Leukocytosis with a left shift and an elevated C-reactive protein (CRP) characterize appendicitis. Ultrasound shows appendiceal thickening, periappendiceal edema, increased peritoneal fluid, hypervascularity (on Doppler) and the "sonographic McBurney's sign" – tenderness in response to pressure from the US probe. CT also shows the enlarged and thickened appendix and periappendiceal stranding. If both guarding and leukocytosis (>10,000/mm^3) are present – probability of appendicitis is high (>90 %); elevated white count and C-reactive protein also increases likelihood of appendicitis (∼90 %). CT has high sensitivity and specificity (>90 %) for appendicitis. US with graded compression has slightly lower sensitivity (85–90 %) but high specificity (>90 %). Initial US, followed by CT in patients with ambiguous findings on US, minimize radiation, useful in children [7, 11, 26, 27].

Scoring systems (Alvarado, Pediatric appendicitis and Ohmann scores) incorporate several features in history, examination and laboratory tests to predict likelihood of disease. Knowledge of the pretest probability is important to maximize utility of scoring systems. When pretest probability is less, a higher score is required to rule in the diagnosis. Patients with a high likelihood of appendicitis should undergo appendectomy; those with a low probability should be discharged or treated for other pathology; those with an intermediate probability should be imaged, and based on the result of imaging, should undergo surgery, or observation until the clinical picture becomes clearer [28].

Differential Diagnosis

Inflammatory, ischemic or other pathology in the right lower abdomen (Cecal diverticulitis, ectopic gestation, mesenteric adenitis, pyelonephritis, ureteric calculus, terminal ileitis) may all mimic appendicitis.

DOI 10.1007/978-1-4939-0779-3_100-1

Treatment

Appendectomy is usually performed through a low transverse (Lanz) or the classic McBurney muscle-splitting incision. Laparoscopic appendectomy is safer and causes fewer complications; these patients have shorter post-operative stays and return to work earlier.

Antibiotic choices in appendicitis include piperacillin-tazobactam and cefoxitin, which are effective against the *E.coli*, *streptococcus* species, *anerobes* and *pseudomonas*, commonly found in appendicitis. Antibiotics are continued until features of infection resolve [24]. Whereas, a single-dose is sufficient in uncomplicated appendicitis, longer (5–7 day) courses are indicated in perforated appendicitis [24].

Wound infection, the most common complication, is minimized by intra-operative peritoneal lavage, which reduces bacterial contamination. Intra-abdominal collections (pelvic, subphrenic, right paracolic gutter) are rare, could follow ruptured appendicitis, and may need open or imaging-guided drainage. Urinary retention, urinary tract infections and pneumonia are more common in the elderly, the debilitated and the immunosuppressed. Involvement of the fallopian tubes in the inflammatory mass may cause infertility. Appendicitis during pregnancy may lead to miscarriage or pre-term labor.

Patients presenting late (after 72 h, with localized infection, appendicular mass on examination or on imaging, absent systemic sepsis and peritonitis) may be managed non-operatively with broad-spectrum antibiotics and image-guided drainage of fluid collections. Those with appendicoliths appear to have a higher likelihood of recurrent infections and merit consideration for interval appendectomy [24].

Cholelithiasis and Cholecystitis

Background

Cholelithiasis is a significant presenting problem in the adult and elderly in the United States (6.3 million men, 14.2 million women aged 20–74 years) [29]. The female predominance persists across ethnicities (non-Hispanic whites, African-Americans and Mexican-Americans), and is five-fold among 20–29 year olds, though less among older age groups. The highest incidence of cholelithiasis appears to be among North American Indians over 30 years (nearly three-fourths). Gallstones are also associated with obesity (sevenfold increase in obese women), physical inactivity, parity, rapid weight loss, lower alcohol consumption, tobacco use, diabetes mellitus, lower alcohol consumption and lower serum cholesterol [29, 30] Other contributing factors and associations include Crohn's disease, ileal resection, medications (ceftriaxone, clofibrate, estrogens, octreotide, steroids), spinal cord injuries and total parenteral nutrition [31].

Pathophysiology

Gallstones develop as a result of precipitation of cholesterol and calcium salts in supersaturated bile [32]. In addition, impaired gall bladder motility, increased biliary nucleation, presence of excess pronucleating proteins and increased mucin production appear to promote gallstone formation [33]. Gallstones are classified as either cholesterol stones (commonest, nearly 80 %) or pigment stones (usually associated with hemolytic disorders – hereditary spherocytosis, sickle cell disease). Black pigment stones containing calcium bilirubinate, form in sterile bile and are rare below 50 years of age; brown pigment stones are formed in the bile ducts and result from chronic bacterial or parasitic infection [33]. Though the majority (80 %) of patients with gallstones are asymptomatic (silent gallstones), the rest present with symptoms and complications requiring intervention.

Gallstones may cause functional dyspepsia, biliary colic, acute cholecystitis, mucocele of the gallbladder, gallbladder perforation and biliary peritonitis, choledocholithiasis, obstructive jaundice, cholangitis, acute and chronic pancreatitis and gall stone ileus. Acute cholecystitis is inflammation of the gallbladder

DOI 10.1007/978-1-4939-0779-3_100-1

wall most often (90 %) following cystic duct obstruction due to gallstones or biliary sludge; it develops in 1–3 % of patients with gallstones [30, 32]. Following cystic duct obstruction, continued mucus production causes gallbladder distention, ischemia, and release of inflammatory mediators, necrosis and perforation, either at the neck or the fundus that has the least blood supply, leading to biliary peritonitis. Secondary poly-microbial infection (*gram-negative bacilli*, *anerobes*, *enterococci*) may complicate cholecystitis and overgrowth of gas-forming bacteria (*clostridium species, E.coli*) within the gallbladder leads to emphysematous cholecystitis.

Diagnosis: History and Examination

Acute cholecystitis has a female preponderance (three-fold) and presents with a rapid onset of severe, cramping right upper abdominal (RUQ) pain initially radiating to the back, then localizing to the RUQ. Abdominal pain lasting over 6 h indicates cholecystitis and not biliary colic [31]. Low-grade fever, chills, malaise, nausea, vomiting and anorexia co-exist [30, 32]. Almost three-fourths of patients report prior episodes of biliary colic. Occasionally the pain may localize in the chest or back [31]. Though vomiting and poor oral intake may lead to oliguria and high-colored urine, orange-colored urine and clay-colored stools suggest complete biliary obstruction due to choledocholithiasis or pancreatobiliary tumors. Mirizzi syndrome refers to a gallstone impacted in the gallbladder neck or cystic duct compressing the common hepatic duct, causing varying degrees of biliary obstruction and jaundice. Elderly and immnucompromised patients may have milder symptoms.

Physical findings include low-grade fever (high fevers suggest gangrene or perforation), tachycardia, scleral icterus (more common in the elderly) and RUQ guarding and tenderness [31]. Murphy's sign (cessation of inspiration in response to pain on RUQ palpation), is characteristic of cholecystitis, has high sensitivity (97.2 %), though less reliable in the elderly [34]. The gallbladder may be palpable in up to 33 % of patients, especially those with first episodes [31]. Hypotension and mental status changes suggest sepsis, more commonly in the elderly, the debilitated and the immunosuppressed.

Diagnosis: Investigations

No single or combination of laboratory abnormalities is either sufficiently sensitive or specific for cholecystitis. Leukocytosis with bandemia, elevations of serum bilirubin, and liver enzymes are seen, though serum bilirubin levels over 4 mg/dL or elevated amylase and lipase suggest choledocholithiasis [31].

Abdominal radiographs may rarely show gallstones or biliary air and seldom help diagnose cholecystitis, but may exclude other conditions such as bowel obstruction or perforation. US is both sensitive (82 %) and specific (81 %) for cholecystitis. Sonographic Murphy's sign (RUQ tenderness induced by the US probe) has a positive predictive value over 90 % in detecting acute calculous cholecystitis. Presence of pericholecystic fluid and gallbladder wall thickening over 4 mm on US are other findings suggesting acute cholecystitis [31]. MRI has comparable sensitivity (86 %) and specificity (82 %) [35]. CT is less sensitive (75 %) than US, has higher specificity (93 %) and is more useful for ruling in or out other abdominal, especially solid organ pathology, and in detecting emphysematous cholecystitis, abscess, gallbladder perforation and peritonitis. CT and MRI findings in cholecystitis are the same as that in US. HIDA (hepatobiliary iminodiacetic acid) scan, performed after injecting technetium-labeled derivatives of iminodiacetic acid, usually visualizes the gallbladder in 30 min and the small bowel in 60 min. Non-filling of the gallbladder within 60 min in patient with acute upper abdominal pain is highly suggestive of acute cholecystitis. HIDA scan has the highest diagnostic accuracy of all imaging modalities in detecting acute cholecystitis (sensitivity 96 %, specificity 90 %) [35].

DOI 10.1007/978-1-4939-0779-3_100-1

Differential Diagnosis

This includes other inflammatory intra-abdominal or pulmonary pathologies (peptic ulcer disease, pancreatitis, appendicitis, renal colic, pyelonephritis, pneumonia, liver abscess, liver tumors and gonococcal perihepatitis) [31]. Most of these can be ruled in or out by a combination of clinical assessment, laboratory analysis and imaging.

Treatment

Treatment involves hospital admission, intravenous hydration, bowel rest, pain relief, and intravenous broad-spectrum antibiotics (ampicillin and gentamicin, ampicillin-sulbactam, piperacillin – tazobactam, a third-generation cephalosporin such as ceftriaxone, or a fluoroquinolone such as levofloxacin) [32]. Early cholecystectomy (within 24–48 h) is recommended. Earlier cholecystectomy within 12–24 h is a consideration in older patients, diabetics, and the immunosuppressed, as rapid disease progression and greater risk of complications (gangrene, emphysematous cholecystitis, empyema, or rupture) are more likely in this subset [32]. Early cholecystectomy is safe, highly successful, feasible with the laparoscope, has a low conversion rate to the open procedure, and associated with decreased hospital stay and earlier returns to usual activities [30]. Delayed cholecystectomy (4–8 weeks after the acute episode) is not recommended as it does not reduce morbidity or conversion to open cholecystectomy, and increases risk of recurrent cholecystitis in the interim [30]. Ill patients, who are poor surgical candidates, benefit from antibiotics and supportive care and a percutaneous cholecystostomy under US or CT guidance.

Laparoscopic cholecystectomy is the gold standard for uncomplicated acute cholecystitis. Open cholecystectomy is preferred in patients with complications such as pancreatitis, gallbladder perforation and peritonitis, sepsis, suspected gallbladder cancer, or cholecystoenteric fistulas. Emergency surgery, dependent functional status, male gender, worsening American Society of Anesthesiology (ASA) class (3 through 5), older age, and presence of comorbidities or laboratory abnormalities (ascites, bleeding diathesis, pneumonia, decreased serum sodium or albumin, elevated white count, BUN, alkaline phosphatase or international normalized ratio (INR) are all predictive of initial decision to perform open cholecystectomy or greater risk of conversion [36].

Acalculous Cholecystitis

Acalculous cholecystitis usually follows major trauma or surgery, resuscitation from cardiac arrest, systemic sepsis or major co-morbidities such as congestive heart failure, end-stage renal disease and cancer [37]. Delayed diagnosis, poor patient status and increased complications (gangrene, perforation and peritonitis) associated with acalculous cholecystitis escalate mortality (around 30 %). Bile stasis, gallbladder ischemia and release of multiple vasoactive and inflammatory mediators are responsible for the cellular hypoxia and mucosal injury initiating this process. Unreliable clinical features, paucity of physical signs and confusing laboratory findings, make early diagnosis a challenge. US is diagnostic – features include wall thickness $\geq$3.5 mm (sensitivity 80 %, specificity 98.5 %), gallbladder distention, sonographic Murphy sign, pericholecystic fluid, intramural gas and a "halo" indicating intramural edema. CT is more accurate (sensitivity and specificity 95 %); findings parallel that on US. HIDA scan is marginally less accurate than CT (sensitivity 80–90 %, specificity 90–100 %) [38]. Treatment includes intravenous hydration, bowel rest, broad-spectrum antibiotics as in calculous cholecystitis, and continued treatment of the primary pathology precipitating this event. Cholecystectomy (laparoscopic or open) is curative; percutaneous cholecystostomy controls the infection in most (85–90 %) patients [37].

DOI 10.1007/978-1-4939-0779-3_100-1

Special Situations

Conservative management of acute cholecystitis is recommended in pregnancy unless pancreatitis, ascending cholangitis, or common bile duct obstruction develops. Surgery is indicated in failure to respond to conservative measures. Laparoscopic cholecystectomy is the most common laparoscopic procedure during pregnancy, ideally performed in the second trimester [13].

Nearly a third of elderly patients with cholecystitis present with minimal abdominal pain and peritoneal signs, not correlating with severity of infection. Empyema of the gallbladder, gangrenous cholecystitis, biliary peritonitis, subphrenic or hepatic abscess may all occur in the elderly with minimal symptoms, no fever or elevated white counts. Emphysematous cholecystitis due to gas-producing organisms is also more common among the elderly, especially in men and diabetics [8].

Oral Dissolution of Cholelithiasis

This is an option in symptomatic patients with small ($\leq$5 mm) cholesterol stones in a functioning gallbladder and a patent cystic duct ($<$10 % of cholesterol stones), who are unfit for surgery [39]. Options include chenodeoxycholic acid and ursodeoxycholic acid administered for 6–12 months. Recurrence is seen in nearly 50 % of patients with multiple gallstones.

Inguinal Hernia

Background

A hernia is a protrusion of a viscus or tissue through an anatomical opening or an abnormal weakness in the wall of its containing cavity. Abdominal wall hernias develop in one in 20 patients; inguinal hernias comprise the majority (75 %) [40]. Other commonly occurring hernias include umbilical, paraumbilical, and incisional hernias; the rest (femoral, epigastric, spigelian, lumbar, gluteal, sciatic) are uncommon. Multiple causes predispose to the development of hernias either by increasing intra-abdominal pressure or stretching and weakening of the abdominal wall (ascites, aging, chronic cough, constipation, heavy lifting, obesity, obstructive uropathy, pregnancy, prior lower abdominal surgery, smoking, and weight loss). Existence of an anatomical defect (inguinal canal, umbilicus, femoral canal) also predisposes to its development [40–42]. Inguinal hernias have a male predominance and are more common on the right.

Anatomy

A hernia comprises of the hernial sac, the coverings of the sac and its contents. The "neck" of the sac is the narrow area usually located at its junction with the peritoneal cavity. The contents of the hernia sac can be myriad – extraperitoneal fat or omentum (omentocele), intestinal loops (enterocele), bladder diverticulum, or ovary and fallopian tube. The composition and types of hernia are outlined in Table 5.

The superficial inguinal ring is an opening in the external oblique aponeurosis just above and lateral to the pubic tubercle. The deep inguinal ring is a defect in the transversalis fascia just above the mid-point of the inguinal ligament. The inguinal canal traverses the two rings and contains the spermatic cord in men (round ligament in women), the ilioinguinal nerve, and the genital branch of the genitofemoral nerve. The inguinal canal is bounded anteriorly by the external oblique aponeurosis, posteriorly by the transversalis fascia, inferiorly by the inguinal ligament, and superiorly by the arched fibers of the conjoint tendon. Whereas in infants the two rings are adjacent and the canal is short, in adults, the canal is oblique, directed downwards and medially, running from deep to superficial. Hesselbach's triangle, which forms the floor of the inguinal canal, is bounded superiorly and laterally by the inferior epigastric vessels, medially by the rectus sheath and inferiorly by the inguinal and pectineal ligaments [40].

DOI 10.1007/978-1-4939-0779-3_100-1

Table 5 Types of hernia

Type	Nature
Reducible hernia	Hernial contents can be reduced into the peritoneal cavity usually be the patient or the surgeon (taxis). Oemntum has a doughy consistency and is difficult to reduce. Bowel loops reduce with a gurgle
Irreducible hernia	Inability to reduce hernial contents-usually due to adhesions between sac and contents or between contents. Predisposes to obstruction and strangulation. Attempts at reduction may reduce the sac with its contents
Obstructed hernia	Bowel obstruction without features of bowel ischemia
Strangulated hernia	Hernial contents become ischemic and gangrenous. May involve omentum or intestine
Sliding hernia (Hernia en glissade)	Type of inguinal hernia in which the posterior wall of the hernia sac is comprised of cecum or sigmoid colon, peritoneum and occasionally a part of the urinary bladder
Richter's hernia	Hernial sac contains only part of the bowel
Littre's hernia	Hernial sac containing a Meckel's diverticulum
Maydl's hernia	Hernial sac contains two loops of intestine with an intraperitoneal central loop that may develop ischemia
Pantaloon hernia	Inguinal hernia with indirect and direct components

Text from multiple sources

Types, Diagnosis, and Complications

Inguinal hernias pass either through the inguinal canal in their entirety (through the internal to the external ring, lateral to the Hasselbach's triangle – *indirect* – two-thirds of inguinal hernias) or through the weakened floor of the canal, through the Hasselbach's triangle (*direct*). The neck of an indirect hernia is thus lateral to the inferior epigastric vessels, whereas that of a direct hernia is medial [40].

In infants and children inguinal hernias usually result from a persistent processus vaginalis present at birth or shortly thereafter. Most children (90 %) with cryptorchidism (maldescended testis) have an associated patent processus vaginalis and may present with an asymptomatic, irreducible, or strangulated inguinal hernia. Adults usually have a more insidious presentation, though a rapid onset may be precipitated by unusual straining or exertion. Patients may complain of a pulling sensation, discomfort, pain, or a bulge in the groin that is progressing. Occasional soreness or burning along the distribution of the ilioinguinal nerve (scrotum, medial upper thigh) may be noticed. Standing, coughing, and straining makes the hernia more noticeable; hence patients are usually examined in the standing position and asked to cough or strain. The skin over the base of the scrotum can be invaginated to feel the superficial ring (*invagination test*). If the patient is asked to cough, the impulse from an indirect hernia is felt at the tip of the finger, whereas one from a direct hernia is felt at its pulp. The internal ring can be occluded by pressure after reducing the hernia (*internal ring occlusion test*); if the patient is asked to strain, an indirect hernia will remain reduced whereas a direct hernia will pouch. In the *Zieman's* technique, the index, middle, and ring fingers are placed over the deep, superficial, and femoral rings and the patient asked to cough, thereby helping to differentiate indirect, direct, inguinal, and femoral hernias. An omentocele has a doughy consistency; an enterocele gurgles on palpation and attempted reduction, and the initial portion of the reduction is more difficult. Bowel sounds can be heard on auscultation over an enterocele.

Irreducibility is diagnosed when the groin lump does not reduce spontaneously in the recumbent position, or on attempts at reduction. Patients with obstructed hernias present with features of small bowel obstruction (colicky abdominal pain, vomiting, abdominal distention, and constipation). Absent cough impulse, recent increase in size, a tense and tender swelling, and a tender distended abdomen indicate strangulation of the hernial contents (rare – 0.55 % of asymptomatic hernias followed over 4 years) [43]. Imaging studies (US, CT) are useful to confirm the diagnosis and document coexisting problems

DOI 10.1007/978-1-4939-0779-3_100-1

(cryptorchidism). Abdominal radiographs help diagnose bowel obstruction (distended bowel, air-fluid levels).

Differential Diagnosis

The differential diagnosis includes other inguinoscrotal pathology mimicking a hernia (vaginal hydrocele, spermatocele, undescended testis, an encysted hydrocele or lipoma of the spermatic cord, or a femoral hernia) [44].

Treatment

Watchful waiting is an option in patients with small hernias and minimal or no symptoms [45]. Most patients, over time, will develop discomfort enough to require surgery. In infants and children, a *herniotomy* – reduction of the hernial contents and ligation of the patent processus vaginalis (hernial sac) at the level of the deep ring – is sufficient. In adults, the posterior wall of the inguinal canal is strengthened either by approximation or imbrication using nonabsorbable sutures (*herniorrhaphy*) or by using prosthetic material (*hernioplasty*). The traditional *Bassini* repair involves approximating the conjoint tendon to the inguinal ligament. The *Shouldice* repair involves a more extensive dissection of the inguinal region to define the layers of the abdominal wall and imbricating the posterior wall of the inguinal canal using stainless steel wire or polypropylene. It is considered the best nonmesh technique for inguinal hernia repair (recurrence 3.6 %) [46]. In the "Lichtenstein tension-free hernia repair," the posterior wall is reinforced with a polypropylene mesh, placed preperitoneally and sutured in position. This acts as scaffolding in which tissue forms, further buttressing the abdominal wall, and significantly reducing the risk of recurrence (0.8 %) [46]. The *plug and patch* technique uses two layers of polypropylene mesh to plug the defect (deep ring or the posterior wall defect) followed by buttressing the posterior wall further with a polypropylene mesh. The mesh may also be placed intra- or extraperitoneally, through laparoscopy. Advantages of laparoscopy include confirming diagnosis of hernia, visualization of the defect and hernial sac, small incisions, and rapid return to work [47]. Disadvantages include need for general anesthesia and mesh, contributing to increased direct costs. Antibiotics are not indicated in elective hernia repairs.

Surgical techniques in irreducible and obstructed hernias are no different except that patients with bowel obstruction need bowel rest, nasogastric suction, and replacement of fluids and electrolytes, which is continued until return of bowel function. Strangulated hernias with ischemic contents require resection of the contents (omentum, bowel). Concomitant mesh repair increases risk of infection and rejection.

Complications

Operative complications include hemorrhage, hematoma, wound infection, and injury to the adjacent structures (bowel, bladder, spermatic cord structures, and nerves) and mesh rejection. Attention to detail and meticulous technique minimize complication. Long-term complications include recurrence (least in the Shouldice and mesh repairs), pain and infertility (injury to the vasa deferentia in bilateral hernia repairs). Over half of patients may experience some degree of pain following surgery; less after the mesh or laparoscopic procedures. Pain may follow injury to the pubic tubercle, spermatic cord, the iliohypogastric or ilioinguinal nerves, or the lateral cutaneous nerve of the thigh. Though pain improves over time, some patients may require trigger point injections, medications, or surgical neurolysis for pain relief. Chronic pain is more common after recurrent hernia repair and in patients experiencing severe pain soon after surgery [47, 48].

DOI 10.1007/978-1-4939-0779-3_100-1

Bowel Obstruction

Background

Intestinal obstruction may be divided into two types – dynamic (mechanical) obstruction of the bowel lumen with continued proximal peristalsis and progressive bowel distention and adynamic (functional) obstruction with absent or inadequate peristalsis [49]. Obstruction may involve any part of the bowel including the esophagus, stomach, small and large bowel (Table 6). Adhesions, neoplasms, and hernias account for most (>90 %) small bowel obstructions, with adhesions accounting for over three-fourths. Malignancy, volvulus, and diverticulitis cause most large bowel obstructions (>80 %) [50]. Proximal to the site of obstruction the bowel distends with air (swallowed air, luminal gas) and fluid (impaired absorption, increased secretion) leading to bowel wall edema, loss of fluids and electrolytes, and dehydration [51]. In *closed loop obstruction* (bowel obstructed both proximally and distally due to adhesions or volvulus) the intermediate segment distends rapidly, with initially venous followed by arterial occlusion that progresses rapidly to ischemia, gangrene and perforation, and supervening infection, making it a surgical emergency.

Diagnosis: History and Examination

Symptoms of bowel obstruction depend on the site of the obstruction. Patients with esophageal obstruction may present with dysphagia, odynophagia, retrosternal discomfort or pain, retching, vomiting, regurgitation, and anorexia. Patients with gastric outlet obstruction (GOO) experience upper abdominal discomfort and vomiting, anorexia, and early satiety. Associated gastritis may cause hematemesis. Fetor is common in both esophageal and GOO. Patients with small bowel obstruction (SBO) generally experience pain, vomiting, abdominal distention, and constipation, in that order, whereas those with large bowel obstruction (LBO) experience initial constipation followed by abdominal distention, pain, and vomiting (the exception is in closed loop obstructions such as cecal or sigmoid volvulus, in which patients experience severe colicky followed by persistent abdominal pain out of proportion to physical findings, abdominal distention, and vomiting) [51]. Abdominal pain is usually colicky, though it becomes persistent in the presence of ischemic bowel or peritonitis; frequency and intensity diminishes with prolonged obstruction. The vomitus is usually clear or contains altered blood in GOO, contains bile in high SBO, is yellow in low SBO, and feculent in LBO. Abdominal distention is minimal or absent in esophageal, gastric outlet and high SBO, central in low SBO, and generalized in LBO [51, 52]. Constipation may be absent initially in bowel

Table 6 Site and causes of bowel obstruction

Site of obstruction	Cause of obstruction (mechanical)	Cause of obstruction (adynamic)
Esophagus	Atresia, Zenker's diverticulum, esophageal webs, goiter, foreign body impaction (food bolus), thoracic aortic aneurysm, benign and malignant strictures, Schatzki's ring, hiatal hernia	Scleroderma, achalasia, pharyngo-esophageal dysmotility (following stroke)
Gastric	Peptic ulcer disease, bezoars, gallstones, carcinoma, caustic injury, gastric volvulus	Diabetic gastroparesis
Small bowel	Annular pancreas, superior mesenteric artery syndrome, midgut volvulus, meconium ileus, adhesions, neoplasms, hernia, strictures, gallstone ileus	Mesenteric vascular occlusion, adynamic ileus (secondary to trauma, shock, peritonitis, metabolic/electrolyte imbalance, medications)
Large bowel	Carcinoma, volvulus (sigmoid, cecal), stricture (diverticular disease, ischemic colitis, radiation), intussusception	Constipation, pseudo-obstruction (trauma, shock, peritonitis, metabolic/electrolyte imbalance, sepsis, medications)

Text from multiple sources

DOI 10.1007/978-1-4939-0779-3_100-1

obstruction due to continued peristaltic activity distal to the obstruction [52]. It may also be absent in partial bowel obstructions (adhesions, Richter's hernia), gall stone ileus, mesenteric vascular occlusion, and in ileus duplex. Continued vomiting, anorexia, and sequestration of fluid in the proximal bowel leads to dehydration, which manifests as fatigue, weakness, dizziness, and syncope.

Physical examination may reveal fever, tachycardia, hypotension, and mental status changes suggesting shock and sepsis (present in ischemic bowel or perforation). Abdominal distention, visible intestinal peristalsis, and hyperactive bowel sounds may be present. Abdominal scars indicating prior surgery is characteristic of adhesion-related obstruction. Guarding and rebound tenderness on palpation or percussion suggests ischemic bowel or peritonitis. Mass over a hernial orifice (inguinal, femoral, umbilical, incisional) is consistent with an irreducible and possibly obstructed hernia. A tense or tender hernia with a history of recent increase in size and absent cough impulse is characteristic of strangulated contents. The rectal examination shows an empty and ballooned rectum.

Investigations

Laboratory studies may show leukocytosis, hypochloremic, hypokalemic metabolic alkalosis (due to vomiting), elevated BUN, and serum creatinine (reflecting dehydration and poor renal perfusion). High white count is also a feature of peritonitis and sepsis. Elevated lactic acid and metabolic acidosis suggest gangrene, peritonitis, and sepsis [53].

Plain abdominal x-rays (low sensitivity – 66 %) may confirm both presence and level of bowel obstruction. In patients with high complete SBO there is little air in the bowel, whereas more distal obstructions produces a "stepladder" pattern of air-fluid levels within bowel loops on erect abdominal x-rays. Presence of differential air-fluid levels in the same loop of and a mean air-fluid level width of at least 25 mm is very characteristic of high-grade SBO [54]. On supine abdominal x-rays, distended jejunal (small bowel folds traversing the length of the lumen – valvulae conniventes) and ileal loops (featureless) are seen. With colonic obstruction, distended colon (haustral folds, not traversing the length of the bowel) is seen. Using contrast (barium or diatrizoate meglumine – gastrografin) to outline the bowel helps delineate the site of obstruction and the transition zone. The contrast can be ingested orally or infused into the duodenum (enteroclysis); it can also be combined with CT (CT enteroclysis – specificity 100 %; sensitivity 88 % in SBO) [54]. Oral contrast is avoided in suspected bowel ischemia or perforation. Barium, diatrizoate, or air enemas are successful in reducing intussusception in the majority of children (70–84 %) [7]. Diatrizoate, though safer than barium, does not provide mucosal detail, and its hygroscopic effect may worsen intravascular volume depletion and electrolyte imbalance.

CT has high sensitivity (90–95 %) and specificity (96 %) in identifying high-grade bowel obstruction (distended proximal and collapsed distal bowel), locates transition zone and also diagnoses volvulus, ischemia (bowel thickening, poor IV contrast filling), perforation, and gangrene (pneumatosis intestinalis, pneumoperitoneum, mesenteric fat edema, ascites) [51]. CT also helps identify those patients without initial clear indications for urgent surgery, likely to fail conservative management and benefiting from early intervention. By incorporating clinical, laboratory, and CT findings into a model (pain $\geq$4 days, guarding, C-reactive protein $\geq$75 mg/L, white cell count $\geq 10 \times 10^9$/L, ascitic fluid volume $\geq$500 mL on CT, reduced CT small bowel wall contrast enhancement), Schwenter et al. found that the risk of intestinal ischemia was 6 % in patients with score $\leq$1. Scores $\geq$3 are highly suggestive of ischemia (sensitivity 67.7 %, specificity 90.8 %) making surgery more likely to be considered in these patients [55]. Bedside US is an option in unstable patients and during pregnancy. US is extremely sensitive (98–100 %) and specific (88–100 %) in diagnosing intussusception. It is noninvasive, rapid, involves no radiation, identifies the apex of the intussusception, provides information regarding reducibility, and monitors reduction; it also identifies alternative diagnoses [7]. MRI also has both high sensitivity (95 %) and specificity (100 %) for SBO and LBO [56]. Colonoscopy is useful in confirming the diagnosis of LBO

DOI 10.1007/978-1-4939-0779-3_100-1

when in doubt, obtaining biopsies of obstructing lesions, derotating sigmoid volvulus, decompressing pseudo-obstruction, stenting strictures, and avoiding unnecessary surgery [57].

Treatment

Principles of treatment include intravenous hydration, bowel rest, bowel decompression by nasogastric suction, correction of fluid and electrolyte imbalance, ascertaining the level and cause of obstruction, and determining necessity for urgent surgery. Early surgery is required after resuscitation in patients with frank peritonitis, ischemic/necrotic bowel, closed loop obstructions, in patients with obstructed/irreducible hernias, and in patients with volvulus or intussusception not responding to endoscopic derotation or hydrostatic reduction respectively. Surgery is also indicated if conservative measures do not result in improvement (optimal duration of conservative management is controversial) and if progressive clinical instability and acidosis indicate worsening ischemia or sepsis develop. Presence of fever, leukocytosis, acidosis and hemodynamic instability, or clinical evidence of peritonitis or bowel ischemia also indicates initiation of broad-spectrum antibiotic therapy (effective against gram-negative organisms and anaerobes).

Surgery may involve laparotomy or laparoscopy, release of adhesions, segmental resection of ischemic or obstructing segments of small/large bowel, and primary anastomosis in the absence of infection or peritoneal contamination. In the presence of active peritoneal sepsis or contamination, the healthy bowel ends are sutured to the skin (jejunostomy, ileostomy, colostomy); the ends reanastomosed after patient recovery a few weeks later. Antibiotics are continued until infection resolves. Patient characteristics predicting increased postoperative morbidity (12–47 %) include older age, comorbid illness (cerebrovascular accident with neurological deficit, CHF, chronic obstructive pulmonary disease), leukopenia ($<4{,}500/mm^3$), renal dysfunction (creatinine >1.2 mg/dL), and low functional status. Wound contamination or infection and resection of bowel also predict increased postoperative morbidity [58]. Risk of death is lower (2–8 %). Advanced age, higher ASA class (≥ 3), chronic illness, treatment delay, and bowel ischemia predict higher mortality [51].

Complications of surgery include hemorrhage, wound infection, intra-abdominal collections, inadvertent trauma to bowel, nerves, vessels, ureter or solid organs (liver, spleen, kidney), recurrent obstruction, atelectasis, pneumonia, respiratory failure requiring ventilator support, urinary tract infection, and renal failure.

Prevention

Lifestyle changes including seat belt use, defensive driving, minimizing alcohol use, and avoiding recreational drug use will decrease abdominal trauma associated with motor vehicle accidents. Incidental appendectomy, though an option and generally safe, is not recommended but may have some value in women presenting with undiagnosed abdominal/pelvic pain as part of laparoscopic evaluation [59] Incidental cholecystectomy is recommended in patients prone to develop cholelithiasis and cholecystitis (hemolytic disorders, gall bladder polyps and cholesterolosis, Porcelain gallbladder and during gastric bypass surgery) [60] Maintaining ideal body weight, exercising, repairing symptomatic hernias, and meticulous operative technique and postoperative care will reduce risk of hernia-related complications and recurrence. No surgical technique has been found to reduce the risk of adhesions causing bowel obstruction significantly, though minimal manual trauma to the intra-abdominal structures, omental interposition between the abdominal wall and intra-abdominal organs, and excluding foreign materials in the peritoneal cavity (sutures) help.

Acute Diarrheal Illness

General Principles

Acute diarrheal illness is a common presenting condition in primary care with the majority of cases attributed to viral gastroenteritis. Acute gastroenteritis in children under the age of five leads to 300 deaths, over 1.5 million outpatient visits, and 200,000 hospitalizations in the USA every year [1]. Annual deaths attributed to diarrheal illness are estimated to be 2.5 million worldwide [2].

Acute diarrhea is defined as increased stool frequency as well as increased water content and volume lasting less than 14 days [3]. Viral infections are the most common etiology of acute diarrhea, with rotavirus attributing to 75–90 % of cases in children [1]. Bacterial pathogens are more likely with recent travel, foodborne illness, or immunocompromised states. The most common bacterial causes of acute diarrhea in the USA include enterohemorrhagic *E. coli*, *Clostridium difficile*, *Shigella*, *Salmonella*, and *Campylobacter* [4].

Approach to Patient

The initial approach to a patient presenting with acute diarrheal illness should include a thorough history and physical exam evaluating the following questions:

1. What is the onset, duration, and consistency of the stool (i.e., bloody, watery, bilious)?
2. Is the patient showing signs of dehydration (i.e., decreased urine output, dizziness)?
3. Has there been any recent travel?
4. Is the patient vomiting (suggestive of a viral illness or foodborne illness)?
5. Is the patient showing signs of invasive bacterial diarrhea (i.e., fever, tenesmus, and grossly bloody stool)?
6. Is the patient pregnant (pregnant women are 12 times more likely to contract listeriosis)?

Diagnosis

Diagnostic testing is not typically indicated for acute diarrheal illnesses; however, further investigation is warranted for patients with longer duration of illness, signs of dehydration, history of being immunocompromised, or historical features indicating a serious bacterial infection. Common characteristic features and management of the covered pathogens are summarized in Table 1.

Lactoferrin is the preferred test for identifying leukocytes in the stool as a marker of inflammation. Fecal leukocytes lack the sensitivity and specificity compared to lactoferrin which is >90 % and >70 %, respectively [5]. Positive occult blood in combination with lactoferrin increases the likelihood of an

DOI 10.1007/978-1-4939-0779-3_101-1

Table 1 Clinical features and management of acute diarrheal illness

Pathogen	Historical features	Symptoms	Management
Viral (*Norovirus*, *Rotavirus*)	Variable, increased risk in day care centers, group living	+/− fever, abdominal pain, nausea/vomiting	Hydration, antipyretics, antispasmodics, loperamide/Lomotil
Salmonella	Consumption of raw milk, undercooked meat, fecal-oral sexual contact	Fever, abdominal pain, +/− nausea, +/− bloody stool	Hydration, antipyretics, antispasmodics
Clostridium difficile	Hospital admission, antibiotics within past 3 months	+/− fever, +/− abdominal pain, +/− bloody stools	Metronidazole 500 mg tid x 10 days; oral vancomycin 125 mg qid x 10 days if severe
EHEC	Consumption of raw beef, seed sprouts, raw milk	No fever, abdominal pain, bloody stool	Oral/intravenous hydration

inflammatory diarrhea. Stool cultures are rather expensive and should only be reserved to use in patients with grossly bloody diarrhea, severe dehydration, history of immunosuppression, or signs of inflammatory disease [6]. Testing for *Clostridium difficile* toxins A and B is indicated in any patient that develops diarrhea after 3 days of hospitalization, during any antibiotic course or up to 3 months after an antibiotic course is discontinued. Testing for ova and parasites is indicated in patients with diarrheal illnesses exceeding 7 days along with one or more features: patients with AIDs, men who have sex with men (MSM), community waterborne outbreaks, children attending daycare, or recent travel to mountainous regions [7].

Treatment

Viral Infections

Viral gastroenteritis accounts for the majority of diarrheal illnesses with the most common causative viruses being *Rotavirus*, adenoviruses, echoviruses, and reoviruses. Ambulatory management generally involves avoidance of solid foods for the first 24–48 h and fluid replacement with oral rehydration with commercially available products (Pedialyte) or following the 2002 World Health Organization-endorsed reduced osmolarity oral rehydration solution by combining 1 l of water, six teaspoons of sugar, and half teaspoon of salt [8]. Antidiarrheal agents such as loperamide (Imodium) or diphenoxylate/atropine (Lomotil) may also be used to reduce duration of illness.

Bacterial Infections

Salmonella

Typically associated with *typhimurium* serotype, *Salmonella* induces mild enteritis associated with fever, nausea, and vomiting which is self-limited to less than 4 days duration. Management is usually supportive in nature with oral rehydration and antispasmodics. Antibiotics are not generally indicated as they will prolong the carrier status [8].

Enterohemorrhagic *Escherichia coli* (EHEC)

Typically associated with the consumption of raw produce, unpasteurized juice, and undercooked poultry or hamburger meat, EHEC may produce severe symptoms to include bloody diarrhea and multisystem organ failure in the very young or old. Also commonly known as Shiga toxin producing *E. coli* (STEC), EHEC typically is managed with supportive care and IV hydration when necessary. Antibiotics are often

DOI 10.1007/978-1-4939-0779-3_101-1

cautioned against as their use may increase risk of developing hemolytic uremic syndrome (HUS) in which the patient develops thrombocytopenia, hemolytic anemia, and renal failure [8].

Clostridium difficile

Clostridium difficile infections are commonly associated with nosocomial-induced diarrhea as well as diarrhea that develops during or soon after antibiotic exposure. *C. difficile* infection is 7–10 times more likely during any point of an antibiotic course [8]. Major complications include fulminant colitis, toxic megacolon, intestinal perforation, and even septic shock. First-line management is to stop the offending antibiotic if possible and introduce therapy with metronidazole 500 mg tid for 10 days for mild to moderate cases. Oral vancomycin 125 mg qid for 10 days is more appropriate for severe infections. Although both are effective, recurrence with *Clostridium difficile* is as high as 15–25 %. For recurrent or severe infections, fecal transplant from a healthy donor is a viable treatment strategy [9].

Prevention/ Family and Community Issues

General hygiene and hand washing can prevent the majority of diarrheal illnesses. Certain populations should avoid high-risk behaviors such as alcoholism, and people with chronic liver disease are at risk for contracting *Vibrio vulnificus* from shellfish, and pregnant women are at risk for being infected with *Listeria monocytogenes* from soft cheeses and unheated deli meats. Vaccines currently available include those to prevent *Rotavirus* in small infants and typhoid fever for travelers [3].

Ischemic Bowel Syndromes

General Principles

The colon can tolerate significantly reduced blood flow with up to 80 % of capillaries not perfusing during bowel rest without sacrificing adequate oxygen delivery [10]. Compromise of blood flow to the colon can present as an acute or chronic process and is always secondary to an underlying disease process ranging from trauma to a hypercoaguable state. Acute mesenteric ischemia is a rare but fatal condition with an incidence of only 12.9 per 100,000 person-years and a mortality rate greater than 50 % [10, 11]. The four major conditions that cause acute mesenteric ischemia include acute superior mesenteric artery (SMA) thromboembolic occlusion, mesenteric arterial thrombosis, mesenteric venous thrombosis, and nonocclusive mesenteric ischemia.

Approach to Patient

The common clinical triad of acute bowel ischemia includes severe abdominal pain out of proportion to physical exam, bowel emptying, and a source of occlusion or decreased blood flow [10]. Chronic ischemia will typically present with a history of postprandial pain (intestinal angina), fear of food, and weight loss. Prompt diagnosis requires a high index of clinical suspicion, focused history and physical exam, and prompt ordering of a high-resolution CT [11]. Common conditions associated with mesenteric ischemia include atrial fibrillation, congestive heart failure, hypovolemia, hypercoaguable states, portal hypertension, and major trauma [11].

DOI 10.1007/978-1-4939-0779-3_101-1

Diagnosis

There is no one single plasma marker sensitive enough to make an early diagnosis [10]. Significant leukocytosis may be the only initial lab abnormality with white blood cell counts often exceeding 20,000 cmm [12]. Signs of metabolic acidosis on arterial blood gas and metabolic panels are often a late finding indicating bowel infarction. Other lab markers of early bowel ischemia include elevated levels of amylase and lipase [11].

Diagnosis typically requires early ordering of abdominal CT with contrast. This allows complete evaluation of both the mesenteric arterial and venous patency. The use of mesenteric vessel angiography has diminished due to the efficiency and availability of CT scans for acute ischemia but still may have high utility in the workup of chronic mesenteric ischemia [11].

Treatment

Acute Mesenteric Ischemia

The approach to management of acute bowel ischemia relies on three essential principles: the cause of the ischemia, severity of presentation, and duration of compromised blood flow. Another key aspect in management is the availability of therapeutic procedures in interventional radiology as well as vascular surgery.

Acute SMA Occlusion

Initial treatment in stable patients includes aggressive parenteral fluid replacement, bowel decompression with nasogastric tube, and/or broad-spectrum antibiotics if sepsis is suspected. In patients with suspected bowel infarction, immediate exploratory laparotomy is warranted. Embolic obstructions require surgical embolectomy of the superior mesenteric artery as the occlusions are typically secondary to a cardiac thrombus and not amenable to thrombolysis due to the high risk of fragmentation and distal embolization [11]. Mesenteric arterial thrombosis due to chronic atherosclerotic occlusive disease of the SMA however is more amenable to endovascular techniques with stenting when possible. Despite this less-invasive approach, exploratory laparotomy may still be necessary to assess the recovery of the ischemic bowel. In more severe cases, aorto-mesenteric bypass may be necessary [11].

Acute Mesenteric Venous Thrombosis

Mesenteric venous thrombosis is best treated medically with anticoagulation using continuous infusion of unfractionated heparin and restoration of circulating blood volume with parenteral fluid replacement. Nonsurgical management has been documented to have as high as 80 % 30-day survival rate [10]. Surgical management is reserved for patients with signs of bowel infarction requiring resection of necrotic bowel [11]. Necrosis typically occurs when venous engorgement obstructs arterial blood flow. When surgery is performed, it often requires extensive removal of affected bowel, and prognosis is typically poor. Patients who do recover often undergo extensive bowel removal and subsequently suffer from short gut syndrome [11].

Nonocclusive Disease

Almost always secondary to critical illness, nonocclusive ischemia is often associated with cardiopulmonary insufficiency and treatment of septic shock. Management is limited to replenishing mesenteric

DOI 10.1007/978-1-4939-0779-3_101-1

circulation and observing for early signs of infarction. Ischemic colitis, a type of nonocclusive ischemia, typically responds to medical management with bowel rest, broad-spectrum antibiotics, and fluid replacement in up to 60 % of cases. Exploratory laparotomy is warranted with any type of nonocclusive ischemia if patients begin to develop signs of peritonitis or clinical decompensation indicating possible bowel infarction [11].

Chronic Mesenteric Ischemia

Chronic mesenteric ischemia is an uncommon condition often occurring in patients older than 60 years of age with a predilection for affecting women threefold more than men [13]. The goals of management are to resolve patient symptoms, improve nutritional status, and prevent possible infarction. When attempted, revascularization with angioplasty and possible stent placement should be as complete as possible. Stent placement is typically warranted when post-angioplasty residual stenosis is 30 % or greater, the area of involvement has a high pressure gradient, or the patient has a history of dissection with prior angioplasty attempts [13].

Prevention and Family and Community Issues

Patients at risk for developing atherosclerotic disease should be managed for maximal risk reduction with smoking cessation as well as management of hypertension and hyperlipidemia. Patients with hypercoaguable states or strong family history of hypercoaguability should be advised on risks of medications which may increase the risk of thrombosis. Any patients with the above risk factors should be made aware of the signs and symptoms of bowel ischemia and advised to seek immediate medical attention if symptoms develop.

Food Allergy

General Principles

The exact prevalence of food allergy is unknown; however, recent studies indicate that it affects anywhere from 2 to 10 % of the population with approximately 8 % of children in the USA having one food allergy, 2.4 % having multiple, and approximately 3 % having a history of severe reactions. The most common offenders are cow's milk, peanuts, and tree nuts in children while shellfish, fruits, and vegetables being the most common in adults. Although somewhat unclear, epidemiologic studies are indicating a potential rise in food allergies among children in the USA [14].

Multiple risk factors are associated with influence on food allergy development as listed in Table 2 and may provide areas of intervention to prevent food allergies. Resolution of childhood allergies to milk, eggs, wheat, and soya is common whereas allergies to peanut, tree nuts, fish, and shellfish tend to persist.

Table 2 Risk factors for food allergy

Male gender (in children)
Asian/Black ethnicity
Atopic dermatitis
Vitamin D deficiency
Reduced consumption of dietary fat
Reduced consumption of antioxidants
Obesity
Increased hygiene

DOI 10.1007/978-1-4939-0779-3_101-1

Approach to Patient

Common assessment for potential food allergies should include the following historical clinical questions:

1. What symptoms does the patient develop (urticaria versus more severe symptoms such as airway compromise)?
2. Does the patient suffer from other signs of atopic disease (eczema or asthma)?
3. Does the patient have any history of difficulty swallowing or choking with known food exposure (indicating possible underlying eosinophilic esophagitis)?
4. Does the patient suffer from an underlying metabolic disorder (lactose intolerance versus true milk allergy)?

Diagnosis

Identifying an underlying food allergy requires careful review of clinical history and familiarization with common clinical manifestations. It is also necessary to be aware of common conditions which appear similar to but are not true food allergies. Examples include gustatory rhinitis in which spicy foods induce rhinorrhea, scombroid fish poisoning where spoiled dark meat fish release histamine-like toxins, and aurico-temporal syndrome where foods that trigger salivation may also induce vasodilation in the capillaries of the lower cheek [14].

General approaches to diagnosis include elimination diets, skin prick testing, serologic IgE measurements, and oral food challenges [15]. Although commonly avoided, oral food challenges can be very beneficial as many food triggers may not be true allergies allowing for significant expansion of the affected patient's diet. There is also a low risk of severe reaction where epinephrine was required in only 2 % of in-office oral food challenges [14].

Treatment

The first-line approach to management is avoidance of the offending agent(s) and preparation to respond to allergic responses. This requires education on prehospital treatment, appropriate use of subcutaneous epinephrine, label reading, and when to seek medical attention.

Prevention/Family and Community Issues

Previous recommendations of allergen avoidance both in pregnancy and early childhood have for the most part been rescinded in general guidelines for food allergy prevention [15]. Newer studies have shown regular exposure to common allergens such as peanuts during pregnancy may actually reduce the likelihood of atopic disease [16]. Despite recommendations for exclusive breastfeeding to reduce atopic disease, there is conflicting data with one study of over 50,000 school-age children showing a greater tendency of eczema in the children who have ever breastfed [14]. Studies have also shown that delayed introduction of common food allergens is also not protective and may even increase risk of developing food allergies [14].

Table 3 Acquired conditions that may contribute to lactose malabsorption

Small bowel bacterial overgrowth (SBBO)
Infectious enteritis (giardiasis)
Celiac disease
Inflammatory bowel disease
Medications
Gastrointestinal surgery
Short bowel syndrome
Radiation enteritis

Lactose Intolerance

General Principles

Lactose is digested primarily in the small intestine where it is broken down by the enzyme lactase into glucose and galactose. In lactase-deficient individuals, lactose is passed to the colon where gut flora break it down to small-chain fatty acids and gas by-products of hydrogen, methane, and carbon dioxide. The main cause of lactose intolerance is downregulation of lactase. There is an ethnic predilection due to non-persistence of the lactase enzyme affecting 5–20 % of Caucasians, 60–80 % of East Indians, 70 % of Latinos, 70 % of African Americans, and >90 % of Southeast Asians [17]. It is also important to point out that lactase deficiency may be secondary to another acquired condition such as those listed in Table 3.

Approach to Patient

Common complaints of a patient with lactose intolerance may include diarrhea, flatulence, bloating, abdominal pain, and borborygmi. Systemic findings may include failure to thrive in children, skin disease, chronic fatigue, and rheumatologic complaints in adults [17].

Diagnosis

Lactose intolerance was recently defined by the NIH as "the onset of gastrointestinal symptoms following a blinded, single dose challenge of ingested lactose by an individual with lactose malabsorption along with absence of symptoms when the person ingests an indistinguishable placebo" [18]. Despite this recognized definition, this test is not currently performed in clinical practice. Objective testing for lactose intolerance includes duodenal biopsies, genetic testing, lactose tolerance test, and H2 breath test.

Although being the reference standard and offering the advantage of ruling out other conditions that may affect the small intestine such as celiac disease, mucosal biopsies of the duodenum hold the highest expense and are the most invasive of all other testings. Genetic testing for the -13910*T genotype which evaluates for lactase non-persistence in Caucasian patients had a high correlation with other tests for lactose malabsorption within European countries. The test however is of limited use in other ethnic groups and would have false-negative results in individuals with secondary causes for clinical lactose intolerance. The lactose tolerance test and H2 breath test are both performed after an oral challenge with a standard dose of lactose. The lactose tolerance test measures change in serum glucose while the breath test measures the hydrogen gas produced by intestinal bacteria in expired air [17].

DOI 10.1007/978-1-4939-0779-3_101-1

Treatment

General reduction of lactose intake instead of complete exclusion should be advocated as the majority of patients can tolerate a minimum of 12 g of lactose, which is equivalent to 8 oz of milk, without symptoms. Patients with symptoms in smaller amounts should bring into question the possibility of a cow's milk protein allergy. Lactase enzyme replacement is another option, but it does cause a change in flavor due to the breakdown of lactose to the much sweeter sugars glucose and galactose. Probiotics may also offer improvement in patients with concomitant IBS by altering gut flora. Tolerance may also be improved by successive increases in lactose ingestion [19].

Prevention/Family and Community Issues

Dietary education for populations at risk and adapting modified menus for broad population dietary programs such as school lunches or adult care facilities are the main modes of prevention.

Marine Poisoning

General Principles

Although more common in coastal rural communities of the Pacific with an annual incidence of 1,200 per 100,000, marine poisoning is being seen in rising numbers after consumption of imported seafood or by travelers to these areas [20]. The three major clinical syndromes that may present with neurologic sequelae include ciguatera, shellfish poisoning, and tetrodotoxin poisoning.

Approach to Patient

Key factors to identify and evaluate for in the workup of a patient with possible marine poisoning include:

1. Type of seafood consumed and timing of ingestion (reef fish associated with ciguatera and puffer fish with tetrodotoxin).
2. Severity of gastrointestinal symptoms (severe in ciguatera while mild with tetrodotoxin poisoning).
3. What are the neurologic symptoms (paresthesias more common with ciguatera while paralysis common with tetrodotoxin and shellfish poisoning)?

Diagnosis

Diagnostic tests are not clinically available in primary care settings; hence, diagnosis is based on clinical symptoms and consumption of offending marine agent within the preceding 24 h. Clinical characteristics of the most common marine poisoning syndromes are outlined in Table 4.

Treatment

As there are no clinically available antidotes, management is restricted to supportive care and mechanical ventilation when indicated [20]. Although an accepted treatment for ciguatera poisoning includes the use of IV mannitol, recent double-blinded studies have shown no significant clinical outcomes when compared to infusion of normal saline [21].

DOI 10.1007/978-1-4939-0779-3_101-1

Table 4 Common marine poisoning syndrome characteristics

Syndrome	Toxin	Source	Symptoms	Onset (hours)	Geographic origin
Puffer fish poisoning	Tetrodotoxin	Puffer fish, toadfish	Mild GI effects, descending paralysis, rapid progression to resp failure when severe	0.5–3	East Asia, China, and Japan
Ciguatera	Ciguatoxins	Reef fish	Severe GI effects, myalgia, paresthesia, ataxia, rarely fatal	3–30	All tropical areas
Paralytic shellfish poisoning	Saxitoxin and gonyautoxin	Bivalve shellfish (mussels, oysters, clams)	Descending paralysis, resp failure when severe	0.5–4	NW/NE USA, southern Chile, North Sea, Japan
Neurotoxic shellfish poisoning	Brevetoxin	Shellfish	Severe GI effects, paresthesia, "temperature reversal," vertigo	3–6	West Florida, Caribbean
Amnesic shellfish poisoning	Domoic acid (diatom algae)	Shellfish	Moderate GI effects, amnesia, CN palsies, seizures	GI <24; neuro <48	East Canada, NE and West USA

Prevention/Family and Community Issues

To prevent potentially fatal poisoning, travelers should use caution when consuming exotic seafood and consult medical travel resources and season-specific information. Shellfish harvesting is quarantined in areas of the USA and Canada at times when toxic sources such as dinoflagellates are the highest in concentration.

Botulism

General Principles

First described in the eighteenth century, botulism is a neurologic disorder induced by a gram-positive spore-forming bacterium, *Clostridium botulinum*. Contraction of the infection typically follows consumption of honey in the case of infant botulism or affected foodstuffs such as home-canned foods and fermented uncooked dishes in foodborne botulism [22].

Approach to Patient/Diagnosis

The onset of symptoms after consumption of contaminated food often occurs within 12–36 h of ingestion. Presentation can vary with an onset of gastrointestinal symptoms (nausea, vomiting, diarrhea) followed by neurologic symptoms. Neurologic complaints of blurred vision and diplopia occur first followed by findings of slurred speech, dysphonia, and difficulty swallowing. Descending paralysis is a late finding leading to compromised diaphragm and intercostal muscles inducing respiratory failure [22].

Diagnosis is based on clinical suspicion, history of ingested food source, and physical exam findings. Definitive diagnosis can be made with toxin detection in serum, stool, or gastric aspirate; however, this should not delay treatment as clinical assays for detection may take days.

DOI 10.1007/978-1-4939-0779-3_101-1

Treatment

Management of suspected clinical botulism involves supportive care to include the use of mechanical ventilation as well as administration of the heptavalent antitoxin. The toxin is targeted against free toxin molecules to prevent paralysis and has little clinical effect on already paralyzed musculature [23].

Prevention/Family and Community Issues

Widespread education for parents of infants to avoid honey consumption for the first year of life as well as education on the risks of improperly home-canned and cured items is essential. Commercial canneries take special precautions to prevent clinical botulism by heating prepared foods to high temperatures or adding acidifying agents to prevent spore formation. Spores have shown to be destroyed by heating to 121 °C for a minimum of 2.5 min [22].

Urinary Tract Infections

The Renal, Urinary, and Male Genital System

Urinary tract infections (UTI) are defined as the presence of significant numbers of pathogenic bacteria in appropriately collected urine and result in over seven million office visits with an estimated one million episodes annually of UTI-related illness requiring hospitalizations. Among children, 1 in 20 girls and 1 in 50 boys have a UTI each year [1].

Four major risk groups have been identified: school-age girls, young women in their sexually active years (including pregnancy), males with prostate obstruction, and the elderly [2]. This chapter discusses important clinical issues in the following categories: UTI in children, UTI in pregnancy, acute uncomplicated lower UTI in young women, recurrent infection in women, acute uncomplicated pyelonephritis in young women, complicated UTIs, UTIs in young men, catheter-associated UTIs, asymptomatic bacteriuria without a catheter, chronic UTI in the elderly, UTIs with spinal cord injuries, and fungal UTIs. The primary goal of UTI diagnosis and management is the prevention of long-term complications of progressive events that affect later-life morbidity or mortality.

Asymptomatic Bacteriuria

With the exception of pregnancy (see below) and prior to urologic surgery, screening for asymptomatic bacteriuria has no apparent value, and if incidentally found, treatment is not necessary.

Even among the elderly where there may be an association between asymptomatic bacteriuria and mortality, a causal link has not been demonstrated [3].

UTI in Children

For boys and girls the incidence of symptomatic infection during the first 6 months of life is similar, but after 6 months to a year it falls off rapidly for boys. Among girls, the first-year incidence is more evenly distributed through the year. During the first 3 months of life, boys are infected more often, presumably related to the uncircumcised patients' susceptibility. In neonates the prevalence is threefold higher among premature infants [4]. For girls the incidence steadily rises with a small transient increase at preschool time and then remains level until sexual activity becomes a factor. Asymptomatic bacteriuria is absent in boys until later in adult life when obstructive problems occur. In girls asymptomatic bacteriuria is present early in infancy and remains fairly constant until the late teens [5].

The primary host-related factors that lead to the development of UTI include infancy, female sex, abnormal defense mechanisms, the presence of urinary tract abnormalities, sexual activity, and lack of circumcision and instrumentation [4]. In children without urinary tract abnormalities, periurethral bacterial colonization is a risk factor for UTI [6].

Escherichia coli accounts for as much as 80 % of cases of UTI [7]. In neonates and complicated cases, *Proteus mirabilis* (mainly in boys), *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Enterobacter* species, *Staphylococcus aureus* (mainly in older children), *Streptococcus viridans*, enterococci, and *Candida albicans* should be considered [7].

Diagnosis

Urinalysis and Culture

In any febrile infant or child the differential diagnosis should include UTI. Screening by urinalysis is first line in diagnosis; however, due to its relatively low sensitivity (approximately 90 %), a negative urinalysis should be confirmed with culture. In a properly collected specimen (urethral catheterization or suprapubic aspiration in infants), a presumptive diagnosis can be made with the presence of any bacteria and five leukocytes per high-power field (hpf) [8].

Imaging Evaluation

Imaging tests should be conducted after the first episode of UTI in girls younger than 5 years, boys of any age, older sexually inactive girls with recurrent UTI, and any child with pyelonephritis [8]. Debate continues about the best radiologic approach for evaluating UTI [9]. The issue centers around the role of radionuclide scans and how these methods may replace or be used in conjunction with traditional ultrasonography (US), voiding cystourethrography (VCUG), intravenous pyelography (IVP), and spiral computer-assisted tomography (CT).

Radionuclide cystography, a method using scintigraphic imaging, gives accurate information similar to that of contrast-based VCUG, with the possible advantage of significantly less radiation exposure [10]. The scintigraphic study using 99 m-technetium dimercaptosuccinic acid (DMSA) has become a leading choice for gauging renal function and identifying renal cortical defects. The DMSA scan is a gold standard for diagnosis of acute pyelonephritis; however, it should not be used as first line due to the exposure of radiation, and it is invasive [11]. When applied at 6–12 months after cortical defects have first developed, the DMSA scan may be the best test for renal scarring. US has the obvious advantage of being a noninvasive test that is strong at ruling out obstruction. The spiral CT is the first choice

for the presence of obstructive stone disease. VCUG gives comprehensive lower tract information and allows grading the severity of reflux [9].

An imaging strategy can be summarized this way. Use renal/bladder US to look for obstruction; use a DMSA scan to identify cortical defects and assess differential function; use a VCUG to detect bladder anomalies, neurogenic defects, residual urine, and urethral abnormalities such as posterior valves, urethral strictures, and the presence of vesicoureteral reflux; and use spiral CT to determine the presence of stones [9].

Management

Early diagnosis and prompt treatment of UTI in infants and young children are crucial. With vesicoureteral reflux, or other urinary tract abnormalities, immediate treatment reduces the risk of renal scarring. In the history, inquire about the defecation pattern and physical examination should include a rectal examination to detect a large fecal reservoir as fecal impaction can obstruct urine flow [12].

Symptomatic neonates should be treated for 7–10 days with a parenteral combination of ampicillin and gentamicin. Young infants with UTI, children with clinical evidence of acute pyelonephritis, and children with upper tract infection associated with urologic abnormalities or surgical procedures can be treated with a combination of an aminoglycoside and ampicillin, or an aminoglycoside and a third- or fourth-generation cephalosporin [4]. For complicated infection, 7–14 days treatment has been recommended; for uncomplicated infection, 3–5 days is adequate [9].

For uncomplicated UTI, oral agents may include amoxicillin, trimethoprim-sulfamethoxazole, nitrofurantoin, or cephalosporins for a duration of 3–5 days. Antibiotic treatment of asymptomatic bacteriuria in children is controversial based on certain issues: there is limited evidence that renal damage is prevented or loss of function reduced; replacement of a low-virulence organism with a more virulent one may occur; and the child may experience unknown long-term side effects of antibiotics [4]. A reasonable approach with asymptomatic bacteriuria is to treat children younger than 5 years or those who have urinary tract structural abnormalities.

UTIs During Pregnancy

Pregnant women with UTIs are at greater risk of delivering infants with low birth weight, premature infants, preterm infants with low birth weight, and infants small for gestational age. In addition, the likelihood is greater for premature labor, hypertension/preeclampsia, anemia, and chorioamnionitis. There is strong evidence that UTI causes low birth weight through premature delivery rather than growth retardation [13].

The risk of pyelonephritis from antepartum asymptomatic bacteriuria may be as high as 30 %. Identification and eradication reduces this risk to less than 5 %. Antepartum bacteriuria has an estimated prevalence of 2–7 % [14].

An optimal time for screening all pregnancies is at the first prenatal visit. A urinalysis and culture should be obtained. If negative, no further cultures are necessary unless there is a history of prior UTI or the patient becomes symptomatic. If the screening culture result is 10^5 colony-forming units (CFU)/mL or higher, treatment for asymptomatic bacteriuria follows.

As in nonpregnant females, *E. coli* is the most common cause of UTI during pregnancy, accounting for more than 80 % of isolates. Other organisms include *Enterobacter* species, *Klebsiella* species, *Proteus* species, enterococci, and *Staphylococcus saprophyticus*.

The first concern regarding treatment during pregnancy is the safety of antibiotics. Considered reasonably safe are penicillins, cephalosporins and nitrofurantoin.

For asymptomatic bacteriuria, a regimen of 3–7 days is used with antibiotics chosen with safety in mind. There is little support for single-dose therapy. Pyelonephritis is managed the same as in nonpregnant females.

Acute Uncomplicated Lower UTI in Young Women

The risk for UTI is increased by sexual intercourse, delayed postcoital voiding, diaphragm and spermicidal gel, and a history of recurrent UTIs [15]. One of three types of infection can account for these infections: acute cystitis, acute urethritis, or vaginitis [3].

Cystitis pathogens include *E. coli*, *S. saprophyticus*, *Proteus* species, or *Klebsiella* species. Symptoms are abrupt in onset, severe, and usually multiple; they include dysuria, increased frequency, and urgency. Suprapubic pain and tenderness and sometimes low back pain also occur. Pyuria is usually present and occasionally hematuria.

Urethritis pathogens include *Chlamydia trachomatis*, *N. gonorrhoeae*, and herpes simplex virus. Symptoms are more likely to be gradual in onset and mild (including dysuria and possibly vaginal discharge and bleeding from a concomitant cervicitis) and include lower abdominal pain. Suspicion is raised if the patient has a new sexual partner or evidence of cervicitis on examination. Pyuria is usually present.

Vaginitis pathogens include *Candida* species, *Gardnerella*, and *Trichomonas vaginalis.* Symptoms include vaginal discharge or odor, pruritus, dyspareunia, and external dysuria without increased frequency or urgency.

With no complicating clinical factors, reasonable empiric treatment for presumed cystitis, prior to organism identification, is a 3-day regimen of any of the following: oral trimethoprim-sulfamethoxazole (TMP-SMX), ciprofloxacin, or levofloxacin. With the complicating factors of diabetes, symptoms for more than 7 days, recent UTI, use of a diaphragm, or age over 65 years, a 7-day regimen can be considered using these same antibiotics.

Recurrent Infections (Cystitis) in Women

Recurrent cystitis can be termed relapse or reinfection. Relapse is defined as a recurrence within 2 weeks of completing therapy for the same pathogen. Reinfection is defined as a recurrence more than 2 weeks after completing therapy for a different species or strain. The vast majority are due to reinfection. For relapse, efforts should be made to rule out a urologic abnormality and to treat for an extended time, such as 2–6 weeks. For two or fewer incidents of UTI per year, therapy can be started, based on symptoms, using either single-dose or 3-day therapy. For three or more UTIs per year, the relation to coitus must be considered. If the UTI is not related to coitus, a low-dose antibiotic, daily or three times weekly, is recommended. This regimen is commonly continued for 3–6 months [16]. If the recurrent UTIs are related to coitus, a single low-dose postcoital treatment may be preferable.

Acute Uncomplicated Pyelonephritis in Young Women

Uncomplicated pyelonephritis exhibits findings suggestive of upper tract parenchymal involvement including fever and flank pain. Urine culture and sensitivity should be performed in all patients with known or possible acute pyelonephritis. This process allows for alteration of empiric treatment.

Characteristic pathogens in acute uncomplicated pyelonephritis in young women include *E. coli*, *Proteus mirabilis*, *K. pneumoniae*, and *S. saprophyticus.* Outpatient management is reasonable for mild to moderate illness without nausea and vomiting. A 10–14-day regimen of the following is appropriate: oral TMP-SMX, ciprofloxacin, and levofloxacin are first line until an organism and sensitivities are available. For severe illness or possible urosepsis requiring hospitalization, the following regimen can be followed: parenteral fluoroquinolone, aminoglycoside with or without ampicillin,

extended-spectrum cephalosporin, an extended-spectrum penicillin, or a carbapenem [17].

Complicated UTIs

Clinically, a complicated UTI may present in the same way as an uncomplicated one. A complicated infection occurs in urinary tracts that have a functional, metabolic, or anatomic derangement predisposing to an infection that is more resistant to typical therapeutic measures.

Characteristic organisms present in complicated urinary tract infections include *E. coli*, *Proteus* species, *Klebsiella* species, *Pseudomonas* species, *Serratia* species, enterococci, and staphylococci. Outpatient management is reasonable for mild to moderate illness without nausea or vomiting. The most effective oral antibiotic treatment is ciprofloxacin or ofloxacin administered for 10-14 days, with ciprofloxacin or ofloxacin being first-line agents. TMP-SMX, amoxicillin, or cefpodoxime could also be used. For severe illness or possible urosepsis, hospitalization is necessary with treatment by parenteral ampicillin/gentamicin, ciprofloxacin, ofloxacin, ceftriaxone, aztreonam, ticarcillin-clavulanate, piperacillin-tazobactam, or imipenem-cilastatin. This regimen should be continued until that patient is afebrile and then may be changed to oral therapy with either TMP-SMX, ciprofloxacin, or ofloxacin for a total of 14–21 days [3].

UTIs in Younger Men

Without underlying structural urologic abnormalities, risk factors for UTIs in young men include homosexuality, lack of circumcision [18], and a sex partner colonized with uropathogens [3].

Management of symptomatic cystitis without obvious complicating factors requires a urine culture to establish the pathogen. This step establishes sensitivity and helps differentiate relapse or reinfection in the event of recurrence. Once the culture is obtained, a 7-day course of TMP-SMX, trimethoprim, or a fluoroquinolone is appropriate.

The traditional approach of undertaking a thorough post-UTI evaluation to rule out a urologic abnormality has been disputed [19, 20]. If pursued in young men who have responded to treatment, the chance of finding a urinary tract defect is low [21].

Catheter-Associated UTIs

Catheter-associated UTI (CAUTI) is the most common acquired infection in long-term-care facilities, and in the intensive care setting, 95 % of nosocomial UTIs are CAUTI [22]. The presence of an indwelling catheter for at least 3 days has been identified as a risk factor for UTI, with a 5–10 % incidence of UTI per day of catheterization, and can be a significant cause of morbidity and mortality in this population.

With short-term catheterization, *E. coli* is the most common organism, followed by *Pseudomonas aeruginosa*, *K. pneumoniae*, *Proteus mirabilis*, *Serratia marcescens*, *Citrobacter* spp., *Staphylococcus epidermidis*, and enterococci [23]. In patients with long-term indwelling catheters, infection may be due to ordinarily nonuropathogenic species such as *Providencia stuartii* or *Morganella morganii.* Yeast may become an isolated pathogen when antibiotics are in use [22, 23].

Treatment in this setting depends on the clinical presentation: baseline prevention, antimicrobials for asymptomatic bacteriuria or symptomatic lower UTI, and antimicrobials for a symptomatic (complicated) upper UTI. Prevention focuses on avoiding catheterization if possible. If catheterization is mandatory, minimize the duration and use a closed drainage system. Short-term use of silver alloy catheters in hospitalized patients reduces the incidence of symptomatic UTI and bacteremia [24]. For short-term catheterization of 3–14 days, daily prophylactic norfloxacin, ciprofloxacin, or amoxicillin has shown benefit [21]. For acquired asymptomatic bacteriuria and symptomatic lower UTI after short-term catheter use, a single dose of TMP-SMX (320–1600 mg) has been shown to be as effective as a 10-day course [25].

Chronic UTIs in the Elderly

Among males the incidence of bacteriuria essentially disappears after infancy and reappears during later adulthood as urinary obstruction due to prostate enlargement becomes prevalent. The incidence of UTI in both sexes steadily rises with age during the elderly years [5]. In addition, other age-related physiologic changes play a role in UTI development including lack of estrogen in women, diminished prostatic secretion in men [26], and altered bacterial adhesion factors in both sexes.

Whereas *E. coli* and *S. saprophyticus* are the most common cause of UTI in young adults, some significant shifts in causative organism occur with the elderly. For nursing homes, *E. coli* remains the most common causative organism with *Enterococcus* being the second most encountered in this population, and *S. saprophyticus* does not occur in this setting. Gram-positive organisms can dominate among men.

The presentation of UTIs among the elderly can be similar to that of younger patients. However, these signs and symptoms can be absent or come to attention as fever of unknown origin, altered mental status (lethargy), gastrointestinal complaints, incontinence, and respiratory symptoms [27]. Urine culture and sensitivity obtained from a catheterized specimen is preferable as the sensitivity of urinalysis is diminished in older adults.

In the elderly, antibiotics require minimal dose adjustment. Consider total body weight and renal function. Duration of treatment is similar to that in other age groups [24].

UTI in Patients with Spinal Cord Injuries

Special considerations for increased risk of UTI with spinal cord injuries include bladder overdistention, vesicoureteral reflux, high-pressure voiding, large postvoid residuals, stones in the urinary tract, and outlet obstruction [28]. Management focuses primarily on proper drainage of the bladder with intermittent catheterization reducing the risk of significant bacteriuria. Development of bacteriuria is all but certain with indwelling and suprapubic catheters. Presenting signs and symptoms have poor sensitivity and specificity, and, as such, caregivers should have a high index of suspicion. Identification of pyuria is generally considered the best indication of UTI in this group.

Fungal UTIs

Fungal UTI is most commonly caused by *Candida* and occasionally by *Cryptococcus neoformans*, *Aspergillus* species, and the endemic mycoses. Most fungal UTIs arise in the setting of urinary catheters, obstructed urinary tracts, diabetics, and those patients on antibiotic or immunosuppressive therapy.

For asymptomatic colonization with *Candida* (except following renal transplantation), no specific antifungal therapy is required. *Candida* cystitis is best treated with amphotericin B bladder instillation (50 μg/mL), systemic therapy (single-dose intravenous amphotericin B 0.3 mg/kg), or fluconazole 200 mg PO for 14 days.

Ascending pyelonephritis and *Candida* urosepsis require systemic antifungal therapy with IV amphotericin B at 0.6 mg/kg/day, duration depending on severity but in general involving a total dose of 2 g. An alternative is fluconazole at 5–10 mg/kg/day (IV or PO) [29].

Laboratory Guides and Interpretation

Pyuria

From a practical standpoint, pyuria represents readily measurable evidence of host injury. The most accurate method, or gold standard, of defining significant pyuria is the leukocyte excretion rate. There is evidence that the significant rate is 400,000 white blood cells (WBC)/h [30]. This measurement is cumbersome – hence the popularity of quicker, simpler, but less accurate screening tests. Those screening tests include microscopic

Table 1 Diagnostic information on common urine screening tests, individually and in various combinations

Screening test	Sensitivity	Specificity	Positive likelihood ratio	Negative likelihood ratio
Nitrite (present or absent)	0.5	0.95	10.00	0.53
Bacteria				
Unstained, spun (2+ on scale of 4+)	0.75	0.8	3.75	0.31
Gram stain, unspun (1/hpf)	0.8	0.85	5.33	0.24
Microscopic pyuria				
Spun (5 WBCs/hpf)	0.6	0.85	4.00	0.47
Unspun (50 WBC/mm^3)	0.65	0.9	6.50	0.39
WBCs + bacteria				
Standard spun[a]	0.66	0.99	66.00	0.34
Enhanced unspun[b]	0.85	0.98	42.50	0.15
Leukocyte esterase (present or absent)	0.2	0.95	4.00	0.84
Leukocyte esterase + nitrite	0.5	0.98	25.00	0.51
Methylene blue	0.6	0.98	30.00	0.41
Uriscreen	0.9	0.9	9.00	0.11
Bac-T-Screen	0.9	0.7	3.00	0.14
Chemstrip LN	0.9	0.7	3.00	0.14

hpf high-power field, *WBC* white blood cell count
[a]5 WBCs/hpf + any bacteria in spun urinalysis
[b]10 WBCs/mm^3 + any bacteria by Gram stain

examination of unspun urine in a counting chamber (WBC/mm^3), spun urine under a coverslip (WBC/hpf), and leukocyte esterase [31]. In general, the WBC/hpf is approximately 11 % of the WBC/cubic mm^3 [32]. Diagnostic information related to these tests is displayed in Table 1.

Bacteriuria

Urine culture is considered the gold standard for defining significant bacteriuria. All other tests are simply screening devices chosen to balance immediate, simple results with accuracy. The most common tests are direct microscopy and the dipstick (nitrite and leukocyte esterase). Commonly used screening tests with approximated diagnostic information are shown in Table 1.

Urine Culture

It is important to realize urine cultures are not 100 % sensitive or specific. The colony count that represents significant bacteriuria varies with age, sex, anatomic location of the infection, and symptoms. Colony counts of what can currently be considered as significant bacteriuria for infection are shown in Table 2.

Table 2 Suggested culture colony count thresholds for significant bacteriuria

Various clinical settings	Significant bacteriuria (CFU/mL)
Infants and children	
Voided	$\geq 10^3$
Catheter	$\geq 10^3$
Suprapubic aspirate (SPA)	$\geq 10^3$
External collection devices	$\geq 10^4$
Adult	
Midstream, clean-catch	
Female	
Asymptomatic	$\geq 10^5$
Symptomatic	$\geq 10^2$
Male	$\geq 10^3$
In-and-out (straight) catheterization	$\geq 10^2$
Chronic indwelling catheter	$\geq 10^2$
Indwelling catheter or SPA in spinal injuries	Any detectable colony count
External collection devices	$\geq 10^5$
Condom collection device in spinal injuries	$\geq 10^4$

Fluid, electrolyte, and acid–base disorders are frequently encountered in family medicine. Detecting and treating these disorders is imperative due to effects on organ perfusion [1]. These disorders present in all age-groups and various clinical settings; but those with chronic diseases are particularly vulnerable to serious complications [2, 3].

Volume Depletion

Volume depletion occurs with both actual volume loss and with relative volume loss by fluid redistribution (such as third spacing). Actual volume loss occurs through various losses: hemorrhage, the gastrointestinal (GI) tract (i.e., poor intake, vomiting, diarrhea), kidneys (urination), and evaporation (through sweating and breathing). Relative volume loss results in decreased intravascular volume without a decrease of total fluid in the body. Whether actual or relative, volume depletion results in decreased "effective circulating volume" (ECV) causing a cascade of multiple compensatory mechanisms. In response to a decreased ECV, cardiac and cerebral blood flow is compromised. Accordingly cardiac and arterial baroreceptors sense the change in mean arterial pressure. This drop in mean arterial pressure triggers a norepinephrine-induced increase in heart rate and heart contractility with peripheral arterial vasoconstriction. Concurrently decreased renal blood flow due to decreased ECV triggers

Family medicine (Taylor). New York: Springer; 2003)

antidiuretic hormone (ADH) release and activates the renin-angiotensin-aldosterone system (RAAS). Once activated, renal sodium is retained and vasoconstriction further promoted. ADH secretion contributes to vasoconstriction and decreased renal water clearance in an attempt to restore the ECV. Intrarenal prostaglandins are released with ADH stimulation and activation of RAAS. These prostaglandins blunt the hypovolemia-induced vasoconstriction in the renal vasculature, thereby disproportionately preserving renal blood flow and glomerular filtration. This physiological response to volume depletion is illustrated in Fig. 1. These vasoconstrictor mechanisms are triggered by volume depletion to protect cardiac and cerebral blood flow. Use of nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme inhibitors (ACE-I) may diminish this renoprotective response [4–6].

Determining true volume status can be challenging even for an experienced physician. Accurate volume status can be especially difficult with the young, elderly, or disoriented patient. Clinically, volume depletion can manifest with low blood pressure, palpitations, dizziness, decreased urine output, and lightheadedness. Objective findings in volume depletion include resting tachycardia, orthostatic hypotension, resting hypotension, however some patients with hypovolemia may not exhibit abnormal vital signs. Chronic hypotension manifests more subtle findings such as general malaise, weakness, anorexia, and mental status changes. Volume status is also difficult when patients appear fluid overloaded (e.g., congestive heart failure [CHF], cirrhosis, and nephrosis) due to excessive renal sodium and water conservation that drives volume disproportionately to the interstitial fluid space

which is known as third spacing. Third spacing refers to the interstitial space between skin and fascia that is not normally perfused with fluids. Third spacing can occur with increased fluid volume (fluid replacement, renal dysfunction), increased capillary hydrostatic pressure (CHF), decreased sodium level (due to sodium loss), lowered albumin (malnutrition, liver disease, protein-losing enteropathy), increased capillary permeability (burns, trauma, disseminated intravascular coagulation, infections), or lymphatic obstruction (iatrogenic removal). Regardless of the cause, third spacing results in decreased intravascular volume. Physical exam findings can be varied due to differing etiologies, however edema is generally present.

Laboratory data can help determine fluid status such as serum osmolality (SOSM), blood urea nitrogen (BUN), urine osmolality (UOSM), and urine specific gravity. With volume depletion the urine specific gravity and UOSM are high (i.e., >1.015 and >350 mOsm/kg, respectively) as a result of ADH-induced renal water conservation leading to concentrated urine. In volume-depleted states, renal hypoperfusion results in prerenal azotemia and functional or nonintrinsic acute renal failure causing BUN to be retained such that the normal 10:1 BUN/creatinine ratio is elevated (e.g., to >20:1). When volume loss is due to hemorrhage, a hematocrit/hemoglobin can be low, however concentration can occur with significant third spacing. Generally with hypovolemia, an increased SOSM, increased serum sodium, and corresponding decreased urine sodium (UNa) is seen, however inappropriate responses can be seen with certain comorbidities.

Volume depletion is treated according to the clinical situation and etiology. Treatment for mild volume depletion occurs with slow restoration of the ECV such as using oral electrolyte solutions. Treatment escalates to infusion of isotonic fluid in more severe settings. In addition to replacing excess fluid loss, volume repletion must also include the replacement of daily obligate fluid losses. The rate of volume replacement depends on the clinical situation. Restoration of ECV results in normalization of postural blood pressure, pulse changes, and urinary excretion of sodium [5]. Once the volume status has been restored, treatment can be directed to restoring electrolyte loss and imbalances.

Volume Excess

Volume excess, or hypervolemia can be caused by excessive fluid intake, excessive sodium intake, chronic hepatic or renal failure, steroid therapy, transfusion reaction, decreased cardiac output, head injury, medications, malnutrition, and mineralocorticoid excess. Volume overload can also be caused by decreased ECV, as discussed previously, which results in renal sodium and water conservation and edema formation (e.g., hypoalbuminemia and left ventricular dysfunction).

Total body volume excess caused by decreased ECV and edema formation may cause symptoms of vital organ hypoperfusion (e.g., syncope, unstable angina, decreased urine output, mental status changes). Depending on the etiology of volume excess, physical findings of CHF, hepatic cirrhosis, and nephrosis might be present. Weight gain may reflect the quantity of the volume retention, and monitoring weight gain can be clinically useful. Evidence of edema may be found in the lower extremities in an ambulatory patient but may be more evident in the presacral area in a recumbent patient. Volume excess may present as pulmonary edema, elevated jugular venous pressure, or prolonged hepatojugular reflux in CHF. Additionally, volume excess may not be readily evident on clinical exam as in a patient with bowel wall edema [7]. Hypervolemia associated with increased ECV causes urine sodium (UNa) wasting (UNa >20 mEq/L) and no excessive water retention (assuming normal osmolality).

Treating volume excess caused by decreased ECV involves increasing cardiac output in heart failure patients and restoring intravascular oncotic forces in patients with cirrhosis and hypoalbuminemia. Removal of some edema by diuretics may be required, typically in the form of intravenous furosemide, especially if the retained fluid compromises ventilation. When third-spaced fluid is significant it should be removed with caution, as removal of large

amounts can cause rapid reaccumulations extracted from the circulating volume, resulting in hypotension. With states of aldosterone excess, an aldosterone antagonist (i.e., spironolactone, eplerenone) is used to decrease sodium reabsorption and edema, but ideally the source of the hyperaldosteronism is removed. In renal failure, diuresis with potent loop diuretics may be required to remove excess volume that may be causing renal hypoperfusion. Careful and deliberate diuresis is very important in CHF.

Sodium Disorders

Appreciating a patient's fluid status is crucial when disorders of sodium concentration are present. Hyponatremia ($[Na^+]$ <135 mEq/L) and hypernatremia ($[Na^+]$ >145 mEq/L) should be approached in terms of free water level status. A firm understanding of tonicity is required when approaching sodium disorders.

Tonicity is the measure of the osmotic pressure gradient between the intracellular fluid compartment (ICF) and extracellular compartment (ECF). Tonicity is affected only by solutes that cannot cross the membrane (cellular membrane) while osmolality is the property of a particular solution. These compartmentalized solutes create an osmotic gradient across the cell membrane [8]. In effective plasma osmolality, which is typically normal within the range of 275–300 mOsm/kg H_2O, only solutes that predominantly do not pass between the ECF and ICF contribute to creating osmotic gradients and effecting flow of water between the ECF and ICF. Sodium is a major plasma solute, and therefore when evaluating hyponatremia, the osmolality should be evaluated.

The plasma osmolality (POSM) is the total osmolality of the solutes in the plasma and can be calculated as

$$P_{\text{osm}} = 2[\text{Na}^+] + \frac{[\text{glucose}]}{18} + \frac{[\text{BUN}]}{2.8}$$

Calculating the effective POSM can be helpful and when different from measured (osmolality gap) can indicate the presence of ethanol, methanol, isopropanol, ethylene glycol, propylene glycone, or acetone. Therefore, evaluating plasma osmolality, effective and measured, would be the first step when approaching sodium disorders. Determining osmolality is also needed when approaching metabolic acidosis disorders which will be discussed later.

Hyponatremia

Hyponatremia (Table 2) and hypoosmolality (i.e., plasma osmolality <275 mOsm/kg) indicate excess water content relative to sodium caused by renal retention of ingested water such as hypovolemic-induced ADH release, SIADH, and excess water ingestion greater than renal free water clearance. Hyponatremia occurs without hypoosmolality (i.e., pseudohyponatremia) in the presence of hyperproteinemia and hyperlipidemia. Pseudohyponatremia can occur with severe hyperlipidemia (hypercholesterolemia and hypertriglyceridemia) and hyperproteinemia (such as multiple myeloma), causing relatively lower proportions of sodium in plasma but maintaining normal osmolality and tonicity between 275 and 300 mOsm/kg H_2O [9–11].

Hyperglycemia is discussed more completely in chapter "▶ Diabetes Mellitus"; however, it is also important to consider its impact on fluid and electrolyte abnormalities. In states where serum glucose is highly elevated, fluid shifts can be profound and electrolyte imbalance substantial. Excessive hyperglycemia obligates large amounts of additional water to extracellular spaces by osmotic-induced intracellular water loss (i.e., cellular dehydration). When evaluating hyperglycemia, the correct sodium should be calculated.

Corrected sodium = Measured sodium + 0.024 × (serum glucose – 100) [12]

Hyperglycemia causes an osmotic diuresis leading both to salt and water losses, total body volume depletion, or decreased renal perfusion. As kidney perfusion decreases, renal ability to excrete glucose is impaired further contributing to hyperglycemia. The hyperglycemic diuresis contributes to total body potassium losses through

urine, though overt hypokalemia may not be evident until fluid loss is replaced and insulin given. Potassium deficits can inhibit cellular glucose uptake and cause cardiac dysrhythmias.

Volume repletion is paramount in treating hyperglycemic episodes and leads to decrease in serum glucose and improved glomerular filtration rate. Isotonic saline is initially preferred, attending to possible hemodynamic instability, and should be started at 15–20 mL/kg/h decreasing to 4–14 mL/kg/h once patient has stabilized [13]. In hyperosmolar hyperglycemic nonketotic syndrome, insulin is a required therapy, though it should not be given until fluid resuscitation is initiated since insulin drives glucose, potassium, and water into cells potentially causing vascular collapse. In diabetic ketoacidosis, higher doses of insulin via continuous infusion are usually required. In order to avoid cerebral edema, fluid should be switched to 0.45 % normal saline when sodium is greater than 135 mmol/L with 5 % dextrose added once plasma glucose is 200 mmol/L [14].

Hypernatremia (see Fig. 3) and hyperosmolality (i.e., plasma osmolality >300 mOsm/kg) reflect a water deficit relative to sodium caused by excess water loss, decreased water intake, decreased water retention, or excess intake of sodium salts.

Understanding osmolality and tonicity is crucial to understanding hyponatremia (Fig. 2), which is the most common occurring electrolyte abnormality [15]. Clinically, hyponatremia can be further categorized by determining volume status [16]; there are three types of hyponatremia: hypovolemic, euvolemic, and hypervolemic. Common causes for hyponatremia are shown in Table 1.

Low-volume hyponatremia occurs in relation of solute to total body water, and sodium loss is mediated either by the kidneys or via extrarenal loss of sodium with water retention [8]. UNa concentration can be a helpful measure of these mechanisms as UNa >20 mmol/L represents sodium loss mediated by the kidneys [17]. In hypovolemic hyponatremia, ingested free

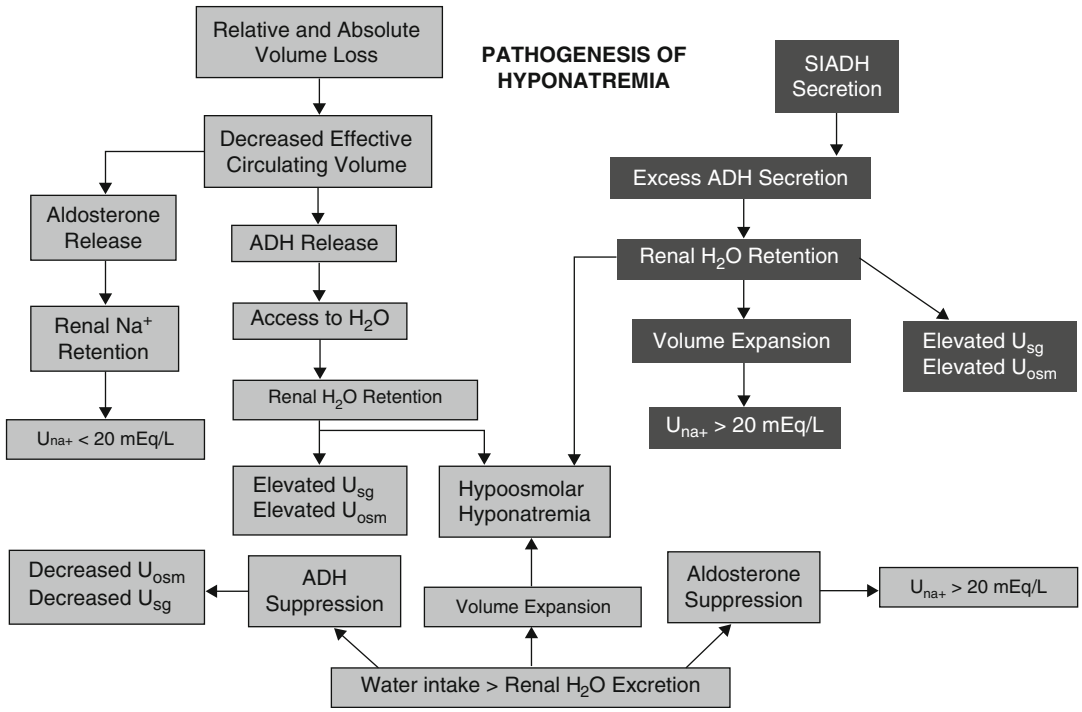

Fig. 2 Pathogenesis of hyponatremia. U_{Na} urine sodium concentration, U_{osm} urine osmolality, U_{sg} urine specific gravity, *ADH* antidiuretic hormone, *SIADH* syndrome of inappropriate ADH secretion (Originally appeared in: Taylor R, David A, Fields S, Phillips M, Scherger J, editors. Family medicine (Taylor). New York: Springer; 2003)

Table 1 Main causes of hyponatremia

Hypovolemic states	Euvolemic states	Hypervolemic states
Osmotic (e.g., glucosuria, bicarbonaturia, ketonuria)	Hypothyroidism	Congestive heart failure
Diuretics	SIADH (see Table 2)	Renal failure
Mineralocorticoid deficiency	Severe pain and/or stress	Cirrhosis
Salt losing nephropathies	Glucocorticoid deficiency	Nephrosis
Cerebral salt wasting	Primary polydipsia	Decreased vascular integrity (e.g., sepsis, anaphylaxis)
GI volume losses (e.g., diarrhea, vomiting)	Beer potomonia	Acute or chroni renal failure
Sweat losses	Dilute formula intake	
Third-space sequestration	Dilute tube-feeding	

References used: [1, 17, 36]
ADH antidiuretic hormone, *GI* gastrointestinal, *SIADH* syndrome of inappropriate secretion of ADH, *ECV* effective circulating volume, UNa urine sodium concentration

water is retained because of the nonosmotic (i.e., hypovolemia-induced vasoconstriction) presence of ADH acting in the distal convoluted tubule and collecting duct [18–21]. With hypovolemic hyponatremia from diuretic use, most commonly thiazide diuretics, the dilutional mechanism in the tubules is inhibited, but UNa concentration is not [21–25]. Thiazide-induced hyponatremia is more common in elderly women than men [26, 27]. Mineralocorticoid deficiency from adrenal gland destruction or inherited deficiencies leads to renal sodium wasting, causing a hypovolemic state and activating vasopressin to further concentrate urine sodium. Elevated serum potassium with hypovolemic hyponatremia should lead to further investigation of mineralocorticoid insufficiency. Cerebral salt wasting is another cause of hypovolemic hyponatremia. After neurological surgery or head injury, a baroreceptor-mediated vasopressin release is activated by urine sodium and chloride loss, though etiology of this process is not well established. Chronic use of proton pump inhibitor-induced hyponatremia is increasingly being elucidated in literature and adds further concerns to long-term proton-pump inhibitors (PPI) use [28]. The PPI-mediated hyponatremia mechanism is unclear but likely related to SIADH or sodium-losing nephropathy [29]. Extrarenal losses leading to hypovolemic hyponatremia include GI losses (i.e., vomiting and diarrhea) and third-space sequestration (i.e., bowel obstruction, pancreatitis, peritonitis, ascites, massive tissue injury, venous congestion). Urine sodium concentrations in these causes are usually <20 mEq/L.

