all have a decrease in audible volume. Decreasing preload is done best by Valsalva maneuvers. A Valsalva maneuver is executed by asking the patient to take a deep breath, hold it, and bear down like performing a bowel movement [5].

Increased preload maneuvers increase venous return and filling of the heart. Squatting position is the easiest method to increase preload. Though maybe variable, most outflow murmurs increase in volume when a patient is squatting, and murmurs caused by hypertrophic cardiomyopathy or mitral valve prolapse decrease in volume [5].

Valvular Heart Disease

Prevalence

The overall incidence of heart murmurs would be impossible to determine as their presence due to innocent and physiologic etiologies can and does change over a patient's life span. Although most cases of valvular heart disease are chronic, many are often asymptomatic; the prevalence of structural changes due to actual valvular heart disease may be easier to delineate. Population-based studies using echocardiography have estimated the prevalence. One study which had well over 11,000 subjects each undergoing an echocardiograph determined a prevalence of about 2.5 %, and although there was no gender difference, this prevalence of disease increases with age >65. A prevalence of <2 % was noted before the age of 65 and an increase to 13.2 % after the age of 75 [1]. The overall etiology of acquired valvular heart disease has changed significantly in the last 50 years due to a sequela of antibiotics and the subsequent decrease in rheumatic fever-related valvular disorders [5, 6].

Table 1 Grade of murmurs

Grade	Characteristics of murmurs
1	Audible under optimal conditions by an expert
2	Easy to hear with stethoscope but soft
3	Moderately loud, no thrill
4	Very loud with a palpable thrill, with stethoscope on chest
5	Audible with stethoscope partly off chest with a thrill
6	Audible without a stethoscope with a thrill

Aortic Stenosis

Etiology

Aortic stenosis has congenital, rheumatic, and degenerative causes, all contributing to increased calcification of the aortic valve and its subsequent eventually problematic stenosis [4, 6]. The aortic valve that is congenitally bicuspid has a greater tendency to calcify and is more vulnerable to infective endocarditis. Rheumatic disease is in decline in developed countries due to the prevalence of antibiotic treatment, but rheumatic aortic stenosis when present is the result of cusp fusion and calcification many years after the episode of rheumatic fever. Degenerative or senile aortic stenosis is an increasingly problematic finding in the elderly. Risk factors for aortic stenosis are similar to those of coronary artery disease and atherosclerotic disease [1, 7].

Symptoms

Initially, aortic stenosis is asymptomatic, and as the stenosis slowly progresses, symptoms become more severe. Symptomatic individuals have

variable presentations with severe stenosis, which may demonstrate syncope, anginal symptoms, and/or heart failure. Patients with signs or symptoms of aortic stenosis need a transthoracic echocardiogram to evaluate the cause of the stenosis, any hemodynamic changes, and left ventricular size and function [4, 5, 8]. Symptomatic stenosis must be addressed, and with the onset of symptoms, the average survival drops to 3 years.

Physical Findings

Incidental asymptomatic murmurs found in elderly patients must differentiate the benign aortic sclerotic valve from the potentially asymptomatic and less common aortic stenosis [1]. Aortic stenosis may be indicated by the presence of a systolic ejection murmur best heard over the aortic area and radiating to one or both carotids. There may be an accompanying early diastolic murmur if there is a coexisting aortic regurgitation present [5].

Natural History and Complications

Degenerative aortic stenosis progresses slowly during its asymptomatic latent period. Once symptomatic morbidity and mortality increase significantly, there may be anginal symptoms even with clean coronaries, debilitating syncope, and progressive heart failure. A 2014 study of patients with severe aortic stenosis undergoing noncardiac surgeries found that they had increased major adverse cardiovascular events mainly due to heart failure, but no difference in postoperative 30-day mortality, but severe aortic stenosis in this study of postoperative patients was the strongest predictor of mortality at 1 year [3, 4, 9].

Medical Therapy

Medical therapy is based on the presence of concomitant coronary artery disease and/or left ventricular dysfunction. For patients with severe aortic stenosis and systolic failure, surgical valve replacement is recommended. However, if medical therapy is chosen, optimizing medical management of left ventricular dysfunction is managed with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) with beta-adrenergic blocking agents. There must be caution regarding rapid blood pressure decreases in patients with stenotic lesions [4].

Timing of Surgery

Once a patient with aortic stenosis becomes symptomatic, whether syncope, angina, or heart failure, the benefits of valve replacement surgery often greatly outweigh the risks. In a patient symptomatic with aortic stenosis, a cardiology consultation is recommended for discussion regarding possible surgical interventions versus transcatheter aortic valve replacement. Surgery may also be considered in asymptomatic patients with severe aortic stenosis and one of the following: a calcified aortic valve, an exercise test demonstrating decreased tolerance or a fall in blood pressure during the exercise, or undergoing another cardiac surgery [4].

Aortic Regurgitation

Acute aortic regurgitation is an early diastolic murmur that is the result of the blood flowing retrograde into the left ventricle and has been described as a blowing decrescendo at the left sternal border best heard when patient has held breath after exhalation and is leaning forward. Aortic regurgitation may present with tachycardia, cardiogenic shock, and pulmonary edema and is a surgical emergency. Acute aortic regurgitation derives from a rapid change in the aortic valve causing an acute abnormality, which may arise from etiologies including infective endocarditis or changes in the aorta such as aortic dissection. Acute aortic regurgitation is the result of life-threatening abnormalities, and early diagnosis with echocardiogram or CT imaging is crucial to facilitate rapid surgical intervention [3–5].

Chronic Aortic Regurgitation

Chronic aortic regurgitation is also a diastolic murmur, and as with all diastolic murmurs, a referral to a cardiologist should be considered for echocardiography and further recommendations [3–5].

Etiology

Aortic regurgitation has age-related etiologies. In patients younger than 50 years of age, the predominant etiologies include infectious endocarditis, Marfan's syndrome, syphilis, post-inflammatory changes, and rheumatic heart disease. For age >50 years, etiologies include bicuspid aortic valve and calcific valvular disease [4, 7].

Symptoms and Physical Findings

Symptoms associated with chronic aortic regurgitation include syncope, angina, and reduced exercise tolerance. As the disease progresses and left ventricular function begins to decrease, symptoms associated with systolic heart failure may arise including lower extremity edema and increasing dyspnea [1, 6, 8].

Aortic regurgitation is a diastolic murmur best heard at the left sternal border but may be associated with multiple other cardiac sounds and clinical signs. These signs may include the following:

An Austin Flint murmur characterized by the mid-diastolic murmur best heard at the apex.

The larger stroke volume may cause an aortic systolic flow murmur.

Traube's sign may present with a "pistol-shot" sound heard at the femoral pulse.

The patient's head may move up and down with the heartbeat; this is de Musset's sign.

Other findings, such as Muller's sign, which is cardiac pulsations noted at the uvula [4, 5].

Natural History and Complications

Chronic aortic regurgitation is a progressive abnormality in which the retrograde flow of blood through the aortic valve leads to increased volume and pressure in the left ventricle leading to long-term compensatory remodeling and eventually decreased ejection fraction, systolic dysfunction, and subsequent left ventricular dilation. Likelihood of a full recovery even with an aortic valve replacement may be decreased once the disease has progressed to severe left ventricular dilation. Therefore monitoring both symptoms and echocardiography are crucial in decision making with chronic aortic regurgitation. Echocardiography in asymptomatic patients may monitor the progression of disease, every 3–5 years in mild severity, every 1–2 years in moderate severity, and every 6–12 months in severe aortic regurgitation [4, 5] (Chapter 9, Valve Disease).

Medical Therapy and Timing of Surgery

The assessment and recommendations of a cardiologist will be helpful in determining the course of treatment for each patient with chronic aortic regurgitation and should be considered based on the patient's overall comorbidities. The most effective treatment for patients who can tolerate cardiac surgery is an aortic valve replacement. Aortic valve replacement should be considered for symptomatic patients with severe aortic regurgitation regardless of left systolic ventricular function, and patients with asymptomatic chronic severe aortic regurgitation and left systolic ventricular dysfunction, or if they have severe aortic regurgitation and are having to undergo another cardiac surgery. In symptomatic patients whose other comorbidities may preclude surgeries, ACE inhibitors/ARB and beta-adrenergic blocking medication have been associated with improved survival [4, 5, 8].

Mitral Valve Regurgitation

Acute mitral valve regurgitation is the result of acute changes in the mitral valve leading to sudden cardiovascular abnormalities secondary to acute left ventricular volume overload. Patients may become hemodynamically unstable and have pulmonary congestion and dangerously low cardiac output. This presents as an acutely decompensated, hypoxemic patient in cardiogenic shock. Rapid diagnosis and early interventions

may be lifesaving. Acute mitral regurgitation is typically the sequela of spontaneous rupture of papillary muscle secondary to an inferior myocardial infarction or from leaflet perforation or chordal rupture secondary to infectious endocarditis. The murmur in the acute decompensation may be short lived because of the decreased pressure gradient between the left atrium and left ventricle; therefore, in suspected acute mitral valve regurgitation, an echocardiogram evaluating the presence and severity of mitral regurgitation is essential. If the valve is poorly visualized on a transthoracic view, a transesophageal approach should be considered. Vasodilation medical therapy with a nitroprusside or nicardipine drip may be helpful in patients whose blood pressures are able to tolerate the lowering of the systolic aortic pressure. Surgical intervention in a timely manner is considered the definitive treatment for acute mitral valve regurgitation [4, 5].

Chronic Mitral Regurgitation

Etiology

Patients with chronic mitral regurgitation may have either primary or secondary chronic mitral regurgitation. Primary chronic mitral regurgitation is due to an abnormality in one or more components of the structure of the mitral valve itself. The leading cause of chronic mitral regurgitation is mitral valve prolapse with the recurrent prolapse weakening the chordae and making them more vulnerable to rupture. Connective tissue diseases and rheumatic fever are also less common contributors to the presence of primary chronic mitral regurgitation. In secondary chronic mitral regurgitation, the mitral valve is a structurally normal but functionally incompetent due to left ventricular dysfunction from severe dilation of the left ventricle. This dilation may be the result of progressive left systolic ventricular dysfunction secondary to coronary artery disease or less common, idiopathic myocardial disease [5, 7, 8, 10].

Symptoms and Physical Findings

Chronic mitral regurgitation can present in its severe stages with symptoms of decreased exercise tolerance and exertional dyspnea. In later stages, all of the hallmarks of the heart in systolic failure may be present. Physical signs include a pansystolic murmur heard best at the apex and may radiate to the axilla, a systolic thrill at the apex, a very prominent apex beat, a left parasternal heave, and a high-pitched S3 [5].

Natural History and Complications

Chronic mitral valve regurgitation has increased preload and decreased afterload in the left ventricle because of the regurgitant valve allowing some of the stroke volume back into the left atrium. Initially the dilation of the left ventricle and left atrium provides a compensatory remodeling. This compensation may facilitate asymptomatic function for years. The progressive changes due to this persistent volume overload eventually lead to clinically significant left ventricular dysfunction. Monitoring symptoms and echocardiograms are the cornerstone of evaluation for both primary and secondary chronic mitral valve regurgitation. Echocardiograms in asymptomatic patients may monitor the progression of disease, every 3–5 years in mild severity, every 1–2 years in moderate severity, and every 6–12 months in severe aortic regurgitation [4, 5, 8, 11].

Medical Therapy and Timing of Surgery

Chronic mitral regurgitation has no medical management recommendations other than continuing those associated with the coronary artery disease and/or heart failure in that may be present. There are different recommendations for surgical interventions based on the etiology and level of symptoms. As primary chronic mitral regurgitation progresses and the left ventricular ejection fraction decreases, patients may benefit from surgery when they are symptomatic from these changes or they are undergoing another cardiac surgery. Due to the overall structural

changes of the heart, the evidence for beneficial outcomes with surgery for asymptomatic secondary chronic mitral regurgitation is less robust. Therefore, in secondary chronic mitral regurgitation, surgery is reserved for symptomatic severe regurgitation [4, 11].

Mitral Valve Prolapse

Etiology

Mitral valve prolapse is the backward movement of one or both of the leaflets of the mitral valve. It is the most prevalent single valvular abnormality, affecting 2–3 % of the general population, and as such mitral valve prolapse is also the leading cause of mild mitral regurgitation [5, 7, 12].

Symptoms

Mitral valve prolapse itself does not increase mortality, and most cases are asymptomatic except some patients may note palpitations. If palpitations are present, a Holter/event monitor may be indicated to further evaluate. Mitral valve prolapse can however lead to mitral regurgitation, and although most mitral regurgitation from mitral prolapse is mild to trace, in some patients, the sequela associated with chronic mitral regurgitation may be significant, leading to decreased exercise tolerance and exertional dyspnea [4, 5].

Physical Findings

The presence of a mid-systolic click associated with a late systolic murmur, which may be high pitched and heard greatest at the apex, may shift with standing and squatting moving closer to the first heart sound and closer to the second heart sound, respectively. As mitral valve prolapse may be associated with mitral regurgitation, an echocardiogram is reasonable to evaluate the presence of this murmur [5].

Natural History, Complications, Medical Therapy, and Timing of Surgery

For mitral prolapse, the most important prognostic indicator is the presence and severity of mitral regurgitation. The development of atrial fibrillation or heart failure as a result of these valvular anomalies is an indication to consider specialty consultation and possibly surgery [4].

Mitral Stenosis

Etiology

The prevalence of mitral stenosis is highly associated with the prevalence of rheumatic fever; as such it is uncommon in developed countries and more common in the developing world. In developed countries, the etiology is mostly degenerative and can be associated with calcium encroachment, e.g., secondary to dialysis [4, 13].

Symptoms

Decreased exercise tolerance, shortness of breath, and exertional dyspnea are the most common presentation of mitral valve stenosis. The symptoms are the result of reduced flow through the valve and as such tend to increase as the mitral valve area decreases. Symptomatic patients with mitral stenosis should be considered for referral to discuss definitive treatment and possible surgical interventions [4, 5, 13].

Physical Findings

Physical findings of mitral stenosis are noted most during the presence of increased physical stress such as in times of exercise, infection, and rapid ventricular response. These physical findings may include a loud first heart sound, an opening snap, and a late diastolic murmur [5].

Table 2 Antibiotics for infective endocarditis prophylaxis for dental procedures

Antibiotic		
Single dose 30–60 min prior to procedure	Adults	Children
Amoxicillin	2 g	50 mg/kg
Cephalexin or clindamycin if penicillin allergy is present	2 g	50 mg/kg
	600 mg	20 mg/kg

Duval and Hoen [15]

Natural History and Complications

Mitral stenosis is generally slow to progress from asymptomatic to severe; in developed countries, rheumatic fever-associated mitral stenosis may lag 20–40 years after the presence of rheumatic disease and may take up to 10 years before the symptoms become disabling. Thus asymptomatic patients can be monitored by echocardiograms. The frequency of echocardiograms is every 3–5 years when the mitral valve area is >1.5 cm squared; then, in severe mitral stenosis, it is every 1–2 years when the mitral valve area is 1.0–1.5 cm squared; then it is once a year when the mitral valve area is <1.0 cm squared [4].

Medical Therapy and Timing of Surgery

Although medical therapies mostly consist of infective endocarditis prophylaxis and some patients may benefit from beta-blockade to decrease exertional symptoms, treatments other than surgical, whether valve replacement or PBV, have not been shown to be as effective [13] (Tables 2 and 3).

Hypertrophic Cardiomyopathy

Etiology

Fifty percent of cases of hypertrophic cardiomyopathy are familial; it is defined as hypertrophic changes that cannot be attributed to pressure changes or volume overload. This is a monogenic disease from a mutation in genes encoding components at the cellular level in the cardiac sarcomere. Global incidence is seen in 1 in 500 of the general population. Annual estimated mortality in patients with hypertrophic cardiomyopathy is 1 %. As hypertrophic cardiomyopathy is known to be an autosomal dominant genetic disorder, screening with noninvasive imaging of first-degree family members of known patients has increased our ability to assess individuals at risk for this condition [16].

Symptoms

Patients with hypertrophic cardiomyopathy may be asymptomatic their entire lifetime, or a subset of patients may present without any antecedent symptoms with a sudden death. Some patients may present with chest pains due to microvascular ischemia secondary to supply-demand mismatch from the hypertrophic myocardium. Both atrial fibrillation and progressive heart failure may result from the structural changes associated with hypertrophic cardiomyopathy [16].

Physical Findings

Although identifying patients at risk for sudden death is crucial, individuals with hypertrophic cardiomyopathy may not have identifiable physical findings, and findings when present may not be highly specific for the disease. The precordial examination may note a significant apical impulse, S3 and/or S4 may be present, and

murmurs may include a systolic ejection murmur in the aortic region that is increased when standing and decreased when squatting [5]. As a patient progresses in heart failure, the physical findings may be more easily identified but again not highly specific for hypertrophic cardiomyopathy unless noted by imaging. Although ECG with suggestive voltage criteria may indicate the presence of LVH due to hypertrophic cardiomyopathy, echocardiography and cardiac magnetic resonance imaging are the cornerstone of diagnosis. The presence of left ventricular dysfunction and the absence of other identifiable causes, especially in the presence of a contributory family history, are diagnostic for hypertrophic cardiomyopathy [16].

Natural History and Complications

Sudden cardiac death is the most devastating and unpredictable complication of hypertrophic cardiomyopathy. The presence of family history of hypertrophic cardiomyopathy-associated sudden death is the greatest predictor of risk; hypotensive blood pressure in response to exercise, unexplained syncope, episodes of ventricular tachycardia, and left ventricular hypertrophy $\geq$30 mm thickness are all considered risks for sudden cardiac death in the setting of hypertrophic cardiomyopathy. As mentioned, many individuals with hypertrophic cardiomyopathy may spend their entire lives asymptomatic. Those that have symptoms, such as heart failure or atrial fibrillation, may progress through all the stages and sequela of these conditions [16].

Medical Therapy and Timing of Surgery

A patient with concerns of hypertrophic cardiomyopathy may benefit from a cardiology consultation. Recommendations on screening of first-degree relatives and recommendations of lifestyle changes may be discussed in addition to medical management. Lifestyle adjustments are aimed at reducing the risks of sudden cardiac death and thus avoiding conditions that may impair or further exacerbate cardiac outflow. It is generally recommended that patients with hypertrophic cardiomyopathy should not participate in high-intensity physical activity. Beta-blockers or the non-dihydropyridine calcium channel blockers, verapamil and diltiazem, are the most studied and the mainstays of medical treatment for hypertrophic cardiomyopathy. Medical management of atrial fibrillation due to hypertrophic cardiomyopathy is rate control and anticoagulation, and heart failure as a sequela is also managed in a manner consistent with left ventricular failure due to other etiologies. When patients continue to have significant symptomatic outflow obstruction in the presence of optimal medical management, surgical considerations may be discussed with a specialist [16].

Murmurs During Infancy

The most common congenital anomalies are the cardiac anomalies. They occur in 0.8–1 % per 1,000 of live births and are a leading cause of death among the congenital anomalies. Early detection of pathologic heart anomalies is critical to reduce morbidity and mortality from these congenital disorders. Signs of innocent murmurs versus pathological murmurs include a murmur present only in systole, a murmur that changes with both body position and respiratory cycle, and a small area of murmur without radiations. Due to heart rate, respiratory cycle, and inability of the patient to respond to verbal instructions, in neonates, this level of auscultation may be challenging. If a murmur is consistently present and/or accompanies other signs of cyanotic structural defect, the patient should undergo echocardiography and if indicated a pediatric cardiology referral [17].

Murmurs During Pregnancy

The hemodynamic changes that are naturally occurring in pregnancy are generally well tolerated in healthy women. The cardiac output can rise from 30 % to 50 % due to changes increasing both heart rate and stroke volume. Blood volume

begins rising in the first trimester and averages 50 % more than in the nongravid state. Preconception management that assesses the lesion and addresses any recommended treatment prior to pregnancy is preferred. Even women who were previously asymptomatic may develop problems with the cardiovascular changes associated with pregnancy. Conditions that help predict risk are the location and severity of disease, the prepregnancy functional capacity, the left ventricular function, and the presence or absence of pulmonary hypertension. Stenotic lesions of the aortic or mitral valves are at the greatest risk with pregnancy-related complications. Women who present already pregnant with suspected or confirmed valvular heart disease must be evaluated as soon as possible. Transthoracic echocardiography and patient history are the principal method of gathering data and risk stratifying these patients. Low-risk conditions can be comanaged with a cardiologist; however, valvular disease with medium to high risk needs to be managed in high-risk centers with high-risk maternal fetal specialists and a specialized cardiologist [18].

Murmurs in the Athlete

The cardiovascular portion of pre-participation exam is meant to screen for the presence of lesions that may lead to sudden death. In addition to family and personal history questions regarding sudden death, exercise-induced chest pain, palpitations, dizziness, dyspnea on exertion, and syncope, the presence of abnormal auscultation is a critical portion of this exam. The presence of any of these red flags indicates a need for activity restriction, additional testing, and likely referral. In addition to auscultating a murmur in an athlete, the patient and family history and composition of the murmur help distinguish between a benign and pathological murmur. A diastolic murmur is pathologic until proven otherwise. Other pathologic signs include changes in intensity when doing physiologic maneuvers, e.g., louder with Valsalva or squat-to-stand maneuvers, loud grade three or more, holosystolic, having family history of sudden death, radiations to carotids or the axilla, and historical red flags accompanying the murmur (exertion chest pain, dyspnea on exertion, and syncope). Benign murmurs may be indicated by the absence of associated symptoms and no significant family history in addition to crescendo-decrescendo, softer sounding grade one or two, normal blood pressure, normal pulses, no significant radiation, without thrill, and early to mid-systolic in timing and no other nonphysiologic heart sounds. Red flags in either examination or history may warrant removal from play until further specialist work-up is completed and recommendations made [2].

Heart Failure

Michael R. King

Contents

Definition

Heart failure (HF) is a clinical syndrome caused by myocardial dysfunction or death. Structurally this could result from left ventricle dilation, hypertrophy, or both. Physiologically, systolic or diastolic dysfunction can cause reduced ventricular filling or ejection of blood, and to compensate, activation of the sympathetic nervous system and renin-angiotensin-aldosterone systems occurs. These neurohormonal changes increase blood pressure and blood volume, further enhancing venous return (preload), stoke volume, and cardiac output to compensate for the cardiac dysfunction. These changes also cause HF symptoms of fluid retention, dyspnea on exertion, and fatigue. Without appropriate therapies and interventions, HF can progressively worsen [1].

Epidemiology

In 2006 there were an estimated 5.1 million people with symptomatic HF in the United States and up to 23 million worldwide. Americans over 40 years old have a 20 % lifetime risk of developing HF [1]. Because of the difficulties of defining and diagnosing HF, true prevalence estimates remain uncertain. HF does increase with age and thus is increasing in the population overall and has continued to increase in hospitalized patients. The overall prognosis of HF is poor with a 50 % mortality rate within 5 years of symptom onset.

MI Myocardial Infarction, *LVEF* Left Ventricular Ejection Fraction

Appropriate management of HF can significantly stabilize the disease with improvement in symptoms, cardiac function, and survival [1].

Causes

Cardiac ischemia or coronary artery disease (CAD) is the most common cause of HF compromising 60–70 % of systolic HF. Heart failure is increasing in older populations because of improved survivorship from treatments of CAD and other common causes of HF including hypertension, diabetes, and valvular disease. Many other cardiac conditions can eventually cause HF: arrhythmias (atrial fibrillation/flutter, heart block), cardiomyopathies (idiopathic, hypertrophic, restrictive, postpartum), and pericarditis. Noncardiac causes should be considered as well and are discussed in the evaluation section [2].

Classification and Staging

The New York Heart Association's (NYHA) classifications are symptom based and are an established predictor of mortality in HF. Class I defines asymptomatic individuals, and Classes II, III, and IV define patients with HF symptoms with mild exertion, moderate exertion, or at rest, respectively (see Table 1). These classes are a reasonable measure of functional capacity, and a patient's class can change as their symptoms improve or worsen. In 2001, the American College of Cardiology (ACC) and the American Heart Association (AHA) created HF stages that emphasized the progression from patients at risk, Stage A; to those with structural heart disease, Stage B; to symptomatic HF with reduced ejection fraction (HFrEF), Stages C and D. Studies have shown that asymptomatic patients with reduced LVEF (Stage B) are as equally represented as symptomatic HFrEF. Table 1 demonstrates the overlap of the NYHA Classes and ACC/AHA stages [1].

Measurement of left ventricular ejection fraction (LVEF), or systolic function, is important for assessing HF and predicting mortality. Symptomatic HF with an EF <40 % defines HF with reduced ejection fraction (HFrEF), or systolic heart failure (SHF), versus an EF of >50 % that defines symptomatic HF with preserved ejection fraction (HFpEF) or diastolic heart failure (DHF) [1]. Among symptomatic patients, both are common with one study reporting 34 % had HFpEF and 66 % had HFrEF [3]. The distinction is important given that HFrEF have effective

evidence-based therapies that improve morbidity and mortality, while HFpEF do not. An ejection fraction (EF) of <45 % is a powerful predictor of mortality with an added increased risk of death with every further 10 % reduction <45 % [4].

Evaluating and Diagnosing Heart Failure

Despite being widely studied, HF remains a clinical diagnosis with no specific symptom, sign, or test clearly establishing or ruling out a diagnosis with certainty. Even more challenging is that both HFrEF and HFpEF can clinically present the same. A thorough history and examination is necessary to assess and confirm HF, investigate for other causes, and identify comorbidities. Table 2 stratifies components of an evaluation that are more beneficial and effective in diagnosing or ruling out HF compared to others with no predictive benefit.

History and Physical Exam

Dyspnea on exertion is a common symptom in HF (sensitivity 97 %) but given that it represents only 30 % of the causes of dyspnea in outpatient settings, it is not specific [5]. Orthopnea, paroxysmal nocturnal dyspnea, and edema are more helpful symptoms, having a small benefit in diagnosing

Table 3 Laboratory evaluation for heart failure and selected alternate causes

Initial labs	Causes or alternate diagnosis
BNP or NTproBNP	Heart failure
Complete blood counts	Infection, anemia
Hemoglobin A1C	Diabetes
Lipid profile	Hyperlipidemia, cardiovascular risk
Liver function (transaminases)	Hepatic congestion, liver disease, alcoholism, drug toxicity
Renal function (blood urea nitrogen, creatinine)	Renal disease, volume overload
Serum electrolytes (sodium, potassium, calcium, magnesium)	Diuretic therapies, arrhythmias
Thyroid stimulating hormone	Hyper/hypothyroid disease
Urinalysis (proteinuria, hematuria, casts)	Renal disease, nephrotic syndrome, glomerulonephritis

Other labs	Causes or alternate diagnosis
Arterial blood gases	Hypoxia or pulmonary disease
Blood cultures	Bacterial endocarditis, systemic infection
Erythrocyte sedimentation rate, C-reactive protein	Infection, rheumatologic diseases
Human immunodeficiency virus	Cardiomyopathy
Ferritin, iron levels, transferrin saturation	Hemochromatosis, macrocytic anemia
Lyme serology	Bradycardia/heart block
Thiamine	Deficiency, beriberi, alcoholism
Troponins, creatine kinase-MB	Myocardial infarction or myocardial injury
Urine or serum drug screens	Illegal drug use, cocaine

BNP B-type natriuretic peptide, *NTproBNP* N-terminal pro-B-type natriuretic peptide

HF (see Table 2) [5, 6]. Although not predictive, reduced exercise capacity, nocturnal cough, and peripheral or abdominal swelling are suggestive of HF. Early satiety, nausea, vomiting, abdominal discomfort, wheezing, cough, fatigue, generalized weakness, and confusion can also be suggestive of HF but are often found in other diagnosis [7].

A careful physical examination can assess the degree of hypervolemia, ventricular enlargement, and reduced cardiac output with HF. A third heart sound (S3 or ventricular gallop) is the most specific and conclusive finding for elevated left ventricular systolic pressures and decreased LVEF (specificity of 99 %). A displaced cardiac apex is also a conclusive finding in the diagnosis of HFrEF. Similar findings that are moderately beneficial in diagnosing include increased jugular venous distention and a hepatojugular reflex (see Table 2) [5, 6]. Other physical exam findings can help assess alternate causes of HF. Cardiac murmurs suggest primary valvular disease. Irregular heart rate or pulses can suggest arrhythmias or atrial fibrillation. Thyromegaly or goiter can indicate thyroid disease. Hepatomegaly can suggest cirrhosis and portal hypertension that can cause volume overload. Other findings can help to assess other differential diagnosis. On pulmonary exam, rhonchi or wheezing can suggest COPD, asthma, or pneumonia, and dullness to percussion can also suggest pneumonia or a pleural effusion [2, 8].

Laboratory and Imaging

An initial laboratory assessment can be useful to evaluate for other differential diagnosis and exclude other causes of HF (see Table 3). Further laboratory assessment should be considered based on suspicion of other causes or if findings suggest further investigation.

B-Type Natriuretic Peptide

B-type natriuretic peptide (BNP) is a cardiac neurohormone that is secreted from the ventricles in response to stretching and increased wall tension from volume and pressure overload. Both BNP and N-terminal pro-B-type natriuretic peptide (NTproBNP), an inactive cleaved fragment of proBNP, are useful in the diagnosis of HF in patients presenting with dyspnea. Although no BNP threshold indicates the presence or absence of HF with certainty, multiple systematic reviews

Table 4 BNP and NTproBNP values and outcomes

Outcome	BNP, pg/ml	NTproBNP, pg/ml
Exclude heart failure	<100	<300
Diagnose heart failure	>400	>450, age <50
		>900, age 50–75
		>1,800, age >75
In acute heart failure:	>200	>5,180
Increased 60–90 day cardiovascular events and mortality		
Outpatient heart failure goals:	<100	<1,700
Reduced exacerbations, hospitalization, and mortality

BNP brain natriuretic peptide, *NTproBNP* N-terminal pro-B-type natriuretic peptide

have shown normal or low levels of BNP or NTproBNP (see Table 4) which can effectively rule out a HF diagnosis (negative likelihood ratio 0.10 and 0.14). Higher values of both have reasonably high positive predictive value of a HF diagnosis, and as the value rises the specificity rises [9–11].

When evaluating HF, providers should be aware that BNP and NTproBNP elevations can be associated with many cardiac (acute coronary syndrome, valvular heart disease, atrial fibrillation, and pericardial disease) and noncardiac causes (older age, anemia, renal failure, pulmonary disease, and sepsis) [1]. Overall, BNP levels do appear to have better reliability than NTproBNP, especially in older populations [12, 13].

The level of BNP and NTproBNP can be useful in establishing the prognosis and severity of HF in acute and outpatient settings [1]. In acute HF, an elevated BNP or NTproBNP (see Table 4) can be a strong predictor of 90-day cardiovascular events and mortality [9, 11, 12]. During a hospitalization, a 30–50 % reduction in patient BNP levels at hospital discharge compared to admission has been shown to lead to improved survival and reduced rehospitalization [12]. Levels of BNP and NTproBNP can improve or lower with appropriate outpatient treatment of chronic HF and appear to correlate with improved clinical outcomes. These observations have led to studies of BNP- or NTproBNP-guided therapies that have shown some inconsistent results. Further meta-analyses reviews, however, have concluded that BNP- or NTproBNP-guided therapy reduces all-cause mortality in acute and chronic HF compared to usual care [11]. Specifically, optimizing management for specific outpatient targets of BNP or NTproBNP (see Table 4) has resulted in improvements in HF decompensations, hospitalizations, and mortality [9, 12].

Electrocardiogram

An electrocardiography (ECG) is a useful initial test to evaluate the heart for structural or physiological abnormalities. The presence of atrial fibrillation, new T-wave changes, or any abnormality has a small benefit in effectively diagnosing HF [14]. A normal ECG or one with only minor abnormalities has a small benefit in effectively ruling out HFrEF or systolic HF (see Table 2) [14]. An ECG is most useful in evaluating other possible causes of HF or reasons for a worsened clinical status. Signs of previous MI or ischemia, left ventricle hypertrophy, left bundle branch block (LBBB), or atrial fibrillation can all be present and assist in guiding further treatment options. A LBBB in the presence of HF is a very poor prognostic sign with increased 1-year mortality overall and from sudden cardiac death [15]. A QRS interval of >0.12 and a LBBB pattern in a HF patient would be a consideration to refer to a cardiologist or electrophysiologist to evaluate for an implantable device.

Chest Radiograph

Patients with suspected HF or acute decompensation should receive a chest radiograph to assess pulmonary congestion, possible cardiomegaly, or alternate cardiac or pulmonary causes of symptoms [1]. The presence of interstitial edema and venous congestion is more beneficial in effectively diagnosing HF with specificities of 96 % and 97 %, respectively. Other findings such as cardiomegaly and a pleural effusion only have a small benefit in diagnosing HF. The absence of

cardiomegaly and venous congestion only slightly decreases the likelihood of HF (see Table 2) [5]. Other potential causes of dyspnea symptoms that can be identified by chest radiograph include pneumonia, COPD, pneumothorax, or a pulmonary mass.

Cardiac Imaging

Echocardiogram (ECHO) remains the method of choice for evaluating suspected HF given its accuracy, availability, safety, and cost. With Doppler imaging, it can provide important information about cardiac anatomy and function including LVEF, wall motion, valvular function, right ventricular function, pulmonary artery pressures, and the pericardium. ECHO is the usual standard for assessing LVEF and differentiating HFrEF (systolic failure) versus HFpEF (diastolic failure). There is no single ECHO parameter sufficiently accurate and reproducible to diagnose left ventricular diastolic dysfunction. Given the lack of consensus, the diagnosis of diastolic dysfunction should result from multiple findings by ECHO [7].

Evaluation for ischemic heart disease in HF with stress echocardiography or nuclear stress imaging is warranted when angina is present given that CAD is the most common cause of HF.

If evidence of ischemia exists, a cardiology referral may be appropriate to consider further evaluation and treatment. Coronary angiography remains an important consideration in patients with angina, those suitable for coronary revascularization, or those with evident reversible myocardial ischemia. In instances of acute HF with pulmonary edema or shock, coronary angiography may be required urgently if acute coronary syndrome is suspected. Cardiac MRI, although not readily available, provides most of the anatomical and functional assessment of ECHO but also can evaluate ischemia and identify inflammatory or infiltrative causes of HF without radiation exposure [2].

Treatment of Heart Failure

Treatment options for HFrEF, ACC/AHA Stages C and D, have been well researched and analyzed compared to HFpEF, and there is reasonable consensus about treatment among expert societies' guidelines.

Heart Failure with Reduced Ejection Fraction

The goals of treatment in HFrEF are to improve symptoms and quality of life, slow the progression or reverse cardiac dysfunction, and improve long-term morbidity and mortality [7]. The standard therapy for HFrEF accomplishes these goals with loop diuretics for fluid and symptom control as well as angiotensin-converting enzyme inhibitor (ACEI), or an angiotensin receptor blocker (ARB) if ACEI intolerant, and beta-blocker therapy to improve morbidity and mortality. Further treatment options should be added based on the appropriate evidence and indications to control symptoms or enhance long-term survival (see Table 5). Appropriate starting doses of drug therapies and evidence-based targets are listed in Table 6.

Diuretics

Loop diuretic therapy is necessary in both HFrEF and HFpEF for managing symptoms and maintaining fluid control. They act to increase sodium excretion by 20–25 % and thus enhance free water clearance and reverse the volume expansion of HF that occurs from renotubular sodium retention after activation of the renin-angiotensin-aldosterone system. Loop diuretics can improve symptoms of pulmonary and peripheral edema within hours but are not sufficient for long-term clinical stability without other indicated therapies. They also have not been proven to have a long-term mortality benefit [1]. The goal of loop diuretic therapy is to manage fluid retention and achieve and maintain a euvolemic state. The appropriate dose titration is achieved once a patient actively diuresis >500–1,000 mL/h. If the effect is not achieved, the dose should be increased or doubled to effectiveness. Furosemide (Lasix) is the most commonly used loop diuretic, but furosemide (Demadex) or bumetanide (Bumex) may be an option if a longer duration of action and more predictable absorptions are

Table 5 Evidence-based therapies and benefits for heart failure with reduced ejection fraction

Recommendation	Evidence-based therapies	Benefits of therapy
Beneficial, effective, recommended	Loop diuretics[c] – titrate to appropriate diuretic response for fluid control and symptom relief (dyspnea, edema)	Relieve signs and symptoms of congestion/volume overload
	Standard therapy for all HF patients, LVEF≤40	
	ACEI[a] – initiate low dose, titrate target doses ARB[a] – if ACEI intolerant, initiate low dose, titrate to target doses	Reduces morbidity (31 % RRR in hospitalizations) and mortality (17 % RRR, NNT* 26)
	β-Blockers[a] – initiate early with low-dose ACEI and titrate to target for dose-dependent benefit	Reduces morbidity (41 % RRR in hospitalizations) and mortality (34 % RRR, NNT* 9)
	In selected patients, on standard therapy	
	Aldosterone antagonists[a] – in NYHA II–IV, LVEF≤35, with persist symptoms	Reduces morbidity (35 % RRR in hospitalizations) and mortality (30 % RRR, NNT* 6)
	Hydralazine and isorbide dinitrate[a] – in African-American, NYHA III–IV, with persistent symptoms	Reduces morbidity (33 % RRR in hospitalizations) and mortality (43 % RRR, NNT* 7)
	ICD[a] – in LVEF≤35, >1 year life expectancy	Reduction in sudden cardiac death
	CRT[a] – in LVEF≤35, sinus rhythm, LBBB, QRS >150 ms, NYHA II[b] or III–IV	Reduces morbidity and mortality
Reasonably beneficial, probably recommended	**In selected patients**	
	Dietary sodium restriction[c]	Reduces symptoms
	ARB[a] – first line, in post-MI, instead of ACEI	Reduces morbidity and mortality
	Hydralazine and nitrates [b] – ACE/ARB intolerance	Reduces morbidity and mortality
	Digitalis[b] – only if persistent symptoms	Reduces symptoms and hospitalizations
	CPAP[b] – heart failure and sleep apnea	Increases LVEF and improves function
	Cardiac rehabilitation[b]	Improves function, quality of life, and mortality
	Omega-3 polyunsaturated fatty acid (PUFA)[b]	Reduces mortality and hospitalizations

[c]Level of evidence C (expert opinion, case studies, standard of care)

needed. Initial, maximum, and equipotent oral and intravenous (IV) dose equivalents are listed in Table 6. The frequency of dosing (daily or multiple times a day) should be guided by the need for more frequent diuresis to maintain an appropriate fluid volume and body weight. Being too aggressive can lead to overdiuresis and adverse renal effects.

Angiotensin-Converting Enzyme Inhibitor

ACEI therapy is indicated for all NYHA classes and ACC/AHA stages of HF. In HFrEF, ACEIs improve symptom control, mortality, and reduce hospitalizations as proven in multiple randomized controlled trials, meta-analysis reviews, and long-term studies. The benefit of ACEI therapy appears

Table 6 Medications in heart failure with reduced ejection fraction

Drugs for mortality and morbidity benefit	Initial doses	Target doses
Angiotensin-converting enzyme inhibitors		
Captopril (Capoten)	6.25 mg TID	50 mg TID
Enalapril (Vasotec)	2.5 mg BID	10–20 mg BID
Fosinopril (Monopril)	5–10 mg daily	40 mg daily
Lisinopril (Zestril, Prinivil)	2.5–5 mg daily	20–40 mg daily
Perindopril (Aceon)	2 mg daily	8–16 mg daily
Quinapril (Accupril)	5 mg BID	20 mg BID
Ramipril (Altace)	1.25–2.5 mg daily	10 mg daily
Trandolapril (Mavik)	1 mg daily	4 mg daily
Angiotensin receptor blockers		
Candesartan (Atacand)	4–8 mg daily	32 mg daily
Losartan (Cozaar)	25–50 mg daily	50–100 mg daily
Valsartan (Diovan)	20–40 mg BID	160 mg BID
β-Blockers		
Bisoprolol (Zebeta)	1.25 mg daily	10 mg daily
Carvedilol (Coreg)	3.125 mg BID	50 mg BID
Carvedilol CR (Coreg CR)	10 mg daily	80 mg daily
Metoprolol succinate CR/XL (Toprol XL)	12.5–25 mg daily	200 mg daily
Aldosterone antagonists		
Eplerenone (Inspra)	25 mg daily	50 mg daily
Spironolactone (Aldactone)	12.5–25 mg daily	25 mg daily or BID
Vasodilators: hydralazine and isosorbide dinitrate		
Fixed dose hydralazine and isosorbide dinitrate (BiDil)	37.5 mg/20 mg TID	75 mg/40 mg TID
Hydralazine and isosorbide dinitrate (Apresoline and Isordil)	25–50 mg and 20–30 mg TID or QID	300 mg and 120 mg daily in divided doses

Drugs for symptom control		Initial doses	Maximum doses
Loop diuretics	**Drug/dose equivalents**		
Bumetanide (Bumex)	1 mg PO/1 mg IV	0.5–1.0 mg/dose	10 mg/day
Furosemide (Lasix)	40 mg PO/80 mg IV	20–40 mg/dose	600 mg/day
Torsemide (Demadex)	20 mg PO/20 mg IV	5–10 mg/dose	200 mg/day
Thiazide diuretics (combination with loops)			
Hydrochlorothiazide (HydroDiuril)		25 mg daily	100 mg daily
Metolazone (Zaroxolyn)		2.5 mg daily	10 mg daily
Inotrope			
Digoxin (Lanoxin)		0.125 mg daily	0.125–0.375 mg daily

IV intravenous, *PO* oral, *BID* twice daily, *TID* three times daily, *QID* four times daily

to be a class effect with all ACEIs being equally effective in improving HF outcomes by inhibiting the renin-angiotensin-aldosterone system that is activated in HF. Guidelines recommend titrating to achieve a target dose (see Table 6) based on the clinical research but lower doses appear to have mortality benefits [1].

Beta-Blockers

Beta-blockers are a standard therapy indicated as an initial treatment for all patients with current or prior symptoms of HFrEF (NYHA Classes II–IV, LVEF <40), unless contraindicated, to reduce morbidity and mortality. Carvedilol (Coreg), metoprolol succinate (Toprol XL), and bisoprolol (Zebeta) are recommended and have proven mortality benefits over other beta-blockers likely due to how they inhibit the sympathetic nervous system which is activated in HF.

Even among these three proven beta-blockers, there are some differences. The COMET trial showed carvedilol (Coreg), an apha-1, beta-1, and beta-2 receptor inhibitor, reduced HF mortality by 40 % compared to 34 % by twice daily, immediate-release metoprolol tartrate (Lopressor), a beta-1 selective inhibitor [16]. Carvedilol (Coreg) proved an obvious benefit; however, this study did not use the previously studied once-daily sustained release metoprolol succinate (Toprol XL), a more reasonable comparison. Importantly, the study did prove a survival benefit, albeit lower, with metoprolol tartrate (Lopressor).

Beta-blockers benefit mortality and disease progression in addition to ACEI therapy and are recommended early after the diagnosis of HFrHF with initiation at low doses along with low-dose ACEI and appropriate titration (see Table 6). The dose should be doubled every 2–3 weeks until target doses and heart rate reductions in proven clinical trials are achieved given the dose-dependent survival and outcome improvement [1]. A meta-analysis review showed that for every five beats per minute reduction in heart rate, there was an 18 % reduction in risk of death [17].

Beta-blockers can cause a 4–10-week increase in symptoms before benefits are realized; thus patients should be hemodynamically stable with minimal to no fluid retention before initiation. Beta-blockers are contraindicated with bradycardia, hypotension, hypoperfusion, second- or third-degree atrioventricular block, or severe asthma or COPD [1].

Angiotensin Receptor Blockers

ARBs are indicated for patients intolerant to ACEIs and have been well studied and proven to be as effective as, but not superior to, ACEIs at improving HF symptoms, mortality, and morbidity. In general, ACEI therapy is considered first-line therapy given the large amount of evidence validating them compared to ARBs. Recent guideline recommendations do suggest ARBs are a reasonable first-line alternative to ACEIs if patients are already taking ARBs for other indications. Systematic reviews have not found an outcome benefit to combined ACEI and ARB therapy and it is not generally recommended but there is limited evidence to support considering the combination in patients with persistent symptoms who cannot take an aldosterone antagonist [1].

Aldosterone Receptor Antagonists

Aldosterone receptor antagonists, or mineralocorticoid receptor antagonists (MRAs), are recommended in NYHA Class II–IV patients who have LVEF ≤35 %. Both spironolactone (Aldactone) and eplerenone (Inspra) improve symptoms and mortality as well as reduce HF hospitalizations when added to standard therapy (see Table 5). MRAs block aldosterone's effects to cause vasoconstriction and volume expansion by sodium reabsorption and potassium excretion in the distal tubule and collecting ducts. A creatinine of <2.5 mg/dL in men or <2.0 mg/dL in women (or GFR >30 mL/min) and a potassium of <5.0 mEq/L are important to avoid the substantial risk of hyperkalemia and renal insufficiency. Careful monitoring of these levels is important at initiation or after a change in therapy. The routine use of an ACEI, ARB, and MRA in combination is potentially harmful and should be avoided [1].

Hydralazine and Nitrates

The vasodilator hydralazine and isosorbide dinitrate combination therapy (see Table 6) is recommended in self-described African-

American patients with HFrEF and NYHA Class III–IV symptoms receiving optimal therapy with ACEI, beta-blocker, and MRA, unless contraindicated [1]. The combination reduces symptoms, quality of life, HF hospitalization, and mortality as shown in the African-American HF Trial (A-HeFT) [18]. Guidelines also suggest a benefit to utilizing the combination in patients who cannot take ACEIs or ARBs due to intolerance, hypotension, or renal insufficiency [1].

Digoxin

Digoxin therapy is reasonable and beneficial for symptom control and to reduce hospitalizations in patients on standard therapy or for rate control in HF and atrial fibrillation [1]. Studies have not proven a mortality benefit, and mortality can worsen with serum digoxin levels >1.2 ng/mL. A level of <1.0 ng/mL is considered therapeutic and should be monitored 1–2 weeks after initiation. Digoxin is renally excreted, and toxicity risk is higher in elderly patients with renal dysfunction and in patients with hypokalemia and hypomagnesemia which are both common in HF patients. Withdrawing digoxin therapy can lead to clinical deterioration and should be done cautiously [8].

Adverse Therapies

Anticoagulation therapy is not recommended in HF without a history of atrial fibrillation/flutter or a history of a thromboembolic event given the significant risk of bleeding. Similarly, antiplatelet therapy, including aspirin, has bleeding risks and has not been proven beneficial and can interfere with HF therapies [1]. Nondihydropyridine calcium channel blockers (e.g., diltiazem [Cardizem] and verapamil [Calan]) have proven to worsen HF symptoms given their negative inotropic effects. Dihydropyridine calcium channel blockers (e.g., amlodipine [Norvasc] and felodipine [Plendil]) appear safe but are only recommended for hypertension control. Drugs that increase salt and fluid retention (nonsteroidal antiinflammatory drugs [NSAIDS], steroids, and thiazolidinediones) can worsen clinical status in HF and should be avoided if possible. NSAIDS can also increase the risk of thrombotic events and cause peripheral vasoconstriction in HF. Phosphodiesterase inhibitors should be used with caution given the risk of hypotension. Many of these drugs are commonly prescribed but given their adverse risks in HF, they should be used with caution or avoided [1].

Implantable Devices

Sudden cardiac death (SCD) from cardiac arrest and ventricular arrhythmias is estimated to occur in a third to half of all HF deaths, thus automatic implantable cardioverter defibrillators (ICDs) are indicated for primary and secondary prevention. In primary prevention, ICDs are recommended for HF patients with a reasonable life expectancy (>1 year) and no history of recent MI (within 40 days). The other criteria includes patients with NYHA Class II–III and a LVEF ≤35 % or NYHA Class I and a LVEF <30 % [1]. Multiple studies have proven the benefit in NYHA Class II–III reducing mortality by 23–31 % [2]. In patients with a history of cardiac arrest, ventricular fibrillation, or hemodynamically destabilizing ventricular tachycardia, an ICD is recommended regardless of EF for secondary prevention of SCD [1].

Ventricular dyssynchrony can occur as HF progresses given that 30–50 % of HF patients have interventricular conduction delay [7]. As a result, cardiac resynchronization therapy (CRT) with biventricular pacing is indicated for patients with NYHA Class III or IV symptoms, a LVEF ≤35 %, a QRS interval ≥0.15 ms, a left bundle branch block (LBBB) pattern, and sinus rhythm to improve mortality and hospitalizations. Studies of CRT vary to include NYHA Class II, a QRS ≥0.12 ms (the level defining dyssynchrony), or a non-LBBB pattern, resulting in varying mortality and hospitalization decreases from 19 % to 37 %. CRT also improves symptoms and quality of life in these studies. Patients who meet criteria for CRT and an ICD should receive a combined device, unless contraindicated [1].

Heart Failure with Preserved Ejection Fraction

In most patients with systolic HF, diastolic dysfunction is also present. In studies of clinical HF,

approximately 50 % of patients have HF*p*EF [19]. Although debated, the definition of HFpEF includes clinical signs or symptoms of HF, preserved or normal LVEF, and evidence of abnormal left ventricular diastolic dysfunction by Doppler ECHO or cardiac catheterization. Specifically, these findings are evidence of impaired left ventricular diastolic filling with increased end-diastolic pressures and a stiff left ventricle with decreased compliance and impaired relaxation. The increased end-diastolic pressures of the left ventricle lead to pulmonary congestion, dyspnea, and other HF symptoms. There is not a consistent agreement on Doppler ECHO criteria for diastolic dysfunction, and at times the results are inconclusive; thus cardiac catheterization remains the gold standard to directly measuring ventricular diastolic pressure [20, 21]. Hypertension is the most important cause of HFpEF with a prevalence of 60–89 %. Patients are likely to be older women with hypertension, obesity, CAD, diabetes mellitus, atrial fibrillation, and hyperlipidemia [19]. Overall with HFpEF, no treatment has been well validated to show a reduction in morbidity and mortality, thus most recommendations are only expert opinion. Blood pressure should be controlled by national guidelines utilizing beta-blockers, ACEI, and ARBs to prevent morbidity, and diuretics should be used for relief of volume overload symptoms [1]. Two very small studies showed the heart rate-limiting calcium channel blocker verapamil (Calan) may improve exercise capacity and symptoms in patients with HFpEF. ACEI and ARB therapy are recommended but limited studies have not shown a definitive reduction in cardiovascular death or HF hospitalizations [2].

Acute Heart Failure Syndrome

Acute heart failure syndrome (AHFS) is a life threatening condition that requires immediate medical attention usually leading to admission to the hospital or intensive care unit. AHFS can occur during an initial diagnosis or arise as a result of deterioration of chronic HF, either HFrEF or HFpEF. Patients can have all the symptoms and findings of chronic HF but also have pronounced volume overload with peripheral and pulmonary edema. This can be a potentially fatal cause of acute respiratory distress with severe dyspnea and hypoxia that can lead to cardiogenic shock. A careful history for precipitating factors and prior exacerbations should be obtained. Diuretic noncompliance often contributes, thus a careful history of medications, dose and frequency of use is helpful. Acutely worsened coronary ischemia, valvular function, or arrhythmias can cause severe HF decompensations. Many noncardiac causes can lead to AHFS: severe hypertension, acute pulmonary edema, chronic lung disease, renal disease, anemia, or infection [2]. In addition to a normal HF evaluation, an arterial blood gas is warranted to accurately assess acid-base abnormalities. Invasive hemodynamic monitoring can be considered when there is evidence of impaired perfusion, uncertainty of fluid status, uncertainty of systemic or pulmonary vascular resistance, worsening renal function, or a need for vasoactive agents [1].

The initial goal of treatment should be stabilization to control hypoxemia or hypotension that can cause under perfusion of vital organs, the heart, kidneys, and brain [2]. Hypoxemia in AHFS is associated with increased risk of mortality thus should be treated if the SpO2 $<$90 %. Noninvasive positive pressure ventilation (NIPPV) should be considered in dyspnea patients with pulmonary edema when the respiratory rate is $>$20 breaths/min whether they have hypoxia or not. NIPPV has proven to decrease the likelihood of intubation, improve respiratory status and dyspnea, and reduce hypercapnia and acidosis. Mechanical ventilation should be considered if NIPPV cannot be utilized or is contraindicated [1]. IV loop diuretics are the first-line therapy to treat pulmonary edema and volume overload by lowering central venous capillary wedge pressures and improving hemodynamic status. Loop diuretic dosing should be equal or 2.5 times higher than the patient's normal oral dose (for dosing and equivalents, see Table 6). A continuous infusion of loop diuretics is not more effective than IV bolus therapy. If necessary, adding a second diuretic to potentiate a diuresis is an option, either with oral hydrochlorothiazide, metolazone, or

spironolactone. Careful monitoring of congestive symptoms, volume status, blood pressure, oxygenation, daily intake and outtake, and daily weights should be utilized. To reduce adverse effects of treatment, daily monitoring of renal function, for overdiuresis or azotemia, and electrolyte disturbances to appropriately replace depleted potassium and magnesium [1].

IV vasodilators, nitroglycerin or nitroprusside (Nitropress), are recommended for persistent congestive symptoms and rapid symptom relief in acute pulmonary edema or severe hypertension not responding to diuretics alone. Blood pressure should be monitored closely and the doses decreased if symptomatic hypotension or worsening renal function occurs [7]. IV inotropic agents such as dobutamine or milrinone (see Table 6) are indicated in AHFS when LVEF is reduced and hypotension (systolic blood pressure $<$90 mmHg) causes diminished perfusion and end-organ dysfunction (low-output syndrome). Invasive hemodynamic and heart monitoring are needed to evaluate heart filling pressures, cardiac index, and possible arrhythmias. When initiating a vasodilator or inotropic therapy, consideration should be given for cardiology or pulmonary consultation. Once hemodynamically stable, the initiation of standard evidence-based therapies for chronic HF is indicated [7].

Counseling and Self-Management

Counseling patients with HF education and strategies for self-care are critically important to enhance treatment compliance and manage worsening signs and symptoms of fluid retention. Counseling and education are also important to improve transitions of care given that HF patients are frequently hospitalized. Although frequently utilized, there is limited evidence to support the daily 2–3 gram sodium restriction or the 1.5–2 L fluid restriction recommended by current guidelines. Daily weights are important to detect early fluid retention, and a weight gain of 2 lb in a day or $\geq$5 lb in a week should prompt contacting or seeing a healthcare provider. Exercise training or regular physical activity is highly recommended as safe and effective to improve symptoms and functional status. Formal cardiac rehabilitation can be useful and effective when clinically stable to improve functional capacity, exercise duration, quality of life, and mortality. In patients with HF and sleep apnea, compliance with continuous positive airway pressure (CPAP) is important to increase LVEF and improve functional status [8].

Prevention

The ACC/AHA Stages A and B do not have symptomatic HF but represent an opportunity for prevention given the risk of developing HF. Stage A patients have normal heart structure and function, and evidence-based disease management of high-risk HF conditions such as hypertension, lipid disorders, diabetes mellitus, obesity, and thyroid disease and secondary prevention of atherosclerotic vascular disease based on current guidelines are recommended.

Controlling hypertension can reduce the rates of HF by 50 %. Because of their strong cardiovascular benefits, ACEIs or ARBs (if ACEI intolerant) are recommended in patients with known atherosclerotic vascular disease or diabetes. Behavior changes including tobacco cessation, regular exercise, and avoidance of alcohol and illicit drug use are also recommended to reduce risk [1].

Stage B patients already have cardiac structural abnormalities including previous MI, evidence of left ventricular remodeling (left ventricular hypertrophy or reduced LVEF), or valvular disease. These individuals' risk of HF progression is significantly higher, and treatments that preserve heart function are a priority. In those with a previous history of MI, ACEIs, ARBs, and beta-blockers are proven effective in reducing overall mortality, cardiovascular death, and symptomatic HF. Evidence-based management of CAD, MI, and chronic angina can further decrease the progression to symptomatic HF [1]. Patients with nonischemic cardiomyopathy, a reduced LVEF with no history of MI, also benefit from ACEI or ARB therapy. The SOLVD study showed a 37 % reduction in the development of symptomatic HF with ACEI therapy. The benefit or ACEI was retained in the same 12-year follow-up study in which ECHO data showed that ACEIs inhibit left

ventricular remodeling by attenuating worsening left ventricular dilation and hypertrophy [22]. Beta-blocker therapy has less evidence to support their benefit but is recommended given many patients will have other indications [1].

General Principles

Cardiovascular death remains the number one cause of death in the United States. It causes more deaths than lung cancer, breast cancer, prostate cancer, colon cancer, stroke, and chronic lower respiratory diseases combined [1, 2]. While most of these conditions require specialist care, often in a hospital setting, patients will present with these complaints to their Family Physician, and we must be able to recognize and assess them. Furthermore, Family Physicians will continue to care for these patients as they live with these conditions. Our patients will turn to us for information, second opinions, and advice. This chapter will look at some of these conditions.

Cardiogenic Shock

Shock is caused when oxygen demand exceeds available supply. This can be caused by increased demand of tissue due to infection, metabolic or endocrine disease, decreased supply, or a combination of the two. Sometimes, inability of tissue to use oxygen can contribute as well.

There are five categories of shock: Cardiogenic, Obstructive, Hypovolemic, Distributive, and Endocrine (see Table 1).

When oxygen supply to tissues is decreased, cells can extract more oxygen from red blood cells to meet demands. However, this can only compensate so much, and once supply drops below a critical level, this mechanism can no longer meet the demands of the tissues.

Cardiogenic shock is due to primary cardiac dysfunction. While there may be adequate volume, the heart is unable to circulate it, and tissues suffer from hypoperfusion and hypoxia.

Myocardial infarction (MI) is the most common cause of cardiogenic shock. Myocarditis, endocarditis, cardiomyopathy, and contusion after chest wall trauma can also cause cardiogenic shock.

Table 1 Shock classification

Name	Causes	Examples
Cardiogenic	Myocardial disease	MI Myocarditis
Obstructive	Mechanical blockage of blood flow beyond the heart	Pulmonary embolus Cardiac tamponade
Hypovolemic	Loss of circulating volume	Blood loss Third spacing
Distributive	Vasodilation and relative inadequate circulating volume	Sepsis Neurogenic shock Anaphylaxis
Endocrine	Thyroid disease Adrenal insufficiency	Thyroid storm Stopping steroid use abruptly

Pathophysiology

Ischemia reduces both contractility and relaxation of the heart. This leads to reduced cardiac compliance and reduced filling. As a result, stroke volume is reduced. This in turn reduces cardiac output (cardiac output = stroke volume X heart rate), which then reduces blood pressure. Compensatory mechanisms such as the sympathetic nervous system and the renin-angiotensin system increase heart rate, afterload, and fluid retention. These in turn cause increased oxygen demand on the heart which already has an inadequate supply [3]. This further widens the gap between oxygen needs and available oxygen, exacerbating shock and end-organ dysfunction.

Definition

Cardiogenic shock is defined as a systolic BP $<$ 80–90 mmHg in the absence of hypovolemia and must be associated with end-organ damage such as cold extremities, oliguria, or mental status changes. This can also be measured as reduced cardiac index (CI) $<$ 2.2 l/min/m^2 (cardiac output to body surface area) or elevated pulmonary capillary wedge pressure $>$ 15 mmHg [3].

Despite numerous advances in revascularization, medication, and mechanical support, cardiogenic shock is still the number one cause of mortality due to acute MI (AMI). Overall, however, the rate of cardiogenic shock has decreased from around 7.5 % (range 5–15 %) in the 1970s to around 4 % in 2003 [4].

Patients who develop cardiogenic shock during a hospitalization for AMI are more than 10 times more likely to die than patients hospitalized for AMI who do not develop cardiogenic shock.

Patients who develop cardiogenic shock after an AMI tend to be older, female, have a do-not-resuscitate order, a history of diabetes mellitus (DM), a history of heart failure (HF), or prior MI.

Management

If a patient develops cardiogenic shock from any cause, the keys to management are improving perfusion and oxygenation. Ideally, PaO_2 (Partial pressure of arterial oxygen) levels should be maintained at more than 60 mmHg using BPAP or intubation as needed. Maintain hemoglobin > 8 to allow for adequate oxygen delivery. Fluid resuscitation needs to be monitored carefully as improving filling pressures is important but must be balanced against fluid overload.

Vasopressors such as norepinephrine (Levophed), dopamine, and dobutamine and intraaortic balloon pump counterpulsation (IABP) are used to give BP support while stabilizing and preparing the patient for revascularization procedures. While dopamine was originally considered the first-line vasopressor in cardiogenic shock, recent evidence suggests better outcomes with norepinephrine. Dobutamine doesn't help hypotension and should only be used in patients who have less hypotension ie SBP> 80 mm Hg in conjunction with vasodilators [5].

Results from the GUSTO-I and SHOCK trials suggest improved survival with emergent revascularization in patients with cardiogenic shock. Percutaneous coronary interventions (PCI) have a class 1A indication in AMI with cardiogenic shock as does coronary artery bypass grafts (CABG) if the patient has suitable coronary anatomy [4]. A class 1A indication means that there are multiple randomized controlled trials showing that the procedure is both effective and useful.

Cardiopulmonary Resuscitation (CPR)

CPR was developed in the 1960s and has been saving lives ever since.

Every 5 years, the International Consensus of CPR and Emergency Cardiovascular Care (ECC) Conference convenes and evaluates the guidelines. The most recent conference took place in 2010, and the American Heart Association (AHA) Guidelines for CPR and ECC were updated.

In a major shift, the usual "ABC's" Airway-Breathing-Circulation protocol was changed to "C-A-B" – circulation, airway, breathing. This change was made to stress that reduced time to first compressions and early use of a defibrillator are the priorities for survival. The AHA has found that oxygen demand is lessened during cardiac arrest and therefore pumping blood to a victim's brain is more important than oxygen [6]. In fact, bystander Hands-Only CPR, where compressions are done without breaths, shows similar outcomes to conventional CPR in adults [7].

The compression rate has been changed from "approximately 100 compressions per minute" to "at least 100 compressions per minute."

Compression depth is now 2 in. for adults as opposed to 1½ to 2 in. for adults. The depth has changed for children as well [8].

Minimizing interruptions to compressions is also emphasized by changes in pulse checks. These should not last for more than 10 s, and if an obvious pulse isn't noted, compressions should continue. Again, trying to confirm a faint pulse may delay in needed compressions, and there are rarely significant injuries caused by chest compressions to patients who were not in cardiac arrest.

Additional changes include the removal of atropine (AtroPen) from the pulseless electrical activity (PEA) and asystole protocol.

Table 2 DeBakey classifications

Type I	Originates in the ascending aorta and propagates to at least the arch
Type II	Originates in and is confined to the ascending aorta
Type III	Originates in the descending aorta

Table 3 Standford classifications

Type A	All dissections that involve the ascending aorta
Type B	All dissections that do not involve the ascending aorta

Waveform capnography has been added to confirm endotracheal tube placement and quality of compressions. Cricoid pressure is no longer recommended during airway management.

Therapeutic hypothermia has been shown to improve outcomes for comatose patients after out-of-hospital arrests with a presenting rhythm of ventricular fibrillation (VF).

Aortic Dissection

Classification

There are two classification systems used: De Bakey and Standford (see Tables 2 and 3).

There are three syndromes included in acute aortic disease, aortic dissection, aortic intramural hematoma (IMH), and penetrating atherosclerotic ulcer (PAU). Aortic dissections comprise 90 % of acute aortic disease. Classic aortic dissection occurs when there is an intimal flap between the true lumen and the false lumen. An IMH occurs when there is bleeding into the aortic wall without a tear. This occurs by rupture of the vaso vasorum into the media of the aortic wall. This can happen either spontaneously or by a penetrating atherosclerotic ulcer [9].

Aortic dissection is often seen later in life, occurring after age 50. In cases that occur in younger patients, physicians should consider underlying connective tissue disorders such as Marfan's syndrome, Ehler-Danlos syndrome, or familial forms of dissection.

Chronic hypertension is the number one cause of aortic dissection and occurs in 75 % of cases. Smoking, dyslipidemia, and crack cocaine use can all contribute to aortic dissection.

Aortic dissection is twice as prevalent in men as women. The incidence is hard to determine as patients may die before reaching care but is estimated to be between 2 and 3.5 cases per 100,000 patient-years [10].

Symptoms

More than 90 % of patients with aortic dissection present with pain. Of the patients that present with pain, 90 % describe it as severe. The pain is abrupt and maximal at outset and is described as sharp, tearing, or stabbing. Some patients may have uncommon presentations which can confound the diagnosis. They may present with acute heart failure, stroke, or syncope and either not have pain or not mention pain due to other distracting symptoms.

Type A dissections occur in 65 % of cases and are more commonly seen in patients between 50 and 60 years of age. Type A dissections are lethal with a 1–2 % mortality rate per hour after onset of dissection. Patients usually have symptoms of immediate, severe chest pain and/or back pain. Patients can also have abdominal pain, syncope, and/or stroke. Acute heart failure is also possible if the dissection involves the aortic valve. Type A dissections are surgical emergencies. Medical treatment alone results in approximately 20 % mortality in the first 24 h. Mortality increases as time passes, with 50 % mortality by day 30. Surgery improves chance of survival, but the 24 h mortality is still high at 10 %.

Type B dissections occur more commonly over age 60. Type B dissections have similar presentations with chest and back pain as the common symptoms. Type B dissections are treated medically and uncomplicated type B dissections have 10 % mortality at day 30 [11].

Diagnosis

A routine chest x-ray (CXR) will be abnormal in 60–90 % of patients, but 12–15 % of patients can have normal CXR, and this cannot be used to exclude the diagnosis.

Electrocardiography (ECG) may be completely normal or extremely abnormal if the dissection involves the coronary circulation. This too cannot be used to exclude the diagnosis.

According to the International Registry of Aortic Dissection (IRAD) which is a clearinghouse of information on aortic dissections, Transthoracic Echocardiography (TTE), or Transesophageal Echocardiography (TEE) was used as the initial imaging test in 33 % of patients, Computed Tomography (CT) in 61 %, Magnetic Resonance Imaging (MRI) was used in 2 %, and Angiography was used in 4 %. For confirmation or further evaluation, TTE/TEE was used 56 %, CT 18 %, MRI in 9 %, and angiography in 17 % [11].

CT is useful for allowing clinicians to evaluate involvement of surrounding organs, local anatomy, and possible ruptures or leaks. However, CT must be done with contrast in order to detect a false lumen and is contraindicated in patients with nephropathy. Contrast-induced nephropathy is a complication even for patients without underlying renal disease. CT imaging is limited by cardiac motion artifact as well as streak artifact from any implanted devices.