Euvolemic hyponatremia can be thought of as dilutional hyponatremia and is related to fluid intake above the kidneys' ability to excrete water (Table 1, Fig. 2) [15, 30]. SIADH is the most common form of euvolemic hyponatremia and occurs when excess ADH is secreted in the absence of volume or osmotic stimuli, resulting in water excess and hyponatremia caused by a variety of disorders including central nervous system and pulmonary diseases (Table 2). Euvolemic hyponatremia can occur in exercise-associated hyponatremia. Interestingly, long-distance running athletes who consumed excessive amounts of water during competition in conjunction with ADH-stimulatory effects of exercise intensity and duration led to hyponatremia [35]. Primary polydipsia [30] (i.e., ingestion of large quantities of water 10–15 L in 24 h) leads to hyponatremia since intake exceeds the kidneys' ability to excrete free water.

Diseases that increase ECF volume through elevated ADH and frequently reduced glomulelar filtration rate (GFR) (e.g., CHF, cirrhosis, nephrotic syndrome, severe renal insufficiency) can lead to hypervolemic hyponatremia [36, 37].

Table 2 Causes of syndrome of inappropriate antidiuretic hormone secretion

Central nervous system disorders causing increased hypothalamic production of antidiuretic hormone
Infections (e.g., meningitis, HIV infection)
Vascular problems (e.g., subdural hemorrhage)
Primary and metastatic cancers
Psychosis
Post pituitary surgery
Hypothalamic infiltrative disease (e.g., sarcoidosis)
Others (e.g., Guillain-Barré syndrome)
Pharmacologic agents
Stimulants of hypothalamic antidiuretic hormone secretion- Haloperidol, Amitriptyline, Thioridazine, Thiothixene, Carbamazepine, Fluoxetine and sertraline, Monoamine oxidase inhibitors, and others
Potentiators of antidiuretic hormone effect- Chlorpropamide, Tolbutamide, Carbamazepine
Exogenous antidiuretic hormone preparations- Vasopressin, Oxytocin
Pulmonary disorders causing increased antidiuretic hormone production
Pneumonias
Tuberculosis
Acute respiratory failure
Others (e.g., asthma, pneumothorax)
Ectopic production of antidiuretic hormone (e.g., bronchogenic carcinoma, oat cell carcinoma of the lung, pancreatic carcinoma)
Pancreatic carcinoma
Prolactinoma
Others
Postoperative patient
Severe nausea

Adapted from: [1, 31–34]

ADH secretion increases in left heart function and decreases due to baroreceptor mechanisms. [37] Low levels of circulating protein in both cirrhosis and nephrotic syndrome lead to hyponatremia through an ultimate decrease in intravascular volume, leading to release of ADH. Edematous causes of hyponatremia from aforementioned conditions are associated with weight gain and edema formation.

Hyponatremia-related symptoms vary depending on the cause of hyponatremia. Patients may be asymptomatic depending on the cause or present with confusion, weakness, irritability, nausea, vomiting, postural dizziness, syncope, and falls, with seizures and coma less common. [38] Symptoms are usually present when serum sodium approaches <120 mEq/L. In severe hyponatremia, neurological symptoms may include seizures and coma. The severity of symptoms depends not only on the level but the rapidity of decline. Patients who develop hyponatremia over time may remain asymptomatic at relatively lower levels of plasma sodium concentration because of brain cell adaptation to hypoosmolality [39].

Treatment of hyponatremia is dependent on the expected cause. In hypoosmolar hyponatremia from volume loss, sodium replacement should almost always be with oral or intravenous isotonic volume repletion. In patients with neurological symptoms or plasma sodium <110 mEq/L infusion of hypertonic saline with free water fluid restriction are often both required. Physicians comfortable with intensive or emergent medicine should direct this treatment. Goal of treatment in these cases is to restore ECV and normalize plasma osmolality. For patients with hyponatremia caused by SIADH and those with severe renal failure, re-equilibrating plasma osmolality is done via fluid restriction. Identifying and removing the source of SIADH secretion is also key. Plasma sodium concentration correction for asymptomatic patients with SIADH should be increased at a rate of 0.5 mEq/L/h until a level of 120 mEq/L is reached; however, more rapid sodium correction might be necessary for those patients with severe neurological symptoms (1.0–1.5 mEq/L/h for the first 10 mEq/L elevation in the plasma sodium concentration). Avoiding excessively rapid correction of hyponatremia decreases the possibility of potentially devastating central pontine demyelinization [40–49]. With hypervolemic hyponatremia, focus of therapy is on restoring ECV by improving ventricular dysfunction in patients with CHF and increasing oncotic pressures in those with nephrosis and cirrhosis. Tolvaptan, a V_2 receptor antagonist, has been approved for treatment of euvolemic and hypervolemic hyponatremia for serum sodium <125 mEq/L or hyponatremia resistant to fluid restriction. This therapy must be done in

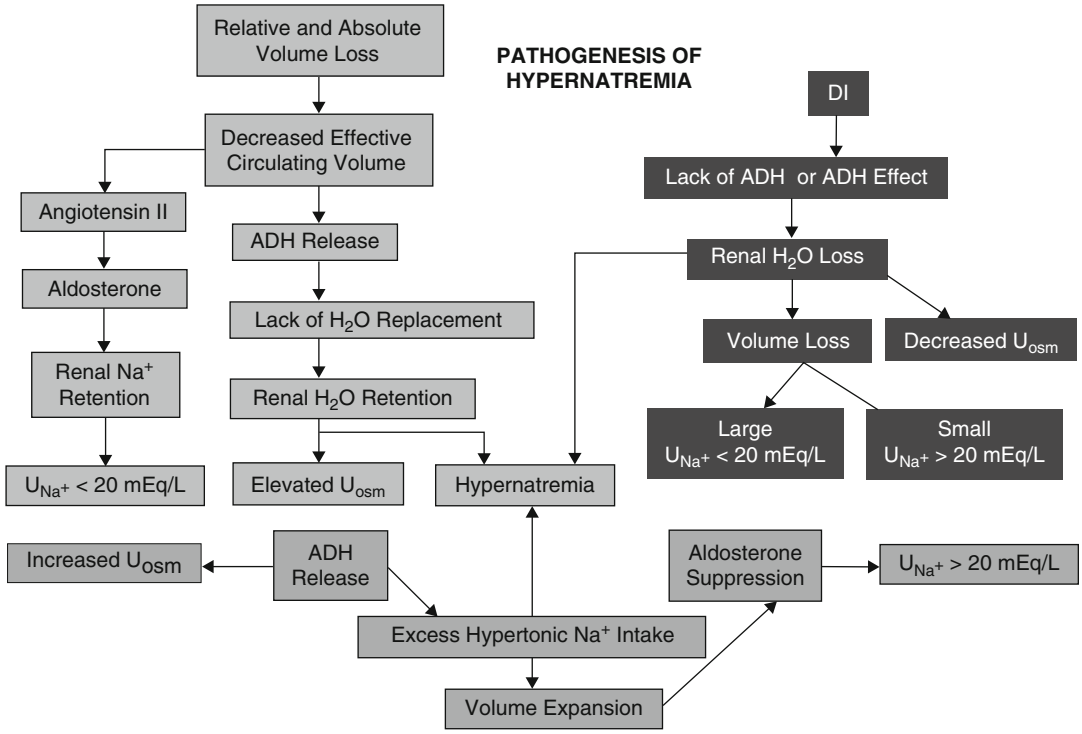

Fig. 3 Pathogenesis of hypernatremia. *DI* diabetes insipidus. (See Fig. 2 for other abbreviations.) (Originally appeared in: Taylor R, David A, Fields S, Phillips M, Scherger J, editors. Family medicine (Taylor). New York: Springer; 2003)

a hospital setting and fluid restriction not be initiated. Tolvaptan dosing remains controversial in preventing the overall disease progression in heart failure [50].

Hypernatremia

Hypernatremia, serum sodium concentration >145 mmol/L (Fig. 3), is caused by increased hypotonic fluid loss (i.e., GI losses, renal loss, insensible losses, or diabetes insipidus where ADH activity or secretion is reduced) exceeding hypotonic fluid intake [31–34, 51–53]. Approximately 1–3 % of all hospitalized patients are found to have hypernatremia [53, 54]. Thirst and access to water are the two most important aspects in preventing hypernatremia [55]. Excessive oral intake of sodium salts and hypertonic volume expansion can also lead to hypernatremia [56] (Table 3).

Table 3 Causes of hypernatremia

Primary Hypodipsia (defect of thirst)
Primary or metastatic tumor, granulomatous disease, vascular disease, trauma
Diabetes Inspidius
Central, nephrogenic
Pure Hypertonic Solute Gain
Ingestion of hypertonic solutions
Ingestion of salt-tablets
Inadequate Fluid Intake with increased free-water loss
Increase sweating, fever
GI losses
Osmotic diuresis
Diuretics

In hypernatremia, plasma osmolality is >300 mOsm/kg. Urine sodium concentration of <20 mEq/L can be seen in a hypernatremic patient with GI or insensible losses with

inadequate hypotonic volume replacement. Additionally, high urine osmolality (e.g., >600 mOsm/kg) is observed in these patients as the kidneys attempt to maintain stable fluid and sodium balance through renal water conservation. When hypernatremia is caused by renal volume losses from diuretics or osmotic diuresis with inadequate hypotonic volume replacement urine sodium concentration is >20 mEq/L, while urine osmolality may be <350 mOsm/kg and is less than plasma osmolality. With the addition of sodium salts for volume expansion, hypernatremia is associated with urine osmolality >350 mOsm/kg and urine sodium concentration >20 mEq/L. Patients with severe hypernatremia (serum sodium concentration >155 mEq/L) without maximum concentrated urine (i.e., 800–1200 mOsm/kg) suggests diabetes insipidus, intrinsic renal disease, osmotic diuresis, or diuretic use [52, 53, 57].

The symptoms of hypernatremia occur due to hyperosmolality of ECF shifting volume out of cells. The rate and severity at which this process occurs dictates symptom development. The most dangerous symptoms are nonspecific weakness and agitation, which signal changes in central nervous system. As hypernatremia increases falls and syncope from disorientation and somnolence are more common. [58] Polyuria can reveal a renal loss of pure water (e.g., diabetes insipidus), osmotic diuresis (e.g., glycosuria), or diuretic use, especially in medications altering ADH function. Also, hypertonic volume expansion or other addition of sodium salts can lead to a patient with the appearance of clinical volume overload (i.e., shortness of breath, pulmonary and peripheral edema, weight gain, systemic and venous hypertension, and S_3 gallop).

Treating hypernatremia depends on the cause. Correction of asymptomatic or chronic hypernatremia that develops over greater than 48 h or previously unknown hypernatremia must proceed slowly (i.e., $[Na^+]$ reduction of 0.5 mEq/L/h) to avoid cerebral edema and resultant neurological dysfunction [59]. In cases when hypernatremia has developed in less than 48 h, or acute hypernatremia, correction can proceed at up to 1 mEq/L/h [59]. Hypernatremia correction that is too slow can also cause complications [60]. When ECV is diminished by hypotonic volume loss, volume expansion with isotonic saline is initially used until signs of hypovolemia have resolved. An added benefit of isotonic saline infusion is that it can contribute to equilibrating plasma osmolality in patients with hyperosmolality. Once euvolemia is re-established, hypotonic fluids (e.g., 0.45 % normal saline or dextrose 5 % in water [D_5W]) can be administered in order to decrease plasma osmolality in pure water losses from the skin or kidneys [3, 60]. Hypernatremia caused by the addition of Na^+ salts is treated with D_5W and diuretics. Calculating free water deficit can be helpful for management; however, total body water and free water loss are grossly underestimated with the most commonly used equation: total body water deficit = correction factor x premorbid weight × $(1–140/Na^+)$ [61]. Previously, treatment of central diabetes insipidus was with administration of ADH preparation (e.g., aqueous vasopressin, vasopressin in oil, and vasopressin nasal sprays); however, DDAVP (desmopressin) is preferred due to the side effect profile and variable efficacy of ADH preparations [62, 63]. Correcting other electrolyte abnormalities and removing the offending agent, which is frequently drug induced, treat nephrogenic diabetes insipidus. Thiazides and a low-sodium diet can be helpful in treatment as well.

Potassium Disorders

Hypokalemia

Plasma potassium levels are typically maintained at 3.5–5.0 mmol/L, with hypokalemia described by potassium levels <3.5 mmol/L. Hypokalemia is a common electrolyte abnormality and commonly the result of non-potassium sparing diuretics. As with hyponatremia (Table 4), plasma hypokalemia can occur due to nonrenal causes with urine potassium (UK) <25 mEq/L (e.g., excessive GI, skin potassium losses) and due to renal causes with UK >25 mEq/L (e.g., sodium-

Table 4 Causes of hypokalemia

Renal potassium loss
Diuretics, current use
Vomiting and nasogastric tube drainage
Magnesium depletion
Mineralocorticoid excess (e.g., primary and secondary hyperaldosteronism, Cushing's disease, licorice ingestion, hyperreninism, Bartter syndrome, Adrenal Adenoma)
Diabetic ketoacidosis
Renal tubular acidosis
Ureterosigmoidostomy
Polyuria
Osmotic diuresis
Correction of chronic hypercapnia
Gastrointestinal loss
Diarrhea
Excess sweating
Intestinal fistulas
Rectal villous adenoma
Geophagia (i.e., clay ingestion)
Laxative abuse
Chloride-losing diarrhea
Intracellular K^+ sequestration
Metabolic and respiratory alkalosis
Excess insulin
Treatment of megaloblastic anemias
Granulocyte-macrophage colony-stimulating factor (GM-CSF)
β-adrenergic agonist
Hypothermia
Catecholamine excess
Hypokalemic periodic paralysis
Pseudohypokalemia
Prolonged standing of collected blood with extremely high WBC count
Blood specimen collected immediately after insulin administration
Decreased K^+ intake
Starvation

losing nephropathies, mineralocorticoid excess, vomiting, diuretics, and hypomagnesemia). However, hypokalemia may be more easily categorized by potassium excreted via kidneys or potassium loss through GI tract or cellular shifts (i.e., potassium driven intracellularly).

Potassium is typically passively reabsorbed in the proximal tubule of the kidney with the movement of sodium and chloride, while being actively reabsorbed in the thick ascending loop of Henle in the medulla via Na-K-2Cl (NKCC2) cotransporter. Increased flow to the distal nephron that occurs in diuretics that are effective more proximally (e.g., loop and thiazide diuretics) lead to increased potassium loss. Additionally, volume depletion activates RAAS causing an increase in potassium excretion. In fact, anything that leads to increases in mineralocorticoid activity and subsequent aldosterone activity will also lead to renal potassium loss.

Potassium can be lost through the GI tract as well with diarrhea often associated with a hyperchloremic metabolic acidosis. Upper GI potassium loss from vomiting is mediated by hypovolemic-induced RAAS activation, along with high levels of sodium bicarbonate and increased distal flow to nephron where potassium is excreted. Also, vomiting causes chloride deficit that leads to metabolic alkalosis that may cause intracellular movement of potassium. The Na-K-ATPase pump in skeletal muscle and hepatocytes regulates most of the total body potassium and can be a source of hypokalemia with pump derangement (reference number here). Increased insulin activity drives potassium intracellularly by increasing pump activity, while β-adrenergic agonists are active at the Na-K-ATPase pump, as well as in the Na-K-2Cl (NKCC2) cotransporter [64, 65].

Metabolic and respiratory alkalosis, hypothermia, and hypokalemic periodic paralysis are also related to extracellular potassium moving intracellularly. As alkalotic states may drive potassium into cells, acidotic states like diabetic ketoacidosis and renal tubular acidosis (RTA) associated with increased UK loss and total body potassium depletion may cause an acidosis-induced increase in plasma potassium and corrected by treating acidotic state.

Hypokalemia coexisting with hypertension should be further evaluated by checking renal levels. If the renin levels are low, the aldosterone level should be measured to evaluate for primary hyperaldosteronism (i.e., high aldosterone levels) or exogenous mineralocorticoid (i.e., low

aldosterone levels as in licorice ingestion). High or normal renin levels can be associated with renovascular hypertension and Cushing's disease. Inadequate potassium intake alone can also cause hypokalemia [66]. Treatment of severe megaloblastic anemias or use of granulocyte-macrophage colony-stimulating factor induces cell production that leads to uptake of hypokalemia [67].

Hemolysis during collection of blood products can lead to spuriously elevated levels of plasma potassium, while also conveying normal plasma potassium when there is true hypokalemia.

Symptoms associated with hypokalemia include generalized weakness, musculoskeletal complaints (muscle cramps, muscle tenderness), GI complaints (anorexia, nausea, vomiting, constipation), polyuria, polydipsia, and cardiac complaints (palpitations, syncope). In skeletal muscle injury and rhabdomyolysis, potassium release from contracting skeletal muscle that would normally cause vasodilation and improved blood flow regionally is blunted in severe hypokalemia [68]. Potassium is also involved in cardiac muscle repolarization allowing for appropriate cardiac muscle relaxation and diastolic filling. With hypokalemia, cardiac repolarization is prolonged leading to classic electrocardiogram (EKG) changes. First noted is decreased magnitude of T waves, then U wave formation, and finally ST segment depression on EKG.

Oral replacement with potassium chloride or potassium bicarbonate and underlying correction of the cause are the mainstays of initial treatment. Intravenous potassium chloride may be used solely or with oral therapy. Typically, 10 mEq of potassium supplementation will increase plasma potassium level by about 0.1 mEq/L with the potassium goal of 4.0 mEq/L to minimize untoward effects of hypokalemia. Foods rich in potassium are less useful in treatment of hypokalemia since potassium in these sources is in the form of potassium citrate or potassium phosphate, which is about 60 % less retained than potassium chloride [69]. Hypokalemia can be corrected intravenously via peripheral line at about 10 mEq/h since higher concentrations cause local irritation along with venous sclerosis. A central line can avoid these adverse effects when an infusion rate of 20 mEq/h or greater is required. In all cases of potassium repletion, frequent plasma potassium measurements should be monitored for efficacy of therapy [70]. Low magnesium must be corrected to ensure potassium is not lost renally during repletion [71]. Diuretics that work in the distal convoluted tubule and antagonize aldosterone receptors (i.e., spironolactone) can decrease kaluresis that is caused by loop and thiazide diuretics.

Hyperkalemia

Hyperkalemia (see Table 5) is less well tolerated by the body than hypokalemia and occurs when extracellular potassium levels are elevated beyond the ability of kidneys, skin, and GI tract to excrete potassium. Extracellular potassium concentration can be affected by potassium shift from intracellular space to extracellular, potassium intake and potassium excretion [72]. The kidneys perform most potassium excretion. Many medications can lead to hyperkalemia. Spironolactone, ACE-I, ARBs decrease aldosterone production,

Table 5 Causes of hyperkalemia

Increased K^+ intake
Decreased K^+ excretion
Acute and chronic renal failure
Decreased effective circulating volume
Hypoaldosteronism- K^+-sparing diuretics, Hyporenin hypoaldosteronism in mild renal disease, NSAIDs, ACE inhibitors, Adrenal insufficiency
Intracellular K^+ extrusion
Metabolic and respiratory acidosis
Tissue injury (e.g., crush, rhabdomyolysis, hematoma resorption)
Insulin deficiency in diabetic ketoacidosis, prolonged fasting; hyperosmolality from hyperglycemia
Drugs (e.g., digitalis intoxication, succinylcholine, and arginine HCI, β-adrenergic blockers)
Hyperkalemic periodic paralysis (from excessive exercise, fasting)
Measurement error
Thrombocytosis
Leukocytosis
Hemolysis of blood sample (i.e., delay after blood draw, cell destruction from vigorous sample shaking
Blood collection from ischemic extremity

References used [1, 75–78]

which can lead to hyperkalemia. Medications such as triamterene, amiloride, and the antibiotic trimethoprim decrease potassium excretion by blocking sodium channels. Other medications (e.g., nonselective beta-blockers, NSAIDs) can increase extracellular potassium by inhibiting Na-K ATPase pump, causing potassium to remain in extracellular fluid space and decreasing aldosterone production [73]. Avoiding a combination of these medications in patients with coexistent renal failure is important [73]. Kidney dysfunction (RTA type 4, CHF, and other causes of hypoaldosteronism) can inhibit potassium excretion [72]. Additional conditions and ingestions affect transcellular movement of potassium leading to hyperkalemia such as metabolic acidosis (0.2–1.7 mEq/L increase in $[K^+]$ for every 0.1 decrease in pH), hypertonicity from hyperglycemia or hypernatremia, insulin deficiency in diabetes mellitus or from starvation, rhabdomyolysis and hematoma resorption or other forms of cellular destruction, digitalis intoxication, and hyperkalemic periodic paralysis from intense exercise or fasting. Hyperkalemia due to measurement error is also quite common and can be caused by hemolysis of red blood cells as a result of collection (i.e., prolonged tourniquet use, fist clenching leading to minor ischemia) [74] or storage, release of K^+ during coagulation of blood samples with increased WBCs (e.g., WBCs $>100{,}000/mm^2$ in leukemia) (or increased platelets (i.e., $>1{,}000{,}000/mm^2$) [74–76].

Hyperkalemia can cause nonspecific symptoms such as muscle weakness, fatigue, malaise, nausea, vomiting, and paresthesias. Peaked T waves are hallmark EKG findings in hyperkalemia, though flattened P waves, increased PR interval, prolonged QRS duration with shortened QT interval may also be present. Uncorrected hyperkalemia can lead to sine wave development with resultant ventricular fibrillation and asystole. Bradycardia, dysrhythmias, and paralysis can also occur.

Treatment of acute hyperkalemia can be done by enhancing potassium cellular entry using insulin, glucose, and inhaled beta-agonists (i.e., albuterol or levalbuterol) [77]. If hyperkalemia is associated with life-threatening dysrhythmias, calcium is used to decrease the threshold of myocardial tissue excitability induced by hyperkalemia, thereby minimizing risk of serious cardiac events. Calcium chloride has more elemental calcium and greater bioavailability than calcium gluconate but is typically associated with tissue necrosis and therefore cannot be infused as rapidly; however, one salt has not been proven more effective over the other [78]. Sodium bicarbonate has not shown to be more effective than placebo [78]. Loop diuretics are effective for excreting total body potassium in patients who make urine and kayexalate. Sodium polystyrene was previously shown to be effective [72], but new data shows no difference compared to stool softeners alone and is associated with increased risk of intestinal necrosis [77, 79, 80]. In patients refractory to these treatments, hemodialysis may prove necessary [78].

Acid–Base Disorders

Metabolic Acidosis

Metabolic acidosis is a primary reduction in plasma bicarbonate concentration leading to hypobicarbonatemia (Table 6), which stimulates compensatory hyperventilation and hypocapnia (i.e., decreased pCO_2). In metabolic acidosis, the compensatory hyperventilation can be determined with the following formula. Full compensation may take several hours.

$$\text{Calculation for expected } pCO_2$$
$$pCO_2 = 1.5 \times [HCO_3] + 8$$

The limit of compensatory hyperventilation in metabolic acidosis is 10 mmHg that may be more difficult to achieve in acute versus acute process. If the rate of the pCO_2 decrease is less or more than predicted, a mixed acid–base disturbance occurs [81–84]. If the actual pCO_2 is too high then an additional respiratory acidosis is present; conversely if the pCO_2 is too low then an additional respiratory alkalosis is present. The clinical scenario must be taken into account when

Table 6 Causes of hypobicarbonatemia[a]

Metabolic acidosis (i.e., decreased pH, decreased[b] and decreased pCO_2[c])
Hyperchloremia, normal anion gap
Bicarbonate loss (hypokalemia and urine pH < 5.5)
GI tract bicarbonate loss (e.g., diarrhea, ureterosigmoidostomy, fistulas, tube drainage)
Renal bicarbonate loss and production failure (e.g., RTA Type 2, RTA Type 1, RTA Type 4, carbonic anhydrase inhibitors)
HCl addition (e.g., NH_3Cl and some hyperalimentation fluids)
Hypoaldosteronism (hyperkalemia, submaximal urinary acidification)
Primary adrenal insufficiency
Hyporeninemic hypoaldosteronism (e.g., during early chronic renal failure, acute renal failure interstitial nephritis, angiotensin-converting enzyme inhibition, and nonsteroidal antiinflammatory drug use)
Aldosterone resistance (e.g., spironolactone, amiloride, triamterene)
Intestinal nephritis
Early renal failure
Acute renal failure
Initial recovery from organic acidosis (variable $[K^+]$ and urine pH)
Normochloremia, large anion gap (urine pH < 5.5)
Excessive production of endogenously generated organic acids
Diabetic ketoacidosis (i.e., excessive β-hydroxybutyrate and acetoacetate)
Starvation ketosis
Alcoholic ketosis
Lactic acidosis
Muscle necrosis
Decreased excretion of endogenous acid metabolites
Renal failure
Ingestion of exogenous agents causing organic acidosis
Methanol
Ethylene glycol
Paraldehyde
Salicylates
Respiratory alkalosis (i.e., increased pH, decreased $[HCO_3^-]$[c] and decreased pCO_2[b])
Increased CNS stimulation
Physiologic and psychogenic hyperventilation
CNS disease (e.g., infectious, trauma, infarct, bleeding, tumors, heat stroke)
Pregnancy
Progesterone-producing tumors
Hepatic encephalopathy
Methylxanthines, nicotine, salicylates
Sepsis
Hypoxia
High altitude
Anemia, severe
Pulmonary embolus, pulmonary edema, pneumothorax
Carbon monoxide poisoning
Mechanical overventilation

[b]Primary acid–base event

[c]Secondary or compensatory acid–base event

approaching acid–base disorders. The etiology for the bicarbonate loss must be determined. Losses can occur with GI bicarbonate loss (e.g., diarrhea), renal bicarbonate loss (e.g., renal tubular acidosis), or bicarbonate titration with fixed endogenous acids (e.g., ketoacidosis) and exogenous acids (e.g., salicylate intoxication). Metabolic acidosis caused by pure bicarbonate loss is characterized by hyperchloremia and a normal anion gap. However, when metabolic acidosis is caused by the addition (e.g., methanol ingestion), retention (e.g., renal failure) [85], or excess production (e.g., lactic acidosis) of fixed acids that titrate bicarbonate, acidic anions remaining in extracellular body fluids cause expansion of the anion gap and a normal chloride concentration [86–88]. In reference to a calculated anion gap, a result of 20–30 has a high chance of metabolic acidosis while a result >30 reflects metabolic acidosis. The anion gap is calculated using serum values with the following formula;

$$\text{Anion Gap} = [\text{Sodium}] - [\text{Chloride}] - [\text{HCO3}]$$

Metabolic acidosis can be divided into three categories: increased anion gap, normal anion gap, and decreased anion gap. Increased anion

gap metabolic acidosis is caused by ingestion of organic acids (salicylates, methanol, ethylene glycol, paraldehyde, propylene glycol), increased organic acid production (lactic acidosis, ketoacidosis), renal failure (phosphates, sulfates), or errors of metabolism (lipid metabolism errors, urea cycle disorders). Normal anion gap metabolic acidosis is due to intake of chloride salts (total parental nutrition, normal saline infusion), GI bicarbonate loss (diarrhea, colostomy, ileostomy, enteric fistula), urological procedures (ureterosigmoidostomy, ureteroileal conduit), ingestions (acetazolamide, magnesium sulfate), and renal bicarbonate loss (RTA, tubulointerstitial renal disease, hyperparathyroidism).

Metabolic acidosis causes extracellular hyperkalemia due to cellular buffering of hydrogen ions (failure of acidosis-induced hyperkalemia suggests total body potassium depletion), but because significant volume loss is a frequent complication (e.g., diabetic ketoacidosis), total body hypokalemia must always be expected (chronic renal failure and hypoaldosteronism may be an exception) [74]. The ingestion of acid toxins (e.g., paraldehyde, methanol, ethylene glycol, and salicylates) is associated not only with the distinct acid metabolite but also lactic acid as vascular collapse ensues [89].

Generally, compensatory responses will not be able to restore pH back to the normal value. Some of the most dangerous effects of acidosis on the body include hyperventilation, depression of myocardial contractility, sympathetic overactivity, peripheral arteriolar vasodilation, hyperkalemia, and cerebral vasodilation with resultant increased intracranial pressure. Many of these conditions can be deleterious and deadly. Therapy for metabolic acidosis is initially directed at restoration of the systemic pH to levels that do not compromise cardiac function or predispose to cardiac dysrhythmias. Dangerous pH levels differ depending on the etiology of the acidosis; in general, however, safe systemic pH exists at 7.2. Severe forms of metabolic acidosis therefore require administration of sodium bicarbonate in amounts necessary to restore the pH to this safe level, with care taken to avoid volume excess and post-treatment metabolic alkalosis by overaggressive alkali therapy [90]. If the metabolic acidosis is severe enough to warrant alkali therapy, physician comfortable with use should manage it [89, 90].

Respiratory Alkalosis

Respiratory alkalosis is a primary reduction in the pCO_2 (i.e., hypocapnia), which stimulates a compensatory cellular and renal reduction in bicarbonate concentration [1]. With primary acute and chronic respiratory alkalosis, the compensatory bicarbonate loss occurs at a rate of 2.0 mEq/L or 5.0 mEq/L for every 10 mmHg decrease in the pCO_2. The limits of these metabolic compensations in acute and chronic respiratory alkalosis are 18 and 12 mEq/L, respectively. If the rate of compensatory bicarbonate loss is less or more than predicted, a mixed acid–base disturbance is present which is discussed later. Respiratory alkalosis is caused by central causes, hypoxia, pulmonary causes, and iatrogenically (excessive controlled ventilation) (Table 6).

Acute hypocapnia may be associated with circumoral and digital paresthesias, lightheadedness, carpopedal spasm, and tetany. The associated hyperventilation is obvious, as it is mostly rate driven. With chronic hypocapnia the respiratory rate may be normal, and the depth of respiration may predominate as the mechanism of pCO_2 removal. Treatment is directed to the underlying cause.

Metabolic Alkalosis

Metabolic alkalosis is a primary increase in plasma bicarbonate concentration (i.e., hyperbicarbonatemia) that causes a compensatory reduction in ventilation and relative hypercapnia (i.e., increased pCO_2) [1]. The bicarbonate accumulation is due to acid loss, alkali administration, intracellular shifts, or bicarbonate retention. With primary metabolic alkalosis the compensatory hypoventilation occurs at a rate of 0.7 mmHg increase in the pCO_2 for every 1.0 mEq/L increase in the bicarbonate concentration. The limit of this compensatory hypoventilation is 55 mmHg because of hypoxia-

induced ventilation. If the rate of pCO_2 increase is less or more than predicted, a mixed acid–base disturbance consisting of metabolic alkalosis and respiratory alkalosis or acidosis is present. The list of potential causes for metabolic alkalosis is extensive, but most common reasons include loss of gastric acid, renal acid loss, hypovolemia, hypokalemia, and diuretic use (Table 7).

Signs and symptoms associated with metabolic alkalosis relate to underlying cause. Metabolic alkalosis caused by volume depletion is characterized by a urinary chloride concentration of less than 10 mEq/L (i.e., saline-responsive), whereas metabolic alkalosis due to a primary increase in distal renal tubule activity (e.g., mineralocorticoid excess) and increased alkali ingestion is characterized by a urinary chloride concentration higher than 10 mEq/L (i.e., saline-resistant). Paradoxically, the urinary pH is usually acidic except when the disorder is caused by excessive alkali ingestion.

Treatment of saline-responsive metabolic alkalosis requires volume repletion with isotonic normal saline, which inhibits the volume depletion-induced retention of bicarbonate, resulting in an alkaline diuresis. With saline-resistant metabolic alkalosis, the source of the excess alkali ingestion must be removed or inhibited. Potassium deficits should also be replete using potassium chloride.

Respiratory Acidosis

Respiratory acidosis is a primary increase in the pCO_2 (i.e., hypercapnia), which stimulates compensatory cellular and renal retention of bicarbonate [1]. With primary acute and chronic respiratory acidosis, the compensatory bicarbonate retention occurs at a rate of 1.0 mEq/L or 4.0 mEq/L for every 10 mmHg increase in the pCO_2. The limits of the metabolic compensations during acute and chronic respiratory acidosis are 30 and 45 mEq/L, respectively. If the rate of compensatory bicarbonate retention is less or more than predicted, a mixed acid–base disturbance consisting of respiratory acidosis and metabolic acidosis or alkalosis is present. Respiratory acidosis occurs through three mechanisms:

Table 7 Causes of hyperbicarbonatemia[a]

Metabolic alkalosis (i.e., increased $[HCO_3^-]$[b] increased pCO_2, increased pH)
Hypovolemia and chloride depletion (i.e., hypochloremia, hypokalemia: urine $Na^+ < 10$ mEq/L, $Cl^- < 10$ mEq/L, pH < 6, $K^+ < 10$ mEq/L
Vomiting
Postdiuretic use
Congenital chloride diarrhea
Bartter syndrome
Acute correction of hypercapnia in hypovolemia
Hypervolemia (i.e., hypochloremia, hypokalemia; urine $Na^+ > 10$ mEq/L, $Cl^- > 10$ mEq/L, pH < 6.0)
Mineralocorticoid excess
Renal artery stenosis
Primary aldosteronism
Adrenal hyperplasia
Excessive alkali (hypochloremia, hypokalemia; urine $Na^+ > 10$ mEq/L, $Cl^- > 10$ mEq/L, pH > 7.0)
Excessive exogenous alkali (e.g., absorbable antacids, milk-alkali syndrome, excessive infusion of $NaHCO_3$)
Excessive endogenous alkali (e.g., $NaHCO_3$)
Acute correction of chronic hypercapnia in euvolemia
Metabolism of β-hydroxybutyrate, acetoacetate, lactate, and citrate
Severe hypokalemia
Hypercalcemia (e.g., primary hyperparathyroidism)
Respiratory acidosis (i.e., lactate, increased pCO_2,[b] increased $[HCO_3^-]$
Suppression of CNS respiratory center
Drugs (e.g., sedatives
Oxygen-induced acute pCO_2 retention in chronic obstructive pulmonary disease (COPD)
Sleep apnea
Disorders of respiratory muscles
Obstructed airway
Extrinsic foreign body
Aspiration
Laryngeal edema or spasm
Bronchospasm
Disturbances of gas exchange across alveolar membrane
Pulmonary edema
Adult respiratory distress syndrome
Diffuse pneumonia
COPD
Loss of ventilatory volume
Pneumothorax
Hemothorax
Pleural effusions

Originally appeared in: Taylor R, David A, Fields S, Phillips M, Scherger J, editors. Family medicine (Taylor). New York: Springer; 2003

[a]Hyperbicarbonatemia = increased $[HCO_3^-]$

[b]Primary acid–base event

(1) excess CO_2 in the inhaled gas, (2) decreased alveolar ventilation, (3) increased production of CO_2. The most likely cause is inadequate alveolar ventilation. A list of etiologies is provided in (Table 7).

Symptoms of respiratory acidosis include shortness of breath and the mental status changes associated with progressive acute and chronic hypercapnia. The treatment of respiratory acidosis is directed to the primary cause to increase the effectiveness of ventilation and pulmonary gas exchange.

Mixed Acid–Base Disturbances

The presence of a mixed acid–base disturbance is usually detected when a primary acid–base event fails to demonstrate the expected compensation. This failure of compensation can predict the presence of a respiratory and metabolic acid–base event occurring concurrently but does not predict the presence of mixed metabolic events or mixed respiratory events. Acid–base maps have similar diagnostic limitations. The mixture of more than two events can be determined by other laboratory evidence but is best detected when historical evaluations suggest multiple acid–base events. Although laboratory data may be the first evidence of acid–base disturbances, utilization of these tools to predict primary and mixed acid–base disturbances must be related with clinical data to ensure that the information is appropriately interpreted (Table 8).

The presence of a mixed acid–base disturbance is best detected by anticipating its presence in

Table 8 Common mixed acid–base disturbances

Disorder	Examples
Predicted by rules of compensation	
Metabolic acidosis and respiratory alkalosis (partial pressure of carbon dioxide reduction greater than predicted for metabolic acidosis)	Chronic renal failure and septicemia
Metabolic alkalosis and respiratory acidosis (partial pressure of carbon dioxide reduction less than predicted for metabolic acidosis)	Lactic acidosis and chronic obstructive pulmonary disease
Metabolic and respiratory alkalosis (partial pressure of carbon dioxide elevation less than predicted for metabolic alkalosis)	Diuretic overuse and psychogenic hyperventilation
Metabolic alkalosis and respiratory acidosis (partial pressure of carbon dioxide elevation greater than predicted for metabolic alkalosis)	Vomiting and adult respiratory distress syndrome
Not predicted by rules of compensation	
Hyperchloremia and large anion gap metabolic acidosis (nonequivalent changes in chloride and bicarbonate concentrations and an elevated anion gap	Diarrhea and chronic renal disease
Metabolic alkalosis and large anion gap acidosis (nonequivalent changes in chloride bicarbonate concentrations and an elevated anion gap)	Vomiting and chronic renal failure
Acute and chronic respiratory alkalosis ($[HCO_3^-]$ reduction greater than predicted for acute respiratory alkalosis and less than predicted for chronic respiratory alkalosis)	Septicemia and psychogenic hyperventilation
Acute and chronic respiratory acidosis ($[HCO_3^-]$ elevation greater than predicted for acute respiratory acidosis and less than predicted for chronic respiratory acidosis)	Acute respiratory failure and COPD
Chronic respiratory acidosis and acute respiratory alkalosis ($[HCO_3^-]$ elevation or reduction inconsistent with expected pCO_2 elevation or reduction for either of these disorders, respectively)	COPD and pulmonary embolus
Metabolic alkalosis and nonanion gap metabolic acidosis (difficult to recognize because $[Cl^-]$ and $[HCO_3^-]$ changes depend on which disorder predominates; if each disorder is of equal magnitude, then $[Cl^-]$, $[HCO_3^-]$, pCO_2, and pH are normal)	Chronic diuretic overuse and diarrhea

COPD chronic obstructive pulmonary disease

clinical settings, although some laboratory findings can be helpful. The compensation in acid–base disturbances minimizes changes in systemic pH but never totally corrects the pH (the possible exception is chronic hypocapnia in persons living at high altitudes). Therefore, the presence of a normal pH with normal [HCO_3^-] and pCO_2 indicates the presence of a mixed acid–base disturbance. Likewise, with primary acid–base disturbances the compensatory event is in the same direction as the primary event; therefore, acid–base disturbances where the compensatory event and the primary event are in opposite directions also indicate the presence of a mixed acid–base disturbance. A large anion gap metabolic acidosis occurring concurrently with a hyperchloremia metabolic acidosis (e.g., a patient with diabetic ketoacidosis and diarrhea) is detected when the anion gap does not account for the amount of [HCO_3^-] concentration reduction. An example of this mixed disturbance is a sign of recovery during the appropriate treatment of diabetic ketoacidosis as β-hydroxybutyrate and acetoacetate (ketone bodies) are hepatically converted to [HCO_3^-], resulting in a transition from the original large anion gap metabolic acidosis to a hyperchloremia metabolic acidosis with less severe systemic pH reductions. The presence of a large anion gap, regardless of the systemic pH, indicates the presence of metabolic acidosis. For example, a patient with plasma metabolic alkalosis caused by diuretic use may have a [HCO_3^-] of 36 mEq/L, and if the hypovolemia becomes severe enough lactic acidosis may ensue. However, an 8 mEq/L drop in [HCO_3^-] caused by titration of lactic acid would result in a [HCO_3^-] of 28 mEq/L, essentially no change in [Cl^-], and an appropriate pCO_2 response with the pH still slightly alkalemic. This process can be detected early based on the concurrent increase in the anion gap as [HCO_3^-] is consumed in the titration with lactic acid and elevated plasma lactic acid – if the potential for this disorder had been anticipated clinically.

The limits of compensation are important factors to consider especially when suspecting respiratory acidosis in a patient with metabolic alkalosis. Although the compensation for metabolic alkalosis is pCO_2 retention, pCO_2 values higher than 55 mmHg do not occur because the resulting hypoxia stimulates ventilation. Therefore, in patients with metabolic alkalosis and a pCO_2 higher than 55 mmHg, primary impairment of ventilation causing respiratory acidosis must also be present. Because the limits of compensation in chronic respiratory alkalosis is a [HCO_3^-] of 14 mEq/L, [HCO_3^-] less than that implies the additional presence of metabolic acidosis. Likewise, the limits of compensation for chronic respiratory acidosis is renal HCO_3 retention to 45 mEq/L, and higher [HCO_3^-] concentrations imply the additional presence of metabolic alkalosis. Because chronic renal disease in its end stages results in a [HCO_3^-] of 12–14 mEq/L, greater [HCO_3^-] reductions would suggest additional causes of metabolic acidosis (e.g., vomiting).

Mixtures of acute and chronic respiratory acidosis as well as acute and chronic respiratory alkalosis can be detected using the rules of compensation for primary acid–base disorders and by plotting pCO_2 and [HCO_3^-] on acid–base maps. Points that define mixtures of acute and chronic respiratory alkalosis or respiratory acidosis may also be consistent with a mixture of acute respiratory and metabolic alkalosis or acute respiratory acidosis and metabolic alkalosis. Mixtures of respiratory acidosis and respiratory alkalosis pose special problems. The more profound event may alter the pCO_2 enough to leave the respiratory-induced metabolic compensation unopposed for hours to days (e.g., a patient with chronic obstructive pulmonary disease who is mechanically hyperventilated, thereby decreasing the pCO_2 and leaving the pCO_2-induced [HCO_3^-] elevation until renal [HCO_3^-] excretion occurs over the following hours to days).

Misc. Electrolyte Disturbances

Magnesium

Hypomagnesemia ($Mg^{2+} < 1.5$ mEq/L) associated with urinary magnesium (UMg) conservation (UMg $<$ 10 mg/day) can be caused by decreased

magnesium intake (e.g., protein calorie malnutrition), decreased magnesium absorption, and extrarenal magnesium loss [1]. Hypomagnesemia associated with urinary magnesium excretion (UMg > 10 mg/day) can be caused by excessive renal magnesium loss (e.g., diuretic use, hypokalemia, hypercalciuria, hypervolemia, and hyperthyroidism). Hypomagnesemia is also caused by chronic magnesium wasting and treatment-induced intracellular magnesium redistribution (e.g., diabetic ketoacidosis and alcoholism).

Hypermagnesemia (Mg^{2+} > 2.5 mEq/L) results when magnesium intake exceeds renal excretion (UMg > 20 mg/day) and when there is decreased renal excretion (UMg < 20 mg/day) caused by excessive renal magnesium tubular reabsorption (e.g., hyperparathyroidism, hypovolemia, hypocalcemia, and hypothyroidism) and GFR (e.g., acute and chronic renal failure and hypovolemia).

Phosphate

Hypophosphatemia (plasma phosphorus <2.5 mg/dL) is caused by increased phosphate renal excretion (i.e., UPO4 > 100 mg/24 h) in diabetic ketoacidosis, hypokalemia, and phosphate deficiency (UPO4 < 100 mg/24 h) in hypoparathyroidism and decreased phosphate intake (e.g., alcoholism, vitamin D deficiency, and use of phosphate binders), as well as intracellular phosphate shifts (UPO4 < 100 mg/24 h) in metabolic and respiratory alkalosis [1]. Hyperphosphatemia (phosphorus >4.8 mg/dL) associated with UPO4 > 1500 mg/24 h is caused by increased release of phosphates into the extracellular fluid by cell lysis (e.g., rhabdomyolysis) and initial anionic redistribution of metabolic acidosis (e.g., diabetic ketoacidosis and lactic acidosis).

Hyperphosphatemia associated with UPO4 < 1500 mg/24 h is caused by decreased renal phosphate excretion (e.g., volume depletion, acute and chronic renal failure, and hyperparathyroidism). Clinical manifestations vary depending on time course and mechanism. Symptom presentation is more severe with acute versus chronic. Symptoms may be mild if from intracellular shift as intracellular phosphate levels are enough for ATP production. Clinically patients may develop respiratory muscle dysfunction, decreased contractility of heart, hemolysis, insulin resistance, myopathy, rhabdomyolysis, and seizures. These symptoms are largely caused by adenosine triphosphate depletion in hypophosphatemia. Treatment is phosphate repletion and may be done either orally or intravenously.

Calcium

Hypocalcemia (Ca^{2+} < 8.5 mg/dL or ionized Ca^{2+} < 4.1 mg/dL) associated with normal or subnormal parathyroid hormone (PTH) is caused by PTH-deficient hypoparathyroidism and severe hypomagnesemia. Since 40 % of Ca is bound to plasma proteins, it is important to adjust for low albumin by adding 0.8 mg/dL for every 10 g/L decrease in normal albumin [1]. Calcium is regulated by parathyroid hormone. When levels of Ca^{2+} are low, PTH is secreted from the parathyroid resulting in increased renal reabsorption as well as increased renal vitamin D production, which stimulates increased intestinal absorption of calcium. Hypocalcemia associated with elevated PTH is caused by chronic renal failure, vitamin D deficiency, malabsorption, drug-induced microsomal enzyme induction (e.g., mithramycin and phenytoin), osteomalacia, and causes of severe acute hyperphosphatemia such as acute pancreatitis, hepatic failure, and other causes of massive tissue necrosis.

Hypercalcemia (total [Ca^{2+}] > 10.5 mg/DL or ionized [Ca^{2+}] > 5.1) with elevated PTH is caused by primary hyperparathyroidism (i.e., excessive production of PTH) and severe secondary hyperparathyroidism of chronic renal failure. Hypercalcemia associated with normal PTH is caused by vitamin D excess, sarcoidosis, hyperthyroidism, increased bone calcium release (e.g., immobilization and bony metastasis), extracellular fluid depletion, thiazides, or milk-alkali syndrome. Clinical manifestations include nephrolithiasis, bone pain, abdominal pain from

constipation, nausea, vomiting, and psychiatric symptoms. Asymptomatic patients with mild hypercalcemia do not need treatment, however if >14 mg/DL or if >12 mg/DL with symptoms should be treated with aggressive saline rehydration followed by furosemide diuresis, calcitonin, and bisphosphonates. Surgery would be indicated for primary hyperparathyroidism.

Diseases of the Kidney

Margaret Baumgarten[a]*, Todd W. B. Gehr[b] and Daniel Carl[b]
[a]Family & Community Medicine, Portsmouth Family Medicine-Eastern Virginia Medical School, Portsmouth, VA, USA
[b]Division of Nephrology/Department of Internal Medicine, Virginia Commonwealth University Medical College of Virginia Campus, Richmond, VA, USA

1 Glomerulonephritis

The nephritic syndrome is acute in onset and associated with oliguria, azotemia, hypertension, and proteinuria of variable quantity. Hematuria (usually dysmorphic) and RBC casts are the hallmark of glomerular inflammation and glomerular basement membrane disruption. A diverse group of diseases cause the syndrome and the presentation is often dramatic and can be life threatening.

1.1 Acute Proliferative Glomerulonephritis/Poststreptococcal Glomerulonephritis

This condition is characterized by diffuse proliferation within the glomerulus and the prototypical disease is poststreptococcal glomerulonephritis. The disease occurs 1–2 weeks after a skin infection or sore throat and may occur in as many as 25 % of patients affected by Group A streptococci, M-type stains [1, 4, 12]. The condition usually develops in children but can occur at any age. Serum complement is typically low, antistreptolysin O and DNAase B titers are high. These patients usually have a dramatic presentation with nephrotic syndrome, RBC casts, hypertension, and acute kidney failure. Milder manifestations with non-nephrotic proteinuria and microscopic hematuria without renal failure can also be seen. Most patients recover spontaneously although persistent urinary abnormalities may persist and a small subset of patients may develop chronic kidney disease (CKD) [1].

1.2 Immunoglobulin A Nephropathy

IgA nephropathy is perhaps the most common form of glomerulonephritis worldwide. IgG-IgA1 immune complexes are deposited in the mesangium of the glomerulus and incite an inflammatory reaction. IgA levels in the blood do not correlate with disease although the pathogenesis may involve a decrease in galactosylation of IgA1 making it susceptible to an antibody response. Primary care physicians are often the first providers who evaluate these patients for gross hematuria following an upper respiratory infection in adolescence or as young adults. Although the condition is often benign, a more aggressive form of the disease can occur which can lead to End-Stage Renal Disease (ESRD). IgA nephropathy often accompanies Henlock-Shonlein purpura which is a condition appearing earlier in life (mean age 6–7 years) and associated with a purpuric rash usually involving the legs and buttocks, abdominal pain, arthritis and arthralgias. The condition, including IgA nephropathy, usually resolves spontaneously with conservative management. IgA deposits with or without associated nephropathy can accompany a variety of diseases including sarcoidosis, HIV infection, liver disease, and inflammatory bowel disease. The significance of these deposits remains unclear. Therapy for typical IgA nephropathy includes omega-3-fatty acids and/or angiotensin-converting enzyme inhibitors, both of which have shown promise in slowing the progression of disease [2].

DOI 10.1007/978-1-4939-0779-3_104-1

1.3 Lupus Nephritis

Patients with systemic lupus erythematosis commonly have renal involvement although the extent of involvement is highly variable. Lupus nephritis is an immune complex mediated glomerular disease with autoantibodies to a variety of antigens (nuclear, double-stranded DNA). These autoantibodies are deposited in the glomerulus, activate complement and elicit an inflammatory response that damages the kidney. Six histologically distinct classes of renal involvement have been described with class 4, diffuse proliferative glomerulonephritis being the most severe. It is not uncommon for glomerular histology to change in a single patient necessitating very close follow-up. Besides following renal function and urinalysis, complement activity and anti-double-stranded DNA titers fluctuate with disease activity. Therapy is best described for class 4 diffuse proliferative lupus nephritis. Treatment with high doses of intravenous and oral steroids and intravenous or oral cyclophosphamide have been successfully employed. Oral mycophenolate mofetil has been shown to be equally effective and has fewer side effects. Recently, intravenous rituximab has also been used although as a second-line agent [3].

1.4 Rapidly Progressive Glomerulonephritis

RPGN, also known as crescent glomerulonephritis, is a dramatic condition causing a rapid, often irreversible, decline in renal function. In fact, if left untreated it uniformly leads to ESRD or death. Crescents are cellular elements that follow the contour of Bowman's capsule, crowding out the capillary loops in the glomerulus, thus the term crescentic glomerulonephritis. Crescents are not specific to any particular type of RPGN but the extent of their presence (>60 % glomerular involvement) denotes the severity of the inflammatory response within the glomerulus. There are three types of RPGN based on distinct pathogenic mechanisms.

1.4.1 Type 1 RPGN

Although rare, this type of RPGN is often the best known of the types of RPGN. It is known as anti-GBM disease when the disorder is confined to the kidney but if there is cross-reactivity to alveolar basement membrane leading to pulmonary hemorrhage it is known as Goodpasture syndrome. Early initiation of therapy is critical in this disorder in order to prevent ESRD. Anti-GBM antibody titers can be followed to monitor therapeutic effectiveness. As there often is a delay in receiving the results of Anti-GBM antibody titers a kidney biopsy is often necessary in order to establish the diagnosis. Intravenous steroids, cyclophosphamide, and plasmapheresis if used early in the course of the disease are usually effective in improving renal function and controlling pulmonary hemorrhage. As this is an antibody mediated disorder, the use of the anti-CD20 agent, rituximab, has also shown promise in controlling the disorder. In most instances, maintenance therapy with cyclophosphamide, mycophenolate mofetil, or azathioprine is necessary to control the disease [4].

1.4.2 Type 2 RPGN

Type 2 RPGN can be produced by any immune complex–mediated glomerulonephritis. The immune complexes can be virtually anywhere within the glomerular structure, mesangial, subendothelial, intramembranous, or subepithelial. What sets this disorder apart is the presence of crescents which are just a result of the intense inflammatory response. Although IgA nephropathy is usually a benign glomerular disease, it can present as Type 2 RPGN leading to ESRD. Most of these glomerular diseases are idiopathic, however. Therapy consists of intravenous steroids and cytotoxic drugs with less reliance on plasmapheresis. Again, early initiation of therapy is critical if ESRD is to be avoided.

DOI 10.1007/978-1-4939-0779-3_104-1

1.4.3 Type 3 RPGN

Type 3 RPGN is also known as pauci-immune complex glomerulonephritis owing to the lack of immune complexes demonstrated in the glomerulus. Despite the lack of demonstrated immune complexes deposited in the glomerulus, circulating antineutrophil cytoplasmic antibodies (ANCA) are usually present and are thought to be critical in the pathogenesis of the disease. Most of these patients will have an underlying small vessel vasculitis such as microscopic polyangiitis (MPA) or granulomatosis with polyangiitis (GPA) (Wegner granulomatosis) and eosinophic granulomatosis with polyangiitis (EGPA). These disorders are systemic diseases and many organ systems are often affected simultaneously. Flu-like symptoms often occur for weeks in these individuals. Rash usually purpuric, arthralgias, symptoms of a peripheral neuropathy, and nonspecific pulmonary symptoms including pulmonary hemorrhage and chronic sinusitis may be present. Asthma is the prominent symptom in most patients but any organ can be involved by this small and medium sized vessel vasculitis. Eosinophilia is usually present but not specific for EGPA. With MPA and GPA circulating ANCA is usually present. Two major classes of ANCA are reported. Antibodies with a cytoplasmic pattern of staining, c-ANCA, are directed toward proteinase-3 whereas antibodies with perinuclear staining, p-ANCA, are directed toward myeloperoxidase. >75 % of patients will have some pattern of positive ANCA with c-ANCA being more common with GPA and p-ANCA positive in MPA. There is considerable overlap in ANCA patterns, however, with some patients even demonstrating a negative ANCA or positivity to both antigen targets (positive c- and p-ANCA). As with the other types of RPGN, early diagnosis and therapy is essential in order to avoid ESRD. Dramatic response to intravenous steroids and cyclophosphamide is the rule with a >90 % response rate. For patients with aggressive pulmonary disease, plasmapheresis should also be employed. Rituximab has also been shown to be of benefit, particularly as maintenance therapy which is necessary for up to 1 or 2 years. Relapse can occur after many years despite remission so close, regular follow-up is essential [5].

2 Nephrotic Syndrome

Nephrotic syndrome is characterized by heavy proteinuria in association with hypoalbuminemia, edema, and hyperlipidemia. In contrast to nephritic sediment, cellular casts and hematuria are uncommonly encountered in nephrotic syndrome.

2.1 Clinical and Laboratory Features

The typical presenting symptom of nephrotic syndrome is progressive edema. Edema generally starts in the lower extremities; however, periorbital edema, genital edema, ascites, pleural and pericardial effusions can be seen in advanced disease. Nephrotic syndrome should be suspected in patients with these findings in the absence of cirrhosis or congestive heart failure. The decrease in oncotic pressure from albumin loss, with a resultant movement of fluid from the intravascular space to the interstitial space, contributes to the edema. More recently, studies have suggested that there is increased renal sodium reabsorption in nephrotic syndrome, which may occur from both glomerular and tubulointerstitial factors. Severe tubulointerstitial inflammation in nephrotic syndrome has been theorized to increase vasoconstrictive agents (e.g., angiotensin II) while decreasing vasodilatory agents (e.g., nitric oxide) [6]. Heavy proteinuria is the hallmark of nephrotic syndrome, and nephrotic-range proteinuria is defined as greater than 3.5 g of proteinuria in a 24 h urine collection. Moreover, not all patients with nephrotic range proteinuria have nephrotic syndrome, which is accompanied by edema, hypoalbuminemia, and hyperlipidemia. The 24 h urine collection remains the gold standard for quantifying proteinuria, although it has limitations in routine screening for proteinuria. Proteinuria evaluated by a urinalysis dipstick is a semi-quantitative

DOI 10.1007/978-1-4939-0779-3_104-1

screening tool available to most physician providers. In addition, the spot urine protein to creatinine ratio is easy to use in the clinic setting, and provides a quantitative value that accurately estimates the 24 h urine value. The value obtained from the spot urine (in mg/mg) will correlate to the protein excretion in grams per m^2 body surface area. Hypoalbuminemia is often less than 3 g/dL in patients with nephrotic syndrome, although the pathophysiology behind this remains incompletely understood. Most patients with nephrotic syndrome have hyperlipidemia, which may manifest as elevated total and low-density lipoprotein cholesterol, lipoprotein (a), and hypertriglyceridemia. The pathophysiological mechanism of hyperlipidemia likely occurs from increased hepatic synthesis, which is stimulated from decreased plasma oncotic pressure. In addition to these clinical symptoms of nephrotic syndrome, there are multiple additional potential complications encountered. Patients with marked proteinuria and hypoalbuminemia have a prothrombotic tendency, and have increased risk of venous thromboembolism. Moreover, patients with membranous nephropathy as well as those with severe disease, with albumin levels less than 2 mg/dL or proteinuria greater than 10 g in 24 h, appear to be at the highest risk of thromboembolic disease. In general, patients with nephrotic syndrome have a 1.7 relative risk increase in developing DVT compared to patients without it [7]. The cause of increased thrombosis is likely multifactorial, including increased fibrinogen levels, enhanced platelet aggregation, and loss of anticoagulants (such as antithrombin III) in the urine. Patients with nephrotic syndrome have increased susceptibility to infection, especially cellulitis and pneumococcal infection. Children and patients with frequent relapsing disease are at the highest risk. The pathophysiology is not completely understood, but urinary loss of IgG may play a role [8]. Finally, nephrotic syndrome can confer a negative protein balance, which can predispose patients to protein malnutrition. Decreased gastrointestinal absorption of protein from severe edema may play a role in this as well.

2.2 Etiology and Work Up

Heavy proteinuria and the nephrotic syndrome can occur from both primary kidney injury as well as secondary systemic diseases. In children, minimal change disease remains the most frequent cause of nephrotic syndrome. The two most commonly encountered primary, or idiopathic, causes of nephrotic syndrome are focal segmental glomerulosclerosis (FSGS) and membranous nephropathy, both of which can effect up to 30 % of adults. In fact, in African-American adults, FSGS accounts for up to 50 % of cases. Table 1 lists the most commonly encountered primary causes of nephrotic syndrome. Systemic diseases frequently lead to nephrotic syndrome in adults, with diabetes and systemic lupus erythematosus (SLE) the most common causes of secondary nephrotic syndrome (Table 2). Accordingly, additional studies are often necessary to further investigate the possibility of a secondary etiology, which include but are not limited to: hemoglobin A1C complement, HIV screening test, hepatitis serologies (to investigate for hepatitis B and C), rapid plasma reagin (RPR) to evaluate for syphilis, serum and urine protein electrophoresis (to screen for multiple myeloma and amyloidosis), and antinuclear antibodies (for SLE evaluation). Although important to evaluate for hydronephrosis and cystic renal diseases, renal imaging will yield little in differentiating between the different causes of nephrotic syndrome, with the exception

Table 1 Causes of primary nephrotic syndrome in adults

Idiopathic or Primary Nephrotic Syndrome	Incidence
Minimal Change Disease	10–15 %
Focal Segmental Glomerulosclerosis	20–30 %
Membranous nephropathy	25–40 %
Membranoproliferative glomerulonephritis	5 %
Other forms of glomerulonephritis	10–20 %

Table 2 Causes of secondary nephrotic syndrome

Systemic diseases
Diabetes mellitus
Systemic lupus erythematous
Sarcoidosis
Rheumatoid arthritis
Amyloidosis (can be associated with AA or AL amyloid)
Vasculitis (cyroglobulinemia, Henoch-Schönlein purpura, etc.)
Celiac disease
Scleroderma
Infections
Viral (hepatitis B, hepatitis C, HIV, mononucleosis)
Bacterial (streptococcal, syphilis, sub-acute bacterial endocarditis, shunt nephritis)
Parasitic (malaria, schistosomiasis)
Medications
Nonsteroidal anti-inflammatory drugs
Gold, heavy metals
Lithium
Penicillamine
Captopril
Antibiotics (ampicillin, rifampin, etc.)
Bisphosphonates (pamidronate)
Anabolic steroids
Interferon
Neoplastic/malignancies
Leukemia and lymphomas (typically minimal change disease)
Solid tumors (membranous)
Hereditary diseases
Sickle cell disease
Fabry's disease
Alport's syndrome
Partial lipodystrophy
Nail-patella syndrome
Familial nephrotic syndrome
Others
Pregnancy associated (pre-eclampsia)
Serum sickness
Obesity
Reflux nephropathy
Allergies (food, pollen, bee stings)

of enlarged kidney sizes in diabetes and infiltrative disease states. A kidney biopsy is often indicated to help diagnose the type of glomerular disease, identify subtype of disease, as well as to evaluate for activity and chronicity of illness. The results can help clinicians identify who will benefit from treatment. However, not all patients require a kidney biopsy, for example a patient with long standing diabetes with a high clinical suspicion for diabetic nephropathy.

DOI 10.1007/978-1-4939-0779-3_104-1

2.3 Minimal Change Disease

Minimal change disease (MCD) accounts for up to 90 % of idiopathic nephrotic syndrome in children, and 10–15 % in adults. MCD often presents suddenly, and can be associated with medications (nonsteroidal anti-inflammatory drugs) and hematological malignancies (leukemia and lymphomas). Treatment with high dose prednisone usually leads to remission. Because of the high rate of remission with steroids, kidney biopsies are generally not performed in children with new onset nephrotic syndrome until after a trial of prednisone. However, MCD can follow a course of remission and relapses; and up to 50 % of adults can relapse after 1 year. Alternative agents, including cyclophosphamide and cyclosporine, can be considered in patients with frequent relapses to decrease steroid exposure.

2.4 Focal Segmental Glomerulosclerosis

FSGS is the most common cause of nephrotic syndrome in African-Americans and accounts for up to 30 % of lesions seen on kidney biopsies. FSGS can be idiopathic as well as seen secondary to HIV, obesity, and sickle cell disease, amongst others. Up to 40 % of patients with FSGS have hypertension, hematuria, and decreased glomerular filtration rate upon presentation. Spontaneous remission is uncommon, and untreated patients with nephrotic range proteinuria often progress to ESRD within 5–10 years. Accordingly, patients with nephrotic range proteinuria are typically started on immunosuppressive agents, with prednisone being the most common initial agent. Response to therapy can preserve long-term renal function in FSGS, and glucocorticoids can lead to partial or complete remission of proteinuria in up to 60 % of patients. Other immunosuppressive medications used in the treatment of FSGS include cyclosporine and mycophenolate mofetil, specifically in patients who relapse or to attenuate steroid exposure.

2.5 Membranous Nephropathy

Membranous nephropathy is the most common cause of idiopathic nephrotic syndrome in adults, occurring in up to 40 % of cases in some biopsy series. Membranous nephropathy can be idiopathic or occur secondarily to systemic disease (SLE), medications, malignancies (solid tumors), and infections (hepatitis B and C). Recent literature has found an association between idiopathic membranous nephropathy with antibodies against phospholipase A2 receptors found on podocytes [9]. Membranous nephropathy is the most common type of nephrotic syndrome associated with prothrombotic events, including DVT and renal vein thrombosis. Spontaneous remission occurs in one third of patients, while one third have stable renal function longitudinally, the remaining third develop progressive renal failure. Because one third of patients do spontaneously remit, immunosuppressive treatment is generally reserved for patients who are at moderate to high risk for progressive renal failure. Factors associated with increased risk for progression include men, increased age, a decline in GFR over 3 months, and greater than 8 g of proteinuria. The most common initial immunosuppressive regimen includes 6 months of therapy with cyclophosphamide alternating with glucocorticoids on a monthly basis [10]. Alternatively, cyclosporine can be used as an induction agent, with increased rates of relapse once discontinued. More recently, rituximab can be used, primarily in patients with positive anti phospholipase A2 receptor status [11, 12].

2.6 Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis is a rare type of nephrotic syndrome, accounting for approximately 5 % of lesions seen on biopsy registries. There are two major types of MPGN. Type I is immune mediated and often associated with hepatitis C and/or cryoglobulins. Treatment usually centers on targeting the hepatitis virus. Type II MPGN, also called dense deposit disease, is rare and complement mediated.

DOI 10.1007/978-1-4939-0779-3_104-1

2.6.1 Treatment

There are few placebo-controlled double-blind studies investigating the impact of immunosuppressive regimens on the different primary types of nephrotic syndrome, with commonly employed agents including glucocorticoids. Nonimmunosuppressive treatment modalities that can be implemented for the nephrotic syndrome, irregardless of the lesion seen on biopsy. It is important to limit sodium intake, often to less than 3 g/day. Furthermore, diuretics are frequently necessary to facilitate a negative sodium balance. Loop diuretics (furosemide and bumetanide) are first-line agents, and may be required to be administered via the intravenous route if there is a concern for intestinal edema in severe cases. In addition, patients may require a second thiazide type diuretic (metolazone) in severe cases.

In addition to treating the edema associated with nephrotic syndrome, treatment should also target attenuating proteinuria. Angiotensin-converting enzyme inhibitors (ACE Inhibitors) or angiotensin receptor blockers (ARBs) in addition to their antihypertensive effects reduce intraglomerular pressure; this in turn can reduce proteinuria [13]. The hyperlipidemia associated with nephrotic syndrome often resolves with treatment of the nephrotic syndrome. However, statin medications are often implemented to assist in controlling the lipid derangements as well.

Complications of nephrotic syndrome, specifically hypercoagulable disorders, are managed on an individual basis. Heparin, followed by warfarin, is used once a clot is detected. The use of prophylactic warfarin in patients at high risk remains controversial.

3 Tubulointerstitial Diseases of the Kidney

Tubulointerstitial injury of the kidney may occur with any of the primary kidney disorders but also may be the principal manifestation of a diverse array of genetic, toxic, infectious, and metabolic diseases. Features usually include non-nephrotic range proteinturia, hematuria, pyuria, and a variety of tubular disorders such as renal tubular acidosis and nephrogenic diabetes insipidus. Cystic kidney diseases are the most common abnormality that the primary care physician first discovers. Cysts may be single or multiple and may be acquired, developmental, or genetic in origin. Cysts may be benign in nature but also may confer an increased risk of cancer. Table 3 details the different types of cystic kidney disease [14].

3.1 Autosomal Dominant Polycystic Kidney Disease (ADPKD)

ADPKD is the most common inherited kidney disease and accounts for 10 % of the ESRD population. Genetic mutations occur on either the short arm of chromosome 16 (PKD1) (85 % of patients) or on chromosome 4 (PKD2) (15 % of patients). Cysts usually arise from the distal tubules and may only affect a fraction of the tubules. These cysts enlarge and crowd out normal nephrons resulting in progressive kidney failure. There is great variability in this process which translates in a variable phenotype for a particular family. The diagnosis of ADPKD is usually confirmed with imaging studies and is age dependent. In patients with a family history and age<40, more than 3 cysts in one or both kidneys establishes the diagnosis. In patients over 60 years, more than 4 cysts in both kidneys are required to establish the diagnosis. Progressive kidney disease is the norm for patients with ADPKD although the occurrence of ESRD is variable. Risk factors for a more rapid progression include family history, childhood onset, male gender, hypertension, urinary tract infection, kidney stones, black race, and sickle cell disease. Hypertension is very common and is sometimes used as a clinical marker for the disease especially when it occurs at a young age. Drugs that disrupt the renin–angiotensin axis are preferred as initial therapy although multiple drugs may be necessary as CKD progresses. Flank pain is the most common manifestation of the disorder and may be debilitating. Gross hematuria associated with cyst rupture, non-nephrotic range proteinuria, urinary tract infection, and kidney stones occur with increasing

DOI 10.1007/978-1-4939-0779-3_104-1

Table 3 Types of cystic kidney disease

Type of cystic kidney disease	Occurrence	Genetics	Radiographic appearance	Progression and complications	Risk of cancer
Simple cysts	Increase with age	unknown	Solitary, multiple, round, smooth fluid filled	Usually none, no calcifications or hemorrhage	<1 %
Complex cysts	Increase with age	unknown	Solitary, multiple, septa, calcification, enhancement, irregular borders	Usually none, hemorrhage, infection	Increase with greater Bosniak category 5–90 %
Acquired cystic disease ESRD	Increase with length of dialysis	unknown	Similar to simple cysts	Similar to simple cysts unless malignant transformation	5–10 %
ADPKD	>1:1,000 live births	PKD1 and PKD2 genes	Enlarged kidneys with numerous cysts	May progress to ESRD, bleeding, infection, kidney stones	unknown
ARPKD	1:20,000 live births	PKHD1 gene	Enlarged kidneys with numerous, uniform cysts	Progressive loss of kidney function, hepatic fibrosis prominent feature	0
Medullary sponge kidney	unknown	unknown	Dilated collecting ducts	Usually none, kidney stones more common	0
Nephronophthisis	1:50,000 live births	Nine genes (ciliopathy)	Corticomedullary cysts with severe atrophy and scarring of cortex, small kidneys	Tubular dysfunction, sodium wasting, DI, RTA, ESRD by age 20	0

frequency. Several extrarenal manifestations of ADPKD often occur. Cysts can occur in other organs besides the kidney with the liver being most commonly involved. These cysts rarely produce organ failure but hemorrhage or infection can occur in these cysts. Infections in any cyst may be difficult to treat as antibiotic penetration into the cyst fluid may be variable. Antibiotics that penetrate the cyst wall are needed such as trimethoprim-sulfamethoxazole, quinolones, erythromycin, tetracyclines, or metronidazole. Cyst drainage may be necessary to successfully eradicate the infection. The most devastating complication of AKPKD is rupture of an intracerebral aneurysm. Up to 4 % of patients with ADPKD will have this complication. There seems to be a family predilection for this complication. Patients with a family history of sudden noncardiac death or aneurysm should undergo screening. MRI angiography and preemptive repair may be indicated. Other complications of ADPKD include colonic diverticuli (80 %) and cardiac valvular abnormalities (25 %). Vasopressin V2 receptor antagonisits (tolvaptan), mTor pathway inhibitors (sirolimus/everolimus), somatostatin analogs (octreotide, lantreotide), and statins (pravastatin) have all shown promise in slowing the progression of ADPKD. Large clinical trials are underway testing the benefits of these therapies that will alter the natural course of this devastating genetic disease [15].

3.2 Chronic Interstitial Nephritis (CIN)

CIN includes a diverse group of diseases that culminate in prominent interstitial fibrosis and tubular atrophy. A similar disease, reflux nephropathy, affects the lower urinary track initially but invariably gives rise to chronic pyelonephritis and is usually discovered in childhood. Diseases in this group include urinary tract obstruction, prolonged ingestion of non-narcotic analgesics, urate nephropathy, hyperoxaluria, heavy metal poisoning with lead, cadmium or mercury, and infiltrative disorders such as lymphoma or sarcoidosis. Drugs that affect the interstitium include lithium, cisplatin, and calcineurin inhibitors such as cyclosporine. The clinical manifestations of CIN are often overlooked as they are often indolent. CKD occurs but progression is usually measured over a number of years. Renal tubular acidosis,

DOI 10.1007/978-1-4939-0779-3_104-1

Table 4 Stages of AKI

	Assessment	
Stage	Serum Creatinine	Urine Output
1	1.5–1.9× baseline or ≥0.3 mg/dl above baseline	<0.5 ml/kg/h for 6–12 h
2	2.0–2.9× baseline	<0.5 ml/kg/h for 12 h
3	≥3.0 baseline, ≥ 4.0 mg/dl[a], or initiation of renal replacement therapy	<0.3 ml/kg/h for ≥ 24 h or anuria for ≥12 h

[a]with an acute increase of at least 0.5 mg/dl

nephrogenic diabetes insipidus, or Fanconi syndrome may be the predominate manifestation. Non-nephrotic range proteinuria with minimal albuminuria often is seen. Renal sonography reveals shrunken, hyperechoic kidneys and a kidney biopsy is usually not helpful. There is no specific treatment for CIN except for treatment of the underlying disorder.

4 Acute Kidney Injury

Acute Kidney Injury (AKI) could be defined as the abrupt (within 1–7 days) and sustained (over 24 h) decrease in glomerular filtration, urine output, or both. AKI is a common condition, which occurs in significant number of hospitalized patients and affects about half of the patients admitted to ICU [16]. Importantly, community based cases comprise one third of all AKI cases [17]. AKI might be difficult to recognize, it does not have any specific symptoms. Detection might be particularly difficult in edematous patients with fluid overload dilution as they can have falsely lower serum creatinine (SCr). AKI typically develops in the setting of another illness and is associated with high mortality, especially in patients requiring dialysis. Term AKI replaced Acute Renal Failure to allow for an earlier detection and treatment of the AKI. Current guidelines define AKI as an elevation in SCr by ≥0.3 mg/dl within 48 h or urine output <0.5 ml/kg/h for 6 h. AKI is staged based on the severity of the impairment (Table 4).

The causes of AKI could be categorized into three groups: prerenal (caused by abnormal perfusion of the kidney), renal (due to intrinsic kidney damage), and postrenal (caused by obstruction of the urinary tract). It is important to determine the cause whenever possible , however most of the AKI cases in the hospital are multifactorial in etiology.

Prerenal AKI accounts for 70 % of the AKI in the outpatient setting [18] and for 21 % in the hospital [19]. Common causes include poor perfusion of the kidney due to hypovolemia, which could be caused by GI losses. Decreased effective volume in patients with congestive heart failure or liver disease may cause prerenal AKI despite the total fluid overload and edematous state. ACE inhibitors and ARBs, nonsteroidal anti-inflammatory medications (NSAIDs) affect renal perfusion and glomerular filtration, further promoting prerenal AKI by impairing renal auto regulation in the setting of hypovolemia. Patients with CKD are especially susceptible to developing AKI [20]. Fractional Excretion of Sodium (FeNa) is often used to differentiate between prerenal and renal causes of the AKI. It could be calculated using formula:

$$\mathrm{FE_Na} = \frac{100 \times \text{Urinary sodium} \times \text{serum creatinine}}{\text{Serum sodium} \times \text{urinary creatinine}}$$

FeNa <1 % is usually consistent with a prerenal cause of AKI. FeNa should be interpreted carefully: it might be low in AKI patients with contrast nephropathy, rhabdomyolysis, and urinary tract obstruction [21] while diuretic use could be associated with FeNa >1 %. A blood urea nitrogen to creatinine ratio >20 is often used to differentiate between prerenal and renal AKI. Recent data, however, does not support its use as a marker for prerenal AKI [22]. Prerenal AKI is often reversible, but can lead to ischemic AKI if not timely addressed.

DOI 10.1007/978-1-4939-0779-3_104-1

4.1 Intrinsic Renal AKI

Intrinsic renal causes could be further subdivided into tubular, glomerular, interstitial, or vascular causes based on the anatomical structure of the kidney. Acute tubular necrosis (ATN) is the most common cause of AKI in hospitalized patients. It is often a result of ischemia or exposure to nephrotoxins including antibiotics or radiocontrast medications. Muddy brown granular casts could be seen on urine microscopy. ATN often occurs with patients with predisposing conditions, usually reversible but may require renal replacement therapy. Rapidly progressive glomerulonephritis can present as AKI. In the presence of active urinary sediment showing proteinuria, hematuria or casts prompt serological assessment is indicated. Rapid recognition and initiation of appropriate immunosuppressive agent is important to reduce the risk of complications and delay the progression of the disease. Acute Interstitial nephritis could be caused by an allergic reaction to medications. It is often resolved with supportive treatment and withdrawal of the affecting agent. Eosinophiluria and white blood cell casts might be found on urine microscopy in some of the patients. Clinical symptoms may include maculopapular rash, fever, and arthralgias. Corticosteroids have a role in the treatment of acute interstitial nephritis. Vascular causes of AKI comprise occlusion of the renal artery or disease of the abdominal aorta. Microvascular disease includes microangiopathic anemia due to thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, HELLP (*H*emolysis, *El*evated *L*iver enzymes, and *L*ow *p*latelets) and may require plasmopheresis. Atheroembolic disease as a cause for AKI should be suspected in a patient with recent arterial intervention or after vascular surgery.

4.2 Contrast Induced AKI (CI-AKI)

This is one of the most common AKI found in the hospital setting. It typically occurs within 72 h of exposure to iodinated contrast and resolves over the following 5 days. Patients with normal kidney function have minimal risk for CI-AKI. Patients with an estimated GFR < 60 mls/min/1.73 m^2, sepsis, hypovolemia, over 75 years of age, intraabdominal pathology, and receiving nephrotoxic medications including NSAIDS are at increased risk. Estimated GFR could be used for assessment of kidney function in patients with CKD, SCr should be used for those with AKI. Unenhanced scanning, low or iso-osmolar iodinated contrast medium should be considered for those who are at risk for developing CI-AKI. Intravenous volume expansion with 0.9 % sodium chloride or isotonic sodium bicarbonate is recommended in patients identified as at high risk of CI-AKI [23]. Common regimen includes infusion at a rate of 1 ml/kg given for 12 h before and after the contrast. Shorter regimen at a rate of 3 ml/kg per h for 1 h before the contrast administration and 1 ml/kg per h for 6 h after may be used if needed (22). *N*-Acetylcysteine is commonly used for CI-AKI prevention due to low cost and lack of the harm data, however recent data does not support its benefits [24].

Postrenal AKI accounts for up to 10 % of the hospital and 17 % of the community AKI cases respectively and results from obstruction of urine flow at different levels. Both urinary tracts need to be obstructed for the AKI to develop unless the patient has single functioning kidney. Obstruction could be mechanical (prostate hypertrophy, prostate and cervical cancer, retroperitoneal fibrosis) or functional (neurogenic bladder). Relieving of obstruction is the treatment and should be done promptly to improve the chance of recovery.

4.2.1 AKI Risk Factors

A number of chronic diseases including diabetes mellitus and cardiovascular disease are associated with development of AKI. CKD and proteinuria [25] are proven to be risk factors for AKI as well as older age, female gender, volume contraction, solitary kidney, septic shock, obesity, use of the nephrotoxic drugs [26] (Table 5), blood product transfusion, and underlying chronic heart, lung, and liver disease [27].

DOI 10.1007/978-1-4939-0779-3_104-1

Table 5 Drugs that contribute to AKI

Radiocontrast agents
Aminoglycosides
Amphotericin
Nonsteroidal anti-inflammatory drugs
β-lactam antibiotics (specifically contribute to interstitial nephropathy)
Sulphonamides
Aciclovir
Methotrexate
Cisplatin
Ciclosporin
Tacrolimus
Angiotensin-converting-enzyme inhibitors
Angiotensin-receptor blockers

4.2.2 Diagnostic Evaluation

Careful interpretation of the clinical history, physical findings, and laboratory values is very important (Fig. 1). SCr is affected by a number of different factors including nutrition, muscle mass, steroid use, presence of gastrointestinal bleeding, age, sex, and muscle injury. SCr may not change until glomerular filtration decreases by 50 %. Measurement of creatine kinase might be helpful in suspected cases of rhabdomyolysis, while the measurement of inflammatory markers and assays that detect specific antibodies (anti-GBM, ANCA anti-DNA) is helpful to diagnose vasculitis or glomerulonephritis. Haptoglobin, lactic dehydrogenase, bilirubin, and free hemoglobin should be measured if the diagnosis of thrombotic thrombocytopenic purpura is considered. Peripheral smear with findings of schistocytes may support the diagnosis of microangiopathic hemolysis. Finding monoclonal proteins in serum and/or urine might provide diagnostic clues. In some cases, when clinical history, diagnosis and imaging tests are not sufficient renal biopsy might be needed to make the diagnosis. Renal ultrasound should be considered in most patients, specifically in older men. Finding of >50–100 ml on the bladder scan in a patient with AKI should raise suspicion of postrenal causes. Research continues to focus on identifying biomarkers of earlier kidney damage detectible before a change in SCr occurs, similar to cardiac biomarkers used for the evaluation of chest pain.

4.2.3 Prevention and Treatment of the AKI

Prevention of the AKI relies on the recognition of its potential causes, avoidance of possible renal insults whenever possible, and treatment of likely AKI triggers. Most of the patients with AKI will require comanagement between primary care physicians, hospitalists, nephrologists, and other subspecialists depending on the underlying disease process. Treatment of AKI is mainly supportive and includes monitoring of volume status, SCr, and urine output and treatment of the underlying cause. Renal doses of medications should be used and nephrotoxic medications should be avoided. Drug monitoring should be used, whenever possible, to guide the therapy, specifically for vancomycin, aminoglycosides, and other medications. When fluid resuscitation is required, isotonic crystalloid solutions are preferred. Small boluses (500 ml over 30 min) are often given followed by assessment of cardiac output. Urine output should be carefully charted and fluids should be discontinued if oliguria persists. In patients with fluid overload and those who present with acute decompensated heart failure and cardiorenal syndrome, loop diuretics either as continuous infusion or intermediate dose boluses could be used [28] with close monitoring of serum electrolytes. Patients who present with severe hyperkalemia or have EKG changes should be treated with intravenous calcium gluconate (10 mL of 10 % solution infused over 5 min) to

DOI 10.1007/978-1-4939-0779-3_104-1

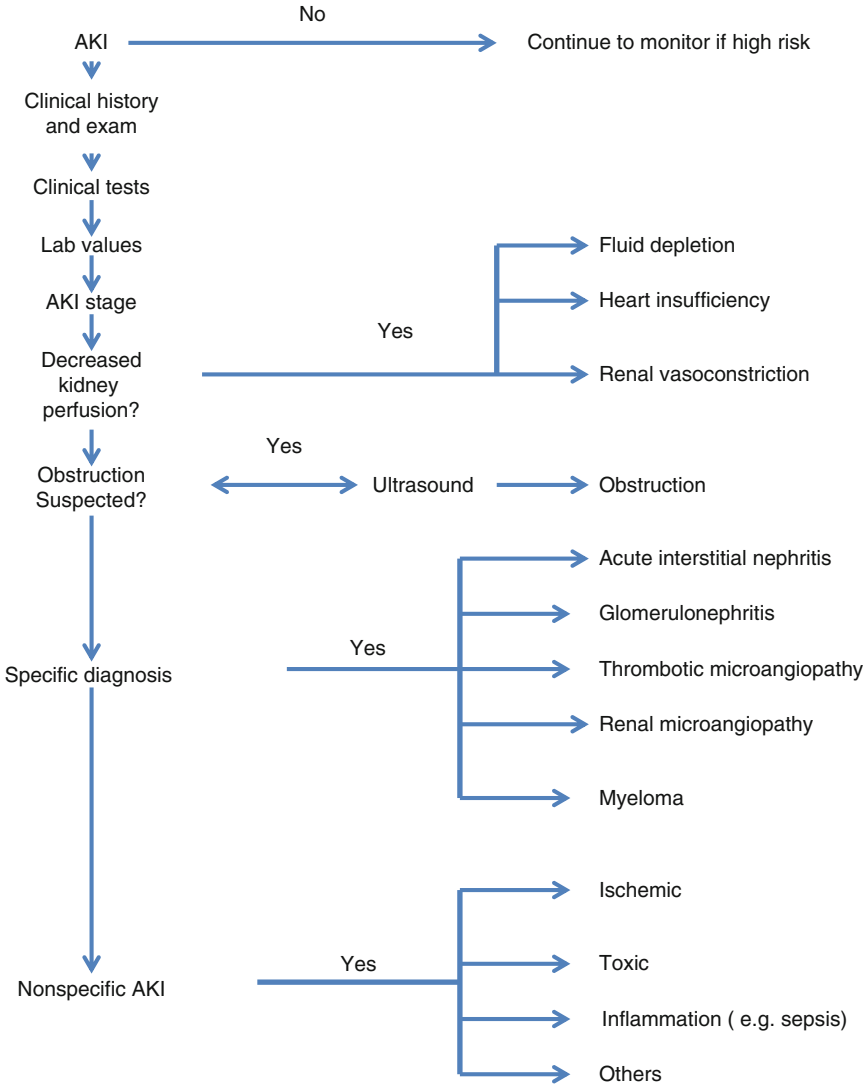

Fig. 1 Evaluation of AKI

stabilize the cardiac cell membrane. IV insulin (5–10 units with 12.5 or 25 g of dextrose) with or without a β_2-Adrenergic agonist could be used to lower potassium by causing intracellular shift. When administered together, they work better than either medication alone; rebound occurs in about 1–2 h. Nutrition 20–30 kcal/kg/day in patients with any stage of AKI is recommended [23], enteral nutrition is preferred. After nephrology consult is obtained, consideration might be given to renal biopsy and disease specific treatment (steroids, plasmapheresis, immunosuppressive therapy) is initiated. For those who do not improve with conservative management or exhibit uremic complications like difficult to control hyperkalemia, metabolic acidosis or volume overload, renal replacement therapy might be required.

4.2.4 Follow Up Care

AKI is an important risk factor for CKD even among patients who recovered completely from this condition. Severity and number of the AKI episodes are risks for development of CKD [29]. Patients with history of AKI should be reevaluated in 3 months for AKI resolution, new onset, or worsening of the CKD [23].

DOI 10.1007/978-1-4939-0779-3_104-1

Table 6 Prognosis of CKD by GFR and albuminuria categories

Persistent albuminuria categories				
Stage	GFR ml/min/1.73 m^2	<30 mg/g	30–300 mg/g	>300 mg/g
1	≥90 normal or high	Low risk	Moderate risk	High risk
2	60–89 mildly decreased	Low risk	Moderate risk	High risk
3A	45–59 mildly to moderately decreased	Moderate risk	High risk	Very high risk
3B	30–44 moderately to severely decreased	High risk	Very high risk	Very high risk
4	15–29 severely decreased	Very high risk	Very high risk	Very high risk
5	<15 kidney failure	Very high risk	Very high risk	Very high risk

5 CKD

CKD is a worldwide problem and is associated with increased mortality, morbidity, and health care costs. Disease affects an estimated 10 % or over 20 million adults in the United States and it is the eighth leading cause of death. one out of three patients with diabetes and one out of five patients with hypertension has CKD [30]. Patients with CKD are at significantly increased risks of cardiovascular disease and stroke [31, 32]. Incidence and prevalence of CKD has continued to rise which might be explained by the increasing prevalence of diabetes mellitus and hypertension, the leading risk factors for CKD. About 1 % of CKD patients are treated with dialysis and/or kidney transplantation, primary care physicians manage most of the nondialysis CKD patients.

5.1 CKD Definition and Detection

CKD is defined by the presence of structural or functional abnormalities of the kidney with or without an accompanying reduction in Glomerular Filtration Rate (GFR). Patients with CKD may have one or more of the following: pathologic abnormalities, markers of kidney damage (i.e., imaging abnormalities and abnormalities in serum or urine, including proteinuria and abnormal urinary sediment), or GFR less than 60 mL per minute per 1.73 m^2 for at least 3 months. CKD is classified into five stages on the basis of GFR. Normal GFR in young adults is about 125 mL/min per 1.73 m^2; GFR < 15 mL/min per 1.73 m^2 is defined as kidney failure. Presence of albuminuria even with normal GFR signifies CKD. Recognition that patients with GFR < 45 ml/min per 1.73 m^2 experience faster disease progression [33] and that proteinuria affects CKD evolution and influences mortality led to modification of the guidelines in 2012 [34]. Table 6 outlines prognosis of CKD by GFR and albuminuria categories [34].

It is now recognized that CKD and AKI are closely connected: AKI can lead to CKD, if the duration of the abnormality is unknown, the possibility of AKI should be considered and appropriate evaluation performed for reversible causes. CKD is a risk factor for developing AKI, patients with CKD are 10 times more likely to develop AKI than those without CKD [35]. Patients who are older, have diabetes, hypertension, obese, and those with cardiovascular disease are at risk for CKD. CKD is often asymptomatic until advanced stages making screening important. When symptoms are present, they include fatigue, hypertension, edema, shortness of breath, leg cramps, poor appetite, and abnormal urination pattern. Two simple tests could identify CKD: serum creatinine to calculate the GFR and urinary albumin to creatinine ratio to detect albuminuria. Annual CKD screening for patients at risk is recommended by several professional organizations [36, 37]. The evidence to support CKD screening in asymptomatic adults is lacking.

DOI 10.1007/978-1-4939-0779-3_104-1

Table 7 Etiology of CKD

Diabetic kidney disease	Diabetes Mellitus Type 2
	Diabetes Mellitus Type 1
Nondiabetic kidney disease	
Vascular diseases	Hypertension, ischemic renal disease
Glomerular diseases	*Primary*: lupus nephritis, vasculitis, membranous nephropathy, minimal change disease, focal segmental glomerulosclerosis, immunoglobulin A nephropathy
	Secondary: infections (e.g., hepatitis B and C, human immunodeficiency virus–associated bacterial endocarditis), amyloidosis, heroin use, malignancy (e.g., leukemia, Hodgkin lymphoma, carcinoma)
Cystic diseases	Polycystic kidney disease
Tubulointerstitial disease	Urinary tract infections, nephrolithiasis, obstruction, sarcoidosis, multiple myeloma, drug toxicity (e.g., proton pump inhibitors, lithium, nonsteroidal anti-inflammatory drugs)

5.2 Etiology

Although the most common causes of CKD are diabetes and hypertension, which account for over two thirds of all CKD cases, CKD can be caused by many other conditions (Table 7). Diabetic kidney disease usually presents as slowly progressing albuminuria, sometimes to the nephrotic range when albumin to creatinine ratio is usually over 2,200 mg per g or protein to creatinine ration is over 3,000 mg per g, hypertension and GFR decline. Hypertensive kidney disease might be associated with albuminuria that develops after GFR decline. Urinalysis can provide diagnostic clues to detection of glomerulonephritis, tubulointerstitial disease, vasculitis, hereditary nephritis, and lupus nephritis; however, it is not routinely recommended in otherwise healthy patients.

A thorough investigation is important in assessing CKD and includes determining the etiology and type of CKD whenever possible and evaluating for comorbidities. Proteinuria refers to increased excretion of any urinary protein, including albumin and other serum proteins (tubular proteins). A normal urinary protein-to-creatinine ratio is less than 200 mg per g; proteinuria is a predictor of total mortality and CKD progression and can help determine the type of CKD. Albuminuria is an abnormal excretion of albumin when albumin-to-creatinine ratio exceeds 30 mg per g. It is further subdivided into microalbuminuria, defined as albumin-to-creatinine ratio of 30–300 mg per g and macroalbuminuria when ratio exceeds 300 mg per g. Albuminuria on a random nontimed urine should be confirmed with subsequent early morning urine sample. If significant, nonalbumin proteinuria is suspected, assays for detection of Bence Jones proteins should be used. Albuminuria and GFR should be assessed annually for patients with CKD [34] and small variations in GFR are common and might not indicate progression. Rapid progression is defined as drop of 5 ml/min/1.73 m^2 per year. At the time of the CKD diagnosis patients should be assessed to identify risk factors for progression: cause of CKD, level of GFR and albuminuria (lower GFR levels and higher degree of proteinuria are associated with CKD progression), age, race/ethnicity, elevated blood pressure, hyperglycemia, dyslipidemia, smoking, and exposure to nephrotoxic drugs.

5.3 Treatment

The goals of CKD treatment is to slow progression of CKD, reduce compilations of decreased GFR, reduce risk of cardiovascular disease, and improve survival and quality of life. Death is more likely than progression to dialysis in any stage of CKD [37], assessment of cardiovascular risk factor smoking status, and dyslipidemia is very important. Salt intake should be reduced to less than 2 g of sodium a day (less than 5 g of sodium chloride). Patients with CKD should be encouraged to participate in physical activity 30 min, five times a week. Target for Hg A1C in diabetic patients should be around 7 %. Level should be set at above 7 % for those with comorbidities, reduced life expectancy, and at risk for hypoglycemia

DOI 10.1007/978-1-4939-0779-3_104-1

[34]. Metformin may be continued in people with GFR $\geq$ 45 ml/min/1.73 m^2. Its use should be reviewed in patients with GFR 30–44 45 ml/min/1.73 m^2 and it should be stopped when GFR is 30 ml/min/1.73 m^2 or less [34].

Therapeutic strategies that have been shown to prevent cardiovascular events in patients with CKD include BP control, statins, and angiotensin-converting enzyme inhibitors and angiotensin receptor blockers. The optimal blood pressure goal is the area of controversy. JNC 8 recommends blood pressure goal of less than 140/90 for patients with diabetes and nondiabetic CKD [38]. Use of ACE inhibitors and ARBs is associated with delaying CKD progression including patients with advanced disease stages and, importantly, offers greater survival. They could be stopped temporarily in the setting of AKI and restarted when creatinine stabilizes. In patients with cardiovascular disease and CKD, levels of BNP and troponin should be evaluated carefully. Patients with an estimated GFR of less than 60 mL per minute per 1.73 m^2 require further evaluation to assess for complications. Evaluation for anemia is recommended in women with hemoglobin levels less than 12 g per dL (120 g per L) and in men with levels less than 13.5 g per dL (135 g per L), in addition to nutritional assessment and evaluation for bone disease. Hemoglobin goals should not exceed 11 g per dL (110 g per L) in patients receiving erythropoiesis-stimulating agents due to the risk of major cardiovascular events. Referral to a nephrologist is recommended for patients with CKD stage 4 and for patients who meet other criteria. Decreased GFR affects pharmacokinetics and pharmacodynamics of many medications, increasing the risk of toxic effects if the dose is not appropriately adjusted. The multispecialty team should manage patients with advanced stages of CKD. Renal replacement therapy might need to be initiated to manage symptoms of kidney failure (serositis), acid-based and electrolyte abnormalities, control volume status, and blood pressure which occur when GFR falls below 10 ml/min/1.73 m^2. Preemptive renal transplantation should be considered for patients with GFR less than 20 ml/min/1.73 m^2 with evidence of progressive and irreversible decline over the preceding 6–12 months. Advanced planning should be offered to all patients with CKD and end of life care discussion should be cared on with those choosing conservative care for CKD.

6 Renal Cell Carcinoma

Renal-cell carcinomas originate from the renal epithelium and account for about 90 % of renal cancers. Established risk factors include hypertension, obesity, and active and passive smoking [39]. Acquired renal cystic disease, ESRD, duration of dialysis and tuberous sclerosis are associated with increased risk for renal cell carcinoma as well. Males have higher predominance than females and disease peaks in sixties and seventies. Clear cell carcinomas account for 70–85 % of renal cell carcinomas followed by papillary type that accounts for 7–15 %: approximately 2–3 % of the cases are genetic. Von Hippel-Lindau syndrome (occurring 1 in 36,000 births), autosomal dominant cancer disorder, is associated with retinal angiomas, hemangioblastomas of the central nervous system and clear cell type renal cell carcinomas. The gene responsible for that syndrome is located on chromosome 3 (3p25–26) [40]. Patients with this syndrome develop multifocal and often bilateral renal tumors earlier in life; they require monitoring of the lesions size. Over 50 % of the tumors are found on the unrelated imaging studies [41] and about 10 % of the patients present with classic triad of symptoms: flank pain, palpable abdominal mass and hematuria. Patients might also present with nonspecific symptoms like fatigue, weight loss, anemia, and micro or gross hematuria. Hematuria should be promptly evaluated by computed tomography (CT) to rule out a renal mass and patients older than 35 or with risk factors may require cystoscopy to rule our bladder carcinoma as well [42]. Paraneoplastic syndromes include polycythemia from abnormal erythropoietin production, unexplained fever, hypercalcemia, and Stauffer syndrome: abnormal liver enzyme consistent with cholestasis jaundice and organomegaly in the absence of liver metastasis. Surgical excision (partial

DOI 10.1007/978-1-4939-0779-3_104-1

or total nephrectomy) is the main treatment for renal cell carcinoma. Radio frequency or cryoablative treatments are alternative approaches, especially in patients with small cortical tumors, hereditary RCC, and multiple bilateral tumors. Prognosis depends on the stage and histological subtype. Approach and type of the surgery depends on the size, location, TNM classification, and other anatomical considerations. About one -third of the patients who undergo surgical treatment for localized disease will have recurrence. Median survival varies from 8.8 to 27 months based on the number of risk factors present.

7 Transitional Cell Carcinoma

Renal transitional cell carcinoma accounts for only 7 % of all kidney tumors, but it is the most common cancer of the renal pelvis. Risks factors include smoking, carcinogens exposure, and analgesic use. Most of the patients present with microscopic or macroscopic hematuria. Over 90 % of patients with superficial and confined disease to the renal pelvis or ureter could be cured. The cure rate drops to 10–15 % for those with deeply invasive tumors that are still limited to the renal pelvis or ureter. Patients with cancer spread through the uroepithelial wall or with distant metastases have poor prognosis. The main prognostic factor is the degree of the invasion into or through the uroepithelial wall. Surgical treatment (laparoscopic or open) varies from conservative to total excision of the ureter with a bladder cuff, renal pelvis, and kidney in an attempt to offer the best chance for cure. Chemotherapy with cisplatin-based taxanes and/or gemcitabine agents could be used as an adjuvant to a surgical treatment, for those who are not candidates due to advanced disease or poor general condition or for patients with metastatic disease [43]. The role of radiation treatment is not well stated, but might be beneficial to patients with stages T3/T4 cancer [43].

8 Bladder Cancer

Bladder cancer is the fourth most common cancer in men. The chance men will acquire it during their life is about 1 in 26; for women, the chance is about 1 in 90 [44]. Over 90 % of the bladder cancer is transitional cell carcinomas. Nearly half of the patents are diagnosed when cancer is in earlier stages, ∼35 % have disease confined to the bladder and 4 % present with distant metastasis [44]. The incidence of bladder cancer increases with age peaking between 50 and 70 years. Risk factors for bladder cancer include smoking, environmental and chemical exposures, chronic irritation and infections, and genetic and molecular abnormalities. Patients treated with long-term cyclophosphamide are also at risk. The main symptom is gross painless hematuria; other symptoms like increased frequency, urgency and feeling irritation with voiding should raise a concern for bladder cancer as well. Evaluation includes urine cytology, cystoscopy, and imaging studies [45]. Several urine tumor markers are commercially available, they have high false-positive and false-negative rates and their role in detection and surveillance of the bladder cancer is controversial [46]. The diagnosis and stage is established by transurethral resection with several options available for urinary diversion. Because of the high recurrence rate regular surveillance is critical in management of bladder cancer. After transurethral resection of the tumor, patients need cystoscopy and voided urine cytology every 3 months for 2 years, then 6 months for 2 years, and then once yearly, indefinitely [45]. Imaging to the upper urinary tract every 12–24 months is also recommended to monitor for cancer occurrence. Intravesicular treatment with the BCG and interferon alfa, mitomycin, doxorubicin, thiotepa or gemcitabine could be used to reduce the recurrence.

DOI 10.1007/978-1-4939-0779-3_104-1

9 Wilms' Tumor

Wilms' tumor amounts for about 7 % of all cancers in children, and it is the most common renal neoplasm in pediatric patients. Boys and girls are evenly affected by this disease. 10 % of the children with this disease have other congenital abnormalities. Wilms'tumor is usually unilateral, but 5 % of the patients develop lesions in the second kidney or have bilateral disease. The mean age for the genetic type is 2 years of age and for sporadic cases is 3 years of age. Some patients may present with abdominal pain and hematuria, but most commonly, patients present with abdominal mass found by caregivers or pediatricians. About one fourth of the patients have hypertension due to excessive renal secretion. CT or MRI of the abdomen is used for diagnosis and staging. Wilms' tumor metastasizes to the abdominal lymph nodes, lungs, and liver. Wilms' tumor has a favorable prognosis. It is a curable disease and nearly 90 % of the patients with Wilms' tumor have over 5 years survival rate. Prognosis depends on the number of factors including tumor size, stage of the disease, the diagnosis, histopathologic type, and other tumor markers. All patients with this tumor should be considered for entry into clinical trials [47].

Diseases of the Prostate

Grant Philips*
Washington Family Medicine Residency Program, Washington, PA, USA

1 General Principles

The diseases of the prostate discussed in this chapter, except for a commonality that they occur in the prostate gland, represent a heterogeneous group of conditions with overlapping symptoms. The incidence of these conditions varies considerably by age. Benign prostatic hypertrophy (BPH) and lower urinary tract symptoms (LUTS) generally affect older men; younger men are at higher risk of acute prostatitis, and prostate cancer peaks in men aged 65–74. Because they represent distinct clinical entities, except for BPH and LUTS, these conditions will be presented separately.

2 Benign Prostatic Hypertrophy (BPH) and Lower Urinary Tract Symptoms (LUTS)

2.1 Definition, Background, and Classification

Benign prostatic hypertrophy (BPH) is an age-related condition characterized by proliferation of the smooth muscle and epithelial cells within the prostatic transition zone. The presence of BPH does not imply that patients will have symptoms or complications due to this condition. The etiology remains unknown.

The term lower urinary tract symptoms (LUTS) allows for a broad description of urinary symptoms in a population of older men without identification of a specific disease-based etiology [1]. The most common cause of LUTS is BPH, but the relationship between BPH and LUTS is complex. The term LUTS independent of BPH has been introduced and is gaining worldwide acceptance, although LUTS secondary to BPH is a clinically useful term. LUTS can be associated with other comorbidities including renal insufficiency, bladder calculi, and urinary incontinence.

The presence of BPH contributes to LUTS in at least two ways. Direct bladder outlet obstruction from enlarged tissue represents a static component, while increased smooth muscle tone and resistance within the enlarged gland itself represent a dynamic component. Thus, BPH, LUTS, and direct bladder outlet obstruction are all inextricably related. Finally, BPH and LUTS can be associated with other comorbidities including acute urinary retention, renal insufficiency, hematuria, bladder calculi, urinary incontinence, and recurrent urinary tract infections.

Older literature tended to separate out these clinical conditions, but heterogeneity in defining BPH and LUTS makes validation across study populations difficult for the purpose of classification. Therefore, consistent with newer literature, these conditions will be discussed together as part of a spectrum of disorders rather than distinct entities.

2.2 Epidemiology

The incidence of BPH is age related. In general, most men who live long enough will develop some form of BPH, with estimated incidences of up to 90 % in men over 70. The incidence of LUTS varies across

*Email: tphillips@whs.org

DOI 10.1007/978-1-4939-0779-3_105-1

epidemiologic studies. Up to 60 % of men experience symptoms after the age of 40, and by age 80 this increases to 70 % [2]. Since the number of people older than 80 is expected to rise considerably, from 9.3 million in 2000 to a projected 19.5 million by the year 2030 [3], the prevalence of LUTS and BPH will increase sharply in the near future.

2.3 Approach to the Patient

Men with symptoms of LUTS may not bring these to the attention of their family physician, dismissing these symptoms as a normal consequence of aging. Although it may be tempting for the physician to act similarly, LUTS is associated with a significant prevalence of urinary tract infections, bladder stones, urinary retention, and to a lesser extent acute renal failure. Men with LUTS also report impairment of disease-specific quality of life including sexual dysfunction; consequently, this condition will have an impact on family members and caretakers as well. Men with severe LUTS also have an increased risk of falling.

Neither the American Academy of Family Physicians nor the US Preventive Services Task Force makes recommendations regarding screening for LUTS or BPH [4]. Although no evidence exists that patient-oriented outcomes are improved by screening for this condition, since men may not bring symptoms of this condition to their physician's attention, and given that LUTS is associated with certain poor patient outcomes and the condition is prevalent, the family physician should consider including questions about LUTS in a general review of symptoms.

3 Diagnosis

3.1 History

Most patients with problems caused by BPH and LUTS present with symptoms of dysfunctional voiding.

These symptoms include urinary frequency, decreased force and caliber of the urinary stream, hesitancy, straining, urgency, and nocturia. Additionally, LUTS should be suspected in men with frequent UTIs and symptoms of the other complications of LUTS (see below in differential diagnosis). Severity of dysfunctional voiding will range from minimal to frank urinary retention.

In our "information age," urologic drugs and alternative drugs are heavily advertised on television. Coupled with the proliferation of medical information on the Internet, patients may become aware of and present with symptoms they discovered through these resources. For example, the website of the official foundation of the American Urological Association, available to anyone with Internet access, lists the following symptoms of LUTS [5]:

- The need to frequently empty the bladder, especially at night
- Difficulty in beginning to urinate
- Dribbling after urination ends
- Decreased size and strength of the urine stream
- Sensation that the bladder is not empty, even after a man is done urinating
- Inability to postpone urination once the urge to urinate begins
- Pushing or straining in order to urinate

Evaluation of LUTS symptoms is easier if clinicians use a standardized and validated tool, the most common being the International Prostate Symptom Score (IPSS) derived from the American Urological Association (AUA) score from the early 1990s (Fig. 1, IPSS). This seven-item self-administered questionnaire allows the clinician to address subjective symptoms in an organized manner. By adding

DOI 10.1007/978-1-4939-0779-3_105-1

The International Prostate Symptom Score (I-PSS)

Patient Name: _____ Date of birth: _____

In the past month	Not at all	Less than 1 in 5 times	Less than half the time	About half the time	More than half the time	Almost always	Score
1. Incomplete Emptying How often have you had the sensation of not emptying your bladder?	0	1	2	3	4	5	
2. Frequency How often have you had to urinate less than every two hours?	0	1	2	3	4	5	
3. Intermittency How often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
4.Urgency How often have you found it difficult to postpone urination?	0	1	2	3	4	5	
5. Weak Stream How often have you had a weak urinary stream?	0	1	2	3	4	5	
6. Straining How often have you had to strain to start urination?	0	1	2	3	4	5	
	None	1time	2 times	3 times	4 times	5 times	
7. Nocturia How many times did you typically get up at night to urinate?	0	1	2	3	4	5	

Quality of life

Quality of Life Due to Urinary Symptoms	Delighted	Pleased	Mostly Satisfied	Mixed	Mostly Dissatisfied	Unhappy	Terrible
If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that?	0	1	2	3	4	5	6

The first seven questions of the I-PSS are identical to the questions appearing on the American Urological Association (AUA) Symptom Index which currently categorizes symptoms as:

Mild (symptom score ≤ 7)
Moderate (symptom score range 8-19)
Severe (symptom score range 20-35)

The International Scientific Committee (SCI), recommends the use of only a single question to assess the quality of life. The answers to this question range from "delighted" to "terrible" or 0 to 6. Although this single question may or may not capture the global impact of benign prostatic hyperplasia (BPH) Symptoms or quality of life, it may serve as a valuable starting point for a doctor-patient conversation.

Adapted from http://www.urospec.com/uro/Forms/ipss.pdf accessed 122714

Fig. 1 The International Prostate Symptom Score (IPSS) (Adapted from http://www.urospec.com/uro/Forms/ipss.pdf. Accessed 27 Dec 2014)

the scores with equal weighting to the questions, a summary score is generated which has been shown to be an accurate reflection of a man's overall symptoms over the preceding month.

Care should be taken while interpreting the IPSS. Men report nocturia with accuracy but tend to overstate daytime frequency. Men with low educational status are more likely to misunderstand the IPSS and tend to misrepresent their symptoms and may receive inappropriate treatment. When administered by a medical professional, many of the inaccuracies disappear, even though the questionnaire is recommended as "self-administered." There are other questionnaires that may capture more patients with LUTS, such as the Core Lower Urinary Tract Symptom Score (CLSS), but the IPSS is recommended (level 2 evidence, Grade C recommendation) [6].

Note that besides the seven symptom questions, there is a final question where patients estimate the overall effect of LUTS symptoms on their quality of life. This last question is used independently as a factor in deciding on the appropriate level of therapy. It is sometimes referred to as a "bother score" in some literature.

A detailed medical history should be obtained to identify other causes of voiding dysfunction or comorbidities that may complicate the treatment.

DOI 10.1007/978-1-4939-0779-3_105-1

3.2 Physical Examination

Along with a general physical examination, a digital rectal examination (DRE) and focused neurologic examination should be performed. DRE provides a relatively crude estimate of prostate size when compared with measurements using transrectal ultrasonography or magnetic resonance imaging, but has positive predictive value of 94 % in identifying prostate above 30 cc [7], and is recommended as part of the work-up by the AUA. Nodules and other indications of prostate cancer may also be discovered by this exam and on occasion will change the evaluation and treatment of men with LUTS symptoms.

3.3 Laboratory and Imaging

A urinalysis (UA) should be ordered in all patients to evaluate for a non-BPH pathologic process as a cause of symptoms. Urinalysis assists in distinguishing urinary tract infection (UTI) and bladder cancer from BPH (if cytology is ordered). Other conditions, such as diabetes, may also be uncovered by the UA. The positive predictive value of the UA to detect serious urinary tract disorders, which are relatively uncommon, is low, but given that the UA is noninvasive and inexpensive, its use is valid. Urine cytology should be considered when symptoms include severe irritable symptoms and dysuria, especially if there is a smoking history.

Prostate-specific antigen (PSA) testing is controversial since the presence of BPH can increase PSA levels and cause confusion and unnecessary testing [8]. The AUA recommends PSA testing when life expectancy is greater than 10 years and if the diagnosis of prostate cancer can modify the management. The National Institute for Health and Care Excellence (NICE) guidelines from Britain suggest that men should be asked if they wish to have PSA testing if symptoms are suggestive of bladder outlet obstruction secondary to BPH, their prostate feels abnormal on DRE, or they are concerned about prostate cancer [9]. In the absence of prostate cancer, the PSA provides a guide to prostate volume and is an indication of the likelihood of response to therapy with 5α-reductase inhibitors.

3.4 Special Testing

Routine cystoscopy, imaging of the upper urinary tract, flow rate measurement, post-void residual volume measurement, serum creatinine measurement, and prostate imaging with transabdominal or transrectal ultrasound are not routinely recommended. These and other tests can be used if there is clinical suspicion that these tests will rule out alternative diagnoses, alter treatment, or change specific outcomes.

Voiding diaries are simple and inexpensive and may provide useful objective clinical information. There is a close correlation between LUTS, as assessed by symptom scores, and data generated by voiding charts.

3.5 Differential Diagnosis

There are many things that cause some of the symptoms of LUTS. These include but are not limited to:

- Prostate cancer, bacterial prostatitis, prostatic abscess
- UTI
- Medications: opiates, decongestants, antihistamines, tricyclic antidepressants
- Bladder cancer, neurogenic bladder, overactive bladder, bladder foreign bodies
- Urethral strictures
- Diabetes and other medical conditions that cause nocturia or polyuria

DOI 10.1007/978-1-4939-0779-3_105-1

4 Treatment

Patients with mild degrees of bother (IPSS < 8) and small glands or patients with moderate to severe symptoms (IPSS ≥ 8) who are not bothered by their LUTS may be managed with watchful waiting and lifestyle modifications. Patients with more severe symptoms or bother can be offered medical therapy. Surgical therapy is reserved for patients who fail medical therapy or have complications. Sexual dysfunction can be an associated symptom and should be addressed (see chapter "► Care of the Obese Patient"). Watchful waiting does not imply the total absence of intervention. Patients should be followed closely and monitored for response to therapy and complications of LUTS.

4.1 Behavioral

Symptoms of LUTS can be improved with patient-instituted behavioral interventions. These include timed voiding schedules, decreasing fluid intake before bedtime, avoiding certain spicy foods and caffeine, smoking cessation, and moderating alcohol consumption. Pelvic floor exercises can be helpful, as is treating constipation. Stopping or reducing dosages of diuretics and other medications that adversely affect the bladder and bladder training may all improve LUTS.

4.2 Medications

Two classes of drugs are used to treat BPH and LUTS: α-adrenergic blocker and 5α-reductase inhibitors. α-Adrenergic blocker has a strong physiologic basis for their effectiveness. Smooth muscle tone of the prostate is mediated by α-receptors, and increased smooth muscle tone leads to a reduction in urinary flow rate and worsening symptoms of LUTS. The other class, 5α-reductase inhibitors, works by blocking the conversion of testosterone to its metabolite, dihydrotestosterone (DHT). DHT promotes growth of the prostate. When DHT absorption into the prostate has been reduced, which takes 3–6 months, the prostate shrinks and symptoms of BPH and LUTS are improved.

α-Adrenergic blockers are considered first-line therapeutic option for men with symptoms who desire treatment (level 1 evidence, Grade A recommendation) [6]. Alfuzosin, doxazosin, tamsulosin, and terazosin are the available drugs. They do not alter the natural progression of the disease. These drugs can be considered equally effective though they have varying side effect profiles. Unfortunately, these medications may aggravate sexual dysfunction associated with LUTS.

Several studies have demonstrated that 5α-reductase inhibitors (dutasteride and finasteride), in addition to improving symptoms, can reduce the risk of acute urinary retention secondary to BPH and the need for surgical intervention (level 1 evidence, Grade A recommendation) [10]. Men with small prostates, less than <40 mL, are less likely to benefit from finasteride.

Prognostic factors suggesting the potential for BPH risk progression include:

- Serum PSA >1.4 ng/mL
- Age >50
- Gland volume >30 cc

Combination therapy with α-adrenergic blocker and 5α-reductase inhibitors can be considered if LUTS is associated with prostatic enlargement. Improved symptom score and peak urinary flow rates are improved when compared to monotherapy when either drugs are used alone. Combination therapy is associated with decreased risk of urinary retention or prostate surgery. α-Adrenergic blocker may be discontinued after 6–9 months of therapy if symptoms improve.

Anticolinergics may be used cautiously in patients that have bladder overactivity, but should be avoided in patients with overactive elevated residual urine volume.

DOI 10.1007/978-1-4939-0779-3_105-1

The PDE5 inhibitors, such as sildenafil, vardenafil, and tadalafil, have shown improvement in symptoms and quality of life in men with LUTS and erectile dysfunction and should be considered if appropriate. There is no recommendation to use these drugs unless the patient had erectile dysfunction.

Effectiveness of phytotherapies (e.g., saw palmetto, African plum) is not supported by evidence [11].

4.3 Referrals

Acute urinary retention is often indicative of end-stage bladder decompensation and is an indication for surgical referral. Referral should also be considered in patients with severe LUTS who either fail medical treatment or do not want medical therapy. These treatments include monopolar transurethral resection of the prostate (TURP), laser prostatectomy, transurethral microwave therapy, transurethral needle ablation, and stents. A discussion of these therapies is beyond the scope of this article. The family physician should inform their patients that these treatments can have significant side effects that are procedure dependent. These complications include but are not limited to operative bleeding severe enough to require transfusion, infection, and the need for further procedures at some point in the future. Possible postoperative complications affecting sexual function include retrograde ejaculation (occurring in approximately one-third of patients) and impotence or erectile dysfunction not present preoperatively.

4.4 Patient Education

Patient education centers around behavioral treatments described above. Additionally, since there is little evidence that any dietary supplement, combination of phytotherapeutic agents, or other nonconventional therapy is effective for the management of BPH/ LUTS, and these treatments can be expensive, the family physician may consider counseling patients against pursuing these treatments. Finally, patients who elect to pursue a watchful waiting treatment plan should be reevaluated at 6 months. Additionally, patients should be educated on the non-pharmacologic treatments that help:

- Fluid restriction particularly prior to bedtime
- Avoidance of caffeinated beverages and spicy foods
- Avoidance/monitoring of some drugs (e.g., diuretics, decongestants, antihistamines, antidepressants)
- Timed or organized voiding (bladder retraining)
- Pelvic floor exercises
- Avoidance or treatment of constipation

5 Prevention

There is no good evidence for any specific primary preventions for BPH, but some literature suggests that weight loss, regular physical activity, vegetable consumption, and reduction of fatty food can reduce the risk of developing BPH. Since these recommendations are in keeping with general good health, patients should undertake these behaviors.

6 Family and Community Issues

There is a clear relationship between LUTS due to BPH and erectile dysfunction. As symptoms increase, there is associated higher rate of sexual dissatisfaction. While there are no studies that directly address this issue, family physicians should consider this and discuss sexual function even if the patient does not

DOI 10.1007/978-1-4939-0779-3_105-1

volunteer this information. Additionally, men may be embarrassed about this condition and might even be pushed to discuss this issue by their spouses.

7 Prostatitis

7.1 General Principles

The term prostatitis encompasses a group of common conditions that are distinct but interrelated clinical entities such as acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis/chronic pelvic pain syndrome, and asymptomatic prostatitis, and all have varying clinical significances, etiologies, treatment plans, and long-term prognoses.

The National Institute of Health (NIH) consensus classification will be used to separate these conditions into their different categories for purposes of discussion. Limited research exists to guide the diagnosis and management of these entities, making prostatitis a challenging condition to manage.

7.2 Definition/Background

The National Institute of Health/National Institute of Diabetes and Digestive and Kidney Diseases classification of prostatitis syndromes is the most accepted classification system. This categorized prostatitis syndromes into four classes with two subclasses [12] (Table 1):

7.3 Epidemiology

The exact incidence of prostatitis is unknown, although it is a common disorder with an estimated incidence in one study of approximately 9.7 % [13]. Though acute prostatitis is often considered a disease of younger men (aged 35–50 years), it does occur in older men as well. Acute and chronic bacterial

Table 1 NIH prostatitis classification

Category	Designation	Description
I	Acute bacterial prostatitis	Acute infection of the prostate gland
		Recovery of bacteria from prostatic fluid
		Purulence of fluid
		Systemic signs of infectious illness (fever, chills, myalgias)
II	Chronic bacterial prostatitis	Chronic infection of the prostate gland
		Recovery of bacteria in significant numbers from prostatic fluid in the absence of concomitant urinary infection
		No significant systemic signs (as in acute bacterial prostatitis)
III	Chronic nonbacterial prostatitis/chronic pelvic pain syndrome (CPPS)	No demonstrable infection
IIIA	Inflammatory	WBC in semen/EPS/post-prostatic massage urine
		Leukocytes in semen, expressed prostatic secretions, or post-prostatic massage urine
IIIB	Noninflammatory	No leukocytes in semen, expressed prostatic secretions, or post-prostatic massage urine
IV	Asymptomatic inflammatory prostatitis	Patients present with BPH, elevated PSA level, prostate cancer, or infertility
	By definition the patient has no symptoms	Microscopy of EPS or semen and/or histologic examination of BPH chips, prostate cancer specimens, or prostate biopsy specimens disclose evidence of prostatic inflammation

WBC white blood cell, *EPS* expressed prostatic secretion, *BPH* benign prostatic hypertrophy/lower urinary tract symptoms

DOI 10.1007/978-1-4939-0779-3_105-1

prostatitis affects less than 5 % of men with prostatitis. Most patients with prostatitis are found to have either nonbacterial prostatitis or inflammatory prostatitis. When evaluating a patient with symptoms of prostatitis, it is important to classify the condition according to the NIH system since treatment options vary with the condition. Approximately 5 % of patients with acute bacterial prostatitis may progress to chronic bacterial prostatitis.

7.4 Acute Bacterial Prostatitis (ABP: Category I)

7.4.1 Approach to the Patient

Acute bacterial prostatitis, category I (ABP), is an often generalized infection. Patients are generally very ill and may be septic. ABP in most patients probably originates from ascending urethral infections and probably results from the reflux of infected urine into the ejaculatory and prostatic ducts that empty into the posterior urethra. ABP may develop in patients after initial prostate biopsy despite pre-procedural prophylactic antibiotic administration.

7.4.2 Diagnosis

History Men present with dysuria, frequency, and suprapubic, pelvic, or perineal pain with variable voiding symptoms. Fever, chills, malaise, nausea, and vomiting are common. Elderly men may have acute mental status changes. Bladder neck spasm may result in urinary retention and is seen in around one-fifth of patients.

Other contributing historical factors include sexual history, history of sexually transmitted diseases or urethritis, coexisting medical problems, and a history of prior prostate procedures and inguinal or pelvic surgery.

Physical Evaluation consists of a complete physical examination, with special attention to the abdominal, genital, and perineal areas. A gentle digital rectal examination should be performed – with a vigorous digital rectal examination, there is a theoretical risk of systemic bacterial dissemination. The prostate is very tender, enlarged, and boggy. A palpable, distended bladder may indicate urinary retention. Other aspects of the physical may be indicative of a general septic state.

Laboratory and Imaging and Special Testing A urinalysis and midstream culture should be obtained in all patients. The presence of more than ten white blood cells per high-power field suggests a positive diagnosis. Other laboratory testings – CBC, electrolyte levels, and blood culture – should be ordered if indicated by the severity of the presentation. Residual urine should be documented by ultrasound if a patient has a palpable bladder or urinary retention is suspected. Serum C-reactive protein is usually elevated and may be obtained if a septic picture is present. Because increased vascular permeability and disrupted epithelium of the prostate gland cause leakage of PSA, checking a PSA is not indicated since levels are usually elevated. If elevated, PSA levels will normalize following treatment, and failure to do so may indicate concurrent prostate cancer. CT scanning is indicated if considering the need to diagnose and drain prostatic or pelvic abscess or for ruling out other pelvic pathology-mimicking prostatitis.

7.4.3 Treatment

Medication Acute prostatitis can be considered a medical emergency. Patients with suspected sepsis or who are severely ill should be hospitalized and treated with parenteral antibiotics. Supportive therapy – fluids, analgesics, and antipyretics – is ordered as indicated. Short-term urethral catheterization may be necessary if there is urinary retention, but carries with it the theoretical risk of bacteremia, especially with traumatic catheterization.

DOI 10.1007/978-1-4939-0779-3_105-1

Initiation of empirical antibiotics is important prior to obtaining culture results. The most common cause of acute prostatitis is the *Enterobacteriaceae* family of gram-negative bacteria, which originates in the gastrointestinal flora. *Escherichia coli* is the most common, but other gram-negative organisms, such as *Klebsiella*, *Proteus*, and *Pseudomonas*, and gram-positive *Enterococcus* species are often isolated as well. Empiric antibiotic therapy should be directed at these organisms with consideration of local sensitivity patterns.

For hospitalized patients, useful agents include combination of penicillin (ampicillin) and an aminoglycoside (gentamicin), second- or third-generation cephalosporins (ceftriaxone, cefotaxime), or a fluoroquinolone (ciprofloxin, levofloxin). Aminoglycosides should be avoided in patients with preexisting renal disease.

Less ill patients may be treated as an outpatient with careful follow-up. Fluoroquinolones are recommended as first-line agents. Compared with concentrations in plasma, drug levels are generally higher in urine, similar in seminal fluid and prostatic tissue, and lower but therapeutic in prostatic fluid. Unfortunately, antibiotic resistance to fluoroquinolones is increasing, and local resistance patterns should be considered when planning therapy.

Patients with acute prostatitis secondary to manipulation have a higher risk of prostate abscess and frequency of multiple infections, with causative organisms other than *E. coli*. Consequently, these men may require modified treatment.

When the acute phase of infection settles down, therapy should be continued with one of the oral antimicrobial agents appropriate for the treatment of chronic bacterial prostatitis (see below). The duration of optimal therapy is unknown, but between 2 and 4 weeks has been suggested [14].

In addition to antibiotic therapy, nonsteroidal anti-inflammatory drugs (NSAIDs) may offer both analgesia and more rapid healing through liquefaction of prostatic secretions.

Sexually transmissible infections such as chlamydia and gonorrhea should be considered, particularly in young men. If chlamydia is thought to be the causative agent, azithromycin 1 g orally stat or doxycycline 100 mg orally twice daily for 7 days is appropriate. If gonorrhea is suspected, ceftriaxone 500 mg intramuscularly and azithromycin 1 g orally are indicated.

Referral Urologic consultation should be obtained in patients with urinary obstruction or other complications that require intervention, such as suspected abscess formation. Infectious disease consultation is indicated for unusual causative organisms, immunocompromised patients, or those who do not respond to initial therapy.

7.4.4 Prevention

Certain conditions, such as diabetes mellitus and promiscuous sexual activity, may predispose to the development of acute prostatitis. Control of diabetes and safe sex practices theoretically decrease the incidence of this condition.

7.5 Chronic Bacterial Prostatitis (CBP: Category II)

CBP is caused by chronic bacterial infection of the prostate, with or without prostatic symptoms. Patients may be asymptomatic and have incidentally noted persistent or recurrent bacteriuria or may present with recurrent urinary tract infection associated with classic symptoms such as frequency, dysuria, urgency, perineal discomfort, and a low-grade fever.

7.5.1 Approach to the Patient

The symptoms of CBP (NIH category II) cannot be distinguished from those of CP/CPPS (NIH category III), and the evaluation must determine which condition exists. Chronic prostatitis is essentially a

DOI 10.1007/978-1-4939-0779-3_105-1

diagnosis of exclusion. The evaluation should exclude other possible causes for the patients' symptoms such as benign prostatic hyperplasia, urethral stricture, and urinary infection. Sexual dysfunction may accompany chronic bacterial prostatitis, although it does not clearly occur more commonly than in men of a similar age without prostatitis.

7.5.2 Diagnosis

History Symptoms of CP/CPPS can vary widely and include pain in the perineum, lower abdomen, testicles, and penis and with ejaculation, bladder irritation (irritative symptoms during micturition), bladder outlet obstruction, and sometimes blood in the semen. Additional symptoms include erectile dysfunction and loss of libido. The patient may be free of symptoms between the episodes. Recurrent infections of the urinary tract with the same pathogen are typical. A patient may also have a history of urethritis, epididymitis, and distal penile pain.

Physical Examination The physical exam may be normal or nonspecific. Important aspects of the physical exam include the abdominal examination followed by careful examination and palpation of the groin, spermatic cord, epididymis,, and testes. The clinician is looking for areas of pain or discomfort, for masses, and for urinary retention. A digital rectal examination evaluates the prostate for tenderness or discomfort, consistency, nodules, and irregularities.

Laboratory and Imaging A urine analysis and culture should be ordered. For patients with recurrent symptoms, the culture often yields repeated isolation of the same organism. The diagnosis of CBP is made with either a four-glass test (initial urine, midstream urine, expressed prostatic secretion, urine after prostatic massage) or with a two-glass test (midstream urine and post-prostatic massage urine). The impracticality of the four-glass test limits its usefulness. The two diagnostic methods can be regarded as clinically equivalent.

Diagnostic criteria for CBP are:

- Bacterial count in the prostatic secretion and/or in the post-prostatic massage urine should be tenfold greater than in midstream urine.
- $\geq 10/mm^3$ in post-prostatic massage urine or $\geq 10/1{,}000 \times$ expressed prostatic secretion.
- Leukocytes or noncellular markers of inflammation (e.g., leukocyte esterase or interleukin-8) must be detected in prostatic secretion and/or in post-prostatic massage urine.
- Leukocytes in ejaculate are $>10^6$ PPL/mL (the test for leukocytes in ejaculate must be performed with special stains (e.g., peroxidase stain), to distinguish leukocytes microscopically from the precursors of spermatozoa).
- Bacteria in the ejaculate alone are not adequate, as the microbiological findings only agree with the results of the two-glass or four-glass tests in about half the cases.

Practical details of the two-glass test: The patient provides a midstream pre-massage urine specimen. The physician performs prostatic massage, and a second urine specimen (initial 10 mL) is obtained. Microscopy and culture of the two screening urine specimens allow the categorization of the majority of patients presenting with a chronic prostatitis syndrome.

Urine culture 48 h posttreatment is useful combined with reevaluation after 7 days of antibiotic treatment to assess clinical response.

Prostate-specific antigen (PSA) testing is not recommended. All forms of prostatitis may falsely elevate the PSA, and a return to normal levels does not rule out prostate cancer. Consequently, testing the PSA in

DOI 10.1007/978-1-4939-0779-3_105-1

this context is essentially prostate cancer screening (see below) and should be discussed carefully with the patient.

Special Testing Special testing is not required for the diagnosis of CBP. If patients have symptoms of obstruction, urodynamic or post-void residual determinations are useful. If patients do not respond to treatment cystoscopy or other urodynamics, studies may be indicated.

The NIH Chronic Prostatitis Symptom Index from the Chronic Prostatitis Collaborative Research Network (CPCRN) is a validated questionnaire (available at http://www.prostatitis.org/symptomindex.html) that can quantify symptoms and help monitor response to treatment. It is an easily self-administered and highly discriminative test.

Sexually active men younger than 35 years and older men who engage in high-risk sexual behaviors should be tested for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*.

Differential Diagnosis LUTS may mimic chronic prostatitis. Chronic lower urinary tract symptoms in young men are often misdiagnosed as chronic nonbacterial prostatitis when in fact they may have undiagnosed chronic voiding dysfunction. Prostate cancer, though usually asymptomatic, may present with symptoms of CBP. Other conditions to consider are stones or foreign body within the urinary tract, bladder cancer, prostatic abscess, and enterovesical fistula.

7.5.3 Treatment

There is considerable overlap between CBP and chronic nonbacterial prostatitis/chronic pelvic pain syndrome (CPPS – class IIIa and class IIb) discussed in the next section. In this section, recommendations for treating CBP category II are emphasized.

Behavioral Changes to daily activities and dietary changes do not have a prominent role in the treatment. Some physicians have advocated the avoidance of spicy and caffeine-containing foods; however, no evidence has indicated any benefit. Sitz baths and perineal massage may help with discomfort.

Medications A trial of antibiotic therapy is an initial treatment. Fluoroquinolones penetrate relatively well into the prostate and are the therapy of choice. Trimethoprim/sulfamethoxazole may be considered, but tissue penetration is less effective, and there may be local resistance. If cultures (urine, EPS, semen) are positive, or the patient notices significant clinical improvement, a total treatment period of 4–6 weeks is recommended. In culture-negative prostatitis, antibiotics should be discontinued after 2 weeks in the absence of clinical improvement. Second-line drugs include doxycycline, azithromycin, and clarithromycin.

The alpha-blockers can help to decrease recurrences by diminishing urinary obstruction due to prostate enlargement or congestion secondary to inflammation. Combination treatment with α-blockers (tamsulosin, terazosin, or alfuzosin) and antibiotics shows a higher cure rate than antibiotics alone. Men with more severe symptoms are significantly more likely to respond. Treatment with an α-blocker for 3–6 months is reasonable but lacking in good-quality evidence. Nonsteroidal anti-inflammatory drugs (NSAIDs) can provide some relief.

If repetitive courses fail and the patient has improved symptoms while on antibiotics, consider long-term, low-dose, suppressive therapy, especially if cultures remain positive. Medications to consider include trimethoprim/sulfamethoxazole or a fluoroquinolone.

Referrals Urology consultation may help in patients that do not respond to treatment or if a more complex differential diagnosis is considered. Surgery is usually not indicated, though some procedures

DOI 10.1007/978-1-4939-0779-3_105-1

have a limited role. Patients with primary bladder neck obstruction who fail medical therapy may benefit from transurethral incision of the prostate. Other procedures may be indicated depending on the coexistent conditions and are best managed by a urologist. Aggressive surgeries for chronic prostatitis generally cause more problems and lack solid evidence to support their use.

Counseling and Patient Education This will be discussed as part of patient education of chronic nonbacterial prostatitis/chronic pelvic pain syndrome (NIH class III).

7.6 Family Issues

As mentioned above, this condition is associated with sexual dysfunction and will often have an impact on the patient's spouse, who may also either push the patient for treatment or even mention this condition in a visit of her own without the husband present.

7.7 Chronic Nonbacterial Prostatitis/Chronic Pelvic Pain Syndrome (CPPS: Class IIIa and Class IIb)

7.7.1 General Principles

This condition is more common than either acute bacterial or chronic bacterial prostatitis. The etiology is poorly understood. Inflammatory and infectious causative mechanisms have been proposed, although there is poor correlation between the amount of inflammation within the prostate gland itself and the degree of symptoms. Psychological stress may be a major contributor to symptom severity, and there may be an association between irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia.

7.7.2 Approach to the Patient

Diagnosis is essentially one of exclusion. The diagnosis of ABP and CBP should be considered and eliminated.

7.7.3 Diagnosis

History Symptoms of CP/CPPS can vary widely and are similar to those of CBP listed above. In most patients, the dominant symptom is pain concentrated in the anorectal and genital areas, but may also affect the entire pelvis. Other symptoms include bladder irritation, bladder outlet obstruction, erectile dysfunction, and hematospermia. Quality of life may also be affected and includes symptoms of depression. Diagnosis requires the patient to have had pelvic pain or urinary symptoms for more than three of the previous 6 months with no evidence of ABP or urinary tract infection in that time [15].

Physical Examination The physical exam is the same as for CBP.

Laboratory, Imaging, and Special Testing A urinalysis and midstream culture should be obtained on all patients. Since leukocytes and bacterial counts do not directly correlate with symptoms, and these abnormalities often present in asymptomatic patients, the utility and importance of this test are limited. The two-glass test can help rule out CBP (NIH class II).

No other tests or imaging is necessary. Since chronic prostatitis/chronic pelvic pain syndrome is a diagnosis of exclusion, additional laboratory or imaging studies are used to rule out other causes of the patients' symptoms and should only be ordered when other diagnoses are considered after a careful history and physical examination. Of note, an elevated PSA should not be attributed to CP/CPPS and warrants further investigation.

Symptoms should be validated with the standard questionnaire of the National Institute of Health Chronic Prostatitis Symptom Index (NIH-CPSI). This questionnaire quantifies symptoms related to pain,

DOI 10.1007/978-1-4939-0779-3_105-1

micturition, and quality of life. Changes in the overall score from baseline of six points correlate with the therapeutic response and can be used to guide therapy.

If there is evidence for obstructive symptoms, uroflowmetry and evaluation of post-void residual are useful. Cystoscopy, CT, or MRI of the prostate are not recommended.

Differential Diagnosis The differential diagnosis is similar to ABP and CBP. The physician should consider diseases of the rectum, the external genitals, the urethra, and the bladder, since the nerves of other pelvic organs may interact with prostatic innervation.

7.7.4 Treatment

Treatment will have to be individualized. Treating this condition may be frustrating for the family physician because guidance in the form of good-quality evidence is lacking: The current understanding of CP/CPPS is not complete enough to determine appropriate interventions for all patients [16].

Behavioral Voiding and pain symptoms associated with CP/CPPS may be secondary to some form of pseudodyssynergia during voiding or repetitive perineal muscle spasm. Some small uncontrolled studies have shown that biofeedback can improve symptoms [17]. Physical therapy and pelvic floor training may help improve symptoms. If depression or anxiety is associated with this condition, treatment with selective serotonin reuptake inhibitor (SSRI) antidepressants can be prescribed.

Medications/Immunizations and Chemoprophylaxis There is no evidence-based or specific treatment for this condition. Of the treatments that have been studied, alpha-adrenergic receptor blockers and antibiotics alone or in combination appear to have the greatest improvement in symptom scores when compared with placebo. Anti-inflammatory medications may also be useful for patients presenting with pain [Grade 2, level C evidence] [18]. When alpha-blockers are used, therapy for at least 6 months is recommended, as this leads to downregulation of the alpha-receptors in the prostate.

Additional therapies such as muscle relaxants (if there is evidence for functional abnormalities in the pelvic floor) and intraprostatic injection of botulinum toxin A are being investigated and may offer additional therapies, but definitive evidence is lacking.

If a patient does not respond to treatment, repeated trials are not warranted. In addition, it is important to consider multimodal therapy with a combination of medications or possible adjunctive therapy with non-pharmacologic modalities. Physical therapy aimed at achieving myofascial trigger point release, performed by a physical therapist, may have benefit in patients with pelvic floor muscle spasm.

Referrals Men with this condition represent a highly complex group of patients, and urology referral is often necessary. One study of patients refractory to medical treatment found that transurethral intraprostatic injection of botulinum neurotoxin type A reduced pain and improved quality of life. By 6 months after treatment, pain had decreased almost 80 % from baseline in the treated group [19].

Counseling CP/CPPS is associated with depression and a poor quality of life. Psychologist referral should be considered in select patients with concomitant psychosocial problems. A cognitive behavioral program specifically targeting CP/CPPS can improve both symptoms and quality of life [20]. This approach addresses pain, urinary difficulties, depressive symptoms, social support, sexual functioning, and overall quality of life issues.

7.7.5 Prevention

There is no known prevention of this condition.

DOI 10.1007/978-1-4939-0779-3_105-1

7.8 Family and Community Issues

Since sexual functioning depression and behavioral issues are common in this condition, appropriate other family members may need to be involved in care plans and counseling.

7.9 Asymptomatic Inflammatory Prostatitis (AIP Class: IV)

By definition, this condition does not cause symptoms. It is diagnosed when inflammatory cells are identified on prostate biopsy. These patients may have presented with BPH, an elevated PSA level, prostate cancer, or infertility. The clinical significance of this condition is uncertain, and treatment is based on the primary reason for the urologic evaluation. When the indication for biopsy is an elevated PSA level, it is important to remember that normalization of the PSA value after antibiotic or 5-alpha-reductase inhibitor therapy does not rule out the diagnosis of prostate cancer, and continued urologic evaluation is warranted.

8 Prostate Cancer

8.1 General Principles

The family physician will usually be more involved in shared decision making regarding screening than in the treatment of prostate cancer. Unfortunately, screening for prostate cancer, threshold levels for prostate-specific antigen (PSA) levels to guide diagnosis and treatment, and the best treatment for diagnosed prostate cancer remain controversial. This places the family physician in the awkward position of interpreting conflicting evidence and recommendations from learned societies when trying to appropriately advise patients. Testosterone is required for the maintenance of a normal, healthy prostatic epithelium and a prerequisite for the development of prostate cancer.

Recommendations of major related organizations regarding screening can be summarized as follows:

The American Academy of Family Physicians (AAFP) and the US Preventive Service Task Force (USPSTF) recommend against screening for prostate cancer, giving it a D recommendation [21, 22].

The *American Urologic Association (AUA)* released a new guideline in 2013 writing that "Men ages 55 to 69 are urged to talk with their doctors about benefits, harms of testing." The AUA recommendation continues, writing: "For men ages 55 to 69 years, the decision to undergo PSA screening involves weighing the benefits of preventing prostate cancer mortality in 1 man for every 1,000 men screened over a decade against the known potential harms associated with screening and treatment. For this reason, shared decision making is recommended for men age 55 to 69 years that are considering PSA screening, and proceeding based on patients' values and preferences" [23].

In a recent review of evidence published in March of 2014 in the Journal of the American Medical Association (JAMA), the authors write: "Available evidence favors clinician discussion of the pros and cons of PSA screening with average-risk men aged 55 to 69 years. Only men who express a definite preference for screening should have PSA testing. Other strategies to mitigate the potential harms of screening include considering biennial screening, a higher PSA threshold for biopsy, and conservative therapy for men receiving a new diagnosis of prostate cancer" [24].

Finally, *the **American Cancer Society*** writes: "Starting at age 50, men should talk to a doctor about the pros and cons of testing so they can decide if testing is the right choice for them. If they are African American or have a father or brother who had prostate cancer before age 65, men should have this talk with a doctor starting at age 45. If men decide to be tested, they should have the PSA blood test with or without a rectal exam. How often they are tested will depend on their PSA level" [25].

DOI 10.1007/978-1-4939-0779-3_105-1

A rational approach can be based on the JAMA recommendations which read: "Because trials have not directly compared different approaches, a reasonable strategy is to inform and involve men not only in the decision whether to screen but also in any subsequent decisions about biopsy and treatment."

8.1.1 Definition/Background

Prostate cancer generally refers to adenocarcinoma originating in the prostate gland. Recommendations regarding this disease change rapidly, so the family practitioner should follow the latest recommendations regarding screening, diagnosis, and treatment of this common condition.

8.1.2 Epidemiology

The lifetime risk of dying of prostate cancer is less than 3 %. About 2 % of all prostate cancer deaths occur before the age of 55 years, 28 % occurring between ages 55 and 74 years and 70 % at age 75 years or older [26]. African American ethnicity and family history in a first-degree relative receiving a diagnosis early in life are the primary risk factors for prostate cancer. Prostate cancer is rarely diagnosed in men younger than 50 years old. More than 75 % of men older than 85 years will have histological evident prostate cancer at autopsy, so it seems that most men who live long enough will get this disease, and this fact should be considered in any discussions regarding screening, diagnosis, and treatment. The incidence of prostate cancer among African Americans is nearly twice that observed among white Americans.

8.1.3 Classification

The Gleason score is used as a prognostic indicator and for planning treatment. This score is based on the sum of the two most common histologic patterns seen on each tissue specimen. In general, tumors are classified as well differentiated (Gleason score 2–6), of intermediate differentiation (Gleason score 7), or poorly differentiated (Gleason score 8–10). Cancer is also classified with regard to its extent (Table 2):

8.2 Approach to the Patient

Most patients with early-stage prostate cancer are asymptomatic. In a patient with symptoms, a thorough evaluation should be undertaken to rule out other causes of symptoms.

8.3 Diagnosis

The diagnosis of prostate cancer is usually made because of an elevated screening PSA level. A palpable nodule on digital rectal examination may prompt a biopsy and the diagnosis. Cancer is sometimes diagnosed as advanced disease because a patient presents with obstructive voiding symptoms, pelvic or perineal discomfort, lower-extremity edema, or bone lesions.

8.3.1 History

Most patients with early disease localized to the gland are asymptomatic. With advanced disease and growth into the urethra or bladder neck, for example, the patient may present with obstructive symptoms:

Table 2 TNM classification of prostate cancer

T1a	Nonpalpable, with 5 % of tissue with cancer, low grade (diagnosed by transurethral resection of the prostate)
T1b	Nonpalpable, with >5 % of tissue with cancer, high grade (diagnosed by transurethral resection of the prostate), or both
T1c	Nonpalpable, but prostate-specific antigen level elevated
T2a	Palpable, one-half of one lobe or less
T2b	Palpable, more than one-half of one lobe, not both lobes
T2c	Palpable, involves both lobes
T3a	Palpable, unilateral capsular penetration

DOI 10.1007/978-1-4939-0779-3_105-1

hesitancy, intermittent urinary stream, decreased force of stream, or hematuria and hematospermia. These symptoms are indistinguishable from symptoms of LUTS described above. Other symptoms of locally advanced disease are lower-extremity edema or discomfort in the pelvic and perineal areas.

Metastasis to the bone may be asymptomatic, but it can cause back pain, pathologic fractures, or spinal cord compression. Prostate cancer most often spreads to the bone, commonly leading to bone pain. Some patients develop spinal cord impingement from the epidural spread of disease, resulting in pain and neurologic compromise that could cause irreversible loss of bowel and bladder function and the ability to walk.

Patients may also present with lymphedema, renal insufficiency, or both as a consequence of obstruction of pelvic lymphatics and urethral outlet obstruction. Visceral metastasis is rare, and any number of symptoms related to the disease of these organ systems may occur.

8.3.2 Physical Examination

Routine digital rectal examination (DRE) as part of a wellness visit is controversial. No studies examined the independent role of screening by DRE [27]. As for men with symptoms suggestive of prostate disease, the DRE has a moderately low sensitivity and specificity for the diagnosis of prostate cancer, with values varying across studies. Walsh et al. discovered that DRE alone had a sensitivity and specificity of 81 % and 40 %, respectively, in diagnosing prostate cancer, with a positive predictive value of 42 % [28]. Since biopsy of a nodule or area of indurations reveals cancer about half the time, prostate biopsy should be undertaken in all men with palpable nodules, even if they have a normal PSA [29].

In patients with symptoms, a general physical exam based on the history will help exclude other causes of their symptoms including LUTS (see above).

8.3.3 Laboratory and Imaging and Special Testing

PSA should be ordered in men suspected of having prostate cancer or for screening if desired. There is no PSA level below which a man can be informed that prostate cancer does not exist. Rather, the risk of prostate cancer, and that of high-grade disease, is continuous as PSA increases [30]. For lower cut points such as 2.5–4.0 ng/mL, approximately 80 % of PSA tests will yield false-positive results. Though a cut point of 4.0 ng/mL has been the historic threshold, the PIVOT study suggests that the greatest benefit is realized when PSA levels are between 10 and 20 ng/mL [31].

Special imaging will depend on the suspected spread of the disease, intention of aggressive therapy, and factors discovered in the history and physical examination. Important considerations for the family physician are:

- Pretreatment serum PSA predicts the response of prostate cancer to local therapy.
- Routine use of a bone scan is not required for staging asymptomatic men with clinically localized prostate cancer when their PSA level is equal to or less than 20.0 ng/mL.
- Computed tomography or magnetic resonance imaging scans may be considered for the staging of men with high-risk clinically localized prostate cancer when the PSA is greater than 20.0 ng/mL or when locally advanced or when the Gleason score is greater than or equal to 8.

8.3.4 Differential Diagnosis

When symptomatic, the differential diagnosis of prostate cancer includes BPH and LUTS and the chronic prostatitis spectrum of disease described above. Other cancers of the abdomen can affect the bladder and bones, and consideration for other cancers is in the differential.

DOI 10.1007/978-1-4939-0779-3_105-1

8.4 Treatment

Treatment of prostate cancer diagnosed by PSA is controversial due in part to the lack of randomized controlled trials, and since the family physician will usually refer patients to specialists, the treatment of prostate cancer will not be discussed in detail here.

As demonstrated in the PIVOT trial, men with low risk or low PSA (<10 ng/mL) have an excellent long-term prognosis with watchful waiting and will represent about 70 % of men diagnosed with prostate cancer [31]. In the European Randomized Study of Screening for Prostate Cancer (ERSPC) trial, biopsy of patients with PSA greater than 3 ng/mL was associated with a reduction in prostate cancer mortality for men aged 55–69 years when compared to the control arm. Nevertheless, it is important to note that PSA is not a dichotomous test, but rather a test that indicates the risk of a harmful cancer over a continuum. In men with a large prostate, older men, and in men with a suspicion of prostatic inflammation, it would be acceptable to withhold biopsy at exceeding 3–4 ng/mL. Unfortunately, evidence to help the family physician decide the best course of therapy based on PSA levels is lacking [32].

8.4.1 Medications/Immunizations and Chemoprophylaxis

Treatment is based on the classification and spread of the tumor. Treatments include watchful waiting; androgen deprivation; retropubic or perineal radical prostatectomy, with or without postoperative radiation therapy to the prostate margins and pelvis; external beam radiation therapy; and brachytherapy (either permanent or temporary radioactive seed implants), with or without external beam radiation therapy to the prostate margins and pelvis.

The PSA level, clinical stage, and biopsy Gleason score are independent predictors of survival without PSA elevation after treatment.

8.4.2 Referrals

Treatment options for prostate cancer are complex and in some cases controversial. Urologic and oncologic referrals are recommended to help guide the family physician.

8.4.3 Counseling and Patient Education

The introduction paragraphs make general recommendations regarding counseling about screening. If the family physician chooses to discuss screening with patients, they should discuss risks and benefits and note that the harms of screening may outweigh any benefit. Benefits of screening include that in the United States, about 233,000 men will receive a diagnosis of prostate cancer, and of those, about 30,000 will die from the disease in 2014 and that about 1 in 100 men may benefit from early diagnosis. Harms include false-positive and negative results and the psychological harm of false-positive test results. Additionally, screening may not improve overall health or increase life expectancy, especially if the cancer has spread at the time of diagnosis. Other harms associated with prostate biopsy include pain, fever, bleeding, infection, and transient urinary difficulties. Harms of treatment include erectile dysfunction, urinary incontinence, bowel dysfunction, and a small risk for premature death. Finally, because at present it is impossible to distinguish tumors that will remain indolent from those destined to be lethal, many men are being subjected to the harms of treatment for prostate cancer that will never become symptomatic.

8.5 Prevention

Epidemiologic studies have suggested that nutritional factors such as reduced fat intake and increased soy protein may have a protective effect against the development of prostate cancer. Vitamins E and C and selenium are not effective at preventing prostate cancer. The use of 5-alpha-reductase inhibitors is under investigation [33].

DOI 10.1007/978-1-4939-0779-3_105-1

8.6 Family and Community Issues

As a final note, there is variability among family physician's approach to screening for prostate cancer. This variability is influenced by personal feelings as well as medicolegal concerns. Patient decision aids may be helpful for the patient and the physician [34]. It is important for family physicians to become familiar with the data and literature on this topic and help patients make the best decisions based on scientific evidence rather than emotional issues that affect both the patient and the physician.

Surgery of the Male Genital System

Joshua L. Latham*
96th Medical Group, FM Residency Faculty, Eglin Family Medicine Residency, Eglin AFB, FL, USA

Testicular Torsion

Testicular torsion is a urological emergency requiring prompt recognition and immediate surgical intervention. The age of onset is typically bimodal peaking in neonates and adolescents; [1] however, physicians must maintain a high index of suspicion in all patients who present with acute scrotal pain. Several key clinical features such as the acute onset of pain, vomiting, and an absent cremasteric reflex aid the clinician in identifying patients who need surgical exploration. Timely restoration of blood flow is imperative to avoid ischemic damage and maintain testicular viability. Therefore, surgical referral should never be delayed for imaging studies or manual detorsion. However, manual detorsion may be attempted as a temporizing measure while awaiting surgery and has been shown to be effective.

Testicular torsion occurs when the testis twists on the spermatic cord (Fig. 1). The rotation of the cord leads to ischemia from vascular obstruction and may cause irreversible testicular damage and necrosis. Incidence rates for testicular torsion range between 1/20,000 and 1/25,000 males per year [2, 3]. While torsions can occur at any age, infants younger than 1 year and adolescents between the ages of 12 and 18 are at greatest risk. There are two anatomical types of testicular torsion, extravaginal and intravaginal (Fig. 1). Extravaginal torsion involves the entire testicle to include the tunica vaginalis, but the underlying pathogenesis is unclear [4]. It almost exclusively manifests in the neonatal period with as many as 70 % of cases occurring prenatally [5]. Intravaginal torsion occurs at any age and refers to the twisting of the spermatic cord within the tunica vaginalis. The most common predisposing anatomic variant leading to intravaginal testicular torsion is the "bell-clapper deformity." It occurs in up to 12 % of males [6] and is characterized by the absence of the posterior attachment between the testis and tunica vaginalis allowing for greater mobility as well as the characteristic horizontal lie of the testis. Even so, not all patients with a "bell-clapper deformity" go on to develop testicular torsion.

The differential diagnosis for acute scrotal pain is extensive (Table 1), but several key historical points and exam findings help identify the patients requiring surgical exploration. Testicular torsion classically presents with the sudden onset of unilateral scrotal pain and is frequently associated with nausea and vomiting. Torsion may occur after trauma or during exercise [7], but often patients will awaken at night with pain. Up to 10 % of patients with testicular torsion have an affected first-degree relative [8], and thus a positive family history may further raise suspicion. Exam findings include tenderness, scrotal edema, a high-riding testis, an abnormal horizontal orientation, and an absent ipsilateral cremasteric reflex. Although highly specific for torsion, a horizontal lie of the testicle occurs in fewer than 50 % of cases [9]. The ipsilateral absence of a cremasteric reflex is both sensitive (96 %) and specific (88 %), but case reports exist of testicular torsions with a normal reflex as well [9]. Skin erythema and/or a reactive hydrocele are also possible but are generally considered late findings and correspond with inflammation beyond 12–24 h. Unfortunately, no single finding consistently excludes the diagnosis or proves to be pathognomonic; however, the presence of unilateral pain occurring in last 24 h, associated nausea/vomiting, an absent cremasteric reflex, and a high-riding testis are the most reliable, predictive factors [10]. As a result, several clinical scoring systems have emerged and are undergoing further validation with

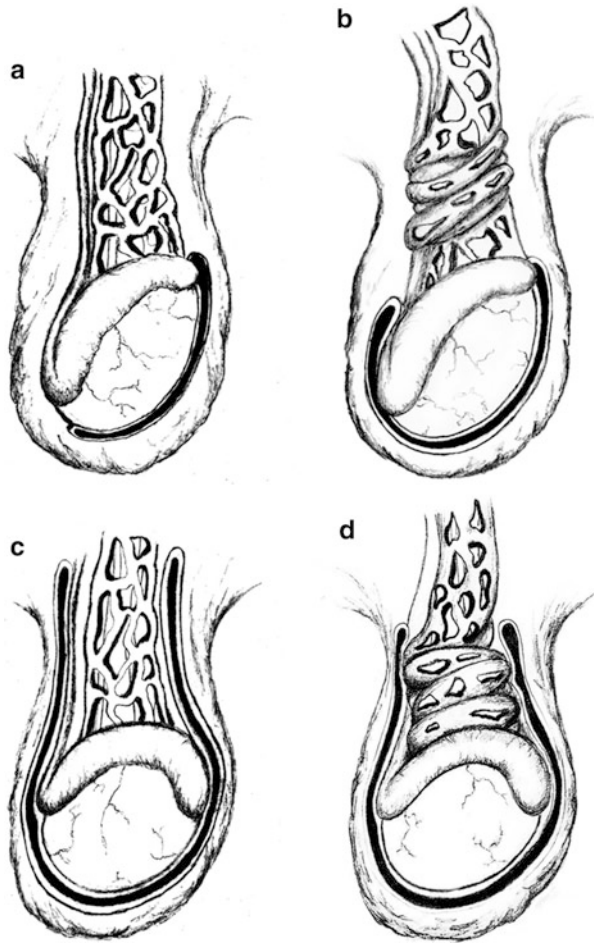

Fig. 1 (**a**) Normal testicular anatomy (*top left*), (**b**) Extravaginal torsion (*top right*), (**c**) Anatomic variant –"Bell-clapper deformity" (*bottom left*) (**d**) Intravaginal torsion (*bottom right*) (Credit: Christine M. Campbell)

promising results that have yielded high sensitivities and lower numbers of unnecessary surgical procedures [10, 11].

When the initial evaluation is consistent with testicular torsion, obtaining additional imaging studies is discouraged to avoid any delay in surgical consultation. However, in cases where the diagnosis remains unclear, color Doppler ultrasonography (CDU) is the test of choice for further evaluation with sensitivity and specificity rates ranging between 89 % and 100 % [12] and a false-negative rate of only 1 % [13]. In the event CDU is not immediately available or the results are inconclusive, the patient should proceed to surgery. Despite the benefits of CDU, time remains the primary drawback, and research is underway to find a point of care test with the accuracy and reliability of CDS. Near-infrared spectroscopy (NIRS) is a technology that uses infrared light to obtain continuous, noninvasive transcutaneous monitoring of deep tissue oxygen saturation [14]. With promising early studies, NIRS has the potential to be a fast, reliable bedside test for testicular torsion in the future [14].

An expeditious urology referral is of primary importance when managing testicular torsion. Irreversible ischemic damage may occur in as little as 6 h, after which testicular salvage rates significantly decline [15]. Preoperative counseling must include the potential need to perform an orchiectomy should the testis be nonviable. The procedure itself involves the intraoperative detorsion and fixation (orchiopexy) of the affected testis via a trans-scrotal approach. In an effort to prevent future torsions, orchiopexy of the contralateral testis is also performed due to the predisposing anatomic defect occurring bilaterally in 80 %

Information from Refs. [1, 7]

of patients [16]. Since the restoration of blood flow is paramount, it is reasonable to attempt manual detorsion [17] while awaiting surgical exploration; however, it should never delay or take the place of surgical intervention. Prior to manipulating the scrotum, ensure the patient has adequate analgesia with intravenous medications, a spermatic cord block, or both. Rotation of the testis is typically performed in a medial to lateral direction (toward the patient's thigh) as if opening a book since the testis often rotates medially with a torsion, yet physicians should keep in mind that a lateral rotation may be present in up to one third of cases [18]. Multiple rotations may be necessary as the testis can be twisted as much as 720°. Indicators of a successful detorsion include the improvement of pain, a lowered position of the testis within the scrotum, reorientation of the testis to a longitudinal lie, and the return of blood flow on CDU. Even in the event of a successful manual detorsion, surgical exploration and orchiopexy are required to reduce the chance of recurrence.

A potential pitfall that physicians must keep in mind is the possibility of intermittent torsion. The diagnosis is often elusive since the pain may be resolved by the time the patient presents for evaluation. A history of spontaneously resolving episodes of acute scrotal pain separated by lengthy periods of time [19] should raise suspicion and is often the only indicator of intermittent torsion. A bulky spermatic cord, mobile testes, and a horizontal lie are possible, but a normal exam doesn't exclude the diagnosis. Nausea and vomiting occur much less frequently, and CDU is only about 75 % sensitive. Therefore, it is imperative that clinicians maintain a high index of suspicion for intermittent torsion and ensure urological follow-up is expedited.

Neonatal Circumcision

Male circumcision is an elective procedure most frequently performed in the neonatal period that involves the surgical removal of the prepuce (i.e., foreskin) for medical, religious, or cultural reasons. Much debate has surrounded the risks versus benefits of this procedure; however, a growing body of evidence has

DOI 10.1007/978-1-4939-0779-3_106-1

emerged that outlines several medical benefits of circumcision. Although rare, complications such as bleeding, infection, or scarring can occur, and physicians must be able to recognize and manage these accordingly. Physicians should provide nonbiased, factual information to parents about the procedure while remaining sensitive to cultural or religious factors when seeking informed consent. The three primary techniques for neonatal circumcision include the Gomco clamp, Hollister Plastibell®, and Mogen clamp.

Male circumcision is one of the oldest and most common surgical procedures with an estimated global prevalence of 30 % [20]. In the United States (U.S.A.), up to 81 % of males are circumcised, but notable differences exist among ethnic groups (91 % of whites, 76 % of blacks, 44 % of Mexican Americans) [21]. When looking at the reasons behind parental decision-making, 30–40 % of parents cited social influence or religious preference, but medical benefits and hygiene were the most common reasons for circumcision and were reported in as many as 67 % of respondents [22].

Opponents of neonatal circumcision voice concerns over procedural risks, pain, psychological trauma, potential decreased sensation, and the infant's inability to give consent. However, decreased sensation or psychological trauma from circumcision have not been supported in the literature [22, 23]. Furthermore, parents are legally authorized to provide consent for medical procedures that are in the best interest of their children, thus any discussion regarding the ethical nature of parental consent would necessarily include all procedures, not just circumcision. Therefore, it is the physician's responsibility to correct common misconceptions and ensure accurate information is communicated to families regarding the potential sequelae of neonatal circumcision. Historically, professional societies have been reluctant to advocate for or against circumcision due to the lack of quality studies and conflicting outcomes. However, recently the American Academy of Pediatrics (AAP) released a policy statement endorsed by the American College of Obstetrics and Gynecologists (ACOG) stating that evidence now suggests the preventive health benefits of circumcision outweigh the risks. Although they do not recommend routine circumcision for all newborns, the task force concluded that the benefits justify access to the procedure for families who choose it [24]. Similarly, the American Urological Association's (AUA) statement highlights the potential benefits of neonatal circumcision and affirms that the incidence of serious complications is extremely low [25]. Both statements emphasize the importance of communicating risks and benefits to parents accurately and without bias.

Potential health benefits of neonatal circumcision include a decrease in urinary tract infections (UTI), penile retractile disorders, penile cancer, and several sexually transmitted infections (STI). Protection against UTIs is greatest in the first year of life with a 90 % reduction; however, additional benefits are also conferred since the lifetime risk of UTI in males is similarly reduced, dropping to 9 % from 32 % in uncircumcised men [26]. Phimosis and paraphimosis are effectively eliminated with circumcision, and balanoposthitis has been shown to occur less frequently in circumcised males. Strong evidence supports the protective effects against penile cancer, but the clinical significance is unclear considering the overall low incidence. A reduction in the acquisition and transmission of human papillomavirus (HPV), herpes simplex virus type 2 (HSV-2), and *Trichomonas vaginalis* has been demonstrated in several studies [27]. Furthermore, a Cochrane review of studies in Africa affirmed the preventive effect of circumcision in heterosexually acquired human immunodeficiency virus (HIV) [28]. In fact, the World Health Organization (WHO) even recommends considering circumcision as part of a comprehensive approach to HIV prevention [29]. When examined collectively by a Mayo Clinic risk-benefit analysis, the benefits of neonatal circumcision over a lifetime exceeded the risks by 100 to 1 [27].

Despite these potential benefits, as with any procedure, risks still exist. Overall, adverse events associated with neonatal circumcision are estimated at <0.5 % in the USA [30] and 1.5 % worldwide [31]. The rate of serious adverse events is even lower at 1 in 5,000 circumcisions [27]. Bleeding is the most common complication and typically occurs along the incised skin edges or due to frenular artery

DOI 10.1007/978-1-4939-0779-3_106-1

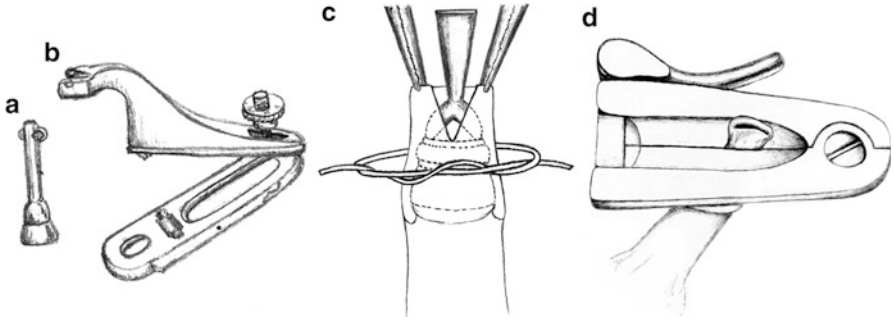

Fig. 2 (**a**) Gomco Clamp (*left*) (**b**) Hollister Plastibell® (*center*) (**c**) Mogen Clamp (*right*) (Credit: Christine M. Campbell)

disruption. The majority of bleeding can be stopped with manual pressure although severe bleeding is possible, especially in the setting of an underlying coagulopathy. If a family history or clinical suspicion of a bleeding disorder exists, consider postponing the procedure until labs can be obtained to rule out a bleeding diathesis. When manual pressure is insufficient to control bleeding, the physician may attempt topical application of lidocaine with epinephrine (1:100,000), silver nitrate, or consider using fine absorbable suture for hemostasis [32]. Another potential complication is a localized wound infection. Most cases are managed with topical antibiotics and close follow-up, but rarely, a severe infection will require systemic antibiotics. In approximately 1 per 1,000 circumcisions [27], a second surgery may be necessary. Reasons for this include excessive/inadequate skin removal, glans injuries, meatal stenosis, urethrocutaneous fistula, epidermal inclusion cysts, and scarring (adhesions, skin bridges, or cicatrix formation). Pediatric urology consultation is recommended for any complications requiring revision.

Neonatal circumcision is typically performed between the first and eighth day of life. Bleeding diathesis, congenital defects (hypospadias, congenital buried penis, etc.), prematurity, and clinical instability are all contraindications. After counseling the family on the risks and benefits, a signed consent should be obtained and a timeout performed prior to the procedure. Physicians must ensure all necessary instruments and supplies are present, sterile, and inspected for defects. Analgesia should be used for all circumcisions and can be provided in various ways. Topical anesthetics such as eutectic mixture of local anesthetics (EMLA) cream are reasonable options but are less effective than infiltrative anesthesia [33]. Oral sucrose is also effective for pain control [34] with some evidence suggesting additional benefit when combined with an anesthetic [35]. A dorsal penile nerve block is performed by infiltrating 0.5 mL of 1 % lidocaine at the 10 and 2 o'clock positions near the base of the penis. The needle should be directed slightly medially as the dorsal penile nerves sit at 1 and 11 o'clock [36]. Another effective infiltrative technique is the ring block. This is accomplished by starting laterally at the base of the penis and subcutaneously injecting 0.5 mL of 1 % lidocaine 180° around the base of the penis. The needle is removed and the process is repeated on the contralateral side so as to form a complete "ring" around the penis [36]. With both infiltrative techniques, ensure aspiration is performed prior to injection and adequate time is given for the anesthetic to take effect.

There are three primary techniques physicians use to perform neonatal circumcision: the Gomco clamp, the Hollister Plastibell®, and the Mogen clamp. All three techniques require the physician to take down adhesions between the glans and the prepuce with blunt dissection prior to removing the foreskin. Care must be taken not to injure the frenulum at the ventral 6 o'clock position. The Gomco clamp is a metal device designed to circumferentially clamp the prepuce during circumcision (Fig. 2). The bell of the device is designed to fit under the prepuce and over the glans, protecting it from injury. Inspecting the device for flaws and ensuring the bell size matches the base plate are necessary safety measures. When used properly, the Gomco clamp reduces the risk of injury to the glans penis and shaft, although the procedure itself may be slightly more time consuming than other techniques as the clamp should be left in

DOI 10.1007/978-1-4939-0779-3_106-1

place at least 3–5 min. The Hollister Plastibell® (Fig. 2) is a plastic device with a grooved bell-shaped ring that is placed under the prepuce and over the glans similar to the Gomco clamp. Once in place, a suture is tied around the prepuce and rests in the groove of the bell, restricting blood flow. The plastic handle is then snapped off leaving the device in place until the prepuce necroses and falls off (usually 6–12 days). Since no incisions are made, bleeding complications are rare. However, if placed improperly or if the plastic ring slips onto the penile shaft, serious complications such as damage to the urethra, glands, or shaft can occur. The Mogen clamp (Fig. 2) is much different from the other techniques. After adhesions to the glans have been taken down, the prepuce is drawn up above the glans, and the Mogen clamp is slid over the prepuce just distal to the glans at the angle of the corona. Prior to closing the clamp, the glans should be manipulated side to side to ensure only skin is in the clamp. Once closed, the prepuce is cut and the clamp removed. The remaining skin is then retracted, exposing the glans. When performed properly, this technique removes more skin dorsally than ventrally. Circumcisions can be performed more quickly using the Mogen clamp, but the glans is not well protected allowing for possible injury. Physicians should undergo specific training and supervision prior to attempting any of these techniques in order to reduce the risk of complications.

Vasectomy

Vasectomy is the most reliable and cost-effective form of long-term contraception for men. It is a safe, permanent procedure performed in the outpatient setting and is highly effective. Complications include bleeding, infection, sperm granuloma, and postvasectomy pain syndrome, but an experienced surgeon can reduce the risk of adverse events. The no-scalpel technique is superior to traditional incisional approaches due to lower complication rates and improved recovery times. A successful procedure may be confirmed by a single semen analysis at least 3 months post vasectomy.

Family medicine physicians perform approximately 13 % of the >500,000 vasectomies done in the U.S.A. each year [37]. Reimbursement for vasectomy averages between $300–$900, which is comparable to or below the costs for long-term female contraceptive options. In contrast to female sterilization, vasectomy is performed in an office setting and avoids the use of general anesthesia making it more cost effective and safer than tubal ligation. The overall failure rate for vasectomy is reported to be <1 % [38]. It is important that patients understand vasectomy is meant to be a permanent form of birth control. While vasectomy reversal is possible, the cost of the procedure is high, and success rates vary [38]. Candidates least likely to seek reversal after a vasectomy are men over 30 in stable, committed relationships [38].

Despite the relative safety and efficacy of the procedure, operative experience significantly impacts complication rates. Physicians who perform less than 10 procedures per year have three times the complications than those performing more than 50 [39]. Bleeding is the most common complication and can lead to hematoma formation. Using the no-scalpel technique, hematoma risk is reduced to 1–2 % from as much as 10 % with incisional methods [40]. The majority of hematomas are managed conservatively with scrotal support, warm baths, and analgesics; however, rare cases may require scrotal exploration or hematoma evacuation. Postoperative infection is another possible complication. As with bleeding, infection risk is reduced by using the no-scalpel technique and occurs in <1 % of cases [40]. Oral antibiotics that cover common skin flora are the first-line treatment for postoperative infections.

Sperm granulomas and postvasectomy pain syndrome are chronic conditions that can arise after vasectomy. A sperm granuloma presents as a painless scrotal mass weeks to months after the procedure and is caused by an immunologic reaction to sperm that leaks from the testicular vas opening. Patients can be reassured that most granulomas resolve spontaneously over time and are generally considered

DOI 10.1007/978-1-4939-0779-3_106-1

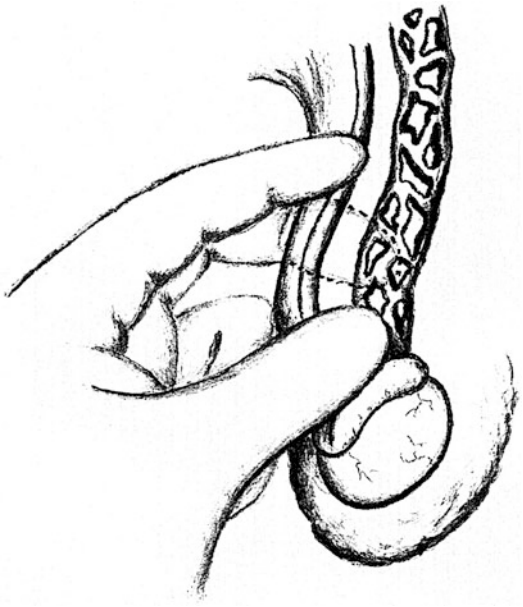

Fig. 3 Isolation of the vas deferens using the three finger technique (Credit: Christine M. Campbell)

protective against epididymal congestion; [41] however, they may also play a potential role in postvasectomy pain syndrome or recanalization leading to vasectomy failure [42]. Postvasectomy pain syndrome refers to varying degrees of chronic pain that persist months to years after a vasectomy secondary to chronic congestive epididymitis [38]. Incidence rates vary in the literature, but according to the AUA, 1–2 % of men experience chronic pain that negatively impacts their quality of life [43]. Management is primarily conservative, but nerve blocks or steroid injections may be considered. Occasionally, refractory cases require additional surgery such as vasovasostomy (vasectomy reversal) or epididymal resection.

Several other medical conditions have been studied for any correlation to vasectomy [44]. No associated increased risks for cardiovascular disease, testicular cancer, or autoimmune disease have been identified. However, a twofold risk for nephrolithiasis was observed in men younger than 46, but the physiological mechanism remains unknown. Any associated risk with prostate cancer remains controversial. Although one study indicated a small increased risk for advanced prostate cancer after vasectomy [45], the AUA guidelines do not recommend routinely counseling patients on a causal relationship between vasectomy and prostate cancer [43].

Preoperatively, a complete urological exam should be performed to ensure the patient has accessible and mobile vas deferens bilaterally without evidence of anatomic abnormalities such as varicoceles, hydroceles, masses, or cryptorchidism. Contraindications for the procedure include local infection, bleeding diathesis, and abnormal findings on exam. Often, physicians may choose to provide an anxiolytic and/or pain medications to be taken orally 45–60 min before the procedure to help relax the patient. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided for 5–7 days prior to the procedure to reduce the risk for bleeding.

The procedure is performed with the patient in the supine position allowing the penis to be draped or taped to the lower abdomen for unobstructed access to the scrotum. The area is prepped with an antiseptic solution and draped using sterile technique. Isolation of the vas deferens is typically performed by using a three-finger technique (Fig. 3) with the nondominate hand. Anesthetic (1 % lidocaine without epinephrine) is infiltrated at the incision site creating a small wheal. A nerve block is then accomplished by fully inserting the needle along the vas sheath toward the inguinal ring and after aspiration injecting 2–5 mL of

DOI 10.1007/978-1-4939-0779-3_106-1

anesthetic into the surrounding tissue as the needle is withdrawn [46]. An emerging alternative to infiltrative anesthesia is the use of a high-pressure jet injector to deliver the anesthesic through intact skin. This does not require a needle and reduces the pain from anesthetic administration; however, the widespread use of this technique is limited by the initial cost of the device.

Accessing the vas deferens should be accomplished by using the no-scalpel technique. Originally developed in China, it is now the preferred technique in the U.S.A. because it reduces procedural time as well as recovery time and has been shown to decrease the risk of bleeding, hematoma, infection, and pain [40]. In contrast to a more traditional incisional approach, the no-scalpel technique utilizes a smooth, sharp-tipped, curved hemostat to puncture a hole in the skin and spread the tissue. The vas deferens is then elevated through the skin with a vas clamp, and the perivasal tissue is dissected or incised, further exposing the vas. The exposed vas can be regrasped with a second vas clamp or towel clip which further elevates the vas out of the skin. The residual tissue and associated blood vessels can then be carefully removed either with blunt dissection or instrumentation to fully isolate 1–2 cm of the vas. The vas is subsequently divided, and although there is no minimum length of vas recommended for removal [43], many physicians will excise 1–1.5 cm.

There are multiple ways to manage the vasal ends including fulguration, ligation, clips, and interfascial positioning. Fulguration (intraluminal cautery or electrocautery) may be used to occlude both ends or just the prostatic end of the vas. Leaving the testicular end open theoretically reduces epididymal congestion but may predispose the formation of a sperm granuloma. Ligation should be avoided due to its higher failure rates [47]. The evidence for the use of clips is underpowered and low quality, while interfascial positioning has been proven to reduce vasectomy failures [48]. Interfascial positioning is performed by using an absorbable suture or clip to separate the vasal ends with the vas sheath. A combination of fulguration and interfascial positioning has been shown to be highly effective [47, 48]. After addressing the vas ends, inspection of the area should confirm hemostasis. The vas can then be gently tucked back into the scrotum by lifting the scrotal skin on each side of the opening. Skin closure is not necessary when using the no-scalpel technique. Physicians may choose to make a second entry point for the contralateral side, or if the original opening was near the midline, the opposite vas can be brought through the same hole.

Postoperative care instructions should be provided to the patient. Having the patient bring a supportive undergarment is beneficial for patient comfort after the procedure. Encourage rest from activity and intermittent application of ice to the scrotum for 48–72 h. Analgesia with acetaminophen or NSAIDs is often sufficient, and pain requiring stronger medications beyond 48–72 h should be evaluated. It is reasonable for patients to resume light activity or work within 2–3 days, but exercise, sexual activity, or lifting should be avoided for 1 week. Remind the patient that an alternate form of contraception is required until infertility is confirmed by postvasectomy semen analysis (PVSA). A single specimen is sufficient as long as 20 ejaculations have occurred and at least 3 months since the procedure have passed [49]. If motile sperm are seen, consider repeating the PVSA in 1–2 months. Vasectomy failure is defined as the presence of motile sperm on PVSA 6 months after the procedure [43].

Selected Disorders of the Genitourinary System

Paul Crawford*
Nellis Family Medicine Residency, Las Vegas, NV, USA

Scrotal Mass

Some genitourinary (GU) disorders present as a scrotal mass and are commonly seen by family physicians for initial evaluation and management. These nontesticular masses include hydrocele, varicocele, indirect hernia, spermatocele, and epididymitis and testicular masses such as testicular cancer. A clinically useful distinction can be made between painful and painless scrotal masses. Although painless masses are not uniformly benign, painful masses are much more likely to require urgent intervention.

Normal testes are firm but not hard, nearly equal in size, smooth, and ovoid. Normal testicular length ranges from 1.5 to 2 cm before puberty and from 4 to 5 cm after puberty. The epididymis is posterolateral to the testicle; the epididymis and testicle are separate but attached. The vas deferens emanates from the tail of the epididymis and joins the vascular pedicle of the testicle to form the spermatic cord. The spermatic cord travels superiorly to the inguinal canal.

Nontesticular Masses

Hydrocele and Indirect Inguinal Hernia

Hydroceles can be differentiated from other testicular masses by transillumination of the fluid with a penlight. Patients with hydroceles also have a palpably normal spermatic cord and inguinal ring above the swollen area. In an upright position or during Valsalva maneuver, hernia and noncommunicating hydrocele enlarge. Scrotal ultrasonography may be helpful in making the diagnosis [1].

Hydroceles are caused by incomplete obliteration of the processus vaginalis allowing a collection of peritoneal fluid between the parietal and visceral layers of the tunica vaginalis surrounding the testicle. Communicating hydroceles have freely flowing fluid between the peritoneal cavity and the tunica vaginalis while noncommunicating hydroceles do not. Hydroceles occur more frequently on the right and are often bilateral [1, 2].

Pediatric hernias are present in 0.1–0.2 % of live births. Risk factors include prematurity and low birth weight. Sudden presentation in an adult of a noncommunicating hydrocele may be secondary to torsion, neoplasm, injury, or infection. Adult hydroceles require no treatment unless they are uncomfortable [1].

Inguinal hernia and communicating hydrocele are indications for surgery in children. Noncommunicating hydroceles often spontaneously close by 1–2 years of age and should not be repaired until that time. Repair by high ligation of the patent processus vaginalis is the same for both hydrocele and inguinal hernia.

Varicocele

A varicocele is a dilation of the venous pampiniform plexus of the spermatic cord, which coalesces into a single testicular vein. The majority are left sided resulting from higher pressures on the left compared to the right. Varicoceles are classically described as feeling like a bag of worms; this feeling increases with Valsalva maneuvers. Varicoceles occur in 15 % of males and usually first appear in adolescence. There is

*Email: paul.crawford@us.af.mil

DOI 10.1007/978-1-4939-0779-3_107-1

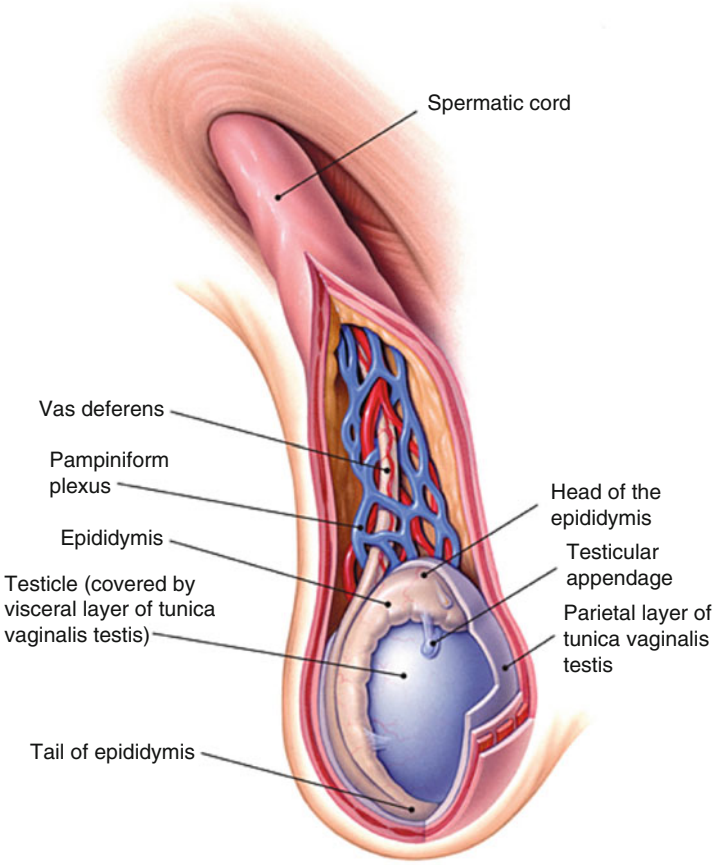

Fig. 1 Anatomy of scrotal contents

conflicting evidence about the association between varicoceles and male infertility [1]. A Cochrane review of ten randomized trials found some increase in fertility from surgical treatment of varicoceles in couples with unexplained subfertility (number needed to treat = 17) [3]. Sudden adult left-sided varicocele may indicate renal tumor, and right-sided varicocele could indicate obstruction of the vena cava.

In adolescent boys, evaluation of testicular size is important to determine the need for surgical correction. Sonography, a comparative orchidometer, or punched-out elliptical rings can be used to determine size. A volume difference between the testicles of greater than 2 cm^3 is the minimal requirement for surgical repair (Figs. 1 and 2).

Spermatocele and Epididymal Cyst A spermatocele or epididymal cyst presents as a painless mass superior and posterior to the testicle and is completely separate from the testicle (cysts of the rete testes, epididymis, or ductuli efferentes). Enlarged and symptomatic cysts should be removed.

Epididymitis

Epididymitis is the most common cause of scrotal pain in adults and is characterized by acute unilateral pain and swelling [1]. The pain usually begins at the epididymis and can spread to the entire testicle (epididymo-orchitis). Other symptoms include fever, erythema of the scrotal skin, and dysuria. It is associated with a C-reactive protein level of more than 24 mg per L (228.6 nmol per L) (96 % sensitive and 85 % specific for epididymitis/orchitis) [4] and increased blood flow on ultrasonography. *Chlamydia*

DOI 10.1007/978-1-4939-0779-3_107-1

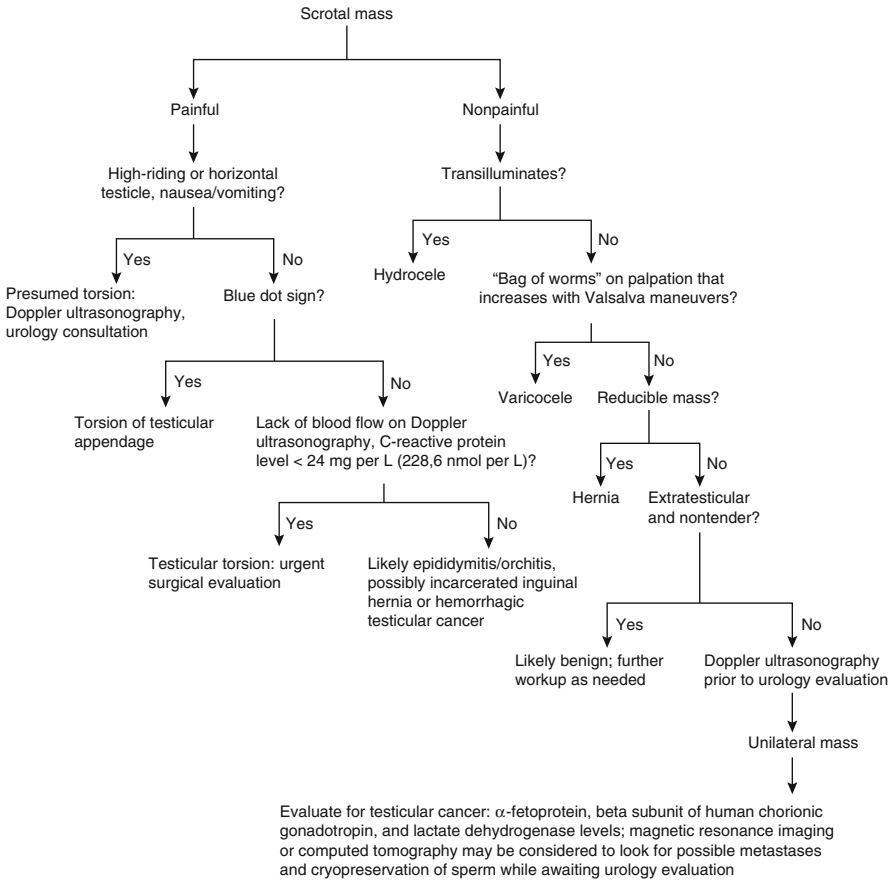

Fig. 2 Algorithm for evaluation of a scrotal mass

trachomatis and *Neisseria gonorrhoeae* are the most common organisms responsible for bacterial epididymitis in males younger than 35 years [5]. Guidelines recommend empiric ceftriaxone (Rocephin) and doxycycline for treatment of suspected epididymitis in males younger than 35 years [6]. Epididymitis may cause a painful swelling of the testicle and is a common cause of a painful testicle in postpubertal males. Presentation is usually of increasing testicular pain and discomfort and can be accompanied by urethral discharge. On exam, the epididymis is enlarged and may be indistinguishable from the testicle. The epididymis is tender and may be indurated [7].