MRI is better than CT at seeing the aortic valve and coronary arteries. It does not require radiation or iodinated contrast material. However, MRI is not readily available in all sites and requires the patient to undergo imaging for a longer period of time. Also certain medical devices make it impossible to use MRI [10].

TTE has excellent specificity in the range of 93–96 % but the sensitivity is lower at only 77–80 %. As such, a normal TTE does not rule out an aortic dissection. TEE, on the other hand has both excellent sensitivity at around 98 % and specificity at around 95 %. Like all ultrasonography, both modalities are operator dependent [10]. This may be a concern in smaller centers where aortic dissection isn't diagnosed frequently.

Management

Initial management for any type of dissection should include stabilizing the patient, controlling pain, lowering blood pressure, and reducing left ventricular contraction with beta-blockers. Initial blood pressure management is aimed at getting systolic blood pressure < 130 mmHg. IV beta-blockers are first-line therapy. These should be used to control heart rate as well, aiming for a pulse < 60 BPM. Nitroprusside (Nipride, Nitropress) can be used but only in conjunction with beta-blockers as nitroprusside can increase LV contractility. If a patient has a contraindication to a beta-blocker, verapamil (Calan, Isoptin SR, Veralan), or diltiazem (Cardizem, Cartia XT, Dilacor XR, Dilt-CD, Taztia XT, Tiazac) can be used. While stabilizing the patient, additional management depends on whether the patient has a type A or type B dissection.

Type A Dissections

Type A dissections should be managed as surgical emergencies. Medical management of type A dissections has a 20 % mortality rate in the first 24 h and 30 % in the first 48 h. Surgical management leads to improved outcomes for these patients. The aim of surgical management is to prevent aortic rupture, pericardial effusions which can lead to cardiac tamponade and death, and aortic regurgitation which can impair coronary artery blood flow leading to myocardial infarction and death. [5D] At 30 days, the mortality rate for Type A dissections managed surgically is between 17 % and 26 %. If managed medically, the 30 day mortality is between 55 % and 60 % [10, 12]. The patient's hemodynamic stability immediately prior to surgery is a key predictor of how well the patient will do during and after surgery. Therefore it is critical that surgery not be delayed for type A dissections.

Type B Dissections

Type B dissections should be managed medically. Uncomplicated type B dissections should be managed medically and those that only require medical management have a low mortality rate around 6 %. Additionally the 5 year survival rate for these patients with optimal medical management is 89 % [12]. The overall mortality rate for Type B dissections treated medically was 10.7 % in the International Registry of Aortic Dissection, IRAD, while those requiring surgery had a 31 % mortality rate. Surgical management is required for complications such as limb ischemia, impending or actual rupture, increasing aortic diameter, intractable pain, or retrograde dissection (type A). Looking at 571 patients in the IRAD with type B dissection, 32 % were complicated. The type of surgery required affected mortality rate for type B dissections requiring surgery. Open surgical repairs had 33 % mortality whereas those who had an endovascular repair had only an 11 % mortality rate [10]. About 25 % of Type B dissections are complicated at presentation [12].

Almost all patients with a type B dissection require intravenous antihypertensives with most requiring more than one antihypertensive medication during hospitalization. Beta-blockers, calcium channel blockers, nitroglycerin (Nitrolingual, NitroMist, Nitrostat), and nitroprusside were the most common initial antihypertensives used in one study of 129 patients. Mean hospital stay is more than 2 weeks with most patients spending a week in the intensive care unit as well [13]. All patients went home on an oral antihypertensive medication. These patients should be closely followed for at least the first 6 months after discharge as most complications that require intervention occur within this time frame. These patients are at risk for future dissections, aneurysms, and rupture. Systemic hypertension, advanced age, aortic size, and a patent false lumen are characteristics that put patients at higher risk for complications. Estimates are that 1/3 of all patients with original medical management will have an aneurysm, further dissection, or surgical requirement within 5 years [14].

Beta-blockers are the cornerstone of therapy as they affect both BP and contractility and are recommended even for patients with well controlled BP. Ideal BP control should be $<$ 120/80 mmHg. Smoking cessation and risk factor modification for atherosclerotic disease are also key components for chronic management of aortic dissection. Surveillance with CT or MRA should occur at 1, 3, 6, and 12 months. After the first 12 months, imaging can be continued annually. Primary care doctors can oversee this surveillance along with cardiologists or cardiothoracic surgeons as appropriate.

Cardiac Syncope

Syncope is defined as sudden temporary loss of consciousness (LOC) with complete spontaneous recovery. It is very important to obtain a good history and physical exam in order to determine if the patient experienced syncope or if another diagnosis is more likely. If the patient did indeed have a syncopal event, the history and physical exam will help the clinician distinguish between the five types of syncope: Cardiac, Neurally mediated, Neurologic, Orthostatic, or Psychogenic (see Table 4).

The differential for syncope includes seizures, dizziness, presyncope, drop attacks, vertigo, and near sudden cardiac death events [15]. The history can usually elicit which of these the patient experienced. The input of any witnesses is vital as the patient often does not remember the event or does not remember the entirety of the event. Studies have shown that the elements that distinguish seizure from syncope include disorientation after the event (post-ictal phase), tongue-biting, frothing at the mouth, and loss of consciousness for more than 5 min. An aura preceding and a headache after the event also suggest seizure [16]. Urinary or fecal incontinence can be seen with either condition but are more common in seizures.

Cardiac syncope is important to distinguish from other causes as it is associated with an increased risk of death from all causes, such as stroke, and from cardiac causes, such as

Table 4 Types of syncope

Name	Situation	Prevalence (%)	Risk of death
Cardiac	Exertional, arrhythmias, palpitations, unprovoked	18	2X increased risk of death from any cause
Neurally mediated	Vasovagal, situational, micturition, defecation, sight of blood	24	None
Neurologic	Steal syndrome, TIA's, neurologic symptoms	10	Increased risk of death
Orthostatic	Dehydration, medication, alcohol, occurs with standing	8	None
Psychogenic	Depression, anxiety, normal exam findings, panic attacks	2	None

All other episodes of syncope are of unknown etiology-38 %

myocardial infarction or arrhythmia. Cardiac syncope is the second most common type of syncope and is seen in about 10–20 % of cases. Patients tend to be older, have a cardiac history, and/or risk factors for cardiac disease such as diabetes and HTN. They may also have palpitations, syncope related to exercise, and/or a family history of sudden cardiac death. They may complain of chest pain or shortness of breath in addition to the syncopal episode. Ventricular tachycardia (VT) is the most common tachyarrhythmia that leads to syncope. Supraventricular tachycardia (SVT) can lead to syncope but this is less common. More often, patients with SVT have less severe symptoms such as lightheadedness, palpitations, and shortness of breath. Bradyarrhythmias such as sick sinus syndrome can also lead to syncope. A massive pulmonary embolism or aortic stenosis is obstructive causes of cardiac syncope. Increased age and male sex, both risk factors for cardiac disease, also suggest a cardiac etiology for syncope.

Risk Factors for Serious Adverse Events After a Syncopal Episode

The San Francisco Syncope Rule (SFSR) is a tool used to determine if a patient has an increased risk of death after a syncopal episode. Systolic blood pressure < 90 mmHg, shortness of breath, congestive heart failure, ECG abnormalities, and hematocrit < 30 were all predictors of serious outcomes [3S]. Another tool is the Risk Stratification of Syncope in the Emergency Department (ROSE) rule. This states that if any of the following 7 risks are present, the patient should be considered high-risk: BNP > 300 pg/ml, HR < 50, hemoglobin < 9, positive fecal occult blood, chest pain, ECG with Q waves, or oxygen saturation < 94 % [17].

Another study looked at death or significant cardiac arrhythmias in the year after a syncopal episode and found that the four most important risk factors were age $>= 45$, a history of heart failure, a history of ventricular arrhythmia, and an abnormal ECG. Patients with none of these risks had a 4–7 % chance of death or a significant cardiac arrhythmia as opposed to those with three or four of these risks who had a 58–80 % chance [17].

History and Physical Exam

In diagnosing and distinguishing between types of syncope, history, and physical exam allow for more accurate diagnosis than any other modality, establishing the diagnosis between 14 % and 25 % of the time. ECG was next at only 10 %.

It is important when taking the history to ask about the patient's position prior to and at the time of the event, last PO intake including fluids, recent exertion, any situational stressors, any new or recently taken medications or drugs, the presence of palpitations or dyspnea, and any family history

of cardiac disease and sudden cardiac death. It is also important to know if the patient has a personal cardiac history including a pacemaker or defibrillator.

The physical exam should include vitals particularly any orthostatic changes and oxygen saturation, cardiac murmurs, arrhythmias, any neurologic changes, or any gastrointestinal blood loss.

Testing

Routine lab testing has little diagnostic value in assessing syncope with <3 % of cases having any significant lab abnormalities [17]. It may be reasonable to check glucose, CBC, and BNP in certain patients.

Carotid massage can be used to check for neurally mediated carotid sinus hypersensitivity in patients over age 40 only after ruling out the presence of bruits. This test should not be performed in patients with a history of transient ischemic attack (TIA), recent stroke or neurologic findings on exam. The test is positive if the patient experiences a pause in heart rate for > 3 s or whose systolic BP drops by more than 50 mmHg. The test should be done in the supine and upright positions [16]. While this is mentioned in most texts, it is not often done in practice.

ECG should be ordered for patients where cardiac syncope is suspected. The ECG can establish the diagnosis in 5–10 % of cases of syncope. One should look for QT prolongation, delta waves, and short PR interval which suggest Wolff-Parkinson-White (WPW), bundle branch block(BBB), particularly right BBB with ST elevation which is seen in Brugada syndrome. One should also look for ST-elevations suggestive of myocardial infarction, bradycardia, seconnd or third degree atrioventricular (AV) node block, SVT, or VT. Any abnormality in the ECG should raise the concern for a cardiac cause of syncope and increased mortality [16].

Telemetry is often ordered for patients who present with syncope but does not frequently help identify the cause. Holter monitoring and more recently loop monitoring may be useful in cases of suspected arrhythmia. These allow for longer periods of monitoring with implantable loop recorders being able to monitor patients for more than 12 months. Symptoms attributable to arrhythmias can be found with loop recorders in 50–85 % of cases [17].

Stress testing and cardiac catheterization should only be used in cases where myocardial ischemia is highly suspected.

Echocardiography is useful to evaluate for structural cardiac abnormalities. It is also useful for determining left ventricular ejection fraction (EF) as an EF < 35 % is an indication for an implantable cardiac defibrillator (ICD). These patients are at high risk for arrhythmias and sudden cardiac death. In these patients, syncope is an ominous sign. Echocardiography is also useful in establishing aortic stenosis as the cause of syncope. This should be suspected in older adults presenting with syncope during exertion.

Electrophysiologic (EP) Testing can be useful in establishing the diagnosis for patients suspected of having sick sinus syndrome, heart block, Ventricular tachycardia (VT), or supraventricular tachycardia (SVT). Those patients with structural heart abnormalities, ECG abnormalities, a clinical history that suggests arrhythmia, or a family history of sudden death should undergo EP testing.

Management

Management of cardiac syncope depends on the underlying cause. If the cause is ischemic, patients should receive optimal medical management along with surgical interventions as needed. Most arrhythmias will require ICD implantation. Patients with sick sinus syndrome and AV node block can be treated with pacemakers. WPW can be treated with catheter ablation therapy.

Sudden Cardiac Death

Sudden cardiac death (SCD) affects between 300,000 and 500,000 people in the United States annually. SCD is usually caused by VT decompensating to ventricular fibrillation (VF) though it may also result from heart failure, bradyarrhythmias, heart block, or pulmonary emboli. SCD is responsible for more deaths annually in the US than stroke, lung cancer, and breast cancer combined. Worldwide, it is responsible for 50 % of overall cardiac deaths [18]. It is the most common presenting sign of coronary artery disease. Risks for SCD include decreased left ventricular EF, Acute MI, prior MI, prior ventricular arrhythmia, and congestive heart failure.

Seventy five percent of cases occur in men with a 4–7 fold higher risk of SCD in men than women < 65. After age 65, the ratio of SCD in men to women is 2:1 or less [18]. Before menopause woman have cardioprotection that decreases their risk of SCD and cardiac disease. However, in women over age 40, coronary artery disease is the most common cause of SCD. Further, women with SCD are less likely to have severely reduced left ventricular ejection fraction or known heart disease which makes it that much harder to establish a risk profile for women.

Primary Prevention

Given that the first arrhythmic event is usually fatal in SCD (or perhaps more appropriately, sudden cardiac arrest (SCA)), it is critical to try to identify people who are at high risk for these events and intervene early. People with known cardiac disease and EF's < 30–40 % are known to be at very high risk for SCD. An EF < 30 % is the biggest independent predictor for SCD and reduced EF predicts SCD in both ischemic and nonischemic dilated cardiomyopathy. The American College of Cardiology (ACC), American Heart Association (AHA), and the Heart Rhythm Society (HRS) published guidelines recommending ICD implantation in people with ejection fractions less than 30–35 % with heart failure [19]. Therefore, it is critical that any patient with known cardiac disease have an evaluation for ejection fraction. Patients with low functional capacity who don't have a reasonable expectation to live more than 1 year are not candidates for ICDs.

Secondary Prevention

Three studies have shown that ICDs decrease mortality in patients with aborted SCD, VT or VF. Therefore, any patient with a history of VT, VF, SCA, or aborted SCD should be evaluated for possible ICD implantation. VT or VF that occur within 48 h of an MI do not need to be evaluated for ICD placement.

Hypertrophic Cardiomyopathy

Definition

Hypertrophic cardiomyopathy (HCM) is defined as LV hypertrophy associated with nondilated ventricles that is not caused by cardiac or other systemic illness. HCM affects approximately 600,000 people in the U.S. Most of those have no symptoms and most have a normal life expectancy. Those that do die from SCD suffer from ventricular tachyarrhythmias. This occurs most often in asymptomatic patients younger than 35. The other two serious complications of HCM are atrial fibrillation (AF) and heart failure with dyspnea.

The complications of HCM are caused by left ventricular outflow tract (LVOT) obstruction, arrhythmias, myocardial ischemia, diastolic dysfunction, and mitral regurgitation [20]. It is critical to establish whether LVOT obstruction is present as management strategies are based largely on this complication.

Diagnosis

The diagnosis of HCM is made by transthoracic echocardiography (TTE) and more recently,

cardiac MRI. Once HCM is diagnosed, first-degree relatives should be screened with TTE. Patients with HCM can undergo genetic testing. If a patient screens positive for one of the genetic markers of HCM, first-degree relatives can be screened with genetic testing as well.

Once a patient is diagnosed with HCM, ECG, and Holter monitoring should be done to look for any tachyarrhythmias. This should be repeated annually or whenever the patient has worsening symptoms of HCM [20].

Children of patients with HCM should be screened annually with TTE starting at age 12 or earlier if puberty or growth spurt begins before age 12. Children in intense competitive sports should also be screened earlier. Adult relatives can be surveyed every 5 years with TTE.

Management

Providers should aggressively manage patients with asymptomatic HCM by evaluating them for other risk factors for cardiovascular disease as these may contribute to complications of HCM. These patients should not participate in strenuous activities or competitive sports. Patients with resting or provoked LVOT obstruction should not be given high-dose diuretics or pure vasodilators as these are harmful. Beta-blockers should be used as first-line medications for symptoms of dyspnea and angina. If patients cannot tolerate these, verapamil can be used. Disopyramide (Norpace) can be added to a beta-blocker or verapamil if symptoms cannot be controlled, however it should not be used alone. Dihydropyridine calcium channel blockers such as amlodipine (Norvasc) should not be used in patients with HCM who have LVOT obstruction. ACE-Inhibitors have not been shown to be useful or harmful in the treatment of symptoms of HCM. Beta-blockers can be used in children but watch for side effects such as depression or difficulty in school.

Surgical interventions such as septal reduction or alcohol septal ablation should only be considered in cases of refractory LVOT obstruction and symptoms that interfere with daily living despite optimal medical management. These should only be performed at experienced centers.

Implantable cardiac defibrillators (ICD's) have been shown to decrease mortality in patients with HCM and tachyarrhythmias. Patients with HCM should receive risk stratification for SCD to determine if an ICD if appropriate. These include prior personal cardiac arrest, history of VF, sustained VT, sudden cardiac arrest (SCA) (recurrence is 10 % per year), family history of SCD, unexplained syncope, documented nonsustained VT, or LV thickness >= 30 mm [20]. An ICD can be implanted in children as well who have any of these high-risk factors.

Patients with HCM, regardless of symptoms, should not participate in intense or competitive sports. One third of all SCD in young athletes are due to HCM. Low-intensity aerobic exercise is recommended.

Venous Thromboembolism

Lawrence Gibbs[a]*, Josiah Moulton[b] and Vincent Tichenor[b]
[a]Faculty, St. Louis Univ. - Belleville Family Medicine Residency, Belleville, IL, USA
[b]3rd Yr Resident,, St. Louis Univ. - Belleville Family Medicine Residency, Belleville, IL, USA

Introduction

Deep vein thrombosis (DVT) and pulmonary embolism (PE) have a shared pathophysiology and together, along with superficial thrombophlebitis, comprise the spectrum of venous thromboembolism (VTE). PE causes 10 % of deaths in hospitals representing the most common preventable cause of death in patients with misdiagnosed or improperly treated DVT [1]. **Evaluating** the patient's history, signs, symptoms and risk factors for VTE is essential for diagnosis along with the use of validated clinical prediction rules. Once diagnosed, multiple effective treatment options are currently available, including well-tolerated new oral anticoagulants, for short- and long-term treatment.

Pathophysiology

Inflammation and Virchow's Triad of endothelial injury, hemodynamic changes (such as stasis or turbulence) and hypercoagulability are the classic elements that bring about thrombosis. The role of inflammation is apparent by the increased frequency of DVT and PE formation in chronic inflammatory conditions such as inflammatory bowel diseases and systemic vasculitis [2]. C-reactive protein elevation has been linked to increased VTE risk. In the Atherosclerosis Risk In Communities (ARIC) study, an elevated C-reactive protein above the 90th percentile was associated with a 76 % increased risk of VTE formation compared to lower percentiles [2]. Endothelial injury and stasis also increase VTE risk via increasing coagulation factors and preventing adequate mixing of anti-clotting factors, respectively [2, 3]. Local injury from indwelling devices, such as pacemaker leads or long-term indwelling central venous catheters, also increase upper extremity DVT formation [3].

Inherited and acquired thrombophilias affecting anticoagulant or pro-coagulant pathways lead to hypercoagulopathy [4]. Common inherited disorders include Factor V Leiden mutation, which causes resistance to degradation by activated protein C, G2021A mutation, and deficiencies in proteins C and S, and antithrombin III. Hyperhomocysteinemia spans both categories, as it involves inheriting a defective enzyme, but is acquired through dietary folate, B6 and B12 deficiency [5]. Antiphospholipid antibody syndrome is an acquired autoimmune disorder characterized by antiphospholipid and anticardiolipin antibodies that increase the risk of recurrent VTE [6].

Inherited coagulopathies are among the rare, but significant risk factors for development of VTE, particularly in younger populations. However, thrombophilia testing remains controversial as absolute VTE risk is only mildly affected by these disorders. Some consensus recommendations encourage screening for anyone diagnosed with VTE under 40 year old, others, including the American College of Chest Physicians, argue against testing [7]. Evidence suggests that family history of unprovoked VTE in a first-degree relative, especially when under 50 year old, may be more important for counseling patients (i.e., pregnancy) on their inherent risk than specific testing results [8].

Table 1 Risk factors for venous thromboembolism

Strong risk factors (odds ratio >10)
Fracture (hip or leg)
Hip or knee replacement
Major general surgery
Major trauma
Spinal cord injury
Moderate risk factors (odds ratio 2–9)
Arthroscopic knee surgery
Central venous lines
Chemotherapy
Congestive heart or respiratory failure
Hormone replacement therapy
Malignancy
Oral contraceptive therapy
Paralytic stroke
Pregnancy/, postpartum
Previous venous thromboembolism
Thrombophilia
Weak risk factors (odds ratio <2)
Bed rest >3 days
Immobility due to sitting (e.g., prolonged car or air travel)
Increasing age
Laparoscopic surgery (e.g., cholecystectomy)
Obesity
Pregnancy/, antepartum
Varicose veins

Epidemiology

Approximately 900,000 new onset or recurrent PE or DVT cases occur annually, with 60,000–300,000 VTE events resulting in death each year. VTE accounts for approximately 1 % of hospital admissions in the US annually, while two-thirds of VTE cases occur in patients who have been hospitalized within the past 90 days [5]. Hospitalization, acute and chronic illness with resulting inflammation, recent surgery, and pregnancy or chemotherapy can all increase the risk of VTE up to 100 fold [4, 5]. The increased risk with cancer is multifactorial, but very evident. Tumors activate coagulation or may compress veins causing stasis. The incidence of VTE during the first 6 months after a cancer diagnosis is 12.4 per 1,000 [5, 9].

Modifiable risk factors for VTE include obesity, hypertension, tobacco use, dyslipidemia, diabetes, diet, stress, hormone replacement and contraceptive use. Patients with a BMI > 30 have a two to three fold higher risk, and may be related to impaired venous return or increased coagulation and inflammation [5]. Age-adjusted VTE incidence is highest among Caucasians (108 per 100,000) followed by African-Americans (78 per 100,000) then Asian and Native Americans [4, 5]. The rate of VTE increases exponentially with age, and may be associated with the biology of aging rather than increasing risk factor exposure. The most significant complications of VTE are venous stasis syndrome, venous ulcers and chronic thromboembolic pulmonary hypertension. The 20 year cumulative incidence of stasis syndrome after VTE and proximal DVT are 25 % and 40 % respectively, while that of venous ulcer is 3.7 % [4].

Diagnosis

Evaluating the history, signs, symptoms and the individual's risk factors for VTE are essential for diagnosis (Table 1). Patients with symptomatic DVT classically present with unilateral calf or thigh swelling, warmth and tenderness. However, peripheral arterial disease (PAD), trauma, infection, and compartment syndrome may share these features. Likewise, patients suspicious for PE commonly present with chest pain, tachypnea, tachycardia, dyspnea and cough. Concurrent DVT symptoms may also be present in those with suspected PE. Congestive heart failure (CHF), acute coronary syndrome (ACS), and chronic obstructive pulmonary disease (COPD) share similar signs and symptoms as PE and may confound the diagnosis [10].

Clinical Approach

Because none of the signs and symptoms of DVT or PE are specific, clinical probability assessment is an essential component in the diagnosis. Clinical prediction rules that incorporate signs, symptoms, and patient risk factors are frequently utilized to categorize patients as low, moderate, or high probability of having VTE [11]. The American College of Chest Physicians (ACCP), American College of Physicians (ACP), American Academy of Family Physicians (AAFP) and the Institute for Clinical Systems Improvement (ICSI) all support use of validated clinical prediction rules to assess pretest probability of VTE to guide diagnostic decision making [11–14].

A variety of formal scoring systems have been developed and validated to assist in stratifying patients with suspected DVT or PE [10]. Well's criteria is frequently used for DVT assessment and assigns a pretest probability category based on risk factor scoring (Table 2). Well's PE criteria and the modified Geneva criteria have similar predictive value and assist providers in determining pretest probability for PE [15]. For Well's PE criteria, the physician assigns points for different clinical criteria which include: signs and symptoms of DVT (i.e., leg swelling and calf tenderness), 3 points; diagnosis of PE at least as likely as an alternative diagnosis, 3 points; prior documented history of PE or DVT, 1.5 points; recent surgery (past 4 weeks) or immobilization for greater than 2 consecutive days, 1.5 points; pulse rate greater than 100 beats/min, 1.5 points; hemoptysis, 1 point; and active or recent (past 6 months) cancer history, 1 point. A patient's pretest probability is considered low for scores less than 2, moderate for scores

DOI 10.1007/978-1-4939-0779-3_88-1

between 2 and 6, and high for scores greater than 6. Though some suggest a simple gestalt approach to pretest probability, determination based on experience is often inaccurate and should be used cautiously [10]. Pretest probability for DVT or PE, along with test availability and risk, should guide subsequent D-dimer and diagnostic imaging (see algorithm) [16].

Diagnostic Algorithms for DVT (Top) and PE (Bottom)

D-Dimer Testing

D-dimers are a byproduct of fibrinolysis formed by the degradation of fibrin within a clot and are acutely elevated in VTE [10]. Current assays are fast, readily available and highly sensitive (over 95 %) for VTE, but not nearly as specific [17]. False-positives can be seen in patients with malignancy, infection, recent surgery or trauma, and pregnancy [11]. It is worth noting that for patients 50 years or older, using an age-adjusted D-dimer, defined as a patient's age multiplied by 10, may be more accurate at ruling out VTE than using the typical fixed D-dimer cutoff of 500 ug/L [18].

DOI 10.1007/978-1-4939-0779-3_88-1

Compression ultrasound (CUS)

Widely available and noninvasive, CUS is the imaging procedure of choice for the diagnosis of DVT [14], with a sensitivity and specificity of 95 % and 98 % respectively when performed by a well-trained operator. Inability to compress a vein with the transducer is diagnostic for DVT, while signs of distention, decreased flow and abnormal doppler signal support the diagnosis [11]. In patients with moderate to high pretest probability of DVT, negative CUS alone, especially if just proximal vessels were tested, cannot exclude the diagnosis of DVT. Repeat CUS 1 week later is recommended for this group [11]. Some limitations include decreased reliability in detecting calf and upper extremity thrombi or poorer detection of thrombi isolated to the pelvis and difficulty distinguishing between old and new clots [10].

Venography

Historically considered the gold-standard for DVT detection, venography involves injecting contrast into the venous system to assess for filling defects or collateral flow. Currently, venography is reserved for times when noninvasive tests cannot be performed or when noninvasive tests yield results counter to clinical suspicion [10]. The PIOPED II trial demonstrated CT venography to be diagnostically equivalent at identifying DVT compared to CUS at the risk of higher contrast and radiation exposure [19].

Computed Tomographic Pulmonary Angiography (CTPA)

Multidetector CT angiography has replaced conventional pulmonary angiography as the reference standard for diagnosing PE with high sensitivity and specificity up to 100 % and 97 %, respectively [16]. Not only does it meet or exceed pulmonary angiography in ability to rule out PE, but it also generates diagnostic information that may suggest alternative or additional diagnoses [16]. Additionally, the PIOPED II trial showed that those with high or intermediate pretest probability and positive CTPA results or those with low pretest probability and normal CTPA results, predictive values in the mid-1990s were achieved [19]. Due to increased ionizing radiation and contrast exposure, consider ventilation-perfusion (V/Q) scanning for pregnant women, obese patients, or those with compromised renal function [10, 20].

Ventilation-Perfusion (V/Q) Scanning

Ventilation-perfusion lung scans are reported as low, intermediate or high likelihood for presence of PE. A normal scan effectively excludes PE (negative predictive value of 100 %), [16] while high pretest probability and a high-probability V/Q scan has a positive predictive value of 96 % [21]. Up to 75 % of cases may result as nondiagnostic low or intermediate probability [21]. As with CTPA, results discordant with pretest probability require further work-up.

Other Diagnostic Testing

Pulmonary angiography may still be considered in select cases where clinical suspicion for PE remains high despite negative prior testing, but it is more invasive and requires higher contrast exposure than CTPA [10]. Those with normal angiography results have a 3-month VTE incidence less than 2 % with 0.3 % incidence of fatal PE [22]. More recent advances in V/Q Single-photon Emission CT (SPECT) have increased its sensitivity and specificity while limiting nondiagnostic results, which plague typical planar V/Q scans [23]. Meanwhile, the PIOPED III trial did show magnetic resonance angiography and venography (MRA and MRV) to have good sensitivity and specificity at detecting PE, but their high percentage of technically inadequate results currently do not support routine use [24]. Additionally, tests like a chest x-ray showing pleural infiltrates, or engorged central pulmonary artery vasculature with a

DOI 10.1007/978-1-4939-0779-3_88-1

paucity of peripheral vessels, or an electrocardiogram showing right bundle branch block with the a S1Q3T3 pattern may increase suspicion for PE but are not specific [10].

Management

Management of VTE centers on initial stabilization of the patient, selection of anticoagulation therapy, and determining treatment duration. Providers may start pharmacological treatment in high risk patients (based on pretest probability) while undergoing testing, and delay treatment until testing is finished for low risk patients [13]. A distal DVT is less likely to embolize than a proximal DVT, and a DVT that does not extend within a period of 2 weeks is unlikely to extend into the proximal veins. Therefore, for acute isolated distal DVT in a patient without severe symptoms or risk factors (i.e., positive D-Dimer, extensive thrombosis, thrombus near proximal veins, absence of reversible provoking factor, prior VTE, or inpatient status), the physician may delay anticoagulation and repeat imaging of the deep veins in 2 weeks [25].

Initial Management

Given the variation of severity in presentations of patients with PE, the provider must ensure hemodynamic stability. For acute massive PE, sub-massive PE with significant right ventricular strain, or extensive acute proximal DVT, direct thrombolysis may be needed to dissolve the thrombus and reduce postthrombotic morbidity [25, 26]. Once the patient is stable, the treatment focus may be shifted toward anticoagulation, which is broadly the same in patients with PE or DVT. Goals of therapy include preventing clot propagation and possible PE (primary or subsequent) and minimizing complications. Resolution of a clot is not a direct goal of anticoagulation therapy [11, 25].

Initial anticoagulation can be accomplished with unfractionated heparin (UH), low-molecular weight heparin (LMWH), fondaparinux, apixaban, or rivaroxaban (see Table 3). UH has long been utilized in the initial treatment of VTE and when given intravenous (IV), is dosed via a nomogram based on periodic monitoring of the patient's activated partial thromboplastin time (aPTT) [28]. IV UH is preferred in the patient with PE who will likely be undergoing thrombolysis, those impaired subcutaneous absorption, or those with increased bleeding risk. UH carries the risk of heparin induced thrombocytopenia (HIT), hemorrhage, and anaphylaxis. The risk of hemorrhage increases with age, comorbidities, and previous bleeding. Due to the risk of HIT, patients on heparin should have their platelet count monitored daily [13].

LMWH and fondaparinux have become the favored initial treatment for uncomplicated VTE. Both have equal efficacy, increased bioavailability, and less frequent dosing when compared to heparin [29]. Meanwhile, rivaroxaban and apixaban are new oral anticoagulants shown to have equivalent or better efficacy and safety as monotherapy for initial and long-term anticoagulation when compared to conventional therapy of LMWH and warfarin [30–32].

Outpatient management may be appropriate in low-risk patients. Criteria for outpatient therapy include patients with good cardiorespiratory reserve, no excessive bleeding risks, a creatinine clearance greater than 30 mL/min, and ability to safely self-administer the medication. However, because of the need for an organized support system and time-of-day considerations for home care agencies, many patients may need hospitalization during the first 24 h to start therapy promptly [13].

Long-Term Anticoagulation

Initial anticoagulation should be initiated with long-term anticoagulation and continued for a minimum of 5 days and 24 h after the patient's international normalized ratio (INR) is above 2.0 (if treated with vitamin K antagonist (VKA) therapy). Bridging therapy via initial anticoagulation provides adequate anticoagulation while the vitamin K dependent clotting factors are depleted. The goal INR value for

Table 3 Treatment table for venous thromboembolism (Compiled from Refs. [27, 28])

Parenteral anticoagulants							
Agent	Mechanism	Dosing	Half-life	Metabolism	Antidote	Monitoring	
Heparin	Binds antithrombin	IV: 80 u/kg bolus, then 18 u/kg.h SC: 333 U/kg, then 250 U/kg q12	90 min	Depolymerization	Protamine	aPTT (1.5-2.0x normal)	
LMWH[a] (Enoxaparin)	Binds antithrombin	1 mg/kg SC BID; 1.5 mg/kg SC daily if BMI <30	3–4 h	Depolymerization desulphation	Protamine	None required	
Fondaparinux[a]	Binds antithrombin	5.0 mg SC if <50 kg 7.5 mg SC if > 50 kg and <100 kg 10.0 mg if >100 kg	17–21 h	Insignificant	None	None required	
Oral anticoagulants							
Agent	Mechanism	Dosing	Half-life	Drug interactions[a]	Antidote	Monitoring	Parenteral anticoagulation
Vitamin K antagonist (warfarin)	Indirect thrombin inhibition	Initial dose of 5 mg–10 mg, changes based on INR	36 h	CYP2C9, CYP1A2, CYP3A4	Vitamin K	INR	Initially required, 5 days
Dabigatran[b]	Direct thrombin inhibitor	150 mg BID	14–17 h	P-glycoprotein inducers/ inhibitors	None	None required	Initially required, 5 days
Apixaban[b]	Factor Xa inhibitor	10 mg BID for 7 days, then 5 mg daily	8–12 h	CYP3A4/5. P-glycoprotein inducers/ inhibitors	None	None required	None required
Rivaroxaban[b]	Factor Xa inhibitor	15 mg BID for 3 weeks, then 20 mg daily or 15 mg daily if CrCl 15–50 mL/min	7–11 h	CYP3A4. CYP2J2 P-glycoprotein inducers/ inhibitors	None	None required	None required
Edoxaban[b]	Factor Xa inhibitor	30 mg or 60 mg daily	6–11 h	P-glycoprotein inducers/ inhibitors	None	None required	Initially required, 5 days

aPTT activated partial thromboplastin time, *BID* twice daily, *BMI* body mass index, *INR* international normalized ratio, *IV* intravenous, *SC* subcutaneous

[a]Not recommended in those with a creatinine clearance (*CrCl*) less than 30 mL/min

[b]Limited data in those with a creatinine clearance (*CrCl*) less than 30 mL/min

DOI 10.1007/978-1-4939-0779-3_88-1

treatment is 2.5, with an acceptable range of 2.0–3.0 [25]. Multiple trials have demonstrated the increased safety of starting long-term anticoagulation at the same time as initial anticoagulation [33, 34].

Warfarin, LMWH, oral and SC factor Xa inhibitors, and oral direct thrombin inhibitors provide long-term anticoagulation [35]. The most common and longest used agent is warfarin, a vitamin K antagonist. Warfarin is preferred due to time-proven efficacy, oral administration, reversibility, and low cost, however periodic lab testing, narrow therapeutic window, need for dosage adjustments, and its interactions with many drugs and foods may limit its use. Various tables and algorithms are available to guide warfarin dosing based on INR testing. One such validated protocol suggests monthly INR testing for patients in therapeutic range and weekly testing for those outside of their therapeutic range [36].

LMWH is also a viable option for long-term anticoagulation with similar efficacy and risk profile when compared to warfarin when used long-term [37]. LMWH is advantageous due to its ease of dosing, wide therapeutic window, no need for testing, and fewer drug/food interactions compared to warfarin. However, it is also more expensive than warfarin, more difficult to reverse, requires subcutaneous dosing, and carries a risk of drug-induced osteoporosis. LMWH is preferred in patients with malignancy [13, 14]. Fondaparinux is a SC agent that is similar to LMWH and may also be used in long-term treatment [25].

Evidence for use of new oral agents suggests they are acceptable for long-term therapy [30–32, 38]. Recent meta-analyses have also shown lower bleeding risk compared to warfarin [39] and good tolerability in elderly patients [40]. However, because evidence for their use is not as strong as the previous agents, the clinician and patient must weigh the benefits (i.e., no monitoring) and risks (i.e., limited reversal) [13].

Length of Therapy

The standard length of anticoagulation therapy is at least 3–6 months. The decision to extend therapy beyond 3 months is based on balancing the benefits of treatment (i.e., reduction in VTE recurrence based on patient risk factors) and the risks of treatment (i.e., increased bleeding) [35]. Patients with an unprovoked proximal DVT of the leg or PE with low or moderate risk of bleeding in whom this is their first or second VTE, patients with VTE and active cancer, or those with genetic thrombophilias may require anticoagulation longer than 6 months [25, 35]. A 3 month duration should be considered in those with provoked VTE from a transient risk factor (i.e., trauma or immobilization) or those at higher risk for bleeding [35].

Additional Therapy

Daily low-dose aspirin (100 mg) after the initial anticoagulation treatment period may be considered. Pooled results of the recent randomized, multicenter WARFASA and ASPIRE trials showed a 32 % reduction in the rate of recurrence of VTE in patients receiving aspirin following anticoagulation therapy [41]. Use of compression stockings is recommended for 2 years in patients treated for symptomatic DVT to lessen risk for post-thrombotic syndrome [25]. Inferior vena cava filters (IVCs) are reserved for those with PE or proximal DVT and a contraindication to or a complication from anticoagulant treatment, or those with recurrent thromboembolism despite adequate anticoagulation [25].

Prevention

Recognizing those factors that increase one's risk for VTE is essential for prevention. Life-long anticoagulation may be appropriate for those with multiple risk factors. Chapter "► Athletic Injuries" discusses VTE prophylaxis for hospitalized and surgical patients in more detail.

Superficial Thrombophlebitis

Superficial thrombophlebitis often coincides with VTE and risk factors include age over 60, male sex, existing infection, and existing bilateral thrombus [42]. Inflammation and pain along the course of a superficial vein are hallmarks of the condition. Duplex ultrasound is used to confirm the diagnosis as well as rule out associated thrombus. However, a patient who is low risk for DVT and whose thrombophlebitis is not in close proximity to the deep veins may not require ultrasound.

Treatment for thrombophlebitis consists of reduction of inflammation, effectively achieved with oral nonsteroidal anti-inflammatory drugs [43]. Anticoagulation is not standard treatment for thrombophlebitis and should only be initiated if the patient is at increased risk for VTE (venous segment >5 cm, inflammation ≤ 5 cm from the deep veins, medical risk factors).

Peripheral Artery Disease

The prevalence of peripheral artery disease (PAD) increases with age from <5 % before age 60 to over 20 % after age 74 with over 80 % of PAD patients identified as current or former smokers [1]. Coronary artery disease (CAD) and cerebrovascular disease occur two to four times more often in patients with lower extremity PAD compared to those without PAD. The amputation rate in the general PAD population is 1 % or less per year but is significantly more common in current smokers and diabetics (7–15-fold increase). Recent trials have reported a combined rate of myocardial infarction (MI), stroke, and vascular death of 4–6 %, while epidemiological studies report annual mortality of 4–6 %. Therefore, the primary importance in diagnosing PAD lies in its role in identifying patients at risk for CAD morbidity and mortality.

Presentation and Diagnosis

Intermittent claudication, "defined as fatigue, discomfort, or pain that occurs in specific limb muscle groups during effort due to exercise-induced ischemia," is the presenting symptom in 10–35 % of patients. Atypical leg pain (including numbness, tingling, or paresthesia) is the presenting symptom in 40–50 % of cases, although in many of these patients, PAD is an incidental finding and not the cause of their leg pain. When combined with cases found through screening, 20–50 % of patients are asymptomatic from their PAD at the time of diagnosis. Critical limb ischemia (CLI) includes chronic rest pain, ulcers, or gangrene due to occlusive arterial disease. CLI is the presentation in 1–2 % of cases, and after 1 year only 50 % will be alive with both legs (25 % will die and 25 % will have at least one amputation). Signs on physical exam include diminished pulses and bruits. Dependent rubor, early pallor when elevating the limb, reduced capillary refill, hair loss, and muscle wasting are signs of chronic ischemia. Acute limb ischemia may be accompanied by the 5 "Ps": pain, paralysis, paresthesias, pulselessness, and pallor. Arterial ulcerations are typically quite painful unless neuropathy is also present as can occur in diabetes.

A resting ankle-brachial index (ABI) in both legs is recommended for diagnosis of lower extremity PAD and should be reported as follows: normal 1.00 to 1.40, borderline 0.91 to 0.99, or abnormal 0.90 or lower [2]. A toe-brachial index should be used in patients with noncompressible vessels (defined as an ABI greater than 1.40). Further imaging is completed with duplex ultrasound and Doppler color flow (which localizes diseased segments and grades lesion severity), MR angiography (especially good for evaluation of arterial dissection and wall morphology), or CT angiography (when MR is contraindicated). Where noninvasive techniques are inadequate and surgery is indicated, fluoroscopic angiography is the test of choice.

Differential Diagnosis

Atherosclerosis is the most common cause of PAD, just as it is for CAD and stroke. Lower extremity PAD may also be caused by thromboembolism, trauma, vascular inflammation, entrapment syndromes, or congenital abnormalities [1]. The differential considerations for claudication include neurogenic claudication (due to lumbar disk disease, spinal stenosis, or osteophytic changes), osteoarthritis, severe venous obstructive disease, chronic compartment syndrome, and shin splints (in younger persons).

Intervention

Atherosclerotic cardiovascular disease (ASCVD) risk factors, including hyperlipidemia, hypertension, and diabetes, should be managed according to current evidence-based guidelines [2]. Tobacco cessation is essential, and pharmacologic therapies should be combined with behavioral treatment if there are no contraindications. Antiplatelet therapy (aspirin 75–325 mg or clopidogrel 75 mg daily) is recommended for all patients with PAD to decrease the risk of myocardial infarction, ischemic stroke, and vascular

death. Supervised exercise training for a minimum of 30–45 minutes, three times per week for at least 12 weeks, improves intermittent claudication. Cilostazol (100 mg twice per day) is the first-line pharmacologic treatment for claudication in the absence of heart failure (HF). Pentoxifylline (400 mg three times per day) may be used as second-line therapy, but the benefits are likely small and not well established. Oral vasodilator prostaglandins, warfarin anticoagulation, vitamin E, and chelation should not be used to treat PAD. Surgical consultation is indicated for occupation or lifestyle-limiting symptoms where nonsurgical therapy has failed or for signs or symptoms of ischemia at rest.

Pericarditis

Acute pericarditis is an inflammation of the pericardium, the avascular fibrous sac that surrounds the heart. Constrictive pericarditis is a term reserved for post-inflammatory changes affecting the pericardium, resulting in impaired diastolic filling of the heart. Acute pericarditis is relatively common and accounts for 5 % of emergency room admissions for chest pain [3]. Some cases are mild and patients may not present for medical care; others can be life threatening. There are numerous etiologies of pericardial inflammation (Table 1). In developed countries, 80–90 % of cases are idiopathic, as no specific cause is found after routine evaluation. These cases are typically thought to be viral in origin [4]. The remaining cases are most often found to be related to post-cardiac injury syndromes, autoimmune disease, and malignancy. Tuberculosis remains the leading cause of pericardial disease in the developing world.

Table 1 Etiologies of pericarditis

1. Infectious
a. Viral: Coxsackievirus, echovirus, Epstein-Barr virus, cytomegalovirus, adenovirus, parvovirus B19, human herpesvirus 6
b. Bacterial: Tuberculosis, *Coxiella burnetii*, rare other bacteria (pneumococcus, meningococcus, gonococcus, haemophilus, streptococcus, staphylococcus, chlamydia, mycoplasma, legionella, leptospira, listeria)
c. Fungal: Histoplasma (more likely in immunocompetent patients), aspergillus, *Blastomyces*, candida (more likely in immunosuppressed patients)
d. Parasitic: Echinococcus, toxoplasma (overall very rare)
2. Autoimmune
a. Pericardial injury syndromes: Post-myocardial infarction syndrome, post-pericardiotomy syndrome
b. Connective tissue diseases: Systemic lupus erythematosus, Sjögren syndrome, rheumatoid arthritis, systemic sclerosis, systemic vasculitides, Behçet's syndrome, sarcoidosis, amyloidosis
c. Autoimmune diseases: Familial Mediterranean fever, tumor necrosis factor receptor-associated periodic syndrome (TRAPS)
3. Neoplastic
a. Primary tumors: Pericardial mesothelioma (overall rare)
b. Secondary metastatic tumors: Lung cancer, breast cancer, lymphoma
4. Other
a. Trauma: Blunt chest trauma, penetrating thoracic injury, esophageal perforation, radiation
b. Metabolic: Uremia, myxedema (rare)
c. Drugs: Lupus-like syndrome (procainamide, hydralazine, isoniazid, phenytoin), hypersensitivity pericarditis with eosinophilia (penicillins), direct toxic effects (doxorubicin and daunorubicin; often associated with cardiomyopathy)

Source: Little and Freeman 2006 [5]

Presentation and Diagnosis

Patients typically present with chest pain. The pain is often sharp, severe, retrosternal, exacerbated with breathing, and relieved with sitting forward. This pain may mimic other diagnoses. Acute pericarditis is diagnosed if at least two of four key findings are present: chest pain consistent with pericarditis, pericardial friction rub ("Velcro-like" sounds heard best at the apex), typical electrocardiogram (ECG) changes (diffuse upsloping ST elevation with PR depression), or significant pericardial effusion (seen on echocardiogram) [4]. The auscultative and electrographic signs may be transient, and repeated examination may be warranted.

Patients with pericarditis may report a viral prodrome. Many have sinus tachycardia and

low-grade fever. Signs of systemic inflammation commonly arise, such as elevated white blood cell count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). Troponin may be elevated. Rarely, patients will present with cardiac tamponade. These patients complain of chest pain and dyspnea. Exam shows jugular venous distention, muffled heart sounds, hypotension, and a paradoxical pulse.

Once the diagnosis of pericarditis is confirmed, the next step is to search for the cause of inflammation. This can be tailored to the patient's presentation and history, to identify possible treatable or life-threatening etiologies outlined in Table 1. Diagnostic pericardiocentesis is typically done only on large effusions. If the diagnosis is not confirmed, but clinical suspicion remains for pericarditis, routine lab evaluation can be done with frequent reexamination and repeat ECG. At times, CT or MRI is used to show pericardial thickening.

Differential Diagnosis

Differential considerations for acute pericarditis include most cardiac syndromes. This includes acute myocardial infarction (AMI), pulmonary embolus, aortic dissection, cardiac contusion, and myocarditis. Consideration must also be given to the other structures in the thorax, to include mediastinitis, esophageal spasm, esophagitis, gastroesophageal reflux, costochondritis, and pneumonia. The ECG changes of pericarditis may be confused with early repolarization [4]. Often the most difficult distinction to make is between acute pericarditis and AMI. Cardiac catheterization may be performed. There will be a lack of angiographic evidence of CAD in cases of acute pericarditis.

Intervention

Initial management of acute pericarditis focuses on treating the underlying cause, if possible. Otherwise, most idiopathic or viral pericarditis resolves spontaneously or with simple, first-line treatment. Nonsteroidal anti-inflammatory drugs (NSAIDs) and colchicine are the basis of the treatment regimen. Often aspirin is used, especially in post-MI patients, but at higher anti-inflammatory doses (650 mg every 6 h) [5]. Indomethacin (50 mg every 8 h) and ibuprofen (600 mg every 8 h) can also be used. NSAIDs can be discontinued or tapered after 7–10 days if the patient's pain is resolved. Some clinicians use the CRP level to guide discontinuation. A proton-pump inhibitor is often used in conjunction for gastric protection. Within the last decade, colchicine (0.5 mg twice daily if weight >70 kg, once daily if weight <70 kg) has been studied for the treatment of acute pericarditis and found to be effective in decreasing the likelihood of persistent symptoms and the risk of recurrent pericarditis [4]. Colchicine is typically continued for 3 months. Corticosteroids do have strong anti-inflammatory properties, but their use is associated with an increased chance of recurrence. They may be required in refractory cases. Patient's lacking high-risk indicators can be managed in the outpatient setting (Table 2). Bacterial pericarditis, while rare, can be life threatening. In addition to antibiotics, intrapericardial fibrinolysis can be effective to prevent evolution to constrictive pericarditis.

Table 2 Predictors of poor outcome in pericarditis

Fever >38 °C
Symptoms developing over several weeks in association with an immunosuppressed state
Traumatic pericarditis
Pericarditis in a patient receiving oral anticoagulants
Large pericardial effusion (>20 mm echo-free space or evidence of tamponade)
Failure to respond to nonsteroidal anti-inflammatory drugs

Source: Little and Freeman 2006

Adequate treatment of acute pericarditis is important in the prevention of recurrent pericarditis or constrictive pericarditis. If symptoms recur, NSAID therapy should be reinstated. Colchicine should be added if it was not used in the initial case. The most significant complication is constrictive pericarditis [3]. Since diastolic filling of the heart is impaired by a fibrotic pericardium, patients develop symptoms of HF and fluid

overload. If the initial case of acute pericarditis was not recognized, the diagnosis may not be initially clear. At times the constriction is transient, but patients often require pericardiectomy for treatment.

Bacterial Endocarditis

Infectious endocarditis (IE) is an infection of the endocardial surface mainly due to bacteria but rarely may be caused by fungi and protozoa [6]. Bacterial endocarditis (BE) may give rise to the classic though not universally found lesion of IE: the valvular vegetation. These vegetations may interfere with valvular function leading to HF and may embolize to produce a wide variety of focal and systemic signs and symptoms. The overall incidence of infectious endocarditis in the United States is estimated at between 3 and 10 cases per 100,000 patient-years, with a slight male predominance (68 %) and a median age of 58 years [7, 8]. While valvular disease is still a major risk factor, it is now uncommonly due to rheumatic heart disease, having dropped from 50 % of cases to less than 5 % over the last 40 years. Untreated BE is almost uniformly fatal; therefore, if BE is suspected, aggressive evaluation and treatment, to include early surgery in some cases, is essential. In-hospital mortality rates have been stable over the past 25 years at 15–20 % with 1-year mortality of almost 40 %.

Effective management of BE relies on targeting treatment to specific organisms. Gram-positive bacteria (predominantly *streptococci*, *staphylococci*, and *enterococci*) are the most common cause of IE and account for 82–89 % of native valve endocarditis in both intravenous drug users (IVDUs) and non-IVDUs as well as non-valvular intracardiac device infections [7]. Fungal, protozoal, and gram-negative causes increase with prosthetic valve endocarditis (PVE) where gram-positive bacteria are responsible for 74 % of cases. The HACEK group (*Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) occurs in 2 % of cases worldwide but only 0.3 % of cases within North America. BE caused by HACEK most commonly occurs in native valve, non-IVDUs. More than two-thirds of BE in IVDUs is due to *Staphylococcus aureus*. In addition, IVDUs have a very high incidence of right-sided valvular involvement, especially the tricuspid valve which is uncommon in non-IVDUs. Nosocomial BE is most commonly related to indwelling catheters or invasive procedures.

Presentation and Diagnosis

Though the primary lesion in BE is in the heart itself, many of its presenting signs and symptoms reflect the systemic nature of the disease [7]. Fever, myalgias, fatigue, headache, and abdominal pain are common in all types of BE. HF is the most common complication and develops in approximately 30 % of cases. Vegetations can embolize to almost any location, causing distant infection or infarction. Right-sided embolic events may lead to specific complaints of chest pain, cough, and hemoptysis. Left-sided embolic events can present as mental status changes, stroke, myocardial infarction, splenic infarction, and renal abscess. Stroke occurs in approximately 17 % of patients, while non-stroke embolization occurs in 23 % of cases. Other complications of BE include osteomyelitis, septic arthritis, and mycotic aneurysms.

With the exception of Janeway lesions, which occur in only 5 % of cases, few physical findings are highly specific for BE. Likewise, Roth's spots (2 %), Osler's nodes (3 %), splinter hemorrhages (8 %), and splenomegaly (11 %) are relatively uncommon since the diagnosis of IE is now occurring earlier in the clinical course [7, 8]. Cardiac murmurs are most often regurgitant with a new murmur occurring 48 % of the time, and worsening of an old murmur is present in an additional 20 % of cases. With the exception of blood cultures, laboratory evaluation is frequently of less value in making the early diagnosis of BE compared to the history and examination. Antibiotic therapy should not be given prior to blood culture collection, particularly in patients with known valvular heart disease and an unexplained fever

[8, 9]. Antimicrobial therapy can be delayed in patients with a chronic or subacute presentation to allow for the collection of 3 sets of blood cultures from peripheral sites drawn at least 6 h apart from each other. At least 2, but preferably 3, sets of blood cultures separated by 30 min should be obtained from patients who present in severe sepsis or septic shock. A positive rheumatoid factor is present in only 5 % of cases, while an elevated ESR or CRP is present in approximately 60 % [7]. Other laboratory findings and imaging may reflect other complications as mentioned above. Serologies may be needed to determine the cause of infection when blood cultures are negative. ECG may reveal conduction abnormalities, indicating the extension of an aortic valve infection to a valve ring abscess, which carries a worse prognosis [6].

The 1994 Duke criteria were modified in 2000 to redefine "possible IE" (reducing the number of patients in this category) and modify the major and minor criteria (increasing the sensitivity) [10]. The diagnosis of "definite IE" is arrived at either through one of two pathologic criteria or through one of several combinations of major and minor clinical criteria (Table 3). The clinical criteria emphasize two main areas: positive blood cultures and evidence of endocardial involvement (Table 4). The latter clinical criterion takes advantage of both transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE) as a safe yet highly sensitive means for identifying endocardial lesions. Guidance as to when TEE is preferred over TTE has been added to the major criteria definitions.

The Duke criteria have been extensively studied and found to have a sensitivity ranging from 75 % to 100 % while maintaining a specificity of 92–99 % [6, 8, 9]. These criteria have also been validated for both the adult and pediatric populations, as well as special groups such as those with PVE. However, since an adequate amount of clinical data must be collected before the Duke criteria can be applied, early empiric therapy should not be delayed if IE is suspected. In this regard, the criteria are best used to assist in sculpting medical therapy and determining a need for surgical intervention.

Table 3 Definition of infective endocarditis according to the modified Duke criteria, with modifications shown in boldface

Definite infective endocarditis
Pathologic criteria
(1) Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen
(2) Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
Clinical criteria[a]
(1) 2 major criteria
(2) 1 major criterion and 3 minor criteria
(3) 5 minor criteria
Possible infective endocarditis
(1) 1 major criterion and 1 minor criterion
(2) 3 minor criteria
Rejected
(1) Firm alternate diagnosis explaining evidence of infective endocarditis
(2) Resolution of infective endocarditis syndrome with antibiotic therapy for ≤4 days
(3) No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for ≤4 days
(4) Does not meet criteria for possible infective endocarditis, as above

[a]See Table 4 for definitions of major and minor criteria.
Source: Li et al. [10], "Proposed Modifications to the Duke Criteria for the Diagnosis of Infective Endocarditis," *Clinical Infectious Diseases*, 2000; 30:633–8, by permission of the Infectious Diseases Society of America

Differential Diagnosis

Virtually any systemic infection should be considered in the differential diagnosis of IE. These include, but are not limited to, pneumonia, meningitis, pericarditis, abscess, osteomyelitis, tuberculosis, and pyelonephritis. Noninfectious etiologies to be considered include stroke, myocardial infarction, rheumatic fever, vasculitis, malignancy, and fever of unknown origin.

Intervention

Once the diagnosis of IE is suspected, antibiotic therapy should be instituted without delay after

Table 4 Definition of terms used in the modified Duke criteria for the diagnosis of infective endocarditis (IE) with modifications shown in boldface

Major criteria
Positive blood culture for IE
Typical microorganisms consistent with IE from 2 separate blood cultures:
Viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*
Community-acquired enterococci, in the absence of a primary focus
Microorganism consistent with IE from persistently positive blood cultures, defined as follows:
At least 2 positive cultures of blood samples drawn >12 h apart
All of 3 or a majority of ≥4 separate cultures of blood (with first and last drawn at least 1 h apart)
Single positive blood culture for *Coxiella burnetii* or antiphase I IgG titer > 1:800
Evidence of endocardial involvement
Echocardiogram positive for IE **(TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE [paravalvular abscess]; TTE as first test in other patients)**, defined as follows:
Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation
Abscess
New partial dehiscence of prosthetic valve
New valvular regurgitation (worsening or change in preexisting murmur not sufficient)
Minor criteria
Predisposition: Predisposing heart condition or injection drug use
Fever: Temperature >38 °C
Vascular phenomena: Major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhages, conjunctival hemorrhages, and Janeway lesions
Immunologic phenomena: Glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor
Microbiologic evidence: Positive blood culture but does not meet a major criterion as noted above[a] *or* serological evidence of active infection with organism consistent with IE
Echocardiographic minor criteria eliminated

Note: *TEE* transesophageal echocardiography, *TTE* transthoracic echocardiography
[a]Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis
Source: Li et al. [10], "Proposed Modifications to the Duke Criteria for the Diagnosis of Infective Endocarditis," *Clinical Infectious Diseases*, 2000; 30:633–8, by permission of the Infectious Diseases Society of America

blood cultures are obtained [6, 9]. Because bacteria in valvular vegetations are relatively protected from host immune defenses, antibiotics chosen to treat IE must be bactericidal, and regimens for their administration must be aggressive and of adequate duration to completely eradicate the organism and prevent relapse. Empiric therapy should be guided by local resistance patterns, but as a general rule for all native valves and prosthetic valves greater than 12 months after surgery, treatment may begin with ampicillin-sulbactam (3.0 g IV q6h) and gentamicin (1.5 mg/kg IV/IM q12h or 1.0 mg/kg IV/IM q8h). In patients with a β-lactam allergy, vancomycin (15/mg IV q12h) and ciprofloxacin (400 mg IV q12h or 500 mg PO q12h) may replace ampicillin-sulbactam. Empiric therapy for prosthetic valves less than 12 months after surgery may begin with vancomycin (15 mg/kg IV q12h), gentamicin (1.5 mg/kg IV/IM q12h or 1.0 mg/kg IV/IM q8h), and rifampin (600 mg PO q12h). The full course of antibiotics is tailored to culture results with some native valve regimens as short as 2 weeks, while all PVE regimens last a minimum of 6 weeks (Tables 5 and 6).

At least two sets of blood cultures should be collected every 24–48 h until a negative culture is obtained. The first day of therapy for determining the duration of antibiotics is the day when blood cultures were initially negative (if initial cultures

Table 5 Antibiotic regimens for native valve endocarditis

Viridans group streptococci and *Streptococcus bovis* (highly penicillin susceptible: MIC ≤0.12 μg/mL)
Penicillin G IV or ceftriaxone IV/IM for 4 weeks
[Penicillin G IV or ceftriaxone IV/IM] and gentamicin IV/IM for 2 weeks
Vancomycin IV for 4 weeks
Viridans group streptococci and *Streptococcus bovis* (relatively penicillin resistant: MIC >0.12 to ≤0.5 μg/mL)
[Penicillin G IV or ceftriaxone IV/IM] for 4 weeks and gentamicin IV/IM for 2 weeks
Vancomycin IV for 4 weeks
Viridans group streptococci and *Streptococcus bovis* (fully penicillin resistant: MIC >0.5 μg/mL)
Ampicillin IV and gentamicin IV/IM for 4 weeks (symptom duration ≤3 months)
Ampicillin IV and gentamicin IV/IM for 6 weeks (symptom duration >3 months)
Staphylococci (in the absence of prosthetic materials)
Oxacillin susceptible
[Nafcillin IV or Oxacillin IV] ± gentamicin IV/IM for 3–5 days
Cefazolin IV may replace nafcillin/oxacillin in patients with non-anaphylactic penicillin reactions
Penicillin G may replace nafcillin/oxacillin if MIC ≤0.1 μg/mL and does not produce β-lactamase
Vancomycin should be used in patients with immediate-type hypersensitive reactions to β-lactams
Oxacillin resistant
Vancomycin IV for 6 weeks
Enterococcus susceptible to penicillin, vancomycin, and gentamicin or streptomycin
Ampicillin IV for 4 weeks (symptom duration ≤3 months) or for 6 weeks (symptom duration >3 months)
Penicillin G IV and gentamicin IV/IM for 4 weeks (symptom duration ≤3 months)
Penicillin G IV and gentamicin IV/IM for 6 weeks (symptom duration >3 months)
Vancomycin IV and gentamicin IV/IM for 6 weeks
Streptomycin may replace gentamicin if isolate is sensitive to the former and resistant to the latter
Enterococcus resistant to penicillin but susceptible to aminoglycoside and vancomycin
β-lactamase-producing strain
Ampicillin-sulbactam IV and gentamicin IV/IM for 6 weeks (>6 weeks if gentamicin resistant)
Vancomycin IV and gentamicin IV/IM for 6 weeks
Intrinsic penicillin resistance
Vancomycin IV and gentamicin IV/IM for 6 weeks
Enterococcus resistant to penicillin, aminoglycoside, and vancomycin
E. faecium
Linezolid IV/PO for ≥8 weeks
Quinupristin-dalfopristin IV for ≥8 weeks
E. faecalis
Imipenem/cilastatin IV and ampicillin IV for ≥8 weeks
Ceftriaxone IV/IM and ampicillin IV for ≥8 weeks
HACEK group
Ceftriaxone IV/IM for 4 weeks (cefotaxime or another 3rd/4th generation cephalosporin may be used)
Ampicillin-sulbactam IV for 4 weeks
Ciprofloxacin IV/PO for 4 weeks (third-line treatment due to limited published in vivo evidence for IE)
Culture-negative endocarditis
Ampicillin-sulbactam IV and gentamicin IV/IM for 4–6 weeks
Vancomycin IV, gentamicin IV/IM, and ciprofloxacin IV/PO for 4–6 weeks
Bartonella
Suspected (culture negative)
Ceftriaxone IV/IM for 6 weeks and gentamicin IV/IM for 2 weeks ± doxycycline IV/PO for 6 weeks
Documented (culture positive)
Doxycycline IV/PO for 6 weeks and gentamicin IV/IM for 2 weeks
Rifampin IV/PO may replace gentamicin if the latter cannot be used

[a]The 2-week regimen is not appropriate for patients with known abscesses, impaired 8th cranial nerve function, creatinine clearance <20 mL/min, or infected with certain species.

Table 6 Antibiotic regimens for prosthetic valve endocarditis

Viridans group streptococci and *Streptococcus bovis* (penicillin susceptible: MIC ≤0.12 μg/mL)
[Penicillin G IV or ceftriaxone IV/IM] for 6 weeks ± gentamicin IV/IM for 2 weeks
Vancomycin IV for 6 weeks
Viridans group streptococci and *Streptococcus bovis* (penicillin resistant: MIC >0.12 μg/mL)
[Penicillin G IV or ceftriaxone IV/IM] for 6 weeks and gentamicin IV/IM for 6 weeks
Vancomycin IV for 6 weeks
Staphylococci
Oxacillin susceptible
[Nafcillin IV or oxacillin IV] plus rifampin IV/PO for ≥6 weeks and gentamicin IV/IM for 2 weeks
Cefazolin IV may replace nafcillin/oxacillin in patients with non-anaphylactic penicillin reactions
Penicillin G may replace nafcillin/oxacillin if MIC ≤0.1 μg/mL and does not produce β-lactamase
Vancomycin should be used in patients with immediate-type hypersensitive reactions to β-lactams
Oxacillin resistant
Vancomycin IV for ≥6 weeks plus rifampin IV/PO for ≥6 weeks and gentamicin IV/IM for 2 weeks
Enterococcus susceptible to penicillin, vancomycin, and gentamicin or streptomycin
Ampicillin IV for ≥6 weeks
Penicillin G IV and gentamicin IV/IM for ≥6 weeks
Vancomycin IV and gentamicin IV/IM for ≥6 weeks
Streptomycin may replace gentamicin if enterococcus isolate is sensitive to the former and resistant to the latter
Enterococcus resistant to penicillin but susceptible to aminoglycoside and vancomycin
β-lactamase-producing strain
Ampicillin-sulbactam IV and gentamicin IV/IM for 6 weeks (>6 weeks if gentamicin resistant)
Vancomycin IV and gentamicin IV/IM for 6 weeks
Intrinsic penicillin resistance
Vancomycin IV and gentamicin IV/IM for 6 weeks
Enterococcus resistant to penicillin, aminoglycoside, and vancomycin
E. faecium
Linezolid IV/PO for ≥8 weeks
Quinupristin-dalfopristin IV for ≥8 weeks
E. faecalis
Imipenem/cilastatin IV and ampicillin IV for ≥8 weeks
Ceftriaxone IV/IM and ampicillin IV for ≥8 weeks
HACEK group
Ceftriaxone IV/IM for 6 weeks (cefotaxime or another 3rd/4th generation cephalosporin may be used)
Ampicillin-sulbactam IV for 6 weeks
Ciprofloxacin IV/PO for 6 weeks (third-line treatment due to limited published in vivo evidence for IE)
Culture-negative endocarditis
Early (≤1 year after surgery)
Vancomycin IV, cefepime IV, and rifampin IV/PO for 6 weeks plus gentamicin IV/IM for 2 weeks
Late (>1 year after surgery)
Ampicillin-sulbactam IV, gentamicin IV/IM, and rifampin IV/PO for 6 weeks
Vancomycin IV, gentamicin IV/IM, ciprofloxacin IV/PO, and rifampin IV/PO for 6 weeks
Bartonella
Suspected (culture negative)
Ceftriaxone IV/IM for 6 weeks and gentamicin IV/IM for 2 weeks ± doxycycline IV/PO for 6 weeks
Documented (culture positive)
Doxycycline IV/PO for 6 weeks and gentamicin IV/IM for 2 weeks
Rifampin IV/PO may replace gentamicin if the latter cannot be used

Source: Baddour et al. 2005 [6]

were positive). If a native valve is replaced during the initial course of antibiotics, US guidelines recommend changing to regimens recommended for PVE; however, European guidelines recommend continuation of native valve treatment. If the resected tissue is culture positive, then the first day of a complete course for PVE should be the day of surgery (if blood cultures were negative before the operation). If the resected tissue is culture negative, the previously counted days of native valve treatment can be subtracted from the total days needed for PVE treatment. When multiple antibiotics are recommended, they should be given simultaneously or in short succession to maximize pharmacologic synergy.

Careful attention should be given to identifying and treating complications. HF in particular must be treated aggressively, since there is a dramatic worsening of prognosis as HF becomes more severe. Therapy of HF should be initiated with guideline-based treatments, but the timing of surgical intervention should be given particular emphasis as the mortality without surgery when HF is present may exceed 50 %. To that end, early consultation with cardiovascular surgery, infectious disease, and cardiology is warranted for all patients with suspected IE. Nearly 50 % of patients will undergo surgical intervention, and in general, surgery should not be delayed because of active IE [6, 8]. Reinfection of newly implanted valves occurs in 2–3 % of cases; however, surgery is associated with a marked reduction of in-hospital mortality. Indications for surgical intervention are listed in Table 7.