Treatment should be directed at the most likely cause. For suspected UTI, ciprofloxacin (Cipro) 500 mg orally twice daily for 10–14 days is usually adequate. In prepubertal boys, an evaluation of the GU system to include urinary system sonography and a voiding cystourethrogram should be considered.

Testicular Masses

Testicular Torsion

Testicular torsion or torsion of the testicular appendages presents as a painful testicle that is often enlarged or demonstrates a mass. These topics are covered in chapter 106.

Acute Orchitis

Acute orchitis presents with sudden onset of testicular pain and high fever, usually with nausea and vomiting. On exam the testicle is tender, enlarged, and may be indurated. The most common causes are

DOI 10.1007/978-1-4939-0779-3_107-1

bacteria and viral infections. Mumps orchitis occurs in 20–35 % of cases of mumps parotitis and presents 3–4 days after onset of parotid symptoms. Management of acute orchitis includes bed rest, scrotal support, ice, and analgesics. Antibiotics are important if a bacterial cause is suspected. Since only 15 % of cases are bilateral, infertility is rare.

Testicular Cancer

Epidemiology and Risk Factors

Although only occurring in 4 out of 100,000 men, testicular cancer is the most common solid tumor among men between the ages of 20 and 34 years old [8]. The most important risk factor for testicular cancer is cryptorchidism – 10 % of cancer cases have a history of cryptorchidism. Cryptorchidism increases testicular cancer risk 3- to 14-fold. Early orchidopexy (before 1 year of age) reduces, but does not eliminate, this increased risk. Orchidopexy later in life is not as effective at reducing rates of cancer. Other risk factors include family history, infertility, tobacco use, and white race [9].

Screening The US Preventive Services Task Force does not recommend screening for testicular cancer with either self- or physician examination [10].

Pathology

Germ cell tumors account for more than 90 % of all testes tumors, the majority of which are classified as pure seminomas or nonseminomas. Most nonseminomatous germ cell tumors are composed of a combination of the following histological patterns: embryonal carcinoma, teratoma, teratocarcinoma, and choriocarcinoma [9].

The most common non-germ cell testicular tumors are Sertoli and Leydig cell tumors. The majority of these tumors are benign. Leydig cell tumors can present with sequelae of increased androgen production such as precocious puberty in boys and virilization in girls [9].

Diagnosis and Evaluation

Patients with testicular cancer are usually asymptomatic, but they may present with acute pain in the testicle or scrotum, dull ache in the scrotum or abdomen, scrotal heaviness, firmness of the testicle, infertility, intratesticular mass, or painless swelling/redness. Five percent of patients present with symptoms of metastasis to include gastrointestinal symptoms, gynecomastia, lumbar back pain, neck mass, and respiratory symptoms (e.g., cough, hemoptysis, dyspnea) [8].

All intratesticular masses should be considered a malignancy until proven otherwise. Patients with testicular masses should have a scrotal ultrasound to confirm the presence of a solid intratesticular mass and to evaluate the contralateral testicle. When cancer is a concern in a patient with a testicular mass, laboratory testing includes α-fetoprotein (AFP), beta subunit of human chorionic gonadotropin (β-HCG), and lactate dehydrogenase levels since >90 % of patients with a nonseminomatous germ cell tumor have elevated levels of one or all of these [8]. Urgent referral to a urologist is indicated for patients with intratesticular masses, even though smaller masses are less likely to be cancerous. Patients with intratesticular masses should generally undergo radical orchiectomy through an inguinal approach; however, there is new evidence that testicular sparing surgery may be satisfactory in selected patients [11]. There is no role for needle biopsy. Once diagnosed with a germ cell tumor, patients should be staged with an abdominal computed tomography (CT) scan and chest radiographs.

DOI 10.1007/978-1-4939-0779-3_107-1

Treatment

Clinical stage and histology determine appropriate therapy. Typical chemotherapy agents include bleomycin (Blenoxane), etoposide (Vepesid), and cisplatin (Platinol AQ).

Seminoma [8, 9]

- Stage I is generally treated with radiation; however, observation and limited chemotherapy are options.
- Stage IIA is treated with radiation to the regional lymph nodes.
- Stage IIB or IIC is treated with three cycles of three-drug chemotherapy.
- Stage III is treated with three-drug chemotherapy; but if there is no response, consider clinical trials of other chemotherapy drug combinations, and if brain metastasis is present, treat with radiation of the brain or surgical removal.

Nonseminoma [8, 9]

- Stage I is treated with retroperitoneal lymph node dissection or observation with monthly follow-up.
  - Stage IB is generally treated with two cycles of chemotherapy.
  - Stage IS patients are treated with full-dose chemotherapy if serum tumor marker levels do not rapidly fall.
  - Stage IIA patients are treated with retroperitoneal lymph node dissection followed by observation with monthly follow-up and frequent laboratory testing OR two cycles of two-drug chemotherapy.
  - Stage IIB or IIC patients receive three or four cycles of three-drug chemotherapy followed by retroperitoneal lymph node dissection if computed tomography still shows lymph nodes. If high-serum tumor marker levels are present, chemotherapy is followed by lymph node dissection.
  - Stage III patients should have three-drug chemotherapy and surgical removal of persistent tumors. Patients with high-serum tumor marker levels often do not respond to usual chemotherapy.

Complications of Treatment

Complications can result from chemotherapy, radiation, surgery, or the disease process. Chemotherapy-specific complications include azoospermia, lung disease (with bleomycin use), neuropathy (with etoposide use), renal or otologic injury (with cisplatin use), increased risk of cardiovascular disease, infertility, recurrence, cardiac mortality after radiation, and second malignancy (e.g., leukemia) after radiation or chemotherapy [8, 9].

Urothelial Tumors (Bladder Cancer)

Epidemiology and Risk Factors

Bladder cancer is the sixth most prevalent malignancy in the United States, accounting for approximately 7 % of cancers in men and 3 % of cancers in women. About 50,000 men and 17,000 women are diagnosed with this disease while 14,000 die from it annually. The incidence of bladder cancer increases with age in men and women. Eighty percent of cases occur in those over 60 years of age [12].

The most significant risk factor for bladder cancer is cigarette smoking, which accounts for approximately 50 % of all bladder cancer cases. It increases bladder cancer risk by four- to sevenfold. Aromatic amine occupational exposures account for 5–10 % of bladder cancer cases in industrialized nations. Chronic infection with *Schistosoma haematobium*, genitourinary tuberculosis, or chronic urinary tract infection are risk factors [12]. Patients treated with cyclophosphamide (Cytoxan) have up to a ninefold increased risk that occurs 6–13 years after the exposure, but administration of 2-mercaptoethanesulfonic

DOI 10.1007/978-1-4939-0779-3_107-1

acid (Mesna) can reduce the carcinogenic properties of cyclophosphamide. Pelvic irradiation can also increase bladder cancer risk.

Pathology

About 90 % of bladder cancers diagnosed in the U.S.A. are urothelial, formerly known as transitional cell, carcinomas.

Squamous cell carcinoma accounts for about 7 % of bladder cancers in the U.S.A. Adenocarcinoma of the bladder is rare, accounting for fewer than 2 % of all bladder cancers. Adenocarcinomas of the bladder are more common in patients with a urachal remnant or in patients who were born with bladder exstrophy [12].

Location

About 96 % of urothelial malignancies occur in the bladder. Upper tract (ureters and collecting system) tumors occur in 2–3 % of patients with bladder tumors, while 30–75 % of patients with upper tract tumors have associated bladder tumors. Bilateral involvement occurs in 2–5 % of all patients with upper tract transitional cell carcinomas.

Screening

Screening for bladder cancer is not recommended [13].

Diagnosis and Staging

Painless hematuria is the most common presenting sign or symptom of bladder cancer. The incidence of bladder cancer in a patient with gross hematuria is 20 % and with microscopic hematuria is 2 % [12]. Other less common signs include urinary frequency, irritability, and dysuria. Although the vast majority of bladder cancers are associated with microscopic hematuria, the hematuria frequently is intermittent, and a negative urinalysis does not exclude bladder cancer. All patients with hematuria should be evaluated with a urine cytology, cystoscopy, intravenous, CT, or MRI. Those with gross hematuria should be further evaluated with a renal ultrasound or CT.

Urine cytology has a high specificity (95–100 %) but a low sensitivity (66–79 %) for the detection of bladder cancer. Tumor markers are not useful [12].

Cystoscopy is the primary diagnostic tool for bladder cancer. Once a tumor is identified, transurethral resection is performed to confirm the diagnosis and to determine the tumor stage. The primary goal of staging is to determine if the cancer is superficial or invasive. TNM staging of bladder cancer is very complex with 14 types of T, 5 types of N, and 3 types of M. Since transurethral resection can frequently understage patients, frequently patients with high-grade Tl disease are treated as if they had muscle-invasive disease [12, 14].

CT examination of the abdomen and pelvis is obtained in patients with muscle-invasive bladder cancer (T2 or higher) and/or high-grade disease to evaluate the perivesicle soft tissue, pelvic and retroperitoneal lymph nodes, as well as the liver and adrenal glands. CT scans are relatively unreliable in determining depth of tumor invasion and may fail to detect lymph node metastasis in up to 40 % of patients with them [12].

CT, MRI, or intravenous urograms or retrograde ureteropyelograms should be obtained in all patients with bladder cancer to exclude the presence of an upper tract transitional cell carcinoma.

Treatment

Treatment of bladder cancer is different for each stage. Low-grade Ta through high-grade T1 cancer is generally treated with transurethral resection and intravesical *Bacillus calmette-guerin* (BCG) or

DOI 10.1007/978-1-4939-0779-3_107-1

mitomycin. T2a through T3b are treated with radical cystectomy followed by either chemotherapy or adjuvant chemotherapy. T4a through metastatic disease is treated with chemotherapy alone or in combination with radiation therapy [12].

Urinary reconstruction following cystectomy is an important component in the management of patients with invasive bladder cancer. Various modalities to restore a semblance of normal urinary function using cutaneous diversions (both catheterizable and noncatheterizable) are in use currently. Other options in which a reservoir is connected directly to the native urethra lessen the impact of cystectomy on quality of life. These diversions can be performed successfully in men and women.

Additionally, radical cystectomy can preserve the neurovascular bundles in men and the vagina in women. Thus, normal urinary and sexual function can be retained despite curative therapy for invasive bladder cancer. Anastomotic strictures can be common, so patients must be followed closely for the development of hydronephrosis and deterioration of renal function.

Urolithiasis

Urolithiasis is common. Family physicians must distinguish it from other causes of abdominal and flank pain. Urolithiasis causes pain when a stone partially or completely obstructs the collecting system or ureter while it migrates. Distal ureteral stones may be associated with dysuria, frequency, and penile or labial pain while stones in the renal collecting system may be painless. Classically, the patient presents with severe, colicky, unilateral flank or lower abdominal pain. The pain may radiate to the groin, scrotum, or labia and be associated with nausea and vomiting, dysuria, gross hematuria, urinary frequency, or fever. Fever is present when associated with UTI. Conditions that may be similar to or mimic renal colic include pyelonephritis, urethritis, prostatitis, vaginitis, pelvic inflammatory disease, pelvic pain syndrome, gallbladder disease, various gastrointestinal diseases, dissecting abdominal aortic aneurysm, ovarian or testicular pathology, ectopic pregnancy, and ureteral tumors [15].

Epidemiology

Lifetime risk of developing urolithiasis is 10–15 % with higher prevalence in the southeastern U.S.A. It is two to three times more common in males than females and affects Caucasians more than Asians and Blacks. Incidence peaks between 30 and 50 years old, and recurrence rates are as high as 40–75 % over 25 years. Frequency of different stone types varies greatly with the population studied. In the U.S.A., calcium stones are by far the most common, with calcium oxalate stones accounting for 56–61 % and calcium phosphate stones accounting for 8–18 %. Less common (in descending order) are uric acid, magnesium ammonium phosphate (struvite), and cystine stones. Children have more struvite than uric acid stones [15, 16].

Etiology

In modern times, obesity and diabetes are common causes of urolithiasis. Other diseases such as primary hyperparathyroidism, type 1 renal tubular acidosis (RTA), Crohn's disease, primary hyperoxaluria, and cystinuria are associated with recurrent urolithiasis but account for less than 5 % of patients with stone disease. An etiology for urolithiasis can be determined 97 % of the time after an appropriate workup. Etiologies of urolithiasis are listed in Table 1. Metabolic abnormalities account for the majority of disease. Sixty percent of calcium stone disease is caused by idiopathic hypercalciuria. Hyperuricosuria, followed by hypocitraturia and hyperoxaluria, are the next most common metabolic abnormalities causing disease. Medications that may also play a role in stone disease are listed in the table. High dietary fructose intake is also associated with urolithiasis.

DOI 10.1007/978-1-4939-0779-3_107-1

Table 1 Causes of urolithiasis [15–18]

Obesity
Diabetes
Hypercalciuria
Idiopathic (absorptive types I and II)
Renal
Unclassified
Primary hyperparathyroidism
Hyperuricosuria
Cystinuria
Gouty crystal deposits
Stones secondary to urinary infection
Renal tubular acidosis type 1
Hypocitraturia
Hypomagnesuria
Hyperoxaluria
Increased dietary fructose intake
Medications and supplements
Allopurinol
Antibiotics (Sulfonamides, ampicillin, amoxicillin, ceftriaxone (Rocephin), quinolones, furans, pyridines)
Carbonic anhydrase inhibitors (Acetazolamide, topiramate (Topamax)
Ephedra alkaloids
HAART (highly active antiretroviral therapy)
Laxatives
Potassium channel blockers (amiodarone, sotalol)
Potassium-sparing diuretics (triamterene)
Sulfonylureas

Evaluation

Family physicians must take a thorough history including presenting symptoms, medical history (e.g., gout, bowel disease), medications and supplements, diet, and family history of stone disease or related illnesses. Physical exam of the flank, abdomen, groin, and genitals is most useful, and physicians should use physical exam to rule out other possible diagnoses. Urinalysis with urinary pH and microscopic examination for red blood cells, white blood cells, and crystals should be performed [19]. Hematuria is 67 % sensitive and 58 % specific for urolithiasis. Presence of white blood cells or crystals can indicate concomitant infection or hyperuricemia. Urine culture should also be obtained to evaluate for infection.

Diagnostic imaging is the next step in evaluation. A prudent and safe first step is to perform an ultrasound of the kidney and collecting system. Patients with a positive ultrasound need not have a CT scan with its attendant radiation. Those with negative ultrasound should progress to unenhanced helical CT–with reported sensitivity of 95–100 % and specificity of 94–96 % in diagnosing urolithiasis. Advantages of this imaging technique include avoidance of intravenous contrast, short duration (approximately 5 min to perform), ability to visualize all stone types, localization of stone within the ureter, identification of secondary signs of obstruction when a stone has recently passed, and ability to diagnose other abdominal and pelvic pathology when urolithiasis is not present. Using Hounsfield density helical CT allows one to differentiate uric acid, cystine, and calcium containing stones from one another and to subtype calcium stones.

DOI 10.1007/978-1-4939-0779-3_107-1

Plain radiography is only useful if other conditions are suspected as the cause of pain due to low sensitivity and specificity. Only calcium-containing stones are radiopaque, but this fact is complicated by the fact that calcifications seen on plain radiograph may or may not be associated with the urinary system.

Intravenous urography (IVU) is a less desirable option than ultrasound or CT scan. IVU can usually detect ureteral obstruction based on dilation of the collecting system or ureter, a delayed nephrogram, or delayed excretion of contrast. IVU is limited in that signs of obstruction may not appear acutely, radiolucent stones cannot be visualized, and many other causes of abdominal pain cannot be evaluated. Intravenous contrast is necessary when performing an IVU and can cause postcontrast nephropathy and numerous systemic reactions.

Approach to Management

Urolithiasis complicated by an infected stone and/or urosepsis is an emergency. Emergent urological consultation for either immediate drainage by percutaneous nephrostomy or retrograde ureteral stent insertion is necessary since these patients have a high mortality. Other indications for urgent urological consultation are anuria, hydronephrosis, concomitant pregnancy, and renal failure. Those patients with refractory pain should also be referred.

In the absence of these conditions, stone size and location determines the next step. Ureteral stones with a width 4 mm or less will spontaneously pass in 80 % of patients while rates fall to 35 % at 5 mm and 25 % at 7 mm. Patients with stones <5 mm in width should be provided adequate analgesia. Maintaining urine volumes greater than 2 L a day is essential. Patients should be instructed to strain their urine and bring in any stones for analysis and should follow up immediately for symptoms of urosepsis. Stone passage may be monitored with plain radiographs, and a urological referral made if stones are not passed within 4–6 weeks. At this time, patients with persistent stones are often offered either ureteroscopy to remove stones or extracorporeal shock wave lithotripsy (ESWL) to remove stones.

Antispasmodics

Calcium channel blockers and alpha blockers should be first-line therapy for urolithiasis. These medications not only reduce the pain from renal colic by reducing smooth muscle spasm in the ureter, they also reduce the time of passage of stones <10 mm by 5–7 days. Alpha blockers should be prescribed as follows: doxazosin (Cardura) 4 mg orally per day or tamsulosin (Flomax) 0.4 mg orally per day. If calcium channel blockers are chosen, then nifedipine (Procardia) 30 mg orally per day should be used.

Analgesia

Adequate pain control often requires a combination of nonsteroidal antiinflammatory drugs (NSAIDs) and narcotics. As a note of caution, patients with reduced renal function should be prescribed NSAIDs only after the risks of further kidney damage are considered and discussed with patients [14, 19]. Any NSAID is acceptable to treat urolithiasis for a short period. Long-term treatment entails more risk, and physicians should consider naproxen (Naprosyn) 500 mg twice daily due to its lower risk of thrombosis. NSAIDs must be held for 3 days prior to ESWL because of antiplatelet effects and risk of bleeding, and aspirin should be held for 7 days prior to ESWL.

Narcotics used for pain control include hydrocodone 5 or 10 mg with acetaminophen 325 mg (Vicodin 10/325) orally every 4–6 h as needed, oxycodone 5 mg with acetaminophen 325 mg (Percocet 5/325) orally every 4–6 h as needed, and codeine 30 mg with acetaminophen 300 mg (Tylenol with codeine No. 3) orally every 4–6 h as needed. An antiemetic such as promethazine (Phenergan) 25 mg orally or ondansetron (Zofran) every 6 h may also be helpful.

DOI 10.1007/978-1-4939-0779-3_107-1

Table 2 Stone composition and diagnosis [14, 15, 17, 18]

Stone composition	Diagnosis
Cystine	Cystinuria
Struvite	Stone due to infection
Uric acid	Hyperuricosuria
	Low pH (gout, diarrhea)
Calcium phosphate	Primary hyperparathyroidism (increased calcium, low phosphorus)
	Renal tubular acidosis (hypokalemia and metabolic acidosis)
	Sodium alkali therapy

Table 3 Dietary changes in response to stone risk profile [14, 17, 18]

Urinary oxalate >45 mg per day	Avoid tea, spinach, dark roughage, chocolate, and nuts
	Take no more than 500 mg of vitamin C daily
Urinary calcium >250 mg per day	Moderate calcium restriction
Uric acid level >700 mg per day	Restrict protein
Sulfate level >30 mmol per day	Restrict protein
Low urine pH	Increase intake of potassium-rich citrus fruits
Low urine citrate	Increase intake of potassium-rich citrus fruits
Low urine pH	Increase intake of potassium-rich citrus fruits

Surgical Management

Stone location and size are the primary determinants when choosing which procedure to use for stone removal. ESWL is minimally invasive and is effective for calculi <1 cm in the ureter and <2 cm in the kidney. Basket retrieval through a cystoscope or ureteroscope is indicated for lower ureteral stones not amenable to ESWL [14]. Larger stones may be treated with percutaneous nephrolithotomy alone or in combination with ESWL. All of these procedures carry minimal surgical risk, and analgesia with either NSAIDs or narcotics is appropriate post procedure. Staghorn renal calculi should always be treated because of their high complication rates. Asymptomatic renal stones do not require treatment but become symptomatic in 50 % of patients over 5 years.

Metabolic Evaluation

All patients with stone disease should have a basic workup to identify underlying metabolic or environmental factors causing stone formation. A more in-depth workup should be completed in patients with recurrent urolithiasis.

Minimal evaluation should include urinalysis (including pH) with urine culture, stone analysis when possible, and serum calcium, phosphorus, uric acid, creatinine, and electrolytes. Table 2 shows stone analysis compared with diagnosis.

If no stone is available to analyze, a 24-h urine collection for a stone risk profile while the patient is on their customary diet should be performed. Expert consensus panels recommend this, but there are no trials to determine its effectiveness. The stone risk profile includes urine calcium, oxalate, uric acid, citrate, pH, total volume, sodium, sulfate, phosphorus, magnesium, and urinary saturation of calcium oxalate, brushite, monosodium urate, and uric acid. Once this is completed, dietary modifications to reduce abnormalities in the stone risk profile should be initiated with a concomitant increase in fluid intake to maintain a urine volume of >2 L a day. These dietary changes include a sodium restriction of 200 mEq daily for all patients. Other dietary changes are listed in Table 3.

DOI 10.1007/978-1-4939-0779-3_107-1

After 1 week, the stone risk profile is repeated and the two completed stone profiles compared. If abnormalities are corrected by dietary modification and increased hydration, then environmental changes are recommended. If abnormalities persist, then appropriate treatment is initiated.

Treatment

In spite of poor evidence, all patients should be told to drink a minimum of 2 L of fluid a day, eat a diet high in potassium-rich citrus fruits, and restrict intake of protein, oxalate, and sodium.

Hyperoxaluria

Nondietary hyperoxaluria (>45 mg per day) is seen with inflammatory bowel disease, small bowel resection, and intestinal malabsorption of fat. Dietary restriction of oxalate is the main form of treatment.

Hypercalciuria

Patients with hypercalciuria (>250 mg per day) associated with hypercalcemia should be evaluated for primary hyperparathyroidism. When hypercalciuria is seen with excess urinary sodium, dietary restriction of sodium 100 mEq per day is recommended. Absorptive hypercalciuria or renal hypercalciuria are the probable causes when the abovementioned conditions are not present. Both can be treated with thiazides such as hydrochlorothiazide 25 mg daily with potassium citrate 20 mEq twice daily. Doses of potassium citrate may be adjusted based on follow-up serum potassium and urinary citrate levels.

Hypocitraturia

High intake of animal proteins is the usual cause of mild to moderate hypocitraturia (100–320 mg per day). It is best treated with potassium citrate 20 mEq twice daily and restriction of animal protein. Chronic diarrhea and renal tubular acidosis (RTA) cause severe hypocitraturia (<100 mg per day). When diarrhea is present, treatment is directed at the diarrhea. Potassium citrate 20–40 mEq twice daily may be given.

Hyperuricosuria

Excess intake of purines causes hyperuricosuria (>700 mg per day) without elevated serum uric acid. Allopurinol (Zyloprim) 300 mg daily and potassium citrate can prevent further stones in combination with dietary restrictions. When hyperuricosuria is found in combination with elevated uric acid and low urinary pH, gout is present. Allopurinol 300 mg daily, along with potassium citrate if urinary pH is low, are recommended.

Prevention of Urolithiasis

There is a poor evidence base for practice patterns to prevent urolithiasis. Regardless, consensus guidelines recommend hydration, dietary therapy, use of potassium citrate, and thiazide diuretics to prevent recurrence in spite of potential adverse effects [15].

[b]Department of Obstetrics and Gynecology, Wayne State University School of Medicine, Detroit, USA

Unintended Pregnancy

Ever since 1980, reducing unintended pregnancy has been a key goal of the Healthy People national health initiative. The unintended pregnancy rate in the United States (US) still remains one of the highest in the developed world. According to the latest National Survey of Family Growth (NSFG) study from 2010, nearly 49 % of the 6.7 million pregnancies in the USA were unintended in 2006 consistent with 52 unintended pregnancies for every 1,000 women aged 15–44 [1]. The outcome of these pregnancies has been remarkably stable over time, with 40 % eventuating in abortion as recently as 2008 [2]. Evidence in the literature suggests that unintended pregnancy poses both immediate and long-term adverse health risks for baby and mother, such as delayed prenatal care, poorer health in childhood, lower breastfeeding rates, and increased exposure to cigarette smoke [3]. Children born from unintended pregnancies are more likely to live in poverty, less likely to graduate high school and experience more behavioral problems in their teen years. These adverse outcomes are significantly amplified in the case of teen mothers, resulting in an average annual cost to US taxpayers from teen parenting estimated at $9.4 billion USD in 2010 [4].

Tools to Help You (and Your) Patient Choose

Contraceptive decisions are a risk analysis that involves assessing the risk of pregnancy, assessing the risk of the contraceptive method, and assessing the probability that the patient will be able to tolerate and use the method effectively. Contraceptive decision making also involves assessing the risk that a method might worsen a medical problem, the risk that the method won't work at all, the risk that the patient won't use the method effectively, and the risk that the patient won't use abortion as a last backup in the event of method failure.

There are well-documented non-contraceptive health benefits to many contraceptives, whose characteristics also play a part in the contraceptive choice process. Such benefits as lower lifetime risk of uterine and ovarian cancer for users of combined hormonal contraceptives (CHCs) or the decreased menstrual flow characteristic of the levonorgestrel intrauterine system (LNG-IUS) need consideration in the process of selecting the optimal method.

The World Health Organization (WHO) published its Medical Eligibility Criteria for Contraceptive Use (MEC) in 1996, perhaps the first publication giving evidence-based guidance on the safety of contraceptive method use for women and men with certain characteristics and medical problems. The United States Centers for Disease Control (CDC) adapted the WHO MEC for use in the United States, reflecting US practice patterns and removing reference(s) to methods that may not be available in the USA. The US MEC was developed with the specific intent to provide evidence-based guidance regarding family planning practices, to address misconceptions surrounding the safe use of contraceptive methods, to reduce medical barriers to safe contraception, and lastly to improve access and quality of care in family

*Email: ggreenbe@med.umich.edu

DOI 10.1007/978-1-4939-0779-3_108-1

planning. It is accessible at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5904a1.htm?s_cid=rr5904a1_e [5], and applications for smart phones and computer tablets are available as downloads as well. Central to the US MEC is a categorization of contraceptive methods based on medical conditions that may have an impact on the ability of a patient to utilize a particular contraceptive method.

The matrices in the US MEC include evidence-based recommendations for the use of contraceptive methods by women and men with particular characteristics and/or medical conditions; it is by no means an exhaustive list. Each condition was defined as either representing an individual's characteristics (e.g., age, history of pregnancy) or a known preexisting medical/pathologic condition (e.g., diabetes or hypertension). Recommendations may be different depending on whether or not a particular method is being initiated or merely continued. The primary focus of the US MEC recommendations is the safety of a given contraceptive method for women with medical conditions or characteristics; the categories listed in Table 1 generally do not take method effectiveness into account, so while a method in Category 1 can be used without restriction as regards safety, that method may be not be optimal for a patient's particular medical condition.

A companion document, the US Selected Practice Recommendations for Contraceptive Use (US SPR), was published in 2013 and represents an adaptation of the WHO SPR for providing guidance to health-care professionals when they counsel patients about contraceptive use [6]. The CDC intends its use to be an evidence-based guidance for common, sometimes controversial contraceptive management questions. The US SPR is slightly different from the WHO document in that, once again, adaptations are made accounting for differences in available contraceptive methods, some of the recommendations for testing prior to contraceptive method initiation and some simplified "missed pill" algorithms. It can be found at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6205a1.htm?s_cid=rr6205a1_w [7]. Both CDC resources are continuously updated to reflect new data as it becomes available, ensuring that they are based on currently available evidence.

Taken together, the US MEC and SPR are powerful resources to help dispel the many myths surrounding contraceptive use which can serve as barriers to effective contraceptive use and thus improve patients' contraceptive experience by avoiding unintended pregnancies.

Health-care providers should provide patients with the most effective contraceptive method(s) that fit their particular clinical situation. Toward this end, not only are the risks and benefits of a particular contraceptive method balanced but also the risk(s) that an unintended pregnancy might pose. For example, it may not be the best practice to recommend a barrier method of contraception to a woman with congenital heart disease such as Eisenmenger syndrome; such a patient should avoid pregnancy at all costs given the attendant 20–60 % maternal mortality of delivery at term. Physicians must continually be aware of the contraceptive needs of patients, remembering that women with medical problems have sex and do get pregnant.

Table 1 Categories of medical eligibility criteria for contraceptive use

1	No restriction for the use of the contraceptive method for a woman with that condition
2	Advantages of using the method generally outweigh the theoretical or proven risks
3	Theoretical of proven risks of the method usually outweigh the advantages – not usually recommended unless more appropriate methods are not available or acceptable
4	Unacceptable health risk if the contraceptive method is used by a woman with that condition

Family Medicine
DOI 10.1007/978-1-4939-0779-3_108-1

Patient Education and Activation

Providing timely, understandable, and clear education regarding the contraceptive method chosen is an essential component to enhance effectiveness. Patient education is fundamental to any patient's ability to make an informed decision regarding contraceptive choice and adherence. There are many resources available for patient self-education on contraceptives. These include office handouts like the one available from the CDC shown in Fig. 1. Web-based resources for patients from the CDC, Planned Parenthood, ACOG, and the Association of Reproductive Health Professionals are also available including interactive tools and videos to help patients decide which contraceptive is right for them.

Contraceptive Effectiveness

The focus of contraceptive choice has changed dramatically over the past few years. Whereas once providers began the process of contraceptive counseling with combination hormonal contraceptives (CHCs) such as pills, patch, and ring, it has become clear that relying on theoretical effectiveness estimates of particular methods may not be in the best interests of patients. While CHCs may have theoretical effectiveness of >99 %, in actual use, failures approach 6–12 pregnancies per 100 woman-years. Inconstant adherence to a strict user-dependent regimen, the cost of many CHCs, and varying insurance coverage for contraceptive methods all combine to make theoretical effectiveness nearly unreachable. In the following figure from the CDC, methods are arranged in tiers from most to least effective. It should be apparent from the table that user-independent methods (intrauterine devices, implants, and permanent contraception) have the lowest failure rates, approaching <1 pregnancy per 100 woman-years.

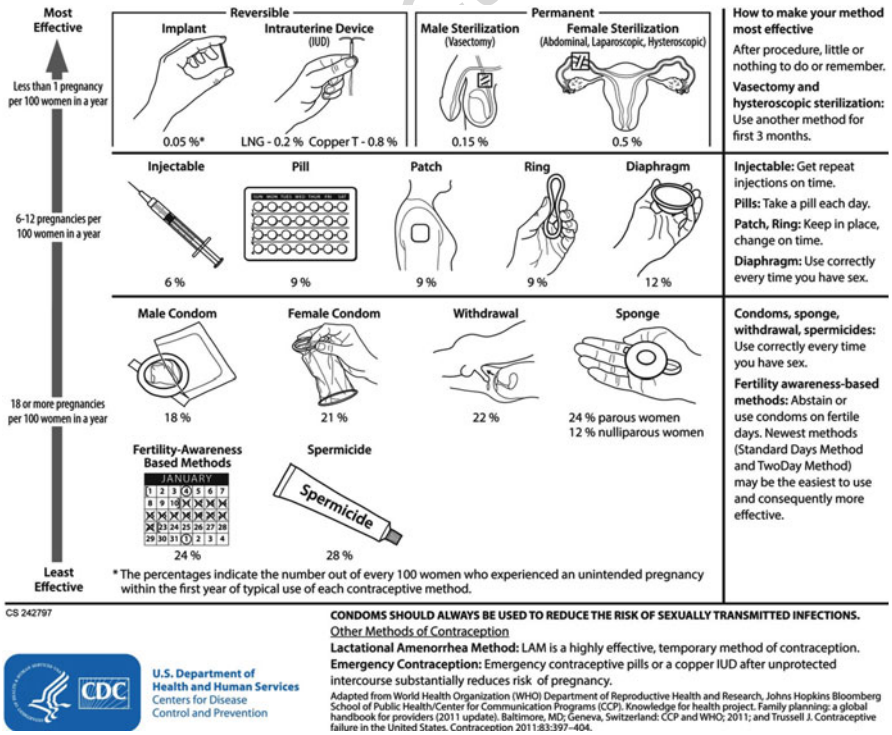

Fig. 1 Effectiveness of family planning methods

Long-Acting Reversible Contraception and the Contraceptive CHOICE Project

An innovative clinical study attempted to determine the impact on the usage of long-acting reversible contraception (LARC) by removing financial and knowledge barriers to access of contraceptive methods including CHCs and LARC (IUDs, implants, and injectable contraceptives) [8]. The results of the study indicated a remarkable 67 % of women who enrolled chose LARC methods (56 % chose intrauterine contraception and 11 % chose the subdermal implant). The same held true for the adolescent population within the study group in which 69 % of 14–17 year olds chose LARC, demonstrating that appropriately counseled teens accept LARC in large numbers [9]. The CHOICE Project demonstrated a clear reduction in the rate of unintended pregnancy in adult and adolescent women and the highest rates of contraceptive continuation out to 24 months of study [10]. Concomitantly the abortion rate for members of the CHOICE cohort was less than half the regional and national rates, and the repeat abortion rates declined significantly as well [11]. As a result of the findings of this ongoing study, national organizations including the American Congress of Obstetricians and Gynecologists (ACOG), the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians (AAFP) have all issued practice bulletins, practice guidelines, and technical reports endorsing the utilization of LARC methods as a means to reduce unintended and teen pregnancy rates [12–14]. The focus of these organizations underscores the need to redirect and emphasize patient counseling efforts toward a "LARC-first" approach to contraception.

Intrauterine Devices and Systems (IUDs and IUS)

Modern IUDs are the most popular means of contraception in the world outside of the USA, with an estimated 100,000,000 users in China alone based on a contraceptive prevalence of 53 % of contracepting women aged 15–44. In the USA, however, IUD popularity and use have waxed and waned at much lower rates, due in large part to economic forces brought about by periodic intense adverse litigation, despite its track record of safety and efficacy.

It has been known for many years that the main mechanism of action of modern IUDs is that of a spermicide [15]. With respect to copper containing IUDs, the copper ion itself has been found to be toxic to human spermatozoa and to human ova; it also enhances inflammatory responses which are toxic to spermatocytes and oocytes. Midcycle tubal washout studies in women wearing copper IUDs demonstrated that no fertilized ova were retrieved from IUD users [16]. These effects occur prior to fertilization; no documented postfertilization effect has been established. The mechanism of action for levonorgestrel-containing IUDs (Mirena®) is strikingly similar to that of copper containing ones. Since levonorgestrel (LNG) is a potent progestin, it exerts a powerful effect on human cervical mucus, thickening it significantly so that it acts as a spermicidal barrier. It directly inhibits sperm capacitation without which fertilization cannot occur while simultaneously causing atrophy of the endometrium, reducing its ability to aid in sperm ascent into the upper genital tract. The atrophic endometrium thus produced is likely also responsible for the dramatic reduction of menstrual flow seen in users of the LNG-IUD.

Currently, there are three IUDs marketed in the USA: the T380A (Paragard®) and two levonorgestrel-releasing IUDs (Mirena® and Skyla®). The latter two are sometimes referred to as intrauterine systems (IUS) as opposed to intrauterine devices. All these IUDs are T-shaped polyethylene devices that conform to the shape of the uterine cavity and are impregnated with barium sulfate such that they are radiopaque. The arms and stem of the Paragard® contain 380 mm^2 area of exposed copper and is approved for 10 years continuous use. Patients with a history of Wilson's disease or known allergy to copper are not candidates to use Paragard®. The LNG-IUS Mirena® and Skyla® contain 52 mg and 13.5 mg levonorgestrel,

DOI 10.1007/978-1-4939-0779-3_108-1

respectively, in a steroid reservoir. Skyla® is smaller than Mirena® and has advantages for use in nulliparous women; it is approved for use for 3 years, whereas Mirena® is approved for 5 years continuous use. All three IUDs have monofilament threads attached at the base to facilitate removal.

The US MEC lists the following as contraindication to IUD use: pregnancy, puerperal sepsis, immediate placement after septic abortion, distorted uterine cavity, cervical or endometrial cancer (awaiting treatment), gestational trophoblastic disease, breast cancer (progestin IUD only), AIDS not on antiretroviral therapy, pelvic tuberculosis, and unexplained vaginal bleeding [17].

A number of myths and misconceptions surrounding IUDs have served as barriers to wider acceptance by providers and hence are barriers to use of these methods by patients. There is no scientific evidence for a postfertilization mechanism of action of IUDs. For many years, providers were unwilling to employ IUDs in patients with a history of or risk factors for pelvic inflammatory disease (PID). However, the risk of developing pelvic infection is increased only in the first 20 days after IUD insertion, implying that bacterial contamination associated with insertion is the cause of infection, not the IUD itself. A review of the WHO IUD clinical trial data of nearly 23,000 IUD insertions and over 51,000 woman-years of follow-up showed the overall PID rate to be quite low and constant after the first 20 days post-insertion [18]. A troublesome barrier to increased IUD usage in the USA is the frequent mandate that women desirous of IUD insertion be first tested for and known to be free of such STDs as chlamydia and gonorrhea. The delay waiting for the testing results is an unnecessary obstacle; there is ample evidence in the literature for same-day screening for STDs and IUD placement, especially in asymptomatic low-risk women [19]. Routine use of prophylactic antibiotics at the time of insertion is not required. Current algorithms for treating mild to moderate pelvic inflammatory disease in women with an IUD in situ do not call for IUD removal, unless there is no significant clinical improvement with standard antibiotic regimens in 72 h [20].

Another myth associated with IUD use is that of infertility, especially in nulligravid women. A case-control study conducted of nearly 2000 infertile women identified exposure to chlamydia associated with infertility; neither tubal infertility nor duration of IUD use was associated with infertility. IUDs have been associated with the development of ectopic pregnancy (EP), due in part to conflicting findings among some published studies. However, a meta-analysis of published literature from 1977 to 1994 showed that the odds ratio (OR) of EP in IUD users was 1.06 (95 % CI: 0.91–1.24) [21]. This data confirms that IUDs are incredibly efficient at preventing pregnancy overall; however, when a pregnancy occurs with an IUD in situ, the pregnancy may be more likely to be ectopic. Most certainly, a woman with an IUD in situ and a positive pregnancy test needs careful evaluation to exclude EP.

IUDs can be inserted any time in a woman's menstrual cycle as long as she and her clinician are reasonably certain she is not pregnant, and in only few circumstances should this require the performance of a pregnancy test. Guidance for this comes from the US SPR in the form of the Table 2, based on and validated by evidence from family planning programs worldwide.

Table 2 How to be reasonably certain that a woman is not pregnant

A health-care provider can be reasonably certain that a woman is not pregnant if she has no symptoms or signs of pregnancy and meets any one of the following criteria:
Is ≤7 days after the start of normal menses
Has not had sexual intercourse since the start of last normal menses
Has been correctly and consistently using a reliable method of contraception
Is ≤7 days after spontaneous or induced abortion
Is within 4 weeks postpartum
Is fully or nearly fully breastfeeding (exclusively breastfeeding or the vast majority [≥85 %] of feeds are breastfeeds), amenorrheic, and <6 months postpartum

DOI 10.1007/978-1-4939-0779-3_108-1

Increased menstrual flow has long been a known feature of copper IUDs; rarely, however is it of such magnitude to cause clinically apparent blood loss anemia. Use of both the Mirena® and Skyla® is associated with substantially decreased menstrual blood loss and has been utilized as a treatment of menorrhagia, a positive benefit of the LNG. Liberalizing insertion protocols by removing provider barriers to IUD use has the potential to expand the population of IUD users dramatically and reduce the unintended pregnancy rate in the USA.

Subdermal Contraceptive Implants

Subdermal contraceptive implants have been available to women in the USA since 1990 when the FDA approved a 6-rod LNG (216 mg LNG) system for 5 years duration after an extensive track record of safety and efficacy in Europe and Southeast Asia. Despite this, widespread litigation regarding complicated and painful removals prompted the manufacturer to withdraw US distribution in 2002 even though none of the claims were proven and US courts disallowed all class action suits. A single-rod subdermal system, Implanon® developed in Holland by Organon, was introduced into the US market in 2006. This system utilized etonogestrel (3-ketodesogestrel, ENG), the biologically active metabolite of desogestrel, a gonane progestin. The implant is a 4 cm long, 2 mm diameter rod made of ethyl vinyl acetate, and impregnated with 68 mg of ENG such that ENG is released in a controlled fashion over 3 years of use. Implanon® was reformulated by the manufacturer to include 15 mg of barium sulfate such that the implant is now detectable by X-ray and CT scan; it is supplied in a preloaded applicator for single use.

The mechanism of action of ENG as a contraceptive is virtually identical to other progestins by inhibiting ovulation through the ovulation suppression at the level of the hypothalamic-pituitary axis (HPA) and the LH surge [22]. ENG also thickens cervical mucus, inhibiting sperm transport to the upper genital tract, providing additional contraceptive activity. The ENG implant is designed for 36 months continuous use, during which ENG serum levels typically range from 196 pg/ml at the end of 1 year and 156 pg/ml after 36 months; both of these values are above the 90 pg/ml thought necessary to inhibit ovulation. Removal of Nexplanon® is associated with prompt decline in ENG to undetectable serum levels within 1 week; this is consistent with a return to ovulation and previous fertility by 6 weeks after removal. Unlike injectable progestins such as medroxyprogesterone acetate (MPA), serum estradiol (E2) levels are essentially within normal levels.

ENG subdermal implants have demonstrated remarkable contraceptive efficacy, with failure rates approaching zero if pregnancies that were not directly related to contraceptive method failure were eliminated from analysis [23]. In a study from Australia of post-marketing surveillance, 218 confirmed cases of unintended pregnancy were identified while using the ENG subdermal implant. However, 21 % of these patients were found to have been pregnant prior to implant insertion, another 39 % were due to "non-insertion" of the implant itself; only 19 % of the pregnancies were tied directly to method failure. Of these, nearly 20 % were secondary to interactions with medications that are known to accelerate the metabolism of progestins such as carbamazepine. As a result, Nexplanon may not be the best contraceptive choice for patients who require the use of hepatic enzyme inducers [24].

The side effect profile of the ENG subdermal implant is similar in many aspects to that of any progestin-only contraceptive method. The most common side effect leading to implant discontinuation is irregular and unpredictable vaginal bleeding patterns (11 % of patients). Although the most frequent change in bleeding pattern is infrequent bleeding and amenorrhea (50 % of patients), nearly 19 % of users experienced frequent or prolonged bleeding. Manipulation of abnormal bleeding patterns with low-dose CHCs, additional estradiol, or doxycycline has met with limited success. This complication emphasizes the importance of careful pre-insertion counseling and patient selection. Though Nexplanon®

DOI 10.1007/978-1-4939-0779-3_108-1

is only FDA approved for the prevention of pregnancy, it appears that dysmenorrhea improves dramatically in users. About 12 % of patients utilizing the ENG subdermal implant can be expected to experience weight gain in the amount of 1–2 kg over the 36 months of use. While women whose weights were >130 %, ideal body weight was excluded from early clinical trials of the ENG implant; a multicenter clinical trial that included women of all weights found no unintended pregnancies in patients that were overweight or obese [25]. Indeed, the CDC-MEC places the ENG implant into category 1 for patients whose BMI is ≥ 30 kg/m^2, meaning there is no restriction on its use for these women.

Injectable Contraceptives

The injectable contraceptive agent, medroxyprogesterone acetate (DMPA) or Depo-Provera®, has a typical failure rate of 1 per 100 woman-years. One of the reasons for the high efficacy is that each 150 mg injection provides 3 months of protection followed by a 4–6-week grace period before the next injection. Depo-Provera may cause excessive uterine bleeding but amenorrhea is more common. Amenorrhea, secondary to endometrial atrophy, occurs in over 90 % of women who use DMPA for more than 2 years [26]. Use of DMPA does not result in irreversible suppression of ovulation but patients need to clearly understand that there may be a delay in return to fertility. The inhibitory effect of DMPA on the HPA may persist for an extended time after DMPA is stopped resulting in the delayed fertility.

DMPA can be safely initiated immediately postpartum with the first injection given within 5 days of delivery. Other acceptable candidates for DMPA include smokers over age 35 and adolescents. It appears to have little effect on blood pressure or thrombosis.

Use of DMPA in adolescents is not associated with a higher risk of incident sexually transmitted infections. Additionally, women who choose DMPA report an improved quality of life, with secondary amenorrhea contributing to this perception. Adolescents using DMPA have lower incidence of repeat pregnancy at 12 months postpartum compared to those choosing CHCs [27]. The lower pregnancy rates with DMPA may be the result of a higher continuation rate compared to CHCs, although it is not as high as that seen with IUDs.

Side effects including weight gain, nausea, and irregular menstrual cycles are commonly reported. There is a reported association between long-term use of DMPA and depressive symptoms that subsides upon discontinuation [28]. There is no evidence, however, that DMPA use increases risk for postpartum depression. DMPA use results in a decrease in ovarian function and a consequent reduction in estrogen secretion which has been linked to a measurable decrease in bone mineral density (BMD). However, there is no evidence that this BMD decrease confers increased fracture risk for long-term users of DMPA. Consequently, the American College of Obstetricians and Gynecologists (ACOG) recommends that concerns over decreased BMD and potential future risk should not prevent its use beyond 2 years given its demonstrated contraceptive benefits [29].

Emergency Contraception (EC)

When primary contraceptive methods fail, unintended pregnancy may be prevented by the use of either hormone(s), selective progesterone receptor modulators (SPRMs), or IUDs. Postcoital contraceptive methods have been available for many decades now, beginning with the high-dose estrogen regimen (diethylstilbestrol, DES) that was widely used in the 1960s. Described in the 1970s, the Yuzpe regimen employed doses of estrogen and progestin available in standard combination oral contraceptives (COCs) taken by the patient within 72 h of unprotected intercourse [30]. Both of these regimens were fraught with

DOI 10.1007/978-1-4939-0779-3_108-1

significant side effects for patients, not the least of which was extreme nausea and vomiting as a result of the high dose of estrogen. In an effort to avoid these adverse effects, LNG was employed alone in a study from the WHO, showing it to be more effective overall [31]. The second generation SPRM ulipristal acetate (UPA) has been found to have higher efficacy than LNG, even when utilized 5 days after unprotected intercourse [32]. Of all methods of EC, the copper IUD (Cu-IUD) has the highest efficacy when employed for EC, with reported rates of unintended pregnancy <1 % [33].

It is likely that EC interferes with the process of ovulation, modifying tubal transport of ovum and/or sperm to interfere with sperm capacitation, and producing luteolysis. EC is only effective during a limited portion during a woman's menstrual cycle. Spermatozoa have a limited life span (120 h) within the female reproductive tract, and the human oocyte survives a mere 12–24 h postovulation. This results in a fertile window extending from 5 days prior to ovulation to 1 day after, the highest rates of conception occurring within 2 days prior to ovulation. Copper ions are released rapidly into the female genital tract shortly after insertion of an IUD such that their concentration reaches levels that are directly toxic to spermatozoa and hence results in decreased mobility, viability, and sperm capacitation and penetration. It is not known whether the Cu-IUD interferes with human blastocyst implantation as there are no in vivo human studies for ethical reasons. Both UPA and LNG negatively affect follicular development and ovulation. LNG can inhibit the LH surge, especially when given 2 or 3 days prior to ovulation. UPA has been shown to inhibit 100 % of follicular ruptures if given prior to the LH surge. The effect of LNG on the LH surge is limited by a narrow time window; if taken prior to the selection of the dominant ovarian follicle, LNG can prevent follicular rupture and ovulation. Taken after LH begins to rise, it cannot prevent ovulation and is ineffective in preventing pregnancy. UPA, however, has a direct inhibitory effect on follicular rupture, accounting for its effectiveness when LH has already begun its rise.

EC efficacy may be compromised in women with higher body mass index (BMI). Though the study was not intended to examine the effect of BMI on EC efficacy, a meta-analysis of two studies comparing the efficacy of LNG and UPA for EC demonstrated markedly decreased efficacy with higher BMI for both. Patients with BMI >26 kg/m^2 who used LNG for EC had the same expected pregnancy rate as if they had not used anything. UPA use in patients with BMI > 35 kg/m^2 was associated with a similar failure rate [34]. There has been considerable debate over the meaning of these findings but there are no published studies to date that refute the BMI effect. Expert opinion appears to favor either the insertion of a Cu-IUD or administration of UPA in obese patients.

The timing of EC is critical for successful avoidance of unintended pregnancy; all oral ECs should be administered and taken as soon as possible after intercourse that is either unprotected or compromised by contraceptive method failure (condom rupture, etc.). The LNG regimen, which consists either of a single 1.5 mg pill (Plan B One-Step®) or 2 0.75 mg pills (generic, Take Action®, and others) taken together, can be effective up to 5 days after unprotected intercourse. UPA is available as a single 30 mg tablet, currently marketed as Ella®. However, effectiveness appears to decline over time from intercourse. (1) Recent data suggests that insertion of a Cu-IUD for EC may be effective at any time during the menstrual cycle.

The only known contraindications to EC are pregnancy and allergy to any of the components in them. It is unknown whether efficacy is compromised in the presence of other medications that induce hepatic enzyme systems responsible for metabolism of steroid hormones. EC with LNG or UPA may shorten cycle length by 1 and 2 days, respectively. Menstrual bleeding may increase following the insertion of a Cu-IUD as might be expected; however, counseling can help patients anticipate and accommodate such changes. Whereas nausea and vomiting were hallmarks of the high-dose estrogen and Yuzpe regimens, few patients utilizing LNG or UPA experience significant nausea.

LNG EC is now available in the USA without prescriptive or age restrictions to women and men, which has the potential to dramatically expand its use; it is relatively inexpensive. UPA is only available in the USA by prescription, a substantial barrier to its use. Even though the Cu-IUD carries the highest EC

DOI 10.1007/978-1-4939-0779-3_108-1

efficacy, getting one inserted in a timely fashion can be problematic; patients must navigate multiple logistic issues, none the least of which is provider ignorance of its use for EC.

Combined Hormonal Contraceptives (CHCs)

This category includes combined oral contraceptives (COCs), transdermal patch, and vaginal ring. All three forms work by suppressing ovulation and follicle maturation and as spermicides by thickening cervical mucus. All three forms are considered to be moderately effective contraception: with typical use, the failure rate is 6–12 pregnancies per 100 woman-years [35].

All CHCs contain an estrogen and a progestin in varying doses and schedules. The estrogen is most commonly ethinyl estradiol and can range from 20 to 50 micrograms (mcg). The progestin is classified by steroid structure, potency, and when the form became available, i.e., first generation, second generation, etc. Given the multitude of choices that have arisen with varying levels of estrogen and progestin, it is helpful to use an aide when discussing CHCs with patients such as Table 3. A pill can be selected that minimizes undesired side effects while maximizing non-contraceptive benefits.

Initiating the CHC the day the prescription is received is preferable to waiting; women are more likely to continue onto the second pack of pills, and they are less likely to become pregnant in the first 6 months of use [36]. All COCs must be taken daily and require a prescription.

Common side effects include dizziness, nausea, breast tenderness, change in menstruation, and change in mood. More serious side effects include elevation of blood pressure, venous thromboembolic disease (VTE), and stroke. While CHCs do increase the risk of VTE from 4–5 per 10,000 women-years to 9–10 per 10,000 women-years, the absolute risk is still small compared to the VTE risk associated with pregnancy and the postpartum period, 29 and 300–400 per 10,000 women-years, respectively. The evidence for increased risk of VTE based on progestin has been conflicting and is most likely not clinically significant.

The contraindications to the use of CHCs include women with active breast cancer, decompensated cirrhosis, acute VTE, history of nontraumatic VTE, prolonged immobilization, diabetes with micro- or macrovascular complications, migraine with aura, any migraine in women over 35 years old, vascular disease or uncontrolled hypertension, ischemic heart disease, malignant liver tumors or hepatocellular adenoma, decreased cardiac function including mild dysfunction if less than 6 months postpartum, less than 21 days postpartum, women over 35 years old who smoke more than 15 cigarettes per day, complicated organ transplant, stroke, systemic lupus erythematosus with positive antiphospholipid antibodies, hypercoagulable disorders, complicated valvular heart disease, and acute viral hepatitis.

There are many non-contraceptive health benefits associated with COCs (and by inference the transdermal patch and vaginal ring). The following benefits have Level A evidence: reduction in risk of endometrial and ovarian cancer [37], reduced blood loss in women with normal menses or menorrhagia, treatment of dysmenorrhea, acne, treatment of premenstrual dysphoric disorders, and for continuous long-term suppression of menstruation [38]. Women who take COCs reduce their risk of endometrial cancer by 50–80 % with longer duration of use resulting in greater risk reduction. Similarly, the greater the duration of COC use, the greater the decrease in ovarian cancer risk. This decrease in risk corresponds to a 20 % reduction for each 5 years of use. COCs can reduce blood loss by 40–50 % and dysmenorrhea in 70–80 % of users.

COCs can be used for extended cycles instead of monthly cycles. Currently Seasonale®, Seasonique®, and Lybrel® are the only FDA approved COCs for this use. However, any COC can be utilized for extended cycle use. Typically, 3 packs of pills are dispensed and taken consecutively followed by a 7 day placebo period. The efficacy is the same as for monthly cycling but there is an increased risk for

DOI 10.1007/978-1-4939-0779-3_108-1

Table 3 Combined oral contraceptives: Side effects, benefits, and special considerations

Clinical situation	Explanation	Contraceptive option
Nausea, breast tenderness, bloating, headache, melisma, or increased blood pressure while on COC	Too much estrogen	EE 30 mcg – norethindrone acetate 1.5 mg (Junel, Loestrin, Microgestin) or
		norethindrone 0.35 mg (Camila, Errin, Jolivette, Micronor, Nor-QD, Nora-BE)
Spotting/bleeding, especially early or midcycle, hypomenorrhea	Not enough estrogen	EE 35 mcg – norgestimate 0.25 mg (Ortho-Cyclen, Mononessa, Previfem, Sprintec)
Mood changes, fatigue, as well as breast tenderness and headache	Too much progestin	EE 20 mcg – levonorgestrel 0.1 mg (Alesse, Aviane, Lessina, Levlite, Lutera) or
		EE 35 mcg – norethindrone 0.4 mg (Ovcon-35, Ovcon-35 chewable)
Breakthrough spotting or bleeding late in cycle	Not enough progestin	EE 20, 30, 35 mcg – norethindrone 1 mg (Estrostep Fe, Tri-Legest Fe) or
		EE 25 mcg – norgestimate 0.18, 0.215, 0.25 mg (Ortho Tri-Cyclen Lo, Tri-Lo-Sprintec, Trinessa)
Weight gain, polyphagia, acne, hirsutism, decreased libido, breast growth and tenderness	Too much androgen	EE 30 mcg – drospirenone 3 mg Yasmin, Ocella, Zarah) or
		EE 35 mcg – ethynodiol diacetate 1 mg (Demulen 1/35, Kelnor 1/35, Zovia 1/35)
Breastfeeding and/or <1 month postpartum	Increased risk of VTE from estrogen. Theoretical effect on breast milk supply	norethindrone 0.35 mg (Camila, Errin, Jolivette, Micronor, Nor-QD, Nora-BE)
Need to minimize effect on cholesterol (hyperlipidemia, hypertension, diabetes)	All have favorable lipid profiles	EE 30 mcg – desogestrel 0.15 mg (Ortho-Cept, Desogen, Reclipsen) or
		EE 35 mcg – norgestimate 0.25 mg (Ortho-Cyclen, Mononessa, Previfem, Sprintec) or
		EE 35 mcg – norethindrone 0.4 mg (Ovcon-35, Ovcon-35 chewable)
		EE 35 mcg – norethindrone 0.5 mg (Brevicon, Modicon, Necon, Nortrel)
Patient taking medications that interact with hepatic enzyme metabolism:	Medication interactions	Preferred reversible method is IUD or standard dose (> = EE 30 mcg) COC
Antiretroviral therapy		
Ritonavir-boosted protease inhibitors		
Anticonvulsant therapy		
Phenytoin, carbamazepine, barbiturates, primidone, topiramate, oxcarbazepine		
Lamotrigine		
Antimicrobial therapy		
Rifampicin or rifabutin therapy		

See Refs. [4, 7, 9, 13, 14, 38]

breakthrough bleeding especially during the first 3 month cycle. The benefits include decreased pelvic pain, blood loss, and headaches with improvement in mood. This is also true for extended use of the transdermal patch and vaginal ring.

The transdermal hormonal patch contains norelgestromin and ethinyl estradiol (Ortho Evra®). A patch containing 6.00 mg norelgestromin and 0.75 mg ethinyl estradiol is placed on the skin of the buttocks,

DOI 10.1007/978-1-4939-0779-3_108-1

abdomen, upper torso, or upper outer arms weekly for 3 weeks followed by a patch-free week which produces a withdrawal bleed. Each patch releases 150 μg of norelgestromin and 20 μg of ethinyl estradiol daily. It leads to higher plasma levels of hormones than typical COCs but does not have the peaks and troughs associated with COC use. It functions in the same manner as combination oral contraceptives but is more convenient in a transdermal route for some women lasting for 7 days. It can be started on days 1–5 of the menstrual cycle. If started after day 5, backup contraception should be used for 7 days.

Common side effects are local skin irritation, breast tenderness, breakthrough bleeding, headache, and nausea. These typically resolve after 1–3 cycles much like the side effects of COCs. The risks, contraindications, and benefits for the transdermal patch are the same as for COCs. VTE risk is similar to that of COCs. It is unclear whether the increased serum concentration of estrogen that occurs with the patch compared to COCs increases the overall VTE risk.

The final option for combined hormonal contraception is a flexible vaginal ring comprised of ethinyl estradiol and etonogestrel (NuvaRing®). It delivers 0.015 mg ethinyl estradiol and 0.120 mg of etonogestrel daily. The ring is placed circumferentially around the uterine cervix for 3 weeks and then removed for 1 week during which a withdrawal bleed occurs. Because hormones are delivered in close proximity to the uterus and ovaries, a lower dose can be used. The vaginal ring offers the lowest dose of hormones of any CHC and avoids first-pass hepatic metabolism. As with COCs, it may be used for extended or continuous cycling with placement of a new ring after week three, but this method is not FDA approved. If removed for more than three hours during weeks 1–2, backup contraception is required. It may be started on days 1–5; however, backup contraception is required for 7 days if started on days 2–5 or if initiated asynchronous to the end of the menstrual cycle.

Common side effects are similar to COCs but also include increased vaginal discharge and irritation. Risks, contraindications, and benefits are equivalent to those of COCs. While the ring results in the lower serum concentration of hormones compared to COCs or the transdermal patch, it is unclear whether this effect is clinically significant. Of note, in clinical trials, women who weighed more than 90 kg had a significantly higher failure rate than lower-weight women. This rate is similar to the failure rate for COCs in women over 90 kg and should not preclude use of either method but appropriate risk counseling should be given.

Barrier Methods

The condom is the oldest form of barrier contraception and has benefits due to its inherent safety as well as potential protection from STIs. The ability of the condom wall to maintain its integrity throughout intercourse is critical to its effectiveness. It has been demonstrated that condom breakage occurs in approximately 1 of 100 acts of intercourse. Factors associated with breakage included vaginal intercourse and minimal foreplay. Data has shown that consistent use of condoms can reduce HIV transmission by up 80 % and non-viral STIs by 59 % [39].

The contraceptive diaphragm is a dome-shaped rubber cup attached to a flexible rim. The rim enables the dome to make a tight seal with the vaginal wall to provide a barrier to sperm and infectious agents. The diaphragm also prevents cervical mucus from neutralizing vaginal acidity, so the vaginal environment remains hostile to the sperm. The diaphragm is inserted by the woman herself vaginally before intercourse so the posterior rim rests behind the cervix in the posterior fornix and the anterior rim fits snugly behind the symphysis pubis. Spermicidal jelly, placed into the dome and around the rim before insertion, helps create a seal between the diaphragm rim and the vaginal wall and adds to its contraceptive efficacy.

Diaphragms are manufactured in various shapes to accommodate the anatomic variance of the female pelvis. They must be properly fitted to be effective, as diaphragms that are too big or too small are not

DOI 10.1007/978-1-4939-0779-3_108-1

effective in preventing pregnancy. Failure rates have been reported between 1 and 19.4 per 100 women-years. Given the challenges in assessing proper fit, education on use, and the development of more convenient, higher efficacious options for women, diaphragms represent at best fair contraceptive effectiveness and use rates have declined.

Spermicides

Spermicides are most often used in conjunction with other forms of contraception, namely, the condom and diaphragm. Spermicides are rarely used as a single contraceptive agent despite that they are simple to use and readily available. Spermicidal agents consist of two components: (1) an inert base (foam, cream, jelly, film, suppository, tablet) that ensures dispersion and holds the spermicidal agent in the vagina and (2) the spermicidal agent, usually nonoxynol-9. Failure rate among typical uses is high, 28 per 100 women per year.

Permanent Contraceptive Methods

Vasectomy

Vasectomy is a safe and effective form of contraception. Performed as an outpatient procedure, it has a very low complication rate. Concerns about association with prostate and testicular cancer in vasectomized men are unfounded. Most men achieve azoospermia within 4 months of the procedure, with long-term sterility greater than 99 %.

Tubal Sterilization

Tubal ligation remains a common method of family planning in the USA. Almost 50 % of female permanent contraceptive procedures occur while women are hospitalized for another surgery or childbirth. The gold standard of female permanent contraception remains either tubal ligation at the time of Cesarean section or interval via laparoscopy or minilaparotomy. A number of tubal occlusive techniques are available for tubal interruption, but bipolar cautery remains the mainstay. Hysteroscopic transcervical tubal sterilization has recently gained popularity, though long-term studies are not yet available that show comparable efficacy with laparoscopic techniques. Because of the permanence of these methods, it is important for patients to think carefully about whether any change such as death or separation from a partner or from a child would make them regret the choice.

Natural Family Planning

Natural family planning (NFP) methods may be useful for those who wish to avoid hormonal, barrier, and surgical methods of contraception. The basis for these methods involves abstinence from intercourse during periods of fertility and requires either recognition or detection of ovulation and the assumption that ovulation occurs only once during the same menstrual cycle. Methods of ovulation detection may incorporate charting cervical mucus changes (the ovulation or Billings method), a combination of mucus charting, symptom identification, and confirmation of a rise in basal body temperature to confirm postovulatory infertility (the symptothermal method) and urinary testing for luteinizing hormone levels.

The Creighton Model Natural Family Planning System is a standardized system of teaching couples how to perform the method accurately. Proponents of NFP cite the absence of side effects of artificial

methods of contraception, the benefits of increased communication between partners, and the opportunity to explore aspects of the sexual relationship other than intercourse. This method is not opposed by any religious organization but does require motivated couples, careful education, and close follow-up to optimize efficacy. Of the NFP methods, only the lactation amenorrhea method (LAM) has been acknowledged as highly effective, but use is limited to very specific and temporary criteria: exclusive breastfeeding, postpartum <6 months, with amenorrhea [40]. Reported pregnancy rates for a typical user of NFP are 24–30 %. Given the presence of many other methods with greater efficacy, NFP should not be recommended unless no other contraceptive method is acceptable to the patient.

Community Issues

Barriers to contraceptive access remain including maintaining insurance coverage, understanding benefits, securing an appointment with a provider, and obtaining prescriptions (1). There is evidence that Title X funding improves access to contraceptive services especially for forms that require advanced training and skill such as LARCs and vasectomy (2). For women with insurance coverage, access to low-cost or free contraceptives has improved with the passage of the Patient Protection and Affordable Care Act which requires this coverage. For women without insurance coverage, many large retail pharmacies offer COCs or POPs at low cost, particularly when a 90-day supply is prescribed. Emergency contraceptives have also become more readily available after a 2013 decision by the US Food and Drug Administration that made Plan B One-Step® available over the counter without a prescription to anyone of childbearing potential. A generic version is approved for ages 17 and older, but proof of age is not required.

Vulvovaginitis and Cervicitis

Jennifer Bain

Contents

Vulvovaginitis and cervicitis refer to inflammatory and/or infectious disease processes of the female genital tract: vulva, vagina, and cervix. Symptoms can include genital itching, pain or discomfort, edema, dysuria, vaginal discharge, odor, and in more severe cases pelvic pain. Female genital complaints are quite common in a family medicine practice so familiarity with the workup and treatment is important. The symptoms can be nonspecific, and there is considerable overlap of presenting features regardless of the etiology of the process. In many cases the patients have already attempted self-diagnosis and even treatment with home remedies or over-the-counter products and medications. Given the nonspecific nature of the symptoms, those self-diagnoses can often times be incorrect, and the products or measures the patient has employed in their attempt to treat those symptoms can lead to more inflammation and exacerbate the condition. It is imperative, therefore, to take a detailed history, perform a focused but complete physical exam, and utilize laboratory measures, including microscopy, in order to arrive at the correct diagnosis.

The most common etiologies for vulvovaginitis and cervicitis include both sexually and nonsexually transmitted diseases, and coinfections are not uncommon. Depending on the disease process involved, the symptoms may be restricted to just one of the areas of the genitals (e.g., the vulva) but often can include more than one or all and be difficult for the patient to determine exactly. The most common causes of vaginal

P. Paulman, R. Taylor (eds.), *Family Medicine*,
DOI 10.1007/978-1-4939-0779-3_109-1

complaints, particularly in reproductive aged women, include bacterial vaginosis, candidal vaginitis, and trichomoniasis. Cervicitis is often one of the sexually transmitted diseases (STDs), such as gonorrhea or chlamydia. The keratinized epithelium of the vulva can be affected by other generalized skin disorders (such as atopic dermatitis or psoriasis) and mycotic infection as well as masses. However, there is considerable overlap and any one of these processes can causes symptoms in any or all of the particular areas of the female genitals. In general, testing for STDs (in particular gonorrhea and chlamydia) should be obtained during the evaluation given considerable overlap in the clinical presentations and the prevalence of coinfections.

The vulva is composed of keratinized stratified squamous epithelium, whereas the vaginal and the ectocervix mucous membrane is nonkeratinized squamous epithelium. There is a transition in the epithelium from the labia to the vestibule. The normal vaginal environment contains lactobacilli that convert the glycogen from these cells into lactic acid and hydrogen peroxide, maintaining the acidic pH (around 4.0) characteristic of the healthy premenopausal woman's vagina. This acidic environment helps to prevent the overgrowth or invasion of pathogenic organisms. Disruption of this normal balance of chemical and biological elements can then lead to infection or inflammation causing vulvovaginitis or cervicitis.

Office Evaluation

Obtaining a good history can be complicated by some patient's reluctance to discuss these issues; often the patients are embarrassed or simply uncomfortable discussing symptoms in the genital area and may not know how to describe their symptoms well. In addition to the usual characteristics of the complaint (their best description of symptoms and their and duration), exacerbating and alleviating factors and any associated symptoms (dysuria, dyspareunia, pelvic pain, fever), it is important to inquire about any previous episodes (and treatments), involvement of any other areas of the body, treatments attempted at home (their success or lack thereof), sexual behaviors (number and gender of partners, as well as if anal, oral, or vaginal penetration is involved), and partner symptoms. Comorbidities can be a complicating factor, as well (diabetes mellitus (DM), human immunodeficiency virus (HIV)).

A complete physical exam should be performed, including a thorough pelvic exam, abdominal or costovertebral tenderness on palpation; close inspection of the skin of the entire area including separation of the labia, noting any atypical findings of the skin or genitals or surrounding structures; and a vaginal speculum examination, noting the presence of any odor, lesions, discharge, or other findings of the vagina and cervix. Document the presence or absence of any discharge and its characteristics, such as color, consistency (thin, thick, frothy, clumpy), origin (if from the cervical os, adherent to the vaginal walls, etc.), or odor; friability or bleeding from the cervix; and any tenderness or masses on the bimanual exam (cervical motion tenderness; tubal, ovarian, uterine, or adnexal tenderness).

Vaginitis

The diagnosis may be narrowed after a thorough history and physical exam described above; however, the identification of the true cause of the patient's symptoms is not possible without performing a simple laboratory evaluation due to the similarities in signs and symptoms. Vaginal specimens can be collected during the speculum exam noted above, including testing for sexually transmitted diseases (STDs) and swabs for preparing a wet mount and KOH specimen. Depending on the method used for the specimen identification (nucleic acid amplification, culture, PCR, etc.), the samples may be taken from the cervical os or the vaginal side walls. There is typically pooling of fluids (mucous and semen) in the posterior fornix, so the best sample is not obtained from this site. The wet mount is prepared using a cotton-tipped swab to collect a specimen from the vaginal side wall. The swab can then be touched directly onto pH paper to determine the pH of the vaginal fluid, then either placed in a test

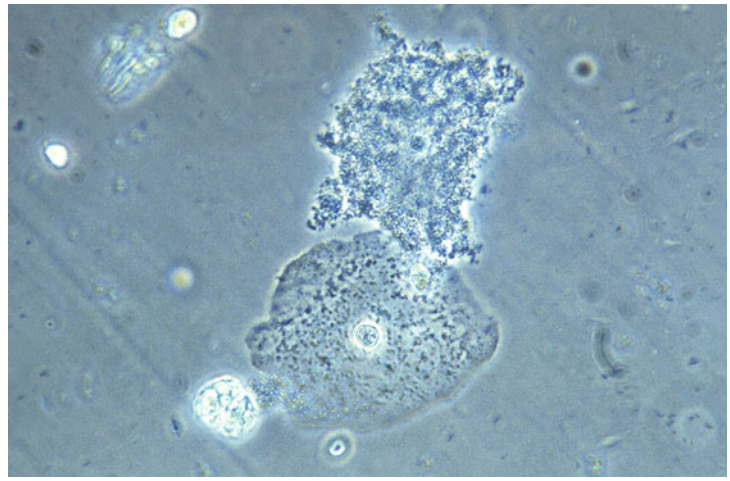

Fig. 1 Two epithelial cells on vaginal wet mount preparation: one normal and the other with the surface studded with coccobacilli, termed clue cell, as seen in bacterial vaginosis (Public Health Image Library from the CDC)

tube with about three drops of saline and a drop is placed on two slides or the swab can directly place the drop of the vaginal specimen on the slides with a drop of saline on one; on the other of these slides a drop of 10 % KOH is placed and then a cover slip is placed over each to examine under the microscope. Before covering the KOH specimen, wafting the aroma from the slide to the nose of the examiner is termed the whiff test and can identify identifying scents associated with certain infections. The best visualization of the elements under investigation would be with the use of the low power (10x) first and then high power (40x) to allow viewing of the smaller elements.

In the case of a healthy vaginal environment, the vaginal discharge is white or transparent, thick, or thin and mostly odorless, and the vaginal pH will be in the normal range (4.0–4.5). Microscopy will show epithelial cells (large, round to somewhat oval cells, sometimes folded, with a relatively small nucleus and clear to somewhat granular cytoplasm) with occasional polymorphonuclear (PMN) cells (or leukocytes; smaller, rounded to oval cells with segmented, larger nuclei), occasional erythrocytes (RBCs: small round cells with no nuclei), and lactobacilli (small rod-shaped bacteria) and even sperm can be seen at times (very small motile organisms with the characteristic tail). When there is an alteration in the healthy vaginal chemical or biological environment, there may be other findings on microscopy: clue cells (epithelial cells that are covered in small, round bacteria, particularly prominent at the edges of the cells) (Fig. 1), fungal elements (buds, hyphae, and pseudohyphae; Fig. 2), a large proportion of PMNs, flagellated trichomonads (Fig. 3), a lack of lactobacilli or PMNs; and higher numbers of basal cells (smaller epithelial cells with a higher nucleus-to-cytoplasm ratio). Identifying these elements on the laboratory evaluation will assist greatly in the accurate diagnosis of the etiology of the patient's complaints.

Bacterial Vaginosis

Bacterial vaginosis (BV) is the most common cause of vaginal complaints in women [1], though many women can be asymptomatic. There is no true inflammation, hence the term vaginosis, rather than vaginitis, and typically there is no vulvar involvement. BV involves a shift in the normal vaginal flora with a lack of lactobacilli and with an overgrowth of anaerobic organisms such as *Gardnerella vaginalis*, *Haemophilus* species, *Bacteroides*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, *Mobiluncus*, and others. The exact mechanism of the alteration in the flora is unclear, but the lack of the lactobacilli raises the pH, no longer prohibiting the growth of the offending anaerobic bacteria, and a massive overgrowth occurs. It appears there is a biofilm [2] produced by the *Gardnerella* on the vaginal side walls that other bacteria then adhere. These

Fig. 2 Vaginal wet mount preparation showing epithelial cells and pseudohyphae of *Candida albicans* (Public Health Image Library of the CDC)

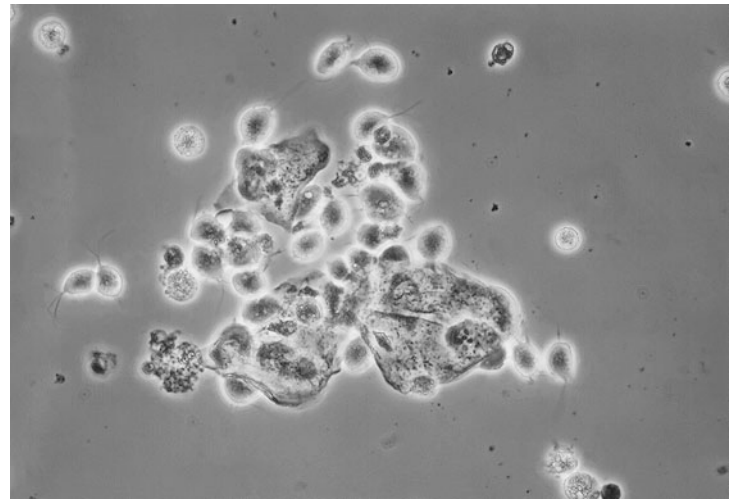

Fig. 3 Vaginal wet mount preparation showing the flagellated trichomonads (Public Health Image Library of the CDC)

organisms produce proteolytic carboxylase enzymes that break down the vaginal peptides and produce amines that give the characteristic "fishy" odor noted during the whiff test. There is desquamation of these cells to produce the classic clue cells (Fig. 1) seen on the wet mount.

BV is not considered a sexually transmitted infection, but sexual activity does seem to be a factor: women with new or multiple sexual partners are at a higher risk, and there is a decrease in risk with the use of condoms and having monogamous sexually active long-term relationships. There is a high prevalence in women who have sex with other women, particularly with new or multiple partners. Other risk factors include douching (which can eliminate the lactobacilli that help to maintain the healthy acidic vaginal environment), smoking, and possibly a genetic component to susceptibility.

The prevalence is hard to determine, as this is not a reportable disease, and can vary considerably based on the population studied [3]. It is commonly found in women of reproductive age, rarely in postmenopause and not in children. There may be no symptoms or just the complaint of an unpleasant odor, worse after intercourse or during menses. A vaginal discharge may be present that is typically thin and off-white (gray or

yellow). Dysuria, dyspareunia, and pelvic pain are not usual complaints and, if present, may be a sign of mixed vaginitis or coinfection. On physical exam a homogenous, thin, sometimes malodorous vaginal discharge may be seen, typically adherent to and smoothly coating the vaginal walls. Acute cervicitis, with a mucopurulent discharge from the cervical os, and even cervical motion tenderness can be seen if there has been assent of the infection into the cervical canal and even to the upper portions of the genital tract, though it is more likely a sign of coinfection.

Diagnosis of BV is made primarily by characteristic laboratory findings, elevated pH, and the characteristic findings seen on microscopy: clue cells with a lack of lactobacilli and PMNs. Amsel's criteria is used when microscopy is available and is considered diagnostic of BV if any three of the following are present: characteristic vaginal discharge (thin, off-white, homogenous, smoothly coating the vaginal walls), elevated pH (>4.5), predominance of the epithelial cells (>20 %) that are clue cells on saline wet mount, and positive whiff test (fishy odor with the addition of 10 % KOH to the vaginal sample). Gram stain is considered the gold standard of diagnosis; however, this requires more time, resources, and expertise. Utilizing Gram stain as the gold standard, Amsel's criteria is >90 % sensitive and 77 % specific [4]. A shift in vaginal flora can be seen on a pap smear specimen; however, the sensitivity is low and should not be relied upon for diagnosis. There is no indication to treat asymptomatic patients with this finding on the pathology report.

There are some serious health consequences as a result of BV: increased risk of preterm delivery in pregnancy, endometrial bacterial colonization and endometritis, pelvic inflammatory disease (PID), postpartum fever, post-hysterectomy vaginal cuff cellulitis, postsurgical abortion infection, and increased risk for acquisition of other STDs (HIV, HSV 2, gonorrhea, chlamydia, and trichomonads). The Centers for Disease Control and Prevention (CDC) does not currently recommend treatment of asymptomatic women, only those with the symptoms and diagnostic criteria above, as there is insufficient evidence of the benefit of treating asymptomatic women at this time [5]. Though this is not considered a sexually transmitted infection, it is a common finding for those women presenting in such a scenario; and the treatment guidelines here are consistent with those of the CDC, in their Treatment Guidelines for Sexually Transmitted Diseases [5].

Treatment of BV is recommended in symptomatic women for relief of symptoms and in presurgical patients undergoing gynecologic procedures (hysterectomy and surgical abortion); partner treatment is not recommended. Several oral and topical regimens are acceptable and effective: metronidazole (Flagyl) 500 mg orally twice daily for 7 days; metronidazole gel 0.75 %, one full applicator (5 g) intravaginally once a day for 5 days; or clindamycin cream 2 %, one full applicator (5 g), intravaginally at bedtime for 7 days. Alternative regimens include tinidazole (Tindamax) 2 g orally once daily for 2 days, tinidazole 1 g orally once daily for 5 days, clindamycin (Cleocin) 300 mg orally twice daily for 7 days, or clindamycin ovules 100 mg intravaginally once at bedtime for 3 days. Oral treatment is as effective as topical, but associated with more side effects, such as metallic taste, nausea, neutropenia, peripheral neuropathy, some drug reactions, and a disulfiram-like effect (nausea/vomiting/diarrhea) with concurrent consumption of alcohol. Clindamycin cream can weaken condoms and either route can be associated with the development of pseudomembranous colitis.

Treatment recommendations for women with bacterial vaginosis in pregnancy include oral medications for those who are symptomatic: metronidazole, either 500 mg twice daily or 250 mg three times daily, or clindamycin 300 mg twice daily, all for 7 days. Despite metronidazole crossing the placenta, there has been no good evidence of teratogenic effects in pregnancy. Though pregnant patients with bacterial vaginosis have an increased risk of complications including premature rupture of membranes and preterm delivery, postpartum endometritis, and post-cesarean wound infection, a routine screening and treatment regimen has not been found to effectively decrease these rates. Topical treatments are

preferred in breast-feeding women, to decrease concentrations of drugs in breast milk and thus infant exposure and complications such as diarrhea and candidal infections due to alteration of gut flora or other toxicities.

Follow-up after treatment is unnecessary if symptoms resolve, though recurrence of BV is very common: usually within the first year after treatment and often associated with a new sexual partner. This could be the result of reinfection or persistence of BV-associated organisms or a failure to restore the normal vaginal flora (in particular a lack of lactobacilli recolonization of the vagina). Simply retreating can be sufficient, particularly if compliance with the initial regimen may have been an issue. If the patient has continued recurrences (>3 in 12 months), suppressive therapy may be indicated: twice weekly metronidazole gel for 4–6 months or oral nitroimidazole followed by intravaginal boric acid (600 mg nightly) and suppressive metronidazole gel. Caution: boric acid can cause death if taken orally. Prevention measures include patient education regarding identifying the presence of the infection (recognizing the odor and/or discharge), risk reduction with consistent use of condoms, limiting the number of sexual partners, and avoiding douching. The use of probiotics (supplemental lactobacillus in various forms) has not been shown to be beneficial.

Candidiasis

The second most common cause of vaginal infection is due to candidiasis [6] (commonly called a "yeast infection") or vulvovaginal inflammation in the presence of candidal species. The presence of candidal species is not considered abnormal as they are typically found in the normal flora of the vagina and skin of healthy women. It is thought there is some disruption to this normal environment that allows the organism to overgrow and cause infection. The diagnosis requires the presence of vulvovaginal inflammation with pruritus of the vulva and vagina, a common complaint. The symptoms are the result of overgrowth of *Candida* and penetration of the superficial epithelial cells. *Candida albicans* is responsible for the great majority of these infections, less commonly with other species such as *C. glabrata* and *C. parapsilosis* [6]. All species produce similar vulvovaginal symptoms, though usually less severe with *C. glabrata*.

Sexual activity is not believed to play a role in the transmission of vulvovaginal candidiasis (VVC). Though many patients have no identifiable risk factors or precipitating condition, there are risk factors that appear to increase the likelihood or frequency of infections [7]. Antibiotic use causes inhibition of the normal bacterial flora and can allow the growth of fungal organisms leading to symptomatic infection. Immunosuppression as a result of medical conditions (such as poorly controlled diabetes or HIV) or use of medications (glucocorticoids and other immunosuppressive agents) has been linked to the development of this infection. The condition is so common that routine screening for any of these factors is not necessarily indicated, unless there is persistence of infection. Behavioral factors can play a role as well: douching (which can alter the normal biological and chemical vaginal environment), use of tampons or pads, and wearing tight and/or synthetic clothing and use of certain contraceptives (such as the vaginal sponge) all seem to increase the rate of this infection.

The prevalence of VVC is difficult to determine given that it is not a reportable infection, and there are often self-diagnosis and treatment with readily available and highly utilized over-the-counter medications, though it does appear that most women are affected with this infection at least once in their lifetime [5, 8]. When patients do present for medical attention, they are often treated merely based on symptoms without confirmation by microscopy or culture. The clinical presentation is typically that of vulvovaginal pruritus, with accompanying burning, soreness, and irritation. Dysuria (usually externally rather than internally) and dyspareunia can accompany the symptoms. There may or may not be a reported vaginal discharge, but if so it is typically described as white and thick or "clumpy," usually with no abnormal odor.

The characteristic findings on physical exam consist of erythema of the vulva and vaginal mucosa, with possible edema, vulvar excoriations, and even fissures. There may be little or no discharge, and if present it is often thick, white, and curd-like (though other cases, it is thin and watery) with no or minimal odor. The cervix typically does not show involvement other than adherence of any discharge that may be present in the vaginal vault. The clinical presentation however can be quite variable and have considerable overlap with other etiologies of vulvovaginitis.

The diagnosis of VVC is made in women with the characteristic findings of vulvovaginal inflammation and confirmed with the presence of *Candida* on the wet mount. The vaginal pH is usually normal, so if abnormally elevated, coinfection or an alternate etiology should be considered. Microscopic findings on wet mount include the presence of budding yeast (oval cells) and pseudohyphae (chains of cells) (Fig. 2). The addition of 10 % KOH to the vaginal sample, which breaks down the epithelial and other cell walls, can allow better visualization of the fungal elements. During inspection of the wet mount, the presence of clue cells or motile trichomonads should be excluded as a concurrent or alternate infection. Routine culture is not typically helpful as it may merely indicate the presence of colonization of *Candida*, not infection. It is more helpful in the setting of resistant or recurrence of candidal infection. There is no other point of care testing that is available or of proven benefit in diagnosing this condition. Pap smear pathology reports may indicate the presence of candidal species; however, again this may merely indicate the colonization of the vagina with this organism and not the presence of infection. There is no indication to treat asymptomatic women in these cases.

Treatment of VVC is for relief of symptoms and based on the classification: complicated or uncomplicated [5]. Uncomplicated candidiasis episodes are sporadic or infrequent with mild to moderate symptoms in women with a normal immune system that is likely to be due to *C. albicans*. Complicated candidiasis involves severe symptoms and recurrent episodes in immunocompromised women and is more likely to be caused by non-*C. albicans* species. Uncomplicated cases typically respond to all azole therapies (oral or topical) within a few days, whereas complicated cases take longer to respond. In either case, partner treatment is not indicated. Over-the-counter topical intravaginal treatments in uncomplicated cases include butoconazole (Gynazole-1) 2 % cream, 5 g daily for 3 days; clotrimazole (Gyne-Lotrimin) 1 % cream, 5 g for 7–14 days; clotrimazole 2 % cream, 5 g for 3 days; miconazole (Monistat) 2 % cream, 5 g for 7 days; miconazole 4 % cream, 5 g for 3 days; miconazole 100 mg, vaginal suppository daily for 7 days; miconazole 200 mg, vaginal suppository daily for 3 days; miconazole 1,200 mg, vaginal suppository for 1 day; or tioconazole (Monistat 1Day) 6.5 % ointment 5 g for 1 day. Prescription intravaginal agents include butoconazole 2 % cream 5 g for 1 day, nystatin 100,000-U vaginal tablet for 14 days, terconazole (Terazol) 0.4 % cream 5 g for 7 days, terconazole 0.8 % cream 5 g for 3 days, or terconazole 80 mg vaginal suppository for 3 days. The only oral agent is fluconazole (Diflucan) 150 mg tablet in a single dose, which maintains therapeutic concentrations in vaginal secretions for at least 72 h. As all are equally as effective, patient preference is often the deciding factor, with the oral medication associated with more side effects and drug interactions, though in the generic form may be less expensive than the over-the-counter treatments.

Complicated VVC is involved in approximately 10–20 % of cases; and recurrent infection is usually defined as four or more episodes in a year [5]. Treatment requires longer therapy: 7–14 days of topical therapy or 100, 150, or 200 mg oral fluconazole every third day for a total of three doses followed by maintenance therapy with oral fluconazole once weekly for 6 months or topical therapy intermittently for the same time frame. Severe VVC typically does not respond to shorter treatment regimens so recommendations are for 7–14 days of topical therapy or oral fluconazole 150 mg repeated in 72 h. Resistance is unusual, and when suspected culture should be performed and treatment with a non-fluconazole therapy for 7–14 days first-line or 600 mg boric acid

intravaginally daily for 14 days for recurrences. In an immunocompromised host, 7–14 days of topical therapy is recommended.

Candidal vulvovaginitis is not associated with adverse outcomes in pregnancy, so treatment is indicated only for relief of symptoms. Only topical regimens (clotrimazole or miconazole for 7 days) are recommended as there have been case reports of certain birth defects with the use of oral azoles, particularly in the first trimester [9]. In breast-feeding patients, both oral and topical treatments are safe and effective as there appear to be no adverse affects reported.

Follow-up is not necessary if symptoms resolve, and partner treatment is not indicated. There is no good evidence that probiotic (either oral or intravaginal) administration provides any benefit for treatment or prevention of VVC. Prevention involves education of patients and reduction in any risk factors present: avoiding douching, improved control of serum glucose levels, compliance with treatment regimens, and minimizing the use of antibiotics.

Trichomoniasis

The third most common cause of vaginitis is caused by the flagellated single-celled anaerobic protozoan *Trichomonas vaginalis*. The organism primarily infects the squamous epithelium of the urogenital tract including the vagina, urethra and paraurethral glands, cervix, bladder, Bartholin glands, and prostate. The disease is sexually transmitted though not reportable, and women can acquire the disease from other women though men usually do not transmit it to other men. The incubation period is unknown, but in vitro studies indicate 4–28 days in about 50 % of patients, and it can persist for months in epithelial crypts and periglandular areas of women [10].

Since this disease is not reportable, the prevalence is hard to determine, but the best evidence shows an approximate rate of 3 % in the general population of women [11]. This of course varies according to the population studied and the method of diagnosis. Many women can be asymptomatic carriers (often eventually developing symptoms), but the typical vaginitis presentation is that of a thin, frothy gray or yellow-green vaginal discharge with pruritus and vaginal irritation with burning. The discharge may have an odor, and there may be dysuria, urinary frequency, lower abdominal pain, and dyspareunia as a result of involvement of the entire urogenital tract.

Risk factors for trichomoniasis are related to sexual behaviors, such as multiple sex partners, history of an STD, and lack of condom use, as well as related to race and socioeconomic status. It is associated with adverse outcomes in pregnant and nonpregnant patients. In pregnancy trichomoniasis has shown to increase the rates of preterm birth, premature rupture of membranes, and low-birth-weight infants. Other poor outcomes in women include increased shedding of HIV in those infected with HIV, atypical PID, infertility, and post-hysterectomy cellulitis or abscess.

The physical exam can show very few signs or extensive findings including erythema of the vulva and vaginal mucosa; the characteristic thin, frothy, gray or greenish vaginal discharge, possibly malodorous; and petechiae of the vaginal mucosa and cervix may be present, producing the appearance of the "strawberry cervix" on the pelvic speculum exam. The vaginal pH will be elevated and the whiff test can be positive but the diagnosis is actually made based on the laboratory findings. The wet mount will show the presence of the characteristic motile flagellated trichomonad (Fig. 3) with a jerky and spinning motion, best visualized with the high-power lens (40x). The motility is required for the diagnosis so it is imperative to examine the wet mount immediately after preparation as the organism becomes sluggish and dies in 10–20 min after collection. The usually oval protozoan's size is approximately that of the PMNs, and there will typically be a large number of leukocytes present on microscopy. The sensitivity of microscopy is dependent upon the experience of the microscopist and collection technique and is only approximately 60–70 % [12]. Culture is more sensitive than wet mount and is a diagnostic option, particularly in patients with negative or unavailable microscopy, but fixing and staining can change the morphology so is not useful. The use of nucleic acid amplification

tests (NAAT) is the most sensitive and specific and can be performed on a self- or clinician-collected vaginal swab or utilizing urine or liquid cytology specimen. These DNA tests allow for testing of other STDs, as is recommended in this circumstance (since risk of one STD raises the risk of having another) but are more expensive and not yet widely available. In addition, the wet mount should be carefully examined to rule out other causes of vaginitis, such as BV and candidiasis.

Treatment of trichomoniasis is recommended for both asymptomatic and symptomatic patients and their sexual partners for relief of symptoms and to reduce carriage prevalence and the poor outcomes noted above [5]. Treatment regimens include only oral medications: metronidazole (Flagyl) or tinidazole (Tindamax) 2 g in a single dose, with an alternate regimen of metronidazole 500 mg twice daily for 7 days. These medications have a high cure rate (90 %), and the intravaginal metronidazole gel is less effective, so it is not recommended. In the case of allergy, there are no other medications shown to have the effectiveness of the oral nitroimidazoles so the CDC recommends a desensitization protocol. Partners should be treated simultaneously (if possible) and patients advised to avoid intercourse until completion of treatment in both partners with resolution of symptoms or in the case of asymptomatic patients, 7 days. Side effects are dose dependent and include nausea and/or vomiting, metallic taste, headache, dizziness, and a disulfiram-like reaction, so alcohol consumption should be avoided for about 24 h after metronidazole and 72 h after tinidazole treatment.

Treatment in pregnant patients has not been shown to decrease the rates of adverse outcomes, and there have been some studies that have indicated an increase risk [5]. For this reason treatment of pregnant patients is recommended, but the treatment of asymptomatic patients is not straightforward: counseling them on their risks and benefits of treatment and offering delay of treatment until 37 weeks can decrease perinatal transmission without putting them at increased risk. Partner treatment can be accomplished at any time, with the consistent use of condoms or avoidance of intercourse to decrease reinfection. Metronidazole 2 g in a single dose is the drug of choice as there is insufficient evidence of the safety of tinidazole in pregnancy. In this population who often has increased nausea and vomiting during pregnancy, the multidose regimen of 500 mg twice daily for 7 days can be used as an alternate regimen. In breast-feeding patients, the 2 g dose of metronidazole is relatively high for the neonate so advise patients to suspend breast-feeding (pump and discard) for 12–24 h after the dose can eliminate this factor (72 h if tinidazole is used).

Patients positive for HIV can have increased shedding of the virus with infection with *Trichomonas vaginalis* and treatment can decrease this shedding. Routine screening of asymptomatic patients in this population is recommended at entry into care and at least annually, as well as 3 months after treatment even if symptoms have resolved [5]. Some evidence has shown more effectiveness with the longer multidose regimen of metronidazole.

Follow-up is not recommended if symptoms have resolved, and routine screening has not been shown to be of benefit. Resistance levels to metronidazole have been found to be low, so in the case of recurrences or persistence of symptoms, explore compliance with treatment in both the patient and her sexual partners as this is thought to be the most common contributing factor. If the 2 g metronidazole dose fails, the use of the 500 mg metronidazole twice daily for 7 days or the tinidazole 2 g single dose is recommended. If this regimen fails, the use of either metronidazole or tinidazole 2 g daily for 5 days is recommended. If continued failure occurs after these regimens, consultation with a specialist is recommended to include sensitivity testing of *T. vaginalis* to both metronidazole and tinidazole.

Prevention is managed with patient and partner treatment as well as patient education regarding the frequency of asymptomatic infections, the sexual nature of transmission, an increased risk for HIV acquisition and transmission, and the importance of both patient and partner compliance with prescription treatment regimens. A discussion regarding changing sexual behaviors through the consistent use of condoms or

abstinence, maintaining a mutually monogamous relationship with a noninfected partner, or limiting the number of sexual partners is indicated.

Cervicitis

Inflammation of the uterine cervix can be effected by many of the already noted conditions and can be due to infectious or noninfectious etiologies, with acute typically the former and chronic the latter. The most common infectious etiologies are the STDs chlamydia, *Neisseria gonorrheae*, as well as herpes simplex viruses, *Trichomonas vaginalis*, and BV (discussed elsewhere). Noninfectious causes can be from mechanical or chemical irritation, radiation therapy, and systemic inflammatory diseases. A significant proportion of patients are asymptomatic and detected incidentally on exam, but when present symptoms typically can include varying degrees of vaginal discharge, postcoital bleeding, dysuria, urinary frequency, dyspareunia, or vulvovaginal irritation. The appearance of the cervix on exam will vary depending on the severity and etiology and can include mucopurulent cervical discharge, cervical friability, vesicular or ulcerative lesions, punctuate hemorrhages of the "strawberry cervix," and cervical motion tenderness with palpation. Treatment is directed at the offending etiology and relief of symptoms. When an etiology cannot be found, there is no recommendation for treatment beyond empiric coverage for STDs, particularly in those patients at high risk. Histologic or cytologic cervicitis in asymptomatic women does not require treatment as it is a very nonspecific finding.

Other STDs: GC, Chlamydia, HPV, Pediculosis, HSV, and Syphilis

There is considerable overlap of the symptoms of these conditions and other STDs, and for this reason, all STDs should be entertained when evaluating patients with vulvovaginal complaints and coinfection may be present. STDs are covered in detail elsewhere in this text but a brief description is given here of some of the similar common presentations. The presentation of vulvovaginitis in herpes simplex virus types 1 and 2 can vary widely based on a number of factors but can have the signs and symptoms of vulvovaginal inflammation with edema, pruritus, dysuria, dyspareunia, local pain and itching, and even vaginal discharge. Typically there are characteristic ulcers present on the labia, vagina, and/or cervix to indicate the etiology. Gonorrhea and chlamydia, if symptomatic, typically appear as mucopurulent cervicitis that when wiped away quickly reappears. HPV is discussed later with genital warts. Pediculosis pubis (pubic lice) typically presents with vulvar pruritus, and lice or nits in the pubic hair will be observed on the exam of the genitals. Primary syphilis can present with painful ulcers and secondary syphilis with condyloma lata: flat, moist papules on plaques that can be white, pink, or yellow and can mimic genital warts.

Atrophic Vaginitis

Atrophic vaginitis is an alteration of the normal premenopausal vaginal biological and chemical environment and inflammation that occurs in the mucous membranes of the female genitalia due to the lack of or decreased levels of estrogen. This often occurs in menopausal women but can also occur during other hypoestrogenic states such as postpartum and lactation and when taking antiestrogenic medications. The lack of estrogen stimulation of the cells of the female genital tract results in less glycogen and thinning of the epithelial cells. The decrease in glycogen then results in the loss of lactobacilli with a resultant decrease in lactic acid and hydrogen peroxide, raising the vaginal pH (>5), thus altering the normal premenopausal flora, and making the likelihood of overgrowth or invasion of pathogenic organisms more likely.

Atrophic changes seen as a result of this process include loss of elasticity and thinning of the vaginal epithelium with shortening and narrowing of the vaginal canal and introitus with loss of rugae as well as decreased vaginal secretions.

Together, these make the area more susceptible to even minor trauma producing bleeding, petechiae, and even ulceration. There are estrogen receptors in the structures of the urinary tract derived from the same embryologic origin, including the bladder, urethra, and pelvic floor musculature, that are affected by this same hypoestrogenic state and produce the symptoms of dysuria, urinary frequency, and hematuria. Abstinence can exacerbate the conditions and sexual activity can actually help to preserve the vaginal epithelium and reduce these symptoms by encouraging increased vaginal blood flow and elasticity [13].

The clinical presentation is varying degrees of vaginal dryness, with burning or irritation, sometimes a yellow malodorous vaginal discharge, dyspareunia, dysuria, and urinary frequency and even vulvar or vaginal bleeding and hematuria (not necessarily related to intercourse). The pelvic exam will show the effects of the hypoestrogenic state with sparse pubic hair, decreased vaginal secretions, introital narrowing, fusion or resorption of the labia minora, and pale, dry vaginal epithelium that appears smooth and even shiny with a loss of rugae. There is loss of labial fat that can make the clitoris or urethral meatus look more prominent or even cause urethral prolapse. The vagina can be shortened, narrowed, and poorly distensible. In fact, in severe cases, the cervix can become nearly flush with the vaginal walls as the fornices are obliterated. The vaginal and cervical tissues may show inflammation, have more prominent blood vessels visible through the thinned epithelial tissue, and can show patchy erythema, petechiae, or ulcers with friability of the cervix and easy bleeding of other structures, and there may be a yellow, malodorous discharge present.

The diagnosis is made based on the clinical findings, though laboratory testing is performed in order to rule out any other coexisting conditions. Measuring serum estrogen levels is not usually necessary or beneficial unless there are questionable findings. The laboratory evaluation will show an elevated pH (>5) and lack of lactobacilli on wet mount with a predominance of parabasal cells and may show many PMNs and the presence of other mixed flora. BV and trichomoniasis should be ruled out by the lack of clue cells or motile trichomonads. Parabasal cells are immature squamous epithelial cells that are rounded with a large nucleus to cytoplasm ratio. The maturation index quantifies the proportions of the types of epithelial cells based on their maturity. The superficial and intermediate epithelial cells dominate the wet mount in premenopausal women, whereas in post menopause, there is an increase in parabasal cells, even to the point that no other types are seen.

First-line treatment of atrophic vaginitis is the use of vaginal lubricants and moisturizing agents. The vaginal moisturizing agents should be used on a regular basis, at least one to two times weekly. And water-soluble lubricants should be used generously during intercourse to decrease discomfort. Though these agents do not reverse the atrophic changes, they can be quite useful, particularly in cases of only mild symptoms. Mechanical measures with intercourse itself, dildos, or mechanical vaginal dilators can be used (with lubrication) by a partner or the patient herself to stretch the vaginal tissue, though little is known about the ideal type and frequency that results in the best outcomes.

For moderate to severe symptoms of atrophic vaginitis, local vaginal estrogen therapy is more effective and actually reverses the changes seen by the lack of serum estrogen [14]. The doses used for this condition (7.5–25 mcg weekly) are lower than that used for control of the vasomotor symptoms of menopause and avoid or minimize the systemic estrogenic effects of increased risk for breast cancer and thrombosis as there is little systemic absorption [15]. Local vaginal estrogen is often more effective in treating the vulvovaginal symptoms of atrophy than oral estrogen therapy. In the USA, these agents are available as conjugated estrogen creams and estradiol in the form of cream (though there is increased systemic absorption), tablet, or ring and appear to be equally effective in relieving symptoms, though the dose and duration to achieve this affect can vary across patients. With all of these forms, the typical dosing regimen is to use daily for the first 2 weeks and then decrease to approximately twice weekly or the dose that is effective in controlling symptoms.

In women with an intact uterus, consideration should be given to adding progesterone, either cyclical or continuous, to decrease the risk of endometrial malignancy, though the very low doses used do not appear to stimulate the endometrium [15].

Selective estrogen receptor modulators (SERMs) can be used in this setting and are approved to treat the symptoms of vulvovaginal atrophy [16]. This medication selectively binds to estrogen receptors acting as an estrogen agonist, inducing changes in the vaginal epithelium and decreasing the vaginal pH, and appears to have no detrimental effects on endometrial tissue. This is a daily systemic medication, and side effects are more common than with topical meds, the most common being hot flashes.

There is insufficient evidence to support the use of alternative or complimentary therapies such as oral or vaginal vitamin D or E. The safety of hormonal use in women either at high risk or with a history of breast cancer or thromboembolism has not yet been established, so these therapies are not recommended for these populations.

Vulvodynia

Vulvodynia is vulvar discomfort (typically burning or pain) of unknown etiology with no visible findings or other medical explanation; therefore, it is a diagnosis of exclusion. Vestibulitis is no longer used to describe this condition, as it implies the presence of inflammation which is not part of the condition [17]. The presentation is that of provoked (with penetration or pressure to the vulva) or unprovoked burning or discomfort of the vulva or particular areas of the vulva (clitoris, vestibule), infrequently with pruritus. The physical exam reveals normal or mild inflammatory changes with hyperalgesia of this area; pain with separation of the labia is common. The pathogenesis is unknown and can vary for each individual, but is most likely a combination of factors, including changes in estrogen concentrations, neuropathic pain, pelvic floor dysfunction, and psychological factors [18]. These factors are then thought to precipitate the mind-brain-body cycle seen in other chronic pain syndromes.

There is paucity of data available, and there is no agreement in diagnosis and treatment strategies [18]. Avoidance of any products (dyes, perfumes, other chemicals) or behaviors (use of tight-fitting clothing, horseback or bike riding, daily use of sanitary pads) that can irritate the area is recommended as well as avoidance of constipation. Use of the application of ice packs wrapped in a soft cloth periodically throughout the day or sitz baths in warm water 10–15 min with subsequent application of a thin layer of petrolatum gel can offer some relief. Pelvic floor rehabilitation or physical therapy by those experienced in this disorder has been utilized. Important is addressing the psychosocial and sexual issues with couples and/or sexual therapy, including cognitive behavioral and mindfulness therapy.

Pharmacologic therapy utilizes medications often used in other types of neuropathic and chronic pain: topical lidocaine, tricyclic antidepressants (desipramine, nortriptyline, amitriptyline), gabapentin, pregabalin, venlafaxine, duloxetine, and estrogen cream. Nerve blocks may be beneficial and require referral to either an anesthesiologist or pain specialist.

Allergens and Irritants

Allergic reactions or inflammation of the vulvovaginal area can occur as a result of exposure to various substances, such as spermicides, soaps, deodorants, detergents, dyes, perfumes, pads or panty liners, latex, douching agents, urine, and more chemicals. There can also be mechanical irritation caused by foreign bodies (dildos/vibrators/personal massagers) particularly if prolonged exposure, as in the case of a retained tampon. Symptoms can include pruritus, stinging, soreness, burning, or even a vaginal discharge. It is important to specifically ask patients regarding the use of any feminine hygiene or other products and the frequency as excessive washing can cause dryness and irritation. Exam will reveal local inflammation and possibly excoriation and often discharge and odor in the case of a retained

foreign body. Contact dermatitis can be seen on the vulva with the typical findings of erythematous maculopapular rash. Coinfection can be present so complete exam including microscopy is warranted. Treatment is avoidance of the offending agents and, in the case of a retained foreign body, removal and treatment of any coinfection (routine use of antibiotics in this setting is not necessary).

Dermatoses

There are a number of generalized skin conditions that can include vulvar symptoms ranging from mild to severe, though these uncommonly affect only the vulva. The symptoms, if present, are typically pruritus and/or irritation/soreness. The exam will often reveal the characteristic findings of the respective conditions: seborrheic dermatitis with pink macular area with scale; atopic or contact dermatitis with erythematous papules; molluscum contagiosum with small pearly, umbilicated papules; folliculitis with inflammation and/or infection of the hair follicles; skin tags that are flesh colored or pigmented and usually pedunculated; and lichen simplex chronicus with thickening or lichenification of the skin. The area may show the results of either acute or chronic changes of redness, excoriations, or even fissures. Aphthous ulcers can present on the mucous membranes of the genital area and are similar to the much more common oral form. Treatment would be directed at the particular skin condition in question, covered elsewhere in this text.

Generalized skin conditions can present with primary genital lesions or can present with a different appearance in the genital area, often related to the presence on mucous membranes and the presence of more moisture. Psoriasis affects the genitals in approx 30–40 % of patients with the disease [19]. On the mucous membranes of the vulva, the lesions tend to have less scale, may appear red, and even have exudate present. Typically the lesions do not involve the vagina, and in some cases, the genitals can be the sole presenting location. Tinea can involve the groin and vulva showing sharply marginated, erythematous dusky red, moist plaques or patches with slight scaling and often with satellite lesions and pustules present. When found in the groin, it is termed tinea cruris. Hidradenitis suppurativa when involving the vulva is typically found in the inguinal and labiocrural folds, mons pubis, and perianal area. Typically there are old scars from previous lesions, and frequently edema is present.

Lichen sclerosis is a primary skin condition of unknown etiology that can occur in genital and extragenital locations. Initially the symptoms can be very subjective with itching, dyspareunia, and dysuria, though the typical presentation is that of pruritus, with the appearance of white papules that coalesce into white plaques: the skin becomes thin and slightly wrinkled ("cigarette paper"). On the vulva it can lead to obliteration or alteration of the normal architecture of the labia minora and stenosis of the introitus or can appear as a figure 8 pattern when involving the perineum and perianal areas. There is an increase in the risk of squamous cell carcinoma so biopsy may be indicated for any suspicious lesion or failure to respond to therapy.

Lichen planus also has an unknown etiology involving the mucocutaneous areas of the body and often has simultaneous oral and genital presentations. Lesions can be papulosquamous with flat white plaques or erosive with red or violaceous, sharply marginated, flat-topped papules or plaques with a thin white lacy network of white or gray lines usually on the labia minora and introitus (sometimes on the vaginal wall). Papulosquamous may be asymptomatic or with some pruritus, whereas erosive are often painful and can even have bleeding.

Fistulas and Crohn's Disease

Rectovaginal, anovaginal, and less commonly vesicovaginal fistulas can cause symptoms of vulvovaginitis, including malodorous vaginal discharge, pruritus, inflammation, and dyspareunia. In some cases stool or gas is passed from the vagina, making the diagnosis much easier. Often these lesions are palpable on rectal exam, usually located in the midline, lower third of the vagina, along the posterior vaginal wall, and on vaginal

exam may be just inside the introitus or hymen. On exam the appearance is that of a red velvety, indurated area. Fistulas can result as a complication of pelvic surgery, vaginal delivery, radiation therapy, more rarely spontaneously, or due to other pathologies such as inflammatory bowel disease. Crohn's disease can also be present on the vulva as knifelike linear ulcers, particularly in the skin folds. Initial presentation can be only vulvar edema or abscesses that break down to form chronic ulcers (which can mimic hidradenitis suppurativa) and/or large vulvar skin tags.

Bartholin Glands and Duct Disorders

Bartholin glands are mucous-secreting glands that begin functioning to provide moisture to the vestibule of the perineum at puberty and typically involute with age, particularly with menopause. They are small (approximately 0.5 cm) and are connected to the vestibule with a short duct (approx 2–2.5 cm) that opens at the 4 and 8 o'clock positions on either side of the vaginal orifice between the hymenal ring and labia. Cysts and abscesses are formed when there is obstruction of the opening of the duct, with resultant accumulation of the mucous secretions proximal to the obstruction, or cystic dilation of the duct and can become infected (though abscesses can occur without the formation of a cyst). They should be differentiated from other masses found on the vulva and perineum such as lipomas, folliculitis, hidradenitis suppurativa, sebaceous cysts, hematomas, Skene gland cysts (located more anteriorly on either side of urethral openings), other vulvar abscesses, hernias, or even extensions of perianal abscesses.

Both cysts and abscesses are typically unilateral and found in the area of the Bartholin gland and should not be fixed to any underlying tissues: this can be suspicious for malignancy. The cysts are typically smaller than abscesses (approx 1–3 cm) and may be asymptomatic though if large can cause some discomfort. Abscesses, which are more common, are typically larger and quite painful, often to the point the patient is barely able to sit or ambulate normally. On clinical exam cysts are usually soft and non-tender, whereas abscesses are soft, painful masses that protrude into the posterior vaginal introitus and often extend into the labia. There can be associated cellulitis with increased warmth, erythema, fluctuance, induration, and edema. The presence of any palpable solid or irregular mass can be an indication of the presence of malignancy, though this is rare, particularly in premenopausal women. If there is any suspicion of malignancy in postmenopausal women with their first occurrence, biopsy should be obtained [20].

Cysts may require no management, unless large and uncomfortable. Abscesses should be treated at the least with incision and drainage (I&D), though some may spontaneously rupture and drain. The risk of recurrence due to healing of the edges of the incision and reaccumulation of the gland secretions is quite high [21], so further management is recommended with either placement of a Word catheter, marsupialization, silver nitrate stick ablation, laser vaporization, or complete excision. I&D involves sterile prep of the area, administration of a local anesthetic with an incision into the protruding mass in the area of the duct opening external to the hymenal ring to drain the contents. Irrigation and hemostats can be used to break up any loculations present within the cyst or abscess. With all of these procedures, there is a risk of labial or perineal edema, hematoma formation, bleeding, cellulitis, scarring, and dyspareunia.

Antibiotics are typically not necessary unless there is accompanying cellulitis or high risk for complicated infection such as recurrence, immunocompromised patients, pregnancy, risk for MRSA, systemic signs of infection, or suspicion of gonorrhea or chlamydia infection. The infection is typically polymicrobial with the most common aerobic pathogens of staph, strep, and E coli and anaerobic bacteroides with sexually transmitted infections (such as gonorrhea, chlamydia, and trichomonads) decreasing in incidence [22]. When indicated, empiric treatment is started before results of any cultures are received and includes amoxicillin-clavulanate (Augmentin) 875 mg BID to cover E coli and strep, with

clindamycin (Cleocin) 300 mg four times a day for staph and bacteroides, both for 7 days. If culture results reveal an STD, it should be treated accordingly.

Word catheter placement involves the placement of a small (stem is approximately 1 in. and diameter is similar to that of a 10 French Foley catheter) balloon-tipped catheter into the incision immediately after the performance of I&D, with inflation of the balloon with 2–3 cm^3 of saline in order to keep it in place and the end tucked into the vagina. If the incision is too large, the catheter will fall out, so it is recommended only about 5 mm incision in this case. The catheter is left in 4–6 weeks to allow epithelialization of a new tract for drainage of the gland secretions; therefore, it is important to ensure the tip is placed within the cyst wall so as to avoid the development of a false tract. At this time the balloon can be deflated and the catheter removed without anesthesia. This procedure is easily accomplished in the office with local anesthesia and is relatively quick and easy, though the patient may experience post-procedure discomfort or the catheter can migrate or become dislodged and fall out before epithelialization, increasing the risk for recurrence. Daily sitz baths after the procedure can help with discomfort.

Marsupialization involves a larger incision over the cyst or abscess or even an excision of an ellipse of the roof of the mass, with the length dependent on the size of the cyst (usually 1–3 cm). Drainage is followed by suturing with eversion of the edge of the cyst wall onto the epithelial surface of the vestibule with interrupted absorbable sutures allowing for the formation of a new ductal orifice for drainage of gland secretions. This procedure is as effective as placement of a Word catheter and also can be accomplished easily in the office setting with local anesthesia, though is somewhat more complicated and time consuming [21]. Again, daily sitz baths are typically recommended.

The placement of a silver nitrate stick (approx 0.5 cm in size) deep within the cyst/abscess after I&D can also be done in the office setting with local anesthesia. The wound is then dressed with gauze and the patient instructed to return in 48 h for debridement of the wound of silver nitrate particles and necrotic tissue. This procedure has been found to be as effective as complete excision [21]. There is significantly more post-procedure discomfort than the previous procedures described and risks of chemical burns to nearby tissue, though there is less healing time, expense, and risk than that of complete excision. Carbon dioxide laser ablation can be accomplished with the use of local anesthesia as well and is effective in treating this condition, though it requires expertise and training in the use of very expensive equipment not typically available in the office setting of family medicine. Complete excision of the gland and duct is definitive treatment though it requires surgical excision in the operating room, with all of the increase in cost and risks inherent to these more involved invasive procedures. For these reasons complete excision is usually used only when recurrent disease fails numerous other attempts at treatment, or malignancy is suspected (though biopsy is the first-line approach). The loss of gland function can rarely cause vaginal dryness and dyspareunia.

Genital Warts

Genital warts are one of the clinical manifestations of infection with the sexually transmitted human papillomavirus (HPV), most commonly types 6 and 11 with low oncogenic potential. Transmission is through direct skin contact during sexual activity, so increased risk exists for patients with increased numbers of sexual partners and history of other STDs, including HIV. Those patients infected with HIV are more likely to develop genital warts than those without [23], and the lesions are more recalcitrant to treatment due to the depressed cell-mediated immunity. The infection itself and the warts are asymptomatic, though there can be pruritus, pain, or discomfort in some patients. The lesions appear as flesh colored or pink, flat, papular, or verrucous papilliform growths on the genital mucosa. They commonly occur around the introitus, but can occur in and around the anogenital epithelium including the cervix, vagina, urethra, perineum,

and perianal skin. Large exophytic masses can cause obstruction of the perianal orifices and interfere with urination, defecation, and vaginal delivery.

Diagnosis is usually clinical, based on visual inspection and can be confirmed with biopsy, though not necessary. The application of 5 % acetic acid solution causes the lesion to turn white and can aid in diagnosis, with or without the use of colposcopy. A similar-looking normal variant of vulvar anatomy is vestibular papillomatosis with monomorphous, symmetrical, soft, closely set projections usually the same color as the mucous membrane of the vestibule (or sometimes more red), whereas warts are firmer, flesh colored, cauliflower-like (multiple projections from a single base). The indication for biopsy prior to treatment is to rule out any malignant or premalignant lesions as squamous cell carcinoma can coexist. Biopsy is recommended when the diagnosis is uncertain; lesions do not respond to standard therapy; the disease worsens during therapy; the lesion appears atypical, particularly if pigmented, asymmetrical, or irregular border, fixed, bleeding, or ulcerated; or the patient is immunocompromised. Colposcopy and biopsy are recommended for any cervical exophytic lesions. Testing for HPV type is not indicated as it does not change management strategies.

Treatment is only indicated for the relief of symptoms, including cosmetic or psychological concerns, as it does not eliminate all cells infected with the virus and it is unknown if it reduces risk of transmission. Spontaneous resolution does occur at varying rates reported (approximately 20–40 %), so expectant management is an acceptable option, though the patient should be counseled that the lesions may spontaneously regress, increase in number or size, or remain unchanged over time. No one treatment option has been shown to be superior to others [5], and not one treatment is right for all patients and every type of wart. Choice of treatment is based on location and size of lesions, patient characteristics (pregnant or immunocompromised), available resources, and clinical expertise, as well as patient preference, including side effects, cost, and convenience. Options include patient- or provider-applied solutions for ablative or immune-mediated destruction of the lesions or surgical techniques. Intra-anal lesions should be referred to a specialist for surgical treatment.

Patient-applied regimens require the patient to be able to identify and reach all of the lesions to be treated. These regimens include podofilox (Condylox) 0.5 % solution or gel, applied to the wart with a swab or finger for 3 days and then no treatment for the other 4 days of the week, up to four cycles; imiquimod (Aldara) 5 % cream applied daily before bed and then washed off 6–10 h after application, three times per week up to 16 weeks; and sinecatechins (Veregen) 15 % ointment, apply 0.5 cm strand and spread with the finger into a thin layer covering the wart three times per day (do not wash off) for up to 16 weeks. Provider-applied regimens include cryotherapy with liquid nitrogen or a cryoprobe every 1–2 weeks; podophyllin resin 10–25 % in a compound tincture of benzoin applied and allowed to dry before patient sits, stands, or dresses and washed off 1–4 h later, weekly, with a limit of <0.5 ml or treating a total area <10 cm^2 with no open or ulcerated lesions; and tri- or bichloroacetic acid 80–90 % apply a small amount to only the wart tissue and allow the white frosting to develop with drying before allowing the patient to move (in order to avoid irritation to surrounding areas), weekly. If pain is too severe or an excess amount is applied, the area can be treated with soap or sodium bicarbonate solution. Surgical excision techniques are recommended for those with larger or greater number of lesions and are typically more expensive and invasive, with more risk associated but do have the advantage of removal of the warts in one visit.

Warts can proliferate and become friable in pregnancy and imiquimod, sinecatechins, podophyllin, or podofilox should not be used. Rarely types 6 and 11 can cause respiratory papillomatosis and laryngeal warts in children, though the route of transmission is unknown, and it is not clear if cesarean delivery prevents this risk [5]. Cesarean delivery may be indicated in the case of large exophytic lesions that may

obstruct the birth canal or increase risk of excessive bleeding.

Most lesions respond to treatment within 3 months. A change in treatment modality is indicated if the lesions do not respond to a full course of therapy or if side effects are too severe. Recurrence is common, particularly in the first 3 months after treatment. Complications are less common if treatment is administered properly, but side effects are quite common. Hypo- or hyperpigmentation is common with the ablative and immune-modulating therapies. Depressed or hypertrophic scarring risk is greater if insufficient time is taken for healing between treatments. Rarely disabling chronic pain syndromes (vulvodynia, hyperesthesia), painful defecation, or systemic effects (due to podophyllin resin) can occur. Local irritation with discomfort and inflammation, pruritus, erosions, and blistering are the most common side effects.

There are vaccines available for the prevention of HPV, at least one of which (the quadrivalent) encompasses types 6 and 11 and is currently recommended for both boys and girls at the age of 11–12 and up to age 26 if not already immunized. The best time for vaccination is prior to sexual activity, but can be given even after the presence of HPV has been diagnosed, as it may confer immunity to other types. Other prevention measures include decreasing the number of sexual partners and use of condoms; although correct and consistent use can decrease the risk of HPV infection, since they do not cover all areas of skin contact with sexual activity, they not eliminate the risk.

The diagnosis of any STD can precipitate many questions and concerns about sexual fidelity of either the patient or her partner. There is a social stigma that is associated with genital warts that may discourage patients from initiating these conversations with their family doctor, so offering counseling and initiating this discussion by the clinician can be very beneficial and is advised. Some of the issues particular to genital warts and HPV can be as follows: the types of HPV that cause most genital warts do not cause the other types of anogenital cancers; diagnosis with HPV of one partner in a relationship does not indicate infidelity in either partner as the virus is usually asymptomatic and there is a considerable lag time between the time of infection and the time of wart formation; it is impossible to determine at what point and from whom the patient acquired the HPV; it is not life-threatening and only in rare and unusual cases leads to cancer; it does not affect a woman's fertility or ability to carry a pregnancy to term; the treatments available can eliminate the wart, but not the virus itself; and it is unknown how long a person remains contagious.

Malignancies

Pruritus can be a presenting symptom of vulvar intraepithelial neoplasia (VIN), which can be HPV or non-HPV associated. They can appear as raised white papules or plaques, but can be red, pink brown, or gray. Typically they are asymptomatic and a biopsy of the lesion is recommended to rule out any high-grade lesions. Advanced cervical intraepithelial lesions can present with vaginal discharge and can mimic cervicitis with friability. A serosanguinous vaginal discharge with or without odor can be present with malignancies in the upper genital tract, such as the endometrium and fallopian tubes. In these cases the usual workup with history, physical, and laboratory evaluation above will rule out these common conditions and often suggests an alternate diagnosis.

Social Issues

Approximately 25–40 % of patients with vulvovaginal complaints will have no identifiable cause after the initial office evaluation, including the history and physical and laboratory studies described above. Getting more detail of history including sexual practices, use of hygienic products, and the timing of or associated symptoms or having the patient refrain from any use of products in the genital area and return for another full exam can be helpful. All of these patients should have cultures or NAAT specimens sent for STDs, including trichomoniasis and possibly *Candida* (if the history and exam support this diagnosis) as not all of these cases will be identified with the use of microscopy.

Vulvovaginitis and cervicitis can be a very sensitive subject for many patients not only because of the vulnerable nature of the examination but can bring up many personal relationship issues: How did they get this condition? And from whom? Is their partner to blame or at risk? What did they do to contribute to the acquisition and how can they avoid it in the future? The physician should understand the sensitive nature of these concerns and anticipate these questions or concerns, realizing some patients may be too uncomfortable to raise the questions at the office visit. Explanations should be given regarding the nature of transmission, any contributing factors, and the importance of compliance and partner treatment when applicable. Patients should be discouraged from douching as this alters the vaginal flora and can contribute to the condition and the patient's symptoms. Use of condoms and limiting the number of sexual partners through monogamous long-term relationships can reduce the patient's exposure to and risk of acquiring these types of conditions. Providing written information or resources for the patient to access is very beneficial in directing them to reliable sites for further information.

Menstrual Disorders

Ann K. Skelton*
Maine Medical Center, Portland, ME, USA

General Principles

Menstrual Cycle

Women experiencing menstrual disorders frequently call upon family physicians. The disorders are heterogeneous and stem from multiple etiologies, spanning the breadth of many disciplines including genetics, metabolism, endocrinology, gynecology, and psychology. Menstrual disorders are well addressed through a comprehensive primary care approach.

Normal Physiology and Patterns

Regulation of the menstrual cycle is a product of complex, delicate interactions among the hormones of the hypothalamus, pituitary, and ovaries. The hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile manner. The pituitary secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH) that act primarily on the theca and granulosa cells of the ovary respectively. With FSH and estradiol stimulation, a dominant follicle develops and releases an egg. Estradiol has a negative feedback effect on FSH, resulting in decreased stimulation of the several other less mature follicles that develop monthly. The follicular phase of the menstrual cycle, under control primarily of FSH, results in ovulation and lasts 10–14 days. During this phase, estrogen stimulates endometrial proliferation, and progesterone receptors are synthesized on endometrial epithelial cells.

When the concentration of estradiol reaches a threshold level for a specific duration, the LH surge occurs. The LH surge triggers ovulation and formation of the corpus luteum. The luteal phase of the menstrual cycle is the period after the LH surge and consistently lasts 14 days after the mid-cycle surge. The progesterone produced by the corpus luteum causes changes in endometrial glandular secretions and in the endometrial stroma. The corpus luteum produces estrogen and progesterone, which have negative feedback results on GnRH and FSH, eventually leading to decreased levels of estrogen and progesterone and involution of the corpus luteum if pregnancy has not occurred.

In the absence of pregnancy, the regression of the corpus luteum and the drop in progesterone levels result in endometrial sloughing, or menstruation. Subsequently, FSH levels increase to prepare for the next cycle.

Normal menstrual cycle intervals are 21–45 days from the first day of one cycle to the first day of the next, with bleeding lasting 3–7 days. Average blood loss is 30–40 mL per cycle. The average age of menarche in the United States is 12 years and menopause is 52. Figure 1 is a graphic illustration of the interactions of key hormones and their effects on the endometrium and ovary during the menstrual cycle.

Terminology

Inconsistency in terminology of menstrual disorders has interfered with clarity in their evaluation and treatment and hampered research efforts in this field. In 2011, the Federation of International Gynecology and Obstetrics (FIGO) published their recommended terminology for abnormal uterine bleeding [1]. Their schema for abnormal uterine bleeding (AUB) is among the terms defined below, with the

DOI 10.1007/978-1-4939-0779-3_110-1

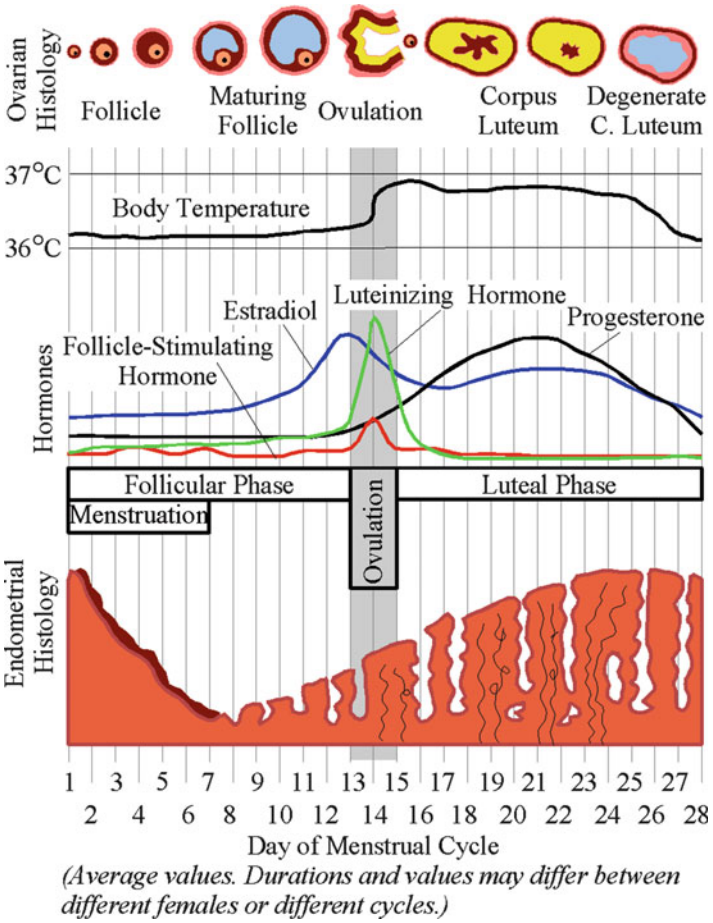

Fig. 1 The menstrual cycle. Chris 73/Wikimedia Commons [GFDL 1.3 (www.gnu.org/licenses/fdl-1.3.html) or CC BY-SA 3.0 (http://creativecommons.org/licenses/by-sa/3.0)], via Wikimedia Commons

recommendation that terminology including menorrhagia, metrorrhagia, and dysfunctional uterine bleeding be discarded in favor of the terms listed under AUB below.

Menarche: onset of first menses

Amenorrhea: absence of menstrual periods

1. Primary amenorrhea: lack of menarche by age 13 in girls without development of secondary sexual characteristics or by age 15 in those with secondary sexual characteristics
2. Secondary amenorrhea: absence of menses for three consecutive cycles in a previously regularly menstruating woman or for 6 months in a woman with oligomenorrhea

Menopause: cessation of menses for 12 months not due to pregnancy or for 6 months in a woman over 50

Abnormal uterine bleeding: bleeding that is abnormal in timing, flow, or duration [1]

- ***Acute AUB***: heavy bleeding of sufficient quantity that immediate intervention is required
- ***Chronic AUB***: abnormal in volume, regularity, and/or timing and has been present for the majority of the past 6 months and does not require immediate intervention
- ***Intermenstrual AUB***: occurs between clearly defined cyclic and predictable menses

DOI 10.1007/978-1-4939-0779-3_110-1

- ***Heavy menstrual bleeding***: characterized by blood loss of greater than 80 mL in a cycle or passing large clots or soaking through pads or tampons within an hour and associated with anemia

Approach to Patient

Any woman presenting with a menstrual disorder should have a thorough and pertinent history and physical examination. The key components of the history are a menstrual, reproductive, and contraceptive history; a general medical history including medications used; and nutritional, exercise, and emotional assessments. A family medical history and history of reproductive or menstrual disorders should also be obtained. The elements of history taking for menstrual disorders are outlined in Table 1.

The focus of the physical examination is on identifying abnormal anatomy such as an imperforate hymen or an enlarged fibroid uterus and assessment for androgen excess, estrogen deficiency, or an endocrinopathy. Elements of a focused physical examination are outlined in Table 2. Laboratory and imaging studies are often required elements of evaluation. They are listed in Table 3 and are discussed under each condition.

Amenorrhea

Primary Amenorrhea

Congenital anomalies are the main cause of primary amenorrhea. These include imperforate hymen or a vaginal septum that will be detected on exam and can be treated surgically. Congenital absence of the uterus and vagina can occur. Androgen insensitivity leads to a 46,XY female who has no uterus or tubes and a blind vaginal pouch. Testes are found within the abdomen or inguinal hernias and require surgical removal due to risk of malignant transformation. Women with Turner's syndrome, 46,XO, never menstruate because ovaries do not develop. Patients with congenital anomalies require specialty consultation. Women with primary amenorrhea and normal sexual development should undergo the same evaluation as patients with secondary amenorrhea.

Secondary Amenorrhea

History and physical examination may point to specific causes of secondary amenorrhea, including the presence of chronic conditions or medications that can alter menstrual patterns. Laboratory evaluation always begins with the pregnancy test. If this is negative, obtaining a thyroid-stimulating hormone (TSH), prolactin level, and FSH and LH will help identify thyroid disorders, hyperprolactinemia, primary ovarian insufficiency, and menopause as the cause for amenorrhea. Primary ovarian insufficiency refers to ovarian follicle depletion or dysfunction prior to age 40. Hyperprolactinemia may be due to benign tumor of the pituitary gland or to medications such as OCPs, tricyclic antidepressants, opiates, antihypertensives, and antipsychotics [2]. If the prolactin level is greater than 200 ng/mL, magnetic resonance imaging (MRI) is recommended to evaluate for a pituitary tumor. If all the tests are normal, consider additional evaluation for evidence of disordered eating, excessive exercise, and poor nutritional status leading to functional hypothalamic amenorrhea. If there is evidence of hyperandrogenism, evaluate further with serum testosterone and 17-hydroxyprogesterone to differentiate among polycystic ovary syndrome (PCOS), late-onset congenital adrenal hyperplasia, or an ovarian or adrenal tumor producing androgens [3]. Elevated levels of LH and FSH make the diagnosis of ovarian failure. If LH is elevated and FSH is normal, further testing can be done for congenital adrenal hyperplasia (17-hydroxyprogesterone), Cushing's syndrome (cortisol levels), and ovarian or adrenal malignancies (testosterone level). If those tests are done, with normal 17-hydroxyprogesterone and cortisol and moderately elevated testosterone, polycystic

DOI 10.1007/978-1-4939-0779-3_110-1

Table 1 Elements of history taking

Menstrual history	Age at menarche
	Usual menstrual pattern
	Cycle length (normal 21–35 days)
	Duration (normal 1–7 days)
	Flow (normal < 1 pad or tampon per 3 h)
	First day of last period
	Moliminal symptoms (breast tenderness, mittelsmerz)
	Dysmenorrhea
Gynecologic and sexual history	Use of contraception
	Pregnancies, deliveries, complications
	Pelvic procedures (e.g., dilation and curettage)
	Pelvic pain
Family history	Age of onset of menarche and menopause in sister(s) and mother
	Similar menstrual dysfunction in others
	Congenital syndromes or anomalies
	Endocrine disorders
General medical history	Changes in weight
	Emotional stressors
	Exercise habits and related disorders such as stress fractures
	Sexually transmitted diseases
	Medications
	Chemotherapy or radiation
	Endocrine or metabolic disorders, particularly diabetes or thyroid disorders
	Disordered eating
	Trauma
	Galactorrhea
Screening for disorder of hemostasis [1]	Heavy menstrual bleeding since menarche
	Postpartum hemorrhage, surgical–related bleeding or bleeding associated with dental work
	Two or more of the following:
	Bruising one to two times monthly
	Epistaxis one to two times monthly
	Frequent gum bleeding
	Family history of bleeding symptoms

ovary syndrome (PCOS) is the likely diagnosis; this condition is described separately below. Highly elevated testosterone levels suggest malignancy of the ovary or adrenal gland [2]. Low levels of LH and FSH may be caused by pituitary failure as well as by hyperprolactinemia. An algorithm for the laboratory evaluation of secondary amenorrhea that minimizes diagnostic error while considering costs by obtaining tests in stepwise fashion is presented as Fig. 2; the authors used a definition of no menses for 6 months in a previously regularly menstruating woman or for 12 months in a woman with irregular menses [2]. The same evaluation may be undertaken after 3 and 6 months respectively to help identify causes and provide treatment in a more timely fashion.

DOI 10.1007/978-1-4939-0779-3_110-1

Table 2 Elements of physical examination

General	Height and weight
Skin	Acne, alopecia, hirsutism, abdominal striae, pallor
Neurologic	Visual field deficit
Neck	Thyroid nodules or enlargement
Breasts	Tanner stage, galactorrhea
Abdomen	Adrenal mass
External genitalia and vagina	Imperforate hymen, vaginal septum, atrophic vaginal mucosa, scant cervical mucus, enlarged clitoris
Cervix	Friability, inflammation, polyps, duplication
Uterus and ovaries	Enlargement of uterus and ovaries

Table 3 Laboratory and imaging evaluation

Test	Condition	Menstrual disorder
Pregnancy test	Positive in pregnancy	Amenorrhea, AUB
Thyroid stimulating hormone (TSH)	Hyper or hypothyroidism	Amenorrhea, AUB, HMB
Prolactin (PRL)	Elevated in hyperprolactinemia due to medication or adenoma	Amenorrhea, AUB
LH	Slight elevation common in PCOS, CAH, Cushing's disease	Amenorrhea, AUB
	Decrease in pituitary failure or elevated PRL	
FSH	Elevated in menopause or primary ovarian failure	Amenorrhea, AUB
	Low in pituitary failure or elevated PRL	
Testosterone	Mildly elevated in PCOS	Amenorrhea, AUB, virilization
	Very elevated in androgen producing tumor in ovary or adrenal	
17-hydroxyprogesterone	Congenital adrenal hyperplasia	Amenorrha, AUB
Cortisol	Cushing disease	Amenorrhea, AUB
CBC	Anemia, platelet count	AUB, HMB
PTT, INR	Disorders of hemostasis	AUB, HMB
Ristocetin cofactor, coagulation factors	Disorders of hemostasis, based on abnormal history screen or labs	AUB, HMB, with positvie screen for hemostasis disorder
Cervical, vaginal culture	Endometritis, cervicitis	AUB, dysmenorrhea
Endometrial biopsy	Endometrial hyperplasia or cancer	AUB
Transvaginal ultrasound	Endometrial hyperplasia, cancer, leiomyomas, possibly polyps or adenomyosis, endometriosis	AUB, dysmenorrhea
Saline infused sonohysterogram	As above, more likely to detect polyps or discrete intracavitary abnormalities	AUB
Hysteroscopy	As above	AUB
Laparoscopy	Endometriosis	Dysmenorrhea
MRI pituitary	Pituitary adenoma	Amenorrhea, AUB
MRI pelvis	Adenomyosis, leiomyomas, endometriosis	AUB, dysmenorrhea

Female Athlete Triad

The female athlete triad, one feature of which is amenorrhea, warrants special note because of its common presentation to primary care physicians and its potential consequences. Osteoporosis and disordered eating are the other two aspects of the triad. In this condition, vigorous athletic training and weight

DOI 10.1007/978-1-4939-0779-3_110-1

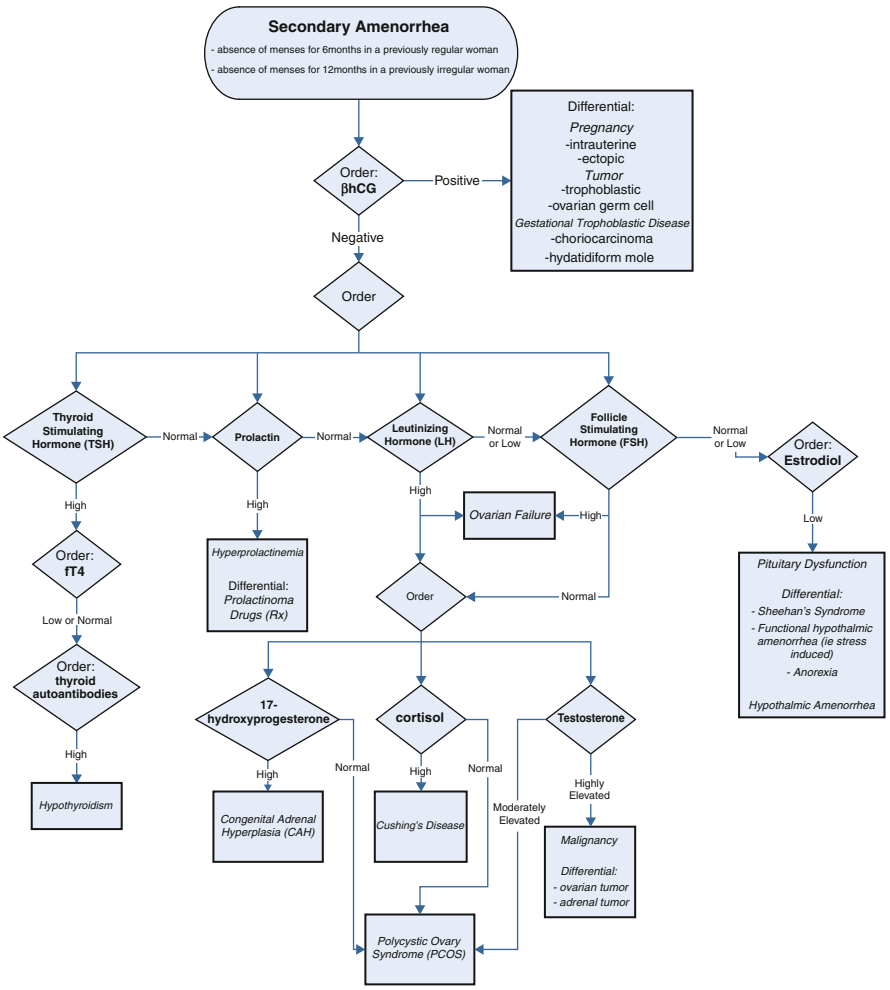

Fig. 2 Algorithm for laboratory evaluation of secondary amenorrhea (Used with permission Roberts-Wilson et al. [2])

changes result in low energy availability, producing hypothalamic dysfunction and either primary or secondary amenorrhea. The associated low estrogen levels lead to osteoporosis. Osteoporosis is especially devastating if it occurs in adolescence when bone density should be peaking. Stress fractures and other fractures due to osteoporosis may be the presenting problems in athletes. The disordered eating associated with the female athlete triad may not meet the strict definitions of anorexia nervosa or bulimia but is prevalent among female athletes. Physicians should review exercise and eating habits with all women presenting with amenorrhea or fractures. Evaluation, as outlined above for secondary amenorrhea, should take place for those young women who have missed three menstrual periods. If no other cause is found, treatment of the eating disorder through counseling, nutritional advice, and possibly medications and a change in exercise patterns will usually result in resumption of menses. Important adjuncts to treatment of the female athlete triad include preventive measures for osteoporosis including ensuring adequate intake of calcium and vitamin D.

Abnormal Uterine Bleeding

Terminology related to abnormal bleeding patterns has been inconsistent. In 2011, the Federation of Gynecology and Obstetrics (FIGO) published recommendations from a panel convened to "develop an agreed pragmatic classification system with a standardized nomenclature to be used worldwide by researchers and clinicians investigating and treating women of reproductive age with AUB" [1]. The

DOI 10.1007/978-1-4939-0779-3_110-1

FIGO schema divides causes of AUB into structural and nonstructural causes, with nine main categories, which are arranged according to the acronym PALM-COEIN:

"Structural" causes = "PALM"
- **P**olyp – endometrial or endocervical
- **A**denomyosis – endometrial tissue within the myometrium
- **L**eiomyoma – submucosal or other
- **M**alignancy and hyperplasia

Nonstructural causes = "COEIN"
- **C**oagulopathy – including chronic anticoagulation (placed here rather than iatrogenic)
- **O**vulatory dysfunction – most often PCOS, hypothyroidism, hyperprolactinemia, stress, obesity, anorexia, weight loss, or extreme exercise or due to medications; also often occurring at extremes of reproductive age: adolescence or perimenopause
- **E**ndometrial – due to a primary disorder of the endometrium, e.g., deficiencies in vasoconstrictor production or inflammation or infection
- **I**atrogenic – including hormonal contraceptives; medications that impact ovulation including tricyclic antidepressants, phenothiazines, and serotonin reuptake inhibitors
- **N**ot yet classified

Evaluation and Treatment of AUB

Women may have more than one factor contributing to AUB and may have conditions that are present but not contributory. Evaluation of AUB begins with the history and physical exam. The patient's age may point toward the anovulation common around menarche or close to menopause. Other historical features listed in Table 1 will help guide the evaluation toward etiologies including infection, tumors, endocrinopathies, medication effects, and disorders of hemostasis. Presence of risk factors for endometrial cancer including hypertension, diabetes, family history, obesity, early menarche, late menopause, or periods of unopposed estrogen should heighten concern for cancer. The general appearance of a patient with AUB may direct the physician toward PCOS or the female athlete triad as causes for irregular bleeding. Some structural causes may be easily discernible on physical exam such as cervical polyps or uterine leiomyomas. Table 2 lists pertinent physical findings that may indicate other disorders.

Treatment of AUB is directed at the primary etiology if one can be found. Usually, treatment has two goals: control of bleeding and prevention of endometrial hyperplasia. Treatment may be medical or surgical and depends of degree of symptoms, desirability of pregnancy, and the patient's preferences.

Authors developed a practical approach to AUB based on how clinicians evaluate and treat AUB [4]. The first steps are taking a history and performing a physical exam, confirming that bleeding is from the uterus. A pregnancy test must be done to confirm that bleeding is not pregnancy related. If not, it can be classified in one of the four categories below. These correspond closely to the FIGO terminology in some cases.

1. Severe acute bleeding – Acute AUB
2. Irregular bleeding – often AUB – O
3. Heavy bleeding – AUB – Heavy menstrual bleeding; often AUB – A, AUB – L, AUB-E
4. Bleeding associated with contraceptive methods AUB – I

Severe Acute Bleeding Severe acute bleeding may be the first presentation of a coagulation disorder in an adolescent. Women on anticoagulants and who have submucosal fibroids may also present with severe acute bleeding.

DOI 10.1007/978-1-4939-0779-3_110-1

After history, physical examination, and a pregnancy test, evaluation may include a transvaginal ultrasound, TSH, CBC, INR, and PTT, with further evaluation for platelet function and clotting factor abnormalities if needed.

Treatment must be provided emergently, with patient's stability directing whether this can be done as an outpatient. An expert consensus panel recommended antifibrinolytic agents (tranexamic acid) and intravenous estrogen as first-line treatment options for acute AUB without disorders of hemostasis, along with possible use of balloon tamponade [5]. Oral estrogen can be used in some cases. Once stabilized, women can be treated with a tapering dose of combination OCP over a month followed by use of oral contraceptives for 3 months. If there are contraindications to combination OCP, cyclic progestins can be used for 3 months. Second-line options for severe acute bleeding include dilation and curettage, endometrial ablation, uterine artery embolization, and hysterectomy. For women with bleeding disorders, management of acute AUB is targeted at the underlying disorder.

Irregular Bleeding For women with irregular bleeding, history and physical exam may point to the cause, including inconsistent ovulation around menarche or menopause, severe systemic illness, endometritis, or medications that interfere with ovulation as listed above under AUB-I. The physical exam may point to androgen excess common in PCOS, described in more detail below, or toward the female athlete triad.

After pregnancy is ruled out, a TSH is obtained, with the addition of prolactin level if there is oligomenorrhea. A pelvic ultrasound may confirm or reveal fibroids as a cause of heavy and sometimes irregular vaginal bleeding, and an endometrial lining thickness of less than 5 mm helps to reassure that AUB is not due to endometrial hyperplasia or cancer. Any patient with AUB over age 35 or at increased risk for endometrial cancer due to unopposed estrogen stimulation should have sampling of the endometrium. Endometrial biopsy is 91 % sensitive and 98 % specific for identification of cancer and 82 % sensitive and 98 % specific in diagnosis of hyperplasia with atypia [6]. The endometrial biopsy procures a small sample of the total endometrium; if a biopsy is normal but bleeding persists, it should be further evaluated with direct visualization with transvaginal ultrasound, hysteroscopy, or saline infused sonohysterogram which can help identify intracavitary abnormalities including polyps and adenomyosis and can direct sites for biopsy [7]. In identification of intracavitary abnormalities, the sensitivity and specificity of these tests is as follows: hysteroscopy 94 % and 89 %, saline infused sonohysterogram 88–99 % and 72–95 %, and transvaginal ultrasound 60–92 % and 62–93 % [6].

Treatment depends on patients' goals and values and the cause of the irregular bleeding. If the patient wants to achieve pregnancy, ovulation induction can be done. If the patient does not desire pregnancy, she can be treated with OCPs for 3 months, with levonorgestrel intrauterine system or with cyclic progestins. If abnormal bleeding does not resolve after 3 months of treatment, higher-dose OCP or progestin can be considered, as well as endometrial biopsy if not already performed. If medical treatment fails, surgical treatments include endometrial ablation, uterine artery embolization, hysteroscopic resection, or hysterectomy. More detail is provided below regarding adjunct evaluation and treatment in PCOS.

Heavy Menstrual Bleeding The initial evaluation for heavy menstrual bleeding includes a history and physical exam. The most common findings are a history revealing heavy menstrual bleeding coincident with menarche, indicating a disorder of hemostasis, chronic anticoagulation therapy, or an exam revealing an enlarged uterus common with leiomyomas. Von Willebrand disease (VWD) is the most common bleeding disorder associated with heavy bleeding; more than 75 % of women with VWD experience heavy menstrual bleeding [5]. Young patients may present with heavy vaginal bleeding as a first sign of coagulation disorder. The degree of suspicion about disorders of hemostasis is mostly based on history; questions sensitive in screening for this are listed in Table 1.

DOI 10.1007/978-1-4939-0779-3_110-1

Laboratory evaluation starts with ruling out pregnancy. A TSH and complete blood count should be done. Evaluation for disorders of hemostasis can be done with INR and PTT, followed by tests of platelet function and evaluation for specific coagulation factors. A transvaginal ultrasound or saline infused sonohysterogram can be done if an anatomic cause is suspected by history or examination. Ultrasound may confirm or reveal fibroids as a cause of heavy and sometimes irregular vaginal bleeding, and an endometrial lining thickness of less than 5 mm helps to reassure that heavy menstrual bleeding is not due to endometrial hyperplasia or cancer. Cultures of the cervix are helpful in those women whose history or physical examination suggests infection as an etiology. MRI is useful in identifying adenomyosis and other structural abnormalities such as leiomyomas.

A systematic review found that levonorgestrel intrauterine system, oral contraceptive pills, extended-cycle oral progestins, tranexamic acid, and NSAIDs were all effective treatments for the reduction of menstrual blood loss in women with AUB thought to be due to endometrial dysfunction. Among these, they found that levonorgestrel intrauterine system, oral contraceptive pills, and antifibrinolytics were all superior to luteal-phase progestins and recommended levonorgestrel intrauterine system over other options [8]. If the response is not adequate, imaging should be obtained if not already done.

Polyps and submucous leiomyomas can be treated by resection, uterine artery embolization, endometrial ablation, or hysterectomy. Endometrial hyperplasia should be sampled and treated. Leiomyomas can be treated with OCPs, levonorgestrel intrauterine system, or surgical resection. Possible adenomyosis can be treated with OCPs, progestin therapy, or the levonorgestrel IUD. Second-line options for leiomyomas and adenomyosis include uterine artery embolization, endometrial ablation, myomectomy, and hysterectomy.

Finally, hysterectomy is an option if the treatments above do not provide adequate relief of symptoms and childbearing is complete. Iron supplementation should be provided if anemia is present.

Bleeding Associated With Contraceptive Methods Abnormal uterine bleeding associated with hormonal contraceptive use is common. History and physical exam should be done to assess for other contributors. The possibility of infection, either cervicitis or endometritis, should be considered and cultures done as indicated.

Irregular bleeding during the first three cycles of OCP and with the use of progestin-only pills, injections, intrauterine systems, or implants is considered normal. Patients should be reassured and encouraged to continue the medication. Taking OCPs regularly can minimize irregular bleeding. Generally, higher-dose combination OCPs cause less bleeding than lower-dose formulations; if bleeding persists, the dose of the estrogen and/or progestin can be increased. Patients using progestin-only contraceptives can be treated with a 7-day course of estrogen by mouth or patch or with a cycle of combined OCP if no contraindications exist. Injections of depot medroxyprogesterone can be given 2 weeks earlier to help with irregular bleeding.

Polycystic Ovary Syndrome

Polycystic ovary syndrome is the most common endocrine abnormality in women of childbearing age. It often presents with menstrual disorders. The cause is unclear but seems to involve both genetic and environmental factors. In PCOS, insulin acts synergistically with LH to enhance androgen production by the thecal cells. It also inhibits hepatic synthesis of sex hormone binding globuin (SHBG), increasing levels of free testosterone [9]. Groups have developed different criteria for the elements of the syndrome. The National Institutes of Health (NIH) convened an evidence-based workshop in 2012 to address some

DOI 10.1007/978-1-4939-0779-3_110-1

of the discrepancies in diagnosis of the syndrome [10]. They upheld use of the inclusive Rotterdam criteria, which require at least two of these three elements and no other reason for the symptoms:

- Oligo or anovulation defined as 8 or fewer menstrual cycles per year
- Clinical (hirsutism) and/or biochemical (elevated serum testosterone levels) evidence of androgen excess
- Polycystic-appearing ovaries with 12 or more antral follicles ranging in size from 2 mm to 9 mm and increased ovarian volume of at least 10 mL

The NIH workgroup found utility in identification of four specific phenotypes for the purposes of both diagnosis and targeting treatment:

- Androgen Excess + Ovulatory Dysfunction
- Androgen Excess + Polycystic Ovarian Morphology
- Ovulatory Dysfunction + Polycystic Ovarian Morphology
- Androgen Excess + Ovulatory Dysfunction + Polycystic Ovarian

Clinical presentation may be due to any of the symptoms, including oligomenorrhea, amenorrhea, infertility, hirsutism, metabolic disturbance often manifest as diabetes, or insulin resistance of the metabolic syndrome with obesity.

A common feature in patients with PCOS is anovulation, with disruption in the usual hypothalamic, pituitary, and ovarian interactions. The resulting menstrual disorders range from amenorrhea to abnormal heavy uterine bleeding. Women with PCOS have abnormal LH levels and patterns of pulsatile release, which result in overproduction of androgens by the thecal cells of the ovary. The obesity often associated with the syndrome decreases the levels of SHBG, increasing the circulating levels of testosterone and estrogen. Usual feedback mechanisms are disrupted by chronic stimulation of hormones, and the delicate balance needed to produce ovulation is upset. Ovulation may occur from time to time in women with PCOS, and contraception should be discussed.

In addition to the virilization associated with chronic anovulation and high levels of circulating androgens and estrogens, potential consequences of PCOS include infertility, an increased risk of endometrial cancer, and possibly breast cancer. Androgen excess increases abdominal fat deposition. This fat deposition aggravates insulin resistance and produces compensatory hyperinsulinism, further enhancing ovarian androgen secretion [11]. The insulin resistance, hyperinsulinemia, and hyperandrogenism associated with the syndrome increase the risk of diabetes and heart disease.

PCOS is a diagnosis of exclusion; other causes of amenorrhea, oligomenorrhea, or abnormal bleeding patters should be sought. A targeted history and exam should be done. Most often, menstrual dysfunction related to PCOS begins at menarche and is associated with clinical findings of hyperandrogenism and obesity. Although a characteristic elevation in the LH/FSH ratio similar to that seen at mid-cycle is common, most patients are diagnosed on a clinical basis. Laboratory testing is most helpful in excluding other diagnoses, including pregnancy, hyperprolactinemia, thyroid disorders, nonclassic congenital adrenal hyperplasia, Cushing's syndrome, premature ovarian failure, menopause, medication effects, and a virilizing adrenal or ovarian tumor.

Treatment of PCOS is aimed at achieving pregnancy if desired; preventing cancers; treating associated hirsutism, alopecia, or acne; and prevention of diabetes and coronary artery disease. Lifestyle modification with diet and exercise are cornerstones of treatment, especially for those with obesity. Weight reduction alone may lead to resumption of ovulation, pregnancy for those who desire it, and significant reduction in metabolic and cardiac consequences of PCOS. Metformin is the most widely used insulin-

Table 4 Differentiating primary from secondary dysmenorrhea

Historical points	Primary dysmenorrhea	Secondary dymenorrhea
Onset	Adolescence, within first few years of menarche	First one or two cycles after menarche for congenital outflow tract obstruction or after age 25
Menstrual flow	Normal	Heavy and/or irregular
Pain with intercourse	No	Yes
Infertility	No	Yes
History of Pelvic Inflammatory Disease	No	Maybe
Pelvic Exam	Normal	Abnormal: bulky uterus; nodular uterosacral ligaments; uterine, adnexal or cervical motion tenderness
Response to NSAIDs or OCPs	Good	Little or no response

sensitizing agent used to treat women with insulin resistance and PCOS. It decreases insulin levels and LH, with an increase in SHBG and lower circulating levels of androgens. As many as half of women with PCOS or anovulatory cycles resume regular menses after 6 months of treatment with metformin [12]. PCOS is the most common cause of anovulatory infertility. Ovulation induction alone or in combination with metformin can help achieve pregnancy. For those women who do not want to conceive, treatment is targeted at amelioration of symptoms of androgen excess and prevention of uninterrupted estrogen stimulation that can lead to endometrial cancer. Oral contraceptives help with both by interrupting the chronic estrogen stimulation, reducing the LH-mediated androgen production, and increasing SHBG. For those with contraindications to estrogen, endometrial protection can be achieved with cyclic oral progesterone, with a goal of a withdrawal bleed at least every 90 days. Progestin-only contraceptives including intrauterine devices, implants, and injections are an alternative for endometrial protection but are often associated with abnormal bleeding patterns [13]. Antiandrogens including spironolactone, flutamide, and finasteride are effective in treating hirsutism and alopecia but have not been shown to augment the effects of oral contraceptives [12]. Antiandrogens may need to be used for 6 months before noting improvement. Screening for diabetes and monitoring lipid profiles is recommended, especially in obese patients.

Dysmenorrhea

Dysmenorrhea is defined as cramping pain in the lower abdomen with menses. Dysmenorrhea is described as primary when there is no discernible pelvic pathology or secondary due to pelvic pathology, most often endometriosis. Primary dysmenorrhea is a diagnosis of exclusion. A thorough history and physical examination will help determine if there is pelvic pathology. Table 4 lists elements helpful in differentiating primary from secondary dysmenorrhea.

Primary Dysmenorrhea

Primary dysmenorrhea is the most common menstrual disorder. Pain usually presents in sharp and intermittent spasms, centered in the suprapubic area. Pain may radiate to the back of the legs or the low back. Systemic symptoms of nausea, vomiting, diarrhea, fatigue, fever, headache, or light-headedness are fairly common. Pain usually begins within hours of the onset of menses and peaks within the first 1–2 days. Most symptoms can be explained by the action of uterine prostaglandins, particularly PGF2. This prostaglandin is released as the endometrium sloughs, causing uterine contractions.

Secondary Dysmenorrhea

The onset of secondary dysmenorrhea is generally later in life than primary, often the mid-twenties. The pelvic pathology may be uterine or extrauterine. Uterine causes of secondary dysmenorrhea are

DOI 10.1007/978-1-4939-0779-3_110-1

adenomyosis, pelvic inflammatory disease, cervical stenosis, polyps, fibroids, and intrauterine devices. Extrauterine causes are endometriosis; inflammation and scarring due to adhesions; functional ovarian cysts; benign or malignant tumors of the ovary, bowel, or bladder; and inflammatory bowel disease. Some of these disorders can be diagnosed with a careful pelvic exam. Imaging with transvaginal ultrasound, MRI, or direct visualization with laparoscopy is often needed to make a certain diagnosis in secondary dysmenorrhea. Additional testing may be needed to evaluate for pelvic inflammatory disease or inflammatory bowel disorders.

Treatment of Dysmenorrhea A Cochrane review of 73 randomized controlled trials demonstrated strong evidence in support of the use of nonsteroidal anti-inflammatory drugs (NSAIDs) as first-line treatment of primary dysmenorrhea [14]. No specific NSAID has been proven more effective than others, and all are most effective when begun 1–2 days prior to anticipated menses and continued for several days. For those unresponsive to NSAIDs or who desire contraception, hormonal contraceptives including estrogen and progesterone combinations as well as progestin-only preparations are the next treatment options. These are delivered orally, intravaginally, topically, via intrauterine systems, or via subcutaneous or intramuscular depots.

Menopause

Sara M. Pope*, Steven Elek IV, Timothy Wilcox and Janelle K. Riley
Puget Sound Family Medicine Residency, Naval Hospital Bremerton, WA, Bremerton, WA, USA

Overview

Menopause is a natural occurrence that marks the end of woman's reproductive years. In layman's terms, menopause is often described as an absence of "periods." However, the process is most accurately defined as the permanent cessation of menses. Clinical menopause is recognized after 12 months of amenorrhea [1]. The normal transition period that occurs prior to menopause is known as perimenopause. This transition begins approximately 4 years prior to menopause and is a result of progressive decline in ovarian function. This transition leads to menstrual cycle disruption, with waxing and waning of ovarian function. During perimenopause and menopause, women will experience many symptoms that include hot flashes, vaginal dryness, as well as mood and sleep disturbances [2]. There are several treatment options, both hormonal and nonhormonal, to combat these unwanted menopausal symptoms.

The Female Reproductive Life Span and the Menopausal Transition

During fetal life, the ovary goes through a series of embryological changes that result in the development of a primordial follicle, which is described as an ovum surrounded by granulosa cells. At the time of birth, a female infant will have approximately two million primordial follicles [3–5]. By puberty, 400,000 primordial follicles remain. Throughout a woman's reproductive life, only 400–500 of the primordial follicles grow into mature follicles and ovulate. By menopause, few, if any, primordial follicles remain [4]. As the number of primordial follicles approaches zero, the production of estrogen decreases. When production of estrogen falls below a critical value, there is no longer feedback inhibition on the production of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) [6, 7]. Eventually, estrogen production by the ovaries falls to zero and can no longer inhibit the production of FSH and LH. Instead, these gonadotropins are produced in large and continuous quantities. These hormonal changes ultimately lead to cessation of menses [8, 9].

The hallmark of the menopausal transition (Table 1) is the change in the menstrual cycles, ultimately leading to cessation of periods. While many women progress through this transition without seeking medical care, a substantial number will have questions about the changes they experience. Women may consult their family physician for advice or reassurance during this time of transition in their health.

Specifically, women may desire to know "what to expect" with regard to the timeline of menopause and their menstrual cycles. Such questions can be challenging for the family physician to address, since the menopausal transition is seemingly characterized by irregularity. Predicting when menopause may occur has historically been difficult; however, in recent years there has been much interest in research directed toward better understanding and anticipating the menopausal transition.

The Stages of Reproductive Aging Workshop (STRAW) originally met in 2001 [10] to discuss the existing data on the menopausal transition. Since chronological age correlates poorly with menopausal changes, the goal of the workshop was to produce a staging system, analogous to the Tanner system for puberty, which could be used to objectively classify a woman's status in the menopausal transition. The

Table 1 Stages of menopausal transition

Early perimenopause	Irregular menstrual cycles Ovulation may fail to occur
Late perimenopause	>60 days between menstrual cycles Skipped menstrual cycles Anovulatory cycles Episodes of amenorrhea Occurs within 1–3 years of FMP VMS may begin
Final menstrual period	Defined retrospectively Final period before 12 months of amenorrhea
Menopause	Cessation of menses for 12 months
Early postmenopause	2 years following the FMP VMS most likely to occur
Late postmenopause	5–8 years after the FMP Increased CV risk Altered bone metabolism Increasing symptoms of urogenital atrophy

FMP final menstrual period, *VMS* vasomotor symptoms

resulting STRAW criteria have been well received and have guided further research in the field. The system was reviewed and updated in 2011 to reflect findings in the subsequent decade [9]. The updated staging system serves as the basis for the following discussion.

Stages of the Menopausal Transition

Late Reproductive Years

Even prior to entering the menopausal transition, women may notice changes in the flow or duration of their menses (e.g. "lighter" menses). Declining ovarian function results in decreased fertility. With a decrease in the number of developing follicles, there is a rise in FSH concentration. This is thought to be the result of decreased feedback inhibition of FSH and LH. Studies [12, 13] suggest that inhibin B secreted by the developing follicles plays an important role, leading to high but variable levels of FSH resulting in changes of bleeding patterns.

Early Menopause Transition

Change in the intermenstrual interval signals the beginning of the perimenopausal period. This change in bleeding patterns is the first symptom noticed by most women. The STRAW + 10 staging system [9] objectively defines this stage as recurrent differences of ≥ 7 days in the length of consecutive cycles. For example, a woman experiences a cycle of 25 days followed by a cycle of 33 days. To meet the criteria, a similar discrepancy between consecutive cycle lengths should recur within 10 cycles [9].

Of course, many women will not present with such detailed records of their periods. The overall concept of cycle length irregularity, however, should be clinically discernible in most instances. The clinical significance of this stage is primarily that it allows physician and patient to be reasonably confident that the menopausal transition has begun. The length of this stage is quite variable.

In late perimenopause, estrogen production falls below a critical level when the number of primordial follicles approaches zero. Women begin to have skipped cycles, episodes of amenorrhea, and an

DOI 10.1007/978-1-4939-0779-3_111-1

increasing frequency of anovulatory cycles. These irregular cycles are the result of dramatic variations in estradiol concentrations.

Late Menopausal Transition

When a woman experiences a gap of greater than 60 days between cycles, she can be said to have entered the "late" phase of menopausal transition. This objective landmark is typically easy to discern in the clinical setting and signifies that a woman is likely within 1–3 years of her final menstrual period (FMP). This stage has additional clinical significance, as the time when many women will begin having menopausal symptoms such as hot flashes.

Final Menstrual Period and Early Postmenopause

The landmark of the FMP is identified in retrospect, when a woman has been amenorrheic for 12 months. The 2 years that follow the FMP are considered the early postmenopausal period and are notable for a high prevalence of vasomotor symptoms.

Late Postmenopause

Late postmenopause describes the phase where menopausal hormone changes have fully stabilized, approximately 5–8 years after the final menstrual period. At this point, many of the symptoms of the menopausal transition will have subsided, but the physiologic implications of the postmenopausal state persist, such as increased cardiovascular risk, altered bone metabolism, and urogenital atrophy.

Laboratory Testing

Discerning a woman's status in the menopausal transition should be thought of as a clinical process guided by the menstrual cycle history. Although research efforts are beginning to better characterize the status of several markers (i.e., follicle-stimulating hormone, estradiol, anti-Mullerian hormone) in the various stages of menopause, lab testing is not required for most women entering menopause at an appropriate age. The North American Menopause Society discourages the routine assessment of hormone levels [14].

Epidemiology

The average onset of menopause is 51 years of age. However, there is considerable variation among women. Approximately 5 % of women undergo menopause after age 55, while in another 5 %, onset will occur between 40 and 45 [7, 15]. This variation is thought to be due to a number of factors. Women with family members with early menopause are more likely to also experience early menopause [16]. Menopause occurs earlier in women of Hispanic or Japanese decent when compared to Caucasian women [17]. Lastly, smoking causes menopause to occur earlier [18–20].

Systemic Effects of Menopause

Menopause reflects a time of significant change for women. All of the effects discussed below can have a substantial biopsychosocial impact, and they represent opportunities for the family physician to improve the quality of life in women. The sequelae of menopause are widely underreported, and intentional screening should be considered part of high-quality care for perimenopausal and postmenopausal women.

DOI 10.1007/978-1-4939-0779-3_111-1

Vasomotor Symptoms

One of the most common and well-known effects of menopause is the hot flash. Classically, these are "sudden episodes of intense heat that usually begin in the face or chest and spread throughout the body, accompanied by sweating and flushing that typically last 1–5 min" [21]. Physiologically, the symptoms largely result from peripheral vasodilation and inappropriate activation of heat loss mechanisms. Therefore, chills may follow the hot flash, as core body temperature is lowered [22]. Peri- and postmenopausal women are apparently predisposed to these reactions due to a narrowing of the thermoregulatory set zone in the hypothalamus [23]. This has been hypothesized as being related to the hormonal changes of menopause, but the exact mechanism remains unclear.

While estimates vary, a definite majority of women (up to 80 %) will experience vasomotor symptoms (VMS) as they pass through menopause [9, 24]. Data on the duration of VMS suggest that the average length of symptoms is 4–5 years, but a subset of women will continue to have troublesome symptoms for 10 years or more [25, 26]. It is important for the family physician to realize that both the experience and reporting of VMS will vary greatly between individuals. On a larger scale, culture and ethnicity have a substantial effect on how women perceive their menopausal symptoms. Thus, the family physician should make treatment recommendations on an individualized basis, taking the patient's unique experience into account.

Women who seek professional advice for their VMS should be counseled on lifestyle interventions and non-pharmacologic measures that may reduce their symptoms. These include smoking cessation, weight loss, stress reduction, lowering ambient room temperatures, and clothing choices [14, 21]. While supportive evidence for these interventions is limited, most are practical or bring other associated health benefits. The most effective treatment for VMS is hormonal replacement therapy. Other nonhormonal treatments that may reduce symptoms include paroxetine, venlafaxine, clonidine, and gabapentin [21]. Currently, no over-the-counter agents have been shown to have clear benefit in reducing VMS [14, 27].

Sleep Disturbances

Perhaps one of the most challenging effects of menopause for the family physician to manage is sleep disturbances. In one large study, 38 % percent of peri- and postmenopausal women reported sleep difficulty [28]. The menopausal transition has been shown in multiple studies to be strongly associated with sharp increases in the incidence of sleep disturbance and insomnia. However, there are numerous potential causes for sleep disruption in peri- and postmenopausal women, and in any given patient, a number of factors may be at play.

Vasomotor symptoms are a leading and clinically obvious cause for sleep disruption in perimenopause. However, even perimenopausal women without vasomotor symptoms have an increased prevalence of poor sleep [28]. Primary sleep disorders such as obstructive sleep apnea, restless leg syndrome, and periodic limb movement disorder all present with increased frequency in menopausal women [29]. Depression, anxiety, and other mood disorders may act as primary or secondary causes of insomnia. The overall health status of the woman must be taken into consideration, as a large number of worsening general medical conditions can contribute to poor sleep. Medications should be reviewed, and sources of chronic and acute pain should be actively managed. Lastly, the available evidence suggests that the hormonal changes of menopause alone contribute to decreased quality of sleep [29].

In summary, the approach to sleep disturbance in perimenopause must be highly individualized and involve careful attention to the patient's specific complaints. As in all age groups, standard sleep hygiene education should be provided. The patient's unique risk factors for sleep disturbance should be addressed. Lastly, hormonal replacement therapy may be considered for sleep disturbances, particularly in women

DOI 10.1007/978-1-4939-0779-3_111-1

who have other menopausal symptoms. The majority of studies that have assessed the effect of HRT on sleep have reported some degree of improved sleep over placebo [29].

Urogenital Changes

Essentially all of the tissues of the lower genitourinary tract in females feature estrogen receptors, including the bladder, urethra, and pelvic floor musculature [22]. With the withdrawal of estrogen during menopause, these structures undergo a number of physiologic changes that can be clinically problematic for women. Previously known as vulvovaginal atrophy, this constellation of findings is now referred to as the *genitourinary syndrome of menopause* (GSM), in order to reflect the broad nature of effects that may be related to this transition.

It is thought that nearly half of women will experience genitourinary symptoms related to menopause [30]. Some women will begin to experience symptoms in the perimenopausal time frame, but prevalence increases steadily in the postmenopausal period [31]. The most commonly reported GSM symptoms are vaginal dryness and dyspareunia. Women may experience dryness, irritation, and pain regardless of whether they are sexually active. Those who are sexually active may experience painful intercourse due to lack of lubrication and decreased elasticity of vaginal tissues. Loss of interest in or avoidance of sexual intercourse commonly results. Urinary tract changes, such as urinary frequency, dysuria, and increased susceptibility to UTIs are thought to be at least partially attributable to the hormonal changes of menopause [32].

The clinical approach includes screening for vaginal symptoms and dyspareunia, which women may be hesitant to voluntarily report. Objective findings on exam may include vaginal pallor and loss of rugae, as well as elevated vaginal pH (>5). It is important for the physician to consider and exclude other causes for the reported symptoms, such as vaginal infection, contact dermatitis, or lichen sclerosus [21, 32].

Once the diagnosis of GSM is established, women should be reassured of the possibility of treatment. Family physicians should bear in mind that the symptoms of vulvovaginal atrophy are unlikely to improve without intervention [21]. For women with vaginal symptoms, local estrogen therapy is effective and has very few contraindications. Risk of endometrial stimulation remains a theoretical risk, so the lowest effective dose should be used and any vaginal bleeding should be investigated [30]. Patients should be appropriately counseled on the unstudied safety profile of long-term use [21]. In women with additional menopausal symptoms, oral hormone replacement therapy (HRT) can be considered, as it is also effective for the symptoms of GSM.

Cognitive Changes

Many women perceive changes in their cognition during the menopausal transition. Memory loss or forgetfulness is one of the most common complaints, but women may also report a decreased ability to concentrate or multitask [14]. Studies investigating this phenomenon have validated some degree of correlation between subjective complaints and objective cognitive performance [33]. It is currently thought that minor declines can be attributable to the menopausal transition period but do not predict level of functioning later in life [14]. However, in a given patient, confounding factors may be in play. Subjective cognitive complaints are more common in the presence of mood symptoms and vasomotor symptoms.

Although a number of trials suggest modest cognitive benefit from HRT, conflicting evidence exists [34]. The North American Menopause Society does not recommend HRT for cognitive concerns or memory loss. Family physicians should focus efforts on optimizing other aspects of the patient's health by treating depression, reducing VMS, promoting sleep, encouraging physical activity, and avoiding medications that may affect cognition [14].

DOI 10.1007/978-1-4939-0779-3_111-1

Mood Changes

The menopausal transition leading up to the final menstrual period appears to be a time of increased risk for symptoms of depression and anxiety [35]. Interestingly, this risk is most prominent in women with a history of past depression, premenstrual disorder, or postpartum depression [36], suggesting vulnerability to affective disorders in times of hormonal fluctuation. Women with vasomotor symptoms are also at significant risk.

Although women may be more likely to present with non-affective complaints, family physicians should be alert to the possibility that depression and/or anxiety could be contributing to symptoms in the perimenopausal female. General symptoms of depression and anxiety should be carefully distinguished from actual mood disorders. The physician should assess the severity of the symptoms and their effect on functioning. Contributing biopsychosocial factors should be explored. Patients with mild depression or anxiety may benefit from cognitive behavioral therapy, whereas the addition of pharmacotherapy should be considered in patients with moderate to severe symptoms [14].

Skin and Hair Changes

The hormonal changes of menopause represent one of the several factors driving the process of skin aging in postmenopausal women. General systemic aging, along with variables such as sunlight exposure and smoking, plays significant roles as well. In general, postmenopausal women may notice thinning of the skin, increased skin laxity and wrinkles, and dryness of the skin [14, 37].

With regard to the hair, women may note hair loss or occasionally hirsutism. Both of these changes may potentially be related to a relative increase in androgens in comparison with estrogen in postmenopausal women. Common hair loss disorders include female pattern hair loss and telogen effluvium [14].

Interestingly, estrogen replacement therapy has been shown to improve various characteristics of both the skin and hair in postmenopausal women [14, 37]; however, treatment of skin or hair changes is not considered to be a primary indication for hormonal therapy.

Cardiovascular Disease

Menopause is a time of escalating cardiovascular (CV) risk in women. It is well known that premenopausal women have, on average, more favorable lipid profiles than men [22]. However, this advantage subsides at menopause, and cardiovascular disease (CVD) remains the number one cause of death in women [14, 22]. Specifically, LDL levels increase and HDL levels decrease as a result of the menopausal transition [22]. The effect of hormonal changes on female lipid profiles led to a large-scale investigation of HRT for reduction of CV risk, with the ultimate finding of inadequate benefit and unacceptable risk for routine use of HRT in CVD prevention.

Family physicians should be aware of the potential for abrupt changes in lipid profiles in the early postmenopausal period [14]. Aside from this, however, the prevention of cardiovascular disease in peri- and postmenopausal females does not differ substantially from other adult populations. Weight loss, exercise, and smoking cessation should be promoted. Blood pressure and cholesterol levels should be optimized. Diabetes mellitus should be screened for at appropriate intervals.

Osteopenia and Osteoporosis

The estrogen deficiency of menopause promotes osteoclast activation, leading to a state in which bone reabsorption exceeds bone formation [38]. Following menopause, risk of fracture grows exponentially with age, and lifetime incidence of osteoporotic fractures is thought to be as high as 40 % in Caucasian women [39].

In peri- or postmenopausal women, the evaluation begins with determining risk of fracture. Dual-energy x-ray absorptiometry (DEXA) objectively evaluates bone mineral density and is recommended for

DOI 10.1007/978-1-4939-0779-3_111-1

average-risk women at age 65. Earlier DEXA screening, however, should be considered in postmenopausal women thought to be at increased risk for osteoporosis [14]. Risk factors to consider include ethnicity (Caucasian and Asian women are at highest risk), low body weight, family history of osteoporosis and fractures, smoking, daily alcohol use, and use of high-risk medications such as systemic glucocorticoids. Some medical conditions can predispose to osteoporosis, such as rheumatoid arthritis or chronic kidney disease [39]. The patient's fall risk should be assessed, and women who have had a prior fragility fracture (fracture with fall from standing) are at particularly high risk for additional fractures. The Fracture Risk Assessment Tool (FRAX) developed by the World Health Organization incorporates many of the above risk factors and can be used to further guide clinical decisions.

Prevention efforts should include educating all women on the importance of adequate calcium and vitamin D intake and weight-bearing exercise. Supplemental calcium and vitamin D should be considered, as the average postmenopausal female receives approximately 500 mg less elemental calcium in her daily diet than recommended levels [39]. However, family physicians should be aware that a definitive fracture reduction benefit from supplementation has not yet been proven [40].

Osteoporosis is diagnosed by history of a fragility facture or by a bone mineral density (BMD) T-score < -2.5 at standard sites. In women with osteoporosis, as well as women with osteopenia and an elevated FRAX risk score, treatment should be considered [39]. Available options include bisphosphonates (Fosamax, Actonel, Reclast), selective estrogen receptor modulator (SERM) raloxifene (Evista), recombinant parathyroid hormone (Forteo), and calcitonin (Miacalcin). Estrogen replacement therapy has been shown to decrease fracture risk, but the benefit does not persist beyond discontinuation of therapy [39]. Estrogen replacement therapy is not currently FDA approved for treatment of osteoporosis.

Menopause Treatment

Overview

Most women manage the transition into menopause independently with approximately 10 % of women seeking medical care. Symptoms of vaginal dryness, hot flashes, night sweats, and sleep disturbance most commonly prompt women to present to physicians [41]. Hormone therapy (HT) has been the mainstay treatment of menopausal symptoms for over 60 years. While HT is effective treatment for menopausal symptoms, some women may have underlying diseases that preclude use of hormones or wish to avoid risks associated with HT. Thus, there is expanding literature to explore alternative nonhormonal therapies.

Hormone Therapy

Hormone therapy may include estrogen therapy alone (ET) or combined estrogen-progesterone therapy (EPT). Estrogen in combination with progesterone or alone is the most effective treatment of menopause-related vasomotor symptoms. Progesterone alone also reduces vasomotor symptoms but not as effectively as estrogen [42].

Indications

Appropriate indications for HT include vasomotor symptoms such as hot flashes, night sweats, and vaginal dryness. Topical hormone therapy may be sufficient for vaginal symptoms without systemic vasomotor symptoms. Up until the 1990s, HT was thought to be potentially beneficial, not only for treatment of menopausal symptoms but also for prevention of chronic diseases. Until the publication of the Women's Health Initiative (WHI) in 2002 [43, 44], HT was widely prescribed for the prevention of cardiovascular disease, dementia, and osteoporosis. The Women's Health Initiative, in contrast to

DOI 10.1007/978-1-4939-0779-3_111-1

previously believed benefit, showed significant risks associated with HT use and even possible worsening of coronary vascular disease (CVD) that it was being prescribed to prevent. In fact, risk for fracture was the only outcome with strong evidence of benefit from HT. This benefit occurred only after 4–5 years of therapy. Although it is not approved by the FDA for the treatment of osteoporosis, it is generally recommended that HT for the prevention of fracture be reserved for high-risk women in whom other therapies are contraindicated [45]. Overall, the physician's decision to offer treatment of vasomotor symptoms may depend on a woman's perception of the severity of symptoms [41].

Effectiveness of Hormone Therapy

Hormone therapy has been consistently shown to be effective at decreasing vasomotor symptoms. Meta-analysis of randomized controlled trials shows incidence of hot flashes with HT reduced by 75 % compared to 50 % reduction with placebo [41]. Stated another way, estrogen has been shown to reduce the frequency of hot flashes by approximately 2.5–3 hot flashes per day [44]. In addition to decreased risk of fractures, HT may offer a small to moderate improvement in sexual function [45]. Improvement in sexual function seems to occur via treatment of menopausal symptoms. Treating other aspects of sexual function with HT is not supported by evidence [46]. Improvements in vasomotor symptoms and vaginal dryness can take, on average, 1–2 months after starting therapy [41].

Formulations

Hormone therapy is available in oral tablets, transdermal patches, and topical or intravaginal preparations. Most women start at a low dose of oral conjugated equine estrogen (Premarin) 0.3 mg or 0.5–1.0 mg of oral or transdermal 17-beta-estradiol (Estrace, Climara, Alora) or intravaginal estradiol valerate (Delestrogen). Dosage can be increased to 1.25 mg daily of conjugated equine estrogens if symptoms are not relieved. Estrogen alone can be used in women without a uterus. However, unopposed estrogen in women with a uterus increases the risk of endometrial hyperplasia [47]. Progesterone, however should be added to estrogen in any woman with a uterus [45]. There is minimal systemic absorption of topical agents, so topical estrogen formulations are safe to use in women with a uterus without the addition of progesterone. Progesterone formulations with a minimum of 1 mg norethindrone (Ortho Micronor, Nor-QD) or 1.5 mg medroxyprogesterone acetate have been shown to be safe as the risk of endometrial hyperplasia has not been found to be significantly different than with placebo. Pre-packaged products simplify the use but may not be available in low doses. Low doses of progesterone can be obtained from progesterone-only pills such as Norethisterone. Continuous regimens of combined estrogen plus progesterone (Prempro) daily can be used in women with a uterus who have been postmenopausal for more than 1 year. Within 1 year of the last menstruation, regimens of daily estrogen with progesterone 10–14 days per month are indicated. For those women who are still menstruating, estrogen should be started on the first day of the menstrual bleeding with progesterone given 14 days later, resulting in withdrawal bleeding around the same time menstruation would be expected [41].

Risks of Hormone Therapy

Known side effects of HT include nausea, breast tenderness, and irregular bleeding, especially early in menopause, as ovarian estrogen production fluctuates [41, 42].

The Women's Health Initiative [41, 43, 48] unveiled many previously unknown risks associated with HT. Studies demonstrated that both ET and EPT therapies increased risk for stroke, coronary vascular disease (CVD), venous thromboembolism (VTE), pulmonary embolus (PE), dementia, and gallbladder disease. Treatment with combined hormone therapy, but not with estrogen alone, increased the risk of breast cancer [45].

DOI 10.1007/978-1-4939-0779-3_111-1

Table 2 Risk of combined hormone therapy in postmenopausal women

Complication	Years of use	Absolute risk (AR)
Coronary event	After 1 year	4 per 1,000
Venous thromboembolism	After 1 year	7 per 1,000
Stroke	After 3 years	18 per 1,000
Breast cancer	After 5.6 years	23 per 1,000
Gallbladder disease	After 7 years	27 per 1,000
Death from lung cancer	After 5.6 years (plus 2.4 years of follow-up)	9 per 1,000
Dementia (>65 years, healthy)	After 4 years	18 per 1,000

Adapted from Marjoribanks et al. [45]

Table 3 Risk of estrogen-only hormone therapy in peri- and postmenopausal women

Complication	Years of use	Absolute risk (AR)
Coronary event	After 1 year	4 per 1,000
Venous thromboembolism	After 1–2 years After 7 years	5 per 1,000 21 per 1,000
Stroke	After 7 years	32 per 1,000
Gallbladder disease	After 7 years	45 per 1,000
Breast cancer	No significant increased risk	

Adapted from Marjoribanks et al. [45]

There are many ways to numerically represent the increased risk posed by ET and EPT. Perhaps the most useful in counseling patients is by using the absolute risk (AR) over a defined time period (see Tables 2 and 3).

When using this data to counsel women on the risks and benefits of HT, there are caveats and nuances to keep in mind. The majority of data was collected in women with a mean age >60 years with only smaller groups of women in the perimenopausal or younger age group (age 50–59). Among women with CV disease, long-term use of EPT increased the risk for VTE. Women taking long-term HT, either ET or EPT, had decreased incidence of fractures [45]. Subgroup analysis suggests that CVD was slightly reduced, rather than increased, in women who were closer to menopause at time of initiation. Additionally, combination HT initiated closer to menopause resulted in somewhat increased risk of breast cancer [49]. Overall, there are limitations with the currently published data, as studies to date have not been designed to specifically evaluate the effect of HT in perimenopausal or younger-aged women. Transdermal preparations may have a somewhat decreased risk of VTE, though further study is needed. Family physicians can expect the literature to continue to evolve in order to address specific factors such as age, proximity to menopause at the time of initiation, duration of HT therapy, and type of hormonal preparation.

Contraindications

Hormone therapy is contraindicated in women with a history of breast cancer, CVD, stroke, dementia, VTE, undiagnosed bleeding, or pregnancy.

Duration

Given the risks associated with HT, it is currently recommended to prescribe HT only in the lowest effective dose for the shortest possible time. Family physicians should regularly discuss with patients the

DOI 10.1007/978-1-4939-0779-3_111-1

ongoing need for continued therapy versus a trial off of therapy. Short-term use of systemic HT is also clinically appropriate as hot flashes disappear within a few years of menopause for two-thirds of women. Urogenital symptoms on the other hand are not self-limited, and frequently long-term therapy is needed, although topical therapy may be sufficient [41]. Women with severe symptoms will need to balance the risk and benefits through informed decision making with their physicians.