Patients who survive an episode of IE remain at increased risk for recurrent infection for the rest of their life. All patients should undergo a complete dental evaluation for the eradication of sources and education on the need for lifelong follow-up care with a dental professional. IVDUs should be referred to a drug treatment program. At the completion of therapy, all patients should have an echocardiogram repeated in order to establish a new baseline for valvular function and morphology. They should be educated on the signs and symptoms of IE and HF as well as any procedural antibiotic prophylaxis that may be needed in the future. Patients who were exposed to aminoglycosides are at risk for ototoxicity, and *Clostridium difficile* diarrhea may present up to 4 weeks after the last dose of antibiotics. All survivors of IE should have $\geq$3 sets of blood cultures drawn prior to starting antibiotics for a subsequent febrile illness.

Table 7 Indications for surgery in infectious endocarditis (IE)

Early surgery (before completion of antibiotics, during initial hospitalization)
Valve dysfunction causing symptoms of heart failure
Left-sided IE caused by *S. aureus*, fungal, or other highly resistant organisms
New heart block
Annular or aortic abscess
Destructive (valve dehiscence, rupture) or penetrating lesions/fistulas
Persistent bacteremia or fevers for more than 5–7 days after starting appropriate antibiotics
Recurrent emboli and persistent vegetations despite appropriate antibiotic therapy
Native valve endocarditis with mobile vegetations >10 mm in length
Complete removal of pacemaker or defibrillator with proven infection of pocket or leads
Surgery (variable timing)
Prosthetic valve endocarditis with recurrence of bacteremia after complete course of antibiotics and negative blood cultures with no other source of infection
Complete removal of pacemaker or defibrillator when valvular IE is caused by *S. aureus* or fungi
Complete removal of pacemaker or defibrillator when undergoing valve surgery for IE

Prevention

Prevention of IE in those with abnormal valvular architecture is covered in detail in chapter ▶ Medical Care of the Surgical Patient. In those with normal valves, prevention is mainly an issue of education on the avoidance of IV drug use.

Cardiomyopathy

The American Heart Association (AHA) published a scientific statement in 2006 which updated the definition and classification of the cardiomyopathies (CMs) [11]. The primary CMs mainly, or only, involve the heart muscle, while the myocardial dysfunction of the secondary CMs represents just one of the many organs damaged by a systemic disorder. This chapter focuses on the primary CMs which are further subdivided into three categories: genetic, mixed (genetic and non-genetic), and acquired. The AHA definition of the CMs specifically excludes myocardial dysfunction directly caused by other cardiovascular abnormalities such as systemic hypertension, valvular heart disease, congenital heart disease, and ischemia from ASCVD.

Most CMs present with the typical manifestations of either systolic (reduced ejection fraction) or diastolic (preserved ejection fraction) HF [12]. Management of the CMs typically includes early consultation with a cardiologist well versed in the pertinent and complex issues surrounding diagnosis and treatment. Possible treatments include lifestyle changes, pharmacologic modification of the neurohormonal axes which contribute to HF progression (angiotensin-converting enzyme inhibitors [ACE-Is], angiotensin receptor blockers [ARBs], aldosterone antagonists, beta-blockers), invasive electrophysiology (cardiac resynchronization, implanted cardioverter defibrillator [ICD]), arrhythmia suppression (pharmacologic and non-pharmacologic), surgery (septal myomectomy, heart transplantation), and therapies targeted at specific underlying causes (chelation, phlebotomy, bone marrow transplant, etc.).

Hypertrophic Cardiomyopathy (Genetic)

Hypertrophic cardiomyopathy (HCM) is defined as "a disease state characterized by unexplained left ventricular (LV) hypertrophy associated with non-dilated ventricular chambers in the absence of another cardiac or systemic disease that itself would be capable of producing the magnitude of hypertrophy evident in a given patient" [13]. Over 1,400 autosomal dominant mutations have been identified in at least 8 genes that encode sarcomere proteins. HCM is seen throughout the world with a global prevalence of approximately 0.2 % which in the United States represents at least 600,000 individuals.

Presentation and Diagnosis

Most affected individuals likely have a normal life expectancy; however, in those that develop symptoms, HCM manifests in three different patterns which are not mutually exclusive: sudden cardiac death (SCD), atrial fibrillation/stroke, and HF that may progress to end-stage disease. SCD due to ventricular tachyarrhythmia may be the initial presentation of HCM with the highest risk in patients <35 years of age.

Dynamic left ventricular outflow tract (LVOT) obstruction, defined as an outflow gradient ≥ 30 mmHg, is typically caused by a narrowing between the hypertrophied ventricular septum and anterior displacement of the mitral valve during systole. Basal obstruction is present at rest, while labile obstruction is only present when physiologically provoked. LVOT obstruction is increased by activities that increase myocardial contractility (e.g., strenuous exercise) or by maneuvers or agents that decrease afterload (e.g., Valsalva, diuretics). Conversely, obstruction is decreased by agents that decrease myocardial contractility (e.g., beta-blockers) or by maneuvers that increase afterload (e.g., squatting).

In addition to common HF symptoms such as fatigue, dyspnea, and orthopnea, patients with HCM often complain of palpitations (due to atrial fibrillation caused by left atrial enlargement), pre-syncope, and syncope. Since most HCM is nonobstructive (outflow gradient <30 mmHg at rest and with provocation), auscultation generally reveals no murmur. Patients with LVOT often demonstrate a 3–4/6 systolic murmur heard over both the left sternal border (due to outflow obstruction) and the axilla (due to mitral regurgitation). An S_4 is often heard due to increased filling from the enlarged atria. Pulmonary congestion is rare except with severe outflow obstruction or end-stage HCM

(when systolic and diastolic dysfunction become manifest) or with atrial fibrillation. The ECG usually reveals a wide array of nonspecific changes including LV hypertrophy, ST changes, T wave inversion, left atrial enlargement, and Q waves. Twenty-four-hour electrocardiographic monitoring is recommended to identify patients who may be a candidate for an ICD, due to ventricular tachycardia, and also may identify atrial fibrillation or flutter. The chest radiograph is often normal or suggestive of atrial enlargement. TTE with Doppler imaging is essential and may be combined with exercise testing to identify labile obstruction. The transesophageal approach may help define subtle mitral valve abnormalities or guide surgical intervention. Cardiovascular magnetic resonance imaging (CMR) can diagnose HCM in patients where echocardiography is inconclusive or hypertrophy is limited to areas that are poorly visualized on echocardiography, such as the anterolateral wall or apex.

Family history, morphology on imaging, response to a short period of deconditioning, and genetic testing can be used to differentiate between HCM and other conditions with LV hypertrophy including physiologic remodeling ("athlete's heart"), hypertensive heart disease, and metabolic or infiltrative storage diseases. In patients with a confirmed mutation, genetic counseling and testing of first-degree relatives is critical as mutation-positive family members may benefit from early identification and treatment, while mutation-negative family members need no further evaluation.

Intervention

All patients with HCM should be counseled to avoid particularly strenuous activity, avoid certain competitive athletics, undergo risk stratification for SCD, and have comorbid ASCVD risk factors managed according to current guidelines since comorbid coronary disease significantly reduces survival in HCM patients. All asymptomatic patients should receive an annual clinical evaluation. Asymptomatic patients with obstructive physiology should maintain proper hydration while avoiding vasodilators, high-dose diuretics, and environmental situations which may cause vasodilation.

Beta-blockade is the first-line treatment for symptomatic patients since the negative inotropic and chronotropic effects decrease outflow obstruction through increased diastolic filling time and decreased filling pressures. Patients without obstructive physiology who also have a reduced ejection fraction (EF <50 %) should be managed according to the current HF guideline. End-stage HCM may present as a dilated cardiomyopathy. Patients without obstruction who have a preserved EF and remain symptomatic after, or do not tolerate, beta-blockade may be managed with verapamil, diltiazem, diuretics, ACE-I, or ARB.

For symptomatic patients with obstruction, negative inotropic agents other than beta-blockers may be used with caution since the vasodilating properties of verapamil and diltiazem may lead to decreased filling, increased obstruction, and sudden death in patients with severe obstruction. Oral disopyramide may be added to a beta-blocker or verapamil if symptoms persist, but it should not be used as monotherapy. If medical management fails, surgical myectomy by experienced operators achieves technical success in 90–95 % of appropriately selected patients. Alcohol septal ablation can be used in patients who are not candidates for open heart surgery. Dual-chamber pacing may be beneficial in patients >65 years of age; however, the benefits seen in younger patients appear to be due to a placebo effect.

In HCM patients with atrial fibrillation, anticoagulation with a vitamin K antagonist to an international normalized ratio (INR) of 2.0–3.0 is strongly recommended. The novel oral anticoagulants and aspirin have not been studied in patients with HCM. Rate control may be achieved with beta-blockers, verapamil, or diltiazem with AV node ablation and pacemaker placement reserved for failures of medical management. First-line agents for rhythm control include disopyramide (with a rate control agent) or amiodarone, while second-line agents include sotalol, dofetilide, and dronedarone. Radiofrequency ablation and surgical maze procedure remain rhythm control options in refractory cases.

Arrhythmogenic Right Ventricular Cardiomyopathy (Genetic)

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is caused by a progressive replacement of the myocardium by fibrofatty tissue [14]. The disease is more common in men with a prevalence estimated as 1 in 1,000–5,000, and it usually demonstrates autosomal dominant transmission with variable penetrance. Mutations identified to date implicate a degenerative process of the cardiomyocyte involving the intercellular mechanical junction (desmosome). Symptoms may include palpitations (due to ventricular tachycardia [VT] of a left bundle branch block morphology), syncope, or aborted sudden death with initial presentation most likely after puberty but before 60 years of age. Sudden cardiac death occurs with an annual incidence of 0.1–3.0 % in adults, and ventricular fibrillation (VF) can occur at any age.

The diagnosis is challenging and requires a high index of suspicion since there is no single gold standard test. The current highly specific criteria from an expert task force combine the results of multiple tests (echocardiography, endomyocardial biopsy, ECG, Holter, exercise stress) using major and minor factors. Modifications to the criteria for first-degree relatives of affected patients have been proposed to increase sensitivity.

Treatment focuses on the prevention of sudden cardiac death. As with HCM, all affected individuals should limit strenuous activity and competitive athletic participation since this has been shown to increase the risk of life-threatening arrhythmias. Universal pre-participation screening in a region of Italy with a high prevalence of ARVC has reduced the annual incidence of SCD in young competitive athletes from 3.8 to 0.4 per 100,000. Medical therapy with beta-blockers or amiodarone can be used in patients with hemodynamically stable VT, while an ICD should be considered in patients with a history of cardiac arrest, syncope, VF, or hemodynamically unstable VT.

Other Genetic Cardiomyopathies

Other less common genetic cardiomyopathies include left ventricular non-compaction, conduction system disease, and the ion channelopathies (long QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia, short QT syndrome, and idiopathic ventricular fibrillation) [11].

Dilated Cardiomyopathy (Mixed)

Dilated cardiomyopathy (DCM) is characterized by an increase in LV volume with an associated reduction in LVEF that is not caused by another cardiovascular condition [15]. The prevalence in the United States averages 36/100,000 which results in 10,000 deaths per year. Up to 48 % of patients currently diagnosed with idiopathic DCM likely have a familial cardiomyopathy. The DCM phenotype is seen in other primary and secondary cardiomyopathies, particularly in their end stage, but these etiologies are no longer considered primary DCM. Some of the causes previously classified as DCM include myocarditis, infiltrative disease (amyloidosis, sarcoidosis, hemochromatosis), peripartum cardiomyopathy, HIV, connective tissue disease, substance abuse (alcohol, cocaine), and doxorubicin administration [16]. HF caused by ASCVD, valvular heart disease, systemic hypertension, and congenital heart disease may also share the DCM phenotype. While the DCM phenotype as a whole has a poor prognosis, with 25 % mortality at 1 year and 50 % mortality at 5 years, truly idiopathic DCM appears to have a better prognosis than many of the secondary cardiomyopathies with less than 50 % mortality at 10 years.

Patients with DCM often present with generalized symptoms of fatigue and dyspnea worsening over months to years [15]. The classic HF symptoms of orthopnea and paroxysmal nocturnal dyspnea are also common. Physical examination reveals pulmonary and, less often, systemic venous congestion. Laboratory tests are recommended to identify other cardiovascular conditions or systemic diseases which may result

in the DCM phenotype. The ECG may be normal but often shows T wave changes, septal Q waves, atrioventricular conduction abnormalities, and bundle branch blocks. Sinus tachycardia and supraventricular dysrhythmias are common, especially atrial fibrillation, while non-sustained ventricular tachycardia occurs in 20–30 %. Echocardiogram with Doppler imaging is still the first-line test for diagnosis. As in HCM, cardiac MRI provides imaging of the entire myocardium while still assessing valvular regurgitation, dyssynchrony, and even ischemia when combined with late gadolinium contrast. Treatment for DCM should adhere to the current evidence-based guidelines for the management of HF as discussed in chapter ▶ Heart Failure.

Primary Restrictive Nonhypertrophied Cardiomyopathy (Mixed)

Diastolic dysfunction is the hallmark of the restrictive cardiomyopathy (RCM) phenotype; LV size, shape, and systolic function are either normal or nearly so [15]. This phenotype may be seen in both HCM and hypertensive HF as well as many secondary cardiomyopathies. These include infiltrative diseases such as hemochromatosis and amyloidosis (the most common systemic cause of RCM), scleroderma, carcinoid, sarcoidosis, radiation therapy, and anthracycline use. Primary restrictive nonhypertrophied cardiomyopathy, or idiopathic RCM, is the least common etiology and occurs both sporadically and in familial forms [11].

The pathophysiology is characterized by decreased cardiac output, increased jugular venous pressure, and pulmonary congestion [15]. Biatrial enlargement accounts for an increased incidence of atrial fibrillation and frequent thromboembolic events. Both right- and left-sided HF symptoms are common presenting scenarios. Examination reveals increased jugular venous pulse and decreased pulse pressure. An S_3 gallop due to abrupt cessation of early rapid filling is common. Echocardiogram is essential to rule out other causes of the patient's symptoms and to assess filling rates and pressures. The myocardium may also demonstrate patterns on echocardiography that are suggestive of a specific secondary etiology.

Treatment with diuretics is indicated for congestive symptoms and there may be a role for aldosterone antagonists, but caution must be exercised to avoid decreasing preload to the extent that cardiac output is further compromised. Transplantation is considered in refractory cases, and there may be less chance of recurrence with idiopathic RCM compared to the secondary cardiomyopathies.

Myocarditis (Acquired)

Myocarditis is an inflammatory disease of the heart muscle [17]. The gold standard diagnosis is by histologic and immunologic criteria from endomyocardial biopsy (EMB); however, the diagnosis is often made clinically. Due to the discrepancies in diagnosis, the true incidence of myocarditis is difficult to estimate. It affects children and adults, but it is more common in younger patients. Myocarditis may be caused by infections (most commonly viral), autoimmune disease, medications, and toxins (Table 8). Within the last 5 years, parvovirus B19 has eclipsed coxsackievirus as the most common etiology [18].

The inflammation of myocarditis is first caused by either direct microbial damage or toxic damage [19]. Myocyte death causes the release of cytokines and activation of the immune system. This exposes antigens that are normally hidden from the immune system which induces both a cellular and humoral immune response. This immune response may resolve, as in acute myocarditis, or persist and result in chronic myocarditis. Ongoing destruction and remodeling of the myocardial tissue will eventually lead to the DCM phenotype.

Presentation and Diagnosis

Some patients have minimal symptoms and may never present to a clinician, while others have a severe course of illness and develop severe, life-threatening symptoms. The European Society of Cardiology has described four main presentations of significant acute myocarditis (Table 9).

Table 8 Etiologies of myocarditis

1. Infection		
Bacteria	Staphylococcus, streptococcus, pneumococcus, meningococcus, gonococcus, salmonella, *Corynebacterium diphtheriae*, *Haemophilus influenza*, mycobacterium, *Mycoplasma pneumonia*, brucella	Diphtheria is a common cause in areas without adequate vaccination
Spirochetes and rickettsia	Borrelia (Lyme disease), leptospira, *Coxiella burnetii* (Q fever), *Rickettsia rickettsii* (Rocky Mountain spotted fever), *Orientia tsutsugamushi* (scrub typhus)	Patients with Lyme myocarditis can be co-infected with *Ehrlichia* or babesia
Fungi	Aspergillus, actinomyces, *Blastomyces*, candida, *Coccidioides*, cryptococcus, histoplasma, mucormycoses, nocardia, sporothrix	
Protozoans and parasites	*Trypanosoma cruzi*, *Toxoplasma gondii*, *Entamoeba*, leishmania, *Trichinella spiralis*, *Echinococcus granulosus*, *Taenia solium*	*Trypanosoma cruzi* (Chagas disease) is a common cause in Central and South America, may also have bundle branch block
Viruses	RNA viruses: Coxsackieviruses A and B, echoviruses, polioviruses, influenza A and B viruses, respiratory syncytial virus, mumps virus, measles virus, rubella virus, hepatitis B virus, dengue virus, yellow fever virus, chikungunya virus, Junin virus, Lassa fever virus, rabies virus, human immunodeficiency virus-1 (HIV)	Viral myocarditis is the most common cause in the developed world Myocarditis is found in autopsies of more than 50 % of patients with HIV (may also be due to antiviral medications)
	DNA viruses: Adenovirus, parvovirus B19, cytomegalovirus, human herpesvirus 6, Epstein-Barr virus, varicella zoster virus, herpes simplex virus, variola virus, vaccinia virus	
2. Autoimmune/immune-mediated disease		
Allergens	Tetanus toxoid, vaccines, serum sickness	
	Drugs: Penicillin, cefaclor, colchicine, furosemide, isoniazid, lidocaine, tetracycline, sulfonamides, phenytoin, phenylbutazone, methyldopa, thiazides, amitriptyline	Drug-induced hypersensitivity can improve after withdrawal of the drug; steroid treatment may be required
Alloantigens	Heart transplant rejection	
Autoantigens	Infection-negative lymphocytic myocarditis, infection-negative giant cell myocarditis	Considered idiopathic if no viruses are found on EMB
	Associated with autoimmune or immune-oriented disorders: systemic lupus erythematosus, rheumatoid arthritis, Churg-Strauss syndrome, Kawasaki disease, inflammatory bowel disease, scleroderma, polymyositis, myasthenia gravis, insulin-dependent diabetes mellitus, thyrotoxicosis, sarcoidosis, Wegener's granulomatosis, rheumatic heart disease (rheumatic fever)	Cardiac sarcoidosis (idiopathic granulomatous myocarditis) must have negative stains for infectious causes for diagnosis
3. Toxins		
Drugs	Amphetamines, anthracyclines, cocaine, cyclophosphamide, ethanol, fluorouracil, lithium, catecholamines, hemetine, interleukin 2, trastuzumab, clozapine	
Heavy metals	Copper, iron, lead	
Physical agents	Radiation, electric shock	
Misc.	Scorpion sting, snake and spider bites, bee and wasp stings, carbon monoxide, inhalants, phosphorus, arsenic, sodium azide, pheochromocytoma, beriberi	

Note: *RNA* ribonucleic acid, *DNA* deoxyribonucleic acid
Source: Caforio et al. 2013 [19], Cooper 2009 [18]

Table 9 Clinical presentation of patients with myocarditis

Clinical presentation	Diagnostic and clinical findings	Length of illness
Chest pain similar to acute MI	ST/T wave changes (ST segment elevation or depression, T wave inversion), elevated troponin (may have time course similar to acute MI or may be elevated for a prolonged period of time), no angiographic evidence of coronary artery disease	Several hours or days
New onset or worsening heart failure	Absence of CAD, no known cause of heart failure, impaired systolic function (LV or RV) seen on echocardiogram, nonspecific ECG signs, bundle branch block, AV block, and/or ventricular arrhythmias	2 weeks to 3 months
Chronic heart failure with symptoms and recurrent exacerbations	Absence of CAD, no known cause of heart failure, impaired systolic function (LV or RV) seen on echocardiogram suggestive of dilated cardiomyopathy or nonischemic cardiomyopathy, nonspecific ECG signs (see point 2 above)	More than 3 months
"Life-threatening condition" in the absence of CAD and known heart failure	Life-threatening arrhythmias and aborted sudden death, cardiogenic shock, *or* severely impaired LV function	Any duration

Note: *CAD* coronary artery disease, *LV* left ventricle, *RV* right ventricle, *ECG* electrocardiogram
Source: Caforio et al. 2013 [19], Cooper 2009 [18]

The most common presenting symptom is dyspnea, but patients will frequently report chest pain or palpitations. Because myocarditis is often caused by viral infection, the patient may report respiratory or gastrointestinal illness 1–4 weeks before symptom onset. Myocarditis should be considered as a possible diagnosis for patients presenting with any cardiac syndrome [18]. These include AMI, HF, pericarditis, arrhythmias, heart block, and SCD. Myocarditis must be excluded in a suspected case of sudden infant death syndrome. The evaluation is complicated by the fact that all of these conditions may coexist with myocarditis.

All patients suspected to have myocarditis should first be evaluated with ECG and echocardiogram. The findings of these studies in myocarditis are variable as described in Table 9. Troponin, ESR, and CRP are often elevated and should be measured. Routine viral serology is not recommended. If the initial evaluation of the patient still indicates myocarditis is likely, the patient should be managed in a center capable of hemodynamic monitoring, cardiac catheterization, and EMB. Patients will frequently require cardiac catheterization to rule out acute coronary syndrome (ACS) as the cause for their symptoms, as there is significant overlap in presentation. CMR is being used more frequently in the evaluation of myocarditis, but current evidence does not justify using it for definitive diagnosis. EMB is safe when done by an experienced clinician and can guide specific therapies.

Intervention

If the patient is hemodynamically unstable, they must be stabilized for transfer to the appropriate care team and intensive care initiated. Ventricular assist devices or extracorporeal membrane oxygenation may be used, often as a bridge to transplant. Stable patients may decompensate quickly, so at a minimum, they should be hospitalized for initial evaluation and observation [19]. All patients with HF should be treated according to current guidelines which include diuretics, beta-blockers, and ACE-I or ARB. Arrhythmias should also be managed according to current guidelines. Digoxin is not recommended as animal studies have shown that it may increase myocardial injury [17]. Temporary pacing may be required if complete heart block is present. ICDs are often not indicated until the acute phase of myocarditis has subsided, as the arrhythmia may also subside. All patients with myocarditis should avoid NSAIDs, as they increase mortality [18]. Exercise should be

avoided for several months. There are no specific preventive measures for myocarditis.

Specific therapies may be indicated in certain cases, especially if an etiology is found on EMB. Antiviral treatment with ribavirin and interferon alfa has shown some benefit; however, it is most helpful early in the course of the viral illness, and myocarditis is often diagnosed too late. Interferon beta has been shown to be effective in some chronic cases. Intravenous immunoglobulin is often used, particularly in pediatric cases; however, the overall data supporting its use is inconclusive, especially for adults. Immunosuppressive therapy can play a role in some cases, especially giant cell myocarditis and chronic myocarditis with DCM unresponsive to traditional treatment. Immunosuppressive agents include cyclosporine, azathioprine, and prednisone.

Stress ("Takotsubo") Cardiomyopathy (Acquired)

Stress cardiomyopathy, first described in Japan, is characterized by apical ballooning that resembles an octopus trap (a takotsubo) which is triggered by acute physical or psychological stress [15]. It is more common in postmenopausal women with a presentation that mimics ACS, often with ST elevation and elevated cardiac enzymes, and is seen in 1–2 % of patients undergoing angiography for ACS. Subsequent studies demonstrate no evidence of ischemia, and the diagnosis is confirmed by the resolution of LV dysfunction within days to weeks after initial presentation.

Peripartum Cardiomyopathy (Acquired)

Peripartum cardiomyopathy (PPCM) shares the DCM phenotype and develops within the last trimester of pregnancy or first 5 months postpartum with an incidence of 1 in 1,300–4,000 live births [20]. Risk factors include multiparity, advanced maternal age, long-term tocolysis, and African descent. It is a diagnosis of exclusion that requires no identifiable cause of HF and no history of heart disease prior to diagnosis. Many patients experience spontaneous recovery in the first 6 months after diagnosis and have an excellent prognosis; however, if cardiomegaly persists past 4–6 months, mortality increases to 50 % at 6 years. PPCM can recur in subsequent pregnancies with the highest risk in patients whose LVEF has not normalized. Anticoagulation is particularly important due to a high rate of venous thromboembolism.

Tachycardia-Induced Cardiomyopathy (Acquired)

The severity of tachycardia-induced cardiomyopathy is correlated with the duration and rate of the inciting tachycardia [20]. Any ventricular tachycardia, frequent premature ventricular complexes, or supraventricular tachycardia with rapid ventricular response may induce this largely reversible cardiomyopathy. Treatment is directed at correcting the causative tachycardia, and subsequent improvement of the cardiomyopathy, while not guaranteed, is expected.

Pulmonary Hypertension and Cor Pulmonale

Pulmonary hypertension (PH) is a complex disease with multiple etiologies. Regardless of the underlying cause, it is defined by a mean pulmonary artery pressure >25 mmHg at rest measured by right heart catheterization (RHC) [21]. The World Health Organization (WHO) classifies PH into five groups which were updated in 2013 (Table 10). All etiologies of PH are felt to have one or more underlying pathophysiologic mechanisms: vascular injury, an alteration in the balance of vasodilatation and vasoconstriction, and thrombotic changes in the pulmonary vasculature. Rarely, PH can be familial, and 70 % of these cases have been associated with mutations of the BMPR2 gene [22]. The right ventricle (RV) is a low-pressure chamber with thin walls, as it normally pumps against the low resistance of the pulmonary vascular bed [23]. With the increased

Table 10 Classification and epidemiology of pulmonary hypertension (PH)

WHO classification		Associated diseases	% of all PH cases	Others
Group 1	Pulmonary arterial hypertension (PAH)	Idiopathic (IPAH), familial, "associated with" (connective tissue disorder, congenital systemic-to-pulmonary shunts, portal hypertension, HIV infections, drugs and toxins), persistent pulmonary hypertension of the newborn, others	4.2 %	PAH 15 cases/million adult population IPAH 5.9 cases/ million adult population
Group 2	Pulmonary hypertension with left heart disease	Left-sided atrial or ventricular heart disease, left-sided valvular heart disease	78.7 %	Up to 60 % of with severe LV systolic dysfunction have PH Almost all patients with symptomatic mitral valve disease have PH
Group 3	Pulmonary hypertension associated with lung diseases and/or hypoxemia	Chronic obstructive pulmonary disease (COPD), interstitial lung disease, sleep-disordered breathing, alveolar hypoventilation disorders, chronic exposure to high altitude, developmental abnormalities	9.7 %	More than 50 % of patients with advanced COPD have PH
Group 4	Pulmonary hypertension due to chronic thrombotic and/or embolic disease	Proximal pulmonary arteries, distal pulmonary arteries, non-thrombotic pulmonary embolism (tumor, parasites, foreign material)	0.6 %	Incidence is 0.5–2 % of survivors of acute pulmonary embolism
Group 5	Miscellaneous	Sarcoid, histiocytosis X, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)	6.8 %	These cases cannot otherwise be classified

Note: *LV* left ventricle, *HIV* human immunodeficiency virus
Source: Galiè et al. 2009 [22] and McLaughlin et al. 2009 [24]

resistance of PH, the RV can hypertrophy and/or dilate, causing right ventricular failure (RVF). While RVF can result from any type of PH, the term "cor pulmonale" has historically been used to describe RVF secondary to diseases affecting the function or structure of the lungs, which would imply WHO group 3 disease.

Presentation and Diagnosis

The presentation of PH is very nonspecific, so the physician's challenge is to be aware of the risk factors for PH and to have an appropriate index of suspicion. The goal of the evaluation and early consultation is to identify an underlying cause, prognosis, and treatment options. The most common presenting symptoms include dyspnea (initially only with exertion), fatigue, chest pain, pre-syncope/syncope, lower extremity edema, and palpitations. Physical exam may be benign at first. With more severe PH, one may appreciate an S_3, the holosystolic murmur of tricuspid regurgitation, or the early diastolic murmur of pulmonic regurgitation. As PH progresses, signs of RVF may develop with increased jugular venous distention, RV heave, and a prominent P2. Significant RVF may be evidenced by an S_4, peripheral edema, hepatomegaly, and ascites.

If a patient has signs, symptoms, or history suggestive of PH, TTE is the next step [21]. If there is evidence of PH, the most common causes

of PH should be considered first (left heart disease, lung disease, and hypoxia; group 2 and 3 disease). A focused evaluation can include further history taking, ECG, x-ray, pulmonary function tests, blood gas analysis, polysomnography, and high-resolution computed tomography. Chest radiograph may show increased hilar structures and enlarged RV and right atrium. ECG usually reveals normal sinus rhythm with right chamber enlargement and a strain pattern. If the diagnosis of heart or lung disease is confirmed, and there are no signs of severe PH or RVF, the physician can continue with appropriate care for the underlying disease. If severe PH or RVF is present, the patient should be referred to a PH expert center for further investigation, including RHC. If heart or lung disease is not evident, the next step is to search for chronic thromboembolic pulmonary hypertension (CTEPH, group 4) with V/Q scintigraphy. This should be done even if the patient does not have a known history of pulmonary embolism as CT pulmonary angiography may not be sensitive enough to confidently rule out group 4 disease [25]. Patients with CTEPH will also require referral and RHC. If this evaluation does not elucidate a cause of PH, broad work-up for pulmonary arterial hypertension (PAH, group 1) and miscellaneous other causes (group 5) is needed at a PH referral center.

Differential Diagnosis

CAD and cardiomyopathies leading to RVF may present with the same symptoms and signs as PH. The nonspecific presentation of the disease often results in significant diagnostic delays.

Intervention

Treatment of PH focuses on management of the underlying disease process [25]. All patients should use supplemental oxygen as needed to keep oxygen saturation $\geq$90 % during rest, exercise, and sleep. If patients have RVF, it should be treated appropriately, typically with diuretics and salt restriction. Patients with CTEPH require long-term anticoagulation. These patients may also require pulmonary thromboendarterectomy, which can be curative. Pulmonary rehabilitation may be valuable for some patients to counter deconditioning. Patients should remain active and exercise but avoid isometric exercises which can increase risk of syncope. Female patients should be counseled to avoid pregnancy, a high-flow state that can worsen symptoms.

Several specific therapies exist for patients with PAH (WHO group 1). Vasodilator response testing should be completed during RHC to identify appropriate candidates since an empiric trial of therapy in a nonresponder can have negative hemodynamic outcomes. Pharmacologic options include calcium channel blockers, prostacyclin derivatives, endothelin receptor antagonists, and phosphodiesterase-5 inhibitors. These group 1-specific drugs are typically not used for group 2–5 disease and may worsen outcomes in those patients. The choice of agent is based on severity of disease; oral medicines are used in lower risk patients, while parenteral therapies are reserved for higher risk patients. The 6 min. walk test or graded treadmill test can be used for risk stratification. The presence of RVF is a poor prognostic factor [23]. Patients with group 1 disease may also benefit from anticoagulation, typically with warfarin to an INR of 1.5–2.5. Lung transplantation may be considered in patients with group 1 disease who fail medical therapy and in group 3 patients who progress to end-stage lung disease.

Obstructive Airway Disease

Aarti Aggarwal and Chidinma Osineme

Contents

Chronic Cough

Cough is the often presenting feature of several non-life-threatening and life-threatening conditions, including obstructive airway disease. It is a vital reflex of the respiratory tract to clear the upper airways. Suppression of this reflex may lead to retention of airway secretions and respiratory infections [1]. A thorough medical history is important to denote whether a cough is acute (<3 weeks), subacute (3–8 weeks), or chronic (>8 weeks). This chapter will focus only on chronic cough.

Chronic cough can present difficulty in diagnosis and result in complications such as vomiting, rib fractures, urinary incontinence, syncope, muscle pain, fatigue, and depression [1]. The most common causes of chronic cough with normal chest radiograph in descending order, include upper airway cough syndrome (UACS) or formerly known as postnasal drip syndrome, chronic obstructive pulmonary disease (COPD), asthma and gastro-esophageal reflux disease (GERD), cigarette smoking or second hand exposure, and ACE-inhibitor use [1, 2]. These causes may occur alone or in combination. The diagnostic goal is to exclude serious conditions that present with chronic cough.

Cough is the primary feature of chronic cough. It is important to note the time of day the cough is most prominent, associated sputum production, as

well as signs of drainage in the posterior pharynx, throat clearing, nasal discharge, cobblestone appearance of the oropharyngeal mucosa, and mucus in the oropharynx are relatively sensitive findings but are nonspecific for UACS [3]. If associated with heartburn, water brash, and belching and/or globus sensation most likely GERD is the cause. It is important to understand that cough alone can still be the only presenting feature of UACS, GERD, or cough variant asthma. Certainly, if the patient is taking an ACE-inhibitor, it may need to be discontinued as it is a possible cause of chronic cough.

After completion of a thorough history and physical examination, it may be helpful to obtain a chest radiograph and pulmonary function testing, bronchial provocation challenge, and sputum eosinophilia. Further investigation may be warranted and can include 24 h esophageal pH monitoring, upper endoscopy or video fluroscopic swallow evaluation, barium esophagram, sinus imaging, high resonance CT scan, bronchoscopy, echocardiogram, and environmental assessment [4].

Chronic cough can be multifactorial. If a patient has limited response to monotherapy, it is important to consider a treatment plan that addresses multiple etiologies. See Fig. 1.

Asthma

Asthma, one cause of ongoing cough, is a common respiratory disorder, characterized by periods of reversible airflow obstruction, inflammation, and hyperresponsiveness of the airways. Unfortunately, in the last 10 years, the number of persons with asthma in the USA has increased by 28 % [2]. Approximately, 39.5 million people, including 10.5 million children, in the USA have been affected by asthma. In 2010, asthma accounted for 3,404 deaths, 439,400 hospitalizations, 1.8 million emergency department (ED) visits, and 14.2 million physician office visits [5, 6].

Asthma exacerbations are triggered by multiple factors including exercise, airway infections, airborne allergens (e.g., pollen, mold, animal

Table 1 Commonly used FDA approved drugs for COPD

Drug name	Drug class	Delivery device	Usual adult dosage
Ipratropium (Atrovent)	Short-acting anticholinergic	MDI/ nebulizer	Two inhalations QID prn/500 mcg QID prn
Albuterol	SABA	MDI/ nebulizer	
Albuterol/Ipratropium (Combivent/duoneb)	Combined SABA and SAAC	MDI/ nebulizer	Two inhalations QID prn 2.5 mg/.5 mg QID prn

dander, dust mites), occupational exposures, and air pollution (e.g., environmental tobacco smoke, particulate matter, and volatile organic compounds) [7, 8]. Although there is no cure, asthma can be controlled with appropriate medical therapies by avoidance of environmental exposures, particularly environmental exposures that may trigger an attack [7].

Common symptoms of asthma are wheezing, coughing, shortness of breath, and chest tightness or pain. Asthma attacks may be classified as mild, moderate, or severe enough to become life-threatening events [4]. The physical signs may be wheezing, rhonchi, or course breath sounds on auscultation. In addition, the patient may appear in respiratory distress with signs of accessory muscle usage, nasal flaring or grunting (in children), and altered mental status. Children may present will nocturnal cough only, while geriatric patients may present with chronic cough in absence of wheezing. In cases when wheezing occurs with exercise alone, the diagnosis of exercise-induced asthma (EIB) should be considered (Table 1).

Asthma is diagnosed on spirometry by observing a change in FEV_1 following bronchodilator administration. An increase of more than 12 % in patients 5–18 years of age, or more than 12 % and more than 200 mL in adults confirms the diagnosis of asthma. Although no single parameter has been identified to assess exacerbation severity, lung function is a useful method of assessment, with a PEF of 40 % or less of predicted function indicating a severe attack in patients 5 years or older [4].

If both the FEV_1/FVC ratio and the FVC are low, the patient has a mixed defect. Alternatively, a restrictive pattern is indicated by an FVC below the fifth percentile based on NHANES III data in adults, or less than 80 % in patients 5–18 years of age. If a restrictive pattern is detected, a consideration for pulmonary referral should be made for further evaluation and treatment.

Asthma exacerbation is defined as an increase in wheezing with or without hypoxia. If hypoxemia is present despite initial bronchodilator therapy, hospitalization should be considered. Management of asthma exacerbation is very similar to COPD exacerbation management with the exception of antibiotic therapy if no clear diagnosis of a bacterial infection is found. See Fig. 2.

In order to determine appropriate medical therapy, it is important to assess asthma severity. This can be done during an office visit by either

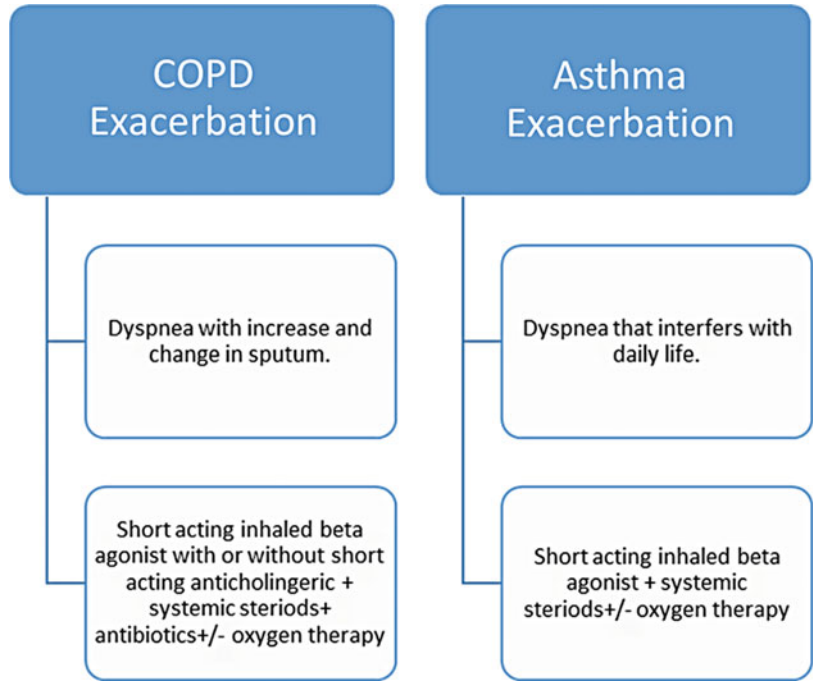

Fig. 2 Recommended treatment plan for asthma and COPD exacerbation

assessing symptoms through asthma assessment tools (ACT, ACQ, or ATAQ) or performing a peak expiratory flow (PEF) rate. There are well-validated questionnaires such as the asthma control test (ACT), asthma control questionnaire (ACQ), or asthma therapy assessment questionnaire (ATAQ) tools that can assist in assessment of asthma severity [4]. A PEF of 80 % or more of predicted or personal best categorizes patients' asthma as well controlled; however, less than 60 % of predicted or personal best indicates very poor control. Either technique has similar benefits in determining asthma control.

Asthma should be reassessed frequently if stepping up therapy or deescalating therapy.

The asthma severity determines the optimal initial therapy regimen (Tables 2 and 3). Close follow-up is warranted to reassess response to treatment and need for additional step up in therapy (Fig. 3). Treating more aggressively to obtain rapid control and then deescalating therapy to a maintenance regimen may be a more optimal approach. All patients regardless of severity should be provided a short-acting beta agonist. The use of a spacer with administration of metered-dose inhaler promotes drug distribution and effectiveness.

Arterial blood gas (ABG) is helpful in the inpatient setting when a patient has an exacerbation of asthma and is associated with moderate to severe hypoxia due to hypoventilation. If severe hypoxemia or hypercapnia is detected on ABG, it indicates the need for assisted ventilator support.

Certainly if avoidance is not helpful, there may be a role for antihistamines and nasal sprays. Consideration of a referral to an allergist may be helpful if allergy desensitization may be helpful for patients with severe asthma.

COPD

Often, the diagnosis of COPD is evident based on patient's history and physical examination alone. Any patient who has chronic dyspnea, cough, or sputum production along with a history of smoking exposure should be evaluated for COPD. However, pulmonary function test (PFT) is required to make a diagnosis of COPD [11]. Chronic obstructive pulmonary disease

Table 2 Stepwise approach for managing asthma for patients >12 years [9]

	Intermittent asthma	Persistent asthma (increasing severity of disease)				
		Mild ◄				► Severe
Preferred treatment	SABA as needed	Low-dose ICS	Low-dose ICS + LABA OR medium-dose ICS	Medium-dose ICS + LABA	High-dose ICS + LABA **AND** consider omalizumab for patients who have allergies	High-dose ICS + LABA + oral corticosteroid AND consider omalizumab for patients who have allergies
Alternative treatment		Cromolyn, LTRA, or theophylline	Low-dose ICS + either LTRA, theophylline or zileuton	Medium-dose ICS + either LTRA, theophylline or zileuton		
		Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma				

(COPD) is a major cause of morbidity and mortality in the USA and worldwide. Though it is one of the most preventable diseases, it affects more than 5 % of the US adults, and it is the third leading cause of death [9]. It is characterized by persistent airflow obstruction that is usually progressive and is not fully reversible. Cigarette smoking is the leading cause of COPD. However, long-term exposure to other irritants such as air pollution, chemical fumes, and household smoke can also contribute to COPD. Also, according to the WHO, passive smoking carries serious risks, especially for children and those chronically exposed [10]. The other rare cause of COPD is a genetic factor that causes deficiency of alpha-1 antitrypsin deficiency. If patient presents with COPD symptoms before the age of 40, consideration should be made to screen for alpha-1 antitrypsin deficiency.

The most common presenting symptoms of COPD include chronic cough, dyspnea that worsens on exertion, and chronic sputum production. COPD can remain unrecognized for number of years given its slowly progressive nature.

On physical examination, patients may have wheezing, decreased breath sounds on auscultation, or have completely normal exam. Since smoking is the most common cause of COPD, it is not uncommon that patients may appear older than stated age. During severe exacerbations, the patient may have labored breathing, appear altered in regards to mental status, and be acutely hypoxic.

Pulmonary Function Testing and Spirometry

Most helpful informations of the PFT are the forced expiratory volume in 1 s (FEV_1), forced vital capacity (FVC), the FEV_1/FCV ratio, and the peak expiratory flow rate (PEFR). The postbronchodilator $FEV_1/FVC < 0.70$ or below the fifth percentile, based on data from the Third National Health and Nutrition Examination Survey (NHANES III) in adults, and less than 85 % in patients 5–18 years of age establishes the diagnosis. Severity of disease is further based on FEV_1 (Table 1 in chapter "► Population Based Health Care").

Patients should be routinely assessed in the clinic about their symptoms of COPD through the use of the COPD assessment test (CAT) and modified British Medical Research Council questionnaire (mMRC) score [12]. This helps to classify patients into four groups: group A (less symptoms, low risk), group B (more symptoms, less risk), group C (less symptoms, high risk), and group D (more symptoms, high risk) [11].

Laboratory and Imaging

Even though no lab is needed for diagnosis of COPD, different lab tests are sometimes ordered depending on the degree of suspicion for alternative diagnosis. For instance, CBC can be done for assessment of anemia as it can also present with dyspnea. Other labs that can be done depending on suspicion of other diagnosis may include

Table 3 Common FDA approved asthma controller medications for patients >12 years

Medication/formulations	Recommended dosing	Indications
Combined medication (inhaled corticosteroid + long-acting beta-2 agonist) Fluticasone/Salmeterol (Advair): DPI 100 mcg/50 mcg, 250 mcg/50 mcg, or 500 mcg/50 mcg MDI 45 mcg/21 mcg, 115 mcg/21 mcg, or 230 mcg/21 mcg	1 inhalation 2×/day; dose depends on level of severity or control	LABAs are used in combination with ICSs for long-term control and prevention of symptoms
Budesonide/Formoterol (Symbicort): MDI 80 mcg/4.5 mcg or 160 mcg/4.5 mcg	2 puffs 2×/day; dose depends on level of severity or control	
Mometasone/Formoterol (Dulera): MDI 100 mcg/5 mcg, 200 mcg/5 mcg	2 inhalations 2×/day; dose depends on severity of asthma	
Leukotriene Receptor Antagonists (LTRAs) Montelukast: (Singular) 4 mg or 5 mg chewable tablet, 4 mg granule packets, 10 mg tablet	10 mg every night at bedtime	Alternative therapy for treatment of patients with mild persistent asthma used as adjunctive therapy with ICSs, LTRAs can attenuate EIB. Monitor liver function
Leukotriene Modifiers Zafirlukast (Accolate): 10 mg or 20 mg tablet Take at least 1 h before or 2 h after a meal	40 mg daily (20 mg tablet 2×/day)	
5-Lipoxygenase Inhibitor Zileuton (Zyflo): 600 mg tablet	2,400 mg daily (give 1 tablet 4×/day)	
Immunomodulators Omalizumab (Xolair): Subcutaneous injection, 150 mg/1.2 mL following reconstitution with 1.4 mL sterile water for injection	150–375 mg subcutaneous every 2–4 weeks, depending on body weight and pretreatment serum IgE level	Adjunctive therapy for patients who have sensitivity to relevant allergens (e.g., dust mite, cockroach, cat, or dog). Monitor patients after injections; be prepared to treat anaphylaxis
Cromolyn (Intal) nebulizer: 20 mg/ampule	1 ampule 4×/day	They are used as alternative Medication They also can be used as preventive treatment before exercise or unavoidable exposure to known allergens
Methylxanthines Theophylline (Elixophyllin, Theo-24, Uniphyl): Liquids, sustained-release tablets, and capsules	Starting dose 10 mg/kg/day up to 300 mg maximum; usual maximum: 800 mg/day	Mild to moderate bronchodilator used as alternative, not preferred, or as adjunctive therapy with ICS. Theophylline may have mild anti-inflammatory effects. Monitoring of serum concentration is essential
Inhaled long-acting beta-2agonists (LABAs) Salmeterol (Serevent): DPI 50 mcg/blister	1 blister every 12 h	LABAs are not to be used as monotherapy for long-term control of asthma The preferred therapy to combine with ICS may be used before exercise to prevent EIB, but duration of action should not exceed 5 h with chronic, regular use

(*continued*)

Table 3 (continued)

Medication/formulations	Recommended dosing	Indications
Formoterol (Foradil Aerolizer): DPI 12 mcg/single-use capsule	1 capsule every 12 h	Anti-inflammatory medications that reduce airway hyperresponsiveness, inhibit inflammatory cell migration and activation, and block late phase reaction to allergen. Effective long-term control medication at all steps of care for persistent asthma. Reduce impairment and risk of exacerbations, but ICSs do not appear to alter the progression or underlying severity of the disease in children
Oral systemic corticosteroids Prednisone: 1, 2.5, 5, 10, 20, 50 mg tablets; 5 mg/cc, 5 mg/5 cc	40–60 mg/day as single or 2 divided doses for 3–10 days (1 mg/kg/day)	Used to gain prompt control of asthma during an acute exacerbation

Abbreviations: *DPI* dry powder inhaler, *IgE* immunoglobulin E, *MDI* metered-dose inhaler, *N/A* not available (not approved, no data available, or safety and efficacy not established for this age group) [10]

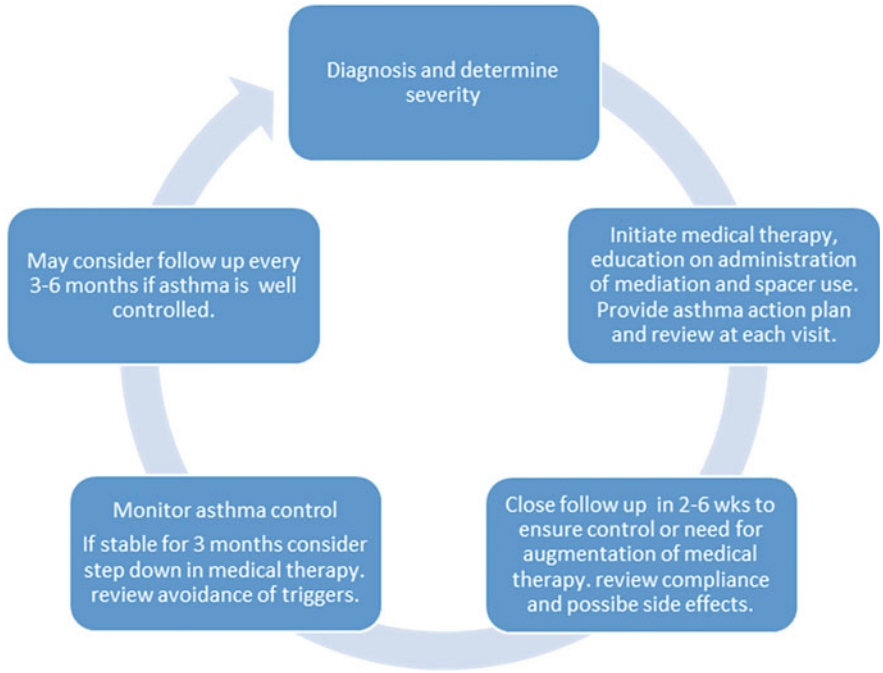

Fig. 3 Maintaining asthma control [9]

plasma BNP for heart failure and urea nitrogen/creatinine for underlying kidney disease. An elevated serum bicarbonate may indirectly suggest chronic hypercapnia [13]. Arterial blood gas (ABG) is helpful in the inpatient setting when a patient has an exacerbation of COPD and is associated with moderate to severe hypoxia due to hypoventilation. If severe hypoxemia or hypercapnia is detected on ABG, it indicates the need for assisted ventilator support.

Though chest radiography or any other imaging is not indicated in diagnosis of COPD, there

are a few radiographic features that suggest COPD such as: a flat diaphragmatic contour due to hyperinflation and increased retrosternal airspace on a lateral radiograph.

Special Testing

If a patient presents with symptoms of COPD and has persistent airflow obstruction prior to age of 40, especially in nonsmoker patient, testing for alpha-1 antitrypsin (AAT) should be considered. A serum level of AAT below 57 mg/dL is diagnostic [11].

Management

The approaches to management of both asthma and COPD are very similar and include avoidance, immunotherapy, exercise, pharmacological therapies, and psychological support.

COPD exacerbation can be defined as baseline change in patient's dyspnea, sputum quantity, and quality. Most of the exacerbations occur due to upper respiratory infection or air pollution, but one third can happen without any known cause [14]. Treatment for acute exacerbation includes consistent use of short-acting bronchodilators, antibiotics, and short course of oral prednisone [15, 16]. A recent study found that 5 days of oral prednisone use is noninferior to 14 days [17]. Oxygen supplementation may be needed depending on severity of symptoms and hypoxia. Interestingly, there is no evidence of superiority of nebulizer to MDI/spacer beta agonist delivery for home or emergency room setting [18].

COPD

For patients with intermittent symptoms, inhaled short-acting beta-2 agonists such as albuterol or/and anticholinergic inhaled medications such as ipratropium (Atrovent) can be used to relieve symptoms for acute episodes. When combined together, they provide additive response [19]. For patients with moderate to severe COPD, they should be on daily long-acting bronchodilators which can include beta-2 agonists like salmeterol (Severent) and/or long-acting anticholinergic such as tiotropium (Spiriva). One study has shown that when comparing tiotropium to salmeterol, it resulted in preventing exacerbations for longer period [19]. Often, when patient's symptoms are not well controlled with one class, these agents can be used together. Also, inhaled corticosteroids are approved in several combinations with long-acting beta-2 agonists. However, these can be considered when patients experience several COPD exacerbations. These are not approved to be used as monotherapy. Pneumonia is an important complication of treatment with inhaled corticosteroid-LABA products [19]. TORCH study has shown that it reduces exacerbation by 25 %; however, it does not slow progression of disease nor does it help to decrease mortality [20]. For patients with very severe COPD, consider starting triple therapy with a long-acting anticholinergic and a combined long-acting beta-2 agonist and corticosteroid. This may be warranted if symptoms persist despite dual medication therapy as it seems to reduce exacerbations and overall mortality [19].

Roflumilast (Daliresp) is an oral phosphodiesterase inhibitor which is indicated for patients with severe COPD associated with chronic bronchitis and history of several exacerbations [19]. Common side effects include nausea and diarrhea. Importantly, long-term oxygen therapy should be considered for patients with persistent hypoxemia of <88 % or PaO2 of 55 mmHg. See Table 3 for list of commonly used inhalers and their dosages.

Prevention of Exacerbations of Asthma and COPD

Climate

The interplay of climate and outdoor and indoor pollution on patients with asthma and COPD is very important. Extreme weather such as dry air of winter or humid air of the summer can impact the severity of both lung diseases. Often, staying indoors during times of extreme weather with

appropriate filtered air conditioning and heating system to maintain a constant climate indoors is vital.

Outdoor Air Pollution

Allergens that are more prominent during the four different seasons can easily cause exacerbations of lung disease. Attempts to avoid both manufactured and natural substances from tree, grass, plants, and molds can assist in control of pulmonary disease.

Indoor Air Pollution

Elimination of both personal and secondhand smoke exposure is very important in limiting factors for exacerbation. In addition, removing potential irritants from carpets, plants, air fresheners, and cleaning chemicals can reduce number of irritants in the indoor environment. Also, changing air filters of the heating and cooling unit monthly is just as important.

Immunization

An influenza vaccine is recommended yearly, October through March, for all asthma and COPD patients. Twenty-three valent pneumococcal vaccine should be offered to all the patients between the ages of 18 and 65 and second vaccination can be done 5 years from previous one or after the age of 65 whichever comes later [11].

Self-Management Education

Important topics which should be discussed include appropriate and proper use of their inhalers and spacer, early recognition of exacerbation symptoms, and perhaps discussion about advance directive [21, 22].

Exercise

Aerobic exercise is vital to improve exercise capacity, quality of life, and decrease health care utilization of patients with asthma and COPD [7]. Physical training lasting for at least 20–30 min, two to three times a week for at least 6 weeks, improves physical fitness in patients with asthma [7]. Pulmonary rehabilitation should be considered for patients who are more symptomatic (CAT $\geq$ 10 or mMRc $\geq$ 2) [7].

Special Populations

Pregnancy and Breastfeeding

The management of asthma does not change in the setting of pregnancy or breastfeeding. It is important to gain control early to prevent the risk of fetal hypoxia. Medications typically used to treat asthma do not confer any contraindication during pregnancy or lactation. Also, vaccination against pneumococcal and influenza during pregnancy is important.

Family and Community Issues

COPD is marked by gradual decline in health and increase in exacerbations over time. Respiratory failure, cardiovascular disease, and malignancy are major causes of death in patients with COPD. Hence, palliative care and hospice care are important components for patients with advanced COPD. Moreover, stepwise decline of quality of life may lead to isolation, depression, and anxiety. It is important to address emotional, family, and community support when caring for patients with COPD and severe asthma.

Prevention

Smoking cessation is a crucial step for all patients with COPD and asthma. It can reduce rate of decline in FEV1 and, hence, can help to slow the rate of progression of disease. It can be done through behavior counseling if patient is ready to quit. Other pharmacological interventions can be used including nicotine replacement therapy (nicotine patches, gum, and inhalers), bupropion (Wellbutrin), and varnicline (Chantix). Studies have shown that the combination of medical

therapy and counseling yields best results for smoking cessation [23].

Introduction

Pneumonia is a lung infection involving the alveoli and can be caused by a variety of microbes including bacteria, viruses, and fungi. It is the leading infectious cause of hospitalization and death in the United States [1]. In 2010, in the United States, pneumonia resulted in 1.1 million discharges from the hospital with an average length of stay of 5.2 days. Pneumonia accounted for 3.4 % of hospital deaths in 2006. In 2013 it accounted for 16.9 deaths per 100,000 population [2]. Pneumonia continues to be the leading killer of young children around the world, causing 14 % of all deaths in children ages 1 month to 5 years [3].

Most instances of pneumonia are attributable to self-infection with one or more types of microbes that originate in the nose and mouth. In healthy individuals, typical upper airway bacterial residents such as *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most common bacteria causing community-acquired pneumonia. Hospital-acquired pneumonia is usually caused by more resistant bacteria such as *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Escherichia coli*. In those with a serious impairment of their immune system, opportunistic microbes are more readily apparent such as fungi, viruses, and mycobacteria [1].

There are many mechanisms used by the lungs to resist infection. Physical mechanisms are structure of the upper airway, branching of the bronchial tree, sticky mucous layer lining the airways, cilia that propel mucous upward, and the cough reflex. If microbes do reach the alveoli, the immune system is usually able to destroy them [1].

A variety of strategies have been used to reduce the incidence of pneumonia. Elements of a healthy lifestyle that reduce the incidence are adequate nutrition, dental hygiene, and not smoking. For those with lung disease or impaired clearance of mucous, aerobic exercise, deep breathing maneuvers, and cough assist devices can facilitate expectoration and lung hygiene. Immunity to certain microbes can be enhanced by immunization [1].

Bacterial Pneumonia

General Principles

Definition/Background/Epidemiology

Pneumonia is a common infection in the parenchyma of the lower respiratory tract that can affect all age populations. There is significant morbidity and mortality associated with pneumonia, especially in the very young and elderly populations. Pneumonia is the leading cause of death in children younger than 5 years of age worldwide [4]. The average yearly incidence of pneumonia, specifically community-acquired pneumonia, is 5–11 per 1000, with most incident cases occurring in the winter months [5]. It is passed from person to person by viral particles on respiratory droplets.

Decisions on how to treat, whether to admit to the hospital or treat outpatient and potential prognosis, depend upon the most likely pathogen and the current clinical picture. In most cases, the pathogen is never isolated – only suspected – prior to initiation of treatment.

Classification

Pneumonia classification is based upon a variety of factors – age, clinical presentation and comorbidities, as well as history of previous hospital admissions or residence in a nursing facility. The best approach is a good history and physical exam in combination with knowledge of the most common causes of pneumonia for the presenting age patient being seen. Community-acquired pneumonia (CAP) must be distinguished from hospital-acquired pneumonia (HAP), healthcare-associated pneumonia (HCAP), or ventilator-associated pneumonia (VAP) before treatment is started. In addition, the cause of the pneumonia must be determined to be bacterial, viral, or atypical in nature before treating.

Bacterial pneumonia, specifically *Streptococcus pneumoniae*, is the most common cause of pneumonia across all ages [4]. Certain comorbidities or risk factors (see footnote of Table 1) such as age greater than 65, alcohol abuse, recent antibiotic use (within the past 3 months), coexisting medical

diagnoses of COPD or CHF, and exposure to day care/nursing home (child or adult) increase the likelihood that the patient may have illness caused by other bacterial causes or have a pneumonia that may require additional or different treatment [5].

In children, the suspected organism that has caused the pneumonia is based upon the age of the child: [5]

Birth to 3 weeks: Group B streptococcus, *Haemophilus influenzae* type b (Hib), *Listeria monocytogenes*, and cytomegalovirus

3 Weeks to 3 months: *Streptococcus pneumoniae*, *Chlamydia trachomatis*, respiratory syncytial virus (RSV) or other respiratory viruses, and *Bordetella pertussis*

4 Months to 4 years: RSV and other respiratory viruses, *S. pneumoniae*, and group A streptococci

5–18 Years: *S. pneumoniae*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*

In general, the same principles apply to adults in attempting to determine the most likely organism affecting the patient. The only difference is that organism and treatment options are not based on age, but on how ill the patient is, associated risk factors (see footnote of Table 1), and the location of treatment (outpatient vs. inpatient vs. intensive care unit (ICU)): [5]

Outpatient with no risk factors: *S. pneumoniae*, *M. pneumoniae* (esp. in the 18–30-year-old age group), *C. pneumonia*, *H. influenza*, respiratory viruses

Outpatient with risk factors: *S. pneumoniae*, *M. pneumoniae*, *C. pneumoniae*, mixed bacteria + virus or atypical, *H. influenzae*, *Legionella*, respiratory viruses and fungi

Inpatient, non-ICU: *S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, *C. pneumoniae*, mixed bacteria + virus or atypical, respiratory viruses, *Legionella*, *Mycobacterium tuberculosis*, *Pneumocystis jirovecii*

Inpatient, requiring ICU admission: *S. pneumoniae (*including drug resistant), *Legionella*, *H. influenza*, gram-negative enteric organisms, *S. aureus*, *M. pneumoniae*, *Pseudomonas* sp., respiratory viruses, *C. pneumoniae*, *M. tuberculosis*, and fungi.

Approach to the Patient

The most important point to consider when evaluating for pneumonia is the patient's age, the time of year, social habits, existing disease processes, travel history, or other exposure history – animals, geography, and other people. This information is best obtained from a thorough history and physical exam.

Attention must be given to determining which of the following categories the patient falls into:

- ***Community-acquired pneumonia (CAP):*** Pneumonia that is not associated with hospitalization, healthcare/long-term care facility, or recent medical treatment or contact with the healthcare system [5].
- ***Healthcare-associated pneumonia (HCAP):*** Pneumonia that occurs in patients who have recently been hospitalized within the past 90 days, reside in a nursing home or long-term care facility, or have received parenteral antimicrobial therapy, chemotherapy, or wound care within the past 30 days [5].
- ***Hospital-acquired pneumonia (HAP):*** Pneumonia that occurs 48 h after admission to a hospital and was not present on admission. This infection is currently the second most common nosocomial infection in the United States and is associated with high mortality and morbidity [5].
- ***Ventilator-associated pneumonia (VAP):*** Pneumonia that occurs 48 h or more after being intubated [5].

Early recognition of risk factors for HCAP, HAP, or VAP with prompt empiric treatment with different antibiotic therapy than previously used is important in the prevention of significant morbidity and/or mortality associated with these illnesses [6, 7].

Diagnosis

History

The most common presenting symptoms in an immunologically competent patient include sudden or recent onset of:

- Cough with purulent sputum
- Dyspnea
- Fever +/− chills
- Pleuritic chest pain

Other important information to obtain from the patient is with regard to recent hospitalizations, current resident location (in elderly patients), medical history, and recent medication (antibiotic) use.

Physical Exam

Physical exam findings can vary from one patient to another, let alone one age population to another. The following exam findings are the most consistent findings in patients with pneumonia:

- Vital signs:
  - Temperature >100 °F (37.8 °C)
  - Tachypnea (>20 breaths/min)
  - Tachycardia (>100 beats/min)
  - Decreased pulse oximetry readings on room air (<92 %)
- General:
  - Septic appearance
- Respiratory exam:
  - Increased tactile fremitus
  - Crackles, rhonchi
  - +/− Egophony
  - Dullness to percussion
  - Decreased breath sounds/air movement

Make sure to look for red flags in patients presenting with pneumonia-type symptoms. Red flag symptoms:

Accessory muscle use (sternal retractions)
Grunting
Nasal flaring
Altered mental status
Apnea

The presence any of these symptoms may indicate a more severe infection requiring admission to an intensive care unit.

Laboratory and Imaging

Chest radiography is the test of choice in patients with clinically suspected CAP. The presence of an infiltrate or consolidation on X-ray is required for the diagnosis of CAP (Fig. 1).

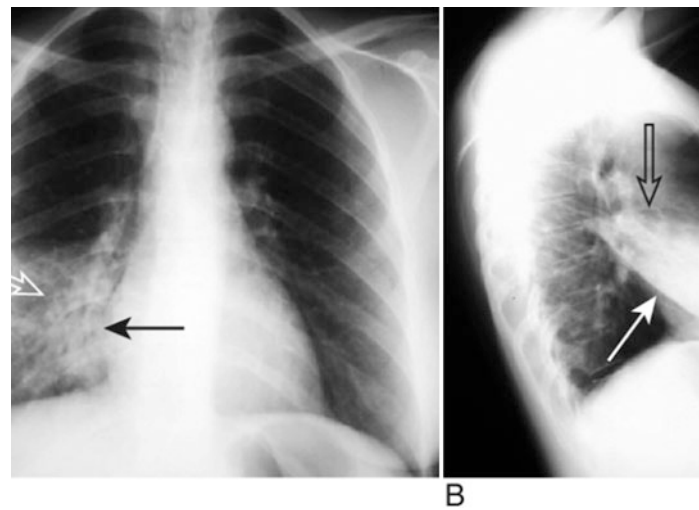

Fig. 1 X-ray of infiltrates in pneumonia [8].

Chest radiography should be performed in:

Any patient with at least one of the following abnormal vital signs:

- Temperature > 37.8 °C (100 °F)
- Heart Rate >100 beats/min
- Respiratory rate >20 breaths/min

Or

Any patient with at least two of the clinical findings:

- Decreased breath sounds
- Crackles (rales)
- Absence of asthma

Routine laboratory testing is not required to establish diagnosis in an outpatient setting. Laboratory testing recommendations differ, though, for patients who are requiring admission to hospital or the intensive care unit for treatment. These include:

- Complete blood count (CBC)
- Basic metabolic panel (BMP)
- Sputum gram stain and culture
- Blood cultures drawn from two separate sites
- Arterial blood gas (ABG) if patient is experiencing respiratory distress

For patients who are being evaluated for HAP, HCAP, or VAP, lower respiratory tract specimens should be cultured. These specimens can come from expectorated sputum or from a bronchoalveolar lavage (BAL) [7].

Special Testing

In patients presenting with severe CAP, special testing for urinary antigens of *Streptococcus pneumoniae* and *Legionella pneumoniae* serogroup 1 has been approved [9]. These tests provide a rapid result, with high specificity and sensitivity, thereby prompting targeted treatment.

Differential Diagnosis

The following might be considered in the differential based upon the patient's signs, symptoms, and comorbidities:

- Influenza
- Viral pneumonia
- Atypical pneumonia
- Acute bronchitis
- COPD exacerbation
- Congestive heart failure (CHF)
- Pleural effusion
- Pulmonary embolism

Treatment

Medications

The most important first determination to make in treatment for a patient with pneumonia is with regard to severity of illness; this should direct the "site-of-care" decision (hospital vs. outpatient, ICU vs. medical ward). Two scoring systems for assisting with the decision on hospitalization are the Pneumonia Severity Index (PSI) and the CURB-65 (*c*onfusion, *u*remia, *r*espiratory rate, low *b*lood pressure, age *65* years or greater). Using one of these criteria, in addition to the clinical picture of the patient, will help guide the appropriate medication and site of treatment [10].

After deciding to admit a patient to the hospital for treatment, the next decision to be made is whether or not the patient needs ICU treatment. According to the Infectious Disease Society of America/American Thoracic Society, there are several clinical criteria that should be considered for ICU admission – meeting three or more of the following:

- Tachypnea, RR >25–30 breaths/min
- PaO_2 or FiO_2 ratio <250
- Multilobar infiltrates
- Altered mental status/confusion
- BUN > 20 (Uremia)
- White blood cell count <4,000
- Thrombocytopenia, platelet count <150 k
- Temperature <36 °C
- Hypotension/septic shock requiring aggressive fluid hydration [10]

Location of treatment guides antibiotic choice for treatment. In most cases, it can be difficult to establish exact organism(s) affecting a patient; therefore, empiric antibiotic therapy guidelines have been established. Table 1 reviews the most likely organisms found in adults based on patient age and treatment location and provides the recommended empiric therapy with current dosing recommendations [5, 7, 9–11].