Monitoring

Regular review of continued need for HT by a woman and her physician is recommended. No specific interval is currently recommended, though every 3–6 months or at least annually seems appropriate.

Nonhormonal Therapy

Nonhormonal therapy may be an appropriate option for women with contraindications to hormonal therapy or those wishing to avoid risks associated with HT. A variety of treatment modalities have been investigated that include antidepressants, clonidine, gabapentin, plant derivatives, and exercise.

Antidepressants

Some selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) have been shown to reduce hot flashes, possibly due to the role serotonin plays in mediating hot flashes. Most of the data comes from lower doses of antidepressants (i.e., venlafaxine 37.5–75 mg or paroxetine 12.5–25 mg) for relative short durations (4–12 weeks). There has also been concern that the efficacy of antidepressants may be decreased in women with a history of breast cancer taking tamoxifen (Soltamox) [44]. This may be due to metabolism of both tamoxifen and some antidepressants through the cytochrome P-450 pathway [41]. Women with history of breast cancer taking tamoxifen are among the most likely to need nonhormonal therapy.

Paroxetine (Paxil): Studies [44] indicate on doses of paroxetine, 12–25 mg daily, women experienced fewer daily hot flashes than women taking placebo (3.2–3.3 versus 1.8 fewer episodes per day). A trial predominantly including women with breast cancer taking tamoxifen on 10–20 mg of paroxetine also had fewer daily hot flashes compared with placebo. Paroxetine was effective at both doses, but not surprisingly, women taking higher doses experienced more adverse effects.

Venlafaxine (Effexor): Additional investigations have shown that women taking venlafaxine at doses from 37.5 to 150 mg per day experienced decrease frequency of hot flashes (30–58 % versus 19 % compared to placebo). Effects were greater with higher doses, though most evidence is from doses of 37.5–75 mg daily. Women who used tamoxifen had similar results [44]. Most recently, a RCT with a head to head trial comparing venlafaxine to estradiol showed slight superiority of estradiol compared to venlafaxine 75 mg daily. In this study, where mean hot flashes in the study group were eight per day, venlafaxine resulted in reduction to 5.5 daily episodes compared to 4.4 in the estradiol group [50]. Additional studies [44] have been done with other antidepressants including fluoxetine (Prozac) and citalopram (Celexa) 30 mg daily with neither showing significant difference.

Clonidine (Catapres): Meta-analysis shows that clonidine in doses of 0.05–0.15 mg daily may reduce hot flashes compared to placebo. Increased effect was seen at 8 weeks compared to 4 weeks of treatment [44]. Transdermal clonidine at 0.1 mg appears more effective than oral clonidine [41].

Gabapentin (Neurontin): At doses of 900 mg per day, gabapentin has been shown to be effective at reducing hot flashes in women with breast cancer, including those taking tamoxifen. Smaller doses of 300 mg per day were not shown to be effective [44].

Plant and Natural Derivatives: Several naturally derived substances have been studied as an alternative for the treatment of menopause. Phytoestrogens are plant-derived products that have estrogenic activity. Soy isoflavones fit within this category and show some potential, although with slight

DOI 10.1007/978-1-4939-0779-3_111-1

Table 4 Systemic effects and treatment of menopausal symptoms

		Hormonal	Nonhormonal
Vasomotor symptoms (VMS)	Hot flash	ET, EPT (Oral, transdermal)	SSRIs: paroxetine (Paxil) SNRIs: venlafaxine (Effexor) Clonidine (Catapres) Gabapentin (Neurontin)
Sleep[a]	Insomnia Poor quality of sleep		Sleep hygiene Cognitive behavioral therapy (CBT) Exercise

Psychological	Memory loss Forgetfulness Poor concentration Depressive mood Anxiety		Treat depression, offer CBT Reduce VMS Promote sleep Exercise, physical activity Avoiding medications that affect cognition
Skin and hair	Thinning of skin Increased skin laxity, wrinkles Dry skin Hair loss Hirsutism		Reassurance
Cardiovascular	Increased LDL level Decreased HDL level		Weight loss Exercise Smoking cessation Optimize blood pressure, cholesterol level Screen for diabetes mellitus
Bone	Osteopenia Osteoporosis		Calcium, vitamin D Bisphosphonates Selective estrogen receptor modulators Recombinant parathyroid hormone Calcitonin

[a]Consider treating other primary causes: hot flashes, depression, restless leg syndrome, obstructive sleep apnea, or periodic limb movement disorder; *ET* estrogen therapy, *EPT* estrogen-progesterone therapy, *SSRIs* selective serotonin reuptake inhibitors, *SNRIs* serotonin-norepinephrine reuptake inhibitors

benefit. Meta-analysis of red clover isoflavones, specifically Promensil and Rimostil, also showed possible slight benefit [44, 51]. Black cohosh, an herbal remedy, has shown mixed results, with possible benefit over placebo in women who have breast cancer. Vitamin E has minimal benefit over placebo, resulting in one less hot flash daily. A number of other natural products including evening primrose oil, dong quai, and ginseng have shown no benefit [41].

Exercise: Current literature is mixed regarding the relationship between physical activity and hot flashes. Physical activity, as an acute trigger of hot flashes, has been anecdotally reported, but there has

DOI 10.1007/978-1-4939-0779-3_111-1

been little investigation. There are ongoing studies about the role of leisure activities versus non-leisure activities and sleep in menopausal women with vasomotor symptoms. Women with higher rates of non-leisure activity actually reported increased sleep [52]. Certainly for overall health, exercise remains a component of a healthy lifestyle, but given the current lack of evidence, it is difficult to make specific recommendations to women regarding the role of exercise for menopausal symptoms.

Acupuncture: Acupuncture has also been tried for combating menopause symptoms. According to a 2013 Cochrane Review, a meta-analysis of eight studies that included 1,115 women concluded there is insufficient evidence to support its use in vasomotor symptoms [53] Table 4.

Not all women will experience menopausal-related symptoms needing treatment; however, a substantial number will have questions about the changes they are experiencing and ways to maximize their health during the menopausal transition. Future evidence-based research will continue to help guide the family physician to successfully treat each woman in a holistic, individualized manner.

Tumors of the Female Reproductive Organs

Paul Gordon* and Genevieve Riebe
Family and Community Medicine, University of Arizona, College of Medicine, Tucson, AZ, USA

Leiomyoma

General Principles

Definition/Background

Leiomyoma or fibroids arise from monoclonal proliferation or numerous copies of the same or very few cells [1] and are stimulated by estrogen and progesterone. They increase their growth rate during pregnancy and regress after menopause. They vary widely in size from a few millimeters to large masses filling the entire abdomen.

Epidemiology

Leiomyoma is the most common benign neoplasm of the female reproductive tract. It is present in 20–30 % of women of reproductive age. However, since many leiomyomata are asymptomatic, the true incidence is unknown. African-American women have a threefold higher incidence than white, Hispanic, or Asian women [2]. In addition, obese and nulliparous women and those with early menarche or infertility have a higher incidence [3].

Classification

The easiest classification system is by anatomic location: (1) intramural, entirely within the walls of the uterus; (2) submucous, beneath the uterine lining; (3) subserous, which distorts the outer surface of the uterus; (4) intraligamentous; (5) parasitic (deriving its blood supply from another organ to which is has become attached; (6) pedunculated, attached to the uterus by a stalk; and (6) cervical.

Approach to the Patient

Risk factors have been identified which aid us in our approach to the patient. Fibroids are subject to hormonal stimuli. They arise with menarche and become inactive after menopause.

Diagnosis

History

Nonpregnant women with leiomyoma are often asymptomatic. The most common systems for which they seek treatment are abnormal bleeding and pelvic pain or pressure. If the myoma significantly distorts the uterine cavity, women may be infertile. Additionally, they may experience increased abdominal girth, urinary frequency, low back pain, and dyspareunia. There are also adverse pregnancy outcomes including malpresentation, dysfunctional labor, abnormal placentation, and abruption.

*Email: pgordon@medadmin.arizona.edu

DOI 10.1007/978-1-4939-0779-3_112-1

Physical Examination

The bimanual exam is the key physical exam procedure to identify a leiomyoma. A lobular, enlarged structure with a rubbery consistency may be found. Larger lesions can also be felt on abdominal exam.

Laboratory and Imaging

Anemia may be found as a result of abnormal uterine bleeding. Hydronephrosis may also be seen due to ureteral compression from the mass. Pelvic ultrasound remains the test of choice for diagnosis. Sonohysterogram or hysteroscopy can be used to confirm submucous leiomyomata.

Special Testing

MRI should be used sparingly due to its cost and the adequacy of other diagnostic imaging procedure. If there is an atypical lesion and concern for sarcoma is present, MRI would be appropriate. Endometrial biopsy can be performed if there is concern for endometrial cancer (see next section).

Differential Diagnosis

The most important diagnosis to be considered in the differential is leiomyosarcoma. It is rare but aggressive. However, of those rapidly growing leiomyomata (6 cm in 1 year), less than 0.1 % of these are malignant. At surgery for women with a leiomyoma, less than 0.25 % have sarcoma. Other diagnoses include solid ovarian tumors or uterine enlargement due to adenomyosis [1].

Treatment

Behavioral

Women with asymptomatic fibroids require no treatment.

Medications/Immunizations and Chemoprophylaxis

Women with abnormal uterine bleeding will often benefit from a trial of cyclic or continuous oral contraceptives or progestins. Prior to surgery, gonadotropin-releasing hormone (GnRH) agonists can decrease size and stop the bleeding. Long-term use of GnRH agonists has side effects such as osteoporosis. Mifepristone, an antiprogestin, may cause significant decrease in myoma size but may cause endometrial hyperplasia.

Referrals

For women whose symptoms continue despite treatment with medications, there are several surgical options. However, there are no well-conducted trials with US women comparing expectant management and various surgical procedures [1]. For women who wish to retain their fertility, myomectomy is generally offered. This procedure consists of removing the leiomyoma and then repairing the defect in the uterine wall. Myomectomy can be performed via laparotomy, laparoscopy, or hysteroscopy depending on the size, location, and number of lesions. For women wishing to preserve their fertility and not wanting surgery, uterine artery embolization can be used. This procedure using angiography decreases blood flow to the uterus. This procedure has high (80–90 %) success rates in decreasing blood flow and size and improving pelvic pressure. Finally, hysterectomy may be offered as a definitive procedure. An Agency for Healthcare Research and Quality (AHRQ) report concludes: “The current state of the literature does not permit definitive conclusions about benefit, harm, or relative costs to help guide women’s choices” [1].

DOI 10.1007/978-1-4939-0779-3_112-1

Table 1 Classification of endometrial cancer

Type I	Type II	Familial
Low grade	High grade	Lynch
Minimal myometrial invasion	Deep myometrial invasion	
Arising in a background of hyperplasia	Serous or clear cell	
Perimenopausal		
Estrogen related		
Younger age		
Obesity		

Counseling
Fibroid tumors can be present in women with recurrent implantation failure, and appropriate counseling regarding their treatment would fall on the family physician [4]. Additionally, there are multiple factors related to successful hysteroscopic endometrial ablation including fibroids that could improve patient counseling.

Prevention
As mentioned above, nulliparity increases the risk of fibroids. Similarly, pregnancy is associated with a reduced risk of fibroids. Mifepristone, an antiprogestin, has been shown to decrease the size of leiomyomata by 50 % [5]. Three WNT/beta-catenin pathway inhibitors, inhibitor of beta-catenin and TCF4 (ICAT), niclosamide, and XAV939, have been shown to block leiomyoma growth and proliferation [6]. Finally, a number of substances have been effective in the chemoprevention of fibroid tumors in quails [7, 8].

Endometrial Carcinoma

General Principles

Definition/Background
Endometrial cancer is the most common gynecologic malignancy and the fourth most common cancer in women after breast, lung, and colorectal cancers [9]. In the last 8 years, both the incidence and death rate from endometrial cancer have increased [9]. Various theories to explain this increase included increasing life span and coexisting medical comorbidities in these women.

Epidemiology
The mean age at diagnosis is 61 years, and 90 % of cases occur in women older than 50 years. Twenty percent of women have this diagnosis before menopause, and approximately 5 % have disease before age 40 [10]. Approximately 72 % are stage I, 12 % are stage II, 13 % are stage III, and 3 % are stage IV.

Classification
Endometrial cancer is commonly classified into three types (Table 1: Classification of Endometrial Cancer). The majority of women have type I. With type I, a genetic predisposition to obesity can increase one's risk of endometrial cancer. Type II occurs more commonly in older women, is more common in black women, and consists of higher-grade tumors. Genetic disease can represent up to 10 % of cases, of which 5 % are associated with Lynch syndrome, the hereditary nonpolyposis colorectal cancer syndrome.

DOI 10.1007/978-1-4939-0779-3_112-1

Approach to the Patient

Risk factors have been identified, and these should be addressed including the possibility of a hereditary component. These risk factors, which will be discussed below, include obesity and reproductive and menstrual factors.

Diagnosis

History

Abnormal uterine bleeding including postmenopausal, menorrhagia, or metrorrhagia is the most common presenting symptom for women with endometrial hyperplasia or carcinoma. Atypical glandular cells on cervical cytology should also be evaluated with colposcopy, endocervical curettage, and endometrial biopsy in women older than 35 or those with risk factors for endometrial cancer [11]. Nearly 70 % of women with early-stage endometrial cancer are obese. Moreover, the relative risk for death for women with endometrial cancer increases with increasing BMI [12]. Continuous estrogen stimulation, both endogenous and exogenous, can alter the menstrual cycle resulting in anovulation. Anovulation results in continuous unopposed estrogen stimulation since there is no corpus luteum to produce progesterone. Obesity, through the peripheral conversion of androstenedione into estrone, results in increased endogenous estrogen and increases in the relative risk (RR) of endometrial cancer up to three times [13]. Estrogen-producing tumors, cirrhosis, unopposed estrogen therapy, and tamoxifen can also result in increased estrogen stimulation in the uterus. Although tamoxifen is an antiestrogen in breast tissue, it can have estrogenic activity in the endometrium [14]. Unopposed estrogen replacement during menopause increases the RR four to eight times, whereas combined estrogen and progesterone replacement therapy decreases the risk of endometrial cancer. Similarly, progestin-containing oral contraceptives or combined oral contraceptive pill decreases the risk of disease by nearly one-half. This increased risk associated with estrogen therapy continues until 2 or 3 years after cessation of therapy [15]. Nulliparity and diabetes are associated with a two- to threefold increase incidence of disease. Nulliparity is related to infertility rather than intentional prevention of pregnancy. Infertility is related to anovulation as discussed above as opposed to tubal factors. Although the incidence in white women is higher than in black women, stage for stage, black women have a less favorable prognosis. Regarding type II disease, these patients account for 10 % of cases, are not related to estrogen excess, tend to occur at an older age, and are poorly differentiated with serous or clear cell histology.

Physical Examination

In women with abnormal uterine bleeding and risk factors as mentioned above, concern for endometrial cancer must be pursued. Although a physical examination including bimanual may be important, the diagnosis is made based on histology. Endometrial biopsy is an office-based procedure for the family physician [16].

Laboratory and Imaging

There are multiple modalities available to evaluate the endometrium. However, there is no recent ACOG Practice Bulletin to guide the clinician in choosing the modality. Endometrial biopsy (EMB) (with a piston catheter) is a simple procedure with good accuracy [17]. There have been a few retrospective studies comparing its accuracy to dilation and curettage (D&C) [18]. Although D&C was slightly better, D&C requires a visit to the operating room and anesthesia, whereas office EMB does not. Goldstein and colleagues who "were among the first Americans to publish on the high negative predictive value of thin distinct endometrial echo in postmenopausal patients with bleeding [19]" recommend beginning the evaluation with endovaginal ultrasound (EV-US). If the endometrial stripe is </4 mm in postmenopausal

DOI 10.1007/978-1-4939-0779-3_112-1

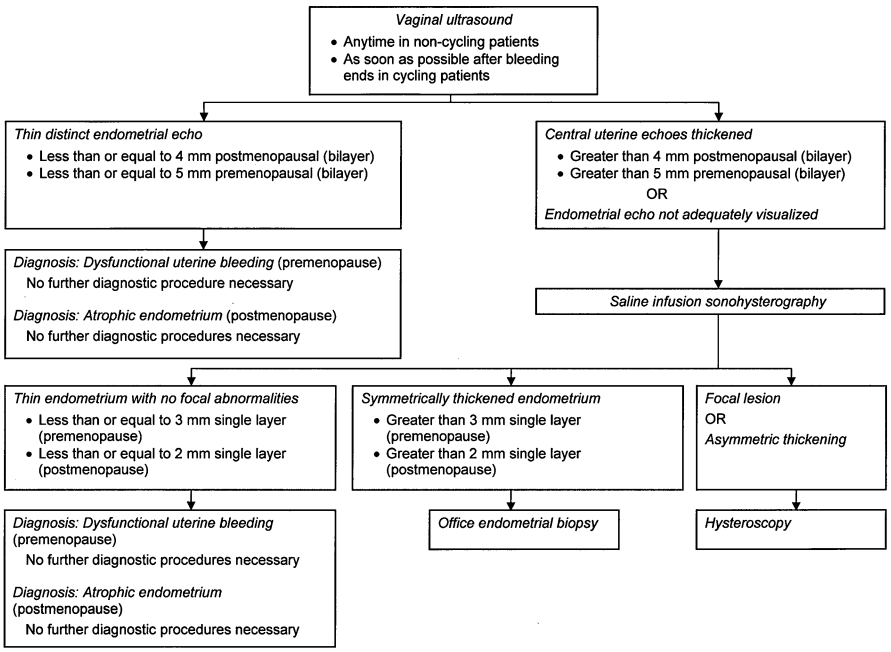

Fig. 1 Ultrasonography-based triage for patients with abnormal uterine bleeding (Originally published in Obstetrics & Gynecology 2010 [20], published with kind permission of Wolters Kluwer Health. All rights reserved)

women or </5 mm in premenopausal women, no further diagnostic procedure is necessary (Fig. 1-Goldstein [20]). Sweet et al. recommend EMB for women <35 years with recurrent anovulation and/or other risks for endometrial cancer. These risks include obese adolescents with 3 years of untreated anovulatory bleeding; women <35 years with chronic anovulation, diabetes, family history of colon cancer, infertility, nulliparity, obesity, or tamoxifen use; or women whose bleeding did not respond to medical therapy [21]. All women >/35 years with suspected anovulatory bleeding should have an EMB performed.

Special Testing

As noted above, Goldstein includes saline infusion sonohysterography in the workup. The benefit of adding hysteroscopy to sonography and biopsy is unclear. A retrospective chart review of more than 400 hysteroscopy/D&C procedures demonstrated that hysteroscopy correctly identified 52 % of patients with hyperplasia and 20 % of those with carcinoma. A negative hysteroscopic impression was not sufficient to exclude the diagnosis of hyperplasia or carcinoma [22].

Differential Diagnosis

The differential diagnosis for abnormal uterine bleeding includes both malignancy as discussed above and benign causes. An ACOG Practice Bulletin [23] reviews benign causes, as does Chapter "► Diseases of the Prostate" in this text. The results of EMB show simple and complex hyperplasia both with and without atypia. The Gynecologic Oncology Group sought to validate the reproducibility of the referring institution's pathologic diagnosis of complex hyperplasia with atypia. They found the level of reproducibility to be poor [24]. Current recommendations are that women with both simple and complex hyperplasia without atypia and those with simple hyperplasia with atypia can be treated with progestins as the risk for endometrial carcinoma is low [13]. Cyclic medroxyprogesterone 10 mg daily for 14 days each month and continuous megestrol acetate 20–40 mg daily are both acceptable as is the placement of a progestin-releasing IUD. However, women with complex hyperplasia with atypia have >40 % incidence of

DOI 10.1007/978-1-4939-0779-3_112-1

coexisting adenocarcinoma, and hysterectomy is the treatment of choice for these women. Alternatively, endometrial intraepithelial neoplasia is a new classification system designed to replace the hyperplasia terminology [25]. If this terminology were to be widely adopted by the pathology community, then this diagnosis may be more useful for clinical decisions than the current hyperplasia classification system.

Treatment

Behavioral

The most important behavioral intervention related to the prevention of endometrial cancer is weight loss, reviewed elsewhere in this text.

Medications/Immunizations and Chemoprophylaxis

As noted above, women with both simple and complex hyperplasia without atypia and those with simple hyperplasia with atypia can be treated with progestins. Cyclic medroxyprogesterone 10 mg daily for 14 days each month and continuous megestrol acetate 20–40 mg daily are both acceptable as is the placement of a progestin-releasing IUD. These women should have a repeat EMB in 3–6 months and referral to a gynecologist if the hyperplasia persists.

Referrals

All women with complex hyperplasia with atypia and those with adenocarcinoma need referral to a gynecologist or gynecologic oncologist, respectively.

Cervical Cancer

General Principles

Definition/Background

Invasive cervical cancer is the third most common gynecologic cancer among women in the United States [9]. There are two histological types of cervical cancer, adenocarcinoma and squamous cell carcinoma. The human papilloma virus (HPV) is detected in 99.7 % of all cervical cancer [26]. Epidemiology, risk factors, diagnosis, screening, prevention, and treatment will be reviewed here.

Epidemiology

Worldwide, cervical cancer is the second most common malignancy [27]. It is estimated that there will be 12,360 new cases of cervical cancer and 4,020 cervical cancer-related deaths in the United States in 2014. Cervical cancer estimates are higher for particular racial and ethnic groups with incidence and mortality being higher in non-white than white women in the United States [28]. The incidence is highest in Hispanics/Latinos at 12.5 per 100,000 and mortality highest in African-Americans with 4.4 deaths per 100,000 cases. There has been an overall decrease of deaths by 30.66 % from 1990 to 2007 [29] and a 50 % reduction in incidence over 30 years from 1975 to 2006 [30].

Risk Factors

Epidemiological risk factors for cervical cancer are well documented. Some are modifiable and speak to the importance of patient education and awareness for increased risk. Human papilloma virus (HPV) infection is a well-established risk factor for cervical cancer. Most risk factors are linked with the increased risk of acquiring HPV including early onset of sexual activity, multiple sexual partners, history

DOI 10.1007/978-1-4939-0779-3_112-1

Table 2 Risk factors for cervical cancer [34]

Risk factor	Relative risk
Menarche to first coitus < 1 year	26.4
Age at first coitus < 16 years	16.1
More than 3 sexual partners before age 20	10.2
Never having a Pap smear	8.0
Cigarette smoking > 20 years	4.0
History of genital warts	2

of sexually transmitted infections, sexual partner (s) infected with HPV, history of vulvar or vaginal intraepithelial neoplasia or cancer, and immunosuppression [31]. In utero diethylstilbestrol (DES), previous treatment of high-grade precancerous lesions, and history of cervical cancer are also risk factors [32]. Socioeconomic status, three or more full term births, young age at first delivery (<20 years of age), and oral contraceptive use may also increase risk. Smoking is associated with an increased risk of squamous cell carcinoma. Other high-risk groups include refugees and women who have immigrated to the United States from countries where cervical cancer screening is not routinely performed and women without access to health care [33] (Table 2).

Classification

Cervical cancer is classified as squamous cell carcinoma, adenocarcinoma, adenosquamous or mixed carcinomas, and small cell carcinoma. Squamous cell carcinoma accounts for approximately 90 % of cervical cancers, adenocarcinoma comprises the other 10 % with adenosquamous, and small cell carcinomas are rare.

Diagnosis

As described in Moore's approach to cancer management, there are four steps involved: (1) Establish the diagnosis, (2) define the extent of disease, (3) determine and implement treatment, and (4) follow the patient for evidence of recurrence and/or treatment-related complications [27].

History

Early cervical cancer may be asymptomatic. Common symptoms of cervical cancer include irregular vaginal bleeding, heavy vaginal bleeding, and postcoital bleeding [31]. Vaginal discharge may also be described and can be purulent, malodorous, bloody, watery, or mucinous [35]. Taking a careful history and proper diagnostic testing must be performed as to not mistaken these symptoms for cervicitis or vaginitis. Advanced cervical cancer may lead to lower back or pelvic pain and bowel and urinary symptoms. Advanced disease that has invaded nearby structures may lead to vaginal passage of urine or stool, hematuria, or hematochezia. Advanced disease may also present with deep venous thrombosis, ureteral obstruction, and lower leg edema from invasive spread [31].

Physical Examination

When a woman presents with a history and symptoms concerning for cervical cancer, a physical exam should be performed. A pelvic examination including a speculum exam for direct visualization of the cervix is paramount. Palpation of the groin and supraclavicular lymph nodes is part of a complete exam. Visualization of the cervix may demonstrate a normal appearing cervix, visible cervical lesion, or large tumor(s). All lesions that are friable and raised or appear to be condyloma should be biopsied. Staging examinations also include a pelvic examination with the addition of a rectovaginal exam and calculation of tumor size and parametrial and vaginal involvement.

DOI 10.1007/978-1-4939-0779-3_112-1

Laboratory and Imaging

Cervical cytology should be performed for all women when cervical cancer is suspected. HPV co-testing is done in screening but is not used for the diagnosis of cervical cancer when a woman presents with symptoms or has a visible lesion. In the initial evaluation of women with suspected cervical cancer, a cervical biopsy may be performed or may be part of a staging procedure. Imaging is typically not used for the diagnosis of cervical cancer, but is useful in staging and evaluation of women with a known malignancy.

Differential Diagnosis

The differential diagnosis of cervical cancer includes mimics of the common symptoms of cervical cancer including irregular or heavy vaginal bleeding, postcoital bleeding, and abnormal vaginal discharge. Cervicitis, structural abnormalities, uterine leiomyoma, endometrial polyps, adenomyosis, endometritis, and pelvic inflammatory disease may all cause abnormal uterine bleeding. Visible cervical lesions including nabothian cysts, mesonephric cysts, cervical ectropion, ulcers from STIs, reactive glandular changes, and endometriosis are also on the differential for cervical cancer.

Treatment

Staging

This is performed before the proper treatment is chosen. Staging of cervical carcinoma is based on clinical staging as defined by the system set forth by the International Federation of Gynecology [27] and should be performed by an experienced clinician. Staging does not include lymph node involvement, though lymph node evaluation must be performed as information regarding involvement affects treatment planning. The most common metastatic sites include the aortic and mediastinal lymph nodes, lungs, and skeleton.

Treatment Options

Treatment options depend on staging including localized disease, locally advanced disease, and metastatic or recurrent. Treatment options vary and may include surgery, radiation, brachytherapy, and chemotherapy.

Referrals

Patients diagnosed with cervical cancer need referral to a gynecologist-oncologist as soon as the diagnosis is made. Referring to other oncology services such as patient-centered support groups and to a social worker to help with financial questions or concerns, additional community resources and support are helpful for the patient as they are coping with a new diagnosis or recurrent cervical cancer.

Screening

In 2012 the US Preventive Services Task Force (USPSTF) updated the 2003 statement on screening for cervical cancer. These recommendations are similar to the ACS/ASCCP/ASCP and ACOG current guidelines.

These recommendations are for women who have a cervix and do not apply to women who have received a diagnosis of a high-grade precancerous cervical lesion, cervical cancer, and exposure to diethylstilbestrol or women who are immunocompromised [32]. Sexual history is not taken into account in the recommendations. Screening recommendations from the USPSTF including techniques, initiation, frequency, and management of abnormal screening results will be discussed here.

DOI 10.1007/978-1-4939-0779-3_112-1

Techniques

Cervical cytology screening techniques include the more common liquid-based cytology and the conventional Papanicolaou (Pap) smears. Both are considered acceptable forms of screening by ACOG [33]. These are discussed collectively as cervical cytology. Available HPV DNA tests include HPV High-Risk, HPV 16 and 18 DNA, and Hybrid Capture 2 HPV DNA. Testing for low-risk HPV types is not useful.

Initiation and Frequency

Cervical cancer screening with a Pap smear is recommended to start at age 21 based on guidelines set forth by US Preventive Services Task Force in 2012, ACS/ASCCP/ASCP, and ACOG [32, 33] (Fig. 2). Annual screening is not recommended for all women. Cytology results from previous Pap smears, age, immune status, and previous HPV testing influence recommended screening intervals.

The ASC identifies groups that may require more frequent testing including individuals with HIV, immunosuppression, and in utero exposure to DES. For HIV patients, ACOG recommends a screening Pap smear twice in the first year after diagnosis and then annually thereafter [36].

All guidelines mentioned above for cervical cancer screening recommend cytology alone for screening every 3 years for women aged 21–29 years. Screening of women between the ages of 20 and 24 has been shown to have no impact on rates of invasive cancer up to age 30 [37]. For women between the ages of 30 and 65 years, cytology alone can be performed every 3 years according to the USPSTF guidelines [32]. The USPSTF states that in this age group, women who wish to extend screening to every 5 years may do cytology with HPV co-testing but that this may lead to additional testing. The ASC/ASCCP/ASCP and ACOG guidelines recommend screening in combination with cytology and HPV testing every 5 years in women ages 30–65.

The USPSTF recommends stopping cervical cancer screening for women older than age 65 with adequate prior screening, not otherwise at risk for cervical cancer [32]. This recommendation defines adequate screening as two consecutive cytology-negative Pap smears with negative HPV co-testing in the 10 years prior to stopping with the last test within 5 years or three consecutive negative cytology tests. In addition, women who have had a total hysterectomy and have no history of CIN 1 or 2 or cervical cancer also do not need continued screening [32]. Women who have had a high-grade precancerous lesion should continue testing for 20 years after management of the lesion.

The Bethesda System from 2001 is a standardized framework for laboratory reports for cervical cytology. The report attests to specimen adequacy and gives a descriptive diagnosis. There have been two revisions since 1988. In 2012, experts from national and international health organizations, federal agencies, and professional societies convened to revise the 2006 American Society for Colposcopy and Cervical Pathology Consensus Guidelines. From this meeting arose new evidence-based consensus guidelines for managing women with abnormal cervical cancer screening tests, CIN, and adenocarcinoma in situ (AIS) [38]. The new longer screening intervals recommended by ASCCP, ACOG, and USPSTF were incorporated into these guidelines. These guidelines are the standard of care for managing abnormal cervical cancer screening tests. They can be found on the ASCCP website (http://www.asccp.org).

Colposcopy

Colposcopy is used to visualize mucosal abnormalities of the cervix that may be suspicious and require biopsy. A colposcope is a low-power magnification device that permits the visualization of abnormalities of the cervix that are consistent with CIN or invasive cancer. During colposcopy, the cervix is washed with a solution of acetic acid which turns areas of the cervix white that have high nucleic acid. Biopsies are then procured and sent for histopathology. Results from colposcopy dictate the next steps in management. The

Cervical Cancer Screening Guidelines for Average-Risk Women [1]

	American Cancer Society (ACS), American Society for Colposcopy and Cervical Pathology (ASCCP), and American Society for Clinical Pathology (ASCP) [2] 2012	U.S. Preventive Services Task Force (USPSTF) [3] 2012	American College of Obstetricians and Gynecologists (ACOG) [4] 2012
When to start screening [5]	Age 21. Women aged <21 years should not be screened regardless of the age of sexual initiation or other risk factors. *(Strong recommendation)*	Age 21. *(A recommendation)* Recommend against screening women aged <21 years. *(D recommendation)*	Age 21 regardless of the age of onset of sexual activity. Women aged <21 years should not be screened regardless of age at sexual initiation and other behavior-related risk factors. *(Level A evidence)*
Statement about annual screening	Women of any age should not be screened annually by any screening method. *(Strong recommendation)*	Individuals and clinicians can use the annual Pap test screening visit as an opportunity to discuss other health problems and preventive measures. Individuals, clinicians, and health systems should seek effective ways to facilitate the receipt of recommended preventive services at intervals that are beneficial to the patient. Efforts also should be made to ensure that individuals are able to seek care for additional health concerns as they present.	In women aged 30–65 years, annual cervical cancer screening should not be performed. *(Level A evidence)* Patients should be counseled that annual well-woman visits are recommended even if cervical cancer screening is not performed at each visit.
Screening method and intervals [6]			
Cytology (conventional or liquid based) 21-29 years of age	Every 3 years. [7] *(Strong recommendation)*	Every 3 years. *(A recommendation)*	Every 3 years. *(Level A evidence)*
Cytology (conventional or liquid based) 30-65 years of age	Every 3 years. [7] *(Strong recommendation)*	Every 3 years. *(A recommendation)*	Every 3 years. *(Level A evidence)*
HPV co-test (cytology + HPV test administered together) 21-29 years of age	HPV co-testing should not be used for women aged <30 years.	Recommend against HPV co-testing women aged <30 years. (D recommendation)	HPV co-testing [8] should not be performed in women aged < 30 years. *(Level A evidence)*
HPV co-test (cytology + HPV test administered together) 30-65 years of age	Every 5 years *(Strong recommendation)*; this is the preferred method *(Weak recommendation)*.	For women who want to extend their screening interval, HPV co-testing every 5 years is an option. (A recommendation)	Every 5 years; this is the preferred method. *(Level A evidence)*
Primary HPV testing [9]	For women aged 30-65 years, screening by HPV testing alone is not recommended in most clinical settings. *(Weak recommendation)* [10]	Recommend against screening for cervical cancer with HPV testing (alone or in combination with cytology) in women aged <30 years. *(D recommendation)*	Not addressed.
When to stop screening	Aged >65 years with adequate screening history. [11,12]	Aged >65 years with adequate screening history. *(D recommendation)* [11]	Aged >65 years with adequate screening history [11, 13] *(Level A evidence)*
Screening post-hysterectomy	Women who have had a total hysterectomy (removal of the uterus and cervix) should stop screening. [14] Women who have had a supra-cervical hysterectomy (cervix intact) should continue screening according to guidelines. *(Strong recommendation)*	Recommend against screening in women who have had a hysterectomy (removal of the cervix). [13] *(D recommendation)*	Women who have had a hysterectomy (removal of the cervix) should stop screening and not restart for any reason. [13] *(Level A evidence)* [15]

Fig. 2 (continued)

DOI 10.1007/978-1-4939-0779-3_112-1

The need for a bimanual pelvic exam	Not addressed in 2012 guidelines but was addressed in 2002 ACS guidelines. [16]	Addressed in USPSTF ovarian cancer screening recommendations (draft). [17]	Addressed in 2012 well-woman visit recommendations.[18] **Aged <21 years**, no evidence supports the routine internal examination of the healthy, asymptomatic patient. An "external-only" genital examination is acceptable. **Aged ≥21 years**, no evidence supports or refutes the annual pelvic examination or speculum and bimanual examination. The decision whether or not to perform a complete pelvic examination should be a shared decision after a discussion between the patient and her health care provider. Annual examination of the external genitalia should continue.[19]
Screening among those immunized against HPV 16/18	Women at any age with a history of HPV vaccination should be screened according to the age specific recommendations for the general population.	The possibility that vaccination might reduce the need for screening with cytology alone or in combination with HPV testing is not established. Given these uncertainties, women who have been vaccinated should continue to be screened.	Women who have received the HPV vaccine should be screened according to the same guidelines as women who have not been vaccinated. *(Level C evidence)*

HPV = human papillomavirus; CIN = cervical intraepithelial neoplasia

[1] These recommendations do not apply to women who have received a diagnosis of a high-grade precancerous cervical lesion (CIN 2 or 3) or cervical cancer, women with in utero exposure to diethylstilbestrol, or women who are immunocompromised, or are HIV positive.

[2] Saslow D, Solomon D, Lawson HW, et al. American Cancer Society, American Society for Colposcopy and Cervical Pathology, and American Society for Clinical Pathology screening guidelines for the prevention and early detection of cervical cancer. CA Cancer J Clin. 2012 May-Jun;62(3):147-72. doi: 10.3322/caac.21139. Available at http://www.cancer.org/Cancer/CervicalCancer/DetailedGuide/cervical-cancer-prevention

[3] USPSTF. Screening for Cervical Cancer. 2012. Available at http://www.uspreventiveservicestaskforce.org/uspstf11/cervcancer/cervcancerrs.htm. These recommendations apply to women who have a cervix, regardless of sexual history.

[4] ACOG Practice Bulletin No. 131: Screening for Cervical Cancer. ACOG Committee on Practice Bulletins-Gynecology. *Obstet Gynecol.* 2012 Nov;120(5):1222-38. doi: http://10.1097/AOG.0b013e318277c92a

[5] Since cervical cancer is believed to be caused by sexually transmissible human papillomavirus infections, women who have not had sexual exposures (e.g., virgins) are likely at low risk. Women aged >21 years who have not engaged in sexual intercourse may not need a Pap test depending on circumstances. The decision should be made at the discretion of the women and her physician. Women who have had sex with women are still at risk of cervical cancer. 10-15% of women aged 21-24 years in the United States report no vaginal intercourse (Saraiya M, Martinez G, Glaser K, et al *Obstet Gynecol.* 2009 Dec;114(6):1213-9. doi: 10.1097/AOG.0b013e3181be3db4.). Providers should also be aware of instances of non-consensual sex among their patients.

[6] Conventional cytology and liquid-based cytology are equivalent regarding screening guidelines, and no distinction should be made by test when recommending next screening.

[7] There is insufficient evidence to support longer intervals in women aged 30-65 years, even with a screening history of consecutive negative cytology tests.

[8] All ACOG references to HPV testing are for high risk HPV testing only. Tests for low risk HPV should not be performed.

[9] Primary HPV testing (HPV testing alone) is defined as conducting the HPV test as the first screening test. It may be followed by other tests (like a Pap) for triage.

[10] No further explanation of which clinical settings HPV testing should be used to screen women aged 30-65 years as a stand alone test.

[11] Current guidelines define adequate screening as three consecutive negative cytology results or two consecutive negative co-tests within 10 years before cessation of screening, with the most recent test performed within 5 years, and are the same for ACS, ACOG, and USPSTF.

[12] Women aged >65 years with a history of CIN2, CIN3, or AIS should continue screening for at least 20 years after spontaneous regression or appropriate management. (Weak recommendation)

[13] And no history of CIN 2 or higher.

[14] Unless the hysterectomy was done as a treatment for cervical pre-cancer or cancer.

[15] Women should continue to be screened if they have had a total hysterectomy and have a history of CIN 2 or higher in the past 20 years or cervical cancer ever. Continued screening for 20 years is recommended in women who still have a cervix and a history of CIN 2 or higher. Therefore, screening with cytology alone every 3 years for 20 years after the initial post-treatment surveillance for women with a hysterectomy is reasonable. (Level B evidence)

[16] 2002 guidelines statement: The ACS and others should educate women, particularly teens and young women, that a pelvic exam does not equate to a cytology test and that women who may not need a cytology test still need regular health care visits including gynecologic care. Women should discuss the need for pelvic exams with their providers. Saslow D, Runowicz CD, Solomon D, et al. American Cancer Society Guideline for the Early Detection of Cervical Neoplasia and Cancer. *CA Cancer J Clin* 2002; 52: 342-362.

[17] The bimanual pelvic examination is usually conducted annually in part to screen for ovarian cancer, although its effectiveness and harms are not well known and were not a focus of this review. No randomized trial has assessed the role of the bimanual pelvic examination for cancer screening. In the PLCO Trial, bimanual examination was discontinued as a screening strategy in the intervention arm because no cases of ovarian cancer were detected solely by this method and a high proportion of women underwent bimanual examination with ovarian palpation in the usual care arm.

[18] ACOG Committee Opinion No. 534: Well-Woman Visit. Committee on Gynecologic Practice. *Obstet Gynecol.* 2012 Aug;120(2)1:421-24. doi: 10.1097/AOG.0b013e3182680517.

[19] For women aged ≥21 years, annual pelvic examination is a routine part of preventive care even if they do not need cervical cytology screening, but also lacks data to support a specific time frame or frequency of such examinations. The decision to receive an internal examination can be left to the patient if she is asymptomatic and has undergone a total hysterectomy and bilateral salpingo–oophorectomy for benign indications, and is of average-risk.

Fig. 2 Cervical cancer screening guidelines (http://www.cdc.gov/cancer/cervical/pdf/guidelines.pdf)

2012 ASCCP guidelines guide practitioners through the standards of care based on histopathology results. These guidelines can be found on the ASCCP website.

Prevention

Primary Prevention

Behavioral intervention to modify known risk factors for cervical cancer may modify the incidence of cervical cancer. Practitioners can use techniques such as motivational interviewing to help patients decide which risk factors they would like to modify. Primary prevention such as quitting smoking, using contraception methods other than oral contraceptive pills, and limiting the number of sexual partners can modify an individual's risk.

Medications/Immunizations and Chemoprophylaxis

HPV is associated with development of anogenital cancers including cervical, vaginal, vulvar, and anal. HPV is divided into two classes: non-oncogenic (low risk) and oncogenic (high risk). Low-risk HPV genotypes including 6 and 11 are associated with condyloma and mild dysplastic changes that typically do not progress. High-risk HPV types including 16, 18, 31, 33, and 35 are associated with moderate (CIN 2) and severe dysplasia (CIN 3). As previously noted the high-risk types are seen in most cervical cancers. Only a small percentage of women with HPV will develop cervical cancer or abnormalities, as HPV alone is usually necessary but not a sufficient precursor for the development of squamous cell carcinoma [33].

Vaccination against the genotypes known to be the etiology of most cervical cancers is given with the intent to reduce the incidence of anogenital cancers. The Food and Drug Administration has approved two vaccines for the prevention of HPV infection. The bivalent three-dose vaccine, Cervarix, is approved for females ages 9–25 years to prevent cervical cancer, CIN 1, CIN 2, and adenocarcinoma in situ caused by oncogenic HPV genotypes 16 and 18 [39]. The quadrivalent three-dose vaccine is approved for females and males ages 9–26 years and protects against HPV genotypes 6, 11, 16, and 18. It is indicated to prevent cancers and intraepithelial neoplasias of the cervix, anus, vulva, and vagina and genital warts associated with the aforementioned genotypes [40].

The American Academy of Pediatrics (AAP) and CDC recommend that girls ages 11–12 years be routinely immunized with three doses of HPV4 or HPV2 and that all girls and women ages 13 through 26 years who have not completed the series should complete the series [41]. The AAP and CDC also recommend that all boys 11–12 years of age are immunized routinely with three doses of HPV4 and if they are ages 13–26 they should complete the series if they have not already [41]. Both vaccines can be given as early as the age of 9.

Long-term effects of HPV vaccination on prevention of cervical cancer and CINs 2 and 3 are unknown, and there are no current trials that provide data on long-term efficacy [42]. Since there is no long-term data to help deduce how vaccination may alter the need for screening with cytology or cytology with HPV co-testing, women who have been vaccinated against high-risk HPV infection should continue to be screened according to the USPSTF guidelines [32].

Secondary Prevention

The Pap smear is a screening tool used to detect changes in cervical cells. In 2012, the American Society for Colposcopy and Cervical Pathology (ASCCP) with partnered organizations revised their 2006 consensus guidelines, recommending management of women with cytological abnormalities. The 2001 Bethesda System terminology [43] is used for cytological classification. Using the algorithms set forth in the ASCCP 2012 guidelines, practitioners are guided through the possible outcomes of cervical cytology from a Pap smear based on results, age, and history of previous Pap smear results. Within the guidelines

DOI 10.1007/978-1-4939-0779-3_112-1

HPV testing only refers to high-risk, oncogenic HPV types only. The 2012 ASCCP guidelines can be accessed at http://www.asccp.org/guidelines.

Ovarian Cancer

General Principles

Definition/Background

Ovarian cancer is the second most common gynecologic malignancy and is the leading cause of death from gynecologic malignancies in the United States [9]. The majority of ovarian malignancies, approximately 95 %, are derived from epithelial cells. Epithelial carcinomas of the ovaries, fallopian tubes, and peritoneum are clinically similar, and there are five main subtypes which include high-grade serous carcinoma, endometrioid carcinoma, clear cell carcinoma, mucinous carcinoma, and low-grade serous carcinoma. The other types of ovarian malignancies include germ cell tumors and sex cord-stromal tumors.

Epidemiology

In 2014, there were 21,980 expected cases of ovarian cancer to be diagnosed, with an expected 14,270 deaths in the United States [9]. It is the fifth leading cause of death among women in the United States [9]. Based on data from 2009 to 2011, approximately 1.3 % of women will be diagnosed with ovarian cancer during their lifetime, and in 2011, the number of women living with ovarian cancer in the United States was 188,867 [44]. Rates for new ovarian cancer in the United States have been falling on average 1.1 % for the past 10 years [44]. Most ovarian cancers, 70–75 %, are found at stages III to IV, and the overall 5-year survival rate is 20–30 % [45]. The 5-year survival rate for ovarian cancer found at stage I is 90–95 % [45].

Risk Factors

The pathogenic mechanisms for ovarian cancer have yet to be explained. Currently, there are two hypotheses – incessant ovulation and exposure to gonadotropins. The theory of incessant ovulation was born out of data which demonstrated that women with history of pregnancy, lactation, or contraceptive use have a lower incidence of epithelial ovarian cancer. The gonadotropin exposure hypothesis is less supported by data and comes from the observation that experimentally induced ovarian tumors have gonadotropin receptors.

Family History/Familial Ovarian Cancer Syndromes

The strongest risk factor for ovarian cancer is family history. It is important to differentiate women who have a history of an isolated family member with ovarian cancer and those that may have a rare familial ovarian cancer syndrome from germ line mutations including BRCA1 or BRCA2 mutations or Lynch syndrome. Women with Ashkenazi Jewish heritage with a single family member with breast cancer before age 50 or ovarian cancer are also considered to have a high-risk family history.

Reproductive/Hormonal Factors

Overall, the data seems to support the hypothesis of incessant ovulation as a risk for ovarian cancer. Women who are multiparous or who take oral contraceptives have a decreased risk of epithelial ovarian cancer. Women with infertility, early menarche, and late menopause may be at an increased risk.

DOI 10.1007/978-1-4939-0779-3_112-1

The Women's Health Initiative found no increased risk for women on combined estrogen-progestin therapy compared with placebo [46].

Environmental

Environmental risk factors include cigarette smoking and exposure to asbestos, a known carcinogen. Increased risk with perineal use of talcum powder is controversial. The association may be explained by the similar structure between talcum powder and asbestos, and decades before, some talcum powder was contaminated with asbestos. Smoking increases the risk of mucinous ovarian cancer, with increasing amount of smoking leading to increased risk [47].

Others

Obesity seems to increase the risk of ovarian cancer [48]. Risk also increases with age.

Diagnosis

History

Ovarian cancer is typically diagnosed at a late stage. However, there is evidence demonstrating that women will present with symptoms, even in early stages, that may get overlooked [49, 50]. Ovarian cancer can cause a myriad of symptoms, and distinguishing these symptoms from symptoms that normally occur in women or those that may be caused by a different medical disorder is problematic. Majority of women with epithelial ovarian cancer will present with a pelvic or abdominal symptoms prior to their diagnosis. Abdominal pain or discomfort and abdominal bloating or swelling are the most common symptoms. Patients may note urinary frequency, early satiety, and back pain. What may help distinguish these symptoms from other medical conditions is their more frequent and severe nature in those with ovarian cancer.

Physical Exam

If a pelvic mass is suspected or woman has symptoms suggestive of an epithelial ovarian cancer, a physical exam is warranted and should include an abdominal, pelvic, rectovaginal, and lymph node exam. A lymph node exam should include evaluation of groin and supraclavicular lymph nodes. If a physical exam is suspicious for a mass or other secondary symptoms of ovarian cancer such as ascites are found, further investigation is warranted with labs and imaging.

Laboratory and Imaging

If a physical exam and history are concerning for possible ovarian cancer, a Ca-125 tumor marker and abdominal and transvaginal ultrasound should be obtained. If the physical exam is benign, waiting two weeks to see if symptoms resolve prior to ordering pelvic ultrasound is reasonable.

Differential Diagnosis: The differential diagnosis for epithelial ovarian carcinoma and tubal and peritoneal carcinoma is variable depending on the presentation of the patient. Patients can have a myriad of symptoms though typically these will be urologic or gastrointestinal in nature. In women who do not have an adnexal mass on exam and imaging, workup for other causes of their symptoms is warranted and may be done simultaneously.

DOI 10.1007/978-1-4939-0779-3_112-1

Staging/Treatment

Referrals

Ovarian, fallopian tube, and peritoneal cancers may require surgery for diagnosis. Primary care providers should refer to a gynecologist-oncologist for the staging of these cancers and their surgical management.

Medications/Chemoprophylaxis

After diagnosis, a gynecologist-oncologist will make recommendations based on the type and stage of the ovarian cancer. The main treatments for ovarian cancer include surgery, chemotherapy, hormone therapy, radiation, and target therapy. Often, two or more different options will be used to treat ovarian cancer.

Prevention

Routine gynecologic care with a primary care provider is an important component of cancer prevention. As part of an annual wellness exam, providers can help screen for familial cancer syndromes by reviewing the patient's family history and any new health changes. Risk reduction for ovarian cancer can also be discussed including quitting smoking and managing weight to prevent obesity. Those with a known familial cancer syndrome or those at risk should be identified during these routine exams and referred to a gynecologist-oncologist and genetic counselor to discuss other options for prevention including chemoprevention, mastectomy, and bilateral salpingo-oophorectomy.

Screening

The yearly well woman exam is an excellent time to evaluate a patient's risk for hereditary breast and ovarian cancer syndromes. Using screening questions to identify those at greater risk is an opportunity to also discuss risk reduction.

The practice bulletin published by ACOG [45] outlines criteria that, if met, would prompt a clinician to refer a patient for a genetic risk assessment. Women with an approximately 20–25 % chance of having an inherited breast or ovarian cancer are recommended to undergo a genetic risk assessment. Genetic risk assessments include a referral to a genetic counselor who will, with the patient's assistance, gather a medical family history and provide education about specific cancers including potential genetic testing and counseling. Women who have a known or suspected ovarian cancer should also be referred to a genetic counselor.

Screening methods for ovarian cancer include measurement of the tumor marker CA-125, serological markers, and ultrasound.

Consensus is that women at average risk should not undergo routine screening for ovarian cancer. The USPSTF gives an evidence level of D for screening asymptomatic women with no known hereditary cancer syndrome [51]. The incidence and prevalence of ovarian cancer makes consideration of a high false-positive rate very important when screening is planned. A potential risk of screening is a false-positive result, which may lead to surgery including laparotomy or laparoscopy and other invasive procedures. Benefits include being able to find ovarian cancer at an earlier stage where it may be more curable. A large trial in the United States showed that screening with CA-125 and transvaginal ultrasound compared with usual care did not reduce ovarian cancer mortality and 15 % of women who had a false-positive result who underwent surgery had a serious complication [52]. The USPSTF, in their recommendation against routine screening, notes that screening may lead to patient harm, including from invasive procedures such as surgery [51].

Screening with the CA-125 tumor marker and transvaginal ultrasound in women with a familial ovarian cancer syndrome who have not had a prophylactic salpingo-oophorectomy is recommended by the National Comprehensive Cancer Network. However, improved survival rates with this screening

DOI 10.1007/978-1-4939-0779-3_112-1

combination have not been demonstrated [53, 54]. ACOG recommends bilateral salpingo-oophorectomy by age 40 for risk reduction in women with BRCA 1 or BRCA 2 mutations[55]. Additional screening methodologies may be recommended, and all screening should be directed by a gynecologist or gynecologist-oncologist.

Benign Breast Conditions and Disease

Chelsey L. Villanueva[a]*, Gabriel Briscoe[a] and Jennifer Bepko[b]
[a]David Grant Family Medicine Residency Program, David Grant Medical Center, Travis AFB, CA, USA
[b]DGMC Family Medicine Residency, David Grant USAF Medical Center, Travis AFB, NV, USA

1 Introduction

Benign breast disease is a common occurrence in family medicine. Patients may present with masses, skin lesions, breast pain, breast feeding complaints, and concerns regarding risk of malignancy. The incidence of benign breast disease rises in a woman's third decade of life and peaks in her fifth and sixth decade of life, whereas the risk of malignancy continues to increase past menopause [1]. Knowledge of basic anatomy and physiology of the breast is important when evaluating breast pain, nipple discharge, breast skin lesions, and breast masses. As with many other conditions, pertinent history taking and physical exam help determine the need for imaging. Many breast conditions may need confirmation with biopsy with those results dictating appropriate follow-up.

2 Anatomy and Physiology

The breast contains glandular, ductal, fibrous, and fatty tissue. Each breast contains 6–20 lobes made of several lobules within which are 10–100 subsegmental ducts, 20–40 segmental ducts, and 5–10 primary milk ducts that emerge at the areola via 6–10 pinhole openings. More lobes are present in the outer quadrants, especially the upper outer quadrants that are a common location for many breast conditions. Hormonal effects on breast tissue include estrogen on the development and elongation of ductal tissue, progesterone on ductal branching and lobulo-alveolar development, and prolactin on milk protein production [2]. The cyclic nature of estrogen and progesterone during the menstrual cycle increases cell proliferation and can yield changes in breast size and consistency.

3 History, Physical Exam, and Initial Workup

A patient may present with complaint of pain, nipple discharge, skin lesion, and/or a palpable mass. The initial assessment of breast complaints includes thorough history taking, a clinical breast exam, consideration for imaging, and possibility of biopsy.

3.1 History

A patient with breast complaints should have a thorough history taken to include the duration of symptoms, presence or absence of nipple discharge, pain, skin lesion or palpable mass, change in size of any masses over time, relation of symptoms to menstrual cycle, and systemic symptoms such as fever, malaise, or chills. Potential personal risk factors for benign breast disease would generally depend on the particular lesion as discussed later in the chapter. Potential risk factors for malignant breast disease include female sex, older age, genetic factors, ethnicity, personal or family history of cancer, menstrual and

Table 1 Elements of history for breast complaint

Symptom characteristics
Onset of symptoms/mass
Change in symptoms/mass over time and relation to the menstrual cycle (if premenopausal)
History of similar symptoms
Discharge: spontaneous or expressed, location, color, amount, timing with pregnancy/breastfeeding, medications, association with visual changes and/or headaches, presence of recurrent irritation
Pain: caffeine intake, hormonal therapy, contraception use
Diet and medications: current medications and history of hormone therapy
Personal and family cancer history: including breast, ovarian, endometrial, color, prostate cancer, relationship to patient, age of onset
History of breast surgery or biopsies: document reason and pathology results
Patient information: reproductive status, reproductive history, lactation status, radiation or chemical exposure, tobacco exposure

Adapted from Andolsek and Copeland [3]

reproductive history, use of hormonal medications, chest radiation exposure, diethylstilbestrol (DES) exposure, and certain benign breast disease. Elements that should be obtained from a thorough history are listed in Table 1.

3.2 Breast Self-Examination

While self-identified masses or lesions warrant a clinical exam, there is conflicting current opinion regarding regular self-breast exams. In 2009, the U.S. Preventive Task Force (USPSTF) recommended against teaching breast self-examination (BSE) in all women (Grade D) due to false-positive findings leading to the need for unnecessary imaging and biopsies [4]. However, the American College of Obstetricians and Gynecologists (ACOG), the American Cancer Society (ACS), and the National Comprehensive Cancer Network recommend teaching breast self-awareness by educating patients about the normal feel and appearance of their breasts [5].

3.3 Clinical Breast Exam

Similar controversy exists to the utility of the clinical breast exam (CBE) as a screening tool. The USPSTF has concluded that there is insufficient evidence to perform a CBE as a screening tool in women over the age of 40 in countries that provide routine mammography screening again citing the concern of high rates of false-positive results and subsequent workup may offset potential benefits [6]. The American Academy of Family Physicians concurs that there is insufficient evidence to recommend CBE as a screening tool [7]. However, both ACOG and ACS recommend CBE every 1–3 years from ages 20 to 39 and annually after age 40 [8]. Although debate also exists for the timing and frequency for screening exams, CBE should be performed with any breast-related complaint. CBE has a sensitivity and specificity of 54 % and 94 %, respectively [2].

The breast exam includes visual inspection, palpation, and nipple expression. In addition to the breast, the exam should include evaluation of the chest, axillae, and regional lymph nodes. With the patient in the seated position, conduct a visual inspection for breast asymmetry, size difference, contour changes (dimpling or flattening), skin color, or changes in nipple appearance. Positioning the patient with arms overhead and then on the waist while leaning forward can enhance subtle changes such as skin retractions. Skin changes suggestive of a malignancy include dimpling, puckering, edema, and thickening of the skin (peau d'orange).

DOI 10.1007/978-1-4939-0779-3_113-1

Breast palpation should be performed with the patient in both seated and supine positions. While still seated, palpate for cervical, supraclavicular, and axillary lymphadenopathy. In the supine position, the ipsilateral arm to the breast should be placed over the patient's head. The breast tissue is examined using the finger pads and progresses in a systematic fashion (either in a spiral fashion or vertical stripe pattern) without missing any areas, including up to the collarbone and axilla. Palpitation of the nipple includes attempting nipple expression by gently compressing the areola between the thumb and index finger. Consider sending any fluid expressed for evaluation. Clearly document all abnormal findings to include location (by quadrant or in relation to the face of a clock), consistency of any masses (soft, firm), mobility, and margins (well circumscribed, smooth, irregular). Benign lesions are typically without skin changes, smooth, soft to firm texture, mobile, and with well-defined margins, while malignant lesions generally are hard, fixed, immobile, and with poor margins [9].

3.4 Imaging

Diagnostic imaging should be performed for any concerning masses. Imaging method is determined by patient's age due to breast density changes over time: women over 30 years of age or younger patients with a higher risk of cancer and palpable breast mass should be initially evaluated with diagnostic mammography with ultrasound [9]. Women under 30 should be evaluated with ultrasound due to increased sensitivity of detecting lesions in dense breast tissue [9]. Breast magnetic resonance imaging (MRI) is not recommended for routine breast cancer screening in women with average risk of developing breast cancer. The ACS recommends MRI screening for women at an increased risk of breast cancer defined as 20 % or greater lifetime risk of developing breast cancer according to family history risk assessment tools, known BRCA1 or BRCA 2 gene mutations, first-degree relatives with BRCA mutations and without personal genetic testing, a history of chest radiation between the ages of 10 and 30, and genetic syndromes such as Li-Fraumeni, Cowden, or Bannayan-Riley-Ruvalcaba syndrome or an affected first-degree relative [8]. Findings on breast imaging are summarized using the Breast-Imaging Reporting and Data System, or BI-RADS [10]. The most recent update combines all three imaging modalities (ultrasound, mammography, and MRI) to standardize reporting results and provide recommended follow-up imaging and/or biopsy guidelines summarized in Table 2.

3.5 Tissue Sampling

Breast tissue sampling may be indicated for suspicious lesions even with normal mammography, as pathology such as lobular carcinoma may not be visible on imaging. Other indications include breast cysts that recur after aspiration, bloody nipple discharge or bloody cyst fluid, skin changes, asymmetry or thickening on exam, nodularity on exam, inflammatory skin changes that do not respond to antibiotics, suspicious nodes, or microcalcifications on mammography.

Biopsies of suspicious lesions are often performed after diagnostic imaging by a qualified physician. Options for tissue sampling include fine-needle aspiration (FNA), core-needle biopsy (CNB), or excisional biopsy. Localizing modalities include ultrasound, x-ray or stereotactic imaging, and MRI. Considering what type of sampling technique is the clinical discretion of the performing clinician and may also depend on the breast size.

Needle biopsy is performed percutaneously with local anesthesia and is a minimally invasive evaluation of abnormalities. FNA allows for diagnosis and treatment of breast cysts, cytological evaluation of abnormal lymph nodes, or when needle biopsy is not possible. CNB utilizes either a vacuum-assisted or automated biopsy devices. Both FNA and CNB allow for marking the biopsy site with a clip for future follow-up or to guide surgical excision. With adequate sampling, an FNA has 98–99 % sensitivity, 99 % positive predictive value, and 86–99 % negative predictive value in detecting malignancy. However, adequacy is dependent on the physician's training and experience level [11]. Ultrasound-guided CNB has

DOI 10.1007/978-1-4939-0779-3_113-1

Table 2 BI-RADS categories

BI-RADS category	Assessment	Likelihood of malignancy	Follow-up recommended
0	Incomplete	n/a	Additional imaging required, in some states within 30 days
1	Negative	n/a	Routine screening
2	Benign finding(s)	n/a	Routine screening
3	Probably benign	<2 %	Short-interval follow-up (repeat mammogram in 6 months) or biopsy
4A	Low suspicion for malignancy	2–10 %	Biopsy should be performed
4B	Moderate suspicion for malignancy	10–50 %	Biopsy should be performed
4C	High suspicion for malignancy	>50 % to <95 %	Biopsy should be performed
5	Highly suggestive of malignancy	>95 %	Biopsy should be performed
6	Known biopsy-proven malignancy	n/a	Surgical excision when clinically appropriate

Adapted from Salzman et al. [9]

a sensitivity of 99 % for palpable lesions and 93 % for nonpalpable lesions [11]. However, excisional biopsy should be considered for evaluation and diagnosis of breast masses in addition to providing therapeutic measures. Excisional and incisional biopsies are performed when masses are suspected to be malignant, when less invasive sampling is inconclusive, unavailable, or suggestive of malignancy.

In addition to particular BI-RADS results, certain benign lesions should be considered for biopsy. A complex sclerosing lesion greater than 10 mm should be considered for excisional biopsy. Low-risk lesions including fibroadenomas (simple or complex), hamartomas, fat necrosis, sclerosing adenosis, columnar cell change or hyperplasia, or radial scar less than 10 mm do not necessarily need surgical evaluation unless there is radiographic discordance or it is associated with atypical ductal or lobular hyperplasia. All high-risk lesions that cannot be sampled should be referred for surgical excision [12].

3.6 The Triple Test

The triple test includes clinical exam, imaging, and tissue sampling. When performed with concordant results, diagnostic accuracy approaches 100 % [11]. Any discordant results may require excisional biopsy. The Triple Test Score (TTS) may aid in interpretation of discordant results. Each component of the test (exam, imaging, tissue sampling) is assigned a score: 1 for benign findings, 2 for suspicious lesions, and 3 for malignant lesions. A score of 3–4 is consistent with benign lesions and may be clinically followed with a repeat exam in 4–6 weeks; >6 indicates possible malignancy that may require surgical intervention. Excisional biopsy is recommended for a TTS of 5 [11]. An approach to management of palpable breast masses is summarized in Fig. 1.

DOI 10.1007/978-1-4939-0779-3_113-1

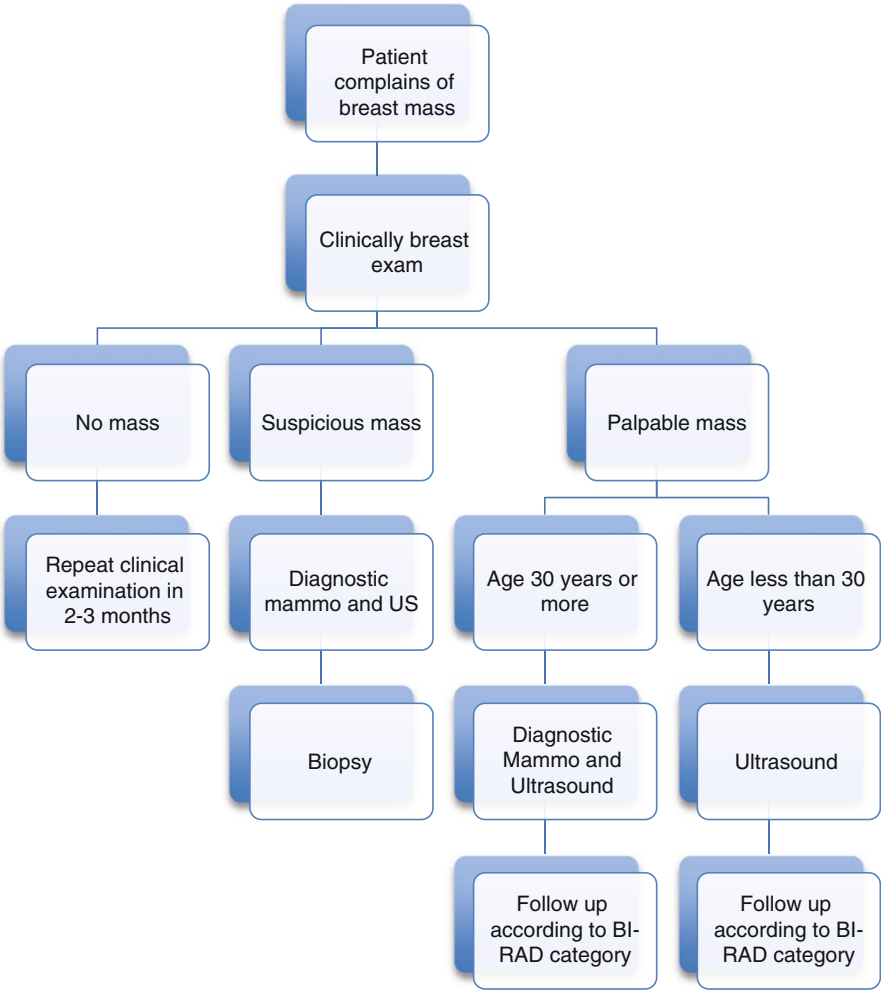

Fig. 1 Management of breast masses (Adapted from Neal et al. [12] and Pearlman and Griffin [13])

4 Common Chief Complaints

4.1 Breast Pain (Mastodynia/Mastalgia)

Breast pain makes up 66 % of breast complaints and can be categorized as cyclical (relating to menses) or noncyclical [9] (Table 3).

4.1.1 Cyclic Versus Noncyclic Breast Pain

Cyclic breast pain correlates to the menstrual cycle typically occurring in the late luteal phase and resolving with menses. It occurs in two-thirds of women and absence of serious disease can be offered. Noncyclic breast pain is not correlated with the menstrual cycle and can be due to pregnancy, mastitis, thrombophlebitis, benign or malignant tumors, trauma, hematoma, and cyst rupture or fat necrosis. Though most cases of noncyclic breast pain occur for reasons unknown, they are likely due to anatomic rather than hormonal causes. Noncyclic breast pain can also be attributed to some medications such as hormonal medications, psychiatric medication, cardiac/antihypertensive medications, and antimicrobials [15].

DOI 10.1007/978-1-4939-0779-3_113-1

Table 3 Summary of management of breast pain

Nonpharmacological interventions
Properly fitting bra, soft supportive bra during sleep, sports bra during exercise
Hot or cold compresses
Massage
Relaxation training
Dietary changes
Decreasing dietary fat intake
Methylxanthine/caffeine reduction (coffee, tea, sodas, chocolate)
Vitamin E
Evening primrose oil
Soy
Pharmacologic interventions – for patients with severe persistent pain
Nonsteroidal anti-inflammatory drugs (NSAIDs) (oral or topical), acetaminophen
Oral combined contraceptives (low estrogen, high progesterone)
Danazol, low dose or during the luteal phase (FDA approved)
Gestrinone
Tamoxifen, low dose or during the luteal phase (not FDA approved)
Bromocriptine
Gonadotropin-releasing hormone agonists

Adapted from Andolsek and Copeland [3] and National Comprehensive Cancer Network [14]

4.1.2 Treatment of Breast Pain

Nonpharmacological Interventions Many women wear improperly fitted bras; therefore, proper fitting of undergarments, wearing a soft supportive bra during sleep, and wearing of a sports bra during exercise may improve breast pain [15]. Cold or heat compresses and massage may also alleviate symptoms. One clinical trial demonstrated a reported decreased of symptoms in 61 % of women who listened to audiocassettes of progressive muscle relaxation for 4 weeks compared to 25 % in women who did not. Dietary changes decreasing dietary fat and methylxanthine/caffeine intake have been suggested; however, to benefit from a lower dietary fat diet, women must decrease their intake to less than 20 % of their daily caloric intake, and there is inconsistent evidence to support the reduction or elimination of caffeine in treating breast pain.

Pharmacological Interventions Vitamin E (alpha-tocopherol) may alter steroidal hormone production and acts as an antioxidant. However, studies have been inconclusive when used for treating fibrocystic breast disease. Evening primrose oil (gamma-linolenic acid), 3,000 mg/day in divided doses for 3–6 months, is often recommended for the treatment of breast pain though conflicting data exists regarding its efficacy. Its mechanism includes restoration of the saturated/unsaturated fatty acid balance and decreased steroidal hormone sensitivity since women with cyclic breast pain may have abnormal fatty acid profiles that may cause epithelial hormonal hypersensitivity. Adverse reactions include nausea, bloating, and lowering seizure threshold; thus, it should not be used in patients with a seizure history. Isoflavones genistein and daidzein found in soy bind to estrogen receptors and can increase the follicular phase of the menstrual cycle to delay menstruation as well as decrease mid-cycle-luteinizing and follicle-stimulating hormone surges and estradiol levels. Evidence supporting its use is limited. Studies are limited regarding the efficacy of acetaminophen or nonsteroidal anti-inflammatory medications (NSAIDs) for breast pain though oral and topical preparations may be of benefit in those without contraindications though evidence is not consistent for benefit.

DOI 10.1007/978-1-4939-0779-3_113-1

Hormonally Active Pharmacological Interventions Hormonally active medications most often used for breast pain are danazol, bromocriptine, or tamoxifen. Possible adverse reactions must be weighed against the potential benefits, and these agents are typically used for 2–6 months then tapered or discontinued. Relapse may occur requiring a second course of the same or different agent.

Danazol is a gonadotropin production and luteinizing hormone surge inhibitor and a weak estrogen antagonist. Currently, it is the only Food and Drug Administration (FDA)-approved medication for breast pain. Initial dosing is 200–600 mg by mouth daily with a maintenance dose of 50–100 mg by mouth daily once symptoms are controlled. Common side effects include headache, nausea, emotional lability and depression, fluid retention, vaginal dryness, hirsutism, amenorrhea, weight gain, menstrual irregularities, hot flashes, and acne. Side effects may be lessened with use of 200 mg by mouth daily only during the luteal phase. Treatment can be stopped after 4–6 months with a favorable treatment response lasting for months to years. Clinical trials have shown 59–92 % of women reporting relief with danazol therapy with corresponding decreased breast volume and density.

Bromocriptine acts as a prolactin inhibitor/dopamine agonist and can be used for cyclical breast pain. Dosing is 1.25 mg by mouth nightly or 2.5 mg by mouth twice a day. Common side effects include nausea, vomiting, postural hypotension, constipation, and dizziness. Severe symptoms limit its use to women that are unresponsive to other agents or with hyperprolactinemia.

Tamoxifen is a selective estrogen receptor modulator used off-label for breast pain. Dosing is 10–20 mg by mouth daily for 3–4 months or for days 15–25 of the monthly menstrual cycle. Adverse effects include menstrual irregularity, menopausal symptoms, vaginal dryness or discharge, endometrial cancer, and deep vein thrombophlebitis. In controlled trials, tamoxifen demonstrated a reduction in pain in 71–96 % of women with cyclic mastalgia and 56 % of women with noncyclic mastalgia.

Gestrinone, a synthetic 19-nor-testosterone derivative, has been shown in a double-blind, placebo-controlled study to yield reduction in breast pain at a dose of 2.5 mg by mouth per week. Its action is similar to danazol and side effects are primarily androgenic.

If oral contraceptives (OCP) and menopausal hormone medications appear causative to breast pain symptoms, the addition of progestational agents (i.e., medroxyprogesterone 5–10 mg 10 days prior to menses, progesterone cream daily the week prior to menses; topical, oral, or parenteral preparations) or switching to a low-estrogen, high-progesterone OCP can relieve cyclic breast pain.

Lastly, gonadotropin-releasing hormone agonists such as goserelin and buserelin (available as subcutaneous implants) have not demonstrated clinical data for the treatment of mastalgia especially given their hypoestrogenic side effects; a decrease in bone mineral density is usually reversible.

4.2 Nipple Pain

The complaint of nipple pain commonly occurs with the onset of breastfeeding. Breastfeeding mothers experiencing pain should have their technique evaluated. Assuring proper positioning and latch as well as releasing the infant's suction prior to removing from the breast are keys to prevention. A certified lactation consultant can be pivotal to the support of the breastfeeding couplet. Topical vitamin E ointment and USP modified lanolin are commonly used but can lead to local skin reactions. Signs of nipple cracking, fissures, blistering, or redness should be examined promptly as well as the infant's mouth. See section on "Mastitis" for further details. If a *Candida* infection is suspected, the nursing mother should receive a course of an oral antifungal, and the infant should be treated as well if topical involvement is present.

Nipple pain in the non-lactating female may be due to local irritation and friction as seen in runners. Small elastic bandages over the nipples and lubricants can be used during activities to reduce the incidence and emollients, or low-dose hydrocortisone creams may decrease symptoms.

Dermatologic conditions can also cause nipple pain. Eczema can manifest as bilateral erythema, scaling and weeping crusts, fissures, vesicles, excoriation, or erosions and can be treated with trigger avoidance

DOI 10.1007/978-1-4939-0779-3_113-1

and topical steroids. If nipple lesions do not resolve or are accompanied by a mass, then prompt evaluation should be performed. Further evaluation should be undertaken if the lesion is ulcerated or weeping in a middle-aged or older woman as this may suggest Paget's disease of the breast.

4.2.1 Mastitis

Acute mastitis, also known as puerperal or lactation mastitis commonly, occurs within the first 3 months of breastfeeding as a result of cellulitis of the interlobular connective tissue within the mammary gland [1]. Incidence ranges from 7 % to 11 % of breastfeeding mothers with a higher incidence in first-time mothers. The most common organisms are staphylococcus and streptococcus species. Risk factors for mastitis include improper nursing technique leading to milk stasis, nipple fissuring/cracks allowing entry for bacteria, stress, and sleep deprivation contributing to a weakened immune system and poor milk production [1]. Presentation includes fever, flu-like symptoms, axillary adenopathy, purulent drainage, and leukocytosis. Acute mastitis can develop into abscess formation in approximately 10 % of cases and rarely septicemia.

Treatment for mild infection includes warm compresses, oral acetaminophen, and oral antibiotics (i.e., dicloxacillin, a first-generation cephalosporin, or clindamycin for at least 10 days). Feeding techniques should be observed and improper techniques corrected. Women should continue to nurse or pump frequently unless unable to achieve a good latch. Nursing can continue with intravenous antibiotics and abscess drainage if a good latch is achieved. Cultures of breast milk or purulent material are of little clinical value except when the infection does not respond to conservative management or oral antibiotics. Close follow-up in 48–72 h is warranted, and biopsy should be considered for atypical presentations or persistent/recurrent infections unresponsive to antibiotics.

Recurrent subareolar abscess (Zuska's disease) is a rare bacterial infection of the breast due to squamous metaplasia of one or more lactiferous ducts that obstructs keratin plugs and causes proximal duct dilation. It is characterized by a triad of draining subareolar cutaneous fistulas; chronic thick, pasty nipple discharge; and a history of multiple, recurrent mammary abscess. It is associated with smoking. Treatment includes abscess drainage and excision of the affected duct and sinus tract [1].

Granulomatous mastitis can be due to infection (tuberculosis), foreign material (silicone or paraffin), or systemic autoimmune disease. Microbiologic, immunologic, and histopathologic evaluation is needed for diagnosis. "Idiopathic granulomatous mastitis" describes granulomatous lesions without an identified cause. Recommended treatment includes surgical excision and steroid therapy. Since 50 % of cases continue with persistence, recurrence, and complications, long-term follow-up is necessary [1].

4.2.2 Ectopic or Absent Breast Tissue

The most common congenital breast abnormality is supernumerary and aberrant breast tissue. The most common location is near the breast and on the chest wall, vulva, and axilla although documented occurrences have been reported outside of the milk line including the knee, thigh, buttock, face, ear, and neck. Variances in nipple components (polythelia) and glandular tissue (polymastia) occur and usually have a separate duct system from normal breast. Ectopic breast tissue responds to physiological changes similar to normal breast tissue, and malignancies in ectopic breast tissue are rare [1].

Underdeveloped breast tissue can be congenital or acquired. Congenital disorders associated with hypoplasia include ulnar-mammary syndrome, Turner's syndrome, congenital adrenal hyperplasia, and Poland's syndrome that are associated with breast cancer. Acquired hypoplasia is usually a result of trauma or radiotherapy. Amastia, the absence of breast and nipple, and amazia, the presence of nipple but absence of breast tissue, are rare [1].

DOI 10.1007/978-1-4939-0779-3_113-1

4.3 Nipple Discharge

Nipple discharge occurs in nearly 7 % of women referred for breast disorder evaluation with approximately 5 % having serious underlying pathology [2]. Pathologic findings include discharge in postmenopausal women or women over 50 years old, persistent discharge, spontaneous discharge, discharge from a single duct, unilateral discharge, gross or occult bloody discharge, clear or serous discharge, or discharge associated with a mass [9].

4.3.1 Galactorrhea

Galactorrhea is defined as milk production more than 1 year after breastfeeding wean or in nulligravid or postmenopausal women. It is most commonly caused by hyperprolactinemia from pituitary tumor, hypothyroidism, or medications such antipsychotics, metoclopramide, opiates, cocaine, and some antihypertensives [16]. Other causes include renal disease and chest wall inflammation from a thoracotomy, burns, herpes zoster, or topical irritation from clothing. Evaluation involves a thorough history, characteristics of the discharge, and laboratory evaluation including renal function, prolactin, and thyroid-stimulating hormone (TSH) levels. Imaging may be needed. Treatment with dopaminergic agonists can be initiated if prolactin and TSH levels are normal [2].

4.3.2 Non-galactorrheal Discharge

Non-galactorrheal, or non-milky, discharge warrants investigation based on the number of ducts involved. Single-duct etiologies include intraductal papilloma, ductal carcinoma in situ, and Paget's disease, thus warranting further investigation. Multiple duct discharge can be due to fibrocystic changes or ductal ectasia (discussed below) and requires further workup if bloody; otherwise, reassurance can be provided for clear, serous, green-black, or non-bloody discharge that commonly occurs with fibrocystic disease [2]. If the discharge is bloody, galactography can be performed to evaluate for space-occupying lesions. Cytological evaluation of discharge fluid has a 35–47 % sensitivity for detecting malignancy and may be of limited diagnostic value.

4.3.3 Mammary Duct Ectasia

Mammary duct ectasia (periductal mastitis or comedomastitis) is a chronic inflammatory reaction resulting in permanent ductal distension. It presents with thick, white or discolored, cheesy nipple discharge; palpable subareolar mass; noncyclic breast pain; or nipple inversion or retraction though it can also be asymptomatic. It can be identified as microcalcifications on mammography. Mammary duct ectasia can mimic invasive carcinoma especially in middle-aged to elderly parous women and may have an association with smoking. Though biopsy may be required to exclude malignancy, mammary duct ectasia should be managed conservatively [1].

4.4 Benign Breast Masses

Risk factors for developing benign breast masses include both genetic influences and environmental exposures. On pathologic examination, benign breast lesions are frequently found to have loss of heterozygosity [2]. Population studies have shown that first-degree relatives of patients with breast cancer have a higher rate of benign breast disease [17, 18]. In addition to increased risk of breast cancer, women with BRCA1 or BRCA2 genetic mutations have a high rate of multiple benign lesions [2].

Hormonal factors likely play a large role in the development of breast lesions. Postmenopausal use of estrogen replacement (regardless of concomitant progestin use) may more than double the risk for benign breast lesions [2]. Conversely, tamoxifen use for breast cancer prevention is associated with a 28 % decrease in prevalence of benign lesions [2]. OCPs have also shown a decreased risk [18]. Early studies have shown that serum levels of estrogen, insulin, C-reactive protein, and adiponectin are independent

DOI 10.1007/978-1-4939-0779-3_113-1

risk factors for benign proliferative breast disease although investigation is needed [19]. Some studies have shown that lifestyle modifications such as increased physical activity; increased intake of vegetable oils, nuts, vitamin E, and fiber; and decreased consumption of alcohol, animal fat, and red meat may lower risk of benign breast disease [20].

Benign breast masses are broadly categorized into three histological categories: nonproliferative lesions, proliferative lesions without atypia, and atypical hyperplasia. This grouping correlates to future risk of developing cancer as the degree of cellular proliferation is related to an increased risk of breast cancer in patients with benign breast conditions [21]. Nonproliferative disease carries no increased risk of breast cancer, but proliferative disease without and with atypia has a relative risk of 1.3–1.9 and 4.1–5.3, respectively [13]. Findings on biopsy, age at biopsy, and family history of breast cancer are risk factors for breast cancer for those diagnosed with benign breast masses. Additional risk factors include increased breast density on mammography, high postmenopausal plasma levels of free estradiol and testosterone, and greater than 20 kg (44 lb) weight gain after menopause, early menopause, early menarche, and late childbearing [2].

Statistically, 9 out of 10 new nodules in premenopausal women are benign [2]. The vast majority of biopsies (approximately 70 %) will demonstrate nonproliferative lesions [1]. Current recommendations suggest that all women with a dominant, discrete, palpable lesion should have surgical referral in addition to imaging based on age and risk factors as described above. If nodularity is vague, thickened, or asymmetric, an exam can be repeated at mid-cycle for one or two menstrual cycles in the premenopausal patient. If resolved, reassurance can be provided; otherwise, the patient should be referred to a surgeon with breast imaging.

4.4.1 Nonproliferative Lesions

Nonproliferative lesions are further divided and include fibrocystic changes of cysts and ductal ectasia, mild hyperplasia, nonsclerosing adenosis, periductal fibrosis, simple fibroadenomas, lobular hyperplasia, juvenile hypertrophy, and stromal hyperplasia. Traumatic lesions that include hematomas, fat necrosis, and lesions caused by foreign bodies are also in the category of nonproliferative lesions. Other lesions in the category include benign tumors such as hamartomas, lipomas, phyllodes tumors, solitary papillomas, neurofibromas, giant adenomas and adenomyoepitheliomas; infections such as granulomas and mastitis; sarcoidosis; squamous and apocrine metaplasia; and diabetic mastopathy.

Cysts Cysts are fluid-filled, round, or ovoid structures derived from the terminal duct lobular units that occur in one-third of women between 35 and 50 years old. Late menopause, hormone-replacement therapy use, and thin stature are associated with increased prevalence of cysts [2]. Cysts represent approximately 25 % of breast lesions [1, 11]. Ultrasonography has the ability to distinguish fluid-filled cysts from solid lesions. Simple cysts as diagnosed on imaging (BI-RADS 2) are almost always benign; therefore, it is not necessary to aspirate these lesions [13]. Complex, complicated, or atypical cysts are characterized by internal echoes, thin septations, thickened/irregular walls, or lack of posterior enhancement on ultrasonography and can be managed with follow-up imaging. An intracystic mass/nodule should be regarded as "suspicious for neoplasm" and consideration for core-needle or surgical biopsy [1]. Non-bloody fluid can be discarded, but if recurrent, a surgical consult should be obtained. Bloody fluid should be sent for pathology and a surgical consult placed [2] obtained.

Fibrocystic Changes Fibrocystic changes are the most frequent benign disorder of the breast of premenopausal women between 20 and 50 years of age, encompassing 50 % of clinical and 90 % of histological presentations [1]. It is commonly described as "lumpy" breasts or nondiscrete, tender or painful breast nodules in multifocal regions or bilaterally. Symptoms usually begin just prior to menses

DOI 10.1007/978-1-4939-0779-3_113-1

and diminish once menses start and are rare in postmenopausal women. Both solid lesions including adenosis, epithelial hyperplasia with or without atypia, apocrine metaplasia, radial scar, and papilloma as well as irregular cysts without discrete mass occur. These changes are thought to be a result of estrogen's predominance over progesterone [1]. FNA can provide symptomatic relief and confirm the diagnosis. Aspiration of clear or milky fluid should be followed clinically for at least 3 months to assure that there is no recurrence [1]. Bloody fluid or no fluid aspirated with a palpable mass, residual mass or thickening, or mass recurrence warrants further evaluation and possible excisional biopsy. Mammography and ultrasonography should also be performed prior to further tissue sampling.

Fibroadenomas Fibroadenoma is the most common benign breast tumor [13]. Typical presentation is a firm, mobile, discrete breast mass, most often unilaterally, though can be multiple and have a bilateral appearance. The peak incidence is 15–35 years of age and is generally discovered by the patient [1]. These lesions tend to grow during pregnancy, in the luteal phase of the menstrual cycle, as well as in the third and fourth decades of life due to an exaggerated hormonal response [2]. If a lesion is clinically and radiographically suspected to be a fibroadenoma, biopsy may be omitted and followed with serial ultrasonography, though some surgeons may recommend that all discrete masses be biopsy proven, especially among BRCA carriers [2]. If performed, biopsy-proven fibroadenomas need not be followed by serial ultrasounds [2]. Fibroadenomas and phyllodes tumors have similar physical and radiographic features, but phyllodes tumors need excision due to risk of malignancy and high rate of recurrence [13].

Fat Necrosis Fat necrosis of the breast typically presents as a superficial small, ill-defined, painless or painful inflammatory mass most commonly in the periareolar region [1, 21]. Causes include accidental trauma, postoperative changes, or radiation therapy. Affected areas either enlarge, remain unchanged, or resolve spontaneously. If symptoms persist longer than 1 week, biopsy should be performed to rule out malignancy as it can also be associated with carcinoma or any lesion that provokes suppurative or necrotic degradation (i.e., mammary duct ectasia, fibrocystic disease with large cysts) [1]. Areas of fat necrosis present as oil cysts, smooth or microcalcifications, asymmetries, or spiculated masses on mammography. Findings on ultrasonography and MRI are varied and depend on the extent of fibrosis, inflammatory reaction, and amount of liquefied fat. Fat necrosis may clinically and radiographically mimic malignancy but has classic histological characteristics [1]. Needle biopsy may be indicated to further investigate findings though it may be avoided if the MRI is conclusive [22].

4.4.2 Proliferative Lesions Without Atypia

These include usual ductal hyperplasia, complex fibroadenomas, sclerosing adenosis, papilloma or papillomatosis, radial scar, and blunt duct adenosis.

Usual Ductal Hyperplasia Usual ductal hyperplasia is characterized by proliferation of epithelial cells within the mammary ducts without distorting the architecture of the ducts themselves. Usual ductal hyperplasia does not confer an increase in breast cancer risk, and no additional treatment is needed [1].

Intraductal Papilloma Intraductal papillomas may present as a breast mass; however, most women will present with serous or serosanguinous nipple discharge [1]. Presentation is during ages of 30 and 50 years [13]. A single, central papilloma is benign and does not confer an increased risk for subsequent breast cancer. However, papillomatosis (at least five separate papillomas in one segment of breast tissue) does increase the risk of malignancy, and therefore, bilateral diagnostic imaging and surgical referral are needed [3]. Up to one-third of women with papillomatosis will have either an existing or subsequent malignancy [13].

DOI 10.1007/978-1-4939-0779-3_113-1

Sclerosing Adenosis Sclerosing adenosis is a benign proliferative disease that can mimic carcinoma on pathology and imaging [1]. It typically presents as a palpable mass or as an incidental finding on screening mammography. No treatment or follow-up is indicated for this lesion.

Radial Scar Radial scar is often found as an incidental finding on pathology; however, it may mimic carcinoma on imaging [1]. When discovered, patients should be referred to surgery for excisional biopsy to ensure benign diagnosis due to the increased risk for malignancy [13].

4.4.3 Atypical Hyperplasia

Atypical hyperplasia encompasses both atypical ductal hyperplasia (ADH) as well as atypical lobular hyperplasia (ALH). ADH confers up to fivefold increase in risk for subsequent breast cancer [13]. Premenopausal women with ADH have a significantly higher risk of developing carcinoma compared to postmenopausal women [1]. ADH appears morphologically similar to ductal carcinoma in situ (DCIS); however, architecturally the cells only fill a small portion of the duct [1]. These lesions are often first detected by microcalcifications on mammography [1]. Due to the increased risk of subsequent cancer, women diagnosed with ADH should be closely monitored with clinical breast examination every 6 months and annual mammograms [8]. ALH appears histologically similar to lobular carcinoma in situ (LCIS), the latter being notable for a greater degree of proliferation. ALH is most prevalent in perimenopausal women and typically found as an incidental finding on pathologic examination [1]. Unlike DCIS, ALH is not a precursor lesion to breast cancer and does not need to be excised; however, it is a risk factor for the development of future breast cancer [13].

4.5 Breast Disease During Pregnancy

The dynamic changes in estrogen and progesterone levels during pregnancy cause increased breast size, firmness, and nodularity returning to the prepregnancy state within 3 months of breastfeeding cessation. Palpable masses in a pregnant or lactating patient that persist for 2 weeks or longer should be evaluated with ultrasound. Ultrasound-guided biopsy may need to be performed for new solid mass in a pregnant or lactating patient. If biopsy is deferred, then close clinical follow-up and repeat imaging is recommended. Overall, eighty percent of palpable breast masses present in pregnancy are benign [23].

Fibroadenomas are the most common benign tumor in pregnancy and lactation. Due to growth that may outpace the increase in vascular supply, these tumors may infarct. Lactating adenomas, which occur in the third trimester and during lactation usually, regress after cessation of breastfeeding. Presentation is typically either solitary or multiple, mobile, and discrete lesions less than 3 cm [1]. These lesions may arise in ectopic locations such as the axillae, chest wall, or vulva and often spontaneously resolve. Surgical treatment may be needed for patient comfort, and there is no increased risk of malignancy [1].

Galactoceles are painless, palpable masses that commonly appear after the cessation of breastfeeding. They occur as a consequence of ductal obstruction and milk inspissations. Most do not require aspiration, but ultrasound-guided aspiration may be indicated if the mass is bothersome. Bloody nipple discharge can occur in the third trimester or during lactation due to minimal breast trauma along with epithelial proliferation and new capillary formation. Without a palpable mass, ultrasound can be performed to exclude papilloma or intraductal carcinoma. Ductography or postpartum MRI can be performed if further evaluation is needed. Mastitis has the highest incidence during the first 6 weeks postpartum [23]; see above for further details.

Table 4 Agents associated with gynecomastia

Cardiovascular medications
Amiodarone, amlodipine, angiotensin-converting enzyme inhibitors, atorvastatin, diltiazem, fenofibrate, digoxin, nifedipine, rosuvastatin, verapamil, spironolactone
Anti-infectious agents
Antiretroviral agents – didanosine, isoniazid, ketoconazole, penicillamine, metronidazole, minocycline
Hormonal agents
Estrogen agonists, estrogens – *whether taking it himself, or absorbing it from a sexual partner who uses vaginal cream or ring*, testosterone, gonadotropin-releasing hormone agonists, human chorionic gonadotropins, phytoestrogens, clomiphene, bicalutamide, nilutamide, anabolic steroids
Psychiatric medications
Diazepam, fluoxetine, haloperidol, mirtazapine, paroxetine, risperidone, tricyclic antidepressants, venlafaxine
Miscellaneous
Alcohol, amphetamines, alkylating agents, cimetidine, cisplatin, corticosteroids, etomidate, finasteride, flutamide, heroin, hydroxyzine, marijuana, meprobamate, methadone, methotrexate, methyldopa, metoclopramide, minoxidil, omeprazole, phenytoin, ranitidine, reserpine, sulindac, theophylline, vinca alkaloids

4.6 Male Breast Conditions

4.6.1 Gynecomastia

Gynecomastia is the proliferation of glandular breast tissue in men due to disruption of the estrogen to progesterone ratio [24]. It can be categorized as physiologic or nonphysiologic. On exam there is palpable, firm glandular tissue in a concentric mass around the nipple-areolar complex. Physiologic gynecomastia makes up one-fourth of cases, is self-limited, and occurs in newborns, adolescents, and older men. Nonphysiologic gynecomastia covers a wide range of diagnoses, and one-fourth of cases are due to idiopathic or unknown causes. This must be differentiated from pseudogynecomastia that is a proliferation of adipose rather than glandular tissue associated with obesity.

Nonphysiologic conditions include persistent pubertal gynecomastia, medications and substances (10–25 %), cirrhosis (8 %), primary and secondary hypogonadism (8 % and 2 %, respectively), hypothyroidism (2 %), renal disease (1 %), refeeding after starvation, and tumors (3 %).

One-half of adolescent males experience gynecomastia typically starting between 13 and 14 years of age or Tanner stage 3 or 4 with resolution in 6 months to 2 years. Persistence beyond 2 years or after 17 years of age warrants further evaluation. If no underlying causes can be found and treatment is desired, testosterone supplementation, estrogen-receptor-modifying agents, or surgical referral are options.

A wide variety of medications are known to cause gynecomastia (see Table 4). Antipsychotics, antiretroviral, and prostate cancer therapies are common culprits. Lavender, tea tree oil, dong quai, soy consumption of more than 300 mg per day, and *Tribulus terrestris* in performance-enhancing supplements have also been linked to gynecomastia. Regression occurs with discontinuation of causative agent within 3 months except with the use of anabolic steroids, marijuana, heroin, or amphetamines.

Treatment includes discontinuing any offending agents and treating underlying causes. Tamoxifen has been shown to have modest effect for physiologic, persistent pubertal, or idiopathic gynecomastia. Raloxifene, dihydrotestosterone, danazol, clomiphene, aromatase inhibitors, and surgery are other options.

Approximately 10 % of patients with testicular tumors present with gynecomastia alone with Leydig cell tumors having the highest frequency due to estradiol secretion. Adrenal, testicular germ cell, liver, gastric, and bronchogenic tumors can manifest with gynecomastia as well. While obtaining an initial history, care should be taken to explore for constitutional symptoms that may indicate malignancy though male breast cancer accounts for approximately 1 % of all breast cancer cases [25].

Breast Cancer

Bradley M. Turner* and David G. Hicks
School of Medicine and Dentistry Strong Health Highland Hospital, University of Rochester Medical Center, Rochester, NY, USA

General Principles

Definition/Background

Except for skin cancer, **breast cancer** is the most common cancer in women worldwide [1], and it is the leading cause of cancer-related mortality, with almost 50 % of cases and nearly 60 % of deaths occurring in lower-income countries [1]. For women in the United States (USA), it is the most common cancer [2, 3], the second most common cause of cancer-related mortality, and the leading cause of cancer-related mortality in women age 20–59 [4]. Family physicians play an important role in screening, diagnosis, and follow-up of breast cancer patients and can be a valuable part of a multidisciplinary team approach [5–10].

Classification

Breast cancer is classified as either in situ or *invasive*. In situ breast carcinoma (CIS) is classified as either **ductal carcinoma in situ** (DCIS), the most frequent type, or **lobular carcinoma in situ** (LCIS). DCIS accounts for 20–25 % of newly diagnosed breast cancers in the USA [11] and is considered a neoplastic, non-obligate precursor of **invasive breast carcinoma** (IBC). Similar to IBC, DCIS treatment involves surgery, with possibly medical and/or radiation therapy. LCIS is not considered a precursor lesion at this time, but *is* associated with an increased long-term risk of bilateral IBC. LCIS is typically treated with follow-up observation. Invasive ductal carcinoma (no specific type), accounts for approximately 75–80 % of IBC, **lobular carcinoma** for about 10 %, with the remaining 10–15 % classified into special histologic types based on specific morphologic features [12].

Epidemiology

Approximately 43 % of IBC is diagnosed in women ≥65 years of age (median age 61) [13], and approximately 20 % in women <50 years of age. Approximately 72 % of breast cancer survivors are ≥age 60, with fewer than 10 % being <50 years of age [13]. A woman has a 1 in 8 (12.3 %) **lifetime risk** (LR) of developing breast cancer and a 1 in 37 (2.7 %) LR of dying from breast cancer [14, 15]. These are average risks, and individual risk will depend on individual risk factors. In January 2014, more than 3.1 million US women were living with IBC [13], with an estimated additional 232,670 and 58,000 new diagnoses of IBC and CIS expected that year, respectively [3, 4]. The LR of developing and dying from **male breast cancer** is 1 in 769 (0.13 %) and 1 in 3,333 (0.03 %), respectively [14, 15]. It is estimated that 2,240 new cases of male breast cancer (median age, 67) occurred in the USA in 2014, with approximately 410 men dying from breast cancer-related causes that year [4].

The **incidence** of IBC rose steadily among women of all age groups until 1985 and then stabilized until 1993. Between 1993 and 1999, in women ≥50 years of age, incidence rates increased again (remaining stable in women <50). The reason for this is not clear, but may be attributable to the prevalence of mammography screening, rising rates of obesity, and increased menopausal hormone use [3]. Subsequent changes in mammography screening rates and decreased use of menopausal hormones may at least partly

*Email: bradley_turner@urmc.rochester.edu

DOI 10.1007/978-1-4939-0779-3_114-1

explain the decline in IBC rates between 1999 and 2004. Since 2004, the incidence of IBC seems to have stabilized again for all women, estimated at 122.2 cases per 100,000 women [4]. Incidence of CIS also rose steadily through the 1980s, but unlike IBC, continued to rise until about 1999, particularly in women ≥50 years of age. As of 2014 [13], the incidence of CIS has generally stabilized in women ≥50 years and older, but continues to increase in women <50 years of age.

After slowly increasing for many years (0.4 % annually from 1975 to 1990), the **mortality** from breast cancer-related causes has improved over the last several years [13]. Death rates have decreased by 2.2 % per year from 1990 to 2007 for women of all ages combined, with a slightly larger decrease among women <50 years of age (3.2 % per year) compared to women ≥50 years of age (2.0 % per year). As of 2014, the mortality from breast cancer-related causes in the USA was 22.6 deaths per 100,000 women [4].

Approach to the Patient

Risk Factors

Improving breast cancer outcomes by early detection remains the cornerstone of breast cancer control [16, 17]. Family physicians are often the first point of contact for patients, particularly for lower-income patients, and particularly in rural areas [5]. As such, they play a critical role in the early detection of breast cancer. Fundamental history taking, although cliché, cannot be overstated [18, 19], as risk factors for cancer may be overlooked during a general history [20]. Identifying specific risk factors for breast cancer is critical in risk stratification for breast cancer screening. A previous history of breast cancer is important to elicit during the history, as it is a significant risk factor for developing a second breast cancer [1]. A family history is critical, because women who have a first-degree relative with breast cancer have almost twice the risk of getting breast cancer as women who have no affected relatives. This risk increases as the number of first degree relatives with breast cancer increases [1]. Approximately 5–10 % of breast cancers are due to germline mutations in breast cancer susceptibility genes, the most prevalent being the **BRCA**1/2 mutations. Women with a BRCA mutation have an increased LR (25–85 %) of developing breast cancer, depending on age and ethnic background [21, 22]. Genetic testing for a BRCA mutation should be considered in women with a personal or family history of breast or ovarian cancer (due to the relationship of the BRCA mutation with ovarian cancer), particularly if the cancer occurred at a young age. Surgical history of previous breast biopsy results (if any) is important, because a history of **atypical ductal hyperplasia** on previous biopsy caries an increased risk of developing breast cancer [23]. Being cognizant of the patients age is important, as the risk of developing breast cancer increases with age (more than 80 % of new diagnoses occur after age 50 [13]). A history of menarche and menopause should be taken. Early menarche and later onset of menopause are associated with an increased risk of breast cancer [1, 24]. Parity history should include age at first birth. Nulliparous women are at increased risk for development of breast cancer, and advanced age at first birth confers a relative risk for breast cancer greater than that of a nulliparous woman. A young age at first birth has an overall protective effect [1, 24]. **Hormone replacement therapy** (HRT) should be discussed, as information on HRT may be confusing to the lay person. The **Women's Health Initiative** (WHI) assessed the long-term effects of HRT in postmenopausal women and found an *increased* risk of breast cancer in women receiving combination HRT (estrogen plus progestin), compared to placebo [25]; however, the WHI estrogen alone trial showed a *decreased* risk for breast cancer in women with previous hysterectomy using estrogen only therapy [26]. More recent data suggests that combination HRT is an acceptable option for treatment of moderate to severe menopausal symptoms in women up to age 59, or within 10 years of menopause [27], and data continues to support that women with decreased risk factors for breast cancer who have a previous hysterectomy might be safely prescribed estrogen alone across all age groups [16, 28, 29].

DOI 10.1007/978-1-4939-0779-3_114-1

The family physician can be an integral part in clarification of these issues, which may result in additional treatment options for certain patients with postmenopausal symptoms. Ethnicity is another risk factor for breast cancer. African American women typically (1) present at an earlier age of onset (median age 54), (2) present at an earlier clinical stage, (3) have more aggressive pathology, and (4) have worse survival outcomes [4, 24]. Other possible increased risk factors for breast cancer which should be discussed include alcohol consumption, lack of physical activity, obesity, and history of radiation exposure [24].

Risk models including the Gail model [30, 31], Claus model [32], and others [33–36] may be helpful in quantifying an individual patients risk for breast cancer and may help to at least partially alleviate concerns in the anxious patient, as the perceived risk is often greater than the actual calculated estimate [37]. A thorough discussion on risk factors during initial and follow-up histories will help the family physician in appropriately directing the patient for screening and, if necessary, diagnostic evaluation.

Screening

Several organizations have made recommendations on screening guidelines [2, 38]. The three classic breast cancer screening tests are **breast self-examination** (BSE), **clinical breast examination** (CBE), and radiographic screening, typically with **mammography**. Several studies [37] have shown that BSE is likely to increase the chances of a woman detecting a benign breast lesion, without any reduction in cancer mortality. The American Cancer Society (ACS) suggests that it is "acceptable for women to choose not to do BSE, or to do BSE occasionally," [38] and currently no organization specifically recommends for a woman to perform BSE [2, 37].

The use of CBE continues to be generally supported by most organizations publishing screening guideline recommendations; however, guidelines differ depending on the organization [2, 38]. Several studies have suggested that the addition of CBE to mammography increases the number of cancers detected, because mammography may miss 10–15 % of palpable masses; however, screening with both CBE and mammography may result in a higher number of false-positive results, compared to women who have mammography alone [2, 37].

There is little debate that radiographic screening reduces rates of breast cancer mortality [2, 37]. There is general agreement that screening mammography should be offered to women 50–74 years of age; however, there are conflicting guidelines for screening women 40–49 years of age, and organizations differ on screening intervals [1, 2, 37]. As with BSE and CBE, screening mammography carries a risk of false-positive results. Estimates are that annual screening of women age 40–69 years of age will result in approximately 16 % of women undergoing unnecessary biopsies [37]. The **United States Preventative Task Force** (USPTF) and the **American Academy of Family Physicians** (AAFP) support routine *biennial* screening for women 50–74 years of age, based on a controversial study supported by the USPTF in 2009 [39]. This study argued two fundamental questions – should mammographic screening maximize (1) the number of breast cancer deaths prevented or (2) the number of years of life gained by early detection? The latter would result in a significant number of false-positive results, leading to unnecessary biopsies, without a significant reduction in breast cancer-associated mortality [37, 39]. The consensus decision within the USPTF was to support maximizing the number of breast cancer deaths prevented, resulting in a reduction in the amount of recommended screening. A recent update of the 2009 USPTF recommendations stated that the decision to have screening mammography for breast cancer in women <50 years of age "should be an individual one" taking into account "a woman's own situation and her values regarding specific benefits and harms."[40] The USPTF is currently in the process of once again updating their recommendations on breast cancer screening [40].

Screening controversies have created the greatest confusion for women with a LR for breast cancer diagnosis of <15 % (as defined by models that are largely dependent on family history), the largest group. Radiographic screening recommendations for a high (≥20 %) or moderate (15–20 %) LR of breast cancer

DOI 10.1007/978-1-4939-0779-3_114-1

diagnosis are less controversial or poorly defined, respectively. **Magnetic resonance imaging** (MRI) is recommended in women at high LR for breast cancer (Table 1) [41]. Ultrasound is not recommended for screening, but may be an option for those high-risk women who either cannot undergo MRI or demonstrate dense breast parenchyma by mammography [41].

What does this mean for the family physician counseling a patient on breast cancer screening? Breast cancer screening should be discussed in relation to the patient's risk factors, the comfort level of the patient and the physician, and the limitations of the physician**.** The patient should be counseled on the differences between **breast self-awareness** (the concept that a woman should know how her breasts normally look and feel, and be aware of changes) and the benefits and limitations of BSE (a step-by-step approach using a specific schedule to examine her breasts). The value of CBE should be discussed, acknowledging the possibility of finding a palpable lesion which may actually be benign. The value of screening mammography should be discussed in the same light, as approximately 1 in 10 women who have a screening mammogram will need further evaluation, and in most cases, additional testing will be negative for cancer [37, 42]. Certainly, women at increased risk for breast cancer should be considered for more aggressive screening. Ultimately the decision should be individualized, keeping the patient's life expectancy, functional status, and goals of care in mind [2, 42, 43].

Diagnosis

History and Physical Exam

Diagnostic evaluation starts with either a presenting complaint on history or an incidental finding on physical examination. After the estimated risk for breast cancer has been determined, the patient should be assessed for specific symptoms. *Any patient at high risk* for breast cancer presenting with *any* of the symptoms or signs below should be considered for referral to a subspecialist. Presenting symptoms specific to the breast include **breast pain**, **nipple discharge**, breast **asymmetry or thickening**, **changes in the breast skin** (color changes, nipple excoriation, eczema, ulcers), and a **palpable mass**. Breast pain without any other findings on physical exam is rarely a sign of carcinoma, and most women with carcinoma do not present with breast pain [44]. Careful history to elicit the duration and frequency of the pain is important, as cyclic breast pain may be related to menstrual cycling. Nipple discharge is also rarely a sign of carcinoma; however, the likelihood of nipple discharge being secondary to carcinoma does increase with age [44]. The physical exam can be helpful in determining if a nipple discharge warrants additional investigation. Most pathologic discharges contain blood and are unilateral and spontaneous. Non-spontaneous, bilateral, and/or non-bloody discharge in a women <40 should be reassured and observed and referred if symptoms persist. Non-spontaneous, bilateral, and/or non-bloody discharge in

a women ≥40 warrants a referral for diagnostic mammogram, with appropriate follow-up. *Any* spontaneous or bloody discharge warrants referral to a subspecialist. Breast asymmetry, thickening, or skin changes should be referred to a subspecialist for consultation, with consideration for diagnostic imaging. Women presenting with a breast mass should be promptly considered for diagnostic imaging but reassured until a final diagnosis is made by the radiologist, as normal structures mistaken for a mass include a prominent rib or costochondral junction, the normal glandular nodularity of the premenopausal breast, the inframammary ridge, or a firm margin at the edge of a previous biopsy site [44]. Suspicious masses tend to be hard, firm, and/or fixed, with irregular borders. Benign masses tend to be more mobile, with more well-demarcated borders. General malaise, bony pain, and weight loss, while not specific for breast cancer, may be other symptoms that women with breast cancer present with, and should prompt additional investigation by the family physician, particularly in women at high risk for breast cancer.

Laboratory and Imaging

The **assessment categories for mammographic evaluation** are outlined in Table 2.

Workup of a suspicious presentation should be tailored to the patients' age and the physician's index of suspicion. Breast asymmetry, breast thickening, breast skin changes, non-spontaneous bilateral non-bloody nipple discharge (women ≥40), any spontaneous bloody nipple discharge, and any palpable breast mass all warrant consideration for diagnostic imaging and appropriate follow-up. For women <30, ultrasound ± diagnostic mammogram is typically recommended (except for skin changes, in which case diagnostic mammogram ± ultrasound is recommended). For women ≥30, diagnostic mammogram ± ultrasound is recommended [44]. Subsequent follow-up is based on the diagnostic imaging findings (Table 3). For all clinical presentations, *any* increase in clinical suspicion should warrant referral. In *any* patient in whom return visits are unsure, or in the extremely anxious patient, referral to a subspecialist with adequate documentation is recommended [43].

Biopsy

A definitive diagnosis of breast cancer is obtained through tissue sampling (needle aspiration, needle core biopsy, or excisional biopsy) by the treating surgeon. The final diagnosis is made by the pathologist. If breast cancer is diagnosed, additional laboratory studies may be requested in preparation for post-biopsy consultations. Several of these studies can be done by the family physician (CBC, liver enzymes, and alkaline phosphatase) at a post-biopsy office visit, reinforcing the family physician as a part of the multidisciplinary treatment team. Other studies may be required, including a bone scan, computed tomography (CT) scan, MRI, or positron emissions tomography (PET) scans. Genetics and fertility

Table 2 Breast Imaging-Reporting and Data System (BI-RADS) categories[a]

BI-RADS category	CATEGORY ASSESMENT
0	Needs additional imaging evaluation
1	Negative
2	Benign finding
3	Probably benign finding
4	Suspicious abnormality
5	Highly suspicious of malignancy
6	Known biopsy-proven malignancy[b]

Clinical presentation	1	2	3	4	5
Breast asymmetry/thickening	Observe[b]			Refer for consultation	
Breast skin changes	Refer for consultation regarding diagnostic imaging[c]				
Non-spontaneous discharge	Observe[d]		Observe[e]	Refer for consultation	
Spontaneous discharge	Refer for consultation regarding diagnostic imaging[c]				
Palpable mass (<30 years old)	Observe[f]		Refer for consultation		
Palpable mass (≥30 years old)	Refer for consultation	Observe[g]	Refer for consultation		

[a]Adapted from National Comprehensive Cancer Network [44]
[b]Physical exam every 3–6 months and repeat diagnostic imaging every 6–12 months for 2–3 years
[c]Surgical consultation prior to deciding on the need for and type of diagnostic imaging
[d]Follow normal screening recommendations
[e]Repeat diagnostic imaging at 6 months, and then every 6–12 months for 2–3 years, if clinical suspicion is low and the discharge is stable or resolving
[f]Repeat diagnostic imaging every 3–6 month for 1–2 years if clinical suspicion is low and the patient has a negative ultrasound or if the mass is a simple cyst
[g]Anything other than a simple cyst, BI-RADS category 2 should be referred for further follow-up (including a negative ultrasound or a BI-RADS category 1 finding)

counseling may be a consideration. Decisions on these additional studies and counseling should always be considered in consultation with the treating surgeon, medical oncologist and radiation oncologist [45].

Treatment

Familiarity with staging and various treatment options makes the family physician a valuable resource to the patient during this difficult time period, again reinforcing the family physician's role as part of the multidisciplinary treatment team.

Staging

After the diagnosis of breast cancer is made, the patient is clinically staged. Staging takes into account clinical, radiologic, and pathologic information, including tumor size, and the presence and extent of both lymph node involvement and metastatic disease to non-nodal tissue [46]. Along with other clinically significant **prognostic factors** (Table 4) staging helps to dictate treatment options, including neoadjuvant chemotherapy, which may reduce the stage and increase the possibility of the patient receiving **breast conserving therapy** (BCT) [1, 46].

Surgery

In 2011, approximately 59 % of women with earlier stage (stage 0–2) breast cancer were candidates for and chose some combination of BCT (as opposed to mastectomy) with or without radiation and /or chemotherapy [3]. This option is less available to women with later stages (stages 3 and 4) of breast cancers. In 2011, approximately 59 % of women with later stages of breast cancer received some combination of mastectomy with or without radiation and/or chemotherapy [3]. Approximately 1 % of women with earlier stage cancer, and approximately 10 % of women with later stage cancer, opted not to have any treatment in 2011 [3], a decision the physician should be prepared to discuss with the patient.

Table 4 Clinically significant prognostic factors in breast cancer[a]

Clinical stage
Tumor grade
Hormone receptor status (ER, PR)
Her-2 status
Paget's disease
Circulating tumor cells (blood)
Disseminated tumor cells (bone marrow)
Multigene signature scores (i.e., Oncotype Dx®)

[a]Adapted from Edge et al. [50]

Radiation

Radiation therapy can be administered locally to the chest wall, regionally based on lymph node distribution and involvement, to part of the breast (partial breast), or to the whole breast (whole breast). The decision as to which type of radiation should be given is made by the radiation oncologist in collaboration with the treating surgeon and medical oncologist, based on the type of mastectomy (partial vs. total), tumor characteristics, margin status, and the presence and extent of lymph node involvement. Although radiation therapy has not been shown to affect survival [1, 46], it has been shown to decrease local **recurrence** by approximately 50 %. Seventy percent of all recurrences occur within 5 years [1, 47]. Risk factors for local recurrence include positive margins, young age, hormone receptor status, larger tumor size, positive nodes, and lymphovascular invasion [1].

Adjuvant Hormonal and Systemic Chemotherapy

Chemotherapy has also been shown to reduce the risk of local recurrence [1]. Current guidelines for adjuvant **hormonal** and **systemic** chemotherapy treatment for IBC vary depending on **estrogen receptor** (ER), **progesterone receptor** (PR), and **human epidermal growth factor receptor-2** (HER-2) expression [1, 46]. The decision as to which type(s) of therapy given is made by the medical oncologist in collaboration with the treating surgeon and radiation oncologist. Hormonal therapy is given for patients with ER- or PR-positive disease, with consideration for menopausal status. For premenopausal women, **tamoxifen** is typically given for at least 5 years, with consideration for ovarian ablation or suppression. For postmenopausal women some combination of an **aromatase inhibitor** and tamoxifen is typically given, with the use of only a single agent at a time, for at least 5 years. Typical systemic chemotherapy regimens for breast cancer will include doxorubicin/cyclophosphamide followed by paxitaxel, either weekly or every two weeks. **Trastuzumab** ± pertuzumab is added for Her-2 positive disease [46]. Multiple other systemic chemotherapy regimens exist. Patients on systemic chemotherapy require periodic cardiac monitoring, and this can be provided by the family physician in coordination with subspecialty consultation. Patients may present to the family physician with a variety of **side effects**. It is helpful to have contact information for all subspecialists on the multidisciplinary team, in case consultation is required for chemotherapy side effects.

Breast Reconstruction

Breast reconstruction is an optional procedure that has been associated with an improved quality of life for many patients. It is typically discussed with the treating surgeon in consultation with plastic surgery, prior to the initial surgery. Reconstruction is adapted to the patient's individual clinical situation including plans regarding radiation, comorbid disease, body habitus, and smoking status. The family physician can play an integral role in co-management of these latter three considerations. Reconstruction options

DOI 10.1007/978-1-4939-0779-3_114-1

include breast implants and/or autologous tissue transplantation (donor tissue taken from another body site such as the abdomen, back, buttocks, or thigh) and typically require a series of procedures: (1) the initial reconstruction (which may occur at the time of the mastectomy or at some point in the future), (2) subsequent surgery on the contralateral breast to improve symmetry, (3) possible revision surgery involving the breast implant or donor tissue site, and finally (4) nipple and areola reconstruction with tattoo pigmentation [46].

Follow-Up Care

Several randomized studies have suggested that in patients with early stage breast cancer, when **follow-up** care is delivered by a family physician compared with **specialist-led follow-up**: (1) there are no differences in **recurrence**-related serious clinical events; (2) there are no differences in health-related quality of life; (3) that patients may be more satisfied; and (4) that overall health-care costs might be decreased [8, 12, 48, 49]. Research has also shown that most recurrences are detected by patients during the intervals between routine follow-up visits [12]. These patients may present to the family physician first. In addition, frequently patients will present to their family physician – not to their specialist – for psychosocial complaints (the most common issue raised during follow-ups [8]) and complaints about posttreatment **side effects** [12]. In women who undergo surgery with radiation, **lymphedema** can be a long-term side effect, if the patient also had either a sentinel lymph node biopsy and/or axillary node dissection (6 % and 20 % incidence of lymphedema, respectively). Other long-term side effects with radiation include numbness, tingling, or tightness in the chest wall, arms, or shoulders. Between 25 % and 60 % of women develop chronic pain. Treatment with **chemotherapy** can lead to impaired fertility and premature menopause (which increase the risk of osteoporosis) as well as cardiomyopathy and congestive heart failure (anthracyclines and HER-2-targeted drugs). Treatment with **aromatase inhibitors** can also cause osteoporosis, as well as myalgia and arthralgia. Treatment with **tamoxifen** can cause postmenopausal symptoms. Patients with breast cancer may also experience cognitive impairments and chronic fatigue [46]. While these complaints may be directly related to posttreatment side effects, some may be warning signs of **recurrence**. *Any* suspicion for recurrence should be immediately referred to the subspecialist for additional evaluation. Certain patients are more appropriate for **specialist-led follow-up** including later stage patients, patients treated with adjuvant hormonal therapy with a planned switch to an alternative agent after 2 or 5 years, high risk of early relapse, significant recurrence-related anxiety, and a history of poor compliance with treatment and/or follow-up [12].

Prognosis

Clinically significant prognostic factors are shown in Table 4. Stage is the single most influential prognostic factor for breast cancer survival [46, 50]. The overall 5 year –**relative survival rate** (RSR) – for women with breast cancer is approximately 89 % for all races, with a noticeably lower 5-year RSR for African American women (79 %) [4]. Localized (stage 0–1) breast cancer has a significantly better 5-year RSR (99 %) compared to regional (84 %) and distant-stage (24 %) breast cancer, reiterating the importance of early detection [4, 46, 50]. Regrettably, only 61 % of breast cancers (52 % for African American women) are diagnosed at the local stage [4]. Continued education, focus on breast cancer risks, and proper screening will hopefully increase the number of women who are diagnosed at an earlier stage.

DOI 10.1007/978-1-4939-0779-3_114-1

Conclusion

There is ample evidence supporting the role of the family physician in the care of patients at risk for and those who have been diagnosed with breast cancer [5, 7–10, 23, 48, 49]. The patient's history, including risk factors for breast cancer, is critical in directing the patient for appropriate screening. The family physician can be valuable part of the multidisciplinary team caring for the breast cancer patient, providing first-line support, evaluation of posttreatment side effects, and early referral for suspected recurrences.

Acute Pelvic Pain in Women

Background

Pelvic pain is a common complaint in both the acute and primary care settings. The differential is broad and is dependent upon the patient's age and whether or not she is pregnant. Aside from reproductive etiologies, genitourinary, gastrointestinal, and musculoskeletal causes must also be considered [1]. Acute pelvic pain has been defined as pain lasting less than 48 h, whereas chronic pelvic pain has been present for at least 6 months [2]. This section will specifically focus on acute pelvic pain with an emphasis on an evidence-based approach using clinical history and physical examination skills.

History

Just as with any patient that enters an exam room, the key to the evaluation of pelvic pain lies within the physician's ability to take a thorough and accurate history. The patient should be asked about the quality, intensity, location, timing, duration, radiation, and exacerbating and alleviating factors. Inquiry should also be made into associated symptoms (urinary, gastrointestinal, and musculoskeletal). Past medical and surgical histories should be obtained, with special attention to gynecologic or abdominal pathology. Sexual history should be taken with emphasis on LMP, sexual partners, and history of sexually transmitted infections [3].

Physical Exam

An important step in evaluating pelvic pain, is the ability to assess the severity of the woman's condition. First, look at her vital signs. Fever is an indication of an inflammatory process, such as infection Hypotension may be a sign of hemorrhage, such as with a ruptured ectopic pregnancy or a hemorrhagic cyst. Next, assess the patient's general appearance. Is she well appearing, toxic, or something in between?

The clinician must then determine if the woman's symptoms are from an abdominal or pelvic source, which can be done through physical exam. The key to an appropriate abdominal examination is assessing for signs of peritoneal irritation. This is confirmed by involuntary guarding, rebound tenderness, and increased pain with an increase in intra-abdominal pressure, such as with movement or cough [4]. Following the abdominal exam, a pelvic exam should be performed for further assessment of the patient's symptoms. The examination should begin by visual inspection of the external genitalia. A speculum examination is necessary to visualize the cervix and vagina [3]. If discharge is present, it should be noted and sampled for further evaluation. Gonorrhea and chlamydia testing would also be warranted at this time. The cervix should be palpated through bimanual exam, taking note of its position and for any tenderness. With the other hand, press down on the lower abdominal wall to assess the uterus for tenderness or masses. There are definite limitations to pelvic examination to include experience of examiner, patient anxiety, and body habitus [5].

DOI 10.1007/978-1-4939-0779-3_115-1

Labs

All premenopausal patients should receive a urine pregnancy test as part of the evaluation. Urine b-hCG tests are sensitive to 25 mIU per mL and positive 3–4 days after implantation [6]. A vaginal wet mount should be obtained and ideally interpreted with microscopy quickly to assess for presence of *T. vaginalis*. White blood cells on wet mount would support a diagnosis of pelvic inflammatory disease (PID). Gonorrhea and chlamydia testing should be performed. Studies have found that vulvovaginal samples are more sensitive than endocervical samples for detecting chlamydia in both symptomatic and asymptomatic woman [7]. Vulvovaginal samples were also found to have the highest sensitivity for detecting gonorrheal infection in a similar study [8]. Other laboratory studies are ordered based upon physical exam and history findings. Leukocytosis may be seen in PID, appendicitis, and pyelonephritis, and thus if suspected, obtain a CBC. Studies have found that only 60 % of women with PID have an elevated serum white blood cell count, which is only of value if elevated [9]. Erythrocyte sedimentation rate (ESR), a non-specific inflammatory marker, may be elevated in PID and ectopic pregnancy, so could be considered. In the pregnant patient, Rh testing is performed if there is concern for threatened abortion [4]. Urinalysis and culture is when patient has urinary-related complaints.

Imaging

Imaging modalities such as ultrasonography, computerized tomography (CT), and magnetic resonance imaging (MRI) are excellent choices in the evaluation of acute pelvic pain due to their high accuracies [10]. The American College of Radiology (ACR) recommends transvaginal and transabdominal ultrasound in the evaluation of acute pelvic pain in both pregnant and nonpregnant patients in the reproductive age group. An MRI is second line in this population if ultrasound is inconclusive or nondiagnostic. CT abdomen and pelvis with contrast should be used only in nonpregnant, reproductive age patients if MRI is not available, as radiation dosage should be taken into consideration. CT, however, demonstrates the improved diagnostic performance in identifying gastrointestinal and urinary causes of pelvic pain. CT scan is 95–100 % sensitive in diagnosing appendicitis, whereas transabdominal ultrasound is approximately 67 % sensitive. IV contrast is required for optimum accuracy in diagnosing pyelonephritis, pelvic venous thrombosis, and most bowel pathologies [11].

Diagnosis/Management

To determine the etiology in a woman presenting with acute pelvic pain, the clinician must utilize the diagnostic tools discussed above. Top priority is to rule out life-threatening conditions, such as ectopic pregnancy, ruptured tubo-ovarian abscess, and appendicitis [3].

The Pregnant Patient

Ectopic pregnancy should be considered in all pregnant women presenting with abdominal or pelvic pain. Women with a history of previous ectopic, tubal surgery, and tubal pathology or who have an intrauterine contraceptive device in place are at an increased risk of ectopic pregnancy. Transvaginal ultrasound is the imaging modality of choice. Early referral is recommended given surgery is the principal treatment option [12].

The most common cause of abdominal or pelvic pain in the pregnant patient is spontaneous abortion. These women often present with dull or cramping pain that may be either constant or intermittent. Vaginal bleeding may be an accompanying symptom. The cervical os should be visualized on speculum exam, which can then be used for classification of the abortion. Pelvic ultrasound is instrumental in the diagnosis. These findings will guide the management either medically or surgically [13].

DOI 10.1007/978-1-4939-0779-3_115-1

Table 1 Infectious Causes of Acute Pelvic Pain

Diagnosis	Risk factors	Clinical signs	Treatment
Pelvic inflammatory disease	Sexually active IUD *N. gonorrhea/C. trachomatis* infection	Fever >101 F Abdominal pain Vaginal discharge +/− CMT on bimanual exam	One time dose of 250 mg IM ceftriaxone + 100 mg of doxycycline BID for 14 days +/− metronidazole Alternate to doxycycline is 1 gm of azithromycin q week for 2 weeks
Tubo-ovarian abscess	Typically a complication of PID, thus presentation per above.	Signs of rupture Hypotension Tachycardia Tachypnea Peritoneal signs Acidosis	If hemodynamically unstable, surgical consultation is advised If abscess less than 9 cm give 250 mg ceftriaxone × 1 dose, 100 mg doxycycline BID for 14 days and metronidazole 500 mg BID for 14 days
Endometritis	Postpartum Postoperative (D&C, hysteroscopy) Previous gonorrhea/chlamydia infection	Fundal tenderness Foul-smelling vaginal discharge +/− fever	Hospital admission with broad spectrum antibiotic (gram positive and gram negative) +/− metronidazole

Infectious Gynecologic Causes of Pelvic Pain

Endometritis

Endometritis, an infection of the lining of the uterus, may occur postpartum or as part of an ascending infection. Women with recent instrumentation of the endometrial cavity such as hysteroscopy or dilation and curettage are at increased risk of endometritis, as are women with a previous episode of PID preceded by confirmed infection with chlamydia or gonorrhea. Symptoms of general endometritis typically include pelvic pain, general malaise, abnormal vaginal discharge, bleeding [14]. Postpartum endometritis is associated with fundal tenderness and foul-smelling vaginal discharge. Acutely, neutrophils may be seen on wet prep and the patient may have a fever. Antibiotics both parenteral and oral are the mainstay of treatment. Due to the polymicrobial nature of endometritis, a combination of broad spectrum antibiotics with both gram-positive and gram-negative coverage is recommended. Providers should also consider adding metronidazole given a reported association between bacterial vaginosis and endometritis [15].

Pelvic Inflammatory Disease (PID) and Tubo-Ovarian Abscess (TOA)

PID is most common in women aged 20–29. Clinically, the diagnosis has been made based on abdominal tenderness with or without adnexal or cervical motion tenderness on bimanual examination, with supporting laboratory findings. Studies have found that clinical symptoms are not as sensitive or specific as laparoscopy [16]. The CDC recommends empiric treatment for PID in sexually active women if they are experiencing pelvic or lower abdominal pain if no cause identified for illness other than PID, and if the patient has cervical motion tenderness, uterine tenderness, or adnexal tenderness. To further enhance the specificity of the minimum criteria and support a diagnosis of PID, the patient should also have either an elevated temperature (>101 F), abnormal cervical or vaginal discharge, increased numbers of WBCs on wet prep, elevated ESR, elevated CRP, or documentation of infection with *N. gonorrhea* or *C. trachomatis*. The recommended outpatient treatment is 250 mg of IM ceftriaxone in a single dose

DOI 10.1007/978-1-4939-0779-3_115-1

plus 100 mg of doxycycline twice daily for 14 days with or without 500 mg metronidazole twice daily for 14 days. An alternative to doxycycline is 1 gm of azithromycin once a week for 2 weeks [15].

Tubo-ovarian abscess is a complication of untreated PID; however, women over age 40 and those with IUDs in place are also at risk. If abscess rupture is suspected, prompt surgical evaluation is necessary. Clinical signs include hypotension, tachycardia, tachypnea, peritoneal signs, or acidosis. In the absence of evidence of rupture, surgical exploration and treatment is generally advised in a woman with signs of sepsis. Women without signs of hemodynamic instability and an abscess less than 9 cm in diameter and are premenopausal are candidates for antibiotic therapy alone [17]. Antibiotic therapy should include coverage for sexually transmitted pathogens (*N. gonorrhea* and *C. trachomatis*) as well as anaerobes. The CDC recommends a minimum of 2 weeks of antibiotic treatment and close follow-up is necessary if outpatient treatment is being considered [15].

Infectious Gynecologic Causes of Acute Pelvic Pain

See Table 1.

Noninfectious Gynecologic Causes of Acute Pelvic

Dysmenorrhea

Dysmenorrhea is a common cause of pelvic pain and is defined as painful cramps that occur with menstruation. Onset is typically 6–10 months after onset of menses. Primary dysmenorrhea refers to menstrual pain in the absence of pelvic pathology. Pelvic examination is necessary only in those individuals that are sexually active. The treatment options for primary dysmenorrhea include nonsteroidal anti-inflammatory drugs and hormonal contraceptives. Secondary dysmenorrhea should be suspected when additional symptoms such as abnormal uterine bleeding, dyspareunia, and noncyclic pain are present and when pelvic examination is abnormal, thereby suggesting an underlying pathology. Further evaluation of secondary dysmenorrhea should start with transvaginal ultrasound once infectious etiologies such as gonorrhea and chlamydia have been ruled out.

Endometriosis is the most common cause of secondary dysmenorrhea. Pelvic exam may reveal increased uterine mobility, adnexal masses, or uterosacral nodularity. The pain of endometriosis is typically cyclic and may be associated with dyspareunia, dysuria, and dyschezia. Adenomyosis is also associated with menorrhagia with possible intermenstrual bleeding. Bimanual exam is likely to reveal an enlarged, tender, boggy uterus in adenomyosis. Leiomyomata presents with cyclic pelvic pain with menorrhagia and fibroids may be appreciated on pelvic examination. The treatment of dysmenorrhea associated with endometriosis is combined oral estrogen-progesterone; however, depot medroxyprogesterone, the etonogesterel implant (Nexplanon), and the levonorgestrel-releasing intrauterine device (Mirena) have also been proven effective [18].

Ovarian Cysts

Functional ovarian cysts are relatively common in women of reproductive age; they tend to be asymptomatic and resolve over the course of 4–8 weeks with expectant management. The rupture of a follicular cyst causes a release of fluid, which may cause acute pain due to irritation of the peritoneum. The pain may be severe initially; however, it resolves without treatment. Corpus luteum cysts, being more vascular, can lead to severe hemorrhage and pain similar to a ruptured ectopic. Stable patients were previously managed through surgical laparoscopy if the diagnosis was not certain; however, CT scan can replace the diagnostic laparoscopy. Hemodynamic compromise, uncertainty of torsion, symptoms unrelenting for over 48 h, increasing hemoperitoneum on ultrasound, or decreasing hemoglobin are indications for surgical intervention [19].

DOI 10.1007/978-1-4939-0779-3_115-1

Adnexal Torsion

Adnexal torsion is an uncommon gynecologic emergency that occurs when the ovary, fallopian tube, or both twist on the utero-ovarian ligament. Prompt diagnosis is necessary to ensure surgical restoration of the blood supply in order to salvage the ovary and tube. This is often difficult as it presents similarly to other pelvic and abdominal conditions and the imaging features associated with torsion may be nonspecific. The patient typically presents with acute onset abdominal pain, within the past 24 h. Other clinical features are leukocytosis, nausea/vomiting, palpable abdominal mass, and fever. Doppler studies should be performed in addition to ultrasonography if torsion is suspected, as lack of arterial or venous flow of the involved adnexa is often seen in those individuals with abnormal Doppler findings. A normal Doppler study does not necessarily rule out adnexal torsion. Ultrasonography with Doppler has been shown to be more accurate in diagnosing adnexal torsion compared with CT scan in some studies [20].

Nongynecologic Causes of Acute Abdominal Pain

Gastrointestinal

Appendicitis is the most common cause of nongynecologic cause of acute pelvic pain. Patients generally present with right lower quadrant abdominal pain with migration of pain from the periumbilical area. Fever, psoas sign, rebound tenderness, and rigidity may also be found on physical examination. If the diagnosis remains unclear, imaging studies with either ultrasonography or CT are useful in making the diagnosis.

Diverticulitis should be suspected in the adult patient with left lower quadrant abdominal pain, fever, and leukocytosis. Patients with suspected diverticulitis are often evaluated with CT scan, which is useful if the differential also includes appendicitis [1].

Urinary Tract Disorders

Pyelonephritis, lower urinary tract infection, and nephrolithiasis can lead to acute pelvic pain. Lower urinary tract infections usually present with dysuria, urgency, frequency, and suprapubic tenderness. Urinalysis and culture can confirm the diagnosis and the patient can be treated with appropriate oral antibiotics. Similar symptoms are often seen in pyelonephritis with the addition of fevers, chills, and costovertebral angle and flank tenderness. If uncomplicated, outpatient management with appropriate antibiotics is warranted.

Nephrolithiasis often presents with severe and colicky pain which radiates from the flank into the pelvis. Associated nausea and emesis may be seen. Urinalysis is positive for blood and imaging studies reveal the stone and a dilated ureter or kidney. Expectant management with pain control and IV or oral hydration is the mainstay of treatment [16].

Conclusion

In the evaluation of acute pelvic pain, the clinician must first rule out the emergent, life-threatening conditions. Given the broad differential, a thorough and complete history, physical examination, and urine pregnancy test are indicated in every patient presenting with pelvic pain. Your clinical judgment should then lead you to order the appropriate labs and imaging as discussed above to arrive at the correct diagnosis.

Pelvic Pain in Men

Women are not the only sufferers of pelvic pain; however, the differential between men and women presenting for pelvic pain varies vastly. The nongynecologic causes as discussed above should be considered in both men and women reporting pelvic pain.

DOI 10.1007/978-1-4939-0779-3_115-1

Table 2 Diagnosis of Toxic Shock is based on the presence of two majorcriteria, or one major criteria and one minor criteria

TSS major criteria (all must be present)	Minor criteria (three or more)
Fever (temp > 102 F) **Rash** Erythroderma followed by desquamation Mucous membrane: oral, vaginal, conjunctival **Hypotension** (systolic BP < 90)	**CNS**: Altered mental status w/o focal deficit **Cardiovascular**: Distributive shock, arrhythmia, non-specific ST wave EKG changes, heart failure **Pulmonary:** Pulmonary edema, respiratory distress syndrome **Gastrointestinal:** Nausea, vomiting, diarrhea **Hepatic:** Elevated liver-associated enzymes **Renal:** Elevated blood urea nitrogen **Hematologic:** Thrombocytopenia, anemia, leukopenia **Musculoskeletal:** Creatinine kinase greater than twice the upper limit of normal **Metabolic:** Hypocalcemia, hypophosphatemia

Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) presents as lower abdominal (pelvic) pain and/or urologic symptoms. The National Institutes of Health (NIH) has classified this syndrome into four categories. Acute bacterial prostatitis (category I) is characterized by acute illness, urinary tract infection symptoms, pelvic pain, and cloudy urine. Patients with chronic bacterial prostatitis (category II) typically present with recurrent symptoms of urinary tract infection with repeated isolation of the same urinary pathogen [21]. CP/CPPS can be further subdivided into inflammatory versus noninflammatory causes, although the symptoms are generally the same. Common presentation includes pain (pelvic, low abdomen, urinary, testicles, and perineum, with ejaculation), difficulty with urination, and at times hematospermia [22].

All men should undergo a urinalysis with culture initially. Gonorrhea and chlamydia testing should be obtained if suspicion, based on sexual history. Diagnostic imaging may be pursued on a case-by-case basis, dependent upon symptoms at presentation. CT scan is considered if abdominal pain is present, whereas ultrasound is the imaging of choice when testicular pain is the chief complaint. Bladder ultrasound and measurement of post-void residual volume is considered with symptoms of incomplete emptying [23].

Alpha-blockers are often prescribed for men with CP/CPPS, although there is lack of substantial evidence to support their use. Alpha-blockers are; however, known to improve lower urinary symptoms, which may also be found in benign prostatic hyperplasia in addition to CP/CPPS. Alpha receptors are located within the central nervous system; thus, blockade has been implicated in reduction of pain in long-term pain syndrome. Alpha-blockers may also reduce inflammation of the lower urinary tract, which has been implicated as one of the causes of CPPS [24].

Toxic Shock Syndrome

Toxic shock syndrome (TSS) was a highly researched topic in the 1980s and after numerous cases was documented associated with higher absorbancy tampons. The incidence of TSS has declined after some of the brands of tampons were discontinued [25]. TSS is caused by a specific strain of *S. aureus* that produces toxin TSST-1 and enterotoxins A–E. The toxins act as superantigens stimulating a release of cytokines, prostaglandins, and leukotrienes. CDC reports symptoms including fever (temperature greater than 102), diffuse macular erythroderma, desquamation (1–2 weeks after onset of rash), hypotension, and multisystem involvement involving three or more organ systems [26]. Abscesses, cellulitis, bursitis, postpartum infections, postsurgical procedures, vaginal infections, and intrauterine devices have been associated with TSS [25] (Table 2).

DOI 10.1007/978-1-4939-0779-3_115-1

Chronic Pelvic Pain

Background

Chronic pelvic pain (CPP) is defined as a non-menstrual, noncyclical pelvic pain that has been present for at least 6 months, not related to cancer, severe enough to interfere with daily activities, often requiring medical or surgical intervention and treatment [27–34]. Reported prevalence rates range from 3.8 % to 24 % in women aged 15–73 years [34], roughly 15 % of the female population [35]. Pelvic pain accounts for up to 39 % of primary care visits [34] and is the single most common indication for referral to gynecology [36]. CPP accounts for up to 20 % of secondary care appointments [37]. In the United States, direct and indirect health-care costs exceed two billion dollars a year [34, 36]. CPP is often associated with negative behavioral, cognitive, sexual, and emotional consequences [38], as well as increased drug and alcohol use and abortion [29, 34]. Patients with CPP are more likely to have a history of spontaneous abortion, military service, c-section delivery, sexually transmitted disease, nongynecologic surgery, nonpelvic somatic complaints, multiple sexual partners, and psychosexual trauma and abuse [28, 30–32, 35, 39].

The pathophysiology of CPP is poorly understood [40, 41] and is often multifactorial. CPP is rarely found to be due to a single cause [36]. Up to 60 % of patients will not receive a diagnosis for their CPP [34, 35]. Symptoms are often suggestive of urinary tract, gastrointestinal, pelvic floor, or gynecological sources [37]. This complex interaction of organ systems, along with the psychological burden associated with chronic pain, has led to the recommendation to treat pelvic pain with a multidisciplinary approach [28, 30–32, 39–41].

History

As with any patient in the primary care setting, history taken from the patient regarding her pain is of utmost importance. A full review of systems is indicated [35], as is a full history of previous work-up for the pain, including all surgical and nonsurgical diagnostic approaches [28, 35]. It is important also to discuss with the patient how her CPP affects her daily activities and sexual function and satisfaction. Treatments tried in the past, both that provided relief and those that did not, are helpful in teasing out the next steps in both diagnosis and management [28].

A discussion with the patient regarding her pain, in terms of character, quality, intensity, radiation, and causative and alleviating factors, should occur [35]. It is important for the provider to differentiate between visceral and somatic pain when taking a history. Visceral pain is typically reported as dull, crampy, and poorly localized and can be associated with nausea, vomiting, and sweating due to autonomic feedback [35]. Somatic pain, because it originates from muscles, bones, and joints, will be reported as sharp or dull and is localized. Neuropathic pain is reported as burning or paresthesia [35].

Physical Exam

The physical exam for a patient with chronic pelvic pain is similar to that for a patient presenting acutely and should be performed gently [28], and chaperones should always be present, with at least one person of the medical team being female [35]. The exam should begin with a gait analysis [31, 32, 34, 35], paying attention to her movement and of her sitting pose. Heart and lung exam, as well as appropriate HEENT exam, should also be part of this comprehensive evaluation. Upon evaluation of her abdomen, listen for bowel sounds in each quadrant. She should then be inspected for scars of her abdominal wall, masses in her abdomen, tenderness, as well as rebound or fluid shifting [31, 32, 34, 35].

A pelvic exam should be performed last and should be performed after the patient voids [34]. First, inspection of the tissues of the external genitalia is key, to note discoloration, scarring, or signs of dermatologic or infectious processes [35]. A moist cotton swab can be used to determine any point

DOI 10.1007/978-1-4939-0779-3_115-1

tenderness of the external structures [28]. A gentle digital exam can help determine if there is pelvic floor weakness, spasms, and tenderness [28, 31, 32, 34, 35]. A speculum exam is necessary to inspect the internal vaginal vault, and samples can be obtained for pap smear (as appropriate), wet prep, and cultures for sexually transmitted infection testing [35]. It is important to note the appearance of the cervix and if there is discharge present [34, 35]. Use of one-half of the speculum with pressure placed posteriorly or anteriorly in the vaginal vault can help assess for pelvic organ prolapse. The pelvic exam is completed with a bimanual exam, noting any cervical motion tenderness and tenderness with palpation of the posterior portion of the bladder or of the ovaries and uterus themselves [28, 34, 35].

A rectal examination is also warranted in the evaluation of CPP. It should include anoscopy to evaluate for lesions, internal hemorrhoids, inflammation, fissures, fistulas, or abscesses [35]. Colonoscopy may be warranted if the patient has a report of hematochezia or is greater than 50 [28].

Psychological assessment should be included as part of the complete evaluation of a patient with CPP and should be performed by a health psychologist or psychiatrist who is familiar with CPP [31, 32]. Factors to be considered with this assessment include the patient's understanding and meaning of her pain; impact on her functional roles; emotional functioning; coping mechanisms; knowledge of what can exacerbate her pain, quality of her relationships with her family, friends, and care team; and social support [31, 32].

Labs and Imaging

Due to the multifactorial etiology and pathophysiology of the source of pelvic pain [37, 35], a six-point system has been developed to assist the physician in guiding the work-up. Named "UPOINT," it consists of recommendations for *u*rinary, *p*sychological, *o*rgan specific, *i*nfectious, *n*eurological, and *t*ender musculature causes [37]:

- *Urological*: assess urine flow and voiding diary; consider cystoscopy, ultrasound, and flowmetry
- *Psychological*: assess for depression, history of abuse, pregnancy losses, coping mechanisms (catastrophizing), feelings of hopelessness or helplessness
- *Organ Specific*: assess genital and urinary structures and anorectal exam and asks questions regarding sexual dysfunction and stooling patterns
- *Infectious*: take samples for urine and genital infections, consider stool cultures
- *Neurological*: assess complaints of paresthesias and dysesthesias, perform neuro testing as part of examination to include sensory, reflexes, and muscular function testing
- *Tender Musculature*: assess by palpating pelvic floor muscles, abdominal muscles, and gluteal muscles

Specifically, labs that are indicated in the evaluation of CPP include b-hCG; pap smear (as indicated by age and history of past pathology on pap smears); gonorrhea and chlamydia testing; wet prep evaluation for yeast, bacterial vaginosis, and trichomoniasis; hemoccult testing; urinalysis; and urine culture. Other testing to consider includes ESR and CRP to evaluate for chronic inflammatory processes, such as inflammatory bowel disease or antitissue transglutaminase antibody tests for celiac disease [28].

Imaging commonly performed includes a pelvic ultrasound, to evaluate the bladder, uterus, and ovarian structures [29]. Transvaginal ultrasound is more sensitive to evaluate for pelvic masses and adenomyosis than transabdominal scanning [31, 32]. In other cases, an MRI may be indicated, as this was found in one study to determine the cause of CPP in up to 39 % of cases [35]. MRI is useful for characterizing pelvic masses and is the imaging modality of choice for diagnosing adenomyosis [31, 32]. Laparoscopy, cystoscopy, and hysteroscopy allow direct visualization of the involved structures and can also be useful for the evaluation of CPP [28, 29, 34, 35].

DOI 10.1007/978-1-4939-0779-3_115-1

Diagnosis and Management

The four most common causes of CPP include endometriosis, adhesions (intra-abdominal/intrapelvic), interstitial cystitis, and irritable bowel syndrome [28, 35].

Several organs and organ systems have been implicated in the cause of CPP [37, 42]:

- Bladder pain syndrome
- Urethral pain
- Vulvar pain syndrome
  - Generalized
  - Local
- Vestibular pain
- Clitoral pain
- Dysmenorrhea
- Pelvic floor muscle pain
- Coccyx pain
- Irritable bowel syndrome
- Chronic anal pain
- Intermittent chronic anal pain
- Pelvic bone stress fracture

The most common cause of chronic pelvic pain is endometriosis [35], defined as the presence of endometrial tissue outside of the endometrial cavity [31, 32, 35]. Incidence is 1–7 % and affects primarily nulliparous women in their 20s and 30s. Unfortunately, diagnostic laparoscopy to determine the presence of endometriosis is negative in half of the cases [29, 31, 32, 36]. Adenomyosis is defined histologically as the presence of endometrial glands and stroma deep within the stroma of the uterus. It is a condition in which the uterus is often enlarged and boggy and is associated with pain, dysmenorrhea, and menorrhagia [31, 32]. Adenomyosis is diagnosed with use of US or MRI and has an incidence in up to 70 % of cases of CPP, occurring in the fourth and fifth decades of life [31, 32]. Adhesions can arise from chronic pelvic inflammatory disease, prior surgery, endometriosis, or unknown factors [31, 32]. Somewhat controversial as a cause of CPP, adhesions are found in up to 50 % of patients undergoing laparoscopic evaluation for CPP. Up to 33 % of women who suffer from CPP have a history of pelvic inflammatory disease, thought to be related to adhesions that resulted from the infection [31, 32]. Uterine fibroids are associated with pain, dysmenorrhea, pressure, and menorrhagia [31, 32].

Interstitial cystitis is a nongynecological source of CPP that is manifested by bladder pain, urinary frequency, urgency, or nocturia. Pain is often suprapubic [31, 32, 35, 37]. Bladder pain syndrome is thought to be caused by a defect in the permeability of the urothelial glycosaminoglycan layer, leading to mast cell activation, histamine release, neurogenic inflammation, and upregulation of afferent nerve signals [37, 43]. Childbirth, surgery, bacterial infections, instrumentation, or autoimmune processes are considered possible insults contributing to bladder pain syndrome [37]. After initial evaluation to rule out infection, voiding diaries can help with diagnosis and to monitor treatment [28]. Cystoscopy to perform intravesical potassium sensitivity testing has a specificity of 83 % and sensitivity of 73 % [28].

Irritable bowel syndrome is the chronic presence of abdominal pain three or more days a month, associated with changes in stool frequency or form (loose vs. solid) [35]. IBS is a diagnosis of exclusion, and other causes such as Crohn's, celiac disease, lactose intolerance, and milk/food allergies must be ruled out. Up to 79 % of patients with CPP have IBS, and 60 % will have associated dysmenorrhea [35].

DOI 10.1007/978-1-4939-0779-3_115-1

Treatments

Medications implicated in the treatment of CPP are primarily analgesics, such as NSAIDs. Naproxen is the preferred NSAID due to long half-life. Medications such as gabapentin and carbamazepine, phenytoin, and clonazepam have also been found to be useful as they inhibit the excessive stimulation of accessory neurons. Tricyclic antidepressants such as amitriptyline have been found to assist with CPP as well, restoring sleep and improving pain tolerance. The use of opioids in the treatment of CPP is controversial, although it may allow return of normal function of the patient if pain is controlled. Due to risk of addiction and the comorbid psychological diagnoses often associated with CPP, it is recommended that opioid use for treatment of CPP be a last resort [28] and in a tertiary center equipped and experienced for management of chronic pain [39]. Selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs) have level III evidence in treatment of refractory pain [28].

CPP associated with endometriosis is often managed with hormonal treatment, such as estrogen-progestin combinations, progestins alone, danazol, or GnRH agonist, with or without NSAID therapy [31, 32]. The theory is that CPP that varies with menstrual cycling will respond to the suppression of the hypothalamic-pituitary-gonadal axis [28].

NSAIDs are the first-line therapy for interstitial cystitis, although studies have not found NSAIDs or opioids to be routinely effective [35]. Pentosan polysulfate sodium (PPS) is approved by the FDA for treatment of IC and is thought to mimic the normal glycosaminoglycan layer that protects the urothelium that is dysfunctional in IC [35, 43]. Treatment may require up to 6 months to be effective, but is effective in up to 32 % of patients [28, 31, 32, 35]. Dietary modifications have also been suggested in the treatment of IC, such as elimination of foods suspected to aggravate the urothelium, including caffeine, alcohol, spicy and acidic foods, artificial sweeteners, and carbonated beverages [28].

IBS can be treated with dietary modifications. Diarrhea-predominant IBS may respond to loperamide, cholestyramine, and rifampin. Constipation-predominant IBS is treated with supplemental fiber, stool softeners, and cathartics such as lactulose and polyethylene glycol. TCAs, muscle relaxants, and SSRIs have also been helpful in treating IBS [35].

It should not be overlooked that women who suffer from CPP also may suffer from concomitant psychosocial problems as related to past history of abuse, both sexual and emotional, as well as anxiety and depression [34]. Treatment of these comorbid conditions is key in treating the whole patient and necessary for success.

Surgical Interventions and Approach to Management of CPP

Denervating procedures, such as presacral neurectomy and uterosacral ligament resection, have been studied as treatment modalities for CPP. The results in the randomized controlled trial (RCT) are inconsistent and cannot be recommended [39].

Hysterectomy may be indicated in the treatment of CPP and up to 18 % of hysterectomies are performed for CPP [39]. Hysterectomy is an acceptable treatment for endometriosis, adenomyosis, and uterine fibroids [31, 32].

Adhesion lysis was not found to be beneficial except in the setting of severe adhesions [40, 41].

Hydrodistention of the bladder by urogynecologists with intravesical instillations with dimethyl sulfoxide or bacille Calmette-Guérin has been shown to decrease pain for IC (2).

Conclusion

Chronic pelvic pain is a multifactorial process, can involve more than one organ system, and should be treated with a multidisciplinary approach to include physical therapy for pelvic floor muscle dysfunction and psychiatry or behavioral health specialists. Successful treatment requires a positive patient-provider relationship. First-line medications indicated for treatment of CPP include NSAIDs and hormone therapy

DOI 10.1007/978-1-4939-0779-3_115-1

for appropriate indications (i.e., endometriosis). Narcotics are not indicated in the treatment of chronic pelvic pain, except in the most extreme of cases and with the assistance of a pain management treatment facility.

Endometriosis

First described over 150 years ago by Rokitansky [44], endometriosis is a disease that is defined by the presence of endometrial tissue found outside of the uterus, such as on the ovaries, on the fallopian tubes, inside the peritoneal cavity, inside the posterior cul-de-sac, and on the bowel; lesions have even been noted in the lungs, the brain, and bones and on or in the skin [44–46]. Primary symptoms reported are pain, increased menstrual flow, and infertility [44–46]. An estimated 10–15 % of all reproductive aged women suffer from endometriosis [44–46]. Up to one-third of patients undergoing evaluation for pelvic pain are found to have endometriosis, with 40 % of infertile women being found to have the disease [47]. Risk factors identified for endometriosis include first-degree relative with endometriosis, early menarche, late menopause, low BMI, Müllerian anomalies, nulliparity, prolonged menses (>5 days), and shorter lactation intervals. Pathogenesis of endometriosis is thought to be multifactorial. In the 1920s, Sampson proposed retrograde menstruation, a theory that continues to be the most widely accepted [45]. It is theorized that endometrial tissue can be transported in a retrograde fashion through the fallopian tubes into the peritoneal cavity [45] and can implant onto other structures. This theory is supported by a study that found menstrual blood in the peritoneal fluid in 90 % of healthy women evaluated at the time of their menses [46].

Another theory suggested in the 1960s by Ferguson is that of coelomic metaplasia, which is related to the theory that the peritoneum contains undifferentiated cells [45]. This theory suggests the transformation of normal peritoneal tissue into endometrial tissue, under the influence of endogenous stimuli such as hormonal or immunological factors to promote the differentiation of cells into endometrial cells [46].

The theory of benign metastasis suggests through lymphatic or hematogenous spread endometrial cells can lead to ectopic endometrial implants and endometriosis is established [45, 46]. It is this theory that is supported by findings of endometrial lesions found in the bone, lungs, and brain [46].

In the setting of the endometrial cells in abnormal locations, appropriate conditions also must be present for them to continue to survive and proliferate. Several processes have been studied and suggested. First, cell-mediated immunity is thought to be impaired in women with endometriosis, thus preventing clearance of the refluxed or otherwise traveled endometrial cells and fragments [45]. Leukocytes do not recognize the endometrial cells as abnormal in location and are thought to be resistant to lysis by the natural killer cells [46]. After the endometrial tissue implants, the immune system is further thought to potentiate the disease. This is thought to occur by increased numbers of leukocytes, macrophages, and cytokines in the peritoneal fluid, leading to inflammation, recruitment of capillaries, and ultimate proliferation of vascular supply to support the endometrial implants. Upregulation of tumor necrosis factor-α (TNF-α) and interleukin-8 (IL-8) in women with endometriosis promotes this proliferation and adhesion of endometrial implants, and local increase in cytokines may help facilitate neovascularization. The expression of vascular endothelial growth factor (VEGF) is found in high concentrations in the peritoneal fluid of women with endometriosis and correlates with the stage of the disease [46].

The inflammatory nature of endometriosis is due to the increased number of macrophages found in the peritoneal fluid. A unique protein similar to haptoglobin was identified from the peritoneal fluid of women with endometriosis, which was found to bind to the macrophages, limit their phagocytic capacity, increase their production of interleukin-6 (IL-6), and positively impact inflammation. Further, the peritoneal fluid

DOI 10.1007/978-1-4939-0779-3_115-1

in women with endometriosis is rich in prostaglandins, and together these processes are thought to contribute to the pain and infertility experienced by patients [46].

Endometriosis affects fertility in up to 40 % of women [47], with an estimated 50 % of women with endometriosis suffering from infertility [44]. As previously discussed, endometriosis is associated with inflammation in the peritoneum. This inflammation is thought to alter ovulation and appropriate oocyte formation [45]. Additionally, the luteal phase is disrupted, likely a result of dysregulation of the progesterone receptors. The inflammatory effects also impact sperm motility, limiting ability of the sperm to fertilize the oocyte. Further, the inflammation can have toxic effects on the embryo and cause implantation failure [45]. Adhesions can develop due to the inflammation processes and lead to poor tubal function, tubal motility, disordered myometrial contractions [45], and ectopic pregnancy.

Treatment of Endometriosis

NSAIDs are considered first-line therapy for treatment of pain associated with endometriosis, but there is inconclusive evidence regarding effectiveness in relieving pelvic pain [47]. NSAIDs work by blocking the activity of COX-1 and COX-2 enzymes, inhibiting prostaglandin production, and inducing apoptosis of ectopic endometrial cells. This is despite the evidence that COX-2 activity has been demonstrated in high concentrations from the ectopic endometrial cells, as well as high levels of prostaglandins in the peritoneal fluid of patients with endometriosis. The side effect profile for NSAID use includes peptic ulcer disease, increased bleeding risk, and anovulation [47].

OCPs are also considered first-line therapy. Their mechanism of action is inhibition of gonadal estrogen, suppressing ovarian activity, reducing estrogen-induced production of prostaglandins, and decreasing inflammation [47]. Best results have been demonstrated with continuous use OCP or those that allow for shorter duration of days off (4 vs. 7) with the placebo pills in a pill pack, limiting the recovery phase of estrogen synthesis. Limitations in OCP use for treatment of endometriosis include desired fertility, increased thromboembolic events in smokers and women aged 35 or older, and quick return of disease state upon cessation of treatment [47].

Other hormonal treatments have been explored in the treatment of endometriosis. Progestins, GnRH analogues, GnRH antagonists, and selective estrogen receptor modulators are a few that have been studied. Progestins work by blocking central and peripheral mechanisms, leading to less mitogenic action and estrogen-induced proliferation of the endometrial tissues. The endometrium becomes atrophic and creates a pseudopregnancy state. A Cochrane review found that 100 mg/day of medroxyprogesterone acetate (MPA) is effective in control of pain; side effects of this include menstrual irregularities, weight gain, and breast tenderness. The levonorgestrel-releasing IUD has been used to treat endometriosis of the rectovaginal septum, providing relief in dysmenorrhea, dyspareunia, pelvic pain, and the size of endometrial implants. Similarly, Implanon (depomedroxyprogesterone acetate) has been seen to decrease pelvic pain in patients with endometriosis. Norethisterone acetate (NETA) causes hypoestrogenism by gonadotropin suppression and ovulation inhibition, leading to development of amenorrhea and atrophy of the endometrium. NETA has been found to help reduce pelvic pain in women with endometriosis and has a positive effect on calcium metabolism. More specifically, a prospective study found that NETA provided relief in women with colorectal endometriosis after 12 months of therapy. Danazol, a synthetic androgen derivative of 17α-ethinyltestosterone, was introduced over 30 years ago for the treatment of endometriosis and works by inducing a hypoestrogenic-hyperandrogenic state which significantly limits endometrial growth. Due to the high androgen levels, side effects such as weight gain, muscle cramps, acne, seborrhea, decreased breast size, hirsutism, and deepened voice have been reported. Gestrinone, a synthetic trienic 19-norsteroid, works by inhibiting the pituitary gland and release of gonadotropins, resulting in ovarian suppression and atrophy of the endometrium and endometrial implants. Although pain is reduced effectively, its use is limited by the anabolic and androgenic side effects [47].

DOI 10.1007/978-1-4939-0779-3_115-1

Table 3 Treatment options for Endometriosis

Medication	Mechanism of action	Effects	Side effects
OCP	Inhibits gonadal estrogen via negative feedback Suppresses ovarian function Reduction in estrogen-induced prostaglandins	Endometrial tissue growth suppressed Protects bone density	Increased thromboembolic events in smokers and women >35 years
NSAIDs	Decreases COX-2 activity Inhibits prostaglandin production Blocks growth of ectopic endometrial cells Induces apoptosis	No sufficient clinical data to prove as effective treatment for pelvic pain associated with endometriosis	Peptic ulcer Anovulation Bleeding risk
Progestins DMPA IUD Nexplanon/ Implanon NETA Danazol Gestrione	Reduces endometrial proliferation Creates pseudo pregnancy state Causes hypoestrogenism Suppresses gonadotropins Inhibits ovulation	Reduction of dysmenorrhea, pelvic pain, and dyspareunia Decreases size of implants Positive effect on calcium metabolism	Menstrual irregularity Breast tenderness Amenorrhea Weight gain Decreased bone mass Muscle cramps Acne Seborrhea Hirsutism
GnRH analogues	Downregulates GnRH receptors on pituitary Suppresses ovarian estrogen production Leads to amenorrhea and regression of endometrium and endometrial implants	Reduces pelvic pain	High rate of recurrence of symptoms after stopping Deterioration of lipid profile Depression Decreased libido Hot flashes Urogenital atrophy Decreased bone mass
Aromatase inhibitors Letrozole Anastrozole Exemestane	Reduces extra ovarian estrogen concentration Inhibits the aromatase conversion of steroidal precursors into estrogens Decreases expression of COX-2	Reduces abdominal-pelvic pain Treatment of recto-vaginal endometriosis	Headache Joint stiffness and joint pain Nausea Diarrhea Flushing Osteopenia/ osteoporosis
Selective estrogen receptor modulators	Estrogen-antagonistic activity at endometrial level	Current data in human studies do not support use	
Immunomodulators Pentoxifylline Infliximab Etanercept	Replaces platelet aggregation by inhibiting platelet phosphodiesterase Suppresses TNF-α, decreasing adhesion and growth of endometrial cells Suppresses angiogenesis IL-12: acts on T and NK cells to increase cytotoxic activity to limit endometrial implantation and growth	Not enough evidence to support use in the management of pain or infertility associated with endometriosis	Increased risk of infections, malignancies

(*continued*)

DOI 10.1007/978-1-4939-0779-3_115-1

Table 3 (continued)

Medication	Mechanism of action	Effects	Side effects
Melatonin	Scavenger of free radicals Broad spectrum antioxidant	No human data	
Selective progesterone receptor modulators Mifepristone Asoprisnil	Induces amenorrhea: mechanisms not yet fully understood	Improves pain Regression of endometrial implants	No significant report
Antiangiogenic agents	Blocks vascular endothelial growth factor Limits implantation and proliferation of endometrial implants	No human data	

Second-line treatment with GnRH analogues works by suppressing GnRH receptors of the pituitary, leading to hypoestrogenism that will subsequently lead to amenorrhea and atrophic regression of endometrial implants. Symptom reduction is seen in up to 50 % of patients, but use is limited due to the worsening of lipid profiles, depression, hot flashes, urogenital atrophy, decreased libido, and loss of bone density. These side effects can be combated with use of bisphosphonates and "add-back therapy" with HRT (hormone replacement therapy). GnRH antagonists recently have been studied, but more clinical trials are necessary before they can be introduced into clinical practice. The mechanism of action is reduction of estrogen levels, but with the advantage of not triggering side effects associated with estrogen deprivation [47].

Aromatase inhibitors, such as letrozole, anastrozole, and exemestane, act by decreasing the conversion of steroidal precursors into estrogen, which also stimulates the expression of COX-2. By blocking this pathway, growth of endometrial tissue is limited and inflammation caused by COX-2 is reduced. Side effects include headaches, nausea and diarrhea, flushing, joint pains and stiffness, and loss of bone density. The effect of these medications is reversible, and "add-back therapy" with HRT or bisphosphonates can be used to combat some of the side effects. Pelvic pain is reduced with use, but will recur after medication discontinuation [47].

Endometriosis is associated with increased free radicals and decreased antioxidants, and melatonin is both a scavenger of free radicals and a natural antioxidant. Use of melatonin has been studied in mice with endometriosis, and results have shown reduced endometrial lesions and increased antioxidant activity [47].

Angiogenesis is the process by which new blood vessels are formed and is necessary for endometrial implants to proliferate. The most important angiogenic factor in the pathogenesis of endometriosis is vascular endothelial growth factor (VEGF). Levels of VEGF are directly correlated to the severity of the disease. By blocking VEGF, the endometrial implants will be unable to proliferate or maintain established implantation. Animal models using antiangiogenic agents have favorable results; no studies have been conducted in humans [47].

Immunomodulators have also been looked at for treating pain and infertility associated with endometriosis, based on the increased levels of cytokines found in the peritoneal fluid of women with endometriosis. Pentoxifylline can suppress the action of TNF-α and vascular endothelial growth factor and influence endometrial implantation, but conflicting results have been obtained in the human studies. Infliximab and etanercept have also been studied in baboon models, again with limited data in humans.

DOI 10.1007/978-1-4939-0779-3_115-1

A Cochrane review has shown that there is not enough data to support the use of immunomodulators in the treatment of endometriosis associated pain or infertility [47].

Treatment of Endometriosis

See Table 3.

Female Infertility

Infertility is defined as the inability to conceive after 1 year of unprotected, regular intercourse or after 6 months if the female partner is aged 35 years or older [48, 49]. A survey from 2006 to 2010 found that over one million US women reported the inability to conceive, with over six million women reporting impaired ability to conceive or carry a pregnancy to term [49]. Similar to rates in other industrialized nations [49], nearly seven million individuals sought out infertility care [49]. Infertility can be due to the female component, the male component, or a combination. Female factors for infertility are discussed here and include ovulation disorders, uterine abnormalities, tubal obstruction or abnormalities, and peritoneal causes [49]. Further, the World Health Organization categorizes ovulatory disorders into three groups. Group I makes up 10 % and is characterized by hypothalamic-pituitary failure. Group II encompassing the majority, 85 %, includes polycystic ovarian failure and other disorders of dysfunction of the hypothalamic-pituitary axis and hyperprolactinemia. Group III, ovarian failure, is made up of approximately 5 % of ovarian disorders [49].

Initial history can assist in identifying a primary cause for infertility and help guide the initiation of the evaluation. Menstrual history, timing and frequency of coitus, prior use of contraception, prior pregnancies and outcomes, pelvic or abdominal infections, mediation use, occupational exposures, substance use, caffeine intake, alcohol and tobacco use, and prior surgery on abdominal and pelvic organs are all important components to a patient's infertility history upon presentation [49].

Ovulation Disorders

Ovulation is suggested in the presence of regular menstrual cycles, and infertile women with this history can be offered serum progesterone testing at day 21 from the first day of their last menstrual period to confirm [49]. In the setting of irregular menses, testing should be conducted later, starting 7 days prior to the onset of predicted onset of menses and continued weekly until it occurs [49]. Serum progesterone levels, drawn at day 21, of 5 ng per mL or higher suggest ovulation [49]. Levels less than 5 ng suggest anovulation, and further investigation should ensue to evaluate for thyroid disorders, hyperprolactinemia, and the like based on symptoms [49].

Serum FSH levels drawn at days 3–5 of the menstrual cycle can assist in determination of ovarian failure. A level of 30 mIU/mL or higher associated with a low estradiol level suggests ovarian failure, and a FSH of 10 mIU/mL or less with low estradiol levels suggests hypothalamic-pituitary failure [49].

Use of urinary LH kits can predict ovulation 14–48 h prior to ovulation and has largely replaced basal body temperature monitoring [48]. Postcoital testing is considered obsolete [48, 49].

Uterine Abnormalities

Structural uterine abnormalities, such as fibroids or bicornuate uterus, can be assessed with ultrasound or hysteroscopy [48, 49]. Fibroids invading the submucosa and intracavitary components of the uterus are associated with lower pregnancy implantation rates [51]. Müllerian abnormalities leading to a septate or bicornuate uterus are associated with the poorest reproductive outcomes [51]. Scarring of the endometrial lining, endometrial polyps, and synechiae are also associated with infertility [50]. Endometrial biopsy to

DOI 10.1007/978-1-4939-0779-3_115-1

determine endometrial dating has not been proven to be predictive of fertility outcomes and should be reserved in cases of suspected chronic endometritis or neoplasia [49].

Tubal Obstruction and Abnormalities

Tubal abnormalities from underlying disease processes or scarring from infection affect fertility by preventing the normal transport of the female oocyte through the fallopian tube. Tubal obstruction can be suggested if pelvic inflammatory disease or other pelvic infections are reported in the history. Most common organisms implicated in PID are gonorrhea and chlamydia, but tuberculosis infection has also been seen as a cause to tubal obstruction [52]. Additionally, endometriosis can cause tubal damage from inflammatory processes due to cytokines, damage to the fallopian tubes from abnormal endometrial implants, and production of adhesions [52]. Evaluation of tubal obstruction is best performed with hysterosalpingography because of its minimally invasive technique and potential therapeutic effect, but if concomitant pathology is suggested by history, a laparoscopy may be indicated [49].

Peritoneal Causes

Adhesions due to prior infections, surgeries, or endometriosis can also contribute to infertility by obstructing or altering the structural function of the fallopian tubes. Laparoscopy is indicated in the evaluation of suspected peritoneal pathology and can be used to lyse adhesions if felt to be contributing to the cause of infertility or, in some cases, pelvic pain [48, 49].

Treatment

The underlying pathology leading to ovulatory dysfunction, such as thyroid disorders, should be corrected when possible [48]. Hypothyroid patients can be corrected with levothyroxine, and hyperthyroid patients can be treated with methimazole, propylthiouracil (PTU), radioactive iodine (Graves' disease), or thyroidectomy. Hyperprolactinemia us treated with dopaminergic agents such as bromocriptine, which can restore ovulation [48]. In patients with PCOS, insulin-sensitizer metformin has been found to increase ovulation although it is not FDA approved for treatment of infertility [48]. Clomiphene citrate is an oral agent that can be used to induce ovulation. A dose of 50 mg a day, on days 3–5 of the menstrual cycle, for 5 days is administered. Ovulation can be determined by basal body temperature monitoring or urinary LH kits [48] or a serum progesterone [49]. If ovulation is not achieved, an increased dose of 100 mg for 5 days can be used. If a higher dose fails to induce ovulation, referral to a fertility specialist is recommended [48, 49]. Side effects of clomiphene citrate include hyperstimulation of the ovaries resulting in twinning or higher-order pregnancies, thrombosis, and increased risk of ovarian cancer [49].

Fallopian tube obstruction is often surgically managed, although success rates are reported as low, and risk for ectopic pregnancies is increased [48]. In vitro fertilization may be indicated if the tubes are markedly damaged [49]. Surgical correction has been successful in the case of submucosal fibroids through myomectomy and has been successful in treating infertility related to uterine abnormalities [50].

Unexplained Infertility

Upward of 30 % of infertility is unexplained [49]. Timing of intercourse with the use of urinary LH kits should be discussed. Also optimizing the health of both partners is key, with avoiding use of tobacco, caffeine, and illicit substances, limiting alcohol, and losing weight to obtain BMI of 30, to name a few of the lifestyle changes recommended [49]. Options for treatment may include use of clomiphene citrate with or without intrauterine insemination [48], but are unlikely to be successful [49]. In vitro fertilization has not been found of benefit in patients with unexplained infertility [48]. Because 50 % of couples who do not conceive in the first year do conceive in the second, couples should be counseled of such prior to engaging in invasive reproductive assistance. Due to the stress that infertility can cause in individuals, the

DOI 10.1007/978-1-4939-0779-3_115-1

couples should also be offered psychological counseling, noting that stress can also contribute to infertility [49].

Disorders of the Neck and Back

James Winger*
Department of Family Medicine, Loyola University Medical Center, Maywood, IL, USA

1 Disorders of the Back

1.1 Low Back Pain (LBP)

1.1.1 General Principles

Definition/Background Low back pain (LBP) is a heterogeneous condition with high prevalence, high morbidity, and large economic burden. According to the 2010 Global Burden of Disease Study, low back pain ranked highest among 291 studied disorders in terms of years lived with disability (YLDs), with a global point prevalence estimated to be 9.4 % (95 % CI 9.0–9.8) [1]. In 2005, direct expenditures for spine problems in the United States were estimated at $85.9 billion, which represented 9 % of the total national healthcare expenditures, similar to costs associated with arthritis, cancer, and diabetes, and only exceeded significantly by those for heart disease and stroke [2]. In the United States between 2004 and 2008, it is estimated that over two million episodes of back pain resulting in presentation for emergency care occurred, yielding an incidence rate of 1.39/1,000 person-years [3]. In workers 40–65 years of age, back pain costs employers an estimated $7.4 billion/year in lost productive time [4]. Commonly, disorders of the neck and back are self-limiting conditions, which require only judicial use of imaging and rarely more invasive treatments. Many national and international groups have produced high-quality, evidence-based recommendations to aid in the diagnosis and treatment of low back pain (Table 1) [5].

Epidemiology A 2002 survey in the United States indicated that low back pain, defined as posterior trunk pain between the costal margins and inferior gluteal folds, was present for at least 1 day in the last 3 months in 26.4 % of respondents with men and women exhibiting similar responses. Prevalence rates were reported highest among Native Americans and lowest among Asian Americans. Increasing income and higher education levels had moderating effects on reported back pain [6]. Throughout the adult life cycle, prevalence rates increase until the 60–65 year age group and then again decline, with the peak incidence of LBP in the third decade of life [7]. Commonly reported factors associated with LBP include anxiety, depression, job dissatisfaction, low levels of social support, low educational status, poor coping skills, ongoing litigation, smoking, and obesity [8]. While the incidence of LBP is increasing, as are its associated medical costs, no commensurate improvements are seen in health status [2].

Progression to chronic LBP that lasts more than 6 weeks is a costly complication, both in terms of medical expenditures and work absences. In those experiencing activity-limiting pain, most will experience recurrent episodes [7], and up to 40 % of those with initial back pain episodes will experience pain chronically [9]. Psychosocial factors (depression, anxiety, coping mechanisms, attitudes, stress, and job satisfaction) better predict the transition from acute to chronic back pain than do patient-specific anatomic factors [8].

The majority of the societal morbidity associated with LBP is accounted for by disability. Disability 1 year after initial lumbosacral injury has been shown to be predicted by injury severity, specialty of the first healthcare provider seen after injury, worker-reported physical disability, number of pain sites,

*Email: jwinger@lumc.edu

DOI 10.1007/978-1-4939-0779-3_116-1

Table 1 2007 recommendations on the diagnosis and treatment of low back pain from the American College of Physicians and the American Pain Society

1. Patients should be classified at initial presentation into the following groups: nonspecific low back pain, back pain potentially associated with radiculopathy or spinal stenosis, or back pain potentially associated with another specific spinal cause. The history should include assessment of psychosocial risk factors that predict the risk for chronic disabling back pain
2. Clinicians should not routinely order imaging or other diagnostic testing in patients with nonspecific back pain
3. Diagnostic imaging and testing should be pursued when severe or progressive neurological deficits are present or when severe underlying conditions are suspected
4. Patients suspected to have either radiculopathy or spinal stenosis should be evaluated with MRI or CT only if potential candidates for surgery or epidural steroid injection
5. Clinicians should provide patients' educational materials regarding the course and prognosis of back pain, advice to remain active, and self-care options
6. For most patients, the first-line medication options are acetaminophen or nonsteroidal anti-inflammatory drugs
7. Clinicians should consider the addition of nonpharmacologic therapy with proven benefits in those not initially improving. For acute low back pain, spinal manipulation; for chronic or subacute low back pain, intensive interdisciplinary rehabilitation, exercise therapy, yoga, acupuncture, massage therapy, spinal manipulation, cognitive-behavioral therapy, or progressive relaxation

"very hectic" job, no offer of accommodation, and previous injury involving a month or more off of work. These factors produce a model predicting disability with a 0.88 (95 % CI 0.86–0.90) area under the receiver operating characteristic (ROC) curve [10].

Natural History LBP is frequently described as a self-limiting condition in that initial episodes resolve in 90 % of individuals within 3 months of onset [11]. Pooled data analysis indicates that the greatest improvement occurs in the first 6 weeks following initial injury with slower improvement through 52 weeks. However, LBP has a high propensity for recurrence and persistence, and levels of pain, disability, and work absence remain mostly constant after 90 days. The current model of episode onset and resolution is currently being challenged in favor of LBP as a chronic relapsing and remitting condition, with differing individual rates of relapse [12]. A 2008 study indicated that in a cohort of nearly 1,000 patients, more than half of those initially absent from work had returned by 14 days and 83 % by 3 months; nearly 30 % had persistent pain at 12 months time [9]. Many patients experience at least one recurrence in the first 12 months following a low back pain episode with a prior episode of LBP being the only strong predictor of future recurrence [13].

Anatomic sites of acute lumbosacral pain vary and may include paraspinal musculature, collagenous structures (tendon and ligament), intervertebral disk, annulus fibrosus, facet joints, central canal stenosis, spinal nerve roots, and the vasculature.

1.1.2 Clinical Presentation

The experience of many individuals with LBP is that of pain and dysfunction that gradually resolve over several days and allow return to the usual activities of daily living [9]. Most individuals with an episode of LBP will not present to medical attention.

History Focused history in a patient presenting with LBP will include onset of symptoms, location of pain, timing of pain, interventions that provide palliation or provocation, and any associated symptoms. Assessment for signs suggesting neurological involvement, such as radiation of pain, weakness, numbness, sensory changes, or bowel and bladder dysfunction, is likewise important. Description of any previous episodes of back pain should be elicited during the interview, as well as any current or pertinent past medical history. Interview of a patient presenting with low back pain should pay particular attention

DOI 10.1007/978-1-4939-0779-3_116-1

to established risk factors for back pain such as known trauma, previous low back pain, missed work, occupational mechanism, and preexisting mood disorder [14].

In addition to standard interviewing approaches, certain additional queries in individuals with low back pain are aimed at identifying neurosurgical emergency, vertebral fracture, or malignancy. A retrospective study of 206 patients with spinal cord or cauda equina compression noted that the presence of bowel and bladder dysfunction as well as saddle sensory disturbance yielded a specificity of 0.92 and a likelihood ratio of 3.46 [15]. Interestingly, this same study noted that these symptoms showed stronger association with MRI diagnosis than did physical examination of the lower extremities, even while only marginally raising the clinical suspicion of neurological compression. A 2013 study evaluating the benefit of screening questions addressing the presence of malignancy indicated that only a prior history of malignancy is informative [16]. The same study also found that prolonged corticosteroid use, older age, and trauma increased the pretest probability of spinal fracture by 15–43 % when present individually and greater when present in combination. Thus, there is relatively little evidence favoring reliance on the so-called "red flag" symptoms to trigger changes in management.

Physical Exam Examination of the patient with back pain is attentive to the presence and extent of signs indicating neurological involvement. Observation of the patient's gait, stance, and posture (absence or alteration of normal lordosis or kyphosis) may provide diagnostic clues. Inspection while attending to patient modesty should include the entire back and posterior pelvis but also the upper and lower extremities. The sequelae of trauma may present as disfigurement, edema, or ecchymosis. Asymmetry and muscle wasting may indicate chronic motor neuropathy. Palpation of bony and other landmarks may assist in the localization of a primary pain source. The spinal range of motion in coronal, sagittal, and axial planes may be useful as an indicator of which movement types trigger a patient's pain; however, this specific assessment is noted to be highly examiner dependent.

A neurologic exam is performed on all patients and should include both upper and lower extremities (Table 2). Manual muscle testing should focus on nerve root myotome testing rather than on specific individual muscles, and strength should be scored with the standard 0–5 scale. Testing of nerve root strength may be assessed as follows: single-leg raising from a chair without the use of hands (quadriceps/L4), heel walking (tibialis anterior/L5), and toe walking (gastrocnemius/S1). The examiner must be aware that deficits in balance or preexisting weakness may affect motor strength testing results. Assessment of pinprick and light touch sensation should be compared to the unaffected contralateral side. Numbness should be specified by dermatomal distribution and may include examination of the perineum and sacral distributions. Evaluation of vibration and position sense may be useful if central processes are included in the differential diagnosis. Signs of upper motor neuron (UMN) dysfunction, such as Hoffmann's reflex,

Table 2 Strength, sensation, and deep tendon reflexes associated with the commonly impinged nerve roots

Nerve root	Strength testing	Sensory innervation	Deep tendon reflexes
C5	Shoulder abduction	Lateral arm	Biceps (C5, C6)
C6	Elbow flexion, wrist extension	Lateral forearm	Brachioradialis
C7	Elbow extension, wrist flexion	Middle of the hand dorsum	Triceps
C8	Finger flexion	Medial forearm	–
T1	Finger abduction	Medial arm	–
L3	Hip flexion	Distal upper leg	–
L4	Knee extension	Anterior knee	Knee jerk (patellar)
L5	Ankle dorsiflexion (heel walking)	Dorsum of the foot	Hamstring reflex (L5, S1)
S1	Ankle plantar flexion (toe walking)	Lateral foot	Ankle jerk (Achilles)

DOI 10.1007/978-1-4939-0779-3_116-1

a positive Babinski's sign or hyperreflexia, may suggest etiology for lower motor neuron dysfunction. Pertinent reflexes include the knee jerk (L4), hamstring reflex (L5, S1), and ankle jerk (S1), as graded on the standard 0–4 scale. Depending on the extent of neurological manifestations, assessment of perineal sensation and anal sphincter tone may be appropriate.

Nerve tension tests such as the straight-leg raise (SLR) and seated slump test (SST) may suggest neural impingement but are positive in most symptomatic individuals with and thus have a poor positive predictive value when applied to all patients with low back pain. In the SST, the patient is seated on the edge of the examination table. With the hands clasped behind the back and neck flexed with the upper body "slumped" forward, the examiner passively extends the knee. A positive finding is reproduction and radiation of the patient's pain beyond the knee. Having the patient extend his or her neck, thus relieving neural tension and lessening or relieving the pain, may provide confirmation of this finding. The SLR is performed with the patient supine and the ipsilateral hip flexed to 90° while the examiner passively extends the ipsilateral knee. A positive test is reproduction and radiation of the patient's pain prior to 60° of knee extension and further relief of such pain with knee flexion. This maneuver may be modified by Lasègue's sign: dorsiflexion of the ipsilateral ankle increasing neural tension and thus worsening the pain response. The femoral stretch test for upper (L2, L3, L4) lumbar nerve root impingement is performed with the patient prone as the examiner passively and slowly flexes the ipsilateral knee. Reproduction of the patient's typical lower extremity pain constitutes a positive test. The crossed SLR (cSLR) and crossed FST (cFST) are performed on the lower extremity contralateral to a patient's typical radiating pain.

These maneuvers may be most useful in those patients with symptoms suggestive of lumbar radiculopathy, such as radiating pain, numbness, or weakness. While the SST and the SLR exhibit similar rates of specificity (0.83 and 0.89), the SST is more sensitive (0.84 vs. 0.52) [17]. The cSLR and cFST are poorly sensitive but highly (>90 %) specific [18]. Thus, neural tension tests may be better applied to those with presenting symptoms suggestive of radiculopathy.

In 2011, Suri et al. evaluated the accuracy of physical exam maneuvers for the diagnosis of midlumbar (L2, L3, L4) and low lumbar (L5, S1) nerve root impingement. The study compared standardized, expert-level examinations to MRI findings in patients presenting to a physiatry spine practice with acute or subacute symptoms suggestive of nerve root impingement. Exam maneuvers testing positive that either increased the likelihood ratio >4.0 or exhibited 100 % specificity for midlumbar nerve root impingement were FST, cFST, sit-to-stand test, medial ankle sensation, and patellar reflex assessment. Achilles reflex testing was the only exam maneuver in which a positive test either increased the likelihood ratio >5.0 (+LR 7.1) [18].

Further examination should include the hips and sacroiliac joints. Range of motion of the femoroacetabular joints should be assessed along with the response to the loading of the acetabular labra. The acronymically named FABER test, also known as Patrick's test, stresses the SI joint by flexing, abducting, and externally rotating the contralateral hip while applying posterior pressure to the ipsilateral anterior pelvis and contralateral knee. A positive response is reproduced pain in the contralateral SI joint.

Given the contribution of psychosocial issues to acute and chronic low back pain, assessment of biopsychosocial stressors should be performed. Minimally, screening for common mood disorders such as anxiety and depression should be done. The presence of nonorganic signs or nonanatomic pain distributions does not exclude orthopedic pain generators but may indicate a need for further psychiatric workup.

It is estimated that a brief physical examination and neurological examination of the L4, L5, and S1 dermatomes, myotomes, and deep tendon reflexes should be sufficient to identify 99 % of potentially serious spinal pathology [19].

DOI 10.1007/978-1-4939-0779-3_116-1

1.1.3 Radiographic and Laboratory Diagnosis

There has been much studied and written about the utilization of imaging strategies as applied to back pain. Published recommendations discourage imaging in the first 4 weeks after presentation [20, 21]. In a 2007 clinical guideline paper, the American College of Physicians and the American Pain Society wrote: "Clinicians should not routinely obtain imaging or other diagnostic tests in patients with nonspecific low back pain [5]." Supporting these recommendations, a 2009 random effects meta-analysis of 1806 patients evaluated the effect of immediate lumbar imaging on clinical outcomes at 3 and 6 months time when compared to usual care without imaging; no differences were found with regard to pain or function levels at the specified time points [22]. Risks of unnecessary imaging include radiation exposure (CT, roentgenography), identification of abnormal tissues with unknown relation to a patient's pain source, diminished self-perceived health, and unnecessary healthcare utilization [21].

Plain-film radiography is best used as an initial evaluation when vertebral compression fracture is of utmost concern, such as those with osteoporosis or with chronic steroid use. Some authors have suggested the use of plain-film radiography combined with the erythrocyte sedimentation rate (ESR) as a cost effective means of addressing risk for cancer or inflammatory spondyloarthropathy. When appropriate, plain-film radiography of the spine should include standing anteroposterior and lateral view of the lumbar spine. In adolescent athletes in whom spondylolisthesis is considered, oblique views of the lumbosacral spine should be obtained. European guidelines actively discourage the use of plain-film radiography and MRI for nonspecific back pain unless in the context of referral for a second opinion [23].