Bacterial pneumonia is typically treated for a minimum of 5–14 days, with length of treatment being dependent upon degree of illness at presentation, age, comorbidities, initial response, and whether patient was hospitalized/ICU or not. Attention should be directed at monitoring length of intravenous therapy and recognizing when to switch to oral therapy. Once a patient is clinically improving and requiring no intervention to maintain hemodynamic stability, he/she can safely be switched to oral therapy to complete the course of treatment [10].

In addition to following the most updated guidelines, it is also important to be aware of local epidemiological data, as well as potential antibiotic-resistant changes with typical bacterial pneumonia treatment.

Different antibiotic choices should be made for patients presenting with HCAP, HAP, or VAP. Multidrug-resistant pathogens must be considered with these infections and treated accordingly [7].

Patient Education

Decreasing a patient's chance of becoming ill with pneumonia is an important part of a primary care physician's job [12]:

Counsel patients who smoke on the importance of smoking cessation.
Encourage scheduled vaccinations.
Educate patients on accepted hand hygiene standards: wash hands regularly with soap and warm water for at least 20 s.
Disinfect frequently touched surfaces.
Teach them about cough etiquette: cover the mouth and nose with a tissue when they cough or sneeze and put used tissues in the waste basket.
If they do not have a tissue, teach them to cough or sneeze into their upper sleeve or elbow, not their hands.

Prevention

Immunizations

Vaccinations against preventable illnesses have long been proven effective in overall patient and population morbidity and mortality. Risk for infection with the most common bacterial pneumonia – *Streptococcus pneumoniae* – can be decreased with immunization. According to the Centers for Disease Control, the following vaccinations are important for prevention of pneumonia:

- Pneumococcal
- *Haemophilus influenzae* type b
- Pertussis (whooping cough)
- Influenza (flu) – yearly
- Measles [4, 13]

Atypical Pneumonias

Mycoplasma pneumoniae

General Principles

M. pneumoniae is considered the most common "atypical" pathogen for community-acquired pneumonia (CAP). The prevalence of *M. pneumoniae* in adults with pneumonia can range between 1.9 % and 32.5 %. Outbreaks can occur in institutional settings such as schools and military bases [14]. It is usually transmitted from close person to person contact via respiratory droplets. The average incubation period is around 2–3 weeks [15], and infections tend to occur during the fall and winter.

Approach to the Patient

Diagnosis

History and Physical

The onset of symptoms is typically gradual over the course of several days. Common symptoms include sore throat, muscle pain, headache, malaise, and chills. Patients also complain of a cough that is initially dry, but becomes productive over the course of the infection. The cough is typically worse at night. Sinus pressure and otalgia can also

Table 1 Target treatment, location, and organisms with empiric antibiotic recommendations

Age	Treatment location	Organisms being targeted	Antibiotic
<65, with no risk factors	**Outpatient**	*S. pneumoniae* *M. pneumoniae* *C. pneumoniae* *H. influenzae*	***Macrolide***: *Azithromycin*, 500 mg orally on day 1 and then 250 mg on days 2–5 *Clarithromycin*, 250 mg orally twice daily *Erythromycin*, 250 mg orally every 6 h or 500 mg orally every 12 h *Doxycycline*, 100 mg orally every 12 h for day 1 and then 100 mg orally daily

occur. The lung exam can be normal on initial examination, but can develop into scattered rales or wheezes during its progression. Extrapulmonary complications can include maculopapular rashes, arthralgia, aseptic meningitis, transverse myelopathy, and Guillain-Barré syndrome. Since the progression is gradual, a patient may not seek medical attention until a few days to a week.

Laboratory and Imaging, Special Testing

Obtaining a chest radiograph may reveal an infiltrate and may be more prominent if the illness has been present for at least 2 weeks [15]. Cultures from throat, nasopharyngeal, or pleural fluid are considered the "gold standard" for diagnosis. A cold agglutinin test can be used as well and usually appears by the end of the first week of illness. Around 72–92 % of patients with pneumonia and positive cold agglutinins (>1:32) will develop a serologic response to *M. pneumoniae*. Serology can be obtained by complement fixation (CF) or enzyme immunoassay (EIA) [14].

Treatment

Macrolides (erythromycin, azithromycin), tetracyclines (doxycycline), and fluoroquinolones (levofloxacin, moxifloxacin) are the typical therapies used to treat *M. pneumoniae*. Macrolides, particularly azithromycin, tend to be the most active against *M. pneumoniae* in in vitro studies [14]. The duration of antibiotic treatment is typically 5 days of azithromycin or 7–14 days with a tetracycline or fluoroquinolone.

Prevention

Use of appropriate hand hygiene and cough etiquette.

Chlamydial Infection

General Principles

Chlamydia is a gram-negative obligate intracellular organisms. It includes *Chlamydia trachomatis*, *Chlamydophila* (formerly *Chlamydia*) *pneumoniae*, and *Chlamydophila psittaci.*

C. trachomatis generally presents as a genital tract or ocular infection, but the latter two can present itself as an atypical pneumonia. Around 10 % of cases of community-acquired pneumonia (CAP) are related to *C. pneumoniae* [16].

Approach to the Patient

Diagnosis

History and Physical

Along with other atypical pneumonias, patients can present with productive cough, sore throat [17], sinus congestion, and malaise.

Patients who have psittacosis, caused by *C. psittaci*, tend to have a history with exposure to infected birds. It often presents in young to middle-aged adults. Symptoms include abrupt fever, headache, dry cough, myalgia, and malaise.

Laboratory and Imaging: Special Testing

Chest radiographs may show infiltrates. For diagnosis, oropharyngeal swabs can be used to culture *Chlamydophila* species. Serology tests, EIA, and polymerase chain reaction (PCR) can be used as well [17]. A chest radiograph can reveal interstitial or lobar infiltrates [18]. As with *C. pneumoniae*, *C. psittaci* can be diagnosed with serologic testing.

Treatment

Doxycycline (100 mg orally twice daily) for 10–14 days is the treatment of choice for both *C. pneumoniae* and *C. psittaci*. Macrolides (azithromycin) can be used as well and are usually the choice for empiric treatment for atypical pneumonia [17, 18].

Prevention

Counsel patients about the importance of hand hygiene and cough etiquette [19].

Viral Pneumonia

General Principles

In immunocompetent adults with pneumonia, 18 % had a viral etiology and in 9 % a respiratory virus was the only pathogen identified. Studies that included outpatients found viral pneumonia rates as high as 36 % [10]. In children, viral etiologies for community-acquired pneumonia have been documented in up to 80 % of children younger than 2 years of age. Older children, ages 10–16, have a much lower percentage of viral pathogens [10].

Epidemiology

In immunocompetent adults, the most commonly seen virus is influenza and in children respiratory syncytial virus (RSV). Influenza affects 5–20 % of the US population annually, resulting in 226,000 hospitalizations and 36,000 deaths. RSV accounts for 25–40 % of pneumonia and bronchiolitis in infants [20].

Other common viruses are adenovirus and parainfluenza. Less common viruses include human metapneumovirus, herpes simplex virus, varicella-zoster virus, SARS-associated coronavirus, and measles virus [10].

Transmission

For influenza and RSV droplet and fomite transmission are the most common methods of transmission.

Influenza has an incubation period of 1–3 days, and viral shedding begins before the appearance of symptoms and within the first 24 h of inoculation. Viral shedding peaks on the second day and in healthy adults is no longer detectable 6–10 days later. In children and immunocompromised adults, prolonged viral shedding occurs up to 21 days [21]. RSV viral shedding has a mean of 6.7 days with a range of up to 21 days [20].

Approach to Patient

Diagnosis

History

Infants with RSV initially present with rhinorrhea and decreased appetite followed by a cough within 1–3 days. Soon after the cough, sneezing, fever, and wheezing occur. In very young infants, the only symptoms may be irritability, decreased activity, and apnea [20].

In adults the presentation is similar to that of community-acquired pneumonia, but they may have symptoms of an upper respiratory infection for less than 5 days prior. The symptoms of an upper respiratory infection are rhinorrhea, sore throat, cough, headache, fatigue, and fever [10].

Physical Examination

The physical examination should target the following areas: general appearance and vital signs, head, eyes, ears, nose, and throat, cardiac, and pulmonary and thorax.

General appearance and vital signs are important in discerning the severity of illness. Is the patient lethargic, or confused? Is the patient tachycardic or hypotensive? These are signs of more severe illness and most likely will require hospitalization.

Examination of the head, eyes, ears, nose, and throat can provide evidence for a preceding upper respiratory infection which would indicate a more viral etiology.

On cardiac examination, if there is a new gallop or murmur, then that can indicate increased severity of illness.

Pulmonary and thorax examination are done to look for abnormal breath sounds and evidence of a consolidation or effusion which again can indicate a higher level of severity (Table 2) [10].

Table 2 Laboratory and imaging recommendations for viral pneumonia [22]

Office-based	
RSV	Antigen detection test supplemented by cell culture Sensitivity of antigen detection tests range from 80 % to 90 % and is reliable in young children Real-time polymerase chain reaction (RT-PCR) assays are more sensitive in older children and adults who may have a lower viral load
Influenza	Rapid influenza diagnostic tests Sensitivity tests range from 50 % to 70 % and specificity tests range from 90 % to 95 %
Hospital-based	
Serology	Complete blood count with differential – to assess severity of infection Electrolytes – to assess hydration, kidney function, and glucose Blood culture for bacterial pathogens
Sputum	Culture and sensitivity for bacterial pathogens
Nasopharyngeal	For RSV and influenza
Chest X-ray	Initially, to assess for presence of consolidation or effusion
CT of chest	For those not responding to initial therapy
Specialized testing	
Serology	Titers for acute and convalescent phase – more important for seroprevalence and epidemiological studies

Treatment

Medications are given based on etiology of viral pneumonia. Influenza is treated with oseltamivir. Herpes simplex and varicella-zoster are treated with acyclovir. No antiviral treatment of proven value is available for other viral pneumonias and a high clinical suspicion for bacterial superinfection should be maintained. For RSV infection, high-risk infants and young children likely to benefit from immunoprophylaxis based on gestational age, certain underlying medical conditions, and RSV seasonality, palivizumab is available. This is a monoclonal antibody given in monthly intramuscular injections during RSV season [22].

Family and Community Issues

Prevention using standard precautions and droplet precautions for at least 5 days is recommended. Wash hands frequently and correctly with soap and water for at least 20 s or use alcohol-based hand gels. Use respiratory hygiene measures such as masks or tissues to cover the mouth for patients with respiratory illness. Avoid sharing cups and utensils. Clean contaminated surfaces.

For influenza yearly vaccination is recommended, and for those whom vaccination is contraindicated, antiviral chemoprophylaxis is recommended. Encourage patients to alert providers when they present for a visit and have symptoms of respiratory infection [20, 21].

Tuberculosis

General Principles

Definition

Tuberculosis is caused by mycobacterium tuberculosis (MTB). This is a large nonmotile rod-shaped obligate aerobic bacterium requiring oxygen for survival. It is commonly introduced to the body through inhalation of droplet nuclei. MTB is usually found in well-aerated upper lobes of the lungs. MTB is a facultative intracellular parasite that is engulfed by macrophages. MTB is released into the alveoli upon death of the macrophage, and the health of the host's immune system is the key factor in expression of TB disease [23].

Epidemiology

One-third of the world's populations is infected with tuberculosis (TB). In 2012, nearly nine million people around the world became sick with TB disease, and there were approximately 1.3 million TB-related deaths worldwide. TB is a leading killer of people who are HIV infected. A total of 9,582 TB cases (or 3.0 per 100,000 persons) were reported in the United States in 2013 [24].

Classification

MTB may be cleared by the host immune system or may progress to latent TB infection or to primary TB. Latent tuberculosis infection (LTBI) means that the host immune system has used the cellular immune system mediated by T-helper cells to contain MTB in a granuloma. 5–10 % of persons with LTBI are at risk of progressing to active TB disease. Immunocompromised persons (HIV, cancer, on immunosuppressing medications) are at greater risk for progression to active TB disease [23].

Approach to the Patient

Diagnosis

Screening

The Centers for Disease Control (CDC) recommends that high-risk populations be screened for latent infection. This includes HIV patients, IV drug users, healthcare workers who serve high-risk populations, and contacts of individuals with pulmonary tuberculosis. A validated risk-assessment questionnaire may be used to identify children who are likely to benefit from screening.

History/Physical Examination

Classic clinical features of pulmonary tuberculosis include chronic cough, sputum production, appetite loss, weight loss, fever, night sweats, and hemoptysis. Extrapulmonary tuberculosis occurs in 10–42 % of patients. In HIV-infected persons, the risk of active tuberculosis increases soon after infection with HIV. Those with a CD4 count of less than 200 cells/mm^3 may have an atypical presentation of tuberculosis with subtle infiltrates, pleural effusion, hilar lymphadenopathy, and other forms of extrapulmonary tuberculosis. At CD4 counts of less than 75 cells/mm^3, pulmonary findings may be absent and disseminated tuberculosis is more frequent. Disseminated tuberculosis presents as a nonspecific chronic

febrile illness with widespread organ involvement [25].

Laboratory/Imaging

Latent infection is diagnosed using the tuberculin skin test (TST) or interferon-gamma release assay (IGRA). In the TST a small amount of tuberculin is injected into the dermis of the skin creating a small, pale bump. In 2–3 days the TST must be read by a trained healthcare worker. A positive reaction is induration measured in millimeters. Those people who have previously been vaccinated with bacillus Calmette-Guérin (BCG) may have a false-positive TST [26]. IGRA measures a person's immune reactivity to MTB. White blood cells from most persons infected with MTB will release interferon gamma when mixed with antigens derived from MTB. IGRA requires a single patient visit and results can be available within 24 h. Vaccination with BCG does not cause a false-positive IGRA test. However, IGRA is more expensive than TST [26].

Active tuberculosis infection is diagnosed using sputum microscopy and culture along with chest radiography. Three sputum samples are obtained for acid-fast bacilli (AFB). In addition a nucleic acid amplification test (NAAT), a complete blood count, and electrolytes are also ordered. Sputum culture is more sensitive than smear staining, facilitates identification of the mycobacterium species by nucleic acid amplification, and evaluates drug sensitivity. Cultures may take 4–8 weeks [23]. 40–50 % of TB cases are AFB smear-negative and 15–20 % have negative cultures [23]. Chest X-ray is often normal but hilar adenopathy is the most common abnormality found in as much as 65 % of cases. Hilar changes can occur 1–8 weeks after skin test conversion. The findings often resolve within the first year of detecting a positive skin test for primary TB [23]. Pleural effusions are also common in active TB infection.

Treatment

Treatment depends on whether latent or active infection is diagnosed.

Latent infection is treated with isoniazid 300 mg daily for at least 6 months and preferably for 9 months. Alternative regimens include isoniazid 900 mg and rifapentine 900 mg weekly for 3 months, rifampin 600 mg daily for 4 months, isoniazid 300 mg plus rifampin 600 mg daily for 3 months, or isoniazid 900 mg plus rifampin 600 mg twice weekly for 3 months. All treatment regimens require directly observed therapy – a person employed by the state health department administers and ensures that the patient diagnosed with latent infection takes their medication [25].

Active TB is treated with a four-drug regimen: isoniazid, rifampin, ethambutol, and pyrazinamide for 2 months (intensive phase) followed by isoniazid and rifampin for 4 months (continuation phase). Pyridoxine supplementation is recommended to prevent isoniazid-induced neuropathy [25]. If there is multidrug-resistant disease, then initial treatment is based on local disease patterns and pending drug-susceptibility results; later-generation fluoroquinolones are preferred (e.g., moxifloxacin or levofloxacin) [25].

For those with active TB, sputum analysis should be done weekly until sputum conversion is documented. Patients who receive pyrazinamide should undergo baseline and periodic serum uric acid assessments. Those who receive long-term ethambutol therapy should undergo baseline and periodic visual acuity and red-green color perception testing. Also patients should be monitored for toxicity with baseline and periodic liver enzymes, complete blood cell count, and serum creatinine [23].

Currently 17 % of newly diagnosed MTB cases are resistant to one or more first-line agents; isoniazid is the most commonly associated with resistance (10 %). There are strains resistant to both isoniazid and rifampin. In 2009 the World Health Organization estimated that 3.3 % of new TB cases were multidrug resistant [23].

Family and Community Issues

Tuberculosis is required to be reported to local public health authorities. For control of pulmonary tuberculosis, control of infectivity is most efficiently achieved through prompt specific drug treatment. It takes 2–4 weeks for vital organisms to disappear in the sputum and 4–8 weeks to be cleared in the sputum.

Patients with sputum smear-positive TB who live in congregate settings should be placed in an airborne infection isolation room with negative pressure ventilation. Patients should cover their nose and mouth while sneezing. Persons entering rooms where TB patients reside should wear personal respiratory protective devices capable of filtering particles less than 1 μm in diameter. Patients whose sputum is negative for bacteria and who do not cough and who are known to be on adequate drug treatment do not require isolation. Handwashing and good housekeeping practices must be maintained according to policy [19].

Histoplasmosis

General Principles

Definition/Background and Epidemiology

Histoplasmosis is a pulmonary infection caused by *Histoplasma* – a fungus found in soil with large amounts of bird and bat guano [27]. People acquire histoplasmosis after breathing in the microconidia (microspores) from the air, often after participating in activities that disturb the soil. Although most people who breathe in the spores become mildly ill, moderate infection may present with a fever, cough, and/or fatigue. Not every person infected with this spore becomes ill; but in patients with weakened immune systems, the infection can become severe, especially if it becomes a systemic infection [27].

Anyone is susceptible to histoplasmosis if they live or have traveled to an area where *Histoplasma* lives in the soil. In the United States, *Histoplasma* mainly lives in soil in the central and eastern states, especially in the Ohio and Mississippi River valleys. *Histoplasma* has been reported worldwide, with localized foci located in Central America, Europe, Africa, and Asia [28]. Outdoor activities often associated with this fungus include cave spelunking, mining, construction/demolition, excavation, chimney cleaning, and farming/gardening.

There are specific populations who are at higher risk for developing the severe forms of histoplasmosis. This population includes patients who have weakened immune response (HIV/AIDS, previous organ transplant, or who are on chronic immune-suppressing medications), infants, and older adults (55 and older).

Approach to the Patient

Diagnosis

History

A majority of patients either will have no symptoms or will present with subacute influenza-like symptoms – dry cough, fever, myalgias, and fatigue – possibly weeks to months after exposure. In patients with acute illness, presenting symptoms can include high fever, headache, nonproductive cough, chills, weakness, pleuritic chest pain, and fatigue. Patients who are immunocompromised are at increased risk for systemic dissemination.

For patients not living in the areas of highest incidence, travel and activity history are important factors in diagnosing this illness.

Physical Examination

In general, the physical exam findings for any acute pulmonary infection will be similar to those for bacterial pneumonia:

- Tachycardia
- Tachypnea, +/− hypoxia
- Decreased or adventitious breath sounds
- Fever >40 °C (102 °F)
- Possible septic appearance

Laboratory and Imaging

Initial presentation resembles community-acquired pneumonia; therefore, the typical lab tests and imaging are completed at that time. These include a CBC and chest X-ray. Based on initial exam and diagnostic findings alone, most patients will likely be treated for a bacterial CAP; not until the patient's condition has worsened or

initial antibiotic therapy has failed will additional special testing completed.

Chest X-ray findings with acute pulmonary histoplasmosis include patchy or diffuse reticulonodular infiltrates; CT scans show +/− mediastinal or hilar lymphadenopathy [29]. At this point, further testing with treatment plan adjustments is recommended.

Special Testing

Definitive testing for histoplasmosis requires cultured growth of the organism, but this can take 4–6 weeks. Several tests are available for diagnosis of histoplasmosis once it is considered the cause of illness. Table 3 provides a list of testing available [28, 29].

For patients who present with diffuse disease or chronic disease with cavitating lesions, HIV testing or differentiation of cause of immunocompromised state should be completed.

Differential Diagnosis

- Pneumonia – bacterial, atypical, viral
- Sarcoidosis
- Other pulmonary fungal infections – blastomycosis, aspergillosis, coccidioidomycosis
- Lung cancer

Treatment

Medications

Table 4 summarizes the most recent recommendations on treatment of histoplasmosis. There has been a recent change in the treatment recommendations, with increased use of itraconazole. Amphotericin B is still highly recommended for patients with severe pulmonary histoplasmosis and for immunosuppressed patients [11, 28–30].

Table 3 Testing methods for histoplasmosis

Diagnostic method	Comments
Antigen detection **Urine** **Serum**	Most sensitive if both urine and blood are tested Acute and chronic infection *CON*: Not as useful in immunocompromised patients – unable to mount antibody response
Culture	Diagnostic *CON*: Takes 4–6 weeks for culture to grow

Prevention and Patient Education

For patients who are immunocompromised, education on high-risk behavior in endemic areas – cave exploration/spelunking, for example – should be provided.

Coccidioidomycosis

General Principles

Definition/Background and Epidemiology

Coccidioides is a dimorphic fungus that is found in the soil of the southwest region of the United States. Coccidioidomycosis is an infection caused by *Coccidioides immitis* or *Coccidioides posadasii* and it is due to the inhalation of spores [31]. The incidence of reported coccidioidomycosis has increased, from 5.3 per 100,000 population in 1998 to 42.6 per 100,000 in 2011 [32]. The reports were from the endemic areas of Arizona, California, Nevada, New Mexico, and Utah. Due to population increases in Arizona and California, the number of infections has risen to about

Table 4 Treatment recommendations for histoplasmosis [28]

Disease acuity	Medications
Mild to moderate	Itraconazole 200 mg orally three times a day for first 3 days and then 200 mg orally once or twice daily for 6–12 weeks
Moderate to severe	Amphotericin B (lipid formulation) 3–5 mg/kg daily IV for 1–2 weeks, followed by itraconazole 200 mg orally three times daily for 3 days and then 200 mg twice daily, for a total of 12 weeks ***Plus*** Methylprednisolone 0.5–1 mg/kg daily IV for the first 1–2 weeks of therapy, in patients with ARDS[a]

[a]*ARDS* acute respiratory distress syndrome

150,000 per year. It is also known as "valley fever" [33].

Approach to the Patient

Diagnosis

History and Physical Examination

Infection is usually acquired by inhalation of the spores and living around the endemic regions of the southwestern United States. Most commonly, coccidioidomycosis usually presents itself as a self-limiting acute or subacute community-acquired pneumonia. This can develop around 1–3 weeks after infection. The patient can present with respiratory complaints, fatigue, or arthralgia. For some patients, fatigue can last from weeks to months. A few patients (0.5 %) infected may develop a progressive pulmonary or disseminated infection (skin, meninges, and bones). Persons of African or Filipino descent and pregnant, diabetic, and immunosuppressed patients have a higher risk of extrapulmonary complications.

Obtaining an accurate travel history is important. The patient should have been exposed in a region where exposure is possible (southwestern United States). The most common symptom is a respiratory illness, particularly if it involves the lower respiratory tract (i.e., pneumonia). The severity of illness varies from a mild respiratory infection to progressive pulmonary lesions or dissemination. The diagnosis of coccidioidomycosis from other causes is difficult without further testing.

Laboratory and Imaging: Special Testing

A sputum culture growing *Coccidioides* species establishes the diagnosis; however, it could take weeks for the culture to grow. *Coccidioides* species is considered by the Centers for Disease Control (CDC) as a select agent, so there are specific guidelines to oversee its handling [34]. Usually a culture is reserved for patients who require hospitalization. For most patients in an ambulatory setting, serologic testing can be used to diagnose coccidioidomycosis. IgM and IgG anti-coccidioidal antibodies are usually the screening test of choice. The most common chest radiograph abnormality is airspace opacity (58 % of patients), followed by pulmonary nodules (22.8 %) and a cavitary lesion (13.2 %) [35].

Treatment

If there are no risk factors or no evidence of extensive coccidioidal infection, a majority of patients do not need any antifungal medication. Follow-up visits every 3–6 months for up to 1–2 years are recommended with serial chest radiographs. This is done to document radiographic resolution or to identify extrapulmonary complications. For patients presenting with a severe illness or have risk factors (i.e., pregnancy), it is recommended to start antifungal therapy. Common antifungals used are ketoconazole 400 mg PO (per os/by mouth) daily, fluconazole 400–800 mg by PO daily, and itraconazole 200 mg PO two to three times per day. For pregnant patients, amphotericin B deoxycholate (0.5–1.5 mg/kg intravenously daily or alternate day) or amphotericin B lipid formulation (2.0–5.0 mg/kg or greater intravenously daily) is used as the antifungal of choice. Depending on the severity, the duration of therapy can range from 3 to 6 months to years.

Prevention

Dust control measures in endemic areas such as face masks, air-conditioned cabs, and wetted soil are recommended. Concurrent disinfection of discharges and soiled surfaces and terminal cleaning must be accomplished [19].

Legionnaire's Disease

General Principles

Definition/Background

Legionnaire's disease is a waterborne, pulmonary infection caused by a gram-negative, nonspore-forming, aerobic bacterium, *Legionella pneumophila*. This pulmonary infection was coined Legionnaire after an outbreak of pneumonia that occurred in people who had attended a convention of the American Legion in

Philadelphia in 1976. *Legionella* is the third most common cause of pneumonia in immunocompetent patients [36].

The bacteria, *Legionella pneumophila*, loves warm water and can be found naturally in the environment. This bacterium can live in and be spread to humans from hot tubs, cooling towers, hot water tanks, large plumbing systems, or fountains. The bacteria reside on droplets of water (vapor or mist) and are inhaled from environments containing water features as described above. The incubation period is usually 2–14 days before patients notice any symptoms.

This organism should be suspected in a patient who has had progressive pneumonia-like symptoms and is resistant to standard treatment for CAP.

Epidemiology

Since being discovered, an estimated 8,000–18,000 people are hospitalized yearly in the United States with this infection [37]. It is considered the second most common pathogen detected in cases of pneumonia requiring admission to ICUs and is the third most common cause of pneumonia in immunocompetent patients [36, 37]. In the past 10–12 years, there has been a notable increase in the number of cases reported. This infection is most often reported in the fall and summer, peaking in August [37].

Approach to the Patient

Factors to consider in a patient presenting with a pneumonia-type picture and potential diagnosis of *Legionella* are:

- Older age, >65 years of age
- Smoking status
- Male
- COPD or other chronic lung diseases
- Immunosuppressed or immunocompromised
- Lung cancer
- Diabetes mellitus

Diagnosis

Prompt diagnosis and early initiation of therapy are important for adequate treatment of Legionnaire's disease [10].

History and Physical Examination

Many symptoms are associated with Legionnaire's disease, but symptoms that are consistently reported include fever, loss of appetite, dyspnea, cough, headaches, and malaise. Some patients have reported diarrhea, confusion, phlegm, and/or blood-streaked sputum/hemoptysis. In most cases, symptoms have an abrupt start. If not recognized and treated appropriately, a mild infection can rapidly turn fatal.

Additional information to glean from a patient is recent travel history (including hotel or cruise ship stay) within 2 weeks of onset of symptoms [4].

Physical exam findings might include:

- Tachypnea, RR >20
- Temperature >40 °C (102 °F)
- Mental status changes, confusion
- Rales on auscultation
- Relative bradycardia
- Generalized abdominal tenderness

Use of special scoring systems, like the Modified Winthrop-University Hospital Infectious Disease Division's Weighted Point System for Diagnosing Legionnaire's Disease in Adults, can be crucial in early infection to diagnose correctly for treatment of Legionnaire's disease.

Laboratory and Imaging

Chest X-rays of patients with *Legionella pneumoniae* can appear identical to X-rays from other types of bacterial pneumonia; therefore, additional testing is required. In general, if these patients are admitted to the hospital, standard blood work should be collected (CBC, BMP, blood cultures × 2, sputum culture/g stain). If *Legionella* is being suspected, there are several options in testing for this organism – the choice of test will likely be driven by what is available within the clinic or hospital laboratory.

Special Testing

When Legionnaires' disease is suspected, both a urinary antigen test and *Legionella* culture of a respiratory specimen should be ordered. The culture requires a special medium, buffered charcoal yeast extract agar (BCYE). The "gold standard" and most sensitive test is the isolation of the organisms by culture from sputum or BAL. The disadvantage to culturing *Legionella* is that it can take 5–10 days for results and is a meticulous process. Cultures can yield a sensitivity of 20–80 %, with a specificity of 100 % [36, 37].

A serum test has been developed utilizing immunofluorescent assay (IFA) and enzyme-linked immunosorbent assay (ELISA). These tests evaluate and aid in diagnosis when the antibody titer increases greater than fourfold [30]. The time required for adequate testing using this method can take up to 3–8 weeks. Sensitivity and specificity of blood serum testing are 70–100 % and 100 %, respectively [36, 37].

A newer test being used in hospitals is the urinary antigen test. An advantage to this test is a fast turnaround time (<1 h) allowing a shorter time from presentation to diagnosis to targeted treatment. The main disadvantage to using this test for detection of *Legionella* is that it is specific for *L. pneumophila* serogroup 1 only [37]. The urinary antigen test yields a sensitivity and specificity of 80–90 % and >99 %, respectively [36, 37].

Differential Diagnosis

- Bronchitis
- Q-fever
- Acute respiratory distress syndrome
- Pneumonia – viral, atypical, bacterial
- Pleural effusion

Treatment

Medications

First-line treatment for *Legionella pneumoniae* follows the guidelines for bacterial CAP – utilizing either a respiratory fluoroquinolone or azithromycin [4, 11, 37] (Table 5).

Immunizations and chemoprophylaxis

There are no vaccines available for prevention of *Legionella* infections.

Table 5 Antimicrobial therapy for *Legionella pneumoniae*

First line	**Levofloxacin** 500 mg IV or orally every 24 h for 7 days or 750 mg IV orally every 24 h for 5 days **Azithromycin** 500 mg IV or 500 mg IV daily for 7–10 days
Second line	**Doxycycline** 100 mg orally twice daily for 5–7 days

Prevention

The most important factor in preventing infection is continued maintenance of water areas, such as hot tubs and heating/cooling water systems.

Family and Community Issues

Awareness of outbreaks and potential contaminants should be considered when multiple cases within a community are diagnosed with *Legionella*.

Mycobacterium Avium Complex

General Principles

Definition/Background, Epidemiology

Mycobacterium avium complex (MAC) is considered to be a non-tuberculous mycobacteria. MAC includes several subspecies: *Mycobacterium avium* subsp. *avium*, *M. avium* subsp. *silvaticum*, *M. avium* subsp. *hominissuis*, *M. avium* subsp. *paratuberculosis*, *M. avium* subsp. intracellulare, *M. arosiense*, *M. chimaera*, *M. colombiense*, *M. marseillense*, *M. timonense*, *M. bouchedurhonese*, and *M. ituriense* [38].

Non-tuberculous mycobacteria (NTM) are normal inhabitants of soil and water. Infections occur because their occupied habitats are shared with humans, animals, fish, and poultry. The habitats include drinking water distribution systems and household plumbing [38].

Patients who receive TNF-α blockers are susceptible to NTM infections and MAC was the most commonly implicated [39].

Approach to the Patient

Diagnosis

History and Physical Examination

Symptoms are nonspecific. Most patients present with a chronic cough, with or without sputum production or hemoptysis, and slowly progressive fatigue or malaise. Constitutional symptoms such as weight loss, fever, and night sweats are less frequent, occurring in 30–50 % of patients, and often indicate advanced disease. Physical examination would be the same as for other types of pneumonia [40].

Laboratory and Imaging

Radiographic abnormalities are more specific and generally follow two distinct patterns. The first is bronchiectasis and nodular lesions mostly involving the lingual and middle lobe. The second is fibrocavitary lesions that mostly involve the upper lobes and resemble pulmonary tuberculosis [40].

Differential diagnoses for cavitary lesions include pulmonary malignancy, sarcoidosis, and infections by non-mycobacterial pathogens such as fungi and *Nocardia* species [40].

Special Testing

Sputum culture is required to make the diagnosis. This can be from at least two separate expectorated sputum samples or at least one bronchial wash or lavage.

Management

Treatment regimens should consist of a rifamycin (rifampin or rifabutin), ethambutol, and a macrolide (azithromycin or clarithromycin). Therapy can be given daily or intermittently depending on the disease type and severity. Nodular bronchiectasis patterns can usually be treated by three times weekly therapy. Cavitary MAC disease involves daily three-drug therapy in addition to IM streptomycin or IM/IV amikacin usually given three times weekly [39].

Pneumocystis Pneumonia

General Principles

Definition/Background, Epidemiology

Pneumocystis pneumonia (PCP) is an opportunistic infection that occurs in immunocompromised patients, such as persons infected with the human immunodeficiency virus (HIV). Patients who are on chronic immunosuppressive therapy are also at risk [41]. Traditionally the nomenclature of the organism was *Pneumocystis carinii pneumonia* (***P. c****arinii* ***p***neumonia), but the name has been changed to *Pneumocystis jiroveci* to distinguish the species that affects humans. The acronym "PCP" is still used today (***P****neumo****c****ystis* ***p***neumonia) to avoid confusion in medical literature [42]. For patients with acquired immunodeficiency syndrome (AIDS), PCP is the most common opportunistic infection, but since the introduction of highly active antiretroviral therapy (HAART), the prevalence of PCP has decreased [43].

Approach to the Patient

Diagnosis

History and Physical

Patients typically have to be in an immunocompromised state to develop *Pneumocystis* pneumonia. The risk of PCP increases as the T-helper cell count (CD4) decreases in a patient. PCP usually occurs when the CD4 count is less than 200 cells/mm^3. Symptoms can include a low-grade fever, progressive dyspnea, or a nonproductive cough. Upon physical examination, a patient may have tachycardia and tachypnea. Auscultating the lung can be within normal limits, but may reveal nonspecific crackles.

Laboratory and Imaging, Special Testing

With PCP, a chest radiograph can show perihilar interstitial infiltrates, which may become more dispersed as the disease process worsens. One may also see lung nodules. If the chest radiograph is normal, a high-resolution computed tomography (CT) scan may show ground-glass attenuation

or lesions cystic in nature. For diagnosis of PCP, an induced sputum (with hypertonic saline) culture should be the initial test of choice. If the culture is negative and still suspected, bronchoscopy with bronchoalveolar lavage is indicated [42].

Treatment

In not acutely ill patients with PCP (PaO2 > 70 mmHg), the treatment of choice is trimethoprim-sulfamethoxazole (TMP-SMX) 15–20 mg/kg PO daily in divided doses. For patients who are acutely ill (PaO2 < 70 mmHg, unable to take PO), a 3-week corticosteroid taper should be added in conjunction with TMP-SMX. The patient should take prednisone 40 mg twice daily for 5 days, followed by 40 mg daily on days 6–11, and then 20 mg daily on days 12–21. For those patients who cannot tolerate TMP-SMX, alternative regimens include oral primaquine (30 mg daily) plus clindamycin (600 mg three times daily), atovaquone 750 mg orally twice a day [14], trimethoprim (5 mg/kg orally three times daily) plus dapsone (100 mg orally daily) [44], or pentamidine 4 mg/kg intravenously daily. Glucose-6-phosphate dehydrogenase (G6PD) deficiency must be checked prior to using primaquine or dapsone [43]. The duration of treatment should be 21 days. Following therapy, it is recommended for the patient to start on PCP prophylaxis.

Prevention and Community Issues

For patients with HIV, primary prophylaxis should be started when the CD4 count is less than 200 cells/mm^3. The prophylactic treatment of choice is TMP-SMX at one tablet (single or double strength) by mouth daily. Other options can include dapsone 100 mg PO daily, atovaquone 1,500 mg PO daily, or pentamidine 300 mg PO nebulized every 4 weeks. With the introduction of HAART, prophylaxis can be discontinued if the CD4 levels go above 200 cells/mm^3 [41].

General Principles

In the USA, primary lung cancer is the most common cause of cancer death and, after skin cancer, the second most commonly diagnosed cancer. It is one of the leading causes of morbidity and mortality in the USA. Between 2005 and 2009, a total of 1,054,393 new cases of lung cancer were diagnosed in the USA; it is estimated that in 2014, there will be 224,210 new cases of, and 159,260 deaths from, primary lung cancer [1]. Lung cancer also imposes a large financial burden on the healthcare system, with 2010 national expenditure for treatment totaling $12.12 billion [2].

However, over the 2005–2009 period, the overall incidence of lung cancer decreased, with a 2.6 % decrease in men and a 1.1 % decrease in women. The incidence and death rates decreased across most ethnicities and in both genders, with no subgroups experiencing an increase. Because cigarette smoking is the predominant risk factor for lung cancer [3], this decline may indicate not only a recent increase in smoking cessation rates but also a decrease in smoking initiation rates. By ethnicity, African-American men, compared to all men and women, have had the highest incidence and death rate over the last decade. Although the gap between African-American men and other men has been closing, this disparity still serves as a reminder of the significance of socioeconomic factors in the incidence and death rates from lung cancer.

Prevention

Efforts at the prevention of lung cancer can be divided into two separate categories: primary prevention through risk factor modification and secondary prevention through early detection of asymptomatic disease.

Primary Prevention

The CDC has declared that reducing tobacco use is a "Winnable Battle." Given that the vast majority of lung cancers develop in association with cigarette smoking, the primary prevention of most lung cancers can be achieved through increased smoking cessation and decreased smoking initiation. As with other neoplastic disease, there are additional risk factors involved, including environmental and occupational exposure, nutrition, and genetic predisposition.

Cigarette Smoking

It is estimated that tobacco cigarette smoking causes 80 % of the lung cancer deaths in women and 90 % in men. Men and women who smoke are 23 times and 13 times more likely to develop lung cancer than men and women who do not smoke, respectively. In addition, exposure to secondhand smoke among nonsmokers increases the risk of lung cancer by 20–30 % [4]. Promisingly, the overall prevalence of current cigarette use in the USA has been steadily decreasing: from 1965 to 2012, the percentage of current cigarette smokers decreased from 52 % to 24.8 % in adult men and 34 % to 19.3 % in adult women [5]. Among high school students, the overall prevalence has also been decreasing: from 1991 to 2011, the percentage of current cigarette smokers decreased from 27.6 % to 19.9 % in high school boys and 27.3 % to 16.1 % in high school girls. In 1997, the prevalence had peaked at 37.7 % in high school boys and 34.7 % in high school girls; it subsequently declined to current levels following the 1998 Tobacco Master Settlement Agreement, perhaps demonstrating the importance of public policy in curbing cigarette use among minors. From the public health perspective, and for the primary physician, encouraging smoking cessation and preventing smoking initiation are among the most important measures that can be taken to prevent lung cancer. Smoking cessation will be covered in detail in another chapter.

Occupational and Environmental Exposure

It is estimated that occupational carcinogen exposures are responsible for 9–15 % of cases (approximately 20,000–34,000) of lung cancer in the USA [6]. Lung cancer is known to be associated with a vast number of workplace exposures, most notably tar and soot, heavy metals (including arsenic, chromium, and nickel), asbestos, silica, and radioactive materials. The list of occupations that involve these substances is extensive and includes mining, manufacturing, printing, painting, and ionizing radiation. Cigarette smoking has been shown to potentiate the effects of some of the occupational carcinogens. In the case of asbestos, arsenic, and radiation, the combined carcinogenic effect can be multiplicative.

Air pollution is becoming increasingly recognized as a risk factor for lung cancer. While different geographic areas have varying components of particulate air pollutants, a 2014 meta-analysis by the World Health Organization classified general outdoor air pollution as a Group 1 (highest risk) lung carcinogen. Indoor air pollution from burning biomass is also a well-known risk factor for lung cancer and is an issue more commonly encountered in the developing world.

Ionizing radiation is also classified as a Group 1 lung carcinogen. In the USA, approximately half of an average individual's annual ionizing radiation exposure is iatrogenic, and most of the remainder is from radon-222 exposure. About half of iatrogenic radiation is due to computed tomography (CT), and the rest is from fluoroscopy and nuclear medicine. In the USA, CT scan usage is sharply rising, and it is estimated that in 2007, 1.5–2 % of all types of cancers (including lung cancer) in the USA were attributable to radiation from CT scans [7]. Nonoccupational radon exposure is estimated by the EPA to have caused 21,100 deaths (13.4 % of all deaths) from lung

cancer in 2003. The EPA has also estimated that 1 in 15 US homes has radon levels at or above the recommended levels and that lowering levels in these homes could prevent 5,000 lung cancer deaths annually.

Nutrition and Exercise

There is growing evidence that diet and exercise play a role in modifying lung cancer risk. A 2009 review found that the risk for lung cancer was 22 % lower in those who ate the highest amount of cruciferous vegetables compared to those who ate a minimal amount [8]. Additionally, a 2007 World Cancer Research Fund report noted that high fruit intake consistently protected against lung cancer (in one analysis, reducing risk by 23 % compared to low fruit intake) and that carotenoid-containing foods probably protect against lung cancer. There was also limited evidence suggesting that non-starchy vegetables, selenium, and physical activity were protective against lung cancer, whereas red meat, processed meat, butter, and high overall fat intake were causes of lung cancer [9]. Attempts to isolate the antioxidants thought to be responsible for the protective effects from carotenoid-containing vegetables have not been successful; high-dose vitamin A supplementation in smokers was actually associated with an increased risk of lung cancer. The interplay of antioxidants contained within foods and the possibility that carotenoids are a marker for a healthier lifestyle rather than protective on their own create uncertainty regarding the mechanisms of the protective effects of a healthy diet. However, the evidence clearly shows that a diet high in fruits and cruciferous vegetables, combined with physical activity, is a significant part of overall lung cancer prevention.

Genetics

The lifetime risk of being diagnosed with lung cancer in smokers is approximately 17.2 % in males and 11.6 % in females (compared to 1.3 % and 1.4 % in nonsmokers, respectively) [10]. That a majority of smokers do not develop lung cancer shows that other factors are involved in the pathogenesis of lung cancer, especially genetic susceptibility. In one study, after adjusting for smoking, age, and gender, a positive family history of lung cancer conferred an odds ratio of developing lung cancer of 1.6, with an increase to 3.6 if two or more family members had been diagnosed [11].

As with other cancers, lung carcinogenesis is a multistep process, involving DNA damage at multiple levels that ultimately causes unchecked cell proliferation. Specifically, mutations within tumor suppressor genes, DNA repair genes, and oncogenes work synergistically to promote tumor growth. Dozens of genes have been noted to have mutations in those with lung cancer, including K-*ras*, *EGFR*, and p53. Recent developments in genomic profiling allow for a million or more genetic variants to be concurrently sequenced, allowing more widespread identification of mutations that may indicate an increased risk of lung cancer. Though genetic testing is not currently used for screening in clinical practice, ongoing research may make it possible that it could one day play a major role in determining susceptibility to lung cancer.

Secondary Prevention

Efforts at secondary prevention have been geared toward early detection through imaging, as other noninvasive tests (serologic, sputum, breath) are only in developmental stages. Until recently, studies had not shown benefits from the imaging of high-risk patients. However, in 2013, the United States Preventive Services Task Force (USPSTF) recommended annual low-dose computed tomography (CT) screening for high-risk current or former smokers (those with a 30 pack-year history and who have smoked in the last 15 years) aged 55–80 years old, to detect asymptomatic disease.

This recommendation was primarily based on the National Lung Screening Trial (NLST), the largest lung cancer screening trial to date, which enrolled over 53,000 patients in academic medical centers across the USA. The NLST demonstrated a 20 % reduction in lung cancer mortality compared to chest X-ray screening, with a number needed to treat of 320 [12]. Subsequent analyses estimate the expense of screening, once fully

implemented, to be approximately $81,000 per quality-adjusted life-year (QALY) gained [13], which is not dissimilar to the costs of screening mammography and colonoscopy. A large criticism of the trial is the possible lack of generalizability of the findings, namely, the participants were healthy volunteers, academic medical centers often have lower surgical complication rates and greater radiological expertise, and modern CT scanners are more advanced than those used in the trial. Also of concern is the inevitable large number of false-positive findings and the harms that would likely result from increased interventions. As of this writing, given the newness of this recommendation, the true benefits and costs have yet to be determined. Further subgroup analyses to identify higher risk groups may hone the recommended population to screen.

Classifications

Lung cancer originates from cells in the respiratory epithelium (resulting in small cell lung cancer, adenocarcinoma, squamous cell carcinoma, and large cell carcinoma) and the pleura (resulting in mesothelioma). Much rarer forms of lung cancer include spindle cell carcinoma, giant cell carcinoma, and carcinosarcomas; they are classified as non-small cell lung cancers. The relative incidence of the most common types is shown (see Table 1) [14]. In recent decades, adenocarcinoma has become the most prevalent type of lung cancer. This may be due to the widespread use of filtered cigarettes, which allow carcinogens to travel further down the bronchial tree, bypassing protective epithelium. Smoking is associated with nearly all types of lung cancer but is most closely associated with small cell and squamous cell cancers. In those who have never smoked, adenocarcinoma is the most common type of cancer [15].

The stage of disease is the strongest predictor of survival, though histology also plays an important part in prognosis [16]. Among the major histological types, adenocarcinoma generally has the highest 5-year survival, and small cell has the poorest survival. For localized disease, the 5-year survival is approximately 60 % for adenocarcinoma, 44 % for squamous cell, 41 % for large cell, and 20 % for small cell. For regional disease, the survival drops to 20 % for adenocarcinoma, 16 % for squamous cell, 16 % for large cell, and 11 % for small cell. With the new implementation of screening CT for lung cancer, cancers may be detected at earlier (more local) stages, which may improve survival and increase the amount of disease amenable to a cure.

Table 1 Lung Cancer Type by Histology

Lung cancer type by histology [15]	Incidence (%)[a]
Small cell lung cancer (SCLC)	18
Non-small cell lung cancer (NSCLC)	74
Adenocarcinoma	46
Squamous cell carcinoma	25
Large cell carcinoma	8
Mesothelioma	<0.02

[a]Due to a combination of sources for the numbers, the total may not add up to 100 %

Diagnosis

Clinical Presentation

The clinical presentation of a lung cancer is driven by the site of origin and the extent of the disease. It is not uncommon for it to be an asymptomatic finding on a chest X-ray or CT scan of the abdomen or chest obtained while working up another problem. Other common presentations are nonresolving infiltrates after treatment for pneumonia, as a pleural effusion or with persistent chest wall or shoulder pain. Because of the endobronchial origin of many lung cancers, cough, hemoptysis, dyspnea, and unilateral wheezing or stridor may be the original complaint. Patients presenting with advanced disease may have weight loss, anorexia, fatigue, persistent fevers, or clubbing.

Lung cancers are associated with a number of syndromes, which can be divided into general categories: (1) the consequences of tumor invasion of the surrounding tissues, (2) the systematic effects of hormonal substances produced by cancers, and (3) cytokines or antibodies triggered by

the immune system's response to the tumor (paraneoplastic syndromes). Local invasion of nerves at the apex of the lung causes Horner's syndrome (cervical sympathetic) or Pancoast syndrome (brachial plexus). Tumor invasion of the mediastinum can block venous return to the heart causing superior vena cava syndrome, invasion of the pericardium causing cardiac tamponade, or erosion into the esophagus causing obstruction or fistulas. Metastatic lesions in the spine can cause spinal cord compression with distal weakness and pain. Tumors can secrete antidiuretic hormone causing hyponatremia, parathyroid hormone causing hypercalcemia, or adrenocorticotrophic hormone leading to Cushing syndrome. These latter hormonal syndromes are more common with SCLC and reflect the neuroendocrine nature of these cancers. The most common paraneoplastic syndrome associated with lung cancer, occurring in 5–15 % of patients, is periosteal swelling of the distal phalanges causing clubbing of the fingers. The myasthenia-like Eaton-Lambert syndrome develops from the production of antibodies to the postsynaptic acetylcholine receptor of the motor end plate.

Diagnostic Approach

Typically, patients with lung cancer present with advanced tumors causing a range of symptoms. Diagnostic decisions center on identifying the tumor cell type and accurately staging the extent of the cancer. With increasing frequency, especially in the context of screening for asymptomatic cancers using low-dose CT scans of the chest, diagnostic decisions revolve around the safest way to evaluate small, indeterminate lung nodules. Recent years have seen a rapid expansion in the complexity of diagnostic algorithms for both of these clinical scenarios. This complexity makes it beyond the scope of this chapter to make any detailed suggestions about workups for particular clinical presentations [17].

Evaluating a Lung Nodule

Lung nodules may be found incidentally on a chest X-ray or through a screening protocol using a CT scan. Incidental lung nodules should be compared with any prior imaging tests. An indeterminate nodule that can be shown to have been stable for at least 2 years requires no further diagnostic evaluation. Nodules found by chest X-ray that cannot be shown to be stable for 2 years should have a diagnostic, thin-section CT of the chest performed. Further evaluation is determined by the pretest probability of malignancy, the size of the nodule (greater than 8 mm or smaller), and nodule characteristics. Further diagnostic steps may include serial CT studies over 2 years, functional imaging with positron emission tomography (PET), bronchoscopy with biopsy, CT-guided needle biopsy, or surgical wedge resection. The choice of which technique to use should involve a team approach involving input from radiologists, pulmonologists, thoracic surgeons, and the patient's preferences. The family physician can play a crucial role explaining the risks and benefits of the various options to the patient and helping to make sure the final decision reflects the patient's values [18].

Staging Non-small Cell Lung Cancer

The diagnostic workup for a patient with a suspected lung cancer is based on the size and location of the suspected tumor, evidence for mediastinal or distant metastatic disease, the efficiency of the proposed workup, the invasiveness and risks of any procedures, the technologies and expertise locally available, and the patient's comorbidities and preferences. Diagnostic technologies are in a period of rapid evolution. It is reasonable to consult a team representing interventional radiology, thoracic surgery, pulmonology, and oncology. Accessing websites from groups such as the National Comprehensive Cancer Network [19] or the American College of Chest Physicians [20] can provide family physicians with current diagnostic guidelines.

The family physician should conduct a thorough history and physical examination, including performance status and noting any weight loss. Routine studies should include the following: a CBC with platelets, a comprehensive metabolic profile, a CT scan of the chest and upper abdomen (including the adrenal glands), and a pulmonary function testing. Counseling on smoking cessation should be performed for current smokers. Discuss with the patient and participating consultants a plan for integrating palliative care into the treatment plan. When there is a high clinical suspicion for advanced disease, PET imaging allows for the choice of a diagnostic biopsy site to confirm the highest stage to be assigned to the cancer.

Staging Small Cell Lung Cancer

The diagnostic evaluation for suspected or known small cell lung cancer follows the same outline as for non-small cell lung cancer discussed above. The aim is to categorize the disease as in either a limited or extensive stage. In addition to the general workup reviewed above, a brain MRI is obtained. For equivocal bone lesions on PET imaging, bone imaging with MRI/radiographs as well as bone marrow aspiration/biopsy may be needed [21].

Treatment

Algorithms for treating lung cancer are now evolving rapidly after years of very modest progress. This has come about through an increased understanding of cancer genomics [16]. Tumors harboring specific acquired genetic alterations are being treated with targeted inhibitors of altered enzymes that are driving cancer growth. Monoclonal antibodies targeted at altered epidermal growth factor receptor (EGFR), anaplastic lymphoma kinase (ALK), and receptor tyrosine kinase (ROS1) are producing exciting clinical response rates [22, 23]. An era of personalized treatment, based on whole tumor genome sequencing, is imminent. The family physician is in the position, working collaboratively with the consulting oncologist, to educate patients about these treatment options and to counsel them about the option of participating in an experimental treatment protocol. In addition, palliative care needs should be addressed throughout the treatment process.

Non-small Cell Carcinoma

Treatment algorithms are driven by tumor stage and pathology. Treatment decisions need to be worked out consensually between the patient and the treatment team of medical oncologists, radiation oncologists, and thoracic surgeons. The family physician can help to facilitate these decisions and advocate for the patient's values and preferences. Early stage disease is treated with surgery or possibly radiation therapy. More advanced stage disease is treated with various two chemotherapy drug combinations and possibly radiation therapy. Metastatic disease should undergo EGFR and ALK mutation testing for possible addition of a targeted monoclonal antibody agent [19].

Small Cell Carcinoma

The performance status of the patient with limited stage disease drives treatment decisions ranging from concurrent chemotherapy and radiation therapy for high-functioning patients to hospice care for patients with extensive comorbidities. Patients with extensive disease are treated with chemotherapy. Whole brain radiation therapy is used for patients with brain metastases. Palliative external beam radiation therapy can be used for bone metastases, superior vena cava syndrome, lobar obstruction, or spinal cord compression [21].

Posttreatment Follow-Up

With the earlier detection of lung cancers and more effective treatments, the family physician will be involved with a growing number of patients who have undergone therapy with curative intent who will need surveillance for

recurrent disease. Coordinate this care with the treating oncologist. A history and physical examination, along with CT examinations of the lungs, should be done every 4–6 months for the first 2 years and then yearly thereafter. Encourage patients to remain current with influenza and pneumococcal vaccinations [24].

Palliative Care

The family physician can play a key role in ensuring as high a quality of life as possible for patients as they move through the continuum from diagnosis to treatment with intent to cure and finally to end of life care. The family physician can educate patients about creating a living will and a durable power of attorney to establish their care preferences. They can explore the patients' interest in the use of complementary and integrative therapies alongside standard cancer therapies. They should question patients about common symptoms such as pain, anorexia, constipation, breathlessness, fatigue, depression, and insomnia and provide care to ameliorate these as much as possible [25–27].

Respiration and gas exchange require coordination between the chest wall, lungs, central nervous system, and pulmonary circulation. A disruption within any one of these systems or a change in the relationship between systems can result in impairments of ventilation, perfusion, or gas exchange. These disruptions can result in debilitating acute and chronic respiratory disorders. This chapter discusses the etiology, epidemiology, clinical presentation, diagnostic criteria, management, and notable public health implications of respiratory system disorders not addressed in prior chapters. Topic areas covered include acute respiratory distress syndrome (ARDS), pulmonary hypertension, pneumothorax, pleural effusion, interstitial lung disease, bronchiectasis, atelectasis, and pulmonary sarcoidosis.

Acute Respiratory Distress Syndrome

ARDS is a rapidly progressive pulmonary disorder occurring in medical or surgical patients. Approximately 190,000 cases of ARDS occur each year in the USA with the highest incidence in patients aged 75–84 years old. In the intensive care unit setting, approximately 10–15 % of admitted patients and upwards of 20 % of mechanically ventilated patients meet criteria for ARDS. The in-hospital mortality rate for ARDS is estimated at 34–55 % [1]. Population data suggest a trend towards improvement in survival for ARDS affected patients – an event thought to be driven by advancements in supportive care and mechanical ventilation. ARDS is characterized by a direct or indirect lung insult that results in the disruption of the alveolar-capillary barrier and stimulates the proliferation of inflammatory mediators. An increase in protein-rich interstitial fluid results in the loss of surfactant, thereby impairing gas exchange and decreasing pulmonary compliance. The majority of ARDS cases in adults can be attributed to sepsis, pneumonia, severe trauma, aspiration, and transfusion-associated lung injury. Risk factors in children are similar to those in adults, with the addition of age-specific disorders, including infection with respiratory syncytial virus and near drowning aspiration injury. Predictors of mortality in the patient with ARDS include severe hypoxemia, failure to improve oxygenation, pulmonary vascular dysfunction, severity of infection, and nontraumatic cause.

Diagnosis

The diagnosis of ARDS should be considered in any patient presenting with dyspnea, hypoxemia, and associated risk factors. A comprehensive evaluation including patient history, physical examination, laboratory testing, and imaging is essential to differentiate ARDS from similar respiratory conditions and to initiate appropriate therapy. The diagnostic criteria for ARDS, according to the 2012 Berlin definition [2], includes: (1) acute onset ($\leq$1 week of new or worsening respiratory symptoms), (2) presence of bilateral opacities on chest radiograph or computed tomographic scan, (3) exclusion of cardiac failure or fluid overload as the origin of pulmonary edema, and (4) impairment in oxygenation (characterized by 200 $<$ Pao_2/FIo_2 ratio $\leq$ 300 mmHg in mild ARDS; 100 $<$ Pao_2/FIo_2 ratio $\leq$ 200 mmHg in moderate ARDS; and Pao_2/FIo_2 ratio $\leq$ 100 mmHg in severe ARDS). Physical examination typically demonstrates evidence of respiratory distress, including tachypnea, tachycardia, and accessory muscle usage. It is important to distinguish ARDS from other conditions that result in acute hypoxemic respiratory failure with bilateral lung infiltrates, including pneumonia (viral or diffuse bacterial), cardiogenic pulmonary edema, acute inhalation injury, and malignancy (Table 1).

Management

The approach to medical support in patients with ARDS includes maintaining adequate oxygen delivery and providing comprehensive supportive care while minimizing ventilator associated lung injury (VALI) and secondary complications. The majority of affected patients will require sedation and mechanical ventilation in an intensive care setting. Treatment of reversible disease processes (e.g., infection) should accompany respiratory

support efforts. Considerations in mechanical ventilation include: (1) low tidal volume ventilation, or lung protective ventilation, which has been shown to improve mortality by reducing VALI and decreasing inflammatory mediator release, (2) titration of positive end-expiratory pressure (PEEP) levels to recruit atelectatic, undamaged alveoli [3], and (3) permissive hypercapnia to minimize VALI due to alveolar over distension. A subpopulation meta-analysis of 11 randomized controlled trials suggests that prone positioning during mechanical ventilation is associated with improved survival, although patient selection should be reserved for severely ill persons failing to improve with low tidal volume ventilation strategies [4]. A spontaneous breathing trial is indicated in the patient who is hemodynamically stable and able to maintain oxygen requirements through noninvasive methods.

Supportive care in ARDS includes the appropriate balance of sedation, analgesia, and neuromuscular blocking agents; nutritional support and management of blood glucose; minimizing nosocomial infections (e.g., catheter associated urinary tract infections and ventilator associated pneumonia); stress ulcer prophylaxis (omeprazole 40 mg orally, intravenously, or via nasogastric tube daily; ranitidine 150 mg orally or via nasogastric tube two times daily or 50 mg intravenously every 6–8 h; sucralfate 1 g orally or via nasogastric tube four times daily) and deep venous thrombosis prophylaxis unless medically contraindicated (enoxaparin 40 mg subcutaneously daily; unfractionated heparin 5,000 units subcutaneously two times daily). While a definitive role for glucocorticoid therapy in the treatment of ARDS has not yet been established, early initiation of corticosteroid therapy may be associated with an increase in ventilator free days [5].

Prevention

A review of current literature and population based studies suggests that potentially preventable hospital exposures contribute to the development of hospital-acquired ARDS in at-risk patients. These exposures include preventable medical and surgical adverse events, inadequate empiric antimicrobial therapy, large volume blood product transfusion, large volume intravenous fluid administration, and documented pulmonary aspiration. Quality improvement efforts to mitigate these exposures may aid in the reduction of hospital-acquired ARDS and improve safety outcomes for critically ill patients [6].

Family and Community Issues

The family physician is essential in coordination of posthospital care for survivors of ARDS. This population is at heightened risk for long-term functional impairments (exercise limitation, decreased physical quality of life) as well as psychological sequelae (depression and anxiety, social isolation) and increased utilization of health care services [7].

Pulmonary Hypertension

Pulmonary hypertension is a progressive disease of the pulmonary circulation defined by a mean pulmonary arterial pressure $\geq$ 25 mmHg at rest measured by right heart catheterization. The condition affects all age groups, both men and women equally. Due to the broad classification system and numerous etiologies for pulmonary hypertension, epidemiological data is limited. Mortality is estimated at 5.4 per 100,000 persons with women and African-American persons adversely affected. Pulmonary hypertension is characterized by one of the following: (1) primary elevation in the pressure of the pulmonary arterial system (pulmonary arterial hypertension) or (2) a secondary elevation in the pressure of the pulmonary venous and pulmonary capillary systems (pulmonary venous hypertension). Pulmonary hypertension can present at any age from infancy to adulthood, although pediatric populations are more frequently diagnosed with pulmonary arterial hypertension due to congenital heart disease or idiopathic etiologies.

Classification

In 1998, the World Health Organization (WHO) sponsored a symposium on primary pulmonary hypertension, from which a new classification system for the disease was developed. Classification of pulmonary hypertension is essential in estimating prognosis and initiating therapy. This classification has undergone minor modifications, with the most recent occurring during the fourth World Symposium on Pulmonary Hypertension (Dana Point, 2008); this classification divides pulmonary hypertension into five categories based on commonalities in pathophysiologic mechanism of disease, clinical presentation, and therapeutic approaches [8]. These five categories include: (1) pulmonary arterial hypertension, (2) pulmonary hypertension owing to left heart disease, (3) pulmonary hypertension owing to lung diseases and/or hypoxia, (4) chronic thromboembolic pulmonary hypertension, and (5) pulmonary hypertension with unclear multifactorial mechanisms. Further breakdown within classes can be reviewed in Table 2.

Diagnosis

A comprehensive evaluation is indicated in all patients with suspected pulmonary hypertension, including patient history, physical examination, laboratory testing, and imaging. Patients most commonly present with dyspnea on exertion and fatigue. As the disease progresses, chest pain, dizziness, cough, syncope, hemoptysis, ascites, and edema may develop. A thorough review of systems should be performed to identify symptoms suggestive of associated and underlying conditions. It is important to distinguish pulmonary hypertension from other causes of exertional dyspnea. The differential diagnosis must include

Table 2 Classification of pulmonary hypertension

1. Pulmonary arterial hypertension (PAH)
1.1 Idiopathic
1.2 Heritable
1.2.1 BMPR2
1.2.2 ALK1, endoglin (with or without hereditary hemorrhagic telangiectasia)
1.2.3 Unknown
1.3 Drug- and toxin-induced
1.4 Associated with:
1.4.1 Connective tissue diseases
1.4.2 HIV infection
1.4.3 Portal hypertension
1.4.4 Congenital heart diseases
1.4.5 Schistosomiasis
1.4.6 Chronic hemolytic anemia
1.5 Persistent pulmonary hypertension of the newborn
1'. Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis
2. Pulmonary hypertension owing to left heart disease
2.1 Systolic dysfunction
2.2 Diastolic dysfunction
2.3 Valvular disease
3. Pulmonary hypertension owing to lung diseases and/or hypoxia
3.1 Chronic obstructive pulmonary disease
3.2 Interstitial lung disease
3.3 Other pulmonary diseases with mixed restrictive and obstructive pattern
3.4 Sleep-disordered breathing
3.5 Alveolar hypoventilation disorders
3.6 Chronic exposure to high altitude
3.7 Developmental abnormalities
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear multifactorial mechanisms
5.1 Hematologic disorders: myeloproliferative disorders, splenectomy
5.2 Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis: lymphangioleiomyomatosis, neurofibromatosis, vasculitis
5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4 Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

coronary artery disease, left-sided heart failure, acute and chronic liver disease, and Budd-Chiari syndrome.

Physical findings arise from compensatory changes in the right ventricle. Common examination findings in early disease include a prominent second heart sound (loud P_2 heard best in the left upper sternal border), systolic murmur of tricuspid regurgitation, increased jugular venous pressure (neck vein distension), ascites, or peripheral edema. The clinician should tailor the physical examination based upon the suspected classification of pulmonary hypertension. Laboratory testing should be ordered based on suspicion of underlying disease and may include a complete blood count with differential, liver function test, brain natriuretic peptide, thyroid studies, antinuclear antibody (ANA), HIV serology, rheumatoid factor (RF), and antineutrophil cytoplasmic antibody (ANCA) [9].

Chest radiography of the patient with pulmonary hypertension classically reveals prominent interstitial pulmonary markings and attenuated peripheral pulmonary arteries. Enlargement of the right ventricle and right atrium and evidence of underlying pulmonary disease (e.g., pulmonary fibrosis) may also be noted. Changes on electrocardiogram do not correlate with disease severity or prognosis but may aid in detecting right ventricular disease. Signs of right ventricular hypertrophy or strain on electrocardiogram may include right axis deviation, incomplete or complete right bundle branch block, increased P wave amplitude in lead II, and R wave/S wave ratio > 1 in lead V1. The transthoracic echocardiogram is useful in the estimation of pulmonary artery systolic pressure and the assessment of right ventricular size, thickness, and function. Evidence of congenital heart disease and the status of the heart valves and septum can also be determined by the echocardiogram. Pulmonary function testing, including lung volumes, diffusion capacity, and spirometry, may aid in characterizing underlying lung disease such as emphysema or pulmonary fibrosis. A six minute walk test can be useful in establishing baseline function, estimating prognosis, and monitoring clinical response to treatment. This involves exercise oximetry during a timed six

Table 3 Treatment of underlying conditions associated with pulmonary hypertension

Category	Treatment goal	Intervention
Pulmonary arterial hypertension	Reduce vascular resistance, endothelial and smooth muscle dysfunction	Advanced therapy strategies
Pulmonary hypertension due to left heart	Reduce left atrial pressure to decrease PAP	Afterload reduction Diuretics
Pulmonary hypertension due to disorders of the respiratory system and/or hypoxemia	Maximize pulmonary function and correct hypoxemia	Continuous oxygen therapy Glucocorticoids Bronchodilators Nocturnal CPAP
Chronic thromboembolic pulmonary hypertension	Restore luminal patency and reduce vascular resistance	Lifelong anticoagulation Vena cava filter Surgical thromboendarterectomy
Pulmonary arterial disease related to infection, inflammatory conditions, or toxins	Reduce vascular resistance, endothelial and smooth muscle dysfunction	Disease modifying antiinflammatory agents Antiinfectious agents Avoiding toxin or causative drugs

PAP positive airway pressure, *CPAP* continuous positive airway pressure

minute walk. Polysomnography may be appropriate if sleep-disordered breathing (e.g., obstructive sleep apnea) is suspected. A ventilation-perfusion (V/Q) scan is the preferred imaging study to evaluate patients for chronic thromboembolic pulmonary hypertension.

Due to the need for cardiac catheterization to confirm the diagnosis of pulmonary hypertension, early cardiology consultation is indicated. The right heart catheterization is indicated to confirm the diagnosis, determine disease severity, and establish therapeutic intervention.

Management

Prognosis amongst patients with pulmonary hypertension is highly variable and depends on both the classification and severity of disease. Untreated, pulmonary hypertension is a progressive disease that can be fatal. An approach to more goal-directed management of pulmonary hypertension may improve long-term outcomes in patients. Such treatment goals, according to the American College of Cardiology, include: (1) modified New York Heart Association functional class I or II, (2) six-minute walk distance $\geq$ 380–440 m, (3) cardiopulmonary exercise test-measured peak oxygen consumption $>$ 15 ml/min/kg and ventilatory equivalent for carbon dioxide $<$ 45 l/min/l/min, (4) brain natriuretic peptide level near normal range, (5) echocardiograph and/or cardiac magnetic resonance imaging demonstrating normal or near-normal right ventricular size and function, and (6) normalization of right ventricular function with right atrial pressure $<$ 8 mmHg and cardiac index $>$ 2.5–3.0 l/min/m^2 [10].

Treatment begins with therapy targeted to any underlying condition (Table 3). Supplemental oxygen, diuretics, anticoagulation, and digoxin therapy should be considered as primary treatment strategies in all patients with pulmonary hypertension. Advanced therapy should be considered in WHO functional class II, III, or IV patients and may include prostanoids, endothelin receptor antagonists, phosphodiesterase 5 inhibitors, soluble guanylate cyclase stimulants, or calcium channel blockers to reduce right ventricular overload based on right heart catheterization findings [11]. Emerging therapies in the treatment of pulmonary hypertension include antiproliferative strategies, transcription factor-based therapy, immune cell-focused approaches, and epigenetic

modulation-based therapy [12]. Patients with idiopathic pulmonary arterial hypertension may be candidates for lung transplantation. Maintenance of updated influenza and pneumococcal vaccinations is recommended.

Pneumothorax

A pneumothorax is defined as the presence of gas within the pleural space and can be classified by etiology as spontaneous or acquired (iatrogenic or traumatic). The spontaneous pneumothorax can further be categorized as primary (no known underlying pulmonary disease) or secondary (known underlying pulmonary disease). The gas may enter through the chest wall and parietal pleura due to trauma or may originate from gas-filled gastrointestinal structures such as a ruptured esophagus or bowel with subsequent escape of gas across the diaphragm from a pneumoperitoneum. Most often the gas originates in the lung with leakage following alveolar or tracheobronchial injury or through the visceral pleura due to focal pulmonary processes.

Primary Spontaneous Pneumothorax

In primary spontaneous pneumothorax (PSP), the pneumothorax results from the rupture of a subpleural bleb, typically in persons with no prior lung disease. The incidence is 7.4 cases per 100,000 in men and 1.2 per 100,000 in women and peaks in persons between 20 and 30 years of age [13]. Risk factors for the development of PSP include cigarette smoking, family history of primary spontaneous pneumothorax, Marfan syndrome, and homocystinuria.

Diagnosis

The most common symptoms of PSP include sudden onset of pleuritic chest pain and dyspnea. The chest pain may be dramatic and severe, localized over the area of pneumothorax and sometimes radiating to the ipsilateral shoulder. The severity of symptoms may be related to the volume of air within the pleural space. Physical examination often reveals a mild tachycardia. Auscultation reveals diminished breath sounds and decreased chest excursion on the affected side. Chest percussion reveals hyperresonance over the affected side. Arterial blood gases may reveal hypoxemia without hypercapnia due to ventilation-perfusion mismatch in otherwise healthy lung tissue.

The chest radiograph in PSP is diagnostic, demonstrating a lucent area of pleural space devoid of the normal vascular markings that divide the edge of the lung from the chest wall [14]. While it is difficult to estimate the size of the pneumothorax by chest radiograph, a 1-in. lucent rim corresponds approximately to a 30 % collapse of the lung. In critically ill patients unable to remain upright, a supine chest radiograph will reveal lucency in the costophrenic sulcus rather than the apex.

Management

Management strategies in PSP are directed at lung reexpansion (removal of air in the pleural space), symptomatic management, and prevention of recurrence. Treatment options depend on the size of the pneumothorax and the severity of symptoms. Small pneumothoraces involving less than 15 % of the hemithorax (<3 cm between the lung and chest wall on chest radiograph) may resolve without therapy, provided no additional leakage occurs. Complete resolution is expected within 10 days. Supplemental oxygen can facilitate resolution by increasing the pressure gradient of nitrogen from the pleural space into the capillaries and facilitating resorption of the pleural air. In uncomplicated cases of PSP, both manual aspiration and small-bore catheter insertion with Heimlich valve are cost-effective and minimally invasive interventions with comparable success rates and shorter hospitalizations as compared to tube thoracostomy [15, 16]. A large pneumothorax or a patient with severe symptoms is associated with increased likelihood of failure of simple aspiration [17] and will likely require chest tube insertion to permit reexpansion of the lung. Video-assisted thoracoscopic surgery pleurodesis, chemical pleurodesis, or thoracotomy should be considered after two ipsilateral PSPs or when a

5- to 7-day course of chest tube therapy fails to result in lung reexpansion. The recurrence rate for PSP is approximated at 30 % and does not appear affected by treatment choice [13].

Family and Community Issues

The strong association between cigarette smoking and rates of PSP provides an opportunity for the family physician to coordinate smoking cessation interventions with a goal to prevent recurrent pneumothoraces.

Secondary Spontaneous Pneumothorax

In secondary spontaneous pneumothorax (SSP), the pneumothorax results from the rupture of a subpleural bleb as a complication of underlying lung disease. The incidence is 6.3 cases per 100,000 in men and 2 per 100,000 in women with peak incidence highest among persons over 55 years of age [13]. While most pulmonary diseases can result in an SSP, the finding is most frequently associated with pulmonary infection (*Pneumocystis jiroveci* pneumonia, Mycobacterium tuberculosis, necrotizing pneumonia), interstitial lung disease, primary or metastatic lung malignancy, cystic fibrosis, and COPD. The pathophysiology of SSP remains unclear. It is thought that air enters the pleural space following alveolar rupture due to a mechanism associated with the underlying lung disease.

Diagnosis

Symptoms, physical examination, and radiographic findings in SSP are similar to those of PSP with several exceptions. Symptoms in SSP can be more severe due to the diminished pulmonary reserve associated with chronic underlying pulmonary disease. Imaging in SSP may require computed tomography of the chest in addition to chest radiograph in order to definitively determine the size and location of pleural air.

Management

Management strategies in SSP mimic those of PSP and are directed at lung reexpansion (removal of air in the pleural space), symptomatic management, and prevention of recurrence. Unlike PSP, the majority of patients presenting with SSP will require hospitalization and pleural drainage due to the severity of underlying lung disease and risk of adverse outcomes. Patients predisposed to hypercapnia due to chronic pulmonary disease (e.g., COPD) may require higher concentrations of supplemental oxygen. Recurrence rates for SSP range from 40 % to 56 % and frequently occur within the first 6 months after the first episode. Due to the marked rate of recurrence, thoracotomy, video-assisted thoracoscopic surgery, or chemical pleurodesis should be performed in all patients undergoing treatment for an initial SSP.

Tension Pneumothorax

A tension pneumothorax can result from either a spontaneous or a traumatic pneumothorax and is a life-threatening emergency. Tension develops as air freely enters the pleural space during inspiration but is unable to escape during expiration. The result of this one-way valve is further lung collapse with shifting of the trachea and mediastinum away from the pneumothorax. Patients with a tension pneumothorax are in acute respiratory distress and have dilated neck veins, tracheal deviation, and absence of breath sounds on the affected side. Patients are in danger of impending cardiovascular collapse unless prompt treatment ensues. Immediate insertion of a large-bore needle (16 gauge) into the affected pleural cavity at the second intercostal space releases the trapped air, relieves the pressure, and results in rapid improvement in cardiac output and blood pressure [14].

Pleural Effusion

Pleural effusions are an accumulation of fluid in the pleural space resulting from a disparity between pleural fluid formation and resorption. Typically, oncotic and hydrostatic pressures regulate this fluid movement; however, decreased capillary oncotic pressure or elevated capillary and interstitial hydrostatic pressures may lead to

Table 4 Pleural fluid characteristics based on light's criteria rule [20]

Characteristics	Transudate	Exudate
Pleural fluid protein/serum protein ratio	<0.5	>0.5
Pleural fluid LDH/serum LDH ratio	<0.6	>0.6
Pleural fluid LDH	< Two thirds of upper limit of normal serum LDH	> Two thirds of upper limit of normal serum LDH
pH	>7.40	<7.40
WBC count	Typically < 1,000/μL	Typically > 1,000/μL

LDH lactate dehydrogenase, *WBC* white blood cell

accumulation of fluid. Pleural effusions are caused by more than 50 disease processes with congestive heart failure, cirrhosis with ascites, pleuropulmonary infections, malignancy, pulmonary embolism, and pancreatitis accounting for more than 90 % of all cases.

Diagnosis

A comprehensive evaluation, including patient history, physical examination, and thoracentesis to sample and analyze the pleural fluid, aids the physician in establishing the etiology of a pleural effusion. Symptoms of pleural effusions are the result of pleural inflammation or mechanical effects of the fluid volume. The most common presenting complaints include pleuritic chest pain, dyspnea, nonproductive cough, and fever. Pain may be referred to the abdomen or ipsilateral shoulder. Patients may be asymptomatic. The pulmonary examination characteristically reveals decreased breath sounds over the area of the effusion. Tactile fremitus, dullness to percussion, and a pleural friction rub are sometimes found over the area of the effusion. The posteroanterior and lateral chest radiographs are the most informative initial diagnostic studies when a pleural effusion is suspected. Effusions that blunt the costophrenic angle represent an estimated 200 mL of fluid on posterioanterior radiographs and as little as 50 mL of fluid on lateral imaging. If uncertainty exists, computed tomography and ultrasound may be utilized.

Once the presence of a pleural effusion is confirmed, the etiology should be sought. This is best done through analysis of pleural fluid obtained by thoracentesis. While only a limited number of disorders can be definitively diagnosed by thoracentesis (e.g., malignancy, hemothorax, fungal infection, esophageal rupture, empyema, and tuberculous pleurisy), even nondiagnostic pleural fluid analysis can aid in excluding potential etiologies. Laboratory testing for pleural fluid analysis should include assessment of gross appearance (color and character), cell count, pH, protein level, lactate dehydrogenase level, Gram staining, culture, cytology, and glucose. The fluid should then be categorized as either a transudate or exudate using an algorithm such as the Light's Criteria Rule (see Table 4). The Light's Criteria Rule can misclassify transudative effusions as exudates in some cases of congestive heart failure, and literature review suggests including additional biomarkers to correctly classify pleural effusions in these patients [18]. The use of soluble biomarkers that correlate with specific disease processes may be a useful adjunctive in evaluating the etiology of the pleural effusion [19].

Transudative Effusion

Transudative effusions result from a disparity between oncotic and hydrostatic pressures in the pleural space. Congestive heart failure is the most common cause of a transudative effusion and is usually bilateral. In these patients, the failing left ventricle leads to increased pulmonary capillary pressure that forces fluid into the interstitium; the failing right ventricle contributes to an effusion by elevating capillary hydrostatic force in the parietal pleura, thus diminishing reabsorption. Hepatic cirrhosis is associated with a transudative right-sided effusion in 5–10 % of cases where ascites is present. Pancreatitis

and subphrenic abscesses can also produce right-sided effusions. While these typically begin as transudates, they often convert to exudative effusions. Nephrotic syndrome and hypoalbuminemia produce transudates as part of a generalized process of increased interstitial edema.

Exudative Effusion

Exudative effusions result from inflammation or infiltrative disease processes affecting the pleura, including impaired lymphatic drainage. They are often due to malignancy, most commonly bronchogenic, breast metastases, or mesotheliomas. While most acute bacterial pneumonias do not lead to effusions, a parapneumonic effusion is seen in 5 % of cases of pneumococcal pneumonia. Viral and mycoplasma pneumonia may also cause effusions, as can tuberculosis. Pleural fluid analysis of the patient with pulmonary tuberculosis demonstrates a low glucose and a predominance of lymphocytes. Organisms are rarely found on acid fast stain, and cultures are positive in only 25 % of cases. Pulmonary embolus is accompanied by effusion in 50 % of cases. Typically small and localized to the area of pleuritic chest pain, the embolus may result from localized interstitial edema or bloody exudates due to infarction. Other less frequent causes of exudates include collagen vascular diseases such as systemic lupus and rheumatoid arthritis.

Management

Treatment of a pleural effusion is directed towards management of the underlying disease process. Appropriate antibiotic therapy usually results in resolution of a parapneumonic pleural effusion, although some effusions require chest tube drainage. Pleurodesis is used for management of recurrent malignant effusions and for transudative effusions that do not respond to maximal medical treatment.

Family and Community Issues

Many pleural effusions reflect chronic disease processes, and the family physician is uniquely positioned to aid in care coordination, support, and patient education. Hospice care may be beneficial for the terminal patient. Some infectious diseases including tuberculosis require community level screening and treatment of exposed family members.

Interstitial Lung Disease

The interstitial lung diseases (ILDs) are a group of heterogeneous disorders classified due to similarities in physiologic, clinical, pathologic, and radiographic findings. In the USA, the prevalence of ILD is estimated to be 20–40 per 100,000 persons. Common histologic findings of ILD include derangement of the alveolar structures in the lung with accompanying inflammation (alveolitis) and fibrosis of the alveolar walls, air spaces, and pulmonary capillaries. The initiating agent is unknown in most cases but is thought to be precipitated by a toxin or antigen. These pathophysiologic changes result in decreased lung compliance and volume as well as impaired oxygen exchange.

More than 150 variations of ILD have been identified and are classified by etiology. Sixty-five percent have no known etiology. Table 5 is an abbreviated list of the more commonly seen ILDs.

Diagnosis

A comprehensive evaluation is indicated in all patients with suspected ILD, including thorough patient history, physical examination, laboratory testing when appropriate, and imaging. In most instances, the thorough evaluation will result in a narrowed range of differentials or specific diagnosis which will assist the family physician in clinical decision-making. The patient history must include onset and duration of symptoms, past medical history, current and past medications and radiation exposure, smoking history, occupational and environmental exposures. The clinical symptoms of ILD are progressive dyspnea on exertion and persistent nonproductive cough. Less frequent presenting symptoms include

Table 5 Common etiologies of interstitial lung diseases

Known etiology	Idiopathic etiology
Drug-induced pulmonary toxicity Amiodarone Gold Nitrofurantoin Penicillamine Farmer's lung Hypersensitivity pneumonitis Inhaled inorganic dust Carbon (coal dust, graphite) Metals (aluminum, hard metal dusts, tin) Silicates (asbestos, beryllium, mica, silica, talc) Radiation induced lung injury	Collagen vascular disorders Eosinophilic pneumonitis Histiocytosis X Idiopathic pulmonary fibrosis Rheumatoid arthritis Sarcoidosis Systemic lupus erythematosus

fatigue, chest pain, hemoptysis, fever, anorexia, and weight loss. The pulmonary examination is typically nonspecific and may reveal bibasilar velcro-like rales. Additional examination findings may include clubbing, cyanosis, or extra pulmonary findings consistent with the underlying pathology. The exam may be normal. Laboratory testing should be pursued with a goal to clarify suspected ILD etiology and may include complete blood count with differential, liver function test, basic metabolic panel, creatine kinase, urinalysis, hepatitis serology, HIV screening, ANA, rheumatoid factor, ANCA, anti-JO-1 antibodies, and anti-ds DNA. Arterial blood gases may be normal or demonstrate a mild hypoxemia that worsens with activity. Hypercarbia is rare, and hypocarbia may be present.

Chest radiography may reveal an array of patterns, including nodular, reticular, or mixed findings. The correlation between radiographic pattern and clinical disease staging is limited; however, the evidence of a honeycomb pattern corresponds directly with poor prognosis. A comparison of prior chest imaging is essential to evaluate disease progression. A normal radiograph is present in 10 % of patients with ILD. High resolution computed tomography is considered the gold standard for assessing morphological changes in pulmonary parenchyma and may be helpful in evaluating diffuse ILD. MRI is emerging as an alternative modality to assess the morphological and functional changes of lung parenchyma in ILD [21]. More invasive diagnostic measures can be utilized when clinical indications exist. These include atypical or progressive symptoms, extrapulmonary involvement, and the absence of a plausible clinical diagnosis. Bronchoalveolar lavage has been shown to be an effective diagnostic tool with fewer complications than transbronchial or thoracoscopic lung biopsies [22]. The majority of ILDs demonstrate a restrictive pattern on pulmonary function tests with reduction in vital capacity, carbon monoxide diffusing capacity of the lungs (DL_{C0}), and total lung volume. Forced expiratory volume in first second/forced vital capacity ratio (FEV_1/FVC) may be normal or increased.

Management

The goal of treatment in ILD is to suppress alveolitis and prevent further lung damage. Untreated, most ILDs progress to end-stage lung disease complicated by cor pulmonale and death due to respiratory failure. The mainstay of treatment for ILDs of unknown etiology is corticosteroids to decrease inflammation. Immunosuppressive and cytotoxic agents have also been used. Bronchodilators and oxygen therapy may be useful in late stages of ILD. With known ILDs, initial treatment begins with identification and removal of the causative agent followed by corticosteroid therapy if the inflammation fails to resolve. There is strong evidence that pirfenidone reduces disease progression in patients with idiopathic pulmonary fibrosis [23] and that combined pirfenidone and pulmonary rehabilitation improves the quality of life in patients with ILD [24].

Family and Community Issues

Despite treatment, many patients with ILD will experience poorly controlled pain, dyspnea, and fatigue that can result in social isolation and diminished quality of life. The family physician should aid in identifying supportive and palliative care needs and facilitating end of life discussions to clarify goals of care.

Atelectasis

Atelectasis is a condition involving the loss of lung volume due to the collapse of alveolar space. Atelectasis can be classified by location (lobe or segment location), amount of lung tissue involved (subsegmental or lobar), or pathophysiologic mechanism (obstructive or nonobstructive). Pediatric populations, particularly infants and young children, are at increased risk of atelectasis due to increased chest wall compliance and decreased collateral ventilation of obstructed alveoli as compared to adults. Widespread diffuse atelectasis due to inadequate surfactant occurs in the premature infant with respiratory distress syndrome or from the lung injury of vapor or smoke inhalation.

Segmental and Subsegmental Atelectasis

Diagnosis

Risk factors for segmental and subsegmental atelectasis include abdominal or chest surgery, inadequate preoperative education, chronic lung disease (FEV_1 less than 1.5 L), tobacco exposure, obesity, cardiac disease, age over 55, recent respiratory infection, muscle weakness, excessive secretions, inadequate postoperative pain relief, and sickle cell crisis. In the postoperative setting, other pulmonary complications such as pulmonary embolus, aspiration, pneumonia, and bronchospasm should be considered, particularly if associated with pleuritic chest pain, hemoptysis, hypoxia, hypoventilation, or fever. The clinical symptoms of subsegmental atelectasis include cough, sputum production, fever, and dyspnea. Physical exam findings demonstrate tachypnea and end-inspiratory crackles. Chest radiography exhibits linear densities in the lower lung fields.

Management

Early ambulation and voluntary deep-breathing exercises reduce pulmonary morbidity in the patient with segmental or subsegmental atelectasis. Exercises should include sustained maximum inspiration with incentive spirometry (10 deep breaths with a 3–5 s inspiratory hold every 1–2 waking hours). In the perioperative period, pre- and postoperative deep breathing with cough and postoperative postural drainage have been shown to reduce atelectasis by more than half [25].

Family and Community Issues

Smoking cessation counseling 2 months prior to surgery should be offered to all patients undergoing elective procedures.

Lobar Atelectasis

Diagnosis

Lobar atelectasis in infants most often involves the right upper lobe. Other considerations in the differential diagnosis of lobar collapse in children include foreign body aspiration, congenital malformations of the bronchial skeleton, external compression from vascular or other structures, and chronic inflammation. Recurrent collapse is common in asthma and cystic fibrosis. Atelectasis should be considered when there is worsening oxygenation on mechanical ventilation. On pulmonary examination, lobar atelectasis produces dullness to percussion with decreased vocal fremitus and breath sounds over the affected lobe. Chest radiography may show an elevation of the hemidiaphragm, displacement of fissures and hilum, and shift of the mediastinum toward the collapsed lobe with homogeneous consolidation of the affected lobe.

Management

The treatment of lobar collapse requires attention to diagnosis and management of underlying disease. Chest percussion and postural drainage via physiotherapy can be beneficial. Bronchoscopy aids in foreign body removal and plays a role in direct treatment of obstructive lesions.

Bronchiectasis

Bronchiectasis is a chronic debilitating airway disease with considerable phenotypic diversity. The prevalence of bronchiectasis varies by

country, although appears to have increased in the USA between 2000 and 2007. Prevalence also appears to increase with age, peaking at ages 80–84 years old. The disease is more common in women than men and appears to have the highest prevalence in Asian populations [26]. The mortality rate of bronchiectasis is estimated between 10 % and 16 % and is associated with bronchiectasis or related respiratory failure. Bronchiectasis is characterized by the irreversible widening of one or more bronchi, often preceded by a significant lung injury such as pneumonia (bacterial, tuberculosis, pertussis), airway obstruction (foreign body aspiration), immunodeficiency, or autoimmune disease; however, there are numerous etiologies that can induce or contribute to the development of bronchiectasis (Table 6). Cystic fibrosis, Mycobacterium avium-intracellulare, bronchopulmonary aspergillosis, primary cilia dyskinesia, α_1-antitrypsin deficiency, hypogammaglobulinemia, rheumatoid arthritis, and Sjögren's syndrome are some additional predisposing diseases.

Table 6 Etiologies of bronchiectasis

Ulcerative colitis
Crohn's disease
Malignancy
Chronic lymphocytic lymphoma
Stem cell transplantation; graft-versus-host disease
Tissue injury
Pneumonia (bacterial, tuberculosis, pertussis)
Childhood infections
Cigarette smoking
Other
Alpha-1 antitrypsin deficiency
Cystic fibrosis
Yellow nail syndrome
Young's syndrome

Diagnosis

Bronchiectasis should be suspected in any patient presenting with chronic productive cough or frequent respiratory infections. Sputum is typically mucopurulent, noncopious, and non-foul smelling, although sputum production is not essential for diagnosis and the nonclassic presentation may include a patient with nonproductive chronic cough. A comprehensive evaluation is indicated in all patients with suspected bronchiectasis, including patient history, physical examination, laboratory testing, and imaging. Additional findings may include wheezing, rhinosinusitis, fatigue, dyspnea, recurrent fever, pleurisy, and hemoptysis. Common physical exam findings include pulmonary rales, rhonchi, or wheezing. The pulmonary examination may vary with cough and posture or be focal and persistent. Laboratory testing should focus on determining the etiology of disease and includes a complete blood count with differential, pneumococcal vaccine titers, immunoglobulin testing (A, E, G, and M), autoimmune evaluation (ANA, RF, aCCP, SSA, and SSB antibodies), alpha-1 antitrypsin level, cystic fibrosis sweat chloride testing (two measurements), CFTR genetic mutation analysis, sputum culture, and smear (bacteria, fungi, and mycobacteria). Bronchoalveolar lavage should be reserved for the patient unable to produce sputum or cases in which imaging appears normal despite high suspicion for the disease. The chest radiograph is abnormal in 91 % of cases and demonstrates patchy infiltrates, dilated and thickened airways (tram lines, ring shadows in cross section), and occasional air-fluid levels. Axial images of HRCT can definitively diagnose

bronchiectasis. PFTs are useful to assess the degree of respiratory impairment due to bronchiectasis and will typically demonstrate an obstructive pattern (reduced or normal FVC, low FEV_1, and low FEV_1/FVC).

Management

The complex clinical manifestations of bronchiectasis, including irreversible lung injury and the inability to clear secretions, necessitate a multifactorial approach to treatment. Management of the disease focuses on: (1) symptom reduction, (2) improvement in quality of life, and (3) prevention of exacerbations. Treatment of the underlying disease process, such as gamma globulin replacement in hypogammaglobulinemia, may aid in delaying or preventing the progression of bronchiectasis. Inhaled bronchodilators, antiinflammatory agents (oral or inhaled glucocorticoids, NSAIDs), antigastroesophageal reflux therapy, and immunizations (influenza and pneumococcal) may be beneficial in some patients. Oral antibiotic regimens are used as preventive therapy in patients experiencing two or more exacerbations within 1 year; a macrolide is the antibiotic of choice (azithromycin 500 mg three times weekly). The role of aerosolized antibiotics in the management of bronchiectasis remains unclear, although early investigations suggest that select inhaled antibiotics may decrease symptoms, lower sputum bacterial density, and improve patient reported quality of life [27]. In acute exacerbations, oral antibiotics are used to reduce both bacterial load and inflammatory mediators, and antibiotic selection should be based on prior sputum culture results (for patients without prior culture data, fluoroquinolones are an appropriate broad spectrum option). While duration of oral antibiotic therapy in the acute exacerbation is ill-defined, first time exacerbations favor a 10-day duration while recurrent exacerbations benefit from 14 days of therapy. Inpatient treatment during an acute exacerbation should be considered for patients demonstrating hypotension, tachycardia, hypoxemia, fever $\geq$38 °C, or failure to clinically improve on outpatient oral antibiotic therapy. While rigorous population-based studies are lacking, airway clearance techniques, particularly high frequency chest wall oscillation (positive expiratory pressure or PEP), are generally recommended and may be beneficial in reducing sputum volume and improving exercise tolerance [28]. Other therapeutic considerations include arterial embolization for life-threatening hemoptysis and lung resection in symptomatic patients who have failed conservative therapy.

Family and Community Issues

Bronchiectasis imposes a notable economic burden on patients and families due to prolonged hospitalizations, frequent outpatient visits, and extensive medical therapy regimens [29].

Pulmonary Sarcoidosis

Sarcoidosis is a multisystem granulomatous disease with no clear etiology or single validated confirmatory test. The condition affects approximately 10–20 per 100,000 persons with women, African-Americans, and individuals aged 20–60 years old most commonly affected. Mortality from sarcoidosis is estimated at 1–5 %. Pulmonary involvement occurs in over 90 % of patients with sarcoidosis and contributes to the bulk of disease-associated morbidity and mortality. Pulmonary sarcoidosis is characterized by noncaseating granulomas which are most frequently found in the alveolar septa, bronchi, and pulmonary vessels and results in the derangement of pulmonary function. While pulmonary sarcoidosis is generally self-limiting and frequently benign, patients with moderate to severe pulmonary involvement suffer from a chronic and debilitating disease that is often difficult to manage.

Diagnosis

A comprehensive evaluation is indicated in all patients with suspected sarcoidosis, including patient history, physical examination, laboratory

testing, and imaging. The most frequent symptoms of pulmonary sarcoidosis are dyspnea, cough, and chest discomfort. Patients may present initially with nonpulmonary symptoms including fever, arthralgias, malaise, and fatigue. Nearly one half of patients with sarcoidosis are identified incidentally on the basis of abnormalities on chest roentgenogram performed for other reasons. Pulmonary exam findings are rare but may include crackles, wheezing, or digital clubbing in advanced disease. Erythema nodosum may be present and is characteristic of acute sarcoidosis.

Laboratory testing should include a complete blood count and differential, liver function testing, blood urea nitrogen, creatinine, glucose, electrolyte panel, serum calcium, and urinalysis. Additionally, serologic testing for HIV and tuberculin skin testing (or interferon gamma release assay) should be performed.

As pulmonary sarcoidosis occurs in 90 % of patients with sarcoidosis, imaging plays an essential role in diagnosis. The most common radiographic finding is bilateral hilar adenopathy. Additional radiographic findings have been organized into a well-known staging system which provides a framework to understand lung involvement [30], although does not correlate to disease progression or prognosis (Table 7). HRCT can aid in further evaluation of chest radiograph abnormalities and identify irregularities in the lung parenchyma. Transbronchial lung biopsy with transbronchial needle aspiration is the preferred diagnostic modality in patients with enlarged mediastinal lymph nodes [31]. Serum angiotensin-converting enzyme levels are elevated in 75 % of patients, although poor sensitivity and insufficient specificity limit its utility as a diagnostic test. PFTs are useful to assess the degree of respiratory impairment and assist in monitoring disease progression. PFTs typically demonstrate a restrictive pattern with reduced DL_{co} and vital capacity.

It is important to distinguish pulmonary sarcoidosis from other granulomatous and infiltrative lung diseases that may have similar clinical presentation. The differential diagnosis must include fungal infections (histoplasmosis, blastomycosis, and *Pneumocystis jirovecii*), mycobacterial infections, hypersensitivity pneumonitis, pneumoconiosis, pulmonary histiocytic disorders, drug-induced hypersensitivity, foreign body granulomatosis, primary immunodeficiencies, and immune reconstitution inflammatory syndrome.

Table 7 Radiographic stages of pulmonary sarcoidosis

	Radiographic findings
Stage I	Bilateral hilar adenopathy[a]
Stage II	Bilateral hilar adenopathy Reticular opacities[b]
Stage III	Reticular opacities[b] Hilar node regression
Stage IV	Reticular opacities[b] Volume loss

[a]Can be accompanied by right paratracheal node enlargement
[b]Typically found in upper lung fields

Diagnosis of pulmonary sarcoidosis consists of three elements: (1) the presence of clinical and radiographic manifestations of pulmonary sarcoidosis, (2) the histopathologic detection of noncaseating granulomas, and (3) the exclusion of other disease processes. Upon diagnosing pulmonary sarcoidosis, clinicians should evaluate the extent of extrapulmonary involvement, including cardiac (electrocardiogram with echocardiography or 24 h Holter monitoring if indicated) and ocular (visual acuity and fundoscopic testing) findings.

Management

The course of sarcoidosis is variable, with some patients experiencing complete resolution in symptoms and others having slowly progressive disease. The approach to the treatment of pulmonary sarcoidosis is a challenge for clinicians due to the complex, multisystem nature of the disease [32]. The majority of patients with pulmonary sarcoidosis do not require therapy due to the absence of symptoms, nonprogression of disease, and likelihood of spontaneous remission. For symptomatic patients with pulmonary sarcoidosis, dyspnea remains the indicator for initiation of therapy. The goal of therapy is to

relieve symptoms and reduce the burden of granulomatous inflammation. Oral glucocorticoids remain the first line therapy for relieving pulmonary symptoms, although steroids have not been shown to modify the overall course of the disease. For this reason, treatment with corticosteroids is usually reserved for patients with worsening symptoms or organ-threatening pulmonary or extrapulmonary disease. The typical initial therapy for symptomatic sarcoidosis is prednisone 0.3–0.6 mg/kg ideal body weight for 4–6 weeks after which the patient should be reassessed (evaluation of symptoms, radiographic imaging, and PFTs). If the reassessment demonstrates stable or improved disease, the dosage can be tapered to 0.2–0.4 mg/kg for an additional 4–6 weeks. A maintenance dose of oral glucocorticoids can be continued at 0.25–0.5 mg/kg per day with reassessment at 4–12 week intervals. Length of therapy in patients who demonstrate positive response to oral glucocorticoids is unknown, although a 12-month treatment course is generally accepted to minimize relapses. There may be a role for inhaled steroids in the treatment of symptomatic pulmonary sarcoidosis; however, there is limited data to support their use. For patients who cannot tolerate glucocorticoids, alternative regimens may include antimalarial drugs (chloroquine, hydroxhycholorquine) or immunosuppressive agents (methotrexate, azathioprine, leflunomide). Complications due to opportunistic infections while on immunosuppression therapy are rare, although clinicians should monitor patients for these risks. Patients with end stage pulmonary sarcoidosis may be candidates for surgical resection, bronchial artery embolization, or lung transplantation. Unfortunately, as many as two thirds of patients will relapse after cessation of treatment.

Family and Community Issues

Studies have demonstrated that treatment of nicotine dependence in patients with active pulmonary sarcoidosis results in restoration of immune responsiveness [33]. This suggests a beneficial role for the family physician in smoking cessation counseling and therapy. In addition, reduction in BMI may contribute to improved PFT results and symptom control in patients with pulmonary sarcoidosis [34].

Gastritis, Esophagitis, and Peptic Ulcer Disease

Alan M. Adelman* and Peter R. Lewis
Family and Community Medicine, Penn State University College of Medicine, Hershey, PA, USA

Dyspepsia/Epigastric Pain

Gastritis, esophagitis, and peptic ulcer disease (PUD) present commonly with epigastric pain or dyspepsia. Dyspepsia refers to upper abdominal pain or discomfort and may be associated with fullness, belching, bloating, heartburn, food intolerance, nausea, or vomiting. Dyspepsia is a common problem. Despite discoveries about the cause and treatment of peptic ulcer disease, dyspepsia remains a challenging problem to evaluate and treat.

Epidemiology

Dyspepsia is a common problem, with an annual incidence of 1–2 % in the general population and a prevalence that may reach 20–40 %. The four major causes of dyspepsia are non-ulcer dyspepsia (NUD), PUD, gastroesophageal reflux disease (GERD), and gastritis. NUD, PUD, GERD, and gastritis account for more than 90 % of all causes of dyspepsia. Less common causes of dyspepsia are symptomatic cholelithiasis, irritable bowel disease, esophageal or gastric cancer, pancreatitis, pancreatic cancer, Zollinger-Ellison syndrome, and abdominal angina. Rarely, patients with coronary artery disease present with dyspepsia. Patients who seek medical attention for dyspepsia are more likely to be concerned about the seriousness of the symptom, worried about cancer or heart disease, and experiencing more stress than individuals who do not seek medical attention for dyspepsia.

Presentation

No single symptom is helpful for distinguishing between the different causes of dyspepsia, but some patient characteristics are suggestive of serious disease. For example, as single symptoms, nocturnal pain, relief of pain by antacids, worsening of pain by food, anorexia, nausea, and food intolerance are not helpful for determining the cause of dyspepsia. Patients older than 45 years or with alarm "red flag" symptoms (i.e., weight loss, dysphagia, persistent vomiting, gastrointestinal bleeding, hematemesis, melena) are more likely to have a serious underlying disorder. With the possible exceptions of PUD and duodenitis, there is no clinically meaningful association between endoscopic findings and dyspeptic symptoms. It is important to inquire about the use of nonsteroidal anti-inflammatory drugs (NSAIDs), as their use is a frequent cause of PUD. Alcohol is a frequent cause of gastritis, esophagitis, and chronic liver disease/cirrhosis which may lead to portal hypertension and esophageal varices with risk of life-threatening gastrointestinal bleeding.

General Approach

Individuals with evidence of complications of PUD (e.g., gastric outlet obstruction or bleeding) or systemic disease (e.g., weight loss, anemia) should be promptly evaluated and, as needed, hospitalized [1–3]. Because age is the strongest predictor of finding "organic" disease on endoscopy, individuals over

Table 1 Usual daily dosage of antiacid medications

Generic (brand) name	Usual daily dosage (po)
Antacids (Maalox, Mylanta)	15–30 mL, 0.5 and 2 h after meals and at bedtime
Histamine-2 receptor antagonists	
Famotidine (Pepcid)	20 mg bid
Nizatidine (Axid)	150 mg bid
Ranitidine (Zantac)	150 mg bid
Sucralfate (Carafate)	1 g ac and hs
Proton-pump inhibitors	
Omeprazole (Prilosec)	20–40 mg qd
Lansoprazole (Prevacid)	15–30 mg qd
Rabeprazole (Aciphex)	20 mg qd
Esomeprazole (Nexium)	20–40 mg qd
Pantoprazole (Protonix)	40 mg qd

the age of 45 years should more readily be evaluated with endoscopy. For the remaining patients there are three commonly used strategies for the evaluation and management of dyspeptic symptoms: (1) empiric therapy including lifestyle modification; (2) evaluation, usually with endoscopy, for a specific cause of the dyspeptic symptoms; and (3) test for *Helicobacter pylori* and treat if positive ("test and treat").

Empiric treatment for dyspepsia consists of standard anti-acid therapy (Table 1). Histamine-2 receptor antagonists (H_2RAs) and proton-pump inhibitors (PPIs) are available over-the-counter and by prescription. If an H_2RA or PPI fails to relieve symptoms, further workup, preferably with endoscopy, should be undertaken.

The second approach to the patient with dyspepsia is thorough evaluation for a specific cause of the dyspeptic symptoms. When available, upper endoscopy is the preferred procedure. Although an upper gastrointestinal (UGI) series is less expensive and may be more readily available, it has a false-negative rate that exceeds 18 % in some studies and a false-positive rate of 13–35 %. In addition, the UGI series is not sufficiently sensitive for detecting GERD and gastritis, two of the most common causes of dyspepsia. A negative UGI does not rule out structural/"organic" disease, and if indicated, further evaluation with upper endoscopy should be pursued. Although more expensive, upper endoscopy has lower false-positive and false-negative rates, biopsies can be undertaken, and testing for *H. pylori* and celiac disease (sprue) can be performed.

The third common approach to the evaluation of patients with dyspepsia is to test for *H. pylori* and treat if positive. (For further information on the evaluation and treatment of *H. pylori*, see below.) This approach is favored [1–3] by recently published reviews.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a common problem with a prevalence of reflux of 10–20 % [4]. It is the fourth most common chronic diagnosis seen in primary care [5]. The incidence of GERD increases during pregnancy and with obesity and tobacco use. Several factors may lead to GERD including hiatal hernia, incompetence of the lower esophageal sphincter (LES), inappropriate LES relaxation, impaired esophageal peristalsis and acid clearance, impaired gastric emptying, and repeated vomiting. Exposure to excessive acid or pepsin can lead to damage of the esophageal mucosa, resulting in inflammation and ultimately scarring and stricture formation. Medications (e.g., theophylline, nitrates,

DOI 10.1007/978-1-4939-0779-3_94-1

calcium channel blockers, and β-adrenergic agonists), foods (e.g., caffeine and chocolate), and alcohol may lower LES pressure and lead to GERD – symptomatic or not. Bisphosphonates may cause local irritation of the esophagus. GERD may occur as an isolated entity or as part of a systemic disorder such as scleroderma. GERD is a risk factor for Barrett's esophagitis and esophageal adenocarcinoma, one of the fastest-growing cancers in the United States.

Presentation

The most reliable symptom of GERD is heartburn, a retrosternal burning sensation that may radiate from the epigastrium to the throat. Patients may also complain of pyrosis or water brash, the regurgitation of bitter-tasting material into the mouth. Belching is frequently described. Symptoms may be worse after eating, bending over, or lying down. Nocturnal symptoms may awaken the patient. GERD can cause respiratory problems including laryngitis, chronic cough, aspiration pneumonia, and wheezing. Atypical chest pain can also be caused by GERD. Finally, patients may complain of hoarseness, a globus sensation, odynophagia (pain with swallowing), or dysphagia.

Diagnosis

A young patient with no evidence of systemic illness typically requires no further workup and can be treated empirically. Older patients, particularly those with the complaint of odynophagia or dysphagia, require evaluation to rule out tumor or stricture. Upper endoscopy is the evaluation of choice. Ambulatory 24-h pH monitoring is the most sensitive test for demonstrating reflux if endoscopy is negative although poorly tolerated by most patients. A barium swallow study or esophageal manometry may be necessary if a motility disorder is suspected, as endoscopy is often normal in patients with this problem.

Management

GERD is treated by both non-pharmacologic and pharmacologic means [4, 6]. Whereas patients with mild disease may respond to non-pharmacologic treatment, patients with moderate to severe symptoms or recurrent disease usually require medication therapy added or intensified, in addition to continuation of lifestyle changes.

All patients with GERD should be advised to reduce weight (if over their ideal body weight), avoid large meals (especially several hours before going to sleep), refrain from lying down after meals, and refrain from wearing tight clothing around the waist. Patients who experience nocturnal symptoms often find relief by putting the head of the bed on blocks 4–6 in. in height. Sleeping on more pillows or on a wedge may be less effective because of nocturnal movements. Because nicotine lowers LES pressure, smoking cessation is recommended. Routine avoidance of foods that can lower LES pressure is no longer recommended.

Patients who do not respond to lifestyle changes alone are treated with pharmacologic agents. The pharmacologic treatment of GERD can be approached in a stepwise process. For mild, intermittent symptoms, antacids or over-the-counter H_2RAs can be used. For persistent or severe symptoms, PPIs are the mainstay of treatment. H_2RAs can be tried first and, if ineffective, PPIs can be substituted. Once a patient's symptoms are controlled, a trial of decreasing the dose of medication (e.g., from twice daily to once daily) or switching from the more expensive PPIs to less expensive H_2RAs may be warranted. There are concerns regarding long-term PPI use such as declining bone mineralization.

H_2RAs suppress acid secretion by competing with histamine, thereby blocking its effect on parietal cells of the stomach. H_2RAs are effective, but both daytime and nocturnal acid production may be necessary to sufficiently inhibited acid production.

PPIs irreversibly block the final step in parietal cell acid secretion and are the most potent antisecretory agents available. In more severe GERD, PPIs are more efficacious than H_2RAs for symptom control

DOI 10.1007/978-1-4939-0779-3_94-1

including extra-esophageal manifestations and esophageal healing and reducing the risk of stricture formation and recurrence. PPIs are less effective when taken on an as-needed basis. They are effective when dosed daily before breakfast, although some patients may require twice-daily (before meals) dosing to achieve symptom control and/or esophageal healing. PPIs are the treatment of choice for erosive esophagitis. Side effects (chiefly headache and diarrhea) resulting in medication discontinuation are rare. As is true for H_2RAs, all available PPIs at equivalent doses are roughly comparable in terms of clinical efficacy. Patients unresponsive to one H_2RA or PPI may be responsive to another agent within the same medication class. Rarely, patients unresponsive to PPIs respond to H_2RAs.

For those patients with GERD who require maintenance medication, periodic examination coupled with efforts to try to reduce medication is warranted. Clinicians should avoid inappropriate prescribing of PPIs and other medications in the treatment of GERD and seek to decrease and "de-prescribe" medications where appropriate and tolerated.

A concern in patients with chronic GERD is Barrett's esophagus. Barrett's esophagus is metaplasia of the cells of the distal esophagus and is considered a precancerous lesion. The risk of development of adenocarcinoma of the esophagus following a diagnosis of Barrett's esophagus may be as high as 2 %. Unfortunately, neither aggressive medical therapy nor surgical therapy for GERD has been shown to alter the progression between Barrett's esophagus and esophageal adenocarcinoma. There is uncertainty as to the efficacy and optimal frequency of endoscopic surveillance of patients with Barrett's esophagus. When dysplasia, the stage between metaplasia and adenocarcinoma, is identified, the recommended frequency of surveillance with esophagogastroduodenoscopy (EGD) and repeat biopsy varies, depending on the severity of dysplasia.

For severe or refractory GERD, the initial approach should be to ensure that the patient is on maximal PPI therapy. If symptoms continue, the addition of a prokinetic agent such as metoclopramide or baclofen should be considered. Metoclopramide can increase esophageal contraction amplitude, increase LES pressure, and accelerate gastric emptying, three of the most significant motility problems in the pathogenesis of GERD. Metoclopramide is a dopamine antagonist that can cause extrapyramidal symptoms and, rarely, tardive dyskinesia. This may limit its use.

Individuals who are intolerant or unresponsive to optimal medical therapy or nonadherent to medical therapy are suitable operative candidates. Laparoscopic fundoplication surgery has been shown to be effective, at least in the short term [7]. Bariatric surgery for obesity may also be helpful [4].

Peptic Ulcer Disease

Most peptic ulcers are caused by either *H. pylori* or NSAIDs. Although infection with *H. pylori* appears to be common, most individuals with *H. pylori* do not develop ulcers. Peptic ulcers may involve any portion of the UGI tract, but ulcers are most often found in the stomach and duodenum. Duodenal ulcers are approximately three times as common as gastric ulcers. In the past, PUD was marked by periods of healing and recurrence. Successful treatment of ulcers associated with *H. pylori* infection greatly diminishes recurrences.

Presentation

Epigastric pain is the most common presenting symptom of both duodenal and gastric ulcer disease. The pain may be described as gnawing, burning, boring, aching, or severe hunger pains. Patients with duodenal ulcers typically experience pain within a few hours after meals and complete or partial relief of pain with ingestion of food or antacids. Pain related to gastric ulcers is more variable and may be characterized by pain that worsens with eating. Both duodenal and gastric ulcers may occur and recur in the absence of pain. Pain is variable among patients with both kinds of ulceration and correlates poorly

DOI 10.1007/978-1-4939-0779-3_94-1

with ulcer healing as documented by endoscopy. Physical examination may reveal epigastric tenderness midway between the xiphoid process and umbilicus, but maximal tenderness may sometimes be to the right of the abdominal midline. Auscultation of the abdomen may reveal a succussion splash which is due to a mixture of air and fluid in the stomach which may be due to gastric outlet obstruction – a rare but potentially serious complication of peptic ulcer disease when the ulcer arises in the pyloric channel or duodenum. Abdominal rigidity is a "red flag" sign that can be associated with ulcer perforation and is an indication for prompt hospitalization and urgent surgical consultation.

Diagnosis

There are two ways that PUD may be diagnosed. First, an ulcer may be diagnosed by either radiographic studies or endoscopy. Although duodenal and gastric ulcers can be diagnosed by UGI studies, upper endoscopy is the investigation of first choice. Gastric ulcers more than 3 cm in diameter or without radiating mucosal folds are more likely to be malignant. In addition to the indications listed earlier in the chapter, endoscopy should be considered in patients with persistent and refractory symptoms even in the presence of negative radiographic studies, those with a history of deformed duodenal bulbs (thus making radiographic examination difficult), and in patients with suspected or confirmed upper GI bleeding. If an ulcer is diagnosed endoscopically, a rapid *Campylobacter*-like organism urease test (CLOtest) is a quick, sensitive test for determining the presence of *H. pylori.* False positives are uncommon while false negatives occur in approximately 5–10 % of cases. The presence of *H. pylori* can also be determined histologically and by culture following biopsy at the time of endoscopy. The second approach to PUD is test and treat. A patient is tested for *H. pylori* and if positive, antibiotic therapy can be initiated without documenting an ulcer. There are three methods for testing for *H. pylori* infection: urea breath test, serology, and stool antigen testing. The stool antigen test is more accurate than serology tests. Urea breath test, using a carbon isotope (^{13}C or ^{14}C), is the most accurate noninvasive test (sensitivity 97 %, specificity 100 %) [8, 9]. The use of proton-pump inhibitors, bismuth preparations, and antibiotics can suppress *H. pylori* and lead to false-negative results.

Most patients, especially those who are asymptomatic posttreatment, do not require documentation of eradication of *H. pylori.* If one wishes to test for cure, a urea breath test (4 weeks after therapy) or stool antigen test can be performed. A falling ELISA titer (1, 3, and 6 months after therapy) may also be used to document eradication. If a repeat endoscopy is performed, a CLOtest may be used.

Treatment

All patients with PUD who smoke should be advised to stop smoking as continued smoking can delay the rate of ulcer healing. Whether or not a patient's PUD is associated with the use of an NSAID, existing NSAIDs should be discontinued and future NSAID use should be avoided and traditional antiulcer therapy begun with either an H_2RA or PPI. For patients who test positive for *H. pylori,* antibiotic treatment should be given. A number of drug regimens have been shown to be effective (Table 2) [8–10]. A PPI is part of every antibiotic regimen. Patients with *H. pylori*-negative ulcers are treated with traditional antiacid agents without antibiotics for 4–6 weeks. Treatment of *H. pylori* in patients with NUD (with negative endoscopy) is controversial.

Table 2 Treatment for eradication of *Helicobacter pylori-a*ssociated peptic ulcer disease

Therapies with proton-pump inhibitor (PPI)
PPI + metronidazole 500 mg bid + clarithromycin 500 mg bid
PPI + amoxicillin 1 g bid and clarithromycin 500 mg bid
PPI + bismuth subsalicylate 525 mg bid + metronidazole 500 mg bid + clarithromycin 500 mg bid
PPI bismuth subsalicylate 525 mg bid + metronidazole 500 mg bid + tetracycline hydrochloride 500 mg qd

Note: All regimens are given for 10–14 days. All regimens are full dose of PPI twice daily

DOI 10.1007/978-1-4939-0779-3_94-1

There are a number of problems with the current antibiotic regimens. First, patient adherence may be a problem because of cost, duration of therapy, and side effects. GI side effects can occur with metronidazole, amoxicillin, and clarithromycin. There is a trade-off between better adherence with the shorter duration of therapy and better eradication rates with a longer duration of therapy. There is no difference in outcome between a 10-and 14-day course of therapy. A second problem is the emergence of antibiotic resistance involving both metronidazole and clarithromycin, which favors the use of triple-drug regimens.

For patients with PUD and no documented *H. pylori*, all H_2RAs effectively heal ulcers in equipotent doses (Table 1). About 75–90 % of ulcers are healed after 4–6 weeks of therapy. The PPIs heal ulcers more quickly than H_2RAs, but healing rates at 6 weeks are not significantly improved over those with H_2RAs. PPIs should be considered first-line medication therapy. Healing rates with sucralfate (Carafate) are comparable to those with H_2RAs. There are no significant side effects although recommended dosing regimens of up to four times daily are likely to limit adherence.

Dietary therapy should be limited to the elimination of foods that exacerbate symptoms and the avoidance of alcohol and coffee (with or without caffeine) because alcohol and coffee increase gastric acid secretion.

Refractory Ulcers and Maintenance Therapy

Most duodenal ulcers heal within 4–8 weeks of the start of pharmacologic therapy. After 12 weeks of pharmacologic therapy, 90–95 % of ulcers are healed. Higher doses of H_2RAs (e.g., ranitidine 600–1,200 mg/day) or PPIs may be used in an effort to heal refractory ulcers. Gastric ulcers heal more slowly than duodenal ulcers, but 90 % are healed after 12 weeks of pharmacologic therapy. PPIs are the drug of choice for gastric ulcers.

Individuals with persistent or recurrent symptoms after pharmacologic therapy should be reevaluated. Adherence with previous treatment recommendations and avoidance of NSAID use should be reviewed. Endoscopy should be performed to document ulcer healing. Antibiotic drug resistance may be a factor in persistence of ulcers secondary to *H. pylori.* Gastric cancer should be excluded by biopsy if a gastric ulcer remains unhealed (see Gastric Cancer, below). Zollinger-Ellison syndrome should also be considered in the case of refractory ulcers.

In patients successfully treated for *H. pylori* or who have discontinued the use of NSAIDs, maintenance treatment with H_2RAs or PPIs should not be needed. Patients with ulcers in the absence of *H. pylori*, complicated PUD (e.g., bleeding or perforation), a history of refractory ulceration, aged greater than 60 years, or a deformed duodenum are candidates for maintenance therapy with H_2RAs or PPIs.

Gastritis/Gastropathy

Gastritis represents a group of entities characterized by histologic evidence of inflammation. Gastropathy is characterized by the absence of histologic evidence of inflammation of the gastric mucosa. Both gastritis and gastropathy may be either acute or chronic. It may be difficult to distinguish the two entities by clinical, radiographic, and endoscopic examinations. Gastritis and gastropathy may occur simultaneously and/or overlap with conditions such as GERD or PUD or may be a manifestation of less common conditions such as Crohn's, celiac disease, or sarcoidosis.

Acute gastritis may be due to infections (mainly *H. pylori*; less commonly viral, fungal, mycobacterial, or parasitic etiologies) and autoimmune conditions (e.g., pernicious anemia, eosinophilic gastritis). Histologic variants of uncertain cause include lymphocytic and eosinophilic gastritis. Gastropathy is

DOI 10.1007/978-1-4939-0779-3_94-1

commonly due to medications (e.g., NSAIDs including aspirin and cyclooxygenase-2 (COX-2) inhibitors, bisphosphonates, potassium, and iron), alcohol, refluxed bile, ischemia ("stress," as is seen in patients with shock, sepsis, trauma, or burns), or vascular congestion (as in portal hypertension or congestive heart failure).

Chronic gastritis may be preceded by episodes of symptomatic acute gastritis (e.g., that due to *H. pylori*) or present without prior warning with dyspepsia and constitutional symptoms. *H. pylori* is the most common cause of chronic gastritis; this association may be accentuated in patients receiving chronic PPI therapy. Pernicious anemia may be associated with chronic gastritis.

These conditions range in presentation from asymptomatic to life-threatening. Of particular interest to the clinician are acute and chronic erosive changes that may be complicated by symptomatic anemia or frank hemorrhage (presenting with melena or hematemesis – see "Upper Gastrointestinal Bleed" below) and chronic atrophic changes that may progress to gastric cancer. Treatment consists of managing the underlying disease and removing gastric irritants.

Upper Gastrointestinal Bleed

Upper gastrointestinal bleed is defined as GI blood loss above the ligament of Treitz [11]. If the bleeding is clinically evident, it may present in one of three ways. Hematemesis may be bright-red or coffee ground-appearing material and usually is indicative of active bleeding. Melena signifies that the blood has transited through the GI tract, causing digestion of blood. Melena may also be caused by lower GI bleeding. And finally, although uncommon, a UGI bleed may present as hematochezia if bleeding is brisk. If subacute or chronic, the UGI bleed may be discovered during the workup of iron-deficiency anemia or hemoccult-positive stools.

Causes

The four most common causes of UGI bleeding are peptic ulceration, gastritis/gastropathy, esophageal varices, and esophagogastric mucosal tear (Mallory-Weiss syndrome). The causes of gastritis/gastropathy are described above. Bleeding due to varices is usually abrupt and massive. Varices may be due to alcohol cirrhosis or any other cause of cirrhosis/portal hypertension such as nonalcoholic steatohepatitis (NASH, "fatty liver" – increasingly common and frequently associated with obesity and the metabolic syndrome) and portal vein thrombosis. Mallory-Weiss syndrome classically presents with retching followed by hematemesis. Other causes of UGI bleeding include gastric carcinoma, lymphoma, polyps, and diverticula.

Diagnosis and Management

The diagnosis and management of the patient with UGI bleeding depends on the site and extent of bleeding. Vomitus and stool should be tested to confirm the presence of blood. Initial management for all patients includes assessment of vital signs including orthostatic changes. Patients with significant blood loss should be hospitalized and typed and matched for blood replacement and large-bore intravenous lines placed for fluid and blood replacement.

A nasogastric tube can be placed and the aspirate tested for blood. Absence of blood may mean that the bleeding has ceased. The routine placing of a nasogastric tube for diagnosis or lavage has been questioned [11].

Once the patient is hemodynamically stable, upper endoscopy can be performed. Rapid upper endoscopy upon presentation of patients in stable condition may hasten diagnosis and limit hospitalization. Endoscopy may not reveal an obvious source of bleeding when bleeding has ceased. Massive hemorrhage

DOI 10.1007/978-1-4939-0779-3_94-1

from varices can make endoscopy impractical. The other more common causes of upper GI bleeding will be readily apparent with use of endoscopy. If the patient continues to bleed and a source has not been identified, push endoscopy or angiography may be used to identify the source of bleeding. Upper endoscopy can be therapeutic as well as diagnostic. Sclerotherapy or ligation of esophageal varices can be performed through the endoscope. A variety of endoscopic treatments are available for bleeding peptic ulcers.

When bleeding is refractory to medical and endoscopically administered therapies, interventional, radiological (such as embolization), or surgical (resection or shunting) interventions should be considered.

There are two additional therapies for bleeding varices [12]. Peripherally administered vasopressin or somatostatin or balloon tamponade are effective alternative treatments for bleeding varices.

Prevention of GI bleeding is more effective than treatment. Smoking and alcohol cessation should be recommended and NSAIDs avoided. Treatment of *H. pylori*-positive PUD or maintenance therapy for *H. pylori*-negative PUD may decrease subsequent bleeding episodes. Nonselective beta-blockers (propranolol or nadolol) can be used to prevent a first-time episode of bleeding in patients with known varices who have never bled.

Gastric Cancer

While the incidence of distal gastric cancer has declined significantly in the United States since the 1930s, there has been an increase of proximal stomach cancers. Individuals moving from Japan to the United States lower their risk of gastric cancer, suggesting that dietary and environmental factors play roles in the pathogenesis of this disorder. Additional risk factors include *Helicobacter pylori* infection, gastric polyps, and chronic gastritis. The majority of gastric cancers are adenocarcinomas.

Early gastric cancers are usually asymptomatic. As the cancer grows, patients may complain of anorexia or early satiety, vague discomfort, or steady pain. Weight loss, nausea and vomiting, and dysphagia (more common with proximal cancers) may also be present. Rarely, paraneoplastic manifestations occur. The physical examination is usually normal in patients with early disease, but a palpable abdominal mass or supraclavicular nodes, enlarged liver, or ascites may be present with advanced or metastatic disease. Patients with gastric cancer may present with GI bleeding, overt or otherwise occult, although this represents a minority of presentations.

Upper endoscopy is the preferred test when gastric cancer is suspected. Upper gastrointestinal (UGI) X-ray studies can detect gastric cancer, but it is not as accurate and biopsy of suspicious lesions can be obtained during upper endoscopy. If an ulcer is suspicious in appearance, alarming symptoms are present, or if the patient is >45 years of age, EGD with biopsy is the preferred procedure. If the initial biopsies are benign, then endoscopy should be repeated at 12 weeks to ensure that the ulcer has healed completely. Benign gastric ulcers should heal within 6–12 weeks.

Surgical treatment is the only definite chance for a cure. Adjuvant chemotherapy with or without radiation for patients undergoing tumor resection may be recommended.

1 Infectious Diarrhea Syndromes

After upper respiratory tract infections, acute gastroenteritis is the most common illness in the United States. Most cases are brief and self-limited. However, the attack rate is estimated at 1.5–1.9 attacks per person per year and is ultimately responsible for 10,000 deaths per year nationally [1]. Viral organisms are the most common cause of infectious diarrhea; however, the bacterial pathogens *Shigella*, non-typhoidal *Salmonella*, *Escherichia coli*, *Campylobacter jejuni*, and *Yersinia* account for the most severe episodes. Protozoal gastroenteritis caused by *Entamoeba histolytica* and *Giardia lamblia* is common in travelers and may cause intermittent symptoms.

1.1 Clinical Approach to the Patient with Acute Diarrhea

The history and physical examination should be directed to address the following questions:

1. Does the diarrhea originate in the small or large intestine? Small bowel pathology is most often associated with frequent large-volume stools described as watery and often following oral intake of any kind. Large bowel diarrhea is associated with even more frequent stools but of smaller volumes (1–2 l/day) and may be associated with tenesmus and even bloody stools.
2. Are there other contacts with similar illness? Viral diarrhea and food-borne causes of diarrhea commonly present in clusters of affected patients. This is especially true for infections contracted in daycare centers, schools, or healthcare institutions.
3. Has there been recent travel? Possible causes may include enterotoxigenic *E. coli*, protozoans *E. histolytica* or *G. lamblia*, or other parasitic infestation.
4. Has there been any consumption of undercooked hamburger meat or poultry? This might suggest *Salmonella* or enterohemorrhagic *E. coli.*
5. Has there been any antibiotic use within the preceding 8 weeks, suggesting a post-antibiotic colitis with *Clostridium difficile* overgrowth?
6. Are there any other predisposing medical conditions for diarrhea, especially diabetes, HIV disease, or bowel surgery?

If the illness proves to be prolonged rather than self-limited, consider the following diagnostic investigations:

1. A stool sample for culture, as well as ova and parasites. This is a simple first step, overlooked by many office clinicians, and, although inconvenient for the patient, provides a foundation of diagnostic information.

*Email: djamesmd@aol.com

DOI 10.1007/978-1-4939-0779-3_95-1

2. A stool sample for *C. difficile* toxin, especially in the elderly patient or someone with a recent antibiotic history.
3. In cases that are culture negative, consider anoscopy/rigid sigmoidoscopy with direct visualization of the rectal mucosa. These are simple examinations, taking just minutes to perform, in the clinic or the Emergency Room, and provide information about the condition of the bowel mucosa. More seriously ill patients may require flexible sigmoidoscopy or even colonoscopy to visualize the bowel and obtain biopsies.
4. If no colon pathology is identified, consider upper GI endoscopy with small bowel biopsies or a small bowel barium enema and follow-through radiologic exam looking for small bowel mucosal pathology.

2 Parasitic Infections of Small Bowel

Parasitic infections of the small bowel are most commonly caused by hookworm (*Ancylostoma* or *Necator* spp.), tapeworms (Cestoda), pinworm (*Enterobius* spp.), and strongyloidiasis (*Strongyloides* spp.). Worldwide, these parasites infect over a billion persons and may cause significant morbidity, especially in children and pregnant women. They are invariably associated with depressed living conditions which include contaminated water supplies, undercooked meats, institutionalization, and poor sanitation facilities.

Hookworm infestation is the most common cause of iron-deficiency anemia in the developing world. Walking barefoot over areas used for human defecation allows the worm to enter the body by penetrating the feet. The worm settles into the small intestine, and symptoms include abdominal pain and diarrhea. Blood work reveals a hypochromic, microcytic anemia. Diagnosis is made by observation of worms or their eggs in a stool sample. Treatment is with mebendazole, albendazole, or pyrantel pamoate. Ivermectin is not active against hookworm.

Tapeworms generally use cattle, pigs, or fish as their hosts. Humans eating undercooked meats containing tapeworm eggs or ingesting water contaminated with tapeworm eggs or larvae may get infected. Inquire about recent travel to underdeveloped areas and working with livestock. Generally, patients will present with nonspecific symptoms such as diffuse abdominal pain, weight loss, and diarrhea; in some cases, pork tapeworm cases may present as a myositis or even a seizure disorder depending on where the parasite has concentrated. Diagnosis is made by examination of stool for ova and parasites. Treatment is with praziquantel, albendazole, or nitazoxanide.

Pinworms (*Enterobius vermicularis*) are the most common worm infestation in developed countries and usually affect young children in daycare or school settings. The most common symptom is anal itching, which is typically worse at night, as the adult worms come out of the anus to copulate on the perineal skin. The worm is transmitted by ingestion of eggs, usually picked up from sharing objects with an infected individual who has performed less than adequate handwashing after wiping or touching their anal area. The eggs may also become airborne from clothing or bedding and be inhaled into the aerodigestive tract. Diagnosis is made by identification of worms or their eggs on a slide made from the perineal area. Treatment is with albendazole or mebendazole and should be offered to the entire family to prevent reinfection.

Strongyloidiasis, or roundworm infection, is caused by the helminths *Strongyloides* sp. The worms are found worldwide, and the most common pathway of infection is contact with soil that is contaminated by *Strongyloides* larvae. Typical risk factors include walking barefoot over contaminated soil, having contact with untreated human waste or sewage, and working with contaminated soils in farming or mining occupations. Common symptoms include abdominal pain, bloating, diarrhea, and nausea or vomiting;

DOI 10.1007/978-1-4939-0779-3_95-1

sometimes, a recurrent red raised skin rash is present along thighs and buttocks. Diagnosis is made from microscopic inspection of stool for larvae; serology is available for diagnosis, and an elevated eosinophil count is often present. Treatment choices consist of ivermectin, thiabendazole, albendazole, and mebendazole. The parasite should be treated even in the absence of symptoms, as hyperinfection carries a high mortality rate [2].

3 Protozoal Infections

The most common causes of protozoal gastrointestinal infection in the United States are *Entamoeba histolytica* and *Giardia lamblia. Entamoeba* infection may produce either an intermittent diarrheal syndrome or a more severe, fulminating illness with a presentation similar to inflammatory bowel disease. Giardiasis produces a more chronic diarrheal illness often accompanied by epigastric symptoms of pain and cramping due to duodenal infestation with the parasite. There is often a travel history which provides valuable historical clues in detecting these illnesses. Amebiasis is common in travelers to the tropics, while giardiasis is endemic to freshwater sources in some Western nations, most notably Russia. Giardiasis may also present in daycare settings, campers who have had contact with freshwater streams, and the severely immunocompromised (i.e., advanced HIV patients). Amebiasis may produce occult or frank blood in the stool, and proctoscopic exam may reveal a friable and erythematous rectal mucosa. Definitive diagnosis is made from an examination of fresh stool, with identification of cysts or trophozoites. Amebiasis is treated with metronidazole, 750 mg po tid for 10 days, followed by iodoquinol, 650 mg po tid for 3 weeks. Giardiasis may be treated with metronidazole 250 mg po tid for 5 days or quinacrine 100 mg po tid for 5 days.

4 Viral Infections

4.1 General Principles

Viral enteric infections are responsible for the majority of gastrointestinal complaints seen in the office or emergency department. Patient complaints include diarrhea, nausea, vomiting, fever, abdominal cramping and/or pain, headache, and malaise. Viral gastroenteritis ranges from a self-limited watery diarrheal illness usually lasting less than a week to a more fulminant illness with intractable vomiting and dehydration resulting in hospitalization or even death. There are three general settings of viral gastroenteritis. The first is a sporadic gastroenteritis in infants, which is most commonly caused by rotavirus. The second is an epidemic gastroenteritis that occurs either in semi-closed populations (families, healthcare institutions, cruise ships) or as a result of food- or waterborne pathogens including noroviruses and caliciviruses. The third is a sporadic acute gastroenteritis of adults, which is usually due to infection with caliciviruses, rotaviruses, adenoviruses, or astroviruses.

4.2 Diagnosis

Physical examination of the patient may reveal hyperactive bowel sounds and mild lower abdominal discomfort with palpation. If history and physical examination are insufficient to make a diagnosis, obtain a complete blood count (CBC) and a stool sample. The CBC often reveals a normal white blood cell count with a slight lymphocytosis, although elevations of the white cell count into the upper teens are possible. Microscopic examination of the stool sample should reveal an excess of water without pus or blood.

DOI 10.1007/978-1-4939-0779-3_95-1

4.3 Treatment

Treatment should focus around rehydration, either orally or parenterally. In many cases, the nausea and vomiting associated with the gastroenteritis are a barrier to oral rehydration. The use of ondansetron (Zofran®) in a dose of 4–8 mg every 4–6 h as the orally dissolving wafer is very useful in settling the nausea and allowing oral rehydration. The medication is effective within 20–30 min. Appropriate oral rehydration solutions follow the WHO guidelines of sodium/potassium/glucose ratios. The WHO solutions are commercially available (Gastrolyte®, Pedialyte®) or can be made at home from distilled water, 6 teaspoons of sugar, ½ teaspoon of salt, and ½ cup (125 ml) of orange juice in 1 l of clean water. Parental 0.9 % saline or Ringers lactate solutions are also appropriate for more advanced cases. In most cases, the diarrhea may subside in 3–5 days. The role of antidiarrheal agents is controversial and does nothing to hasten resolution of the illness [3].

5 Bacterial Infections

Bacterial enteric infections are associated with symptoms of diarrhea, vomiting, and abdominal discomfort. The symptoms result as a direct effect of bacterial toxin on the intestinal wall stimulating secretion of water into the intestinal lumen or by actual invasion of the bacteria into the intestinal wall.

5.1 *Escherichia coli*

This bacterium causes diarrhea by either of the previously mentioned mechanisms. At least five forms of gastroenteritis may result, including enteropathogenic, enterotoxigenic, enteroinvasive, enterohemorrhagic, and enteroadherent types. Diagnosis is often difficult, because *E. coli* is found commonly in stool as normal flora. The enterotoxigenic type of gastroenteritis is associated with travel (traveler's diarrhea), while the enterohemorrhagic variety is often associated with undercooked poultry or hamburger meat. Most cases of coliform gastroenteritis are brief, and the associated fever, diarrhea, and abdominal cramps are self-limited; however, the very young patient and the elderly patient may have a much more fulminant illness with frankly bloody diarrhea, dehydration, and possible acute hepatorenal failure. These patients will need prompt hospital admission and aggressive fluid management.

In patients with significant symptoms and suspected invasive disease, a Gram or Wright stain of the stool reveals numerous polymorphonuclear leukocytes and erythrocytes. Stool culture is necessary, and treatment is supported with oral/parenteral fluid replacement and analgesia. Chronic cases of *E. coli* enteritis may require antibiotic therapy for resolution (ciprofloxacin 250–500 mg po bid for 7–10 days is a reasonable choice) [4].

5.2 *Salmonella*

Five distinct clinical syndromes are associated with *Salmonella* infections: (1) gastroenteritis (about 75 % of infections); (2) bacteremia with and without gastrointestinal involvement (10 % of cases); (3) typhoidal "enteric" fever (85 of cases); (4) localized infections in bones, joints, and meninges (5 %); and (5) a symptomatic carrier gallbladder state.

Salmonella enterica, serovar Typhi, produces a typical gastroenteritis with headache, nausea, vomiting, diarrhea, and fever lasting for 2–4 days. Solid food restriction, analgesia, and fluid and electrolyte repletion are effective treatment. Other serotypes may produce a more severe illness lasting up to 3 weeks, occasionally accompanied by bacteremia. Stool examination in these cases will reveal fecal leukocytes, and culture is required to identify the organism. Antibiotics are not required in those with only mild illness and no evidence of bacteremia. Patients with more severe illness or documented bacteremia may require hospitalization for parenteral fluid replacement and antibiotics. Reasonable choices include

DOI 10.1007/978-1-4939-0779-3_95-1

ciprofloxacin, 400 mg IV q12h for 10 days, or ceftriaxone 1–2 g IV daily AND azithromycin 500 mg IV/po daily for 3–5 days.

5.3 *Campylobacter jejuni*

Campylobacter jejuni is probably the most common cause of inflammatory diarrhea in developed countries. Infection may vary from an asymptomatic case to severe enterocolitis. A typical episode begins with fever and malaise, followed within 24 h by nausea, vomiting, diarrhea, and lower-quadrant abdominal pain. The diarrhea may be profuse, contains plenty of leukocytes, and is often frankly bloody tinged. Infection is usually self-limited and lasts 5–7 days. Reservoirs of infection include contaminated water, milk, meat, and poultry; also implicated are domestic pets, particularly cats and dogs. Diagnosis is not always obvious from history, physical examination, or typical initial lab work, which may reveal a significant leukocytosis. Stool culture is required for diagnosis. Treatment includes fluid replacement and analgesia. Indications for antibiotic treatment include high fever, prolonged course of symptoms >7 days, increasingly bloody stools, or history of immunocompromise, including HIV. Antibiotic treatment choices include azithromycin, 10 mg/kg/day (adults simplified to 500 mg daily 3 days), or ciprofloxacin, 500 mg po bid 7 days. Clindamycin is also an alternative, 150–300 mg po tid 7 days [5].

5.4 *Yersinia*

Yersinia enterocolitica is responsible for a spectrum of illnesses, ranging from simple gastroenteritis to invasive ileitis and colitis. In older children and adults, *Yersinia* infections may cause a mesenteric adenitis, with symptoms mimicking acute appendicitis. Diarrhea is a fairly constant feature, often with accompanying fever and abdominal crampy pains. Duration of illness lasts 14–46 days. *Yersinia* may cause radiographic findings mimicking Crohn's colitis, including bowel wall nodularity, mucosal thickening, and aphthous ulceration. The illness is usually self-limited, and antibiotics are generally not necessary. In patients who have significant clinical illness or severe radiographic changes, antibiotic choices include TMP-SMX 1–2 tablets bid, third generation oral or parenteral cephalosporins, or ciprofloxacin.

5.5 *Shigella*

Shigella organisms may cause a severe, invasive diarrhea (dysentery), especially in infants and the elderly. The diarrhea is frequent, bloody, and mucoid, due to invasion of the colonic epithelium by the organism. The clinical course is biphasic, beginning with watery diarrhea, malaise, and fever; this is followed by tenesmus and frank dysentery within 24 h. Children tend to have a milder infection, lasting 1–3 days; adults may suffer symptoms for 7 days. In severe cases, symptoms may persist for 2–4 weeks. The stool will contain pus and blood, and a stool culture is mandatory for accurate diagnosis. Therapy includes fluid and electrolyte repletion, as well as antibiotics. Antibiotic choices that include third generation oral or parenteral cephalosporins, ciprofloxacin, TMP-SMX, or ampicillin are reasonable, effective, and readily available. Treatment should be continued for 14 days [6].

6 Conditions Associated with *Clostridium difficile* Infection

6.1 General Principles

Clostridium difficile is associated with a colitis that usually follows broad-spectrum antibiotic usage for unrelated conditions. The colitis is associated with a persistent diarrhea, causing significant morbidity and a not-insignificant mortality rate among affected patients, the majority of whom are elderly persons. When the normal bacterial flora of the colon is altered by antibiotics, *Clostridium difficile* overgrows and

DOI 10.1007/978-1-4939-0779-3_95-1

releases a toxin which causes mucosal inflammation and damage. Diarrhea follows this damage and may last for weeks, with significant dehydration, abdominal pain, and weakness. *Clostridium difficile* infection (CDI) occurs primarily in hospitalized patients, but may be seen in the community. By CDC estimates, a 30 % reduction in the use of broad-spectrum antibiotics would result in a 26 % decrease in CDI [7].

6.2 Diagnosis

Diagnosis of CDI should be suspected in any patient with persisting diarrhea who has received antibiotics within the previous 3 months, has been recently hospitalized, or has a recurrence of diarrhea 48 h or more after hospital discharge. Physical examination of these patients reveals varying degrees of dehydration and abdominal tenderness. Patients may appear frankly septic. Rigid proctosigmoidoscopy or flexible endoscopy reveals an inflamed and edematous colonic wall with raised yellow-white pseudomembranes (hence the previous term for this condition as pseudomembranous colitis). Laboratory findings generally reveal a leukocytosis, electrolyte disturbances, and often a raised serum lactate, especially in those with colonic megacolon or ischemia from CDI. Stool assays are confirmative, with most hospital and outpatient labs offering a rapid enzyme-linked immunoassay for the detection of glutamate dehydrogenase (which is produced by *C. difficile*) or stool toxins produced by the bacteria. The best radiologic examination is CT scanning of the abdomen with IV contrast enhancement. CT generally reveals a markedly thickened and inflamed bowel wall with visualization of colonic wall lesions and sometimes areas of ischemic change. Plain radiographs are useful in demonstrating areas of colonic distention (diameter $>$10 cm) or megacolon, which has a more grave prognosis.

6.3 Treatment

Treatment of CDI begins with fluid and electrolyte replacement and ensuring there is no area of bowel ischemia that would require urgent surgical consultation. Stabilized patients with only mild diarrhea and no fever, abdominal pain, or leukocytosis can be managed supportively, with immediate discontinuation of any preceding antibiotic therapy. Patients with mild to moderate diarrhea associated with radiographic changes of colitis and leukocytosis/pain will require cessation of preceding antibiotics, as well as oral metronidazole (500 mg po tid 10–14 days) or oral vancomycin (125 mg po qid for 10 days). In patients with aggressive disease and significant complications of megacolon/ischemia/sepsis, inpatient admission with both IV metronidazole (500 g tid) and po or rectal vancomycin (500 mg po or pr qid) may be required.

Relapse occurs in 20–30 % of patients, despite appropriate initial therapy. First relapse should be treated with metronidazole +/− oral vancomycin, depending on the severity of the relapse. Subsequent relapses should be treated with pulse-dose vancomycin, or fidaxomicin 200 mg po bid for 10–14 days.

Since the last edition of this chapter, a new therapy for recurrent CDI has proven to be superior to antibiotic therapy. The therapy is fecal microbiota transplantation (FMT), and the concept is not a new one. FMT has been used sporadically by practitioners throughout the ages, but only recently has been systematically studied and applied to CDI patients. Briefly, FMT requires a distillate of stool from a healthy donor being transplanted into the small or large bowel of the recipient. The fecal material from the donor recolonizes the bowel of the patient with normal flora and is nearly always associated with a dramatic resolution of symptoms and the return of normal bowel health [8]. FMT may be delivered via NG tube, in an appropriately packaged oral form (“crapsules”), or by enema. Donors should be thoroughly screened for multiple conditions, including Hepatitis A, B, and C, as well as HIV. Although the FDA currently at the time of this writing considers FMT to be an investigational treatment, multiple Internet websites are available which actually walk the general public through giving themselves a fecal transplant from an unscreened community donor. It is probable that commercially prepared, medical-

DOI 10.1007/978-1-4939-0779-3_95-1

grade fecal material will be available for patient use within the next few years, and FMT will be standard of care for CDI.

7 Malabsorption

Malabsorption syndrome refers to the inability to absorb or digest one or more nutrients. Inability to absorb certain nutrients leads to a high osmotic load within the bowel and results in the presenting symptoms. The segment of involved intestine specifies the extent of the malabsorption.

Diarrhea is the most common symptom of malabsorption. It is usually watery and of moderate volume. Steatorrhea is the result of fat malabsorption and is characterized by pale, malodorous stools which float on the surface of the toilet water. Weight loss and fatigue are a physiologic follow-up to malabsorption, and patients may try to compensate by increasing caloric content. Flatulence and abdominal distention result from the fermentation of undigested nutrients into methane and other gases. Edema may result from chronic protein malnutrition or obstruction of small bowel lymphatics. Anemia is common and may be microcytic or macrocytic, depending on the segment of the involved bowel. Malabsorption syndromes have recently been linked to neurologic manifestations resulting from electrolyte disturbances, vitamin malabsorption, or antigen-antibody complexes resulting from the body's own immunologic response to contact with certain nutrients (Table 1).

8 Celiac Sprue and Controversies Regarding Gluten

8.1 General Principles

Celiac sprue is also known as celiac disease and gluten enteropathy. It is estimated to affect 1 % of the population and is a chronic disease of the digestive tract. There is a hereditary component, with 10 % of first-degree relatives having the disease. The pathophysiologic changes of this disease are seen in the small bowel, with destruction of intestinal villi and lengthening of the intestinal crypts. The degradation of absorptive surface of the small bowel leads to symptoms of maldigestion and malabsorption. The cause of these pathophysiologic changes is an immunologically mediated inflammatory response to gliadin, an alcohol-soluble fraction of gluten. Gluten is a protein found in wheat, rye, and barley and is among the most heavily consumed proteins on Earth, providing roughly 20 % of all the calories consumed by people. Thus, for individuals who manifest this inflammatory condition, consumption of any gluten-containing product causes further trouble.

Celiac sprue has a variable spectrum of presentation, with some individuals having minimally troubling or even undetectable symptoms, while other people are quite disabled, with the inflammatory sequelae affecting multiple organ systems. The most common symptoms include chronic diarrhea, cramping,

Table 1 Correlating malabsorption syndromes to symptoms

Diarrhea	Most common symptom
Steatorrhea	Whipple's disease, pancreatic failure
Weight loss	Whipple's disease, pancreatic failure, sprue, celiac disease, inflammatory bowel disease
Flatulence and distention	Lactose intolerance, celiac disease
Edema	Pancreatic failure
Microcytic anemia	Celiac disease
Macrocytic anemia	Crohn's ileocolitis
Neurologic symptoms, rashes	Celiac disease

DOI 10.1007/978-1-4939-0779-3_95-1

weight loss, fatigue, skin rashes, growth abnormalities, anemia, bleeding diatheses, neurologic symptoms (seizures, paresthesias, motor weakness), and osteopenia. There is a bimodal age distribution of the disease, the first at 8–12 months and then between 20 and 40 years of age. Some patients appear to have minimal symptoms and findings under middle age, when diagnosis becomes more obvious.

8.2 Diagnosis

Diagnosis relies in no small measure in keeping celiac sprue as part of a differential diagnosis of abdominal pain and diarrhea. A good history is essential, as physical exam may provide few clues. Workup should be performed while the patient is still consuming gluten. This maximizes the return on workup, as presumably the patient has ongoing inflammatory changes. A CBC and metabolic profile should be performed, with attention to levels of serum proteins, calcium, magnesium, iron, and cholesterol. Antibody testing, with the presence of IgA anti-tissue transglutaminase (IgA TTG), is the best first test, and if positive, small bowel biopsies obtained through upper GI endoscopy are required for confirmation. In patients younger than 2 years of age, combine IgA TTG with testing for IgG-deamidated gliadin peptides (DGP IgG). Measurement of endomysial IgA and reticulin IgA should also be performed to quantitate mucosal damage. Stool studies looking for fecal fat are helpful to document steatorrhea, and orally administered absorption studies like D-xylose or lactose are useful in quantifying carbohydrate malabsorption. On the cutting edge is genetic testing with confirmatory serology. The presence of HLA-DQ2.5 with positive IgA TTG and DGP IgG has strong specificity and sensitivity for the disease. The best single radiologic study for diagnosis is a barium small bowel follow-through, which usually shows dilatation of the small intestine and a coarsening or even obliteration of the fine mucosal pattern [9].

8.3 Treatment

Treatment is based on a gluten-free (no products containing wheat, rye, or barley in any form) diet. In refractory patients, corticosteroid administration may help; if there is still no response despite steroids, consider other possibilities such as small bowel lymphoma.

There has been a recent trend in both the mainstream North American press and various medical writers over the last several years to implicate gluten as a relative culinary “poison.” These writers contend that gluten is responsible for multiple medical conditions, including arthritis, asthma, schizophrenia, multiple sclerosis, and inflammatory bowel disease. Many patients may present to the clinic complaining of vague digestive symptoms that have abated after they stopped consuming gluten, thus coining the condition labeled “non-celiac gluten sensitivity.” This condition is difficult to quantify histologically or biochemically and seems to follow a pattern of self-diagnosis. Management of patients who believe they have gluten sensitivity is conservative. It is unlikely they will comply with a diet containing gluten to maximize laboratory testing to actually prove the existence of a true medical condition, so allowing them to follow a diet of their choice with periodic bland reassurance from the medical perspective seems the least contentious [10].

9 Irritable Bowel Syndrome

9.1 General Principles

Irritable bowel syndrome (IBS) is a common gastrointestinal problem encountered by family physicians. Patients with IBS may have some, or all, of symptoms including: abdominal pain, distention, altered bowel habit, urgency, flatus, and a sense of incomplete evacuation. Synonymous terms include spastic colon, mucous colitis, and irritable colon. Patients with IBS have disordered motility of the entire gut. IBS

DOI 10.1007/978-1-4939-0779-3_95-1

Table 2 Rome III criteria for diagnosis of IBS

Relieved by defecation
Onset associated with a change in stool frequency
Onset associated with a change in stool form or appearance
Altered stool frequency
Altered stool form
Altered stool passage (straining and/or urgency)
Mucorrhea
Abdominal bloating or subjective distention

has no underlying anatomic abnormality or inflammatory component; however, patients with IBS tend to have some element of secondary psychiatric morbidity, with anxiety, depression, and somatization being the most common. IBS is typically found in young or middle-aged adults, with a 2:1 female-to-male ratio.

9.2 Clinical Presentation

The hallmark of IBS is abdominal pain associated with defecation. Diagnosis is delineated by the Rome III criteria and requires at a minimum that patients have abdominal pain or discomfort at least 3 days per month during the previous 3 months that is associated with the symptoms listed in Table 2. The pain is reliably relieved by defecation, and there is invariably a change in the frequency of stool and a change in stool form. The frequency of stool is usually more than three bowel movements daily or less than three movements per week. IBS has four distinctive bowel patterns: IBS-D (diarrhea predominant), IBS-C (constipation predominant), IBS-M (mixed diarrhea and constipation), and IBS-A (alternating diarrhea and constipation), and it is not uncommon for patients to switch between subtypes over the course of a year.

9.3 Clinical Approach to the Patient with Suspected IBS

The extent of investigation depends on how closely the history and patient physical examination fit the defining characteristics of IBS. Typically, the physical examination is normal, apart from some vague lower-quadrant tenderness and perhaps some palpable bowel loops. Features on history and physical examination that argue against IBS include a steady downhill course, significant weight loss, nocturnal symptoms, onset after age 60, cachexia, or abdominal mass. Basic laboratory workup includes obtaining a CBC, comprehensive metabolic profile to look for electrolyte abnormalities, serum albumin (to rule out a malabsorptive condition), erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), stool culture, stool for *C. difficile* toxin, and stool for ova and parasites. Colonoscopy is indicated for those patients over age 40, especially if symptoms are of recent onset or if there is a history of bowel malignancy.

9.4 Management

IBS is a chronic illness, with periodic exacerbations. Successful management requires a strong relationship between patient and provider. Management must be individualized and directed toward reduction of symptoms as well as reduction of secondary anxiety, which is invariably present. After an appropriate workup, reassurance that there is no serious pathologic process at work is very helpful. Dietary restrictions are probably unnecessary, except in cases of lactose intolerance. However, useful dietary interventions include fiber supplementation to improve symptoms of diarrhea and constipation, judicious water intake, caffeine avoidance, and avoidance of legumes to reduce flatulence. Psychological interventions, cognitive behavioral therapy, dynamic psychotherapy, and hypnotherapy are all more effective than placebo and may be of value. Pharmacologic interventions which have some value in the management of symptoms

DOI 10.1007/978-1-4939-0779-3_95-1

include anticholinergics (dicyclomine and hyoscyamine), tricyclic antidepressants (amitriptyline, imipramine), prokinetic agents (metoclopramide, domperidone), antidiarrheals (loperamide, diphenoxylate), serotonin 5-HT3 receptor antagonists (alosetron), chloride channel activators (lubiprostone), guanylate cyclase C agonists (linaclotide), and antispasmodics (peppermint oil, pinaverium, trimebutine, cimetropium/dicyclomine). Generally, no one agent is a panacea, and most patients will require ongoing reworking/refinements of various medications over the years for adequate symptom control [11, 12].

10 Diverticular Disease

10.1 General Principles

Diverticulosis of the colon results from herniation of the mucosal and submucosal layers through the muscularis layer. This often occurs at points where nutrient arteries penetrate the muscularis. The incidence of diverticulosis in Western populations increases with age and is observed to include roughly 65 % of individuals by age 85. Diverticulitis is the inflammatory complication of diverticula and is seen in 20 % of persons with diverticulosis. The risk of diverticulitis increases with the number and distribution of diverticula. The exact cause of diverticulosis is elusive, but risk factors include obesity, a low-fiber diet, and constipation.

10.2 Clinical Presentation

Colonic diverticula are generally asymptomatic and found incidentally on colonoscopy or other imaging study of the colon. The most common location is over the length of the sigmoid colon in Western populations, where colonic intraluminal pressures are the highest; however, in Asian populations, diverticula are more common along the right side of the colon. Inflammation of a diverticulum results from an impaction of the diverticular sac from some colonic debris. The impaction results in increased susceptibility of the thin-walled diverticular sac to invasion by colonic bacteria. This in turn leads to microperforation of the sac wall with localized inflammation (peridiverticulitis), localized peridiverticular abscess formation, or, in some cases, wider inflammation with pericolonic abscess formation. Most of the time, only one diverticulum is involved, and the inflammation remains localized, healing with a residual area of pericolic fibrosis. Repeated attacks of diverticulitis may lead to segmental narrowing of the colon and possible obstruction.

Diverticulitis with a large perforation may lead to pericolonic abscess, which can extend along the bowel wall or rupture into adjacent organs, creating fistulas between the colon and vagina, urethra, bladder, or overlying abdominal wall. Rarely, free perforation of a diverticulum may occur and present with frank peritonitis.

Patients with acute diverticulitis present with pain, usually in the left lower quadrant. Right lower-quadrant pain may also occur; consider right colon disease or even appendicitis. Signs of peritoneal irritation, fever, leukocytosis, and possibly a palpable mass may also be present in advanced cases.

10.3 Diagnosis

A patient history, physical examination, and an awareness of the disease provide a starting point for diagnosis. For an acute episode, consider a CBC, basic metabolic profile (to define any dehydration or renal issues), and a computed tomography (CT) scan of the abdomen and pelvis with IV contrast. CT scanning is very helpful in making the diagnosis and delineating the extent of disease. Common CT scan findings may include pericolic fat stranding due to inflammation, diverticula, bowel wall thickening, soft tissue inflammatory masses or phlegmons, abscesses, and fistulas. See Fig. 1 for an example of a CT

DOI 10.1007/978-1-4939-0779-3_95-1

Fig. 1 This is an IV-contrasted scan, sagittal plane. Note the multiple sigmoid diverticula; the arrow points at a small area of abscess formation (Image courtesy of David James MD)

image of diverticulitis with a small pericolic abscess. Plain abdominal radiographs are less helpful, but are useful to delineate any free air under the diaphragm or bowel obstruction.

In nonacute cases, flexible sigmoidoscopy, colonoscopy, or air contrast barium enema will reveal the disease, as well as helping to rule out other disorders such as inflammatory bowel disease or colonic carcinoma. Keep in mind that a common cause of colonic bleeding is from a ruptured diverticulum. The right colon is the source of 70 % of these bleeds, which are usually duller red and copious. Luckily, these are a low-pressure venous bleed and are usually self-limiting. Obviously, urgent colonoscopy should be scheduled as soon as the bleeding stops to investigate the bleeding source.

10.4 Treatment

Asymptomatic patients do not require any specific treatment apart from general advice to increase dietary fiber intake. Patients with only mild tenderness, no leukocytosis, and no fever may be managed as outpatients, with oral antibiotics. Acutely ill patients will need inpatient management and a surgical consultation. See Table 3 for treatment options [13, 14].

11 Microscopic Colitis

11.1 General Principles

Microscopic colitis is the term used to describe patients who have persistent unexplained non-bloody diarrhea. These patients will have an endoscopically and radiologically normal-appearing colon, but biopsies show unique inflammatory changes. Microscopic colitis was previously known as collagenous colitis (CC) and lymphocytic colitis (LC). The characteristic feature of LC is the infiltration of lymphocytes into the colonic epithelium; CC shares this finding, but in addition, there is a thickening of the subepithelial collagen table. Whether LC and CC represent a continuous spectrum of the same disease process remains an unproven theory. Incidence is relatively rare and is most commonly found in people over the age of 40. LC affects men and women equally, while CC is 20 times more frequent in women than

DOI 10.1007/978-1-4939-0779-3_95-1

Table 3 Management options in diverticulitis

Mild diverticulitis, localized tenderness, no peritoneal signs	No fever, leukocytosis, CT scan showing little or no inflammatory changes	Outpatient management acceptable	TMP-SMX 1 DS tablet po bid PLUS metronidazole, 500 mg po bid, OR Ciprofloxacin 500 mg po bid PLUS metronidazole 500 mg po bid, OR moxifloxacin 400 mg po daily, OR amoxicillin/sulbactam 875 mg po bid, ALL for 10 days
Moderate disease, regional tenderness, localized peritoneal signs	Fever, leukocytosis, CT scan suggesting localized inflammation, no abscess or perforation	Inpatient management advisable	Ciprofloxacin 400 mg PLUS metronidazole 500 mg IV q12 h, OR Ceftriaxone 1 g 1–2 g daily PLUS metronidazole 500 mg IV q12 h, OR Piperacillin/tazobactam 4.5 g IV q6–8 h, OR Ertapenem, 1 g daily, OR meropenem 1 g IV q8 h
Severe disease with pan-abdominal tenderness and peritoneal signs	Fever, +/−leukocytosis, elevated serum lactate, CT scan suggesting abscess formation, perforation with free air	Inpatient management and surgical consultation mandatory	IV antibiotics as above

men. Consequences of this condition are limited to the stress of ongoing diarrhea and malabsorption and may include weight loss, electrolyte abnormalities, dehydration, and chronic fatigue. Most of these patients will have had diarrhea for years, with multiple consultations and radiologic studies before diagnosis is made from endoscopically obtained colonic tissue biopsies of the rectosigmoid and ascending colon, and most have been labeled as diarrhea-prominent IBS.

11.2 Etiology

No specific etiology has been determined, but some evidence suggests that certain antidepressant drugs (SSRIs and sertraline) may increase the risk of CC. Other drugs, notably ranitidine, proton pump inhibitors, ticlopidine, ASA, flutamide, simvastatin, carbamazepine, and lisinopril, have also been implicated. Other patients may have other autoimmune conditions including uveitis, autoimmune thyroid disease, idiopathic pulmonary fibrosis, juvenile DM, and pernicious anemia. One-third of patients with celiac disease also have histologic findings consistent with microscopic colitis, and the diagnosis of microscopic colitis should be considered in those patients with a presumptive diagnosis of celiac disease in whom diarrhea does not resolve after elimination of gluten from the diet. A gluten-free diet does not seem to treat microscopic colitis in the absence of celiac disease.

11.3 Treatment

Treatment is graduated, and it should be noted that some patients have clinical courses marked by spontaneous remissions and relapses. Drugs known to be associated with microscopic colitis should be stopped before other treatment is started. See Table 4 for management options [15].

DOI 10.1007/978-1-4939-0779-3_95-1

Table 4 Management steps in microscopic colitis

Step 1: Symptom control	Loperamide or diphenoxylate/atropine as needed
Step 2: Moderate disease and persisting symptoms	Bismuth subsalicylate 2–3 262 mg tabs qid 2 months, mesalamine 3 g/day 8 weeks, and/or cholestyramine 8 g/day
Step 3: More severe colitis	Budesonide 9 mg daily 6 weeks with no taper, OR prednisone 60–80 mg/day for 2 weeks, with a tapering dose for a further 2 weeks
Step 4: Refractory disease and symptoms	Azathioprine 2 g/kg/day or methotrexate 15 mg/M^2 BSA po/IM twice weekly

12 Inflammatory Bowel Disease

12.1 General Principles

Inflammatory bowel disease includes at least two forms of idiopathic intestinal inflammation: ulcerative colitis (UC) and Crohn's disease (CD, also known as regional ileitis). Etiology appears to be a dysregulated immune response to host intestinal microflora. There is an increased incidence in persons with asthma or COPD, and persons with IBD are at higher risk for the development of bowel malignancy. Prevalence varies between 5 and 10 per 100,000 persons. Both disorders occur equally in men and women, with spikes of peak incidence between the ages 15 and 30 and then again between ages 55 and 65.

The manifestations of IBD generally depend upon the segment(s) of intestinal tract involved. Symptoms are not specific, but may include:

- Irregular bowel habit, predominantly with bouts of diarrhea often with passage of mucus
- Intestinal cramping and abdominal pains
- Fever and sweats
- Malaise, fatigue, and progressive weight loss
- Arthralgias, and in the case of CD, extra-intestinal manifestations such as arthritis, osteoporosis, uveitis, dermatitis, or liver disease
- Growth retardation and delayed or failed sexual maturation in children
- Grossly bloody stools
- Perianal disease, abscess, and fistula formation (50 % of those with CD)

12.2 Clinical Presentation

12.2.1 Crohn's Disease

Crohn's disease (CD) produces a transmural inflammation of the alimentary tract anywhere along its length, with ulceration of the mucosa and formation of granulomas, fistulas, and abscesses. The inflammation may be segmental, with relatively normal tissues interposed between involved areas ("skip lesions"). Involvement of the terminal ileum and colon is common. Pain is more frequent in the right lower quadrant and may be associated with a palpable mass due to chronic inflammation.

12.2.2 Ulcerative Colitis

In contrast to CD, UC produces a nontransmural inflammation of the mucosa and superficial submucosa, typically of the rectum and distal colon. Inflammation may occur proximally, extending into the right colon. Major symptoms include abdominal pain, fever, rectal bleeding, diarrhea, and tenesmus. The severity of symptoms correlates with the intensity of inflammation and extent of bowel involved.

Fig. 2 Sagittal CT scan with IV and oral contrast demonstrating a thickened terminal ileum typical of Crohn's ileocolitis with substantial inflammatory changes to supporting mesentery; note also the free fluid around the liver and in the pelvis (Courtesy of David James MD)

12.3 Diagnostic Approach

Diagnosis of IBD requires a careful history, a general physical examination of the patient, and appropriate laboratory, radiologic, and endoscopic examinations. Stool examination is important, as other conditions may mimic IBD. Stool samples are generally heme positive, with microscopic examination revealing neutrophils and eosinophils. Colitis caused by bacterial pathogens as *Salmonella*, *Campylobacter*, *C. difficile*, or protozoans (amebiasis) may mimic IBD, so a stool examination for ova and parasites and a stool culture are prudent. Laboratory investigation begins with a CBC and metabolic panel. Expect a mild anemia with a microcytic smear from chronic low-volume blood loss and an elevated WBC from the chronic inflammatory (rather than infectious) condition. Serum proteins may be decreased, especially in CD, from chronic malabsorption from small bowel inflammation. Similarly, serum B_{12} levels may be depressed from poor vitamin uptake in a diseased ileal region of the bowel. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels will be elevated, and they can be used serially to assess the general level of inflammation. In children, there is some evidence for using the level of fecal calprotectin levels to diagnose IBD.

Radiologic evaluation is important in making the diagnosis. Plain films form a foundation in the workup. In UC, plain films may reveal irregularity of the colonic wall, with telltale "thumbprinting" due to local bowel wall edema. Occasionally, air in the bowel wall (pneumatosis coli) or even free air from perforation may be seen. Megacolon is defined by a bowel luminal diameter of 10 cm or greater and is a serious complication of UC which may require surgical intervention. In CD, plain films may reveal nephrolithiasis, osteopenia, or sacroiliitis. Air contrast films will reveal the extent of colonic disease in CD and define the presence of fistulas, submucosal edema, and pseudodiverticula formation. Upper GI studies with oral contrast and follow-through technique are useful for the definition of small bowel disease in CD. CT scanning with a minimum of IV contrast is an ideal study to define the presence and extent of bowel pathology in UC and CD and is often the initial radiologic evaluation of an ill patient in the emergency department setting (see Fig. 2). CT scanning is also the ideal modality to reveal associated IBD pathology, including abscesses, fistulas, mesenteric edema/streaking, free fluid, and bowel wall

DOI 10.1007/978-1-4939-0779-3_95-1

thickening. CT enterography is a CT contrast study wherein the patient ingests a substantial amount of oral contrast prior to scanning. This technique allows careful examination of the small bowel and is replacing plain film follow-through upper GI enemas as a diagnostic modality to define small bowel pathology. Magnetic resonance imaging (MRI) has been shown to be equivalent to endoscopy in predicting severity and extent of colonic disease, edema, and fistulas. MRI has a higher sensitivity than CT or endoscopy to delineate the pelvic and perirectal complications of CD. MR enterography is also a choice when radiation exposure from repeated CT scanning may be an issue [16].

12.4 Management

The management of inflammatory bowel disease has become increasingly sophisticated over the last decade and is best approached as a team, involving frequent collaborative consultations with gastroenterology and surgical specialists. Most patients will require a combination of both medical and surgical therapies over the course of their lifelong disease. The medical approach for IBD includes symptom relief and therapy to produce mucosal healing. Usually, a stepwise escalation of medical therapy is required until a response is achieved. The two primary goals of therapy are remission (induction) and prevention of disease flares (remission). Surgical therapy is indicated for patients who fail medical therapy and suffer from disease complications.

Current trends in management emphasize deep mucosal healing, especially in CD. Combination therapy using both anti-TNF (tumor necrosis factor-like) agents and immune modifiers earlier in the course of IBD may result in elimination of inflammation, reduction in surgical procedures, and reduction in hospitalization for many patients.

Patients with IBD will require symptomatic therapy, especially when active inflammation is not related to symptoms. Treatment with antidiarrheal agents (loperamide or diphenoxylate) should be avoided, as they may produce toxic megacolon in individuals with significant colonic inflammation. Antispasmodic medication (hyoscyamine, dicyclomine, scopolamine) may be used for symptomatic relief. In patients with significant ileal disease from CD, diarrhea may be due to bile salt malabsorption, and cholestyramine resin may be helpful.

12.5 Stepwise Approach to IBD Therapy

The first step in IBD therapy is an aminosalicylate. No one aminosalicylate has been shown to be superior, so mesalamine, 500–1,000 mg po qid for 8 weeks, is a reasonable first choice. It is more effective in UC than CD and will not maintain a remission of CD. Mesalamine is also available in enema and suppository form and is useful for the treatment of localized distal colitis. For CD, the addition of metronidazole 500 mg bid-tid PLUS ciprofloxacin 500 mg po bid for 2–4 weeks has been shown to be helpful, especially if the patient has perianal disease or an inflammatory mass on abdominal CT scan (refer again to Fig. 2 for an illustration).

If the patient fails to respond to aminosalicylates in an appropriate dose, addition of corticosteroids as a second step follows. Depending on the extent of the disease flare, 10–60 mg po of prednisone daily is indicated. Once a clinical response is seen, the dose should be tapered and then ceased. If the patient relapses during the steroid taper, the next step of therapy, immune-modifying agents, needs to be considered.

Immunomodulating agents include azathioprine, 6-mercaptopurine, cyclosporine A, tacrolimus, and methotrexate. Consideration should be given to the use of anti-TNF agents (infliximab, adalimumab, golimumab, or certolizumab pegol) or the integrin antagonist, vedolizumab, if disease flares are frequent (two or more flares per year), if the patient requires a prolonged or more intense steroid dosage, or if the patient's bowel inflammation appears to be refractory to steroids. Immune modifiers generally have a 2–3

DOI 10.1007/978-1-4939-0779-3_95-1

month onset of action and are not appropriate for induction of a remission. These agents are of value in primary treatment of fistulas in CD and maintenance of remission.

The use of immunomodulating agents requires a thorough patient evaluation prior to initiation of use. In particular, patients require screening for occult tuberculosis, hepatitis, or intra-abdominal abscesses. Frequent monitoring of hematologic values (CBC) and liver function is required. Patients requiring step 3 therapy benefit from concurrent care from a gastroenterologist with knowledge of advanced IBD therapy [17].

Surgical therapy is curative for UC. However, as CD can involve any part of the alimentary tract from mouth to anus, surgery is only a stopgap and may lead to complications such as recurrent bowel obstruction from adhesions or short gut syndrome. In UC, surgery is indicated for intractable colon inflammation unresponsive to medical therapy, intolerance to medical therapy, perforation, toxic megacolon, or precancerous changes on colonoscopy. The most common surgical choices are proctocolectomy with ileostomy and total proctocolectomy with ileoanal anastomosis. In this last option, a multistage procedure involves performing a diverting ileostomy and creating an ileal pouch that is anastomosed directly to the anus. The rectum and its mucosa are removed. After the ileoanal anastomosis is healed, the ileostomy is taken down, and flow through the anus is reestablished. In female patients planning to get pregnant, proctocolectomy with ileostomy is preferred, as it avoids the extensive pelvic dissection and high subsequent infertility rate with ileoanal anastomosis.

In CD, surgery is indicated for disease complications (fistula, stricture), rather than for a primary cure. Approximately 70 % or more of patients with CD will require surgery, and modern techniques emphasize bowel-length sparing procedures. In patients with severe perianal disease, a diverting ileostomy or colostomy is an option that improves their quality of life. Percutaneous abscess drainage and endoscopic balloon dilatation of strictures are options in carefully selected patients. Involve surgical consultants early with these patients, and remember that medically refractory disease is a relative contraindication for surgery [18].

[b]Department of Family & Community Medicine, Thomas Jefferson University, Philadelphia, PA, USA
[c]Department of Family Medicine, University of Michigan Health System, Ann Arbor, MI, USA

Pancreatic disease causes significant health issues ranging from pancreatitis and pancreatic cysts to cancer. To reduce this burden, family physicians need a systematic approach to evaluation and treatment.

Acute Pancreatitis

Background

Acute pancreatitis, an inflammatory disease of the pancreas, is one of the most common gastrointestinal disorders requiring hospitalization. It has a reported annual incidence of 13–45 cases per 100,000 persons [1]. Acute pancreatitis is hypothesized to be caused by unregulated activation of trypsin within pancreatic acinar cells, leading to the autodigestion of the gland and local inflammation [2].

Approach to the Patient

Etiology

The most common causes are gallstones (40–70 %) and alcohol use (25–35 %) [3]. In patients greater than 40 years of age, a pancreatic tumor can be considered as a possible cause. For the remainder of patients for whom no etiology is established (15–25 %), this is referred to as idiopathic acute pancreatitis.

Diagnosis

Acute pancreatitis is diagnosed when two of these criteria are present: (1) abdominal pain consistent with the disease, (2) serum amylase and/or lipase greater than three times the upper limit of normal, and (3) characteristic findings from abdominal imaging [3].

History and Physical

Patients with acute pancreatitis typically describe a history of constant epigastric or upper quadrant pain, with radiation to the back, chest, or flanks. On examination, the upper abdomen can be tender, and bruising caused by bleeding due to pancreatic necrosis can be seen in the periumbilical region (Cullen's sign) and flanks (Grey Turner's sign). Also, extension of inflammatory exudates to the diaphragm may result in shallow respiration [2].

DOI 10.1007/978-1-4939-0779-3_96-1

Laboratory Studies and Testing

For initial laboratory studies, serum amylase alone cannot be used reliably for the diagnosis. Serum lipase is more specific for acute pancreatitis and remains elevated longer than amylase. However, serum amylase and lipase may be high in the absence of acute pancreatitis. Another important laboratory marker in assessing severity is C-reactive protein (CRP), an acute phase reactant that reaches a peak concentration 72–96 h after symptom onset. It is significantly higher in patients with necrotizing disease [4]. Genetic testing may also be considered in young patients (less than 30 years old) if no cause is evident and a family history of pancreatic disease is present [3].

Imaging

A transabdominal ultrasound should be performed in all patients with acute pancreatitis to assess for gallstones. While a contrast-enhanced CT (CECT) provides greater than 90 % sensitivity and specificity for the diagnosis of acute pancreatitis, its routine use is not needed. Magnetic resonance imaging (MRI) is comparable to CECT in the early assessment of acute pancreatitis, and MRI employing magnetic resonance cholangiopancreatography (MRCP) has the additional advantage of diagnosing choledocholithiasis and pancreatic duct disruption. MRI can be substituted for CECT in patients with contrast allergy and renal insufficiency (can perform without gadolinium contrast and still diagnose pancreatic necrosis). Either follow-up CECT or MRI is useful for patients lacking clinical improvement, with clinical deterioration, or when invasive intervention is considered [3, 5].

Differential Diagnosis

The differential includes cholecystitis, cholelithiasis, cholangitis, choledocholithiasis, peptic ulcer disease, gastritis, chronic pancreatitis, acute or chronic alcohol consumption, perforated ulcer, early appendicitis, bowel obstruction, mesenteric ischemia, gastroenteritis, post-traumatic injury, or malignancy [6].

Treatment

Severity Prediction

Most episodes of acute pancreatitis are mild and self-limited, requiring brief hospitalization. Approximately 20 % of patients develop severe disease with local and extrapancreatic complications involving hypovolemia and multiple organ dysfunction. Therefore, risk stratification of acute pancreatitis is important. The revised Atlanta classification now divides acute pancreatitis into three categories: (1) mild, no organ failure or local complications; (2) moderate, local complications and/or transient organ failure (less than 48 h), the presence of shock, gastrointestinal bleeding, pulmonary insufficiency, or renal failure; and (3) severe, persistent organ failure (greater than 48 h). Various scales can assess injury to extrapancreatic organs – the greater the number of organs injured, the greater the score [2, 3].

Fluid Therapy

Early aggressive intravenous hydration is most beneficial during the first 12–24 h to correct third spacing and maintain an adequate intravascular volume. Fluid requirements should be reassessed at frequent intervals – within 6 h of admission and for the next 24–48 h – using caution in patients with cardiovascular, renal diseases, or other comorbidities [3].

Nutrition

Patients with mild to moderate acute pancreatitis do not require nutritional support and can start oral feeding once abdominal pain decreases and inflammatory markers improve. For patients with severe acute

DOI 10.1007/978-1-4939-0779-3_96-1

pancreatitis, necrotic pancreas, or organ failure, enteral nutrition should be started within 48 h: [5] nasogastric or nasojejunal feeding is comparable in efficacy and safety [7]. Avoid parenteral nutrition due to risk of infections and other line-related complications, unless the enteral route is not available, not tolerated, or not meeting caloric requirements [3].

Pain Management

Adequate analgesia is important for patients with acute pancreatitis. For mild cases, non-opioid drugs may be enough to manage pain. Narcotic agents are often needed for severe cases [8].

Antibiotics

Intravenous antibiotic prophylaxis is not recommended for the prevention of complications in acute pancreatitis. In severe pancreatitis with infected necrosis, coverage for gram-negative organisms (using carbapenems, quinolones, metronidazole) is strongly recommended as soon as possible after a severe attack [5].

Causative Therapy

Early endoscopic retrograde cholangiopancreatography (ERCP), preferably within 24 h, is indicated for concomitant cholangitis, significant persistent biliary obstruction, or severe biliary pancreatitis without biliary sepsis or obstruction. It is not indicated in mild pancreatitis of suspected or proven biliary etiology in the absence of biliary obstruction [3].

For mild gallstone-associated acute pancreatitis, early cholecystectomy (preferably during the same hospitalization) is recommended, and no later than 2–4 weeks after discharge. In patients with severe gallstone-associated acute pancreatitis, cholecystectomy should be delayed until there is sufficient resolution of the inflammatory response and clinical recovery [3].

Complication Management

Pancreatic necrosis is the most severe complication as it is frequently associated with pancreatic infections. It occurs when a local area of nonviable parenchyma becomes infected with bacteria originating from the gut, leading to infected necrosis, pancreatic abscess, or infected pseudocysts. A pseudocyst is a pancreatic fluid collection that has been enclosed by a wall of granulation tissue that results from pancreatic duct leakage [2]. In acute necrotizing pancreatitis, the findings of necrosis on CECT and a persistent severe inflammatory response syndrome (SIRS) should prompt fine needle aspiration (FNA) with gram stain and culture to differentiate sterile and infected necrosis. For patients with sterile necrosis in the first week, mortality is between 10 % and 40 %. Surgery is indicated for the presence of massive pancreatic necrosis (greater than 50 %) with a deteriorating clinical course and in patients with progression of organ dysfunction or no signs of improvement. In infected necrosis, after 3 weeks, mortality ranges between 20 % and 70 %. Antibiotics should be used for treatment first, and if patients remain ill and infected necrosis has not resolved, then minimally invasive necrosectomy is recommended [3].

Chronic Pancreatitis

Background

Chronic pancreatitis is a progressive inflammatory change of the pancreas that results in permanent structural damage, leading to impairment of exocrine and endocrine function [9]. The incidence of chronic

DOI 10.1007/978-1-4939-0779-3_96-1

pancreatitis is between 5 and 12 cases per 100,000 persons per year, which accounts for more than 120,000 outpatient visits and 50,000 hospitalizations annually [10].

Causes

Most cases are due to alcohol abuse, ductal obstruction, genetic mutations, systemic disease, autoimmune pancreatitis, tropical pancreatitis, and idiopathic pancreatitis [11, 12]. Cigarette smoking has been found to be an independent, dose-dependent risk factor for acute and chronic pancreatitis [13].

Diagnosis

History/Physical Exam

The primary clinical manifestations are abdominal pain and pancreatic insufficiency. The abdominal pain is typically epigastric, radiates to the back, worsens postprandially, and may be alleviated with leaning forward. This pain may occur sporadically but become more continuous as the condition progresses. Clinically significant fat and protein deficiencies do not occur until over 90 % of pancreatic function is lost [14]. At variable states of progression, this may result in steatorrhea, indigestion, weight loss, and malaise. While the classic triad of pancreatic calcifications, steatorrhea, and diabetes mellitus strongly suggests the diagnosis of chronic pancreatitis, most cases are challenging to identify given the potential absence of symptoms and normal laboratory or imaging studies in over 20 % of cases [15].

Laboratory

Since chronic pancreatitis is a patchy, focal disease that leads to minimal increase in pancreatic enzymes in the blood, serum concentrations of amylase and lipase are usually normal or may be slightly elevated. Significant fibrosis can also result in decreased abundance of these enzymes within the pancreas. Thus, pancreatic enzyme levels should only be used when suspecting acute not chronic pancreatitis. While complete blood counts, electrolytes, and liver function tests tend to be normal, elevations of serum bilirubin and alkaline phosphatase may suggest intrapancreatic compression of the bile duct. Markers of autoimmune chronic pancreatitis include an elevated ESR, IGG4, rheumatoid factor, ANA, and anti-smooth muscle antibody titer [16].

Direct pancreatic function testing for secretin with suggestive clinical features can also be used to diagnose chronic pancreatitis. However, this test is invasive, usually done under fluoroscopy, and not readily available [17].

Fecal elastase is also thought to suggest exocrine deficiency and may be used to evaluate steatorrhea [18].

Imaging

Diagnosis can be confirmed by pancreatic calcifications on imaging (abdominal plain film or CT) or a pancreatogram revealing beading or ectatic branching of the main pancreatic duct [14].

When comparing imaging studies, the sensitivity and specificity of ultrasound for the diagnosis of chronic pancreatitis are 60–70 % and 80–90 %, respectively, which is slightly less than corresponding values for CT, which are 75–90 % and 85 %, respectively [19]. These values drop in early disease for both forms of imaging. Magnetic resonance cholangiopancreatography (MRCP) is becoming the diagnostic test of choice since it can demonstrate calcifications and pancreatic duct obstruction while avoiding risks of radiation without the invasiveness of the prior test of choice, endoscopic retrograde cholangiopancreatography (ERCP). Endoscopic ultrasonography (EUS) may also be as sensitive as ERCP when done

DOI 10.1007/978-1-4939-0779-3_96-1

by a highly skilled gastroenterologist [15] and provide additional procedures that may detect earlier disease missed by approaches aforementioned [20].

Classification

The Cambridge classification system divides severity of disease into category I equivocal changes, category II mild to moderate, and category III considerable changes based on ERCP findings [21].

Differential Diagnosis

Due to its nonspecific presentation, it is important to differentiate from other diseases such as pancreatic cancer, acute pancreatitis, autoimmune pancreatitis, pancreatic endocrine tumors, pancreatic duct stones, pseudocysts, hepatobiliary disease, systemic autoimmune disease, or lymphoma [14].

Treatment

Treatment for chronic pancreatitis focuses on pain management, correction of pancreatic insufficiency, and management of complications.

Recommendations begin with alcohol and tobacco cessation and consumption of small low-fat meals [22]. If pain is persistent, pancreatic enzyme supplements can be initiated. Oral intake should be avoided to minimize pancreatic stimulation. Analgesics with opiates and/or NSAIDs can be used. Adjuvant therapy with neuropathic agents (i.e., gabapentin or pregabalin) and tricyclic antidepressants (i.e., amitriptyline and nortriptyline) may provide additional pain control [23, 24].

Pancreatic enzyme supplementation is based on suppression of pancreatic exocrine secretion, and while several studies do show benefit from placebo effect, it has also been shown with some evidence as a reasonable addition to measures above for patients with persistent pain [25].

In cases of refractory pain, EUS may be diagnostic and therapeutic, with procedures such as celiac plexus block and celiac plexus neurolysis and EUS-guided drainage of pancreatic fluid collections [20]. Extracorporeal shock wave lithotripsy in conjunction with EUS can help remove larger or impacted pancreatic ductal stones [26].

Finally, surgery is reserved for refractory pain. Although medical treatment and endoscopic interventions are primarily offered to patients with chronic pancreatitis, approximately 40–75 % will ultimately require surgery. Although pancreaticoduodenectomy has been considered the standard surgical procedure, its high postoperative complication and pancreatic exocrine and/or endocrine dysfunction rates have led to a growing popularity for duodenal-preserving pancreatic head resection such as the Frey procedure [27].

Nutritional deficiencies have been documented in advanced disease, including fat-soluble vitamins, vitamin B12, zinc, calcium, magnesium, thiamine, and folic acid [28]. Monitoring levels and supplementing accordingly along with screening for diseases or symptoms associated with these deficiencies are also important.

DOI 10.1007/978-1-4939-0779-3_96-1

Pancreatic Cysts

Background

In the past two decades, the prevalence of pancreatic cysts diagnosed in US adults has dramatically increased [29]. In the USA, 20 % of patients who undergo MRI for nonpancreatic diseases are found to have a pancreatic cyst [30]. The most common include pseudocysts, serous cystadenomas (SCA), mucinous cystic neoplasms (MCN), and intraductal papillary mucinous neoplasms (IPMN) [31].

Distinguishing SCA from MCN and IPMN is key as SCA is benign while MCN and IPMN are potentially or overtly malignant lesions.

Clinical Presentations

There is no typical presentation or physical exam findings. IPMNs are more likely to be found in males while SCA and MCN are mostly seen in women. There is no alcohol abuse or history of pancreatitis in SCA, MCN, or IPMN. Malignant potential is rare in SCA, moderate to high in MCN, and low to high in IPMN [31].

Diagnosis

Transabdominal ultrasound has difficulty visualizing the entire pancreas and is highly operator dependent. The preferred imaging options are CT, MRI, and endoscopic ultrasound. ERCP can be used but it can only help diagnose IPMN and is an invasive test. MRI has been considered superior to CT for characterizing morphological features of pancreatic cysts [32]. However, CT was shown to have an accuracy rate of 80 % for discriminating between mucinous and non-mucinous cysts [33], while MRI had less interobserver agreement [32]. EUS provides another option if CT and MRI imaging are not diagnostic, particularly in showing internal septa, mural nodules, solid masses, vascular invasion, and lymph node metastases. EUS can be combined with FNA of the lesion for collection and analysis of fluid and solid components. Cyst fluid with elevated carcinoembryonic antigen distinguishes mucinous from non-mucinous cysts but cannot determine malignancy potential [34]. Cyst fluid cytology can be helpful, but the fluid often has low cellularity. Because expertise in this procedure and technique is not readily available, consult with a local radiologist and endoscopist to determine the best locally available imaging approach.

Management of Pancreatic Cysts

The initial steps are to assess patient symptoms and determine the cyst size, location, and presence of main branch involvement. If the patient has no symptoms, cyst <1 cm with no solid components or thickened cyst walls, main duct <5 mm with no abrupt caliber changes, and no mural nodule, then imaging surveillance in 2–3 years is recommended. Further EUS is not needed. If the patient has obstructive jaundice with a cystic lesion in the head of the pancreas, enhancing solid component within the cyst, or main pancreatic duct ≥ 10 mm, then surgical resection should be considered. If the cyst is ≥ 3 cm, there are thickened cyst walls, the main duct is 5–9 mm, a mural nodule is present, or the main duct has abrupt caliber changes with distal pancreatic atrophy, then the patient should undergo EUS to further define the lesion [34].

DOI 10.1007/978-1-4939-0779-3_96-1

IPMN

First described in the mid-1980s, IPMN is a cystic neoplasm of the pancreas – a slow-growing tumor with malignant potential. There are three types of IPMN: main duct, branch duct, and mixed type. Main duct IPMN features segmental or diffuse dilation of the main pancreatic duct of >5 mm without other causes of obstruction. Because the rate of malignancy is very high (up to 70 % in reported surgical series), in surgically fit patients, the recommendation is for surgical removal of the affected portion of the pancreas or entire pancreas (total pancreatectomy) if the entire duct is involved [33].

Branch duct IPMNs may be found in various locations throughout the gland and are seen with equal frequency in both genders. Their management is challenging and lifetime risk of malignancy is not entirely known. There is no medication to treat these cysts – only options are surveillance and surgical removal. Important factors to consider include the patient's age, symptoms, the size of the cyst, and whether or not there is a solid component or mural nodule.

MCN

MCNs are defined by the presence of ovarian stroma and are usually located in the pancreatic body and tail. Cancer is very rare in MCN <4 cm without mural nodules [31, 34]. It is most commonly diagnosed in middle-aged women. In surgically fit patients, resection is routinely recommended, while observation is recommended for elderly frail patients.

Surgical resections should be done at high-volume institutions, generally those that perform 15 or more pancreatic resections annually. These institutions have reported decreased mortality, hospital length of stay, and overall cost compared to low-volume institutions [35].

Pancreatic Cancer

Background

Pancreatic cancer is the fourth leading cause of cancer-related deaths in the USA [36]. The incidence is equal in both genders but slightly higher in African-Americans compared to Caucasians [37]. Over 90 % of these cancers are pancreatic ductal adenocarcinomas (PDAC). There are several risk factors associated with the development of PDAC: tobacco use, alcohol use, obesity, and type 2 diabetes for 5 or more years. Routine screening for pancreatic cancer in asymptomatic adults who are at average risk is not recommended due to lack of mortality benefit [35]. However, a provider can consider screening individuals from families with known genetic defects predisposing them to pancreatic cancer or with familial pancreatic cancer. Expert opinion recommends screening with CT or EUS [38].

Clinical Manifestations

Abdominal pain, jaundice, pruritis, dark urine, and acholic stools may all be presenting symptoms as a result of obstruction within the biliary tree [39]. Nonspecific findings from cancers of the pancreatic body or tail include unexplained weight loss, anorexia, early satiety, dyspepsia, nausea, and depression [40]. Also, a sudden onset of atypical type 2 diabetes (a thin adult 50 years or older) that is difficult to control suggests pancreatic cancer [41].

Patients may present in early stages with normal exams or advanced disease with manifestations of liver involvement such as abdominal tenderness, jaundice, and cachexia. A nontender, distended, palpable gallbladder in a jaundiced patient (Courvoisier's sign) is 83–90 % specific but is only 26–55 % sensitive

DOI 10.1007/978-1-4939-0779-3_96-1

for a biliary obstruction due to malignancy [39]. Advanced pancreatic cancer, like other abdominal malignancies, can be associated with recurring superficial thrombophlebitis (Trousseau's sign) or left supraclavicular lymphadenopathy (Virchow's node). Subcutaneous areas of nodular fat necrosis (pancreatic panniculitis) may be evident in rare cases [42].

Diagnosis

CT is the gold standard for diagnosing and staging patients with pancreatic cancer [43]. A pancreas protocol CT involves triphasic (i.e., arterial phase, late phase, and venous phase) cross-sectional imaging that allows for enhancement between the parenchyma and adenocarcinoma. When CT is not possible (i.e., not available, contrast allergy, etc.), MRI with contrast can be used for diagnosis and staging.

If a pancreatic mass is identified, subsequent EUS and FNA are indicated. If no mass is identified and no evidence of metastatic disease is present, further EUS or ERCP is indicated [35].

The most common serum tumor marker used for PDAC is carbohydrate antigen (CA) 19-9, which is expressed in pancreatic and hepatobiliary disease. In symptomatic patients, it can help confirm the diagnosis and predict prognosis and recurrence after resection [35]. However, CA 19-9 is not tumor specific and therefore is not a sufficient individual screening tool for asymptomatic patients [44].

Staging

Once a mass is identified and FNA confirms tissue diagnosis, EUS can determine the tumor size and extent of lymph node metastases and assess for portal venous system involvement to complete the staging [35]. In addition to EUS, chest CT and serum liver enzyme tests are useful to determine surgical candidacy [35]. A multidisciplinary team with expertise from surgery, diagnostic imaging, pathology, interventional endoscopy, and medical and radiation oncology is highly recommended to define surgical candidates [35].

Management

Surgical resection is the only potentially curative treatment for PDAC. Around 15–20 % of patients have resectable disease, but only around 20 % of those who undergo surgery survive to 5 years [35]. Although postoperative mortality is less than 5 %, the median survival is still only 12–19 months [35]. Pancreatic resections should be done at high-volume institutions, generally those that perform 15 or more pancreatic resections annually [35].

The classic operation for resection of a carcinoma of the head of the pancreas is a pancreaticoduodenectomy (Whipple procedure). For surveillance in patients with resected pancreatic cancer, expert consensus recommends history and physical examination every 3–6 months for 2 years and then annually [45]. Monitoring for recurrence with CA 19-9 levels, CT scans, and EUS every 3–6 months can also be considered, although evidence is limited that earlier treatment improves patient outcomes [46].

Over 80 % of patients present with unresectable disease. Some studies have addressed the use of chemoradiation with or without chemotherapy to convert unresectable disease status to resectable. Post-resection, these patients have similar survival rates as those initially determined to be resectable [35]. The primary treatment for advanced pancreatic cancers is palliation (i.e., adequate nutrition and pain control), which may have some effect on survival.

Diseases of the Liver

David T. O'Gurek*
Department of Family & Community Medicine, Temple University School of Medicine, Philadelphia, PA, USA

Diseases of the liver encompass a wide variety of clinical conditions that range from mild abnormalities on liver testing to end-stage liver disease with intrahepatic and extrahepatic manifestations and complications. These also range from acute, self-limited presentations to fulminant disease with rapid liver failure to chronic, low-level disease and also to chronic liver disease that progresses slowly over time. While the history and physical signs of this broad range of clinical disorders are quite similar, often with nonspecific findings with broad-range differentials, laboratory evaluation is critical to sorting through these disease processes. It is critical for family physicians to have an understanding of liver pathology and the laboratory assessment of the hepatic system.

"Liver function tests" is often a misnomer used to describe a variety of tests that assess hepatic synthetic function (e.g., serum albumin, prothrombin time), excretory function (e.g., serum bilirubin, direct bilirubin), necroinflammatory activity (e.g., alanine aminotransferase or ALT/SGPT, aspartate aminotransferase or AST/SGOT, and γ-glutamyltransferase or GGT), and cholestasis (alkaline phosphatase). While these tests can aid in the correct identification of liver disease, a single elevation must be confirmed with a second test. Furthermore, normal or minimally abnormal tests do not preclude the presence of significant liver disease or possibly advanced disease or cirrhosis. While these tests will demonstrate liver disease, they are nonspecific and require specific testing based on risk factors, history, and laboratory evaluation directed at specific etiologies.

The major causes of liver disease include infectious hepatitis, excessive alcohol usage, and toxic hepatopathy from drugs or other substances; however, less common metabolic abnormalities can also result in chronic liver disease and cirrhosis (see Table 1). This chapter will review the more common causes and their associated complications.

1 Viral, Alcoholic, and Drug-Induced Liver Disease

1.1 Hepatitis A

Hepatitis A virus (HAV) is an RNA enterovirus that is a common worldwide disease affecting the liver, spread through fecal-oral contamination with occasional outbreaks through food sources. It can range in severity from a mild illness lasting a few weeks to a severe illness lasting several months; however, it is most commonly an acute, self-limited disease. Those at risk for worsening disease include the elderly as well those with chronic hepatitis B or hepatitis C with cirrhosis [1].

1.1.1 Clinical Presentation and Diagnosis

History should be targeted at collecting the chronology of symptomatology. The manifestations of HAV vary by age. While the manifestation in children is typically silent or subclinical, adults often present with signs and symptoms. With an average incubation period of about 30 days, HAV causes a prodrome of generalized fatigue, anorexia, nausea, vomiting, and fever which typically abate with the onset several days to a week later of jaundice with dark urine, acholic stools, and diffuse pruritis [2]. Clinical suspicion

DOI 10.1007/978-1-4939-0779-3_97-1

Table 1 Uncommon causes of chronic liver disease and cirrhosis

Disease	Description	Diagnostic testing
Autoimmune Hepatitis	Hepatic inflammation of unclear cause with hepatitis, hypergammaglobulinemia, and liver-associated autoantibodies; 2 subtypes of the disease; treatment usually with immunosuppression	Antinuclear antibody (ANA); anti-smooth muscle antibody
Alpha-1 antitripsin deficiency	Genetic disorder causing metabolic liver disorder in children; affects both hepatic and pulmonary systems	Alpha-1 antitripsin activity
Cystic Fibrosis	Autosomal recessive disorder most commonly affecting Caucasion population; cirrhosis with portal hypertension common	Sweat chloride testing
Hemochromatosis	Autosomal recessive disorder resulting in dysregulation of iron absorption and resulting in iron toxicity to liver and other tissues; "Bronze diabetes"	Transferrin saturation
Primary Biliary Cirrhosis	Female predominance; often asymptomatic; diagnosed with persistently elevated signs of cholestasis, normal biliary imaging and presence anti-mitochondrial antibody	Anti-mitochondrial antibody
Wilson's disease	Genetic disorder disrupting copper attachment to ceruloplasmin and resultant defective biliary secretion; Kayser-Fleischer rings on ophthalmologic exam; treatment with D-penicillamine	Ceruloplasmin

particularly for HAV infection is increased if there are specific risk factors by history including exposure to HAV in the household or close contact, exposure to raw vegetables or fruit or other uncooked or undercooked foods, exposure to drinking water that is not sanitized, or travel to areas endemic for HAV [3].

Despite clinical suspicion, the symptoms are indistinguishable from other forms of viral hepatitis and other possible liver or biliary conditions, and therefore, laboratory evaluation is necessary for diagnosis. Laboratory findings often demonstrate transaminitis followed by elevated total and direct bilirubin and elevated alkaline phosphatase levels. With any type of viral hepatitis, alanine transaminase (ALT) is typically higher than the aspartate transaminase (AST), and the range for both in HAV infection is typically between 500 and 5,000 U/L [4]. Diagnosis is confirmed with detection of serum immunoglobulin M (IgM) anti-HAV antibodies, which typically becomes positive within 5–10 days of infection, concurrently with onset of jaundice. This will remain positive for 4–6 months following acute infection and therefore can be used to determine whether illness which has resolved was related to HAV. Total anti-HAV (IgM and immunoglobulin G) or immunoglobulin G (IgG) levels are checked to confirm immunity or past exposure and will remain positive for a patient's lifetime.

1.1.2 Management

The treatment of HAV infection is solely supportive, and hospitalization is reserved for patients with significant dehydration requiring parenteral fluid resuscitation or those with complications. Patients should be advised not to return to school or work until fever and jaundice have subsided, and hepatotoxic agents such as alcohol or medications should be avoided during the acute illness. The best treatment strategy for HAV infection remains a preventive strategy with immunization.

1.1.3 Prevention

The prevention of HAV infection begins with the practice of sanitary practices such as hand washing, heating foods appropriately, and avoiding water and foods from endemic areas. Preexposure prophylaxis with vaccination is the most widely used prevention strategy with the recommendation that all children

DOI 10.1007/978-1-4939-0779-3_97-1

should receive the hepatitis A vaccine as part of routine childhood immunizations, beginning the series between 12 and 23 months of age which includes a two-vaccine series with one immunization and a repeat dose 6 months later. Additionally, those at increased risk including those traveling to endemic areas (available at http://www.cdc.gov/travel), men who have sex with men (MSM), users of injection drugs, people with chronic liver disease such as hepatitis B or hepatitis C, people treated with clotting-factor concentrates, parents adopting children from endemic areas, and those that work with HAV-infected animals or in HAV research labs should also receive vaccination [5, 6].

Postexposure prophylaxis is available if a health individual has been exposed to HAV within the past 2 weeks as prophylaxis efficacy beyond this time is not well known. The preferred prophylaxis by the Center for Disease Control (CDC) is a single dose of single-antigen vaccine for individuals between 12 months and 40 years of age, but immunoglobulin may also be used [5]. Indications for postexposure prophylaxis include previously unvaccinated household or sexual contacts with confirmed disease, unvaccinated staff and attendees of child care centers with one or more cases in the center or two or more household cases of attendees, and food handlers in facility with confirmed case; however, schools, hospitals, and work settings are not appropriate for prophylaxis with an episode of a single case [5, 7].

1.2 Hepatitis B

Hepatitis B virus (HBV) is an incompletely double-stranded DNA virus belonging to the family of hepadnaviruses that is spread through contact with blood, semen, or other bodily fluid of an individual infected with HBV. Dissimilar to HAV, HBV causes both an acute illness as well as a chronic disease state. Although anyone can become infected with HBV, those at greater risk include individuals with multiple sexual partners, individuals with other sexually transmitted infections, MSMs, individuals with IV drug use, those living with someone with chronic HBV, infants born to infected mothers, individuals exposed to blood through their work, patients on hemodialysis, and those traveling to countries with moderate to high rates of HBV infection.

1.2.1 Clinical Presentation and Diagnosis

The history and presenting symptoms may vary depending upon the current state of the disease process whether in its acute phase or chronic phase. Most cases of acute hepatitis B are asymptomatic, and those with symptoms are more likely to be adults or over the age of 5. The average incubation period of HBV is 75 days, longer than that of HAV, and then patients proceed to have a prodrome with symptoms similar to that of HAV with fever, malaise, anorexia, and nausea followed by jaundice, darkening of the urine, and right upper quadrant pain.

During acute infection, elevations occur in the transaminases, both ALT and AST, with a typically higher elevation in ALT compared to AST. The alkaline phosphatase and total and direct serum bilirubin levels may be normal in someone presenting with anicteric hepatitis. As these tests are nonspecific markers for HBV infection, specific HBV testing must be obtained. Hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) can be detected in the serum as well as high levels of IgM antibodies to the viral core antigen (IgM anti-HBc) during the acute phase [8]. An immune response targeted to clear the virus would clear the HBeAg and subsequently the HBsAg resulting in development of antibody to HBeAg and HBsAg with the appearance of antibodies to HBsAg indicating recovery from acute infection [8].

From acute infection, patients can go on to develop chronic hepatitis. Chronic HBV (CHB) infection is defined as presence of disease defined by HBsAg for at least 6 months [9]. The risk of development of CHB infection is lowest in adults (<5 %) and highest in neonates whose mothers are HBeAg positive (>90 %) [10]. Most patients with CHB are asymptomatic unless they develop complications from their CHB either intrinsic to the liver or extrahepatic manifestations. History may not reveal a prior history of

Table 2 Laboratory evaluation of phases of chronic HBV infection

	Immune tolerant	Immune reactant	Inactive HBY carrier	HBeAg-negative CHB	HBsAg negative
ALT	Normal	High	Normal	Normal or high	Normal
HBsAg	Positive	Positive	Positive	Positive	Negative
HBV DNA	High	High	Low or undetectable	High	Undetectable
HBeAg	Positive	Positive	Positive	Positive	Negative

Table 3 Evaluating the HBY panel

Test	Result	Interpretation
HBsAg	Negative	Susceptible (no immunity)
Anti-HBc	Negative	
Anti-HBs	Negative	
HBsAg	Negative	Immune (due to infection)
Anti-HBc	Positive	
Anti-HBs	Positive	
HBsAg	Negative	Immune (due to vaccination)
Anti-HBc	Negative	
Anti-HBs	Positive	
HBsAg	Positive	Acute infection
Anti-HBc	Positive	
IgM anti-HBc	Positive	
Anti-HBs	Negative	
HBsAg	Positive	Chronic infection
Anti-HBc	Positive	
IgM anti-HBc	Negative	
Anti-HBs	Negative	
HBsAg	Negative	Four possible
Anti-HBc	Positive	Interpretations[a]
Anti-HBs	Negative	

Source: Immunization Action Coalition publication "Needle Tips," Available at www.immunize.org

[a]Possible Interpretations

1. May be recovering from acute HBV infection
2. May be distantly immune and test is not sensitive enough to detect low level anti-HBs
3. May be susceptible with false-positive anti-HBc
4. May be chronically infected and have an undetectable level of HBsAg

acute hepatitis given that acute episodes are often characterized by nonspecific symptoms and can be asymptomatic. Nonspecific symptoms of CHB may include fatigue or develop subacute symptoms of hepatitis. Physical examination should be directed at evaluating for stigmata of chronic liver disease (CLD) such as jaundice, splenomegaly, ascites, peripheral edema, encephalopathy, or signs of portal hypertension.

Current thinking endorses that there are phases of CHB infection including an immune tolerant phase, immune reactant phase, inactive HBV carrier state, HBeAg-negative CHB, and HBsAg-negative phase [8, 11]. Laboratory findings associated with CHB infection is dependent upon the status of the chronic infection (see Table 2). Not all patients experience every phase, and the duration of phases can be variable; moreover, reversion or reactivation can occur between different phases without warning [12]. Family physicians must be comfortable interpreting HBV serologies (see Table 3) to determine the status of the

DOI 10.1007/978-1-4939-0779-3_97-1

disease not necessarily for the particular phase in the CHB disease process but more so for overall management and prevention of complications and spread of disease.

1.2.2 Management

The role of the family physician largely in the management of HBV, both acute and chronic, is correct identification and diagnosis of the disease as well as its status and severity. There is no specific treatment for acute HBV infection; however, with identification of CHB infection, family physicians must complete a thorough evaluation on patients with special emphasis on risk factors for complications (coinfection with hepatitis C virus or HIV, alcohol use, and family history of HBV infection and liver malignancy). Laboratory evaluation on the status of CHB infection including assessment of liver disease, markers for HBV replication (HBeAg, anti-HBe, HBV DNA), and tests for coinfection should be performed. While screening for hepatocellular carcinoma with alpha-fetoprotein levels and ultrasounds are recommended as part of the pretreatment and management algorithms, screening remains largely controversial, and evidence is not present for overall effects that such screening improves overall survival. A liver biopsy is often necessary to determine the extent and severity of disease in the process of deciding upon treatment. Individuals should also be vaccinated for hepatitis A.

The role of treatment is prevention of complications from CHB infection including cirrhosis, hepatic failure, and hepatocellular carcinoma. Current treatments include conventional interferon alpha, pegylated interferon alpha, and nucleoside/nucleotide analogues (NUCs), most notably lamivudine. Treatment regimens with specifications on criteria, drug regimen, and laboratory monitoring have been developed, most notably by the American Association for the Study of Liver Diseases (AASLD) [9] and the European Association for the Study of the Liver (EASL) [11].

1.2.3 Prevention

Vaccination remains a significant mechanism of prevention of HBV infection. Its enormous impact was demonstrated with reduction of the incidence in acute HBV infection in the USA from 300,000 cases annually to 79,000 cases annually from the late 1980s to 2001 [13]. Vaccination is recommended for all children and adolescents, adults in certain ethnic groups, health care workers, and high-risk groups [14].

Routine screening for HBV infection is recommended for all pregnant women, which should be done through HBsAg at the first pregnancy visit. Screening is beneficial due to the significant benefit of postexposure prophylaxis in reducing the mother-to-child vertical transmission of HBV [15] accomplished through administration of HBV immune globulin and HBV vaccine to the infant within 12 h of birth. HBV is not an indication for a cesarian section as no current evidence suggests it to reduce transmission, and it is important to note that CHB infection is not a contraindication to breastfeeding.

Other screening can be performed on individuals at risk for HBV; however, routine universal screening is not recommended. Preventive strategies that also target these at-risk individuals that are part of a comprehensive public health strategy at risk reduction include screening of blood and blood products, needle exchange programs, and routine condom use. Postexposure prophylaxis is also available for health care workers and others exposed to bodily fluids from an individual with known or confirmed HBV infection.

1.3 Hepatitis C

Hepatitis C virus (HCV) is a single-stranded RNA virus transmitted through percutaneous exposure to infected blood and blood products as well as through sexual transmission; however, sexual transmission is less common. It can lead to both acute as well as chronic infections. HCV is likely responsible for the majority of hepatitis caused by what was formerly known as “non-A, non-B hepatitis.”[16]. Risk factors for HCV infection include IVDA; HIV; recipients of blood transfusion, blood products, or organs before

DOI 10.1007/978-1-4939-0779-3_97-1

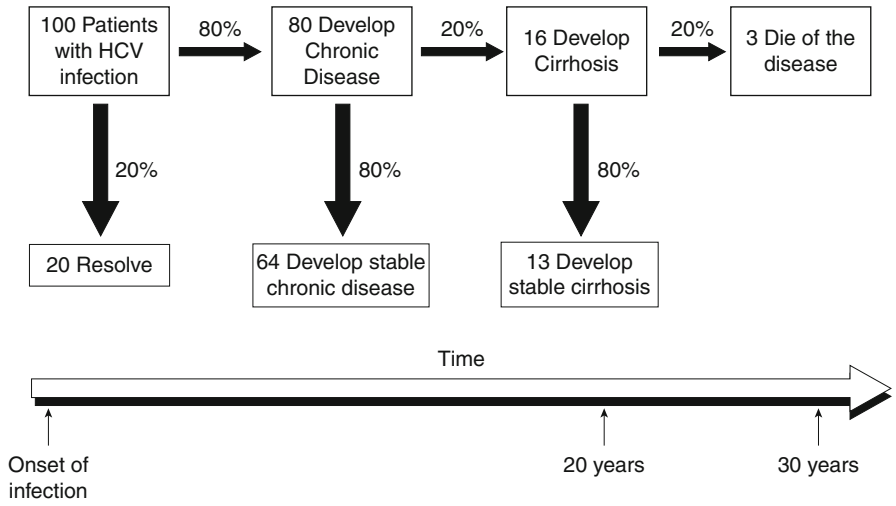

Fig. 1 The natural history of HCV infection is said to follow the "80/20 rule." While this is representative of population data, the percentages are approximate and vary based on several cofactors

1992; hemodialysis; sexual contact with those with HCV infection; piercings and tattoos; maternal-to-child transmission at birth; and sharing common household products such as razors or toothbrushes with someone infected with HBV.

1.3.1 Clinical Presentation and Diagnosis

In comparison to HBV and HAV infections, the acute phase of HCV hepatitis is much less likely to be symptomatic; if symptoms do develop, they are similar to the prodrome associated with HAV and HBV with nonspecific symptoms such as fatigue, nausea, anorexia, myalgias, arthralgias, weakness, and weight loss. Due to the largely asymptomatic presentation, it is unusual to perform diagnostic and laboratory evaluation unless an individual has a confirmed acute exposure. In this situation, a hepatitis viral load PCR test should be ordered to assess for possible transmission as antibody development is delayed.

HCV acute infection is much more likely than that of HBV infection to progress to a chronic infection. The definition of chronic HCV infection is the presence of virus for at least 6 months. Despite variations in data and studies, on average approximately 80 % of individuals with acute HCV infection will progress to chronic infection, [17, 18] with 20 % of those patients going on to develop cirrhosis (see Fig. 1) [18]. Therefore, it is clear that much more so than HBV, the chronic disease burden of liver disease secondary to HCV is significant. Symptoms of chronic HCV infection tend to be infrequent and again are nonspecific and typically mild, similar to that of acute infection. With acute infection being frequently asymptomatic, targeted history at risk factors is important in deciding to perform further clinical evaluation. Physical examination, similar to that of HBV, should be directed at evaluating for underlying signs of chronic liver disease or extrahepatic involvement with signs of cirrhosis and portal hypertension.

Laboratory evaluation with transaminases is not typically reliable to assist in the diagnosis of chronic HCV infection. The transaminases are typically normal and are only above 2 times that of normal in about 25 % of patients and are rarely 10 times that of normal [19] and cannot be correlated with liver pathology. Formal diagnosis requires evaluation of the presence of antibody (HCAb) to HCV in the blood. Formerly, the initial test was an enzyme-linked immunoassay (ELISA) with the need for a recombinant immunoblot assay (RIBA) test performed for confirmation; however, newer third-generation ELISA testing enables a single antibody test with confirmation through further testing with a molecular assay that detect and/or quantify HCV RNA. The presence of HCV RNA for 6 months confirms chronic infection while a positive HCAb and negative HCV RNA suggests previous exposure to HCV with spontaneous clearance.

DOI 10.1007/978-1-4939-0779-3_97-1

1.3.2 Management

Similar to HBV infection, the role of the family physician in the management of HCV is correct identification and diagnosis of chronic HCV infection. Once diagnosed, patients should also be screened for HIV, as well as adequate immunity to HAV and HBV should be determined and provided if no immunity is apparent. In addition to making the diagnosis, the family physician should identify patients who qualify for treatment which includes assessment of fibrosis as the HCV viral load is not a sign of disease severity and fibrosis remains the most reliable prognostic factor to predict progression, morbidity, and mortality [20]. A number of methods are available to determine the degree of fibrosis with liver biopsy previously serving as the diagnostic standard; however, there remain significant concerns about performing a liver biopsy on an individual with normal transaminases, and inadequate sampling can limit test performance [21]. The most appropriate approach is to combine vibration-controlled transient liver elastography with direct serum biomarkers [22]. Biopsy is reserved when these two measures are discordant in their assessment of cirrhosis or inflammatory damage.

The goal for HCV treatment is virological cure or sustained virological response (SVR), defined as the absence of detectable HCV RNA for at least 12 weeks. However, due to exposure, HCAb will remain positive for the patient's lifetime. SVR results in reduction of symptoms as well as both intrahepatic and extrahepatic complications of chronic HCV infection. While immediate therapy is reserved for patients with advanced fibrosis, compensated cirrhosis, liver transplant recipients, or severe extrahepatic complications, therapy should be considered earlier in the course given that SVR has significant benefits at reducing the overall complications. Treatments are determined based on the genotype and subtype of HCV infection as they have varying responses to different therapies. Genotype 1 is the most common form of chronic HCV seen in the USA and with previous drug therapies was known to be the most resistant to treatment.

The American Association for the Study of Liver Diseases (AASLD) and the Infectious Disease Society of America (IDSA) developed a guideline for the recommended treatments of chronic HCV infection directed at each individual genotype and subtype (found at http://www.hcvguidelines.org) [23]. It is important to note, however, that significant recent advancements have occurred in the development of regimens for the treatment of HCV infection that are now being utilized as first-line therapies. Whereas most patients formerly received a regimen including interferon and ribavirin, recent years have brought newer antivirals to the scene including boceprevir (Victrelis) and telaprevir (Incivek) that reduced the use of interferon, yet side effects remained significant. Advancements and drug approvals in 2014 led to even newer therapies, potentially removing the need for ribavirin use as well, including sofosbuvir (Sovaldi) and simepravir (Olysio), sofosbuvir/ledipasvir (Harvoni), and partiaprevir/ombitasvir/dasabuvir (Viekira Pak). The AASLD and IDSA guideline is viewed as a living document during this time of significant advancements in the field of HCV treatment and also provides information on monitoring both prior to and after treatment [23].

1.3.3 Prevention

It is in large part due to the number of genotypes and subtypes of HCV that vaccine development against HCV has been difficult. Primary prevention should be targeted at reducing risk factors for transmission. Such strategies include screening of blood and blood products, needle exchange programs, and routine condom use. Education on these topics should not be reserved solely for those in contact with those infected with HCV but for all to ensure an appropriate public health strategy. Based on risk factors, individuals should be appropriately screened for HCV infection with an HCAb. This is recommended by the USPSTF as well as an additional recommendation that one-time screening be offered to all adults born between 1945 and 1965 due to high prevalence in this population [24].

DOI 10.1007/978-1-4939-0779-3_97-1

Despite maternal-to-child transmission being the largest cause of HCV infection in children, routine testing of all pregnant women is not recommended. Additionally, inconclusive evidence remains on whether specific labor management strategies are effective at reducing transmission. Most practice involves limiting internal fetal monitoring, rupture of membranes, and instrumented deliveries. It is important to note that HCV infection is not a contraindication to breastfeeding. Newborns of mothers infected with HCV should be tested for HCV transmission; however, this is complicated by passage of maternal HCAb through the placenta. While diagnosis can be made earlier with two positive HCV RNA between 2 and 6 months of age in an infant, [25], the American Academy of Pediatrics (AAP) recommends testing with an HCAb at 18 months or later since HCV treatment is not recommended for infants less than 3 months [26].

1.4 Other Viral Agents

Hepatitis D and E are far less common viral hepatitides that have been demonstrated to cause infection. Hepatitis D virus, previously known as delta hepatitis, is an incomplete virus which is structurally an RNA virus that requires helper function of HBV to replicate and cause both an acute and chronic hepatitis. It is transmitted similarly to HBV and either occurs as coinfection or superinfection in an individual with chronic HBV. Hepatitis E virus is rare in the United States. It is similar to HAV such that it is transmitted via the fecal-oral route and only causes a self-limited acute infection. There are no vaccines or treatments currently available for hepatitis D or E viruses; however, hepatitis D can be prevented in an individual without HBV infection through the HBV vaccine.

1.5 Alcoholic Hepatitis

Alcoholic liver disease (ALD) is a serious health problem worldwide that encompasses several disease processes including alcoholic fatty liver disease (with or without steatohepatitis), alcoholic hepatitis, and cirrhosis. Excessive alcohol consumption can result in both short-term and long-term liver damage. Regular alcohol use, even for several days, results in fat deposition in the liver hepatocytes or steatosis (fatty liver). While abstinence reverses the process, steatosis places individuals who continue to drink at increased risk of progression to fibrosis and cirrhosis. Cirrhosis only develops, however, in a small number of patients with ALD [27]. While the mean intake of regular alcohol to result in liver disease is approximated to be around 100 g/day for more than 20 years, [28], lesser amounts can potentially result in ALD as regular consumption of 30 g/day increases the risk for development of cirrhosis [27].

1.5.1 Clinical Presentation and Diagnosis

Given that excessive, regular alcohol consumption is necessary, most patients with ALD are often between 40 and 50 years old [29]. Careful history should be obtained from patients as they often will cease drinking with onset of symptoms due to disease severity. Excessive, regular alcohol consumption may not represent daily drinking as patterns of drinking can vary to include weekends or intermittent heavy drinking behaviors that family members are unaware. While long-term drinking (more than 20 years) is typically the overall course, individuals can present with ALD who have been drinking for shorter duration.

The individual will usually present with similar symptoms to that of viral hepatitis including fatigue, anorexia, jaundice, fever, right upper quadrant or epigastric pain, abdominal fullness, or bloating. Physical examination can demonstrate jaundice, icteric sclera, hepatomegaly, as well as possible findings of more chronic liver disease with cirrhosis including muscle wasting, ascites, or sequelae of portal hypertension. A bruit may be heard over the liver, a feature of more severe alcoholic hepatitis, has been demonstrated in over 50 % with ALD [30]. While history can suggest that alcohol is the etiology for

DOI 10.1007/978-1-4939-0779-3_97-1

Table 4 Common potential hepatotoxic medication agents

Over the counter (OTC) agents	Acetaminophen (Tylenol)
	NSAIDs (ibuprofen, naproxen, etc)
Anti-arrhythmics	Amiodarone
	Diltiazem
Antibiotics	Isoniazid
	Nitrofurantoin
	Amoxicillin/clavulonic acid
	Rifampin
	Tetracycline (minocycline, tetracycline)
Antiepileptics	Phenytoin
	Carbamazepine
	Valproic acid
Antifungals	Azoles (ketonazole, fluconazole)
	Amphoteracin
	Terbinafine (systemic)
Anti-hyperglycemics	Sulfonylureas (glipizide, glyburide)
	Thiazolidinediones (pioglitazone)
Anti-hyperlipidemics	Statins (rosuvastatin, simvastatin, etc)
	Nicotinic acid (niacin)
	Fibrates (gemfibrozole, fenofibrate)
Endocrinologic agents	Methimazole
Hormonal agents	Anabolic steroids
	Estrogen & Oral contraceptives
	Testosterone
Rheumatolic agents	Methotrexate
	Quinadine
Psychiatric agents	Atypical antipsychotics (quetiapine, etc)
	Nefazodone
	Trazodone
	Venlafaxine

symptoms, one cannot completely rule out other causes of liver injury, and therefore, history and laboratory evaluation is needed to rule out other etiologies.

Laboratory findings associated with alcoholic hepatitis include transaminitis with AST-to-ALT ratio of 2:1 (levels are typically less than 300 IU/L and rarely higher than 500 IU/L), elevated serum bilirubin, elevated gamma-glutamyltransferase (GGT), and a leukocytosis with neutrophil predominance. Other laboratory findings can suggest severity of disease such as moderate to severe disease that would result in an elevated international normalized ratio (INR), anemia secondary to thiamine or folate deficiencies, low albumin and prealbumin in the setting of malnutrition, and thrombocytopenia from bone marrow suppression from alcohol or related to portal hypertension. Abdominal imaging (ultrasound, computed tomography, or magnetic resonance imaging) can also be utilized to assess for degree of steatosis, ascites, and cirrhosis. Liver biopsy is often helpful in assessing the severity of hepatocellular damage; however, it is not required for diagnosis.

DOI 10.1007/978-1-4939-0779-3_97-1

1.5.2 Management

The overall management of alcoholic hepatitis for the family physician is targeted at patient education and safe cessation of alcohol. The potential complications due to alcohol use as well as a result of the alcoholic hepatitis such as ascites, hepatic encephalopathy, malnutrition, and alcohol withdrawal with or without delirium tremens should be treated as supportive care. Lifetime cessation of alcohol is critical to prevent the progression of disease, and patients should be supported through the process.

While a number of therapies and treatments have been studied or suggested in the use of treatment of alcoholic hepatitis including psychotherapy, corticosteroids, pentoxifylline, infliximab, etanercept, nutritional support, oxandrolone, vitamin E, and silymarin (milk thistle extract), only corticosteroids and pentoxifylline have been shown to demonstrate improvements on mortality in specific populations with disease [31]. Despite evidence suggesting these treatments have efficacy, their use remains controversial. Liver transplantation may be necessary in severe cases; however, due to alcohol use being the etiology of their underlying disease process, patients often need to demonstrate sobriety for 6 months prior to consideration, and patients who might qualify for liver transplant may suffer significant complications during this time period.

1.5.3 Prevention

As ALD results from prolonged excessive alcohol intake, there is certainly a window of time for both screening and intervention to occur to combat alcohol misuse. Family physicians play a critical role in screening individuals for alcohol use and misuse. The United States Preventive Services Task Force (USPSTF) recommends that "clinicians screen adults aged 18 or older for alcohol misuse and provide persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce alcohol misuse"[32].

1.6 Drug-Induced Liver Disease

Due to its role in clearing and metabolizing chemicals, the liver is a particular target for damage from drugs. The cellular damage that occurs as part of drug-induced liver disease is typically a result of the drug or metabolite having a direct toxic effect on the liver or an immune-mediated response that causes liver injury. While liver damage from drugs and medications is common except in rare cases of drug-induced hepatitis, the majority of damage is reversible with cessation of the substance with a return to normal function [33]. One of the most frequent causes of hepatic injury due to a drug is from acetaminophen, which can be either acute or chronic use. It has been shown that over 1,000 drugs have caused liver disease on more than one occasion, [34] and therefore a comprehensive list is not easily developed. Table 4 lists some of the more common drugs that can induce liver damage.

1.7 HIV Liver Disease

Despite advancements in treatment that has made HIV infection a chronic illness, it remains a major global health issue. While HIV does not result in a direct injury or primary disease process in the liver, data demonstrates the burden of liver disease in patients with HIV is large, with liver disease being second only to AIDS-related complications in causing mortality [35]. Due to similarities in transmission routes, patients with HIV may also be coinfected with HBV and/or HCV. In fact, of liver-related deaths in patients with HIV, 66 % were secondary to complications of HCV and 17 % secondary to complications of HBV [35]. This is largely secondary to fibrosis and complication rates in patients coinfected with HIV and either HBV or HCV being much higher [36]. Patients with HIV are also at risk of developing opportunistic infections that may also cause liver damage including mycobacterium tuberculosis (Tb), mycobacterium avium complex (MAC), and cytomegalovirus (CMV).

Entry inhibitors			Nelfinavir (NFV)
	Maraviroc (MVC)		
	Enfuvirtide (INN;T20)	**Enhancer**	
			Cobicistat (COBI)

In addition to infectious etiologies, increasing recognition of highly active antiretroviral therapy (HAART) as a source of liver damage is also occurring. Monitoring transaminases is recommended for newly diagnosed and newly treated patients as HIV infection with high viremia alone may result in transaminase elevation with reduction as HAART is initiated [37]. Additionally, many patients with HIV whose liver enzymes are elevated are asymptomatic during this time [38]. Due to combination therapies, it can be difficult to determine the culprit drug resulting in liver damage. Table 5 lists drugs from HAART regimens with documented liver toxicity [39].

Patients with HIV should also be appropriately screened for other potential etiologies of liver disease including alcohol-induced disease, drug-induced liver disease, and nonalcoholic fatty liver disease (NAFLD). NAFLD is the hepatic manifestation of metabolic syndrome, [40] and is noted to have significantly higher rates in those infected with HIV compared to the general population [41].

1.8 Hepatocellular Carcinoma

Despite most malignancy involving the liver being due to metastatic disease commonly from colorectal cancer, hepatocellular carcinoma (HCC) remains a significant cause of morbidity and mortality worldwide. Most of the disease burden remains in developing countries where HBV infection is endemic; [42] however, HCC secondary to HCV infection is a significant cause of cancer-related death in the USA, with the incidence tripling and the 5 year survival rate remaining below 12 % [43]. While significant risk factors are largely infection with HBV or HCV, other diseases affecting the liver are also potential risk factors. HCC is rarely seen in individuals younger than 40 years of age, and peak incidence occurs around age 70 with a predilection for males as the rates are two to four times higher in males than females [44].

1.8.1 Clinical Presentation and Diagnosis

Almost all patients with HCC have underlying cirrhosis, and therefore presentation of HCC is almost indistinguishable other than typical signs of cirrhosis including fatigue, upper abdominal pain, weight loss, early satiety, encephalopathy, and potentially jaundice. HCC can be suspected in a patient who

DOI 10.1007/978-1-4939-0779-3_97-1

develops acute decompensated cirrhosis who has previously been stable. Solid liver lesions are often noted with screening in patients at risk for HCC through ultrasound screening, which according to the AASLD should be performed in high-risk patients every 6 months [45]. As previously noted, it is increasingly recognized that alpha-fetoprotein lacks adequate sensitivity and specificity to be utilized as a screening or diagnostic aid [46]. Ultrasound findings are monitored based on their size with testing and diagnosis becoming increasingly possible with the use of noninvasive imaging techniques. Biopsy, although reassuring, cannot completely rule out the presence of HCC, and lesions, despite normal biopsy, need to be followed until disappearance or progression to malignant disease [47].

1.8.2 Management

Based on the staging at diagnosis (Barcelona Clinic Liver Cancer (BCLC) staging system), [48] there are several potentially curative or palliative approaches to treatment [49] including resection, radiofrequency ablation, chemoembolization, medication therapy, and liver transplantation. While family physicians should be aware of the potential treatment options for HCC and remain supportive in the care, treatment of HCC is typically performed in conjunction with hepatologist or gastroenterologist management.

1.8.3 Prevention

Prevention of HCC is targeted at modification of the underlying risk factors for HCC. HBV vaccination remains an effective prevention strategy for avoiding HBV viral infection and resultant cirrhosis. Primary prevention seems to be the most effective strategy at prevention. While treatment of HBV infection and HCV infection does reduce the risk of development of HCC, it does not completely eliminate this risk.

2 Family Issues of Diseases of the Liver

The family physician is challenged with being on the front lines of prevention, patient education, risk factor assessment, diagnosis, management, and monitoring of patients and families afflicted with liver diseases. Indeed, as many common medications can cause liver damage, family physicians must be aware of the pharmacological properties of the medications they are prescribing and use caution in patients to avoid drug-drug interactions as well as use safe medications in patients with liver disease. Additionally, as family physicians care for patients across the age spectrum, diagnosis of viral hepatitides as well as appropriate testing and treatment targeting at reducing maternal-to-child transmission is important information for the practicing family physician. While the family physician has a duty to respect the privacy of his patient with regard to possible diagnosis of HBV and HCV chronic infections, he also cares for their family members and has the unique role to protect privacy but also protect his patients from transmission. Furthermore, as alcohol-related disorders cause not only physical damage but also rifts in relationships and connections with family and friends, the family physician has a critical role in coordinating care as well as a comprehensive addiction treatment program including patient and family. Poised with an effective role in public health, family physicians ensure appropriate education and counseling occurs for patients and family members on risk reduction as well as discussion of typical course and prognosis for chronic liver diseases. While the complications of chronic liver disease are often managed by a multidisciplinary team, the intrinsic value of the family physician in this process due to the above cannot be understated.

DOI 10.1007/978-1-4939-0779-3_97-1

3 Conclusion

Diseases of the liver represent a variety of conditions that vary in chronicity, complications, and management strategies. With viral hepatitides, alcoholic liver disease, and drug-induced liver disease being some of the most common forms of both acute and chronic liver disease, the family physician plays a critical role in the diagnosis and management. Due to the significant family issues associated with liver disease and the family physician's role in diagnosis and management, it is critical that the practicing family physician have an awareness of the diagnosis, management, and prevention strategies and approach them with an evidence-based perspective.

Diseases of the Rectum and Anus

Kalyanakrishnan Ramakrishnan*
Department of Family and Preventive Medicine, University of Oklahoma Health Sciences Center, OK, Oklahoma, USA

Anatomy of the Rectum and Anal Canal

The rectum extends from the rectosigmoid to the anorectal junction (about 15 cm); the anal canal measures about 5 cm, extending from the lower border of the anal crypts at the dentate line to the anal verge [1]. The rectum and the anal canal above the undulating dentate line are lined by columnar epithelium and below by stratified squamous epithelium that transitions to the skin at the anal verge [1]. Innervation above the dentate line is sympathetic (L-1 to L-3) and insensate; below is somatic (pudendal nerves, S2–S4) [1]. The vascular supply of the anorectal region is through the superior, middle, and inferior hemorrhoidal vessels.

Hemorrhoids followed by anal fissures, anorectal abscesses and fistulas, fecal incontinence, rectal prolapse, pruritus ani, proctitis, hidradenitis suppurativa, condyloma acuminatum, and anorectal cancer are common problems pertaining to the anorectal region.

Hemorrhoids

Background

Hemorrhoids represent the enlarged normally found fibrovascular cushions (hemorrhoidal cushions) lining the anal canal [2]. Hemorrhoidal cushions help exercise bowel control by sustaining a resting pressure; vascular engorgement associated with increasing intra-abdominal pressure (as in laughing, coughing, sneezing) closes the anal canal, helping maintain continence. The nerve feedback from the hemorrhoidal cushions helps differentiate between flatus, liquid, and solid stool [3]. Aging and repeated straining associated with constipation cause degeneration and weakening of the securing fibrous tissue, detachment of the cushions from the internal sphincter, and prolapse. The overlying mucosa also becomes loose, bulges into the anal canal, and becomes thin and friable due to continued trauma by feces and ulcerates, sometimes causing bright red rectal bleeding.

Epidemiology

Hemorrhoids are most common in both sexes between 45 and 65 years of age with hemorrhoid-related symptoms being experienced by nearly one in two Americans over 50 [4]. Predisposing factors include older age, irregular bowel habits, decreased fiber intake, obesity, pregnancy, ascites, positive family history, and absent valves within the hemorrhoidal veins. Hepatic cirrhosis, portal hypertension, and portal vein thrombosis also predispose to hemorrhoids.

Classification

Hemorrhoids may be located above (internal) or below the dentate line (external) or both above and below (intero-external) [5]. Based on symptoms of bleeding and prolapse, hemorrhoids are classified as grade 1 or first degree (bleeding without mucosal prolapse), grade 2 or second degree (bleeding and mucosal

*Email: kramakrishnan@ouhsc.edu

DOI 10.1007/978-1-4939-0779-3_98-2

prolapse reducing spontaneously), grade 3 or third degree (bleeding and mucosal prolapse, requiring manual reduction), and grade 4 or fourth degree, representing persistent prolapsed hemorrhoids with or without complications (strangulation, ulceration, fibrosis, gangrene, sepsis) [5, 6].

Diagnosis

History

Patients with hemorrhoids experience painless bright red bleeding during or after stooling. Constipation and straining may be present. With second degree or more advanced hemorrhoids mucus discharge, a sense of incomplete defecation, pruritus ani, and a perianal rash are noticed. Thrombosis or ulceration leads to perianal pain and swelling, bleeding, and a bloodstained discharge [7]. Blood from more proximal sources (polyps, diverticula, angiodysplasia, ischemic colitis) is usually darker or clotted blood mixed with stool. Fever, throbbing pain, redness, swelling, and inability to sit indicate perianal sepsis. Abdominal discomfort and distention, anorexia, weight loss, and worsening constipation or persisting diarrhea should suggest cancer, ischemic colitis, or inflammatory bowel disease (IBD).

Examination, Special Testing

Physical examination usually yields little information in healthy patients. Features of anemia should suggest a different pathology. Jaundice, hepatosplenomegaly, and enlarged abdominal wall collaterals characterize hepatic cirrhosis and portal hypertension. A palpable abdominal mass suggests possible colon cancer and, if tender, a peridiverticular mass. Perianal inspection, digital rectal examination (DRE), and anoscopy in the left lateral (Sims') or the knee chest position complete the initial patient assessment. Perianal inspection may reveal skin tags, prolapsed and thrombosed hemorrhoids, anal fissure or abscess, perianal excoriation, fistula, cancer, or condyloma. Patient bearing down during DRE or anoscopy relaxes the sphincter and also causes second- and third-degree hemorrhoids to prolapse. Uncomplicated hemorrhoids are impalpable and non-tender; thrombosed or fibrosed hemorrhoids are palpable; and prolapsed and strangulated hemorrhoids are tender. Insertion of a side-viewing anoscope causes hemorrhoids to bulge into the lumen. When examining a patient in the Sims' position, the anal cushions (internal hemorrhoids) are usually located at the 11 o'clock (left anterior), 3 o'clock (right lateral), and 7 o'clock (left posterior) positions. Prolapsed hemorrhoids should be reduced to minimize risk of strangulation and ulceration. Patients over 50 years with rectal bleeding should undergo a colonoscopy, even though hemorrhoids are detected [8].

Treatment: Nonoperative

Adequate fluid and fiber intake (20–35 G daily) is the primary first-line nonoperative therapy for patients with symptomatic hemorrhoids of all grades [5]. Multiple symptoms associated with hemorrhoids (bleeding, prolapse, and pain) improve on increasing fiber intake. Sitz baths (a warm water bath in which the patient squats or sits), analgesics, and anti-inflammatory medications relieve pain and decrease tissue edema and sphincter spasm in patients with thrombosed hemorrhoids and after hemorrhoidectomy [9]. Oral flavonoids and topical preparations such as Preparation H, glyceryl trinitrate 0.2 % ointment applied three times daily for 14 days, and nifedipine 0.3 % with lidocaine 1.5 % ointment applied twice daily for 14 days also decrease symptoms associated with hemorrhoids and its complications [10, 11]. Exercising and losing excess weight are also beneficial.

Office Procedures

The rubber-band ligation (RBL) technique is useful in treating grades I through III internal hemorrhoids. A small rubber band is loaded onto a hollow applicator, the hemorrhoid is grasped 1 cm or more above the dentate line and pulled inside the applicator, and the rubber band is released at the base of the hemorrhoid,

DOI 10.1007/978-1-4939-0779-3_98-2

which sloughs off over 5–7 days. Moderate pain can follow RBL. One or more hemorrhoids can be banded at the same or subsequent office visits [5]. RBL is successful in most (85 %) patients, though over one-third may require repeat banding [12]. Suction ligation, in which an anoscope/ligator is attached to the wall suction (vacuum suction ligation), is associated with less bleeding and post-procedure pain. Complications following RBL are rare (<1 %) and include band placement at or near the dentate line (requires removal and replication), urinary retention, rectal bleeding (post-procedure or 7–10 days later, usually self-limiting), extrusion of the band, pain, ulceration, thrombosis, and perineal infection [3].

Sclerotherapy involves injection of an irritant (5 ml sodium morrhuate, 5 % phenol in oil or hypertonic saline) through the anoscope into the submucosa at the apex of the hemorrhoid, causing ischemia and fibrosis, fixing the hemorrhoid to the rectal wall, decreasing bleeding and prolapse. Though effective in grades I, II, and III hemorrhoids, the majority of patients over time experience recurrence [13]. Complications include mucosal sloughing, thrombosis, abscess formation, and bacteremia.

Infrared photocoagulation (direct application of infrared waves) produces superficial tissue destruction, reducing blood flow and tethering the hemorrhoid to the underlying tissues. It is most useful in grades I and II hemorrhoids [5].

In-Hospital Surgery

Hemorrhoidectomy is indicated in patients with intero-external hemorrhoids and grades III and IV hemorrhoids, in patients recurring after office procedures, or in patients intolerant of office procedures [5]. The procedure, performed under general or regional anesthesia, requires distal bowel preparation to minimize soiling during and after surgery. Preoperative antibiotic administration is unnecessary. In open hemorrhoidectomy, the hemorrhoid is excised after ligating the pedicle, and the raw area is allowed to granulate. In closed hemorrhoidectomy, the raw area is closed primarily. The LigaSure procedure involves sealing of the hemorrhoidal tissue between the LigaSure forceps during dissection, minimizing tissue destruction, blood loss, and post-procedure pain [14]. Bleeding, urinary retention, wound infection, fecal incontinence, and anal stricture may follow surgery (all uncommon). In the "stapled hemorrhoidopexy," (hemorrhoidectomy) a ring of anal mucosa with the underlying fibrovascular cushions is removed using a modified, circular anastomotic stapler. Though bleeding, wound complications, constipation, and pruritus are decreased, and recurrence rates are similar to conventional hemorrhoidectomy [15]. The Doppler-guided transanal hemorrhoidal ligation involves suture ligation of the hemorrhoidal vessels after localizing them with Doppler ultrasound. This procedure, also applicable to grades III and IV hemorrhoids, allows most patients to be discharged at 24 h and return to work in 2–3 days. Long-term recurrence is under 10 %, though higher for grade IV hemorrhoids [16].

External Hemorrhoids

Most patients with thrombosed external hemorrhoids (perianal hematoma) improve with sitz baths twice daily, stool softeners, and analgesics. Patients presenting within 72 h of onset of symptoms benefit from evacuation of the clot [5]. This is usually performed under local anesthesia using lidocaine (1–2 %). Following clot clearance, bleeding from the base and edges is managed with sutures, packing, or electrocautery, and analgesics, stool softeners, and sitz baths are continued until healing is complete. Perianal skin tags may cause irritation or interfere with hygiene but rarely require excision.

Prolapsed and strangulated hemorrhoids are best managed with stool softeners, analgesics, rest, warm soaks, and ice packs to decrease pain and swelling, minimizing constipation and tissue ischemia. Swelling and pain resolve over several days; the residual hemorrhoid may then be managed by RBL or

DOI 10.1007/978-1-4939-0779-3_98-2

hemorrhoidectomy. Immediate excision leads to excess tissue removal, anal canal narrowing, and infection. Spreading perianal infection and tissue necrosis occasionally occur, requiring immediate debridement and broad-spectrum antibiotics [3].

Nonhemorrhoidal Anorectal Diseases

Anal Fissure

Epidemiology and Classification

Anal fissures are painful linear cracks in the anal mucosa distal to the dentate line. They may be acute (<8 weeks) or chronic (symptoms persisting >8–12 weeks) [17]. Anal fissures are more common in younger adults and have an equal sex distribution. The majority (over 90 % in men; 75 % in women) are posterior; anterior fissures have a female preponderance. Lateral or multiple fissures may follow trauma, infections (syphilis, tuberculosis, anorectal abscesses, herpes, or human immunodeficiency virus – HIV – infection), cancer, and IBD [18]. Low fiber intake, chronic diarrhea or constipation, excessive laxative use, and anal trauma (including surgery) also predispose to anal fissures [18]. Fiber increases stool volume and bulk minimizing anorectal trauma during defecation. Anal surgery predisposes to tissue ischemia through fibrosis, increasing the risk of nonhealing fissures.

Diagnosis

Diagnosis is clinical. Severe pain initiated by and persisting after defecation is characteristic of acute fissures [17]. Bright red blood is often seen in the toilet paper, stool, or toilet bowl. Constipation (due to painful evacuation and unwillingness to defecate), perianal discharge, pruritus, and a perianal mass may also be present.

Acute fissures usually appear as midline tears, with a skin tag extending distally from the base of the tear (the "sentinel pile"). There is significant perianal spasm; DRE or anoscopy is painful. Chronic fissures are less painful and tender and evidence more scarring and raised edges, the floor exposing the white horizontal fibers of the internal sphincter.

Perianal tenderness and induration or lateral, multiple, or recurrent fissures should prompt a search for a more definitive cause. Dark-field microscopy of perianal discharge may demonstrate spirochetes. Serum antibody testing may detect treponemal or HIV antibodies. Imaging studies (endoanal ultrasound, computed tomography (CT), magnetic resonance imaging (MRI)) are useful in revealing the extent of anal involvement and perianal/extra-anal extension of infection or malignancy. Endoscopy is valuable in detecting proximal bowel pathology (IBD, malignancy) associated with chronic or multiple fissures; biopsies confirm IBD or cancer.

Treatment

Nonoperative treatment improves pain and bleeding, heals fissures in nearly 50 % of patients, and is advocated initially in both acute and chronic fissures [17]. Measures include fiber supplementation, bulk laxatives, sitz baths, topical corticosteroid, local anesthetic, or medicated creams (nitroglycerin ointment, diltiazem gel, and nifedipine with lidocaine ointment) (Table 1). They relieve constipation and minimize sphincter spasm and pain, hastening healing, and should probably be continued for 6 weeks in acute fissures before surgery is considered. Injecting botulinum toxin (Botox) relaxes the internal sphincter hastening cure. Topical nifedipine ointment, when combined with Botox injection, induces lasting healing in most chronic fissures [19]. Surgery is, however, consistently superior to medical therapy in chronic fissures and may be offered without initial conservative treatment failure [17].

DOI 10.1007/978-1-4939-0779-3_98-2

Table 1 Treatment options in acute and chronic anal fissures (text from multiple sources)

[a]Nonsurgical measures – in acute and chronic fissures	
Dietary fiber/fiber supplements	Increase dietary fiber to 20G–35G daily Fiber supplements (psyllium, Citrucel, Fibercon) Increase intake gradually over 6 weeks. Bloating a side effect
Sitz baths	Patient sits in a shallow tub of warm water, to which some salt is added, for 15–20 min Relieves pain and itching, relaxes perianal spasm, removes discharge, and assists with healing of raw areas
Medicated gels/ointments (all applied twice daily for 6–8 weeks)	Nitroglycerin 0.2–0.4 % ointment Diltiazem gel or ointment 2 % Nifedipine 0.3 % with lidocaine 1.5 % ointment Relieves pain and spasm and assists with healing
Botulinum toxin	Twenty units injected into the internal sphincter muscle on both sides. Relieves pain and spasm and assists healing
Surgical measures – in acute fissures not responding to nonoperative measures and in chronic fissures	
Lateral internal sphincterotomy (LIS)	Full thickness of internal sphincter divided distal to the dentate line away from fissure (usually lateral). Relieves spasm and assists healing
Tailored LIS	Sphincterotomy stops at the apex of the fissure. Relieves spasm and less risk of incontinence compared to LIS
Subcutaneous fissurotomy, anal advancement flap	In patients with preexisting continence problems or in those with normal sphincter tone (postpartum women) Sphincter not divided Less risk of postoperative incontinence

[a]Usually continued for 6 weeks

Lateral internal sphincterotomy (open or closed) is the recommended surgical treatment for acute anal fissures not responding to conservative treatment and in chronic fissures (Table 1) [17] The internal sphincter muscle distal to the dentate line is incised laterally (as most fissures are anteroposterior), decreasing sphincter pressure and promoting healing. The upper third of the sphincter and the anal mucosa remains intact, maintaining continence [20]. The sentinel pile may be resected at the same sitting. Sphincterotomy relieves pain (95 %) and results in healing in most (93.3 %) patients with chronic fissures [21]. Resulting incontinence to flatus and liquid stool is potentially minimized by halting the sphincterotomy at the apex of the fissure (tailored sphincterotomy) rather than extending it to the dentate line [17]. Patients with preexisting continence problems or normal sphincter tone may benefit from techniques that preserve the internal anal sphincter (anal advancement flap and subcutaneous fissurotomy) [17].

Anorectal Abscess

Pathogenesis and Classification

Anorectal abscesses originate from cryptoglandular infections at the dentate line (occluded anal gland duct with superimposed bacterial overgrowth and suppuration) [22]. Anorectal abscesses may be perianal, ischiorectal, intersphincteric, or supralevator. A perianal abscess (most common) is a collection of pus in the perianal tissues. The abscess may extend into the ischiorectal fossa (ischiorectal abscess – unilateral or bilateral), forming a horseshoe-shaped collection, or, more rarely, tracks upwards between the sphincters (intersphincteric) and through the levator ani musculature (supralevator). The infection is generally polymicrobial, involving both gram-negative organisms and anaerobes, indigenous to the gut.

DOI 10.1007/978-1-4939-0779-3_98-2

Diagnosis

Patients with perianal abscess present with perianal swelling and throbbing pain, aggravated by pressure and defecation. Systemic symptoms (fever, chills, vomiting, and diaphoresis) characterizing sepsis are generally absent. Ischiorectal and higher-level suppurations often result in dull throbbing perianal or pelvic pain and systemic symptoms [23]. Physical examination in perianal abscess reveals a brawny red, extremely tender, indurated perianal mass. DRE is extremely uncomfortable but might reveal induration extending along the lateral anorectal wall in an intersphincteric or ischiorectal abscess. Supralevator abscesses usually have few local physical findings.

Treatment

Incision and drainage as an office procedure (under local anesthesia with or without conscious sedation) is the treatment of choice in perianal abscess [22]. The incision is deepened to enter the abscess cavity; any slough is removed, the cavity irrigated with saline and a drain left in, or the cavity is packed loosely; the raw area heals by secondary intention. Antibiotics, unnecessary in uncomplicated perianal infections, do not decrease recurrences or healing times [22]. Antibiotics effective against both aerobes and anaerobes are a consideration in diabetics, in those immunosuppressed, in those with extensive perianal cellulitis or prosthetic devices, and in those with systemic sepsis. Over a third of patients may have recurrent perianal infection or a fistula following drainage, more frequent in those under 40 years of age [24]. Patients with ischiorectal or intersphincteric abscesses may require a more formal drainage procedure under general anesthesia; any associated fistulous tract is laid open at the time of abscess drainage, or a seton (suture, rubber band, Silastic vessel loop) left in the fistulous tract, and the abscess cavity is allowed to heal.

The diagnosis of supralevator (pelvic) abscess usually requires initial confirmation by imaging (US or CT) to delineate its extent and determine the underlying cause (colitis, appendicitis, cancer) [25]. These patients usually require a combination of broad-spectrum antibiotics, imaging-assisted drainage, and treatment of the underlying cause. A temporary colostomy for fecal diversion may be necessary to enable resolution of distal (anorectal) infection.

Anorectal Fistula

Pathogenesis and Classification

Anorectal fistula (fistula-in-ano) is an abnormal tract connecting the anorectum to the perianal skin lined with granulation tissue and producing a mucopurulent or feculent perianal discharge. Nearly 80 % follow cryptoglandular infection and spontaneous rupture or drainage of a perianal abscess and denote continued perianal infection and/or formation of an epithelialized tract [22]. Anorectal fistulas may also complicate IBD, radiation, cancer, actinomycosis, lymphogranuloma venereum (LGV), tuberculosis, trauma, and foreign body. It is twice as common in adult males; among infants it is seen solely in boys.

Anorectal fistulas are classified into intersphincteric (type 1, fistulous tract in the intersphincteric plane, most common, 45 %), transsphincteric (type 2, tract passing from the anal canal through the external sphincter to the ischiorectal fossa, 30 %), suprasphincteric (type 3, tract passing from the anal canal along the intersphincteric plane and over the puborectalis muscle into the ischiorectal fossa, 20 %), and extrasphincteric (type 4, tract outside the sphincter complex passing through the ischiorectal fat and levator ani muscles connecting the rectum and the skin, least common, 5 %) [26]. Fistulas may also be designated as simple (most common, usually intersphincteric and low transsphincteric fistulas) or complex (high transsphincteric, extrasphincteric, or suprasphincteric fistulas) based on the risk of fecal incontinence following surgery. Anterior fistulas in women and fistulas associated with IBD (Crohn's disease) and cancer or following radiation are also considered complex [27].

DOI 10.1007/978-1-4939-0779-3_98-2

Diagnosis

Symptoms include perianal pain and swelling followed by purulent or bloodstained perianal drainage and dyschezia. Passing bowel contents through the perianal opening indicates a high (rectal) internal opening. History of abscess drainage (in 50 % of patients), other anorectal surgery, radiation, or pelvic trauma may be present. Perianal examination and DRE may reveal redness, swelling, induration, fluctuance, and external openings of fistulas with drainage or granulations. The "Goodsall's rule" states that all fistulous tracts posterior to a line, drawn between the ischial spines with external openings within 3 cm of the anal margin, have a curvilinear course to the posterior midline of the anal canal. Tracks with anterior external openings originate from the nearest crypt and have a straight course to the anal canal.

Proctosigmoidoscopy is useful in visualizing the internal opening(s) and may show other mucosal abnormalities such as proctitis [27]. Imaging studies (endoanal ultrasound, CT, MRI) are useful in defining anatomy and guiding management in patients with complex fistulas.

Treatment

The goal of treatment is to obliterate the fistulous tract and openings while causing negligible sphincter disruption and maintaining continence. Treatment is determined by the etiology and anatomy of the fistula, degree of symptoms, and patient comorbidities [27]. Asymptomatic fistulas associated with Crohn's disease do not need treatment. Fistulotomy (fistulous tract laid open and allowed to heal) is highly successful, maintains continence, and is recommended for simple perianal fistulas, including Crohn's fistulas; marsupialization (suturing mucocutaneous edges) may further enhance wound healing [22, 27]. Coexisting abscesses are drained. Complex or recurrent fistulas, prior surgery, female sex, preexisting incontinence, and Crohn's disease increase risk of persisting or recurrent infection and postsurgical incontinence. Fistulectomy (complete excision of the tract and surrounding tissue in one block) results in larger tissue defects, requires longer healing times, and produces more incontinence while not improving recurrence rates. Anal fistulas in infants and children respond well to abscess drainage and antibiotics; immediate fistulotomy is avoided.

Debridement of the fistulous tract and injection of fibrin glue is an option in both simple and complex anal fistulas, especially in patients at risk for incontinence [22, 27]. A bioprosthetic anal fistula plug closing the internal opening, endoanal advancement flaps, and passing a seton (suture, rubber band, Silastic vessel loop) through the fistula tract to initiate a foreign body reaction and scarring are other options in treating complex fistulas. The seton is gradually tightened to cut through the fistula; fibrosis maintains sphincter integrity.

Perianal involvement including fistulas may be seen in over half of patients with Crohn's disease. Medical measures result in healing in many patients [27]. Surgical approaches, though less effective with higher recurrence rates, are useful. Permanent fecal diversion or proctectomy is rarely required for severe persisting disease [27].

Anal Incontinence

Background

Anal incontinence is the inability to control the evacuation of bowel contents (flatus or feces) or recurrent uncontrolled passage of fecal material for at least 1 month, in an individual with a developmental age of at least 4 years [28]. It is frequently seen among the elderly (over 65) and approaches 50 % among nursing home residents, many of whom are also incontinent of urine. Fecal incontinence is twice as common among Caucasian as in African-American women. Functional limitations, hypertension, neurological

DOI 10.1007/978-1-4939-0779-3_98-2

disorders, obesity, physical inactivity, pregnancy, smoking, and type 2 diabetes mellitus also increase its prevalence [29]. Fecal incontinence may also follow anatomical or physiological changes resulting from trauma, surgery or disease, changes in stool characteristics, cognitive deficits, malabsorption, medications, or underlying psychiatric conditions (Table 2) [28]. Congenital anomalies, developmental disorders, encopresis (fecal retention), and mental retardation are the predominant causes among children [28]. Incontinence causes significant limitations in social interactions and loss of self-esteem, and increases health-care costs.

Diagnosis

A problem-specific history should be obtained [28, 30]. Examination should address the patient's general well-being with particular focus on neurological disorders and deficits and abdominal and anorectal pathology. Generalized weakness, balance and gait disturbances, and need for ambulatory aids indicate functional incontinence. A speculum and a digital rectovaginal examination may detect perineal and anal hypotonia and intrarectal pathology. Contracting the perianal muscles over the palpating digit also helps assess pelvic floor integrity. Pelvic organ prolapse is best evaluated by asking the squatting patient to strain (Valsalva). Proctosigmoidoscopy detects rectal ulcers associated with prolapse, inflammatory bowel disease, and neoplasms. Colonoscopy is recommended in patients over 50 years.

Table 2 Common causes and mechanisms of fecal incontinence (modified from text in Ref. [28])

Enumeration of causes	Mechanism
Congenital Anorectal anomalies – rectal agenesis, imperforate Anus Spina bifida – meningocele, meningomyelocele	Sphincter weakness, impaired anorectal sensation, loss of stool awareness, pudendal neuropathy
Trauma (including surgery) to pelvic floor muscles, pudendal nerve, and the spinal cord Anorectal surgery Colon resection Pelvic and anorectal trauma, spinal trauma Vaginal delivery – spontaneous or assisted	Possible sphincter weakness, pudendal neuropathy, impaired rectal accommodation
Neurological impairment Cerebrovascular accident Dementia (Alzheimer's disease, multi-infarct dementia, normal pressure hydrocephalus) Diabetes mellitus Intracranial injury Meningoencephalitis Multiple sclerosis Neoplasm (brain, spinal cord) Pudendal neuropathy due to trauma or traction injury Spina bifida (meningocele, meningomyelocele)	Impaired anorectal sensation, pelvic floor dysfunction, loss of stool awareness, impaired rectal accommodation
Miscellaneous Anorectal prolapse Fecal impaction Malabsorption Medications (anticholinergic agents, antidepressants, caffeine, laxatives, muscle relaxants) Physical disabilities (aging, disease, or trauma) Proctitis (inflammatory bowel disease, radiation) Psychiatric disorders	Pelvic floor dysfunction, altered stool characteristics, anorectal hypersensitivity, willful soiling, functional incontinence

DOI 10.1007/978-1-4939-0779-3_98-2

Imaging and physiologic studies complement clinical evaluation. Endoanal ultrasound (EUS) identifies sphincter defects in suspected sphincter injury. Anal manometry evaluates maximum resting and squeeze pressures in the anal canal, the rectoanal inhibitory reflex, and the rectal sensation and compliance. Most patients with fecal incontinence have manometric abnormalities. Electromyography (EMG) identifies injury to the sphincter muscles. Pudendal nerve terminal motor latency (PNTML) measures intactness of the pudendal nerve-anal sphincter neuromuscular unit; PNTML abnormalities correlate well with poor surgical outcomes.

Treatment

Goals of treatment are to reestablish normal evacuation, improve lifestyle, and restore functional capacity. Conservative measures improve continence, quality of life, psychological well-being, anal sphincter function, and patient coping strategies. Mucocutaneous and soft-tissue complications (skin excoriations, decubitus ulcers, abscesses) should be handled through judicious drainage, antibiotics, antifungals and barrier creams, or, in extreme cases, temporary or permanent fecal diversion until healing. Underlying IBD, diabetes mellitus, or malabsorption should be treated [28]. Agents precipitating inappropriate stooling (laxatives) are avoided. Increasing dietary fiber improves stool consistency; antidiarrheal agents reduce frequency and urgency in stooling [30]. Patients with fecal impaction benefit from disimpaction through suppositories, enemas, or manual evacuation, followed by using stool softeners and laxatives (polyethylene glycol), bowel retraining (regular toilet use after meals), and treating underlying behavioral problems.

Biofeedback (neuromuscular training) is a first-line treatment option in motivated patients with some preserved sphincter tone and impaired rectal sensation not responding to conservative measures [30]. It is often combined with pelvic floor muscle exercises and stimulation to enhance pelvic floor strength.

Disposable anal plugs alleviate fecal leak and seepage but are difficult to tolerate. Injecting biocompatible material into the anorectal submucosa or the intersphincteric space augments the perianal/perirectal tissue and approximates the anal mucosa, thereby closing the anal canal and/or raising the anorectal pressure to avert fecal incontinence [30]. Short-term improvement is noticed in over half of patients [31].

Surgery should be considered in patients who have failed conservative measures and neuromuscular training. Patients with significant symptoms and a defined defect of the external anal sphincter benefit from sphincteroplasty by plication or imbrication (70–80 % of patients improve) [30]. Those with more extensive sphincter damage may need an autologous gracilis or gluteus muscle transfer (dynamic graciloplasty) or implantation of an artificial bowel sphincter. Both procedures have significant potential complications, and long-term outcomes are not encouraging. Sacral nerve stimulation, in which electrodes are implanted in the second and third sacral nerve roots, stimulating the muscles of the pelvic floor appears to achieve full continence in nearly half (47.2 %) of patients [30, 32]. Children and patients with neurological disorders benefit from an antegrade continent enema procedure that offers periodic colon washout through an appendicostomy or a cecostomy. Permanent fecal diversion is another alternative in paralyzed, immobile patients with nonhealing decubitus ulcers.

Rectal Prolapse

Background

Rectal prolapse is defined as protrusion of the layers of the rectal wall through the anal canal. The prolapse may be mucosal (partial), when only the mucosal and submucosal layers protrude, or full thickness (complete), when all layers overhang the anal canal [33]. It is seen more often among older women

DOI 10.1007/978-1-4939-0779-3_98-2

(sixfold increase compared to men); men tend to present at younger ages. Rectal prolapse is thought to commence as an intussusception from the rectosigmoid region at the level of the peritoneal reflection, progressing distally through the anal canal on continued exertion. Multiple factors predispose to prolapse (Table 3).

Diagnosis

Patients present with dull perianal pain, rectal bleeding or mucorrhea, and fecal/urinary incontinence. Irreducibility and strangulation of the prolapsed segment cause severe and persistent perianal and abdominal pain and distention, fever, vomiting, and diaphoresis; gangrene may supervene. Perianal inspection is best accomplished with the patient sitting or squatting, and it assists in differentiating full-thickness prolapse from mucosal prolapse or prolapsed hemorrhoids [34]. Mucosal prolapse is thin and often segmental; full-thickness prolapse may be segmental or circumferential, plum colored with concentric mucosal folds. Prolapse longer than 5 cm usually contains a fold of peritoneum; larger prolapses contain small bowel. DRE identifies anal sphincter hypotonia; anoscopy may reveal a solitary rectal ulcer, present usually on the anterior rectal wall in 10–15 % of patients [34]. Imaging studies, colonoscopy, and urodynamic studies are useful in further defining the diagnosis and identifying coexisting cystocele or colorectal pathology [34]. Physiologic tests (anorectal manometry, electromyography, and pudendal nerve testing) help identify and evaluate associated pelvic floor dysfunction and colonic inactivity [34].

Treatment

Nonoperative approach yields poor results [34]. Increased fiber intake, fiber supplements, and stool softeners improve constipation, minimize straining, and may help heal rectal ulcers. Biofeedback is useful in retraining and enhancing sphincter function and improves continence and constipation following surgery [35]. Rubber-band ligation or transanal excision is beneficial in patients with second-/third-degree mucosal prolapse without ulceration [36].

Transabdominal rectopexy is the procedure of choice in patients with full-thickness rectal prolapse, considered fit for laparotomy [34, 37]. Laparoscopic approach has fewer postoperative complications and a shorter hospital course when compared with open rectopexy. Prosthetic meshes (polypropylene, polytetrafluoroethylene) are used to reinforce attachment of the mobilized rectum to the sacral

Table 3 Common causes of rectal prolapse in infants/children and adults

Infants/children	Cystic fibrosis
	Disturbances in bowel function (chronic diarrhea, constipation)
	Hirschsprung's disease
	Parasitic infestations
	Poor nutritional status
	Neoplasms (polyps)
	Neurological disorders (spina bifida, meningocele, meningomyelocele)
Adults	Aging (age-related tissue degeneration, weakness, and intercurrent illness)
	Cerebrovascular accident
	Dementia
	Increased intra-abdominal pressure (chronic constipation, chronic cough, heavy lifting, obesity)
	Multiparity (direct injury to pelvic floor muscles, nerves, and connective tissues caused by maternal expulsive forces). Large fetus, prolonged second stage of labor, episiotomy, anal sphincter laceration, epidural analgesia, operative deliveries, and oxytocin use are also considered risk factors
	Pelvic floor muscle weakness following spinal or pelvic trauma including surgery
	Psychiatric illness
	Pudendal neuropathy

Information from multiple sources

DOI 10.1007/978-1-4939-0779-3_98-2

promontory, inducing fibrosis and minimizing risk of recurrent prolapse and fecal incontinence. Rectopexy also helps heal rectal ulcers. Coexisting uterovaginal prolapse may also be corrected (rectocolpopexy).

Perineal procedures (mucosal sleeve resection, Delorme procedure, and perineal proctosigmoidectomy, Altemeier procedure) are useful in patients unfit for laparotomy. Patients with short, full-thickness rectal prolapse may undergo the Delorme procedure; longer-segment prolapses require a proctosigmoidectomy.

Pruritus Ani

Background

Intense perianal itching (pruritus ani) is experienced by 1–5 % of people, more often by men (two- to fourfold increase) between 30 and 60 years of age [38, 39]. The long-standing itch-scratch cycle eventually causes dryness and hyperpigmentation, infection, ulceration, and scarring of the involved skin. Irritability and depression often coexist [39]. Pruritus ani may be idiopathic; though in up to three-fourths of patients, an underlying local or systemic cause may be identified [40].

Causes

Hemorrhoids (20 %), anal fissure (12 %), idiopathic proctitis (6 %), and condyloma/ulcerative proctitis (5 %) are the predominant causes [38]. All these pathologies produce mucus or fecal soiling, initiating or aggravating the pruritus. Other causes include atopic and contact dermatitis, bacterial and fungal skin infections, clothing (retains moisture), medications (antibiotics, colchicine, laxatives, steroids), other dermatologic conditions (psoriasis, lichen planus, lichen sclerosis), parasitic infestations, systemic diseases (diabetes mellitus, hepatorenal disease, anemia, hyperthyroidism and underlying anxiety), and various foods (alcohol, caffeinated drinks, chocolate, citrus fruits, milk products, peanuts, spices) [40].

Diagnosis

Diagnosis is usually based on history and examination focusing on the gastrointestinal tract and skin, including nails. The perianal region is closely inspected for primary perianal pathology and skin changes. Bacterial/fungal cultures and patch or Scotch tape testing establish the diagnosis of infections, parasitic infestations, or contact dermatitis. Endoscopy and biopsy are useful in diagnosing colitis. Manometric studies help diagnose motility disorders. Perianal skin biopsies may be required when the diagnosis is obscure or if a premalignant or cancerous lesion is suspected.

Treatment

The principles of management include ruling out secondary causes, eliminating all irritants (soaps, talcum powders, certain foods and fluids), avoiding trauma (scratching, vigorous scrubbing, using toilet paper), keeping the perianal skin clean and dry (cotton underclothes changed daily to minimize moisture accumulation, washing with water after stooling, and drying the skin), and ensuring regular bowel movements with normal consistency stool (increasing dietary fiber and adequate fluid intake) [41]. Using white, undyed, unscented toilet tissue minimizes allergic skin reactions. Those with diurnal hyperhidrosis should be encouraged to change their underclothes frequently to restrict perianal moisture accumulation. Low-potency steroids may help break the itch-scratch cycle. Underlying psychiatric issues (anxiety, obsessive-compulsive disorder) need treatment. Mittens or socks over hands may reduce nocturnal scratching. Vaseline may be applied locally if the skin is dry and thickened.

DOI 10.1007/978-1-4939-0779-3_98-2

Topical capsaicin cream diluted in paraffin applied three times daily over 4 weeks relieves intractable perianal pruritus in over 70 % of patients [42]. Perianal intradermal injection of methylene blue (15 ml of a 1 % solution diluted with 0.5 % lidocaine) also eases symptoms in a majority (60 %) of patients with intractable pruritus, the improvement persisting over 4 years [43].

Infectious Proctitis

Background

Proctitis is defined as an inflammation of the anorectal mucosa, usually seen in adult males. Causes include sexually transmitted diseases (STDs – gonorrhea, chlamydia, syphilis, genital herpes), chemical irritation, IBD, ischemia, radiation, trauma, and miscellaneous causes (immune deficiency, vasculitis, other infections – amebiasis, *Clostridium difficile* infection, campylobacter infection) [44]. Radiation proctitis may be acute or chronic, and its incidence is probably related to radiation dosage, area of exposure, method of delivery, and use of cytoprotective agents [45].

Diagnosis

Patients usually present with perianal or lower abdominal pain, blood or mucus per rectum, change in bowel habits (diarrhea or constipation), sense of incomplete defecation, and tenesmus. Abdominal examination may show lower abdominal fullness and tenderness. Proctosigmoidoscopy may reveal mucosal edema, erythema, friability, bleeding, ulceration, inflammatory exudate, or herpetic vesicles limited to the anorectum. In chronic radiation proctitis, mucosal pallor, changes in vascularity, strictures, ulcerations, and fistulas may be seen [45]. The anal discharge can be analyzed (gram stain, nucleic acid detection and DNA amplification tests, and bacterial, fungal, or viral cultures) to detect infections. Stool studies (ova, cysts, parasites, *Clostridium difficile* toxin, and antigen) also help diagnose bacterial infections and parasitic infestations [46]. Endoscopy is useful in detecting proximal bowel involvement, especially in IBD; biopsies may be obtained for confirmation. Contrast imaging assists in detecting obstruction and fistula formation – consequences of IBD and radiation.

Treatment

The principles of management include providing symptomatic relief and addressing primary causes (Table 4). Antispasmodics and a low-residue diet relieve diarrhea and tenesmus. Steroid or mesalamine enemas are useful in patients with IBD. Antibiotics and antivirals administered appropriately help resolve specific infections [46]. Campylobacter proctitis and acute radiation proctitis are usually self-limiting; the latter resolves with discontinuing radiation for short periods. Chronic radiation proctitis may require more intensive management depending on its extent (grade) and symptomatology and may involve the use of anti-inflammatory agents (oral sulfasalazine with steroid enemas), sucralfate enemas, short-chain fatty acid, or pentosan polysulfate enemas. Antioxidants (vitamins A, C, and E) reduce diarrhea and tenesmus and supplement the beneficial effects of other treatment measures [45]. Hyperbaric oxygen improves symptoms by enhancing tissue oxygenation, impeding bacterial overgrowth and toxin production, and stimulating angiogenesis. When administered (90 min at 2 atm daily five times a week), considerable improvement is noticed; these patients require less medication or other invasive treatment measures [47]. Topical formalin (10 %) applied during proctosigmoidoscopy cauterizes and seals the fragile vessels in radiation-damaged tissues. Endoscopic electrocoagulation and laser photocoagulation are other options to control refractory bleeding. Surgery is reserved for patients with uncontrollable pain, fistula, bleeding, fecal incontinence, and obstruction and may involve a diverting colostomy, strictureplasty, or pelvic exenteration [45].

DOI 10.1007/978-1-4939-0779-3_98-2

Table 4 Treatment options in proctitis Ref. [44–47]

General measures	Hydration, analgesics, and antidiarrheals in acute proctitis Low-residue diet Antispasmodics
Cause-specific treatment	
Campylobacter infection	Erythromycin 500 mg twice daily for 5 days
Chlamydia infection	Doxycycline 100 mg orally twice daily for 7 days. Three-week therapy in men intimate with men and if HIV+
Crohn's colitis/proctitis	5-ASA (foam, gel, suppository, enema) Oral mesalamine 2.4 G daily in divided doses Topical steroids (enemas, foam, suppositories) In patients failing to respond to topicals – oral 5-ASA/mesalamine Oral prednisone (20 to 60 mg daily) – in patients not responding to topical steroids Azathioprine 1.5–2.5 mg/kg/day orally – patients not responding to or dependent on steroids. Used as steroid-sparing therapy
Giardiasis	Metronidazole 750 mg orally three times daily for 10 days followed by paromomycin 25–30 mg/kg per day three times daily for 7 days for eradication of cysts in bowel lumen
Gonococcal proctitis	Ceftriaxone 250 mg IM once + doxycycline 100 mg orally twice daily for 7 days
Herpes simplex proctitis	Acyclovir 400 mg three times daily for 7–10 days Famciclovir 250 mg three times daily for 7–10 days Valacyclovir 1G orally twice daily for 7–10 days
Shigella infection	Ciprofloxacin 500 mg orally twice daily for 7 days
Radiation proctitis	
Grade 1[a]	Watchful waiting
Grades 2 and 3	Anti-inflammatory agents (oral sulfasalazine or mesalamine, steroid enemas, oral steroids, oral metronidazole) Antioxidants (vitamins A, C, E)
Grades 2 and 3 (no response to anti-inflammatories)	Rectal sucralfate or pentosan polysulfate Short-chain fatty acid enemas Hyperbaric oxygen at 2 atm for 90 min
Grade 3 (no response to above measures)	Chemical cauterization – formaldehyde 10 % applied for 2–3 min Endoscopic coagulation Argon or YAG laser photocoagulation
Grade 4	Surgery (fecal/urinary diversion, local excision, stricturoplasty, pelvic exenteration). Often requires reconstruction using vascularized flaps

[a]Grading based on intensity of symptoms, degree of ulceration and stricture, and presence of complications (hemorrhage, fistula, perforation, obstruction). Grade 0, no symptoms; grades 1–3, increasing intensity of symptoms; grade 4, uncontrollable pain/urgency or development of complications; grade 5, sepsis, multiple organ failure usually resulting in demise

Hidradenitis Suppurativa

Background

Hidradenitis suppurativa is a chronic recurrent inflammatory skin disorder affecting the hair and areas carrying apocrine sweat glands and adjacent connective tissue; perineal involvement occurs more often in men [48]. Pathophysiology involves occlusion of the ducts of the hair follicles, stasis and dilatation of the apocrine glands, secondary bacterial infection, abscess formation, development of sinuses and fistulas, and ultimately fibrosis and hypertrophic scarring. Cryptoglandular infection or Crohn's disease may coexist.

DOI 10.1007/978-1-4939-0779-3_98-2

Diagnosis
Diagnosis is clinical and based on the characteristic history and physical findings of chronically draining sinuses with malodorous discharge and hypertrophic skin [7]. Proctosigmoidoscopy may show evidence of anal gland infections or IBD. Incontinence, lymphedema, and malignant transformation to squamous cell carcinoma (rare) are all possible sequelae.

Treatment
Treatment is usually prolonged and unsatisfactory in advanced stages. Broad-spectrum antibiotics (clindamycin, tetracyclines, rifampin) administered orally or applied topically reduce pain, redness, and discharge. Abscesses need drainage and sinus tracts may be de-roofed or marsupialized. Isotretinoin is useful, though contraindicated in women of child-bearing age due to potential teratogenicity. Immunosuppressants (steroids, cyclosporine, infliximab, etanercept) also show promise but increase risk of concurrent infections and malignancy. Radiation, cryotherapy, and laser surgery are other options. Wide excision of the involved skin and underlying connective tissue followed by skin grafting or flap closure may be necessary in recalcitrant disease and, rarely, may also require temporary fecal diversion [48].

Condyloma Acuminatum

Background
Anal condyloma acuminatum (warts) is caused by sexual (usual) or nonsexual transmission of the human papillomavirus (HPV), typically low-risk subtypes 6, 11, 42, 43, and 44 [49]. Most (90 %) are caused by types 6 and 11. These warts are more frequent in men who have sex with men and practicing receptive anal intercourse, in those with multiple sexual partners, and in the immunosuppressed, in whom the warts are more aggressive, relapse earlier, and are more often dysplastic [7]. Buschke-Löwenstein tumor (giant condyloma acuminata) is a rare and rapidly progressing variant, locally invasive, causing extensive destruction of surrounding tissue [7].

Diagnosis
Patients with perianal warts are typically asymptomatic, but depending on the size and location of the warts, they may cause pain, itching, drainage, foul odor, bleeding, or dyschezia. Patients may also exhibit anxiety, guilt, anger, and loss of self-esteem [50]. Anal warts may be perianal or intra-anal; the diagnosis is made by visual inspection. The lesions are usually found over sites traumatized during intercourse, vary from 5 to 15 in number, and, occasionally, coalesce into plaques (more common in diabetics and the immunosuppressed) [50]. Proctoscopy displays the intra-anal condyloma, usually confined below the dentate line. Biopsy confirms the diagnosis and rules out malignancy, and HPV typing categorizes the lesion as pertaining to low- and high-risk subtypes. Biopsy is, however, required only in failure of response to usual treatment measures, if dysplasia or malignancy is suspected, or in immunosuppressed patients. Complete genital examination should be performed to check for penile, scrotal, and cervicovaginal lesions; women should be offered a Papanicolaou (PAP) smear. Anal warts in children should arouse suspicion of sexual abuse, though vertical transmission at birth is possible.

Screening, Prevention, and Treatment
Current sexual partners as well as partners within the last 6 months should be screened for warts and other STDs. Condom use should be encouraged to minimize recurrence and infecting partners. Smoking

DOI 10.1007/978-1-4939-0779-3_98-2

cessation measures should be implemented. Both sexes between 9 and 26 years of age should be offered the quadrivalent HPV vaccine (Gardasil) to prevent infection by high-risk strains 6, 11, 16, and 18.

Multiple patient-applied local therapies (podofilox 0.5 % solution or gel applied twice daily for 3 days a week – 4 such cycles, imiquimod 5 % cream applied daily at bedtime for 16 weeks, sinecatechin 15 % ointment applied three times daily for 16 weeks) are available. They may all cause local redness, burning, induration, and ulceration. Both sinecatechin and podofilox are not yet considered safe for use during pregnancy. Clearance rates of 40–70 % have been noticed with these treatment modalities [50]. Office therapies include application of acetic acid solutions, cryotherapy and electrosurgery, laser surgery, or scissor excision. Trichloro or bichloroacetic acid 80–90 % solution applied weekly works by coagulating proteins and is safe for use during pregnancy. Cryotherapy using liquid nitrogen is also safe during pregnancy but may also need to be repeated at regular intervals. Pain, irritation, and drainage are side effects of the treatment. Response rates parallel that of patient-applied therapies. Electrosurgical excision and destruction (fulguration) are also effective for removing condyloma. The smoke plume generated during destruction carries HPV particles; hence there should be appropriate smoke evacuation techniques, and both patients and health-care providers should wear masks to prevent inhalation of the particles. Scissor excision under local anesthesia using lidocaine with epinephrine to minimize pain and bleeding is useful where smaller numbers of lesions are involved. Both electrosurgery and sharp excision have high success rates (90–100 %). Larger warts, especially in children, intra-anal warts, and Buschke-Löwenstein lesions require excision under general anesthesia. Recombinant interferon alpha may be injected under lesions or used as adjuvant therapy after surgical excision or fulguration [49–51].

Anal Canal Cancers

Squamous cell carcinoma (SCC) is the most common type of malignancy in the anal canal followed by the cloacogenic, basaloid, epidermoid, and mucoepidermoid subtypes [52]. Half of patients present with localized disease, the rest with regional nodal or distant metastases. A strong causal relationship exists between oncogenic strains of HPV (types 16 and 18) and SCC. Anal intraepithelial neoplasias (high grade, low grade) are precursors of SCC [52]. Most patients with anal canal cancers present with a slow-growing intra-anal or perianal mass, bleeding, discharge, pain, and occasionally inguinal lymph node or intra-abdominal masses due to hepatic metastases. The diagnosis is evident in most patients on examination of the perianal region, DRE and anoscopy. Biopsies from the primary and enlarged inguinal nodes should be taken for confirmation of the diagnosis and spread. The extent of thoracoabdominal spread should be evaluated by imaging of the chest, abdomen, and pelvis; endoanal ultrasound and MRI delineate the extent of local spread into the sphincters and perirectal lymphadenopathy. Chemotherapy (mitomycin-C and 5-fluorouracil) and radiation are the recommended treatment modalities for both the anal canal primary and inguinal disease; small superficial lesions may be excised. Cisplatin may be substituted for 5-fluorouracil. Abdominoperineal resection of the rectum and anal canal is an option in recurrent or persisting disease (seen in 20–30 % of patients) and has a 50 % cure rate [7]. Presence of distant metastases denotes poor prognosis with median survivals under 1 year. Melanoma of the anal canal usually has a poor outcome as most patients have widespread metastases at the time of diagnosis. Wide excision or abdominoperineal resection may be offered for local control in patients with disseminated disease.

Colorectal Cancer

Travis C. Russell*
US Air Force/USUHS, Las Vegas, NV, USA

General Principles

Introduction

Colorectal cancer (CRC) is currently the third ranked cancer in terms of morbidity and mortality in the United States [1]. There were 102,480 new cases in 2013 alone, with 50,830 deaths which affected 9 % of the US population of that same year [1]. CRC affects men and women equally with the probability of developing invasive CRC being roughly 1 in 19 over the average American male's lifetime and 1 in 21 for females, with 90 % of those cases in both sexes after age 50 [1]. This has significantly changed over the last 25 years with a 30 % decrease in the incidence and mortality from the 1980s due to multiple factors [1]. The highest mortality rates remain among African Americans (49.6 per 100,000) compared to Caucasians (33.1 per 100,000) [1]. The lowest incidence rates are found in the Asian American and Pacific Islander populations (73.5 per 100,000) [1]. The cost of care is also staggering with $14 billion spent in 2010 alone and projected costs to rise 20 % by 2020 [2]. Even with the significant decrease in incidence and death over the last 25 years, the projected increase in cost is 20 % by 2020, and this is without the assumption that an aging population will result in an increase in the number of people over age 50 as the baby boomers age [2].

Americans have a 5 % chance over their lifetime of developing CRC based on the most current population data. CRC has an insidious, and sometimes asymptomatic, presentation which necessitates a good routine screening policy in the healthcare system especially as this is the best prevention modality when compared to all other risk factor adjustments. There are multiple risk factors including polyps, genetic predisposition, diet, medications, social habits, and other associated conditions which can increase the risk of CRC. Multiple diagnostic and screening modalities are available, and these can be tailored based on the patient, resources available, and the provider's abilities to do in-office procedures. Colonoscopy and flexible sigmoidoscopy are procedures that family medicine doctors can learn and then provide for their patients if they so desire. Once CRC has been diagnosed, surgery is the generally best used treatment modality, and if found early, the prognosis for CRC remains positive overall.

Presentation

One of the major challenges of CRC is the appropriate diagnosis, especially as symptoms may be mild or the patient may be completely asymptomatic. Anemia is the most common presenting sign, 51 % of cases, for those with CRC [3]. Those with lower grade tumors were less likely to have anemia (29 %) compared to those with higher grade tumors (59 %) [3]. However, as anemia is the most common sign of CRC, then all males with anemia and all post-menopausal females with anemia should always be evaluated for CRC. Beyond anemia, 66 % of patients have GI symptoms and 25 % have nonspecific symptoms (Table 1) [3]. Patients with symptoms are often symptomatic for an average of 14 weeks, but there is no association between duration and stage of CRC [4]. For specific sites, distal cancers involving the rectum, sigmoid, and descending colon are associated more commonly with rectal bleeding (OR 3.45; 95 % CI 1.71–6.95), constipation (OR 3.16; 95 % CI 1.38–7.24), and anemia (OR 1.34; 95 % CI

Table 1 Most common primary symptoms for patients presenting with a new diagnosis of CRC

Hematochezia – 33.7 %
Abdominal pain – 22.3 %
Weight loss – 5.6 %
Weakness – 4.8 %
Obstruction – 4.4 %
Perforation – 1.2 %

1.16–1.54) [4]. Proximal cancers are more likely to involve nonspecific GI symptoms such as abdominal pain, weight loss, and weakness which is why a thorough history involving familial CRC and personal screening is imperative in these nonspecific cases.

It is important to note that 12 % of patients presented with CRC without any active symptoms [3]. In these cases, metastasis or perforation may be the most common presenting factor with CRC. For metastatic disease, the initial location of the cancer determines location due to blood and lymphatic flow from various sections of the colon. Colon cancer is more likely to metastasize the liver and lung, and rectal cancer is more likely to metastasize to the lung and bone [4]. Lytic or other lesions in these cases should prompt the provider to ensure that a patient's CRC screening is up to date. Patients can present with obstruction or perforation as an initial symptom of CRC, with large bowel perforation very suggestive of CRC [5]. Those who present with an emergent condition, usually obstruction and/or perforation, have a poorer prognosis compared to other patients with CRC with a hazard ratio (HR) of 1.68 (95 % CI 1.49–1.90) and to those undergoing elective surgery [5]. This makes clinical sense as emergency surgery in general has more risk than planned, and perforation means that the surgeons will be working with a non-sterile cavity which is certainly more prone to infection.

Risk Factors

Polyps

Polyps, or adenomas, are one of the single most important risk factors for the development of CRC with the greatest risk found in those polyps that are largest. Various examples of polyps are shown below in Fig. 1, and overall they are an example of what is found on colonoscopy and flexible sigmoidoscopy. Historically, for adenomas measured in vivo, a single polyp greater than 1 cm has a relative risk (RR) of 3.5 (95 % CI 2.4–5) for developing CRC compared to an RR of 6.5 (95 % CI 3.3–11.8) for those who have multiple polyps $\geq$ 1 cm [6]. The 1 cm measurement is based on the colonoscopist visual evaluation and measurement which is often confirmed with the samples returned to pathology. In comparison, small tubular adenomas, defined as $<$ 1 cm, had no statistically significant increase if the patient only had 1–2 of these sizes of polyps (95 % CI 0.1–1.3) [6]. Loberg et. al looked at the actual versus expected mortality for CRC in 2014 by showing that those with small polyps, $<$ 1 cm, had an SMR (standardized mortality ratio) of 0.75 (95 % CI 0.63–0.88) compared to larger adenomas which were associated with a higher mortality SMR of 1.16 (95 % CI 1.02–1.31) [7]. Other associated risks for polyps include those that are of high grade, such as tubulovillous or tubular adenoma with high-grade dysplasia. Any patient with high-risk polyps should notify their immediate family as this can affect their screening (as described in the screening section below).

DOI 10.1007/978-1-4939-0779-3_99-1

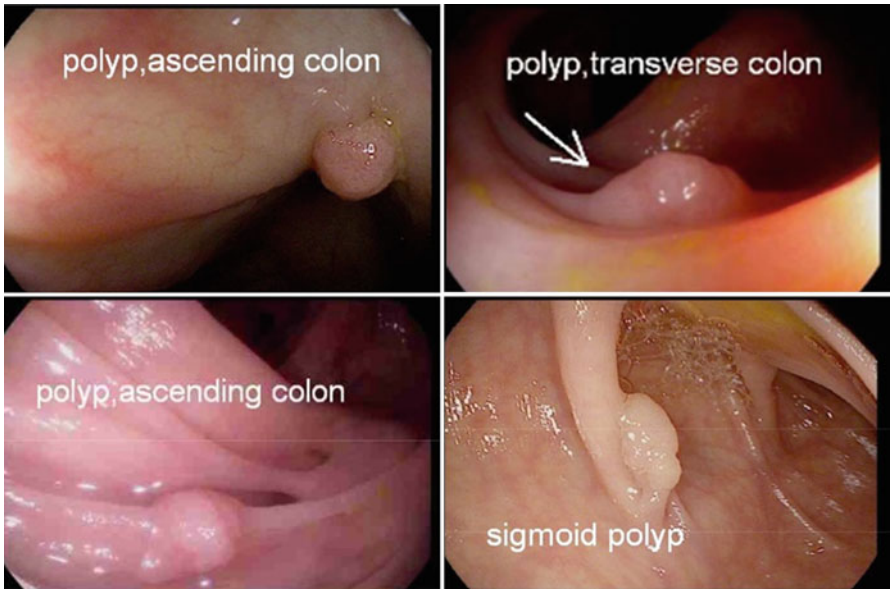

Fig. 1 Various examples of polyps seen on colonoscopy

Genetics

Genetics are the second most significant CRC risk factor behind high-risk adenomas. CRC risk is elevated in first-degree relatives of those with large adenomas, RR 1.35 (95 % CI 1.25–1.46), and those with advanced adenomas, RR 1.68 (95 % CI 1.29–2.18), compared with control cases [8]. Other studies show that the risk for CRC, or high-risk adenomas, is RR of 4.36 (95 % CI 1.60–10.21) in first-degree relatives compared to those without any family history [9]. The two most specific genetic conditions are familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC) or Lynch syndrome. FAP affects 1 in 10,000 births and is associated with an increased burden of polyps, sometimes >100, and CRC on average by age 39 [10]. Hereditary nonpolyposis colorectal cancer (HNPCC), or Lynch syndrome, is more rare than FAP but still has an average CRC diagnosis at age 45 [10]. Whereas FAP is due to loss of function of cancer regulation APC gene and has a large polyp burden, HNPCC is due to a mutation in the "housekeeper" genes and is associated with less polyp burden during colonoscopy [11]. Both of these conditions require more aggressive screening than usual risk patients and should be sent to gastroenterology for evaluation with possible genetic screening.

Diet

Many patients would like to know what diet changes they can make in order to decrease their risk of colorectal cancer. Multiple diets including vegetarian, low red meat, Western, Mediterranean, and supplements have been evaluated with mixed results. Koushik et. al in a 14-study meta-analysis in 2005 showed that there was no significant overall decrease of overall CRC for diets with increased fruits/vegetables (RR 0.91; 95 % CI 0.82–1.01) [12]. However, when specific CRC site was evaluated, diets high in fruits/vegetables (>800 gm/day) was associated with a statistically significant decrease for distal CRC (RR 0.74; 95 % CI 0.57–0.95) compared to proximal CRC (RR 1.02; 95 % CI 0.82–1.27) [12]. Diets high in processed meat, defined as the highest tetrile compared to the lowest tetrile, had a higher risk of CRC compared to other categories (RR 1.5; 95 % CI 1.04–2.17) [13]. High consumption of red meat was also associated with higher risk of rectal cancer (RR 1.71; 95 % CI 1.15–2.52) [13]. This data is limited by confounding factors but it is reasonable to educate patients that diets low in processed/red meats and high in fruits and vegetables may be healthy options for the prevention of CRC besides the

DOI 10.1007/978-1-4939-0779-3_99-1

other positive health implications in these diets. In other meats, long-term consumption of fish and poultry was inversely related to CRC but not statistically significant (RR 0.84; 95 % CI 0.7–1.02) [13]. Beyond meats and vegetables, diets high in calcium and dairy products, highest quintile compared to the lowest, are also inversely associated with colorectal cancers (RR 0.79; CI 95 % 0.7–0.89) [14]. However, at this time there is not one specific "CRC prevention diet," and patients should be educated on the facts and allowed to make their own decisions regarding their diets.

Medications

Besides diet, medications have been evaluated for either the prevention or association with CRC. Daily use of aspirin is associated with a significant reduction in the incidence of adenomas in controlled trials (RR 0.82; 95 % 0.7 −0.95) and a 22 % reduction in the incidence of CRC in cohort studies [15]. Furthermore, in those diagnosed with CRC, regular use of aspirin is associated with decreased incidence of distant metastasis (OR 0.69; 95 % CI 0.57–0.83) but did not have any significant reduction for local/regional spread (OR 0.98; 95 % CI 0.88–1.09) which is consistent with other RCTs [16]. Currently, the USPSTF recommended against (D recommendation) using ASA or NSAIDs for the prevention of CRC [16]. It should be noted that as of fall 2014, this data is under review, and the USPSTF is looking at their recommendations regarding ASA and CRC, but this review will take some time. Supplements are also pushed in media and advertisements for colon health, and this has been evaluated in a few studies. Meta-analysis has shown that each 10-nmol/L increase in blood 0,25-(OH) vitamin D is associated with a 6 % reduction in risk for CRC (95 % CI 3–9 %), but the USPSTF states that there is not enough evidence to recommend Vitamin D supplementation for the prevention of cancer (I recommendation) [17, 18].

Social

Obesity is a risk factor for CRC. Each 5 kg increase in abdominal body fat for men is associated with a 22 % increase in the incidence of CRC in men and a 9 % increase in the incidence for women (RR 1.24; 95 % CI 1.2–1.28) [19]. There is no data published about the time when this fat places the patient at risk or if weight loss during a given time reduces the risk, but healthy weight should be encouraged, and stressing cancer reduction may help patients (among the plethora of other health benefits). Other lifestyle choices such as tobacco use and alcohol are also important risk factors for CRC. Smoking was associated with an increased risk in high-risk adenomas with current smokers having an increased risk (RR 2.14; 95 % CI 1.86–2.46) compared to former smokers (RR 1.82; 95 % CI 1.65–2) [20]. Alcohol consumption was also associated with an increased risk for CRC with heavy drinking (RR 1.21; 95 % CI 1.13–1.28) associated with a higher risk than moderate (RR 1.52; 95 % CI 1.27–1.81) [21]. These diet factors are consistent with the healthy weight, no smoking, and low alcohol consumption recommendations that are already made by family medicine providers.

Associated Conditions

Ulcerative colitis (UC) is a type of inflammatory bowel disease that affects the lining of the colon, and historically, UC was associated with a pooled standardized incidence ratio (SIR) of 5.7 (95 % CI 4.6–7) [22]. Observed over time, the risk of developing CRC for those with UC is 2 % at 10 years (of active disease), 8 % at 20 years, and 18 % at 30 years with all values irrespective of disease extent [22]. However, recent data from Western societies shows that over the last 20 years, CRC incidence associated with UC has been on the decline either due to a steady/declining incidence of UC or due to improved screening

DOI 10.1007/978-1-4939-0779-3_99-1

[23]. This data only applies to Western societies as UC in other regions of the globe is either increasing or those specific countries do not have regular screening for CRC. Other associated conditions such as abdominal radiation as a child is also associated with an increased SIR of CRC as an adult (IR 4.2; 95 % CI 2.8–6.3) [24]. These two conditions are important in the overall health review of the patient and should be considered when discussing their risk for CRC.

Pathogenesis

There are two main pathways for non-syndrome CRC that are important in the pathogenesis: the sporadic and the serrated pathways. The sporadic pathway for CRC is associated with multiple chromosomal segment deletions with a loss of heterozygosity (LOH), with 17p, 18q, and 5q being the most common mutations [11]. The genetic model for CRC is thought to be that adenomas form when normal mechanisms which regulate epithelial renewal are disturbed [25]. Normal intestinal cells have a high turnover due to apoptosis and exfoliation, with proliferation of cells occurring extensively at the crypt base [25]. Mutations in the APC gene, a tumor suppression gene, tend to happen first, and then p53 tumor suppression gene mutations happen later in the formation of the adenoma [25]. In CRC, 75 % had LOH on the 17p chromosome which is associated with the p53 gene [11]. New cellular data has also shown that besides the chromosomal instabilities, sporadic CRC is associated also with a mutation in the KRAS gene; as this gene is basically the molecular "on/off" switch, mutations in this gene are associated with continued proliferation of cells which then lead to cancer [26]. These mutations cause rapid proliferation of the cells and nucleus changes which are consistent with cancer in general.

The second significant pathway, or serrated pathway, involves DNA hypomethylation which suppresses the expression of certain genes and causes mutations in the gene responsible for directing cell growth, the BRAF gene [11]. These polyps are more common in the proximal colon and lack the classic features of dysplasia seen in typical adenomas [11]. There are nonnuclear changes in the histology of serrated adenomas which look more like the "hyperplastic" or benign polyps, and therefore, an accurate pathology diagnosis is paramount [11]. Unlike traditional adenomas, serrated adenomas are due to microsatellite instabilities and mutations in the BRAF gene but not the KRAS gene [26]. Serrated polyps are associated with the Serrate polyposis syndrome which requires at least 1 of the following criteria: (1) at least 5 serrated polyps proximal to sigmoid, with 2 or more $\geq$10 mm; (2) any serrated polyps with a family history of serrate polyposis syndrome; or (3) $>$20 serrated polyps of any size throughout the colon [27]. As discussed below in the screening, these polyps have increased risk of developing into CRC compared to hyperplastic polyps and require increased surveillance.

Diagnosis and Screening

As noted previously, screening for CRC has been paramount for the 30 % decrease in the incidence of CRC over the last 25 years. The Multi-Society Task Force on Colorectal Cancer (MSTFCC) 2008 guidelines for screening methods and timeframes are listed below in Table 2 with the most specific testing being colonoscopy [28]. Colonoscopy is considered the "gold standard" for screening procedures as it reviews the entire colon and is both diagnostic and therapeutic compared to other testing modalities [28]. Furthermore, if any of the other tests are positive, then a full colonoscopy is recommended to evaluate and treat any polyps or CRC noted on the study [28]. Although the MSTFCC recommends all modalities below, it is important to note that the US Preventive Services Task Force (USPSTF) does not

DOI 10.1007/978-1-4939-0779-3_99-1

Table 2 2008 Multi-Society Task Force on Colorectal Cancer (MSTFCC) guidelines for CRC screening methods and recommended timeframes

Study	Timeframe	Diagnostic	Therapeutic
Colonoscopy	10 years	Yes	Yes
Flexible sigmoidoscopy	5 years[a]	Yes	Yes
Double contrast barium enema	5 years[b]	Yes	No
CT colonoscopy[c]	5 years[b]	Yes	No
Fecal DNA testing[c, d]	3 years	Yes	No
Fecal immunochemical testing (FIT)	Yearly	Yes	No
Fecal occult blood testing (FOBT)	Yearly	Yes	No

[a]FOBT recommended at the same time
[b]Bowel prep is still required
[c]The USPSTF rates these as "I" level recommendations as per their guidelines. There is insufficient evidence to asses for the benefits and harms of these modalities
[d]Newly FDA approved with every 3 years as the initial recommendation with limited data [32]

recommend CT colonoscopy or fecal DNA testing as there is not enough evidence regarding the benefits and harms of this practice [18].

The USPSTF recommends screening for colorectal cancer in all normal risk adults beginning at age 50 and continuing until the age of 75 (A recommendation) [18]. They recommend against routine screening in those 75–85, but this should be considered in the totality of the patients' health status including life expectancy and other comorbid conditions (C recommendation) [18]. As of this time, the USPSTF recommends against screening for CRC in any adult over the age of 85 (D recommendation) [18]. The MSTFCC agrees with the USPSTF findings, with the American College of Gastroenterology also recommending that African Americans start screening at age 45 [29]. For those individuals with increased risk of CRC, single first-degree or two second-degree relatives with a diagnosis of CRC or advanced adenoma, the MSTFCC recommends screening at 10 years before the family member was diagnosed, or by age 50 depending on which comes first [28, 29]. An advanced adenoma is considered $\geq$1 cm in size, or with villous elements or high-grade dysplasia [29]. Patients with a personal or family history of FAP/HNPCC have different evaluation schedules, and family medicine providers should consider sending these patients to gastroenterology for a consultation [29].

After the procedure is performed, the follow-up depends on the findings of the initial baseline colonoscopy, outlined in Table 3 below [27]. In those individuals with family history who have a normal initial colonoscopy, they should have continued screening every 5 years per routine instead of the normal 10 years for average risk adults [18, 27, 29]. If the polyp surveillance colonoscopy, listed in Table 3, is negative, then the MSTFCC recommends a return to the 10-year surveillance for average risk adults [18]. Diagnosis is based on pathology results and patients should be notified of their results and the appropriate follow-up interval.

Procedures

Endoscopy

The two options for endoscopy are flexible sigmoidoscopy and colonoscopy, which both can be performed by family medicine providers. Colonoscopy has a low-risk profile with a perforation being one of the most feared complications, but only happening in 0.6 per 1,000 cases [28]. The patient should be aware that perforation may require surgery, admission to the hospital, and antibiotics and, in some cases, may result in patient death. Other serious complications, most commonly bleeding requiring hospital admission or transfusion, are also rare and only occur in 25 per 1,000 cases [28]. However,

DOI 10.1007/978-1-4939-0779-3_99-1

Table 3 2012 recommendations for surveillance and screening intervals for average risk patients

Baseline colonoscopy findings	Recommended surveillance interval (years)
No polyps	10
Small (<10 mm) hyperplastic polyps in the left colon	10
1–2 small (<10 mm) tubular adenomas (TA)	5–10
3–10 tubular adenomas	3
More than 10 small TAs	<3
One or more large (≥10 mm) TA(s)	3
One or more villous adenomas	3
Adenoma with high-grade dysplasia	3
Sessile serrated (SSA) polyp(s) < 10 mm with no dysplasia	5
SSA polyp ≥10 mm, or those with dysplasia	3
Serrated polyposis syndrome	1
Piecemeal removal of a ≥10 mm TA	6 months to ensure complete removal

colonoscopy is very effective at finding polyps with miss rates of only 2.1 % for ≥10 mm polyps (85 % CI 0.3–7.3 %), 13 % for 5–10 mm polyps (95 % CI 8–18 %), and 26 % for adenomas 1–5 mm (95 % CI 27–35 %) [30]. Although the miss rates seem large for the very small polyps, the clinically significant large polyps which are more likely to become CRC have a very low miss rate [6]. Flexible sigmoidoscopy, known as "flex sig," is a shorter version of colonoscopy which only goes to the splenic flexure and must be combined with FOBT/FIT in order to have a satisfactory procedure [28]. Flex sig is technically easier to perform and requires less of a bowel prep, usually an enema, and it is usually covered by insurance plans. A positive flex sig or concurrent FOBT/FIT normally indicates recommendation for a full colonoscopy especially for high-risk polyps.

For any provider doing colonoscopy, there are specific recommended quality markers which include (1) a screening colonoscopy adenoma detection rate (ADR) >15 % for females and >25 % for males, (2) a ≥7 min withdrawal time, and (3) a 95 % cecal intubation rate for screening colonoscopies [31]. ADR is one of the best outcomes-based markers as ADR is inversely proportional with the risk of interval CRC with pooled (male and female) ADRs >28.41 % associated with a hazard risk of 0.70 of interval CRC (95 % CI 0.54–0.91) [32]. Also, even though >6 min withdrawal time is associated with a quality procedure, those providers with ≥10 min of withdrawal time is associated with a better ADR overall [31]. These metrics should be tracked in order to help with credentialing and ensure that all endoscopists are meeting their quality indicators.

Fecal Screening

Various types of fecal testing are available for primary care to include fecal occult blood testing (FOBT), fecal immunochemical testing (FIT), and fecal DNA. FOBT is highly sensitive, but not very specific, as it looks for heme in the stool when combined with hydrogen peroxide based on a peroxidase-like effect of heme [28]. There can be many false positives including diets high in red meats, medications, and non-lower GI tract bleeding. Other options include the FIT which utilizes specific antibodies to look for globin in the stool [18]. This increased specificity compared to FOBT is due to the test specifically targeting human globin and that globin is normally broken down in the small bowel as compared to heme; this decreases the amount of false positives that can be problematic with FOBT. The newest approved fecal testing is fecal DNA which tests for specific mutations as listed above in pathogenesis. This test has 92 % sensitivity for CRC detection and, like FIT, does not require special diets or medication alterations

DOI 10.1007/978-1-4939-0779-3_99-1

[32]. All of these tests are recommended to be performed as above in Table 3, and patients should be educated that these tests detect large polyps and CRC but are not an actual therapy.

Radiological Screening

Two radiological screening options include double contrast barium enema and CT colonoscopy. Both of these require some bowel preparation, have a very low risk of perforation, and are considered appropriate by MSTFCC screening recommendations [28]. Also for both tests, if 1 or more polyp >6 mm is seen on imaging, then a complete colonoscopy is recommended [28]. These tests do not have to be combined with FOBT/FIT. The double contrast barium enema uses plain film imaging where first barium is passed via a tube to the rectum and then air is passed through that same tube to improve the contrast of the image. CT colonoscopy, or virtual colonoscopy, uses air pumped into the colon as contrast and then uses 3D imaging of the colon to evaluate for CRC and large polyps. As a general rule, neither of these tests requires any significant sedation. These imaging tests can be considered in patients who do not want the sedation required for colonoscopy but want more advanced testing than fecal testing.

Overview of Colonoscopy Procedure

After appropriate informed consent has been obtained, the patient undergoes complete bowel prep the day before the procedure. This usually includes only clear liquids the day before the procedure and then use of a commercially available bowel prep which is usually provider or location dependent. As a general rule, only high-risk groups are given pre-procedure antibiotic prophylaxis which should be decided after reviewing the most up-to-date guidelines published by the American Heart Association. The patient is gowned and placed in the left lateral decubitus position. Sedation, either conscious or complete, is given for analgesic and anxiety control. The provider examines the rectum with a digital exam to evaluate for any masses and ensures that the colonoscopy can pass completely through the rectum. Using a high-definition chromographic colonoscopy, the provider inserts the scope and insufflates either air or CO2 until the lumen becomes apparent. The scope is then passed into the sigmoid colon which is one of the most difficult locations of the procedure. The sigmoid may either have adhesions from prior procedures or have diverticula disease (see Fig. 2). Maneuvers such as rightward torqueing and withdrawing of the scope may be required to reduce loops, and lower left quadrant pressure can be very helpful in splinting the colonoscope to ease movement. The colonoscope continues to be advanced until the cecum is reached and pictures are taken of the appendicle orifice and the terminal ilium. The scope is then withdrawn while maintaining direct visualization of the bowel wall and taking at a minimum 7 min to withdrawal of the colonoscope. Obtain any necessary biopsy noted, and remove any polyps seen with either forceps biopsy or snare. These biopsies and polyps should be sent to a certified pathologist for evaluation, and the colonoscopist should track these on some systems to ensure results were sent to the patient and they can

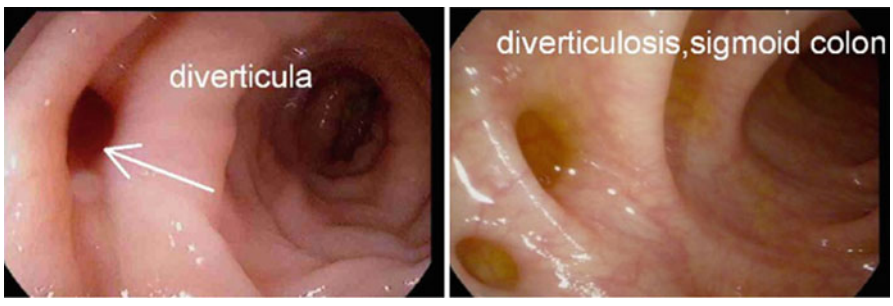

Fig. 2 Various diverticula noted in the sigmoid colon during colonoscopy

DOI 10.1007/978-1-4939-0779-3_99-1

calculate their quality markers. In the rectum, the scope should be retroflexed to evaluate the dentate line for any rectal masses [33].

Treatment

Beyond complete polyp removal during colonoscopy as possible, there are more steps required when dealing with large masses suspected to be CRC. The tumor-node-metastasis (TMN) staging system from the American Joint Committee on Cancer (AJCC) is the current standard for colorectal cancer staging [34]. This scale applies various metrics based on the primary tumor (T), regional lymph nodes affected (N), and distant metastasis (M) [34]. The TMN system is data driven, has a continuous process improvement system, has comprehensive rules to ensure uniform application, and is multidisciplinary in design [34]. Surgery is the primary modality of treatment and staging for cancers of the lower gastrointestinal tract [35]. For early stage cancers, standard resection is the only therapy required for treatment, and this can either be done laparoscopically or via open resection [35]. There are no significant differences in CRC mortality, recurrence, or number of lymph nodes harvested when comparing open versus laparoscopic resection of colorectal cancer [36]. As the stage of tumor increases, the chance of cure with surgery decreases and adjuvant therapies such as chemotherapy and radiation therapy are required to increase the probability of cure in patients with CRC [35].

Chemotherapy agents such as fluoropyrimidine/oxaliplatin are used as first-line agents in 71 % of cases by 2007 with bevacizumab being the other first-line agent option [37]. Patients who were treated in US academic centers are also more likely to receive anti-EGFR monoclonal antibodies, but this has decreased by approximately 18 % recently due to the limited use in patients with KRAS tumors [37]. Chemotherapy and surgery are also useful in metastatic non-resectable CRC as palliative agents which can improve patients' symptoms and extend survival to the point where some oncologists argue that metastatic CRC can be considered "more of a chronic illness than an acutely fatal one" [38].

Imaging has a limited role overall in the diagnosis and management of CRC. CT is recommended as the initial radiological evaluation for staging CRC to assess extent of disease and evaluate metastases to lung and/or liver [39]. Besides initial CT for staging purposes, there are a few other important imaging modalities for CRC. PET-CT is useful for postoperative recurrence of disease and evaluates extra-hepatic disease in high-risk patients [39]. MRI is the recommended methodology for patients with rectal cancer who are candidates for surgery in order to improve local T-staging and N-staging [39].

Prognosis

When found early through appropriate screening modalities, CRC overall has a very good prognosis compared to some other cancers. For all patients with CRC, the overall 5-year survival rate is 65.2 % [40]. Five-year stage-specific survival rates are listed below in Table 4 and are based on the 6th edition of the American Joint Committee on Cancer (AJCC) published in 2004 [40]. Based on the TMN stage, it is clear that tumors that invade other organs locally and/or distant metastasis carry with them a worse prognosis than localized tumors.

DOI 10.1007/978-1-4939-0779-3_99-1

Table 4 2004 American Joint Committee on Cancer (AJCC) stage specific survival rates for CRC

AJCC stage	T stage	N stage	M stage	5-year survival rate (%)
I	T1 or T2	N0	M0	93.2
IIa	T3	N0	M0	84.7
IIb	T4	N0	M0	72.2
IIIa	T1 or T2	N1	M0	83.4
IIIb	T3 or T4	N1	M0	64.1
IIIc	Any T	N2	M0	44.3
IV	Any T	Any N	M1	8.1

T1 tumor involves submucosa, *T2* tumor involves muscularis propria, *T3* tumor invades through the muscularis propria into the subserosa or into nonperitonealized pericolic tissues, *T4* tumor invades other organs or structures and/or perforates viseceral peritoneum, *N0* no regional lymph node metastasis, *N1* metastasis to one to three regional lymph nodes, *N2* metastasis to four or more regional lymph nodes, *M0* no distant metastasis, *M1* distant metastasis [40]

Prevention

The best prevention for the development of CRC is screening. As previously listed, incidence of CRC has decreased by 30 %, and survival has improved by 30 % over the last 25 years which is most likely due to improved screening and treatment with colonoscopy during the precancerous polyp stage [1, 6, 7]. Looking at the 2006 annual report on CRC addressing the impacts of screening, it has been shown that nearly half of the 30 % decrease is from screening and treatment of precancerous polyps [41]. This is one of the reasons that it is imperative to encourage screening in the patient population which is consistent with the strong recommendation from the MSTFCC and with the A level recommendation from USPSTF [18, 28]. Based on the data available, without a doubt, it can be stated that "screening for colorectal cancer saves lives" which is impressive given the multitude of other cancer screening tests that have fallen out of favor or have decreased the aggressiveness of surveillance.

Other prevention options as discussed above do not have strong recommendations. Currently, the USPSTF does not recommend ASA/NSAIDs, calcium supplementation, or vitamin D supplementation for the prevention of CRC [16–18]. There are studies that address diet and CRC, as listed above in the diet section under risk factors, and these diets can be considered for those patients who want to aggressively decrease their risk of CRC, but they are not recommended as a panacea for prevention for CRC. However, due to the other positive health considerations, a proper balanced diet should be recommended by the family medicine provider. Many studies are continually ongoing regarding these prevention factors, and all providers know that recommendations change over time.

Family and Community Issues

Outside of the support for those with CRC, one of the best things families can do is to encourage their spouses and other loved ones to get a screening colonoscopy. Although there may be a stigma associated with this test, open conversations with those patients who are old enough to get a screening colonoscopy should be performed by the family medicine doctor. For those patients who do not wish to undergo

DOI 10.1007/978-1-4939-0779-3_99-1

invasive screening, then fecal studies are appropriate. For community aspects, besides the overwhelming financial costs, support and awareness of CRC and screening options are paramount [2]. These can include options from education campaigns on various media and social media sites to ensure that all insurance plans include reasonable screening options for CRC.

Surgical Problems of the Digestive System

Brian Coleman* and Kalyanakrishnan Ramakrishnan
Department of Family and Preventive Medicine, University of Oklahoma Health Sciences Center, Oklahoma, OK, USA

Recent developments in the field of general surgery have generated significant innovations in the management of patients with abdominal pathology. Advances in imaging (FAST – focused assessment with sonography in trauma, computed tomography (CT) angiography) have enabled earlier and a more precise diagnosis to be made and minimized the role of exploratory surgeries for trauma. Minimally invasive (keyhole) and "robotic" surgeries have also provided greater precision in treatment while minimizing surgical trauma, enabling maximal postsurgical preservation of organ function and earlier patient return to normal activity. However, the cardinal surgical principles (judicious preoperative assessment, meticulous operative technique, and prevention of postoperative complications) remain unchanged.

Abdominal Pathology

The abdomen has long been considered a "Pandora's box", a cavity within which many varied and undetected pathologies may progress unchecked. Diseases of the digestive system comprised nearly eight million (6.1 %) emergency room visits in 2010; over ten million patients (8 %) sought emergency care for abdominal pain [1]. Apart from problems related to the abdomen and pelvis, pain from vertebral pathology radiating anteriorly may present with abdominal pain. Patients with cardiopulmonary diseases (pneumonia, pulmonary embolism, pneumothorax, acute coronary syndrome) may also present with upper abdominal pain, mimicking abdominal pathology. Abdominal wall pathology (Herpes Zoster, rectus sheath hematoma) and systemic diseases (diabetic ketoacidosis, porphyria, and sickle cell disease) also present with abdominal symptoms [2, 3].

Some Key Terms and Maneuvers

Abdominal pain is the cardinal-presenting symptom, and the most confounding and potentially life-threatening complaint evaluated by an emergency room or family physician. Abdominal pain may be *acute* (lasting a week or less) or *chronic*. It may also be *parietal* (sharp, well-defined and localized, and usually due to inflammation of the parietal peritoneum) or *visceral* (ill-defined, dull and gnawing pain arising from the abdominopelvic viscera often associated with parasympathetic overdrive producing bradycardia, diaphoresis, and nausea). *Referred pain*, pain experienced at a site distant from the focus of involvement, follows nerve roots subserving intra-abdominal and other (usually cutaneous) regions converging at the same levels in the spinal cord. An "*acute abdomen*" is an intra-abdominal process (inflammation, infection, following trauma) producing acute abdominal pain and other symptoms requiring urgent evaluation, hospitalization, and often surgical intervention. *Guarding* is voluntary contraction of the abdominal wall muscles in response to underlying peritoneal/visceral irritation. It may be reduced by distraction techniques such as using a stethoscope to palpate the abdomen, and by administering

*Email: brian-coleman@ouhsc.edu

DOI 10.1007/978-1-4939-0779-3_100-1

analgesics. *Rigidity* is the involuntary contraction of abdominal wall muscles that resolves only after anesthesia. "*Rebound tenderness*" is worsening of abdominal pain following sudden release of pressure of the palpating hand. It indicates peritoneal irritation. *Rebound tenderness* may also be elicited by abdominal percussion, patient coughing or jolting the bed or having the standing patient rock back on his heels [4]. Examination techniques eliciting characteristic responses as well as classic sites for referred pain will be discussed under the sections on individual abdominal pathologies.

Evaluation of Patients with Abdominal Pathology

History

Careful history and examination is crucial in diagnosing abdominal pathology. Initial history and examination should be focused to rule out life-threatening causes, which if found, mandates immediate specialist consultation for corrective action. The core symptoms of abdominal pathology are abdominal pain, nausea, vomiting, diarrhea or constipation, hematemesis/melena, dysuria/hematuria, abdominal distention, anorexia, weight loss, menstrual irregularities, and jaundice. Fever reflects inflammatory/infective states. Characteristics of abdominal pain that need to be elicited include duration, nature (colicky, persistent, burning, sharp), location, onset, intensity, radiation, migration, and provoking/relieving factors. Nausea and vomiting may follow vagal response to pain, peritoneal irritation, toxemia, or abdominal distention. Feeding often precipitates pain and emesis. Repeated retching or gastroduodenal irritation/ulceration may produce hematemesis or melena (passage of black, smelly, sticky, slimy stool). Diarrhea is a feature of irritation (infection/inflammation) involving the small or large bowel; constipation may indicate mechanical bowel obstruction or ileus. Anorexia usually accompanies significant abdominal pathology. Urinary symptoms (oliguria, dysuria, frequency, hesitancy, urgency, and hematuria) indicate genitourinary pathology. Jaundice denotes hepatobiliary or pancreatic involvement [2, 3]. Fever reflects inflammatory/infective states. Back pain may indicate retroperitoneal organ involvement (renal colic, pyelonephritis, abdominal aortic aneurysm).

History of trauma, especially prior surgery, is significant. Post-operative adhesions cause over three-fourths of all episodes of bowel obstruction. Embolism from a mural thrombus associated with atrial fibrillation and low flow states secondary to congestive heart failure may cause mesenteric ischemia and bowel infarction. Diabetic ketoacidosis (edema of the mesentery), sickle cell crises (infarction of liver, spleen, or kidney), acute intermittent porphyria (possible visceral ischemia), and renal insufficiency may all cause abdominal pain, confirming the association with cardiorespiratory and systemic illnesses [2, 5].

History of amenorrhea in women of child-bearing age may indicate pregnancy. Many features of abdominal pathology (nausea, vomiting, constipation, dysuria, pelvic/abdominal discomfort) are features of normal pregnancy. Medications (anti-arrhythmics, nonsteroidal anti-inflammatory agents – NSAIDs, steroids, beta-blockers, anticoagulants, and over-the-counter medications and supplements) often contribute to abdominal crises and interfere with assessment by causing abdominal pain, bleeding, arrhythmias, bradycardia, and hypotension. Alcohol and recreational drug use/abuse also promote or worsen abdominal pathology [6]. In evaluating infants and young children, history is obtained from the parent or caregiver; older children often provide a coherent history, though clarification should be sought from the caregiver. Menstrual and sexual histories are important in adolescents and older age-groups [7].

Abdominal pathology in elderly patients is more difficult to evaluate. Cognitive impairment and poor pain perception complicate assessment of pain. Increased intestinal transit time predisposes to constipation and ileus. Immunosenescence of B and T cells result in inadequate febrile and leukocytic response, increasing risk of infections. Decreased renal function delays clearance of medications. Chronic diseases and prior abdominal surgery, more frequent in older people, also impact pain perception and disease

DOI 10.1007/978-1-4939-0779-3_100-1

progression. Elderly patients are usually on multiple medications (beta-blockers, NSAIDs, anticoagulants, narcotics, antidepressants) all of which contribute to modify perception and progression of abdominal pathology, and influence its prognosis [6, 8].

Physical Examination

Presence of shock (hemodynamic compromise) suggests systemic sepsis, significant intra-abdominal bleeding or peritonitis. Signs of trauma (closed head injury, chest, pelvis, long bones) should be identified. Cardiorespiratory, pelvic/rectal examination, and examination of the back complement evaluating acute abdomen.

A systematic approach (inspection, auscultation, palpation, and percussion) is recommended. All hernial orifices (umbilical, inguinal femoral) and incisions should be palpated for masses (possible hernia). Presence of guarding, rigidity and rebound tenderness on abdominal palpation suggests ischemic bowel or peritonitis. Recent increase in size, tenseness, tenderness, or absent cough impulse over a hernia suggests ischemia of contents (entrapped bowel or omentum). Reexamination enables the provider to detect evolving pathology. Palpatory signs consistent with specific pathology (Murphy's sign in cholecystitis or Rovsing's sign in appendicitis) may be detected. Percussion is useful to detect free fluid, gaseous distention, and rebound tenderness. Auscultation detects abnormal bruits and borborygmi (peristaltic sounds); increased bowel sounds indicate mechanical bowel obstruction, whereas decreased or absent sounds denote adynamic ileus.

Peritoneal signs are often absent in pregnancy. Lifting and stretching of the abdominal wall prevents underlying inflamed organs from abutting and involving the parietal peritoneum, minimizing guarding. In the later stages of pregnancy women should be examined in the lateral decubitus position to palpate organs obscured by the gravid uterus. In supine patients, the right hip should be elevated slightly to avoid compressing the inferior vena cava, which may produce supine hypotension syndrome [9].

Additional Testing: Laboratory Tests

Initial tests include a complete blood count, urinalysis, and analysis of liver and kidney functions. Other specific tests reflecting inflammation/change in organ function are useful in disorders of the pancreas, and in ischemic bowel. Most acute abdominal pathology initiates an inflammatory response and also impacts the function of the involved viscera, which is reflected in changes in body fluid composition. Patient symptoms (bleeding, vomiting, diarrhea, or hematuria) also influence laboratory values. Some changes seen in acute abdominal pathology include anemia (bleeding), leukocytosis (inflammatory response), hematuria, pyuria, bacteriuria (urinary tract infection, renal trauma), elevation of blood urea nitrogen (BUN) and creatinine (dehydration, poor renal perfusion), elevation of bilirubin and liver enzymes (hemolysis, poor hepatic perfusion, biliary obstruction), elevation of amylase and lipase (pancreatic inflammation), and increased lactic acid (hypotension and shock, bowel ischemia and gangrene). Women of child-bearing age should have a pregnancy test. Cardiorespiratory pathology (pneumonia, pulmonary embolism, myocardial ischemia) presenting with abdominal symptoms need to be ruled out by thoracic imaging, measurement of cardiac enzymes, or D-dimer levels.

Age, pregnant state, medications, and preexisting disease states can affect laboratory values and their utility in diagnosis. The white cell count and alkaline phosphatase may be elevated during normal pregnancy; fever and leukocytosis may be absent in acute abdomen in the elderly [8, 9].

Additional Testing: Imaging

Ultrasonography (US) is recommended in suspected pathology of the gall bladder, spleen and pelvic organs (diagnosis of cholelithiasis and its complications, splenic trauma, ectopic gestation, pelvic inflammatory disease) – Table 1 [10]. It is also recommended in children and in pregnant women.

DOI 10.1007/978-1-4939-0779-3_100-1

Table 1 Recommended imaging studies based on location of acute abdominal pain/organ

Epigastrium	Acute abdominal series[a] (erect chest, erect and supine abdominal x-rays), CT (stomach, pancreas)
Right upper quadrant	US+, CT[b] (liver, gall bladder, hepatic flexure)
Left upper quadrant	US, CT (spleen, splenic flexure, pancreas)
Umbilicus	US, CT (pancreas, abdominal aorta, transverse colon)
Right/left lumbar	US/CT (kidney, ascending/descending colon)
Right iliac fossa	US/CT (cecum, appendix, right tube and ovary)
Left iliac fossa	US/CT (sigmoid colon, left tube and ovary)
Hypogastrium	US/CT (urinary bladder, uterus, prostate, seminal vesicles)
External genitalia (males)	US (testes, appendages)

Text from Ref. [10]
+ Ultrasonography
[a]Plain x-rays useful in detecting bowel perforation (free peritoneal air), bowel obstruction (distended bowel, air-fluid levels) and ischemic bowel (pneumatosis)
[b]Computed tomography – using oral/rectal and intravenous contrast

Table 2 Special diagnostic studies in patients presenting with an acute abdomen

FAST	Rapid, reliable, performed bedside in unstable patients. In suspected trauma to solid organs, mesentery. AAA leak
Angiography	Mesenteric ischemia, vascular abdominal emergencies (AAA leak), solid organ trauma (diagnostic and therapeutic embolization)
DPL	Bedside in unstable patients. Saline infused into peritoneal cavity and return analyzed for bowel contents, bile, blood and pus cells. Useful in detecting intraperitoneal bleeding, perforation, peritonitis
Magnetic resonance imaging	If CT contraindicated (iodine allergy, poor renal function). Useful in pregnancy
Helical (spiral) CT	Suspected pulmonary embolism, abdominal trauma
Saline/air/barium enema	In diagnosis and non-operative reduction of intussusception
Non-stress test	Detects fetal well-being. Useful in decision making regarding delivery at later stages of pregnancy at time of laparotomy

Text from Refs. [7, 9, 11]
AAA abdominal aortic aneurysm, *CT* computed tomography, *DPL* diagnostic peritoneal lavage, *FAST* focused assessment with sonography in trauma

Computed tomography (CT) has greater sensitivity and specificity for bowel (diverticulitis, appendicitis), pancreatic and retroperitoneal (kidney and abdominal aorta) pathology, and is the imaging modality of choice in suspected bowel ischemia. Magnetic resonance imaging (MRI) is useful in patients with iodine allergy or renal dysfunction, and in pregnant women. Other special and focused diagnostic tests are outlined in Table 2 [11, 12]. FAST (focused abdominal sonography in trauma) and EMBU (emergency bed-side ultrasound) are both rapid, reliable, performed bedside and do not interfere with continued resuscitation.

Limited radiation exposure (<5 rad) during pregnancy is safe; greatest fetal risk is between 8 and 15 weeks gestation. Most imaging studies in this generally young and healthy subset involves exposure well below this threshold. If considered necessary, the abdomen should be shielded during diagnostic imaging in pregnancy and patients should be counseled on risk of miscarriage, genetic disease, congenital anomalies, and growth restriction. Both US and MRI are safe during pregnancy [13].

DOI 10.1007/978-1-4939-0779-3_100-1

Children are more radiosensitive and have more opportunities to develop radiation-induced cancers (estimated as 1.5–2 % of all cancers in the United States) [7]. Hence radiation exposure should be selective and minimized in this age-group.

Preparing the Patient for Surgery

Preoperative Testing

Once the diagnosis and/or the decision to operate is made, further pre-operative testing should be based on the need to clarify and optimize the patient's physical status and monitor resuscitation and recovery. Patients who have been assessed and determined to have no preoperative indication for laboratory tests can safely undergo surgery with tests drawn only as indicated during or after surgery. Tests should be ordered only when initial evaluation would have indicated the need for the test even if surgery had not been planned.

Resuscitation

Resuscitation commences with evaluation and optimization of airway, breathing and circulation and should precede diagnostic imaging. Cerebral hypoperfusion and mental status changes increase risk of aspiration. Presence of pallor, cyanosis, mottling, prostration, hypotension and tachycardia in addition to confusion suggest sepsis and dehydration, or ongoing bleeding. Multiple studies have shown that early administration of analgesia does not interfere with subsequent ability to diagnose and treat acute abdominal pathology, nor does it impact outcome [2]. Antibiotics are not administered in stable and immunocompetent patients unless an infective source is evident or identified; immunocompromised patients require early and pre-operative broad-spectrum antibiotic administration [11]. Fluid and electrolyte imbalances due to vomiting and third-space sequestration should be corrected, any hypotension reversed, renal perfusion optimized and adequate urine output ensured prior to operative intervention, unless emergency surgery is indicated for continued bleeding or progressing sepsis. It is important to recognize need for transfusion, identify and treat life-threatening causes of acute abdominal pain and continue to monitor patients closely until recovery.

Perioperative Glucose Control

Patients with diabetes mellitus have poorer surgical outcomes, higher perioperative morbidity (coronary events, renal failure, infections) and longer postoperative hospital stays [14]. In critically ill patients requiring intensive care, a lower glycemic target (80–110 mg/dL) is recommended; a fasting glucose under 110 mg/dL and a random glucose under 180 mg/dL are considered desirable in patients less critically ill. Glucose, insulin and potassium are infused judiciously in the perioperative period to maintain these parameters. Hydration should be maintained and acidosis (ketosis), hypoglycemia and hypokalemia avoided. Oral agents are withheld on day of surgery. Pre-operative medication regime is restored in stable patients in whom oral intake is tolerated. Metformin is usually held for 48–72 h following surgery or contrast-enhanced imaging and restarted after normal renal function is re-established.

Laparoscopic Surgery

Evidence-based guidelines recommend laparoscopic surgery in patients with perforated peptic ulcer, acute cholecystitis, acute appendicitis, for adhesiolysis in patients with bowel obstruction caused by adhesions, gynecological disorders, and following abdominal trauma. Diagnostic laparoscopy is useful for assessing peritoneal intactness and avoiding laparotomy in stable patients with penetrating abdominal trauma. It is also valuable in stable patients with blunt abdominal trauma to exclude intra-abdominal

DOI 10.1007/978-1-4939-0779-3_100-1

Table 3 Etiology of acute abdominal pain in patients seeking emergency care

In children/adolescents	In adults/elderly
Acute appendicitis/cholecystitis	Acute appendicitis/cholecystitis
Small/large bowel obstruction (intussusception, volvulus, hernia, atresia, meconium ileus)	Small/large bowel obstruction, bowel perforation
Ectopic gestation	Acute pancreatitis
Twisted ovarian cyst, testicular torsion	Diverticulitis
Renal/ureteric colic	Mesenteric vascular occlusion
Pelvic inflammatory disease	Ischemic colitis
Meckel's diverticulitis	Renal/ureteric colic
	Ectopic gestation

Text from Refs. [7, 9, 11]

Table 4 Life-threatening causes of abdominal pain

Cause	Features
Ruptured abdominal aortic aneurysm	Hypotension, pulsatile abdominal mass, abdominal/low back pain. CT diagnostic
Rupture liver/spleen	Secondary to trauma, mononucleosis, rarely malaria, hematologic conditions. Abdominal pain, hypotension
Ruptured ectopic pregnancy	Amenorrhea, lower abdominal pain, hypotension
Hollow viscus perforation	Sudden severe initially localized then spreading abdominal pain, vomiting, abdominal distention, possible history of trauma including surgery and endoscopy
Intestinal ischemia/ infarction	History of CAD, atrial fibrillation. Sudden severe abdominal pain out of proportion to findings, hypotension, prostration
Myocardial infarction	Upper abdominal pain, tachycardia, hypotension, minimal abdominal findings

Text from multiple sources

injury. Laparoscopy results in decreased hospital stay, earlier return of bowel function, less postoperative pain, earlier ambulation, and less incidence of wound infection and incisional hernia. Optimal gestational age at which to perform laparoscopic surgery during pregnancy is unclear, but an upper limit of 26–28 weeks is recommended [13, 15]. Complications include visceral and vascular trauma during entry and dissection, pneumothorax, air embolism, carbon-dioxide narcosis and low cardiac output.

Etiology of Acute Abdominal Pain in Patients Seeking Emergency Care

Mid-gut volvulus, intestinal atresia and meconium ileus occur in newborns and infants; intussusception and Meckel's diverticulitis occur in infants and children; appendicitis and acute urogenital pathology are seen in children, adolescents and young adults (Table 3). Incidence of bowel obstruction, diverticulitis and consequences of atherosclerosis (aneurysm and bowel ischemia) increase with age [7, 8, 11]. Unusual causes of emergency room visits with abdominal pain in children include constipation, Henoch-Schonlein purpura, pneumonia, streptococcal infection (tonsil tummy), gastroenteritis and functional abdominal pain [7]. Both pregnancy-related causes (miscarriage, ectopic gestation, placental abruption, uterine rupture) and unrelated causes (appendicitis, cholecystitis) may cause acute abdominal pain requiring surgical intervention during pregnancy [13].

DOI 10.1007/978-1-4939-0779-3_100-1

Life-Threatening Causes

Early recognition and management of continued bleeding, bowel ischemia and infarction minimizes the high associated mortality. History of amenorrhea should be obtained from women of child-bearing age. Myocardial ischemia is a consideration in elderly patients with upper abdominal pain (Table 4).

Abdominal Trauma

Background

Abdominal trauma accounts for over one-eighth of all traumatic injuries. The majority (75 %) follow blunt trauma, mainly motor vehicle and auto-pedestrian accidents (50–75 %), and direct blows to the abdomen (15 %) [16–18]. As blunt injuries usually involve multiple organs within and outside the abdomen and pose diagnostic challenges, they have a higher mortality compared with penetrating injuries [18]. Abdominal organs are especially vulnerable to lower chest wall, back, buttock or pelvic trauma. The spleen, followed by the liver, is the most common solid organ involved; the bowel is the most common hollow viscus injured. Penetrating injuries usually involve the bowel and liver. Stab wounds to the abdomen are three times more common than gunshot wounds, though gunshot wounds account for almost all (90 %) mortality due to penetrating injuries.

Abdominal trauma, also the second leading cause of death among physically abused children, accounts for nearly 10 % of children admitted to pediatric trauma centers; most (85 %) follow blunt abdominal trauma (BAT). Children under 2 years of age are at greatest risk of abuse [17, 19]. The thin abdominal wall in children and larger proportional size of solid organs compared with adults place them at higher risk for abdominal injuries after BAT. The liver, spleen and kidney followed by the gastrointestinal tract are most commonly damaged in children [17].

Diagnosis

Patients with BAT may present a difficult diagnostic challenge. Nearly half of patients may have no localizing features on admission. History may not always be available due to associated injuries, lack of witnesses, mental status changes, and drug and alcohol use. Physical examination should comprise whole body evaluation including the cranium and cervical spine, chest, abdomen, pelvis and long bones. In penetrating injuries, entry and exit wounds should be carefully evaluated as they predict nature and extent of injury. Hypotension, most often caused by solid viscus or vascular injury has high specificity for abdominal trauma [18, 20]. Abdominal distention, guarding, rebound tenderness and rigidity, presence of a seat-belt sign, and concomitant femur fracture also have high specificity for intra-abdominal injuries [20]. However, physical examination is only 55–65 % sensitive in BAT [17].

Management

Initial management should optimize patient's airway, breathing, and circulation. Laboratory analysis should focus on documenting patient status and stability, and the need to detect and correct ongoing bleeding, fluid, electrolyte and acid–base imbalance, and renal and tissue hypoperfusion. Serial measurements help direct resuscitative efforts and monitor patient response. A complete blood count, urinalysis, a comprehensive metabolic panel (evaluating liver and kidney function), serum amylase and arterial blood gases are obtained initially. Patient is also typed and cross-matched as preparation for possible packed cell transfusions. Acidosis, hematuria and anemia have high specificities for intra-abdominal injury [20]. Adequate intravenous access (two large-bore peripheral lines or central venous access) is obtained, a nasogastric tube is inserted to decompress the proximal bowel and a Foley catheter is placed to monitor urine output.

In hemodynamically unstable patients (systolic blood pressure ≤90 mmHg) with BAT, bedside ultrasound (FAST – focused assessment with sonography in trauma), when available, should be the initial diagnostic modality performed to identify the need for emergent laparotomy [16, 21]. FAST has lower sensitivity (79 %) but higher specificity (95 %) for BAT. FAST is quick, performed bedside, identifies the presence of free fluid but not its etiology or the injury, and may be absent when performed early before enough fluid (400 mL) accumulates. Accuracy of FAST is extremely operator-dependent [16, 21].

Diagnostic peritoneal lavage (DPL) involves introducing an infra-umbilical catheter by an open, semi-open or closed technique under local anesthesia with or without conscious sedation, after decompressing the stomach and urinary bladder [22]. Aspiration of 10 mL of blood is considered positive. If none is aspirated, 1 L of normal saline or lactated Ringer's solution is infused into the peritoneal cavity, allowed to drain out and examined for red blood cells (>100,000/mm^3 considered positive), white blood cells (>500/mm^3 considered positive), amylase, bile, food particles and bacteria [22]. The presence of lavage fluid in an intercostal chest tube or Foley catheter is also documented (suggesting diaphragmatic or bladder rupture). DPL is useful in both blunt and penetrating injuries in patients with altered mental status or hemodynamic instability when FAST is not available. It is also indicated in significant trauma to other systems (thorax, cranium, pelvis, long bones) requiring surgical intervention and equivocal abdominal findings. DPL does not identify the source of bleeding or retroperitoneal injuries. Prior abdominal surgery, obesity, hepatic cirrhosis, pregnancy and coagulopathy are contraindications. It has largely been superseded by FAST in unstable patients and helical CT in stable patients.

Helical CT has both high sensitivity and specificity (97–99 %) for intra-abdominal injury though less than one-fifth of CTs are positive for trauma and fewer patients (3 %) end up requiring surgery [20]. CT is expensive, time-consuming, needs expertise for interpretation, and involves infusion of contrast and radiation, with risks of contrast-induced nephropathy and radiation-induced cancer. Clinical prediction rules have been developed to minimize its use and optimize its value. One rule consisting of seven variables (hypotension, Glasgow coma scale <14, costal margin tenderness, abdominal tenderness, femur fracture, hematuria ≥25 RBC/hpf, hematocrit <30 and chest x-ray showing rib fracture or pneumothorax) has high sensitivity; patients without any of these variables have negligible risk of intra-abdominal injury and are unlikely to benefit from abdominal CT scans [23]. CT may be performed with only intravenous contrast; ingesting oral contrast is unnecessary even when bowel injury is a concern [16].

Intravenous pyelography and cystourethrography are of value when damage to the urinary tract is suspected by the presence of lower abdominal, retroperitoneal or perineal trauma, hematuria or urinary retention. Laparoscopy is most useful for assessing penetrating injuries to the thoracoabdominal region in stable patients (especially the diaphragm). It has little value in BAT, assessing hollow viscus or retroperitoneal injuries, or evaluating the extent of injury to solid organs like the liver or spleen [18].

Surgery involves laparotomy, identifying the injury, staunching bleeding sources, repairing rents in hollow or solid viscera, excising organs injured beyond repair (spleen, kidney, bowel segments), peritoneal washout, and closing the incision either primarily or secondarily based on the degree of wound contamination and need for re-exploration. Resuscitation with fluids, packed cells and blood products are continued. Invasive monitoring and ventilation in an intensive care unit may be necessary in critically ill patients until recovery.

Appendicitis

Background

Inflammation of the appendix follows luminal obstruction by fecoliths, Peyer's patches, foreign bodies, worms, and rarely tumors (carcinoid, carcinoma). The resultant rising intraluminal pressure causes

DOI 10.1007/978-1-4939-0779-3_100-1

distention, ischemia and perforation. The parietal peritoneum, surrounding bowel and omentum attempt to localize the infection, on occasion, forming an appendicular mass. Perforation is more common among patients at extremes of age and in pregnant women.

Over 250,000 cases of appendicitis are diagnosed annually; the peak incidence occurs in the second decade of life (median age at diagnosis – 10–11 years) [24]. There is a slight male predominance (1.4:1). Appendicitis is also the most common non-obstetric surgical emergency during pregnancy.

Diagnosis: History and Examination

Classic symptoms of appendicitis (seen in <50 % of children) include dull periumbilical pain migrating to the right lower abdomen, nausea, vomiting, anorexia and low-grade fever [24]. Urinary frequency and urgency, diarrhea and tenesmus are more common in pelvic appendicitis. In adults, right lower abdominal pain and migration of pain best predict appendicitis; absence of fever or pain before vomiting greatly reduces its likelihood. Pain may shift to the right lumbar area and even to the right upper quadrant of the abdomen in the later stages of pregnancy.

Guarding and tenderness in the right lower abdomen (McBurney's sign – most specific) and rebound tenderness (elicited on palpation/percussion) predict appendicitis. The presence of the inflamed appendix causes spasm of the adjacent abdominal wall and retroperitoneal musculotendinous structures resulting in overlying rigidity, and pain on ipsilateral hip hyperextension or internal rotation (psoas sign, obturator sign). Increase in intra-abdominal pressure as in coughing reproduces pain (Dunphy's sign). Palpation of the left iliac fossa shifts the bowel and intra-colonic air producing greater pressure over the inflamed appendix, worsening the pain (Rovsing's sign). Vomiting, rectal tenderness, rebound tenderness, and fever have greater positive predictive value in children than in adults, whereas right lower quadrant tenderness is less helpful [24–26].