Advanced imaging may play an important role in the evaluation of a patient when severe (urinary retention, saddle anesthesia) or progressive neurologic deficits are present (Fig. 1) or when severe conditions such as metastatic cancer, vertebral infection, or the cauda equina syndrome are suspected [5]. Magnetic resonance imaging is generally preferred over CT due to the lack of ionizing radiation and better visualization of soft tissues and the spinal canal. In patients with signs and symptoms suggestive of nerve root compression or spinal stenosis, evaluation with MRI or CT should only be done in individuals who are potential candidates for surgery or image-guided epidural steroid injection [5].

Radiographic abnormalities are common in the spine and show poor correlation with patients' presenting pains. A 2000 study of 408 patients demonstrated no significant associations between segmental distribution of symptoms and the presence of anatomic impairment, while only severe nerve compression and disk extrusion were shown to be strongly predictive (OR 2.72 and 3.34) of pain present below the knee [24].

1.1.4 Differential Diagnosis

Nonspecific Low Back Pain It is theorized that the majority of acute low back pain has paraspinal anatomic structures as a pain generator. Paraspinal musculature, spinal ligaments, and annulus fibrosis of the intervertebral disk are all poorly imaged and may be sites of injury that account for the most common types of low back pain [25].

Osteoarthritis Degenerative osteoarthritis of the axial spine is estimated to be present in 40–85 % of individuals [26], and arthritis in general is a leading cause of disability and decreased quality of life. Spondylosis (lumbar spine degeneration) has been defined as intervertebral disk degeneration and same vertebral-level osteophytosis. As in other joints, spinal arthritis is characterized by changes to the articular cartilage and subchondral bone, inflammatory response of the synovium, and inappropriate bone and cartilage overgrowth. Radiographic features of spondylosis include vertebral osteophytosis, disk space narrowing, and facet joint osteoarthritis. Recent longitudinal studies with a large number of patients have highlighted the discordance between radiographic findings and patient symptoms [26].

DOI 10.1007/978-1-4939-0779-3_116-1

Fig. 1 Imaging of the pathologic spine. (**a**) T2-weighted sagittal MRI image of the lumbar spine of a 64-year-old man reveals multilevel spondylosis with disk pathology including protrusion and extrusion with migration at levels L3–L4, L4–L5, and L5–S1. (**b**) Plain-film x-ray image of lateral cervical spine in an 84-year-old woman shows extensive and widespread spondylosis and osteoarthritis with anterior bridging osteophytes and ossification of the anterior longitudinal ligament and moderate to severe disk degeneration. (**c**) T2-weighted axial MRI image of the lumbar spine of a 22-year-old man at the L5–S1 level demonstrates right foraminal disk protrusion and disk bulge, causing mild central canal stenosis, severe right-sided neuroforaminal narrowing, and moderate left-sided neuroforaminal narrowing with mild bilateral facet hypertrophy

Intervertebral Disk Herniation Progressive failure of the successive layers of the annulus fibrosus is responsible for the ultimate failure of the structure of the intervertebral disk. Gradual desiccation of nuclear material results in a centrifugal disorganization of collagenous layers in the inner and outer annuli. This disorganized tissue cracks and fissures, eventually resulting in channels that permit herniation of the nuclear material through the annulus.

Disk herniation occurs typically in a posterior (paramedian) or posterolateral direction, these being the weakest areas of the disk. Depending on the anatomic location of the disk disfigurement, resultant symptoms may border on radiculopathy (posterolateral) to frank myelopathy or neurogenic claudication (paramedian). Disk disfigurement may range from disk bulge to herniation, protrusion, and extrusion [27].

The hallmark of disk herniation presentation is radiating pain. While the outer layer of the annulus fibrosus is poorly innervated, like other chronically degenerative collagenous tissues, the pathologic outer annuli exhibit neoinnervation that show positive staining for substance P, which has been associated with pain generation [27]. Paresthesias and numbness may be present and with prolonged symptoms weakness may occur in the distal musculature from lower motor neuron compromise.

DOI 10.1007/978-1-4939-0779-3_116-1

Diagnosis is commonly clinical, based on a combination of reported radicular pain in a dermatomal distribution, neuropathic signs, and positive nerve-tension testing findings. As up to 30 % of asymptomatic individuals have radiographic evidence of lumbar disk pathology, radiographic study is not commonly indicated without severe or rapidly progressive neuropathic symptoms [28].

Spinal Stenosis Degenerative lumbar spinal stenosis describes the effects of degenerative changes in the spinal canal on the vascular and neural elements of the lumbar spine [29]. Symptoms vary and may include gluteal or lower extremity pain that may occur with or without back pain, especially when seen in older patients. Walking and upright exercise typically worsen symptoms, and patients may relieve symptoms with forward flexion or recumbent posture. As in other syndromes mediated by degeneration, symptoms are slowly progressive. Prognosis may only be favorable in up to one half of patients, with few treatments significantly altering the course of the disease. If needed for diagnostic or interventional purposes, MRI or CT myelogram are the preferred imaging modalities.

While not supported by extant literature, certain exam findings may be associated with the diagnosis of spinal stenosis: the Romberg test, thigh pain exacerbated by extension, sensorimotor deficits, leg cramps, and abnormal Achilles tendon reflexes all may be present. There is insufficient evidence to recommend for or against pharmacological intervention or physical therapy (grade of recommendation, I), while the use of a lumbosacral corset is associated with increased pain-free walking distance. Epidural steroid injections may provide short-term (up to 6 months) relief in patients with radiculopathy or neurogenic claudication; these injections should be fluoroscopically guided. If medical/interventional treatment of moderate spinal stenosis is insufficient, surgical decompression is suggested to improve outcomes and patient pain scores [29].

Osteoporosis Osteoporosis is estimated to affect up to 30 % of all women over the age of 65. Associated fractures occur in up to 50 % of all affected individuals, leading to profound morbidity and healthcare resource utilization. The United States Preventive Services Task Force currently recommends screening via dual-energy x-ray absorptiometry (DEXA) in women with increased fracture risk aged 60–64 and all women aged greater than 65 [30]. In addition to age and sex, risk factors include low BMI, personal history of fracture, Caucasian or Asian race, > two alcoholic drinks daily, caffeine and tobacco use, history of falls, low level of physical activity, low calcium and vitamin D intake, and use of certain predisposing medications. Initial treatment includes fall prevention education, intake of calcium >1,200 mg/day, intake of vitamin D >800 IU/day, and treatment with bisphosphonate osteoclast inhibitor medication. Compression fractures of the vertebra are the most common type of osteoporotic fracture and may be painful; symptoms usually resolve over the course of 3–4 months. Up to 4 % of patients presenting to primary care offices with back pain will have a vertebral compression fracture [16]. Patients with vertebral compression fractures usually do not present with pain radiation, as there typically is no neural compromise. Plain-film radiography may indicate a loss of vertebral height associated with compression fracture, and diagnosis of low-impact fractures in susceptible individuals should prompt further investigation. Currently, there are no serum biochemical markers used to aid in diagnosis [31].

Neoplasia Fewer than 1 % of individuals presenting to primary care offices with back pain will be diagnosed with a malignancy [16], and the spine is a more common site of metastasis than primary tumor. Risk factors for spinal malignancy include age >50 years, history of malignancy, and recent unintended weight loss. Symptoms include unrelenting pain that is not improved with rest and may be worse at night. Initial evaluation may include plain-film radiography enhanced by the ESR.

Symptomatic secondary metastases are estimated to occur in approximately 10 % of all cancer patients, and cadaveric studies find 30–90 % prevalence of spinal metastases [32]. Spinal metastases are most

DOI 10.1007/978-1-4939-0779-3_116-1

likely to originate from the breast, lung, prostate, or hematopoietic system and may arise via hematogenous spread, local extension via lymphatics, or perineurium or extension through the intervertebral foramina.

Primary spinal tumors are rare, affecting 2.5–8.5/100,000 patients yearly [33]. Multiple myeloma is a malignant clonal proliferation of plasma cells characterized by the presence of these cells in the bone marrow and monoclonal immunoglobulins in the serum and/or urine. Rarely, a solitary plasmacytoma may be the only manifestation of disease and may be present in the vertebral column. These tumors commonly present with spinal cord compression; thus, serum and urine protein electrophoresis should be performed in all patients with pathological vertebral fractures in which primary malignancy is not evident. Lymphomas may arise in the bones or compress the spinal cord via invasion of the epidural space.

Facet Syndrome The lumbar zygapophyseal joint is a commonly cited source of spinal pain; dysfunction may be associated with unilateral or bilateral pain radiating to one or both buttocks, groin, and thighs but not proceeding below the knee. Pathological degeneration of the synovial joint may be noted on CT evaluation, and thus intra-articular anesthetic injection has long been a treatment for this condition. However, as with many other areas of degeneration within the axial skeleton, there is incomplete correlation between radiographic findings and patients' reports of pain [34]. Thus, today diagnostic anesthetic block of the small nerve fibers innervating the facet joints (medial branch block or MBB) is considered a gold standard for lumbar facet joint syndrome diagnosis. Due to the fleeting response to MBB seen in treated patients, a longer-lived treatment is now utilized: lumbar medial branch neurotomy (LMBN). Thermal coagulation at temperatures in excess of 80 °C denature intracellular proteins and produce results that last on average, longer than those achieved with MBB [34]. A 10-year clinical audit noted that among 174 patients treated with LMBN, 68 % exhibited good or excellent results.

Ankylosing Spondylitis Characteristic of the spondyloarthropathies is ankylosing spondylitis (AS). It is an inflammatory arthritis that commonly affects the axial spine with possible extension to peripheral joints, eyes, and bowel. AS exhibits symptoms onset in the late teens, but the delay between the symptom presentation of lumbosacral pain and stiffness and eventual diagnosis averages 8 years [35], primarily due to the difference in distinguishing the symptoms of AS from nonspecific mechanical low back pain in the young active population. While there is limited diagnostic utility in plain-film radiology, MRI has permitted the identification of the inflammatory sequelae of this disease, aided by serum markers of inflammation such as ESR and CRP.

Visceral Diseases Uncommonly, back pain may be the only presenting concern in a patient with organ system-based disease. Typically, visceral pain referred from intra-abdominal and retroperitoneal organs differs in quality from musculoskeletal pain; however, this difference may be subtle and overlooked.

Dissecting thoracic or abdominal aortic aneurysm is described as "tearing" pain that is acute and severe. This condition is found in up to 4 % of those patients over 50 with increased prevalence in smokers and those with diagnosed hypertension and hyperlipidemia. Some patients will have a pulsatile abdominal mass, and presentation may include diaphoresis and signs of impending circulatory failure such as hypotension and tachycardia [36].

Myocardial infarction may present as mid-thoracic pain that radiates to the left arm or axilla. It is most common in those older than 45, with risk factors including family history, hyperlipidemia, hypertension, obesity, and others. Presenting symptom constellation may include diaphoresis, dyspnea, anterior chest heaviness or pain, nausea, vomiting, and a sense of impending doom.

Acute low back pain associated with abdominal pain in a woman of childbearing age may indicate ectopic pregnancy. Back pain is described as part of a classic symptom triad including amenorrhea and

DOI 10.1007/978-1-4939-0779-3_116-1

vaginal bleeding. Hypovolemic shock may be present in up to 20 % of cases, and associated back pain may be located in the L1 and L2 dermatomes of the pelvic organs.

Acute pancreatitis commonly presents with "boring" thoracolumbar pain when the pancreatic duct is obstructed. Patients with acute pancreatitis may have a history of gallstones or binge drinking, and diagnosis is usually achieved with assessment of serum lipase and amylase as well as CT demonstration of glandular inflammation.

Vague back pain that occurs with increasing gastric acidity levels may represent a duodenal ulcer. Inflammation, injury, and ulceration of the mucosal lining of the digestive tract are associated with *H. pylori* infection, smoking, and alcohol ingestion.

Urological conditions such as nephrolithiasis and urinary tract infection commonly present with varying back pain. Ascending urinary tract infections may exhibit low lumbar pain or perinephric pain from ribs 9–11 on either side of the low thoracic spine if pyelonephritis has developed. Unilateral thoracolumbar pain radiating to the ipsilateral flank and toward the groin may indicate a ureteral stone [36].

1.1.5 Management

Stratified Primary Care Management Multiple international management recommendations for low back pain recommend stratification of patients into groups based on risk for morbid pathology and risk of progression to chronic back pain. A 2011 study known as STarT Back evaluated this model on the basis of economic and patient-centered metrics when compared to usual care in English general practices [37]. This study included greater than 850 adult patients and evaluated changes in the Roland Morris Disability Questionnaire (RMDQ) at 12 months time as well as quality-adjusted life years (QALY) and healthcare costs between stratified and non-stratified groups. Individuals were stratified into one of three groups: "low-risk" patients had one visit and were educated as to the good prognosis and that further treatment was not necessary nor beneficial; the medium-risk group was referred for further physiotherapy; and the high-risk group was referred for "psychologically informed physiotherapy" [37]. The stratified (interventional) group had significantly improved RMDQ scores at 4 and 12 months and 0.039 additional QALYs and cost savings compared to the non-stratified control group. The low-risk group intervention was found to be non-inferior to usual care, indicating that the minimum intervention did not lead to worse outcomes than the current best practices. Differences were present between matched risk groups at 4 and 12 months but lost statistical superiority at the latter time point [37].

Another study of stratification in family medicine practice demonstrated similar results. In 2014, Foster published results showing modest improvements in patient overall outcomes, improved use of healthcare resources, and reduced sick certification without increased healthcare costs. Direct patient benefits of stratification intervention included improvements to physical function, fear avoidance beliefs, satisfaction, and work absenteeism. Changes to physician behaviors included decreased NSAID prescription, increased appropriate referral to physical therapy, and fewer sickness certifications [38].

Thus, stratified care for low back pain is shown to demonstrate moderate clinical and economic benefits and can be implemented successfully into a family medicine practice.

Activity For most patients, especially those with nonspecific low back pain, rapid return to normal activities, including work, is recommended. However, these patients should initially avoid heavy lifting, twisting, and bodily vibration [5].

Bed Rest The harmful physiological adaptations to organismal inaction are dramatic and well established. The complications of bed rest are myriad. Muscle mass loss may approach 2 % daily in the first 3 weeks of enforced rest; this is primarily due to catabolism of muscle proteins by enzymes activated

DOI 10.1007/978-1-4939-0779-3_116-1

by inactivity. Joint stiffness and loss of capsular compliance begin soon after immobilization. The risk of thromboembolic event, pulmonary atelectasis, and pressure ulcers rise along with inactivity.

When bed rest is prescribed for acute lumbosacral injury, the aforementioned complications are risked. Bed rest in acute low back pain is not associated with either quicker resolution of pain or return to regular activity [39]. Regular activity as tolerated maximizes the return to function and decreases patient pain score report.

Pharmacological

Non-opiate Analgesics For most patients with low back pain, acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are the first-line pharmacological treatment. Acetaminophen is recommended by the American Pain Society and American College of Physicians as the first-line pharmacological treatment of nonspecific back pain due to its record of safety in other settings of musculoskeletal pain. Acetaminophen carries a low risk of harm; it is not associated with the risk of either gastrointestinal bleeding or myocardial infarction and is relatively well tolerated [40]. Hepatotoxicity may be seen at doses approaching the recommended maximum daily allowance (3 g/day), and so caution must be taken in those patients with preexisting liver conditions or heavy alcohol use.

NSAIDs exert their anti-inflammatory, analgesic, and antipyretic effects via the inhibition of the cyclooxygenase (COX)-2 enzyme. Nonselective NSAIDs (celecoxib) also inhibit COX-1, which is responsible for gastric mucosal protection via prostaglandin production. A review of different NSAID formulations indicates similar efficacy when compared to placebo in acute and chronic back pain and similar intra-family efficacy. Thus, treatment decisions may rely on side effect profile, prior response to NSAIDs, cost, and dosing schedule. Each member of the class is associated with gastrointestinal and renal adverse effects, including gastrointestinal ulcers, hemorrhage, and perforation, as well as decreased glomerular filtration. A 2006 meta-analysis of 138 individual studies revealed an approximate twofold class-wide risk elevation in myocardial infarction when compared to placebo, except naproxen, which showed no such increased risk. Cardiovascular, gastrointestinal, and renal risks should be taken into account prior to prescribing or recommending NSAIDs for nonspecific low back pain. The long-term use of NSAIDs may be combined with misoprostol, a prostaglandin that decreases the risk of gastrointestinal ulceration, or a proton pump inhibitor [40].

Opiate Receptor Agonists There exists significant controversy regarding the use of opiate receptor agonist medication in low back pain. Opiate receptors are widely distributed throughout the brain, spinal cord, and intestinal tract and are activated by morphine and its derivatives and homologues. While considered the strongest class of pain relievers, they carry significant potential for dependence and abuse due to their effects on the dopaminergic reward system of the brain. In 2009, the American Pain Society and the American Academy of Pain Medicine published joint guidelines on the use of opioids for chronic noncancer pain to aid practitioners in decisions regarding this class of medication [41]. Primary among these recommendations include time-limited rather than symptom-limited course of medication. Acute pain should be treated with short-acting opioids, while the use of long-acting slow release formulations may decrease euphoric effects and therefore abuse potential. Common adverse effects include constipation, nausea, somnolence, and pruritus.

Tramadol is a synthetic agent with weak affinity for the α-opiate receptor. Clinically, it has greater efficacy than NSAIDs and is relatively comparable to weak opiates [41]. Tramadol has similar adverse effect tolerability to acetaminophen-opioid combinations; however, it has been linked to the serotonin syndrome when used in combination with serotonin receptor antagonists.

DOI 10.1007/978-1-4939-0779-3_116-1

Skeletal Muscle Relaxants Medicines known as "skeletal muscle relaxants" are neither related pharmacologically nor structurally. Those commonly used for the relief of musculoskeletal spasticity are baclofen, carisoprodol, cyclobenzaprine, metaxalone, methocarbamol, tizanidine, and orphenadrine. It is unclear if these medications work to relax muscles or if their effects stem mostly from sedation [40]. Medications in this grouping have been shown to demonstrate short-term pain relief for acute low back pain, but no agent has been shown to be more effective than others [42]. These medications carry a high rate of adverse side effects, and sedation commonly limits their use. Several studies have indicated the equivalence of benzodiazepines when compared to skeletal muscle relaxants for acute low back pain, suggesting similar benefit. All medications here referenced may be more effective when combined with an NSAID or acetaminophen [40].

Antidepressants Certain antidepressants with noradrenergic antagonist activity may have pain-modulating properties independent from their effects on mood disorders. Tricyclic antidepressants (TCAs) such as amitriptyline have long been used in chronic pain conditions, and, in recent years, serotonin and norepinephrine reuptake inhibitors (SNRIs) such as duloxetine, venlafaxine, and desvenlafaxine carry for similar indications. TCAs show small benefit over placebo for chronic nonspecific pain in some meta-analyses, while SNRIs have shown benefits for certain types of chronic pain. High rates of adverse effects limit the use of these medications and prevent their use as a first-line treatment [42].

Systemic Corticosteroids While it has been suggested that the inflammatory response associated with extruded intervertebral disk nuclear material may be stemmed with oral corticosteroids, several studies in the setting of lumbar radicular pain have demonstrated no improvement versus placebo. Similarly, despite the euphoric effect achieved by some patients, these medications are also without effect in nonspecific acute low back pain [40].

Disease-Modifying Antirheumatic Drugs (DMARDs) There is no role for antitumor necrosis factor (TNF)-α biologic therapy in the treatment of nonspecific low back pain [40]. There is, however, an established role for these medications for the treatment of diagnosed inflammatory spondyloarthropathies [43].

Exercise Whether done in the home setting or under the guidance of a physical therapist, stretching and strengthening activities are commonly prescribed for acute nonspecific back pain. A meta-analysis of 11 studies utilizing the McKenzie (directional preference) method indicated significant improvement in pain and disability after 1 week of therapy [44], resulting in a recommendation for usage [strength of recommendation taxonomy (SORT) B]. Evidence suggests that there is a mild benefit for exercise protocols in chronic nonspecific back pain and little to no improvement when compared to other treatments in acute back pain [45].

Back School Education is commonly utilized in the treatment of low back pain; it is apparent, however, that there is little to no standardization on what constitutes back school curriculum, and thus, these approaches vary widely. A 2005 study analyzed nineteen randomized controlled trials that study the effects of back schools on nonspecific low back pain. While only identifying six studies of rigorous methodology, it was concluded that there is moderate evidence indicating decreased pain and improved function or work status in an occupational setting over short and intermediate time frames when back schools were compared to pharmacological treatment, myofascial therapy, or placebo [46]. Thus, in certain applications, back schools may play an important role in the treatment of low back pain.

DOI 10.1007/978-1-4939-0779-3_116-1

Psychological Intervention Cognitive-behavioral therapy (CBT) is a method of psychotherapy that attempts changing cognitive processes to affect changes in behavior, thought, and emotional responses. CBT has been applied to chronic pain settings with varying results. In the setting of chronic pain, CBT has improved pain experience, positive coping, and social role function when compared to placebo or other treatments [47].

Spinal Manipulation A 2004 Cochrane meta-analysis concluded that spinal manipulation was superior only to sham treatments and inert interventions. It demonstrated no advantage of "usual care," analgesic medication, physical therapy, exercise, or back school. Chronic pain applications were found to yield similar results. These results were unaffected by the presence of pain radiation, study quality, manipulator, nor therapy combinations [48].

Acupuncture A Cochrane review of studies investigating the use of acupuncture in the treatment of low back pain found acupuncture to be effective for pain relief and equivalent to other complementary or conventional treatments. For short-term relief of chronic pain, acupuncture was more effective than sham procedure and placebo. Data regarding the effects on short-term low back pain were inconclusive [49].

Surgery Evidence is very clear that there is no role for surgery of the spine outside the conditions of sciatica, pseudoclaudication, or spondylolisthesis [50]. Prolonged or worsening neurological symptoms in the setting of diagnosed disk disease unresponsive to or inappropriate for ESI should stimulate referral for surgical evaluation.

Lumbar diskectomy is the most common operation in the United States for reasons related to disk herniation, but there remains poor evidence supporting its use when compared to conservative treatments. Newer treatments in minimally invasive spine surgery (MISS) offer lower perioperative morbidity to patients.

The most common diskectomy approaches are standard and microscopic lumbar diskectomy (MLD), distinguished by the size of incision, amount of excised tissue, and use of magnification to improve precision. A 2012 meta-analysis comparing the two declared that the MLD approach was equivalent to the standard approach in terms of patient pain improvement and may present fewer complications due to operative techniques. Further application of MISS has resulted in tubular transmuscular (micro) diskectomy, in which a tubular retractor is placed through the paraspinal musculature. The lack of statistical discrimination among many approaches indicates that currently the skill and expertise of the performing surgeon likely have the greater determination on outcome when compared to the surgical approach [51].

The largest and longest-term comparison between nonsurgical and surgical approaches was published as the ten-year follow-up to the Maine lumbar spine study ($n = 400$) [50]. Ten years after initial presentation, postsurgical patients were more likely to be satisfied with their current condition when compared to the medically managed patients (71 % vs. 56 %, $P = 0.002$), whereas there was insignificant difference between the two groups with regard to improvement in the initial presenting symptom and work and disability status [50].

1.2 Chronic Low Back Pain

Low back pain of greater than 6 months duration develops in a small percentage of patients. These conditions carry a very low likelihood of a specific diagnosis, and symptomatic cure is unlikely. Treatment should be supportive, with efforts aimed at improving pain and function. While the mechanisms of initial injury and chronic pain propagation are unclear, it is proposed that these disorders are primarily

DOI 10.1007/978-1-4939-0779-3_116-1

mechanically induced, and then maladaptive physical and cognitive compensations produce a mechanism for an ongoing pain [52].

A recent systematic review demonstrated predictors favoring persistent disabling back pain: maladaptive coping behaviors, nonorganic signs, functional impairment, significant comorbidities, and psychiatric comorbidities. Factors such as low level of fear avoidance and functional impairment predict recovery at 1 year time [53].

The transition from acute to subacute to chronic pain appears to be one strongly mediated by psychosocial factors rather than anatomic or disease-based factors [54]. Therefore, many interventions attempting to prevent chronicity transformation have utilized psychological approaches. A 2013 study implementing CBT interventions to prevent chronicity transformation concluded that operant conditioning may be included in physical therapy practices toward this end [55].

2 Disorders of the Neck

2.1 Cervical Radiculopathy

2.1.1 General Principles

A common cause of neck pain is impingement of the cervical nerve roots exiting the spine. This is frequently caused by disk pathology, facet joint osteophytes, or degenerative disk disease, further affected by intraneural edema or inflammatory mediators such as substance P. The annual incidence of cervical radiculopathy was found to be 83 in 100,000 persons based on a recent study [56].

The nomenclature of the cervical nerve roots differs from that elsewhere in the spine. The presence of an eighth cervical nerve root determines that most cervical nerve roots exit the spinal canal superior to their correspondingly named vertebra; the C7 nerve root exits at the level of the C6–C7 intervertebral disk. The exception to this rule is the eighth cervical nerve root, which exits between the C7 and T1 vertebral levels. The most commonly affected nerve root is the C7 root, which is impinged at the level of the C6–C7 intervertebral disk.

2.1.2 Presentation

When compared to chronic spondylosis of the cervical spine, pain associated with radiculopathy is more commonly unilateral [57]. The most common mechanism of acute cervical radiculopathy is that of annular failure of the intervertebral disk resulting in disk deformation or frank extrusion of nuclear material. Chronic radicular symptoms, which may occur in up to two thirds of patients, are more commonly associated with chronic spondylosis, usually characterized by facet joint osteophytosis or disk degeneration [27].

As with lumbar radiculopathy, the clinical presentation is highly dependent on the exact impinged nerve root or roots; however, clinical and symptom overlap does occur. Pain in proximal nerve root distribution is accompanied by distal distribution neuropathy (paresthesias or other sensory dysfunction). Commonly, referred pain from unilateral cervical radiculopathy is vaguely localized to the ipsilateral neck, shoulder, or medial scapular border [57], whereas radicular pain may follow a dermatomal distribution.

On physical examination, pain is usually exacerbated by neck extension as well as neck rotation toward a patient's symptomatic side, which narrows the neural foramen (Spurling's sign). Conversely, a patient may find mild relief with neck flexion, shoulder abduction, and scapular retraction. Altered deep tendon reflexes corresponding to the affected nerve root may be present. Upper motor neuron findings such as hyperreflexia, clonus, and Hoffman's sign should be absent: their presence should stimulate search for myelopathic conditions.

DOI 10.1007/978-1-4939-0779-3_116-1

2.1.3 Diagnosis

The differential diagnosis of cervical radiculopathy encompasses pathologies of the neck, shoulder, viscera, and extremities. Thus, trauma, myelopathy, degenerative spondylosis, rotator cuff pathology, myocardial ischemia, zoster, and other conditions should be considered at differential diagnosis [56, 57]. As noted with lumbar radiculopathy, plain-film x-ray is of limited use, given the poor correlation between findings and the patient's report of symptoms. Similarly, in the absence of certain findings suggesting cancer, myelopathy, or acute pathologies, it is recommended that practitioners delay advanced imaging until after a suitable period of conservative treatment has failed [58]. MRI or CT are best utilized as a confirmatory test of nerve root compromise, in anticipation of referral to spine subspecialist and possible interventional treatment, with limited evidence available to recommend for or against the use of electromyography (EMG) [58].

2.1.4 Management

The prognosis of cervical radiculopathy is optimistic and well described [27, 56, 57]. The majority of patients will improve over time, with 75–90 % having no or minimal further sequelae. Management decisions must be made with reference to this high rate of recovery. A 2011 evidence-based review addressed the available literature on the medical, interventional, and surgical management of degenerative cervical radiculopathy [58].

The following interventions have insufficient evidence to recommend or discourage their use: medication, physical therapy, traction, cervical manipulation, and cervical collar. Several of these have demonstrated improvement in patients' symptoms in uncontrolled trials. Cervical manipulation has been rarely associated with emergent vascular and nonvascular complications then requiring definitive surgical treatment [58]. Similar consideration should be used when applying pharmacological treatments to cervical radiculopathy as were discussed with regard to lumbar radiculopathy.

Injection of an anti-inflammatory steroid and anesthetic mixture into the epidural space may provide symptom relief for up to 60 % of patients and delay or negate the need for surgery in an additional 25 % [58]. Potential complications such as spinal cord damage and death may be considered when developing an interventional treatment plan for those patients with cervical radiculopathy.

Surgical referral is appropriate in individuals who have documented cervical radicular symptoms that are intolerable and resistant to a prolonged (6 weeks) course of conservative treatment.

2.2 Acute Cervical Strain

2.2.1 General Principles

The acute cervical strain caused by acceleration-deceleration and subsequent energy transfer to the neck is known as whiplash. It commonly occurs during motor vehicle accidents, but also during sporting activities. It may result in a variety of bony and soft tissue injuries, manifest by myriad symptoms. This constellation is known as whiplash-associated disorders (WAD) [59]. These conditions generally have a positive prognosis, with 87 % and 97 % cited as having recovered from their injuries at 6 and 12 months; however, this optimism is debated [59].

2.2.2 Presentation

Common symptoms after MVA are neck pain (88–100 %) and headache (54–66 %), but also commonly seen are neck stiffness, shoulder pain, arm pain or numbness, and others [59]. As in other injuries of the axial spine, issues surrounding the compensation for injury and work delay clinical improvement. In 2001, Côté reviewed a Canadian study investigating the association between insurance systems and claim-closure and compensation times after WAD. In the no-fault province of Quebec, the median claim-closure time was 30 days and 4.1 % of claimants were still compensated at 1 year. In Saskatchewan under

DOI 10.1007/978-1-4939-0779-3_116-1

the tort system, the median claim-closure time was 433 days and 57 % were still compensated at 1 year [60].

2.2.3 Diagnosis

An acute cervical injury in the setting of an appropriate mechanism of injury is suitable for the diagnosis of whiplash-associated disorders. Care must be taken not to overlook other conditions that can be present with cervical and cranial trauma, such as fracture, intracranial hemorrhage, mild traumatic brain injury (mTBI), and others. Typically, diagnostic testing and imaging are only utilized to exclude these other conditions.

2.2.4 Management

Management of whiplash should be multimodal and include an assessment of psychological wellness in accordance with the biopsychosocial model. Patients' beliefs, coping strategies, locus of control, and disability should also be measured [59]. It has been suggested that active interventions may be more effective in those with WAD. These have been shown to be beneficially long term on pain, global perceived effort, or participation in daily activities [59]. Patients should be educated and reassured regarding the positive prognosis [61]. Active therapy for comorbid mood disorders should be addressed immediately. Return-to-clinic and emergency room visit criteria should be discussed. If applicable, continuing care of mTBI should be provided [61].

2.2.5 Prognosis

The prognosis of acute whiplash is favorable for most individuals. Age, gender, baseline neck pain, baseline headache, and radicular complaints all have independent influence on recovery. It is well recognized that nonmedical factors may also strongly affect recovery. The above Canadian study further noted that when Saskatchewan changed its insurance systems from tort to no-fault, it achieved a 54 % reduction in median time to claim closure [60]. The influence of jurisdiction on recovery is further highlighted by chronic whiplash, which is low in historically no-fault provinces (Quebec), less litigious countries (Greece), and where whiplash is not compensated (Lithuania) [60].

2.3 Cervical Myelopathy

2.3.1 General Principles

Chronic atraumatic compression of the cervical spine due to spondylosis is the most common cause of spinal cord compression in the world [62]. It is understood that 40–60 % of untreated cervical spondylotic myelopathy (CSM) cases will progress with worsening neuropathy, neuroinflammation, and apoptosis. Radiographic evidence of cervical stenosis is insufficient to produce the syndrome, as some patients with significant stenosis never develop myelopathy for reasons that are unclear.

2.3.2 Presentation

The clinical presentation in CSM varies greatly, depending on the site and type of lesion and whether it produces motor or sensory and upper motor neuron or lower motor neuron signs in the upper or lower limbs [63]. Onset is typically between ages 50 and 70, of insidious onset and progressive and unremitting. These characteristics may help distinguish it from other neuropathic syndromes, such as peripheral compression or multiple sclerosis.

Symptoms may include neck and/or upper limb pain, weakness, numbness or loss of sensation in the upper or lower extremities, and bladder symptoms such as incontinence or urinary frequency.

DOI 10.1007/978-1-4939-0779-3_116-1

Physical exam may reveal signs consistent with upper motor neuron dysfunction: hyperreflexia and/or clonus, Hoffman's sign, Babinski's reflex, multilevel nerve root weakness, sensory loss, or signs of spasticity in the lower limbs [63].

2.3.3 Diagnosis

Plain-film x-ray is commonly obtained in individuals with CSM. With the advent of cross-sectional imaging, however, MRI and intrathecal enhanced CT (CT myelography) have become the studies of choice to evaluate this condition [63], as they are able to aid in the calculation of intracanalar dimensions. The role of EMG is to evaluate for the presence of other conditions that may mimic the findings of CSM, such as peripheral compressive lesions. Cerebrospinal fluid and blood analysis may be used to similarly exclude other neurological conditions [63].

2.3.4 Management

Myelopathy is a progressive disorder and little evidence exists that nonoperative treatment halts or reverses its progress. Thus, nonoperative treatment (intermittent bed rest, the use of collar, anti-inflammatory medication, and discouragement of high-risk activities) is reserved only for asymptomatic patients or those with mild symptoms. Referral or comanagement with a neurologist is recommended. For individuals with moderate to severe or rapidly progressive myelopathic symptoms, surgical referral is warranted [64].

Disorders of the Upper Extremity

Ted C. Schaffer* and Monica C. Schaffer
UPMC St. Margaret FPRP, Pittsburgh, PA, USA

Because of the functional importance of the upper extremity to human activity, patients with injuries in this region frequently require diagnostic and therapeutic assistance from the family physician. A working knowledge of basic anatomy is helpful for establishing a differential diagnosis for upper extremity complaints. This chapter discusses common disorders in this region, but there are many unusual problems that may also present in an office situation.

1 Clavicle

The clavicle is the connecting strut that links the arm and shoulder with the axial skeleton. The clavicle is anchored medially by the sternoclavicular and costoclavicular ligaments, while the acromioclavicular and coracoclavicular ligaments anchor it to the scapula. A thorough examination of any shoulder injury should include palpation of the clavicle and evaluation of the acromioclavicular (AC) and the sternoclavicular (SC) joint motion.

1.1 Clavicular Fractures

Fractures of the clavicle, which account for 2–4 % of all fractures, have a bimodal distribution, with the most common causes from a direct blow to the shoulder or a fall on an outstretched arm. In young adults and children, mechanisms include sports injuries, motor vehicle accidents, and falls, while in the elderly, falls are a common mechanism [1]. The majority (60–80 %) of fractures occur in the middle third of the clavicle. Historically, nonoperative treatment was advocated for almost all middle clavicle fractures, even with severe displacement. In recent years, however, there has been a reconsideration of the role of operative intervention for both return to play and reduction of complications in part due to improved surgical technique [2]. Because of remodeling capabilities, almost all midshaft fractures in children and adolescents can be managed nonoperatively. Either a figure-of-8 brace or sling can be worn for comfort, usually for 2–4 weeks, with some data suggesting that a sling may be better tolerated [2]. In adults, the incidence of midshaft complications such as nonunion or neurovascular compromise is often reduced by surgical intervention. While an individualized approach is currently advocated, those with fracture displacement, shortening, or significant comminution, and those with tenting of the skin do best with surgical intervention. When there is minimal displacement, a sling or figure-of-8 brace remains an appropriate treatment; however, the patient should be advised that there may be a permanent bump at the site of callus formation. Fractures of the distal third (15–25 %) will require surgery if there is evidence of displacement, while nondisplaced fractures may be managed without surgery. At times, painful long-term arthritis of the acromioclavicular joint will necessitate surgical resection of the distal clavicle. Fractures of the medial head of the clavicle are rare (5 %) and are generally managed without surgery. However, it is vital that the patient be assessed for a posterior dislocation of the medial head, usually by CT scan. Such an injury can compress the great vessels or compromise the airway. Immediate elevation of the impacted segment and urgent cardiovascular or orthopedic consultation are recommended.

1.2 Acromioclavicular (AC) Joint Dislocations

Dislocations of the AC joint result from a direct fall onto the anterior shoulder. Management of this condition is determined by the extent of the dislocation. Specific treatment for this problem is covered in Chapter ▶ Bites and Stings.

1.3 AC Joint Arthritis

Osteoarthritis of the AC joint is a common condition causing anterior and superior shoulder pain with the potential for significant disability. Causes include primary degeneration of the fibrocartilaginous meniscus, posttraumatic (prior AC joint injury), inflammatory, and septic arthritis. Weightlifters and throwers are also at risk for this problem [3]. On examination, the patient is point tender over the AC joint. Forward flexion of the arm to 90° followed by adduction of the arm across the body (the crossed body adduction stress test) compresses the joint and reproduces the pain [4]. Initial treatment includes rest, ice, nonsteroidal anti-inflammatory drugs (NSAIDs), and avoidance of aggravating activity. For refractory cases, a corticosteroid injection into the AC joint using an anterior and superior approach may provide some benefit [3]. For cases unresponsive to conservative management, resection of the distal clavicle can alleviate persistent pain.

2 Scapula

Isolated injuries of the scapula are rare, but occasionally, a direct blow over the involved area results in a fracture [5]. Because of the high impact involved, scapular fractures are frequently associated with other thoracic injuries such as rib fractures and pneumothorax. Treatment for fractures of the body of the scapula includes immobilization with a sling until subsidence of pain within 2–4 weeks, followed by progressive exercises. If the acromion or glenoid is fractured, orthopedic referral is necessary because of potential implications to shoulder mobility and function [5].

3 Shoulder

As the pivotal connection between the upper extremity and the axial skeleton, the shoulder is a frequent source of musculoskeletal problems. Its great range of motion is available only at some compromise to bony stability. Most shoulder stability is provided by periarticular soft tissues. A careful physical examination attempts to identify which components are contributing to a specific problem. Disorders extrinsic to the shoulder may also cause referred pain to this area. An evaluation of the cervical spine should be included for any problem presenting as shoulder pain.

Functionally, the shoulder is composed of four joints: sternoclavicular, acromioclavicular, glenohumeral, and scapulothoracic articulation. The major joint is the glenohumeral joint, in which the humeral head is three times larger than the glenoid socket. A fibrocartilaginous glenoid labrum provides depth to the socket and adds stability. During overhead motion of the arm, the humeral head is maintained in the socket by the four muscles of the rotator cuff. Originating from the scapula, these muscles maintain fixation of the humeral head and, based on their humeral insertion, assist in various arm motions. The supraspinatus assists in abduction and forward flexion, the infraspinatus and teres minor create external rotation, and the subscapularis causes internal rotation [6]. Also, vital for proper shoulder motion are the scapulothoracic muscles (rhomboid, trapezius, serratus anterior) and the deltoid.

DOI 10.1007/978-1-4939-0779-3_117-1

3.1 Traumatic Dislocation of the Shoulder

3.1.1 Anterior Dislocation

The major traumatic injury to the shoulder is the dislocation of the humerus from the glenohumeral joint. About 95 % are anterior dislocations caused by a fall on an outstretched hand or resisted force when the shoulder is abducted and externally rotated [7]. Examination reveals a squaring of the shoulder, loss of the roundness of the deltoid muscle, prominence of the acromial edge, and an anterior mass which is the humeral head. The arm is held in slight external rotation and abduction. Before reduction is attempted, a neurovascular exam should access damage to the axillary nerve with loss of sensation and diminished deltoid contraction. This injury, present in up to 30 % of dislocations, is usually a transient neuropraxia that requires several weeks for recovery.

If evaluation reveals no other abnormality, then immediate reduction is acceptable, even without prereduction radiographs, before muscle spasm sets in and makes manipulation more challenging [8]. A number of maneuvers have been described to relocate the shoulder. Initial attempts emphasize gentle longitudinal traction on the arm while passive abduction and external rotation is performed. If there has been a delay, then sedation may be required to effect muscle relaxation. With any maneuver, care must be taken to avoid excessive torquing of the humerus, which could lead to humeral fracture or brachial plexus injury.

After relocation and repeat neurovascular evaluation, the patient is placed in a sling for immobilization. A rehabilitation program is then instituted to strengthen the supportive musculature, restore motion, and prevent recurrent dislocation. Young patients, especially under age 20, are at increased risk for recurrence (75–90 %), and there is now evidence to suggest that surgical stabilization be considered as the initial treatment for young physically active patients [8]. Surgery is often recommended for those with recurrent dislocations. For those over age 50, the risk of recurrent dislocation is much less (10 %), but the increased risk of adhesive capsulitis and loss of shoulder motion requires that early shoulder mobility be emphasized. In this population, an exercise program should be initiated after only 1 week of immobilization. Elderly patients are also at greater risk for concomitant avulsion fracture of the greater tuberosity or tears of the rotator cuff.

3.1.2 Posterior Dislocation

Posterior dislocations comprise only 3 % of shoulder dislocations but are missed on initial radiographs as often as 60–80 % of the time [9]. They should be particularly suspected if there is a history of seizures, alcohol use, or electrical injury. On physical examination, the arm is held in internal rotation, rather than the external rotation of an anterior dislocation. Orthopedic consultation should be obtained if this injury is suspected.

3.2 Periarticular Shoulder Problems

Most shoulder problems involve the soft tissue periarticular shoulder structures rather than the glenohumeral joint. Because these supporting structures are vital to stability, a small injury to one component may cause significant problems in shoulder motion and function. Classification is made difficult by frequent overlap of symptoms, and the phrase subacromial impingement syndrome is an umbrella term [10] which includes the following subsets:

3.2.1 Rotator Cuff Injuries

Patients with rotator cuff injuries present either with abrupt onset of pain after a fall or sudden activity associated with the acute onset of pain or with a more insidious onset over weeks or months, often aggravated by repetitive overhead use, due to chronic degeneration or inflammation. Those with cuff injuries tend to have more pain with overhead activities that affect the lateral aspect of the deltoid. The

DOI 10.1007/978-1-4939-0779-3_117-1

pain is worse with movement and eases with rest, but recurs at night with fewer distractions to the pain [6]. Impingement of the cuff occurs chiefly in the supraspinatus as it courses underneath the acromion and coracoacromial ligament.

Full-thickness cuff tears due to chronic impingement are more common in middle-aged or elderly patients. The tenuous vascular supply of the supraspinatus as it inserts on the humerus is a likely etiology. Examination will demonstrate limited range of motion and a painful arc between 60° and 120° where the cuff comes into greatest contact with the overlying acromial arch. When the patient is unable to hold their arm in 90° of abduction, a significant tear has occurred. Chronicity is implied when there is atrophy of the supraspinatus or infraspinatus tendons. Each tendon of the rotator cuff can be isolated and tested [10]. While small or partial cuff tears can be managed with physical therapy, larger cuff tears warrant MRI and subsequent orthopedic opinion for potential surgery. With any rotator cuff injury, an extensive rehabilitation program of 3 to 6 months will be needed to regain full motion and strength.

3.2.2 Subacromial Bursitis

The subacromial bursa separates the deltoid muscle from the underlying rotator cuff. Irritation of underlying structures, as with impingement, may result in an inflammatory bursitis. Often there is a history of overuse or trauma, followed by the insidious onset of pain and limited active range of motion. A corticosteroid injection using a lateral or posterior approach can provide dramatic relief [6]. Calcific tendonitis, usually within the insertion of the supraspinatus insertion, may cause an acute inflammatory reaction of the overlying subacromial bursa. Roentgenograms demonstrate a calcific deposit superior and lateral to the humerus. Needle aspiration of the calcific mass along with lidocaine and corticosteroid injection can relieve the pain. Other treatment options include extracorporeal shock wave therapy and ultrasound guided needling or surgical excision of the calcific deposit [11].

3.2.3 Biceps Tendonitis and Rupture

The long head of the biceps tendon, which is palpable in the bicipital groove, may be irritated as it courses through the glenohumeral joint within the subacromial bursa and inferior to the supraspinatus tendon on its way to its attachment at the superior sulcus of the glenoid labrum. Pain may be isolated to the biceps tendon, but more often there is diffuse tenderness throughout the subacromial region. The short head of the biceps attaches to the coracoid process and is rarely involved in inflammatory problems of the shoulder. In most cases, rupture of the long head of the biceps tendon occurs as a result of advanced impingement in middle-aged or elderly patients. There is a sudden pop associated with lifting a heavy object with the elbow in flexion [12]. The patient experiences mild discomfort with ecchymosis in the upper arm and a palpable bulge of the biceps muscle mass. Because the short head of the biceps remains intact, treatment is usually symptomatic as little functional loss occurs. Surgery is generally reserved for high-performing athletes and manual laborers who need full supination strength and those who cosmetically object to the "Popeye" deformity that results from the tear. In contrast, rupture of the distal biceps tendon results in significant loss of 60 % of supination strength [13] and will often require surgical repair.

3.3 Glenohumeral Disorders

3.3.1 Osteoarthritis

Because it is non-weight bearing, the true glenohumeral joint is subject to less mechanical stress than the lower extremity. Arthritic changes often occur in response to prior injury. Inflammatory arthritis with erosive changes and joint effusions may occur with severe rheumatoid arthritis. Treatment for any degenerative arthritis is primarily aimed to relieve pain and inflammation, including rest, NSAIDs, physical therapy, and corticosteroid injection into the true joint space. Surgical intervention with joint replacement is an option for refractory cases [6].

DOI 10.1007/978-1-4939-0779-3_117-1

3.3.2 Labral Injuries

The fibrocartilaginous labrum serves to deepen the glenoid fossa and increase glenohumeral stability. Injuries to this structure can occur via several different mechanisms, including traumatic subluxation of the glenohumeral joint, and with excessive throwing. Advances in shoulder arthroscopy along with imaging such as MR arthrogram have improved assessment of these injures. The most common injury is a SLAP lesion, defined as superior labral anterior-posterior, and is best described in overhead athletes. While there may be some role for physical therapy, many injuries are best treated with arthroscopic repair, especially in young active athletes [14].

3.3.3 Adhesive Capsulitis

A poorly understood entity, adhesive capsulitis (also termed frozen shoulder or periarthritis) is characterized by a progressive, painful restriction of shoulder motion. Primary adhesive capsulitis has no apparent initiating event, is more common in the nondominant shoulder of women aged 40–60, and is bilateral in 20 % of cases [15]. When there is a secondary cause of shoulder stiffness such as immobilization, cuff injury, and trauma, the prognosis may not be as good, with permanent loss of shoulder motion. Initial treatment for either kind includes NSAIDs, corticosteroid joint injection, oral prednisone, and physical therapy. For refractory cases, surgical options include manipulation under anesthesia or shoulder arthroscopy [10].

3.3.4 Osteonecrosis

Although less common than osteonecrosis (avascular necrosis) of the femoral head, osteonecrosis of the humeral head can be caused by a number of illnesses such as alcoholism, sickle cell disease, and Gaucher's disease and as a consequence of proximal humeral head fractures [16]. The most common cause, however, is long-term steroid use. MRI may be useful for early diagnosis, as radiographs do not show subchondral collapse and humeral head flattening until later in the disorder. Treatment depends on the severity and chronicity and includes rest, analgesics, physical therapy, and arthroscopic debridement and core decompression for early cases. For more advanced disease, hemiarthroplasty or total joint arthroplasty may be the only options available.

4 Humerus

Proximal humeral fractures are common osteoporotic fractures which occur in elderly patients after a fall on an outstretched arm, with the fracture line occurring at the surgical neck of the humerus. While they are often impacted, fortunately about 76 % of these fractures are nondisplaced and can be managed nonoperatively (Fig. 1). Initial evaluation should include neurovascular assessment of the brachial plexus, axillary nerve, and axillary artery. If there is less than 1 cm displacement and less than 45° of angulation, treatment is by sling immobilization for 1–2 weeks followed by supervised active range of motion. The major complication is loss of joint mobility with potential development of adhesive capsulitis. Even with rehabilitation, some loss of shoulder abduction can be expected.

When a fracture involves the greater or lesser tuberosity or there is associated humeral head dislocation, there is greater risk of long-term complications including rotator cuff injury in up to 40 % of patients [16], and orthopedic consultation should be obtained. With trauma to the humeral shaft which occurs with young patients from high-velocity injuries, integrity of the radial nerve should be tested.

DOI 10.1007/978-1-4939-0779-3_117-1

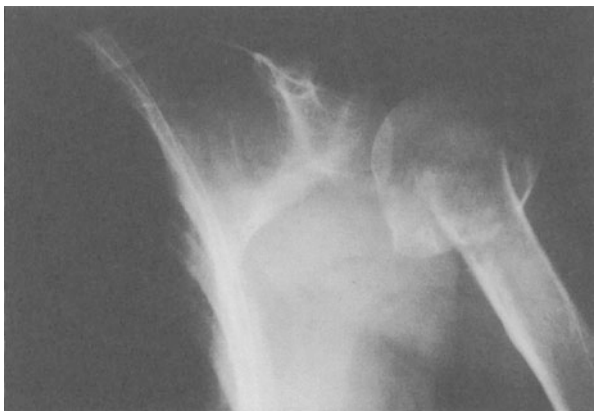

Fig. 1 This impacted humeral fracture in an elderly woman is neither displaced nor severely angulated. It was successfully managed with an arm sling for a week followed by rang-of-motion exercises and course of physical therapy (Originally published in Taylor [17], published with kind permission of Springer Science+Business Media New York, 2003. All rights reserved)

5 Elbow

5.1 Fractures of the Radial Head

While most elbow fractures are complex and require orthopedic referral, in adults the one third that involve the proximal radial head and neck can often be managed by the family physician. The patient presents with a history of a fall on an outstretched hand, pain on rotation or elbow extension, and tenderness over the radial head. Radiologic examination is important, as the fracture is often subtle. At times, the only finding is a posterior fat pad sign which occurs when blood that has entered the joint space displaces the fat pad posteriorly. A small anterior fat pad is a normal finding, but a large anterior fat pad, or "sail sign," is also indicative of a radial head fracture (Fig. 2). Criteria for orthopedic referral include >2 mm fracture displacement, >3 mm depression of the head, $>30^\circ$ fracture angulation, severe comminution, $>$ one third of the articular surface involved, and mechanical block to movement [18]. Management of a nondisplaced radial head or neck fracture emphasizes pain relief and early mobilization. A sling and posterior elbow splint extending from mid-humerus to beyond the wrist are worn for 1–2 weeks, and forearm rotation is begun as soon as pain permits, usually within a few days. Regular follow-up for this injury is important, as it may take several months for the patient to regain motion and some degree of extension, and 10–15° loss of full extension is common but does not affect function. With severe angulation of the radial head or severe fracture angulation, surgical repair may be necessary. In adults, excision of the radial head is one consideration, but in children, the radial head is necessary for adequate lengthening of the radius.

5.2 Epicondylitis

5.2.1 Lateral Epicondylitis

A common source of lateral elbow pain, lateral epicondylitis typically affects the dominant extremity and is usually associated with repetitive and forceful activity involving wrist extension. The eponym of "tennis elbow" is somewhat of a misnomer because the problem occurs more often in patients ages 30–64 and in nonathletic circumstances. The process is more degenerative from repetitive microtrauma rather than inflammatory and is generated by repetitive wrist extension especially by the proximal attachment of the extensor carpi radialis brevis (ECRB) into the lateral epicondyle. The condition is usually self-limited, although recovery may take 12–18 months for spontaneous resolution. A number of treatment options have been attempted including corticosteroid injection, ultrasound therapy, iontophoresis, botulinum

DOI 10.1007/978-1-4939-0779-3_117-1

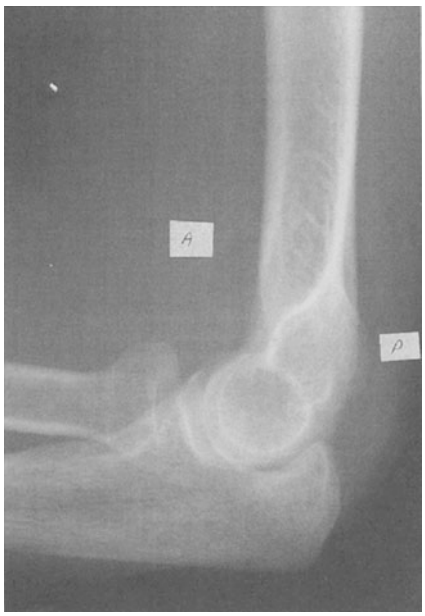

Fig. 2 Fat pad signs. A nondisplaced radial head fracture with both a posterior (P) and a prominent anterior (A) fat pad evident on this lateral view. The posterior fat pad is indicative of blood in the joint space from an occult fracture, displacing the fat from the joint space (Originally published in Taylor [17], published with kind permission of Springer Science+Business Media New York, 2003. All rights reserved)

toxin A injection, prolotherapy, low-level laser, platelet-rich protein injection (PRP), autologous blood injection (ABI), extracorporeal shock wave therapy (ESWT), bracing, and physical therapy. Current literature does not support any treatment as more effective for this disorder [19]. For the unusual situation where there are continued symptoms and disability in spite of other treatments, a number of surgical options both open and arthroscopic are available. For initial assessment, patients should at least be counseled to avoid the offending activity when possible, obtain ergonomic relief (such as adjusting a computer workstation), and use a "palms up" approach for lifting to use wrist flexors thereby resting the wrist extensors.

5.2.2 Medial Epicondylitis

Known by the eponym of "golfer's elbow," medial epicondylitis affects the musculotendinous origin of the common flexor component of the lower arm region where it attaches to the medial epicondyle. The clinical conditions are similar to those in patients with lateral epicondylitis, although this entity is less frequent in occurrence. The important difference is that pain occurs with activity of the flexor compartment of the wrist, and there is often palpable tenderness over the medial epicondyle. As with lateral epicondylitis, a number of treatment modalities have been attempted without any definitive preference.

5.3 Nursemaid's Elbow (Annular Ligament Displacement)

Previously described as subluxation of the radial head, nursemaid's elbow is now referred to by the more anatomically correct term annular ligament displacement. This injury typically occurs in a child ages 6 months to 5 years when there is traction force applied to a pronated arm, causing the annular ligament to slip over the radial head and become trapped in the radiohumeral joint. The patient will hold the arm in pronation and slight flexion against the body. Two forms of reduction have been described. Supination of the elbow with simultaneous flexion has a long history of success, but a more recent description of hyperpronation followed by extension may have a slightly better reduction rate [20]. If the history of

DOI 10.1007/978-1-4939-0779-3_117-1

injury is consistent and the manipulation is successful, no radiographs are necessary, as recovery by the child is almost immediate. To prevent recurrence, parents and caregivers should be educated about the injury mechanism for this benign entity.

5.4 Olecranon Bursitis

Due to its subcutaneous location, the olecranon bursa is susceptible to pressure, trauma, infection, and inflammatory conditions. Olecranon bursitis may be septic or aseptic in nature, although the clinical appearances of the two entities have overlapping features. The optimal management of this entity is ill defined. When infection is suspected, either antibiotics alone or aspiration with antibiotics is performed, with surgical drainage as an option for severe or refractory cases. The most common infecting organism is *Staphylococcus aureus*. With routine aseptic bursitis, or with traumatic bursitis, aspiration of joint fluid is often performed. For aseptic bursitis, the fluid is serous, sanguineous following trauma, and purulent in the case of infection or inflammation such as gout or rheumatoid arthritis. The use of corticosteroid injection may be attempted in recurrent aseptic bursitis, although there is little evidence for significant improvement [21]. When recurrent bursitis results in a thickened fibrotic mass, the only recourse may be surgical excision of the entire bursa.

6 Wrist

6.1 Fractures of the Distal Radius

Because of the close proximity to the radiocarpal joint, fractures of the distal radius are considered wrist injuries. In children, the most common injury is the buckle, or torus, fracture, which occurs with a fall onto an outstretched hand. Radiographic findings may be subtle, with only a slight cortical disruption of the extra-articular radius seen on a lateral film (Fig. 3). While a short arm cast for 3–4 weeks is an acceptable treatment, more recent data suggests that a splint for the same time frame is an acceptable treatment and potentially more cost-effective [22]. When a child presents with a "sprained wrist," evaluation must be done carefully, as the epiphyseal plate is weaker than the ligaments during this period of rapid growth. With normal roentgenograms and tenderness over the epiphyseal plate, a Salter I fracture is presumed, with recommended immobilization for 2–3 weeks.

In adults, the most common radial fracture is Colles' fracture which occurs when a patient over 50 falls onto an outstretched arm. The "silver fork" deformity is caused by dorsal displacement of the distal fragment. The ulnar styloid may also be fractured. Reduction of Colles' fracture may be attempted, but the physician must be aware of potential complications of this fracture, including median or ulnar nerve compression, damage to the flexor or extensor tendons, and radioulnar arthritis [8].

Nondisplaced distal radial fractures that are nonarticular can usually be treated with cast immobilization for 6 weeks in adults. Low-impact intra-articular nondisplaced fractures in the elderly may only require cast immobilization, although the patient should be advised that some residual arthritis may occur. For displaced fractures or intra-articular fractures in young patients, treatments such as percutaneous pinning or open reduction with internal fixation may be required to minimize long-term problems in the joint [23].

6.2 Carpal Fractures

Approximately 60–70 % of carpal bone fractures involve the scaphoid, with young adults having the highest fracture incidence. The usual mechanism is a fall on an outstretched, pronated, and ulnarly deviated hand with the wrist in more than 90° of dorsiflexion. Fracture location and appearance determine the likelihood of complications, with proximal scaphoid fractures (15 %) having a higher risk of

DOI 10.1007/978-1-4939-0779-3_117-1

Fig. 3 Buckle (torus) fracture. A small cortical disruption is visible in the metaphysis of the distal radius (Originally published in Taylor [17], published with kind permission of Springer Science+Business Media New York, 2003. All rights reserved)

complications. Distal (5 %) and waist (80 %) fractures have a better prognosis than proximal (15 %) fractures, and if the fracture is nondisplaced, it can be managed by the family physician, although surgical intervention is an option when rapid return to sport or work is desired. A fracture more than 1 mm displacement, or any fracture with a delayed diagnosis, will also likely require orthopedic intervention [24]. Initial plain film radiographs may appear normal with undisplaced scaphoid fractures. When there is tenderness in the anatomic snuffbox (between the extensor pollicis brevis and extensor pollicis longus tendons) or the scaphoid tubercle (palmar hand surface), options include splint immobilization for 7–10 days with repeat radiographs or MRI. Because of the high risk of nonunion, scaphoid fractures require prolonged immobilization – generally 8–12 weeks for waist fractures. Because of the subtle nature of these fractures, often with little wrist swelling, there is a tendency by some patients to avoid initial treatment. Subsequent nonunion places the entire wrist at risk for significant avascular necrosis or arthritis, with more complicated and less successful salvage therapy performed to maintain vascular integrity and wrist congruence [24].

Other fractures of the carpal bones are uncommon and frequently require special radiographs or CT/MRI in order to visualize the pathology. The triquetrum is the second most commonly injured carpal bone (15 %), and if there is a nondisplaced fracture of the triquetrum, it can be managed by cast immobilization for 4–6 weeks [25]. A meticulous examination of the painful area indicates which carpal bones are likely to be involved. Because serious sequelae are common, including ulnar or median neuropathy and chronic wrist instability, orthopedic intervention is usually advised.

6.3 Wrist Instability

Although fractures of the carpal bones are unusual, sprains and other minor traumatic wrist injuries are common. A number of serious wrist injuries have been described as physicians have gained greater appreciation for the complex interactions of other ligaments and multiple articulations within the carpal complex [26]. The MRI has been especially useful in delineating wrist abnormalities, while plain radiographs may be helpful for certain problems such as lunate dislocations and scapholunate dissociations. Because distinguishing between a serious wrist injury and a minor sprain can at times be

DOI 10.1007/978-1-4939-0779-3_117-1

challenging, the physician should be suspicious about wrist injuries which fail to resolve within a 3–4-week period of time and proceed with MRI and/or orthopedic consultation.

6.4 TFCC Injuries

The triangular fibrocartilage complex (TFCC) is a small meniscus located distal to the ulna. This tissue serves to absorb impact to forces on the ulnar aspect of the wrist. Injuries can be acute, due to sudden impact, or chronic, due to repetitive loading such as gymnastics. As with carpal stability, the physician should be suspicious of TFCC injuries when ulnar wrist pain does not respond to 3–4 weeks of splinting. MRI findings will guide management which may include arthroscopic repair or debridement [27].

6.5 De Quervain's Tenosynovitis

A stenosing tenosynovitis, de Quervain's tenosynovitis occurs as the first extensor compartment, comprising the abductor pollicis longus and the extensor pollicis brevis tendons, courses over the radial styloid and through a fibro-osseous tunnel that holds the tendon against the bone. Thickness and swelling within this region produces radial-sided wrist pain associated with thumb movement. There is often an occupational or vocational history of repetitive hand motion such as knitting, sewing, or painting. The diagnosis is confirmed by the Finkelstein test and performed as follows: after passive adduction of the thumb into the palm, ulnar deviation of the wrist elicits a sharp pain that reproduces the patient's symptoms. Initial treatment will often include a corticosteroid injection, which has been shown to be successful 60–90 % of the time [28]. Other treatment options include NSAIDs and a thumb spica splint. On occasion, surgical release of the tendon sheath is required for symptomatic relief.

6.6 Intersection Syndrome

Inflammation can also occur at the crossover of the first and second extensor compartments of the wrist, located 4–8 cm proximal to the distal radius. Pain and tenderness are noted in this region, and at times there is fusiform swelling [29]. The problem occurs as an overuse syndrome from repetitive wrist extension, such as rowing, pulling, or weight lifting, and should be distinguished clinically from the more distal problem of de Quervain's tenosynovitis. Initial treatment should include splinting, relative rest, and NSAIDs, with corticosteroid injection reserved for more refractory cases.

6.7 Ganglion Cysts

Ganglion cysts are fluid-filled masses stemming from the joints of the hand or wrist, which can arise from many articulations. The most common locations are the volar wrist adjacent to the radial artery and the dorsal radial wrist adjacent to the scapholunate interval. Degeneration of the joint capsule leads to an extravasation of fluid through a 1-way valve. These lesions may be asymptomatic or painful with activity. Reassurance for asymptomatic lesions is appropriate; spontaneous resolution can occur in up to 42 % of patients over 6 years [28]. For symptomatic cysts, aspiration can be attempted although caution must be used with aspiration of volar cysts due to the close proximity to the radial artery. A large bore needle (18 or 20 gauge) is inserted into the mass and fluid, usually a thick jellylike substance, can be aspirated. There is a 30–40 % chance of resolution with aspiration. For recurrent ganglia, surgical excision can be offered, although even here there is a variable recurrence rate of as much as 40 % [28].

6.8 Carpal Tunnel Syndrome

The most common compressive neuropathy of the upper extremity, carpal tunnel syndrome, is discussed in Chapter ▶ Care of the Dying Patient.

DOI 10.1007/978-1-4939-0779-3_117-1

7 Hand

7.1 Metacarpal Fractures

The most common fracture is a "boxer's fracture," which is a fracture at the neck of the little finger that gets its name due to a high prevalence among amateur pugilists. Because of the mobility of the fourth and fifth metacarpals, volar angulation of the distal fragment of less than 30–40 is acceptable without the need for bone manipulation [30]. While angulation is acceptable, a rotation injury around the longitudinal axis of any metacarpal necessitates orthopedic referral for surgical pinning. For a boxer's fracture with mild angulation, an ulnar gutter or volar splint with the metacarpophalangeal (MCP) joint at 90° is applied for 3–6 weeks. Midshaft fractures of the fifth metacarpal can be managed similarly if the angulation is less than 20°. Nondisplaced fractures of the second and third metacarpals can be treated with a short arm cast, but careful physical examination must be performed to ensure that there is no rotation or angulation present, as these bone problems necessitate surgical correction. The unusual fracture that involves either the articular surface of the metacarpal base or metacarpal head mandates orthopedic consultation because of the potential for later complications.

Intra-articular fractures of the thumb require surgical correction, such as Bennett's fracture (with proximal dislocation of the metacarpal bone) or Rolando's fracture (a comminuted intra-articular fracture of the metacarpal base). The more common extra-articular fracture of the thumb, if not angulated more than 30°, can be managed with a short arm thumb spica cast with the thumb in a flexed position.

7.2 Arthritis of the Thumb

Arthritis of the basal joint of the thumb, the first carpometacarpal joint, is the second most common hand arthritis after DIP (distal interphalangeal) joint arthritis. Patients, often middle-aged or elderly females, complain of pain at the base of the thumb with vigorous activity. Progression of disease can lead to significant functional disability with simple tasks such as opening jars or turning doorknobs. Over time the base of the thumb enlarges, producing a "squaring of the thumb" on physical examination. A grind test, with axial loading of the CMC joint, will reproduce the pain. Radiographs will demonstrate narrowing of the joint space and osteophyte formation. Treatment options include activity modification, thumb splinting, NSAIDs, and intra-articular corticosteroid injections [28].

7.3 Infections

Prompt diagnosis and treatment are important with hand infections because hand stiffness, contractures, and even amputation can result from missed diagnoses or delayed treatment. *Staphylococcus aureus* remains the most common species with an increasing prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA). Immunocompromised patients (diabetes, HIV, IV drug users) are at higher risk and often will have polymicrobial infections [31].

7.3.1 Palmar Space Infections

Infections of the palmar space are potential disasters because spread in the deep space tissues can occur rapidly. Pain, tenderness, or swelling of the palmar surface suggests a deep hand infection, as does a recent history of minor trauma. Evidence of a palmar space infection mandates early orthopedic consultation, as surgical drainage is the primary intervention. Animal bites in this area will often warrant prophylactic antibiotics, especially the deep puncture wounds inflicted by cat bites [32].

7.3.2 Dorsal Hand Infections

Infections of the dorsal hand may appear worse than palmar infections because of the dramatic swelling within the loose connective tissue, but the prognosis is generally good. Oral antibiotics and outpatient

DOI 10.1007/978-1-4939-0779-3_117-1

drainage are usually satisfactory. Before treatment, however, the palmar surface must be inspected to be sure that the dorsal infection is not originating from a deep palmar infection that has ruptured to the dorsal surface. Lacerations over the MCP joints warrant special precautions, especially those of the fourth or fifth metacarpal. The usual history for this injury is an altercation in which the patient has punched another person in the teeth and sustained a human bite (fight bite). The patient frequently denies this history on initial questioning. A human tooth contacting a clenched fist usually violates the extensor tendon and joint capsule and may injure the metacarpal head, inoculating the MCP joint [32]. When this injury is suspected, a hand surgeon should be contacted to consider early operative debridement. A good rule to remember is that *all* lacerations over the MCP joints are human bites until proven otherwise.

7.4 Dupuytren's Contracture

Dupuytren's contracture is an idiopathic thickening of the palmar fascia, resulting in asymptomatic contractures of the fingers primarily at the MCP joint but at times involving the PIP joint. The subsequent deformity can be functionally disabling. Although the etiology is unknown, there is autosomal dominance with variable penetrance which occurs primarily in middle-aged men of Celtic origin [33]. The inflammation and subsequent contracture of the palmar aponeurosis may progress over many years. Treatment of this entity has been limited, and corticosteroid injections have not been beneficial. While surgical correction remains the mainstay of treatment, in recent years, the use of collagenase and other enzymatic injections has offered some promise as an alternative to surgery [33].

8 Finger

8.1 Fractures

8.1.1 Distal Tip Fractures

Crush injuries of the tip of the finger cause pain because of the closed space swelling. Even when the fracture is comminuted, the fibrous septae provide stability during bone healing. Protective splinting of the tip and DIP joint for 2–4 weeks should be followed by range of motion and strengthening of the DIP joint. Patients should be informed that these fractures are often complicated by hyperesthesia, cold sensitivity, pain, and numbness that may last for 6 months after the injury [34]. For any fracture associated with a nail bed injury, the nail bed or matrix must be repaired to minimize aberrant nail growth. Subungual hematomas, with or without associated fracture, can be decompressed with an electrocautery device or heated paper clip, creating a hole at the distal tip of the lunula.

8.1.2 Middle and Proximal Phalangeal Fractures

Examination to determine stability after a finger fracture is the key to management of these injuries. Assessment of angulation is made with radiographs, while rotation stability is determined by clinical examination. With finger flexion, all fingers should point toward the palmar thenar eminence [35]. Evidence of finger overlap indicates rotation instability, even if radiographs demonstrate minimal angulation (Fig. 4). Nondisplaced extra-articular fractures of the middle or proximal phalanx can be managed by 1–2 weeks of immobilization followed by dynamic splinting with "buddy taping" to an adjacent finger for 4–6 weeks during activity [35]. Large intra-articular fractures involving the middle or proximal phalanx are usually unstable fractures that will require percutaneous pinning or compression screws. Small (<25 %) avulsion fractures of the volar middle phalanx are frequent injuries that occur with a hyperextension injury (Fig. 5). In addition to the fracture, there is disruption of the volar plate, a structure that prevents hyperextension of the proximal interphalangeal (PIP) joint. These injuries are managed by 2–3 weeks of immobilization with 20–30° of flexion at the PIP joint, which allows maximal length of the collateral

DOI 10.1007/978-1-4939-0779-3_117-1

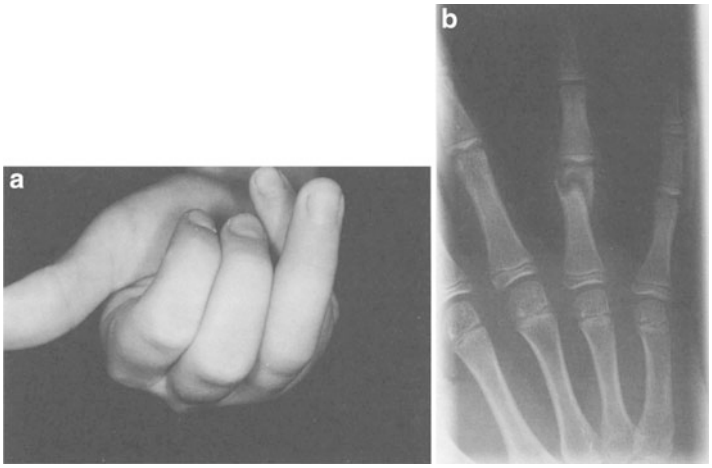

Fig. 4 Rotation deformity of the ring finger (**a**) indicates that surgical fixation is necessary to reduce the fracture. The radiograph (**b**), with only mild angulation, demonstrates why clinical examination for rotation is necessary for evaluating a finger injury (Originally published in Taylor [17], published with kind permission of Springer Science+Business Media New York, 2003. All rights reserved)

PIP ligaments and permits early finger rehabilitation. A buddy taping program during activity or sports, with gauze placed between the fingers to reduce skin maceration, should continue for an additional 4–6 weeks. Failure of the volar plate to heal properly may result in hypermobility at the PIP joint.

8.2 PIP Joint Dislocations

With sudden hyperextension, the middle phalanx may dislocate dorsal to the proximal phalanx. This dislocation, known as a "coach's finger," is easily reduced by gentle traction on the finger, with volar pressure on the middle phalanx of the PIP. Successful relocation produces immediate relief and resolution of the deformity [34]. Radiography should still be performed to look for evidence of subluxation, PIP joint instability, and middle phalanx volar plate fracture. Because the dislocation results in disruption of at least the fibrocartilaginous volar plate, the PIP joint should be immobilized in 20–30° of flexion and managed similarly to the volar plate fracture described above. Early range of motion exercises after just 1–2 weeks of immobilization have been shown to improve finger mobility and earlier return to function [34]. Lateral joint injuries with mild instability on stress testing (<15° of deviation) can also be managed with flexion splinting and subsequent buddy taping. Treatment of complete lateral dislocations and volar dislocations is more complex and referral to a hand surgeon is usually advisable.

8.3 Tendon Injuries

8.3.1 Mallet Finger Injuries

Forced flexion of the distal interphalangeal (DIP) joint on an extended finger avulses the extensor tendon as it inserts into the distal phalanx, and the patient cannot actively extend the distal phalanx. If left untreated, mallet finger leads to a swan neck deformity from PIP joint hyperextension and DIP joint flexion [36]. Orthopedic referral is indicated only if there is subluxation of the DIP joint or if there is a large bone fragment involving >25 % of the articular surface. Usually, radiographs will demonstrate either no fracture or only a small avulsion fragment. This injury is treated by placing the DIP joint in extension for a period of 8 weeks, while the PIP joint is permitted to move freely. A number of commercial and homemade splints are available, and there is no clear preferred method. The key is constant prolonged splinting, which is vital to permit tendon healing [36]. The patient is advised that flexion of the DIP joint even once before adequate healing will result in tendon avulsion and necessitate reinitiation of the entire

DOI 10.1007/978-1-4939-0779-3_117-1

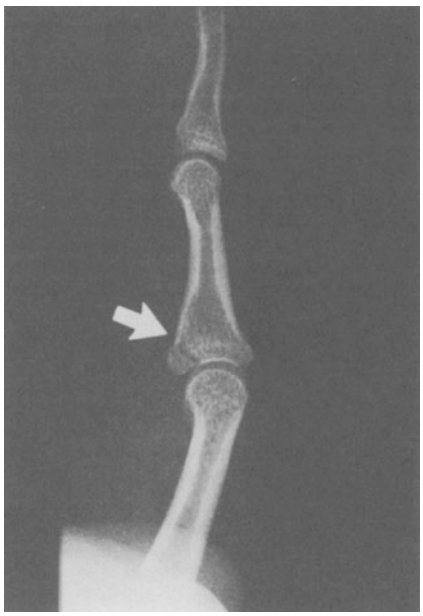

Fig. 5 This fracture of the middle phalanx implies that the distal volar plate has been disrupted. A combination of splinting and buddy taping for several weeks is required to allow the volar plate to heal (Originally published in Taylor [17], published with kind permission of Springer Science+Business Media New York, 2003. All rights reserved)

process. During any splint change, care is exercised to maintain finger extension. Hyperextension of the joint is also avoided, as this may lead to necrosis of the dorsal skin.

8.3.2 Central Slip Injuries

The central extensor tendon of the finger courses over the proximal phalanx and inserts into the base of the middle phalanx. A laceration or crush of the extensor tendon over the dorsum of the PIP joint, or volar dislocation of the PIP joint, damages the central portion of the extensor tendon. When this central slip is damaged, sudden forced flexion of the PIP joint results in loss of extension at the PIP joint and hyperextension of the DIP joint. The resulting contracture is known as a boutonniere deformity, named after the French term for buttonhole [37]. Tenderness of the central slip region is an injury to this structure until proven otherwise. A potential central slip injury without fracture is treated by maintaining the PIP joint in extension for 2–6 weeks. The stiffness that results from the collateral ligament tightening is much easier to treat than is correction of an established boutonniere deformity.

8.4 Trigger Finger

As the flexor tendon courses through the hand, a nodular thickening at the MCP level impinges the tendon. The cause is inflammation at the A1 pulley, the first of five pulleys which guide the flexor tendon into the finger. Although the problem is located at the MCP head, the patient will often complain of more distal pain at the PIP level. During finger extension, there is a catching or locking of the PIP joint as the stenosed tendon becomes trapped in the pulley. Trigger finger is more common in middle-aged women, in the dominant hand, and in patients with diabetes. Initial management is a tendon sheath injection with a small amount of a corticosteroid (e.g. 10 mg triamcinolone) directly into the stenosed area (Fig. 6). Initial steroid injection has a success rate of about 57 %; a second injection may increase the success rate to 86 % [38]. If the trigger finger persists, surgical release is necessary. For pediatric cases, a trigger thumb is more common than a trigger finger, and surgical intervention, not corticosteroid injection, is the recommended treatment.

DOI 10.1007/978-1-4939-0779-3_117-1

8.5 Gamekeeper's Thumb

Damage to the ulnar collateral ligament (UCL) that occurs with a sudden hyperabduction is termed a gamekeeper's or skier's thumb. The UCL is vital for open grasp and pinch action of the hand. Swelling and tenderness of the ulnar side of the MCP joint suggest this injury. A radiograph of the thumb is obtained to ensure there is no fracture before the UCL is tested. To examine for instability, the MCP joint is stressed with the interphalangeal (IP) joint in both extension and flexion to test both the accessory and proper components of the collateral ligament [39]. An unstable joint, which opens up >35° or 15° more than the normal contralateral UCL, or a radiograph which shows a large avulsion fragment, necessitates orthopedic referral for probable surgery. With a complete tear, the interposition of an adductor aponeurosis between the ends of the torn ligament (termed a Stener lesion) prevents ligament healing unless surgery is performed. Early repair within several weeks optimizes return of hand function. If there is tenderness, but the UCL is stable, a thumb spica splint or cast is applied for 1–2 weeks and the joint is then reassessed for instability.

8.6 Infections

8.6.1 Paronychia

Inflammation of the tissue immediately surrounding the nail, known as a paronychia, is commonly caused by an acute (<6 weeks) or chronic (>6 weeks) infection. The infection is often introduced by minor trauma such as nail biting (onychophagia) or manicuring. Redness and swelling occur along the nail folds and fluctuance is common. Early infections may be treated with warm soaks and topical or oral antibiotics [40]. Treatment of a superficial abscess involves a scalpel incision between the nail fold and the nail plate with evacuation of pus; a finger block before incision is optional. The incision is made parallel to the nail plate to avoid damage to the germinal nail matrix. In the unusual event of a deeper subungual abscess, more extensive surgery with partial nail removal is required to drain the abscess. A chronic paronychia is often associated with occupational water exposure such as dishwashing or bartending. The infecting organism is often *Candida albicans*. Environmental modification plus oral antifungal medication is often successful. Surgical management is reserved for refractory cases [40].

8.6.2 Felon

Painful abscesses within the distal pulp space, felons typically occur after a minor puncture wound. Tense distension within this closed space can cause compromise to soft tissues and digital vascularity [31]. Early surgical drainage is usually required to prevent loss of the pulp tissue or to prevent other complications such as osteomyelitis or tenosynovitis. Following a digital block, a felon is drained by one of several

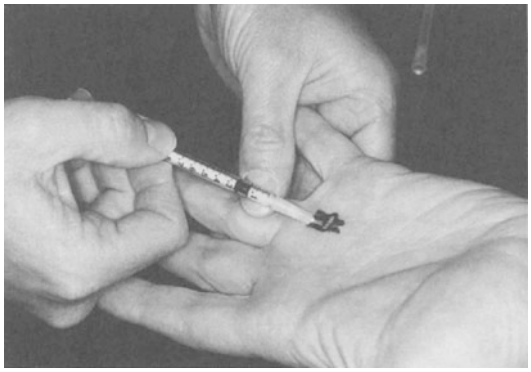

Fig. 6 Injection of a trigger finger is performed in the A_1 pulley at the MCP level. The needle can be directed proximally (as shown) or distally (Originally published in Taylor [17], published with kind permission of Springer Science+Business Media New York, 2003. All rights reserved)

DOI 10.1007/978-1-4939-0779-3_117-1

surgical techniques. A lateral incision or longitudinal palmar incision is most common. Incision of the radial side of the index and ulnar side of the thumb and little finger is avoided to prevent sensory problems in these sensitive areas. Packing material is placed and changed frequently along with administration of oral antistaphylococcal antibiotics.

8.6.3 Tenosynovitis

Pyogenic flexor tenosynovitis results when a puncture wound inoculates the flexor sheath. Kanavel's 4 signs of flexor tendonitis include a flexed resting posture of the digit, palpable tenderness of the flexor sheath, fusiform swelling of the digit, and severe pain on passive extension [31]. The latter sign is the most specific for flexor tenosynovitis and mandates immediate surgical consultation, since early debridement and aggressive care may allow salvage of finger and hand function.

Disorders of the Lower Extremity

Jeff Leggit[a]*, Patrick M. Carey[b] and Jason B. Alisangco[b]
[a]Department of Family Medicine, Uniformed Services University of the Health Sciences, Bethesda, MD, USA
[b]Fort Belvoir Family Medicine Department, Fort Belvoir Community Hospital, Fort Belvoir, VA, USA

The lower extremities provide the stable platform for locomotion and all movements while upright. They are subject to much higher force loads than the upper extremities. Walking has an impact force of 1.2–3 times a patient's body weight (BW) and running can increase the impact force anywhere from 7-10 times BW. Compounded over a lifetime, the lower extremities are subject to tremendous loads. Multiple intrinsic and extrinsic factors increase the risk for lower extremity injuries. These include but are not limited to musculoskeletal abnormalities (e.g., pes cavus), obesity, advancing age, chronic illness (e.g., diabetes, COPD), training errors, certain medication use, and previous trauma.

This chapter will discuss in detail those conditions most commonly seen and managed by the family physician in an ambulatory setting as well as those less common entities that have high morbidity if not properly recognized.

Hip Injuries

Hip Fracture

General Principles

Hip fractures are extremely common. In 2010, there were 258,000 hospital discharges in the United States for hip fractures in those >65 and the rate increased 10 times for those >85. Thirty percent patients die within a year of their hip fracture [1]. Aging is associated with several impairments including osteoporosis, muscle weakness, imbalance, hearing loss, and presbyopia. These age-related factors combined with comorbid medical disorders and polypharmacy place seniors at high risk for falls and subsequent hip fractures. With the aging population, the prevalence is only expected to increase.

Diagnosis

Classically, patients will complain of a sudden onset of hip pain and inability to walk after a fall, although those with minimal displacement or impaction may be able to ambulate. Insufficiency fractures (normal stress to abnormal bone causing a fracture) may occur in the absence of overt trauma. Patients may also complain of groin, thigh, buttock, or knee pain. Physical exam will show localized tenderness in the hip and groin with limited range of motion.

Initial assessment of the patient with a hip fracture should focus on a complete history and physical exam as there may be coexisting injuries (i.e., traumatic brain injury). Radiographic examination should include anterior/posterior (AP) pelvis and cross-table lateral hip views with careful avoidance of frog leg positioning due to risk of fracture displacement. Computed tomography (CT) scanning is useful when plain films are inconclusive. Any elderly or at-risk patient (i.e., chronic steroid use or known osteoporosis) with hip pain and a history of a fall requires a thorough radiographic assessment. The differential

[e]Internal due to iliopsoas or labral pathology and external due to iliotibial band

diagnosis includes dislocation, ligamentous sprain, muscle injury, and chondral or labral pathology. (Note that many of these conditions may coexist with any fracture.) See Table 1 for a list of differential diagnosis for hip-related pain.

Treatment

Immediate treatment of an isolated hip fracture (except avulsion fractures) consists primarily of providing adequate analgesia and urgent orthopedic surgery consultation. Most fractures should be repaired surgically within 48 h; however, nonoperative management is appropriate when surgical risk is too great or when life expectancy is limited.

The family physician may be asked to assist with pre- and perioperative management to include cardiac risk evaluation. The most current American Heart Association and American College of Cardiology guidelines should be consulted for the latest recommendations, but in general, if there are no active cardiac conditions and the patient had been able to walk a flight of stairs, surgery can proceed [1]. Thromboembolic events are potential life-threatening complications associated with hip fractures. Antithrombotic prophylaxis should be started with low-molecular-weight heparin 12 h after hip fracture surgery and continued for 14 days along with intermittent pneumatic compression until the patient is ambulatory [2].

The family physician has a major role in primary and secondary fracture prevention which are very similar and include risk factor reduction through smoking cessation, moderation of alcohol use, osteoporosis management (prevention, detection, and treatment), and fall prevention (to include home assessment). Reducing polypharmacy and medication reconciliation should also be addressed. High-risk medications include sedatives, hypnotics, behavioral health medicines, antihypertensives, and anticoagulants. Although the best strategy for restoring mobility and function after a fracture has not been determined, a combination of weight-bearing exercise, proprioception/balance training, and muscle

strengthening is advocated [3]. Prophylaxis with bisphosphonates should be offered regardless of osteoporosis status to those patients with hip fractures receiving a prosthetic. The use of bisphosphonates has been shown to increase prosthetic survival [1]. Bisphosphonates should be administered along with appropriate doses of calcium and vitamin D unless contraindications exist. A recent review of cushioned hip protectors showed that they have little effect on hip fractures and compliance is poor at best.

Stress Fractures

The lower extremities are the site for 80–95 % of stress fractures [4]. Table 2 lists intrinsic and extrinsic risk factors which must be addressed for prevention as well as recurrence avoidance. Definitive diagnosis requires radiographic confirmation. Plain radiography should be ordered but radiographic findings often lag or are very difficult to appreciate. Bone scans lack specificity and remain positive for months to years even after a patient has fully recovered and therefore are not recommended. Magnetic resonance imaging

	Fifth metatarsal
	Treatment recommendations
	Refer to musculoskeletal specialist due to high morbidity
Correct risk factors	**Correct risk factors**

Consider bone mineral density testing if history of multiple low-risk stress fractures or a single high-risk stress fracture

(MRI) is the modality of choice for diagnosis. Stress fractures can be segregated into low and high risk depending on their ability to heal. See Table 3 for a list of each type of fracture and treatment recommendations based on type.

Around the hip, femoral neck stress fractures (FNS) require discussion as there is high morbidity if not promptly diagnosed and appropriately managed. Female athletes and those unaccustomed to running or impact forces (i.e., basic military recruit) are the most common patient populations. Pain can be focal or diffuse and even radiate to the knee. There is a paucity of physical exam findings. A high index of suspicion is required and radiographic assessment is mandatory if the diagnosis is considered. It would be prudent to have patients be non-weight bearing while awaiting a definitive diagnosis. If confirmed, all patients with FNS should be referred for definitive management [5].

The hip contains a number of apophyseal sites which are subject to injuries ranging from apophysitis to fractures (avulsions or stress). See Fig. 1 for hip and upper leg anatomy. Unless an avulsed fragment is displaced >2 cm, nonoperative management is recommended and consists of decreased activity with gradual resumption as pain allows. Correction of any modifiable risk factors (Table 2) is required to prevent recurrence.

Hip Dislocation

General Principles

The focus of this section is simple dislocations of the femoral head outside of the acetabulum. Complex dislocations have an associated fracture, and after the dislocation is reduced, fracture management dictates therapy. Dislocations are not subtle injuries and require immediate referral to an orthopedic surgeon. The most common mechanism of injury is a high-energy motor vehicle accident which carries the risk of other major traumatic injuries. Other mechanisms include a fall from a height, automobile-pedestrian accidents, and athletic injuries [6].

Posterior dislocations are most common and present as a flexed, adducted, and internally rotated leg. Anterior dislocations are rare, more likely to occur during sporting events, and present in external rotation with slight flexion and abduction.

Diagnosis

Because of the high-energy mechanism of injury, a thorough clinical examination should be performed, beginning with airway, breathing, and circulation following standard Advanced Trauma Life Support®

DOI 10.1007/978-1-4939-0779-3_118-1

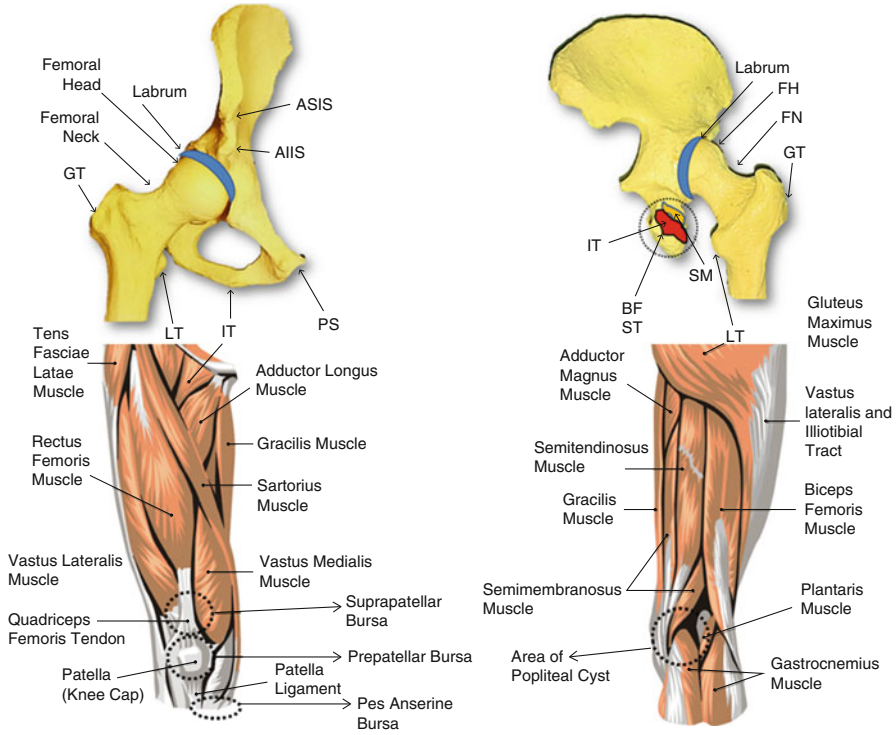

Fig. 1 Hip and upper leg anatomy. AIIS = anterior inferior iliac spine (rectus femoris origin); ASIS = anterior superior iliac spine (sartorius origin); PS = pubic symphysis (adductor brevis/longus and gracilis origin); IT = ischial tuberosity (hamstring origin (BF = biceps femoris/ ST = semitendinosus/ SM = semimembranous)); GT = greater tuberosity (gluteus medius/ minimus insertion); LT = lesser tuberosity (iliopsoas insertion); FH = femoral head; FN = femoral neck (Muscle figures adapted and used by permission from fpnotebook.com)

protocols and assessing for neurologic or vascular injury. An AP pelvis radiograph is usually adequate for the diagnosis of a hip dislocation. A posteriorly dislocated femoral head appears smaller than the contralateral side and will be outside of the acetabulum, while an anteriorly dislocated femoral head appears larger. A cross-table lateral film provides a second view of the relationship of the femoral head to the acetabulum. Unless there is suspicion of an occult femoral neck fracture, a CT is not needed prior to emergent reduction. The differential diagnosis is the same as for fractures but includes subluxations.

Treatment

Hip dislocation is a severe injury that requires prompt attention. Emergent reduction reduces the period of avascularity to the femoral head and should be accomplished as atraumatically as possible and ideally within 6 h. If neurovascular compromise is not present, a fracture should be ruled out prior to any attempts at reduction. If there is no associated fracture on postreduction films and proper joint alignment is achieved, the leg should be extended and externally rotated, and a knee immobilizer should be placed to prevent inadvertent flexion at the hip [6]. All patients with hip dislocation must be referred to an orthopedic surgeon who will guide rehabilitation. Patients are at risk for avascular necrosis and subsequent osteoarthritis (OA). They should be encouraged to maintain an ideal body weight as well as core and hip strength to mitigate morbidity.

DOI 10.1007/978-1-4939-0779-3_118-1

Femoroacetabular Impingement (FAI)

General Principles

FAI comprises a constellation of bony overgrowth conditions in and around the hip joint. The condition is caused by supraphysiologic or excessive motion in normal hips or normal motion through the hips with atypical morphology which leads to bony changes and eventual impingement [7]. The impingement deformities include acetabular overgrowth or acetabular retroversion (abnormal position changing the way the femur articulates with the acetabulum) producing a pincer (pinching) lesion and femoral neck bony buildup producing a cam or "pistol-grip" deformity (abutting up against a normal acetabulum). However, the most common is a mixed type with features of both (see Fig. 2). General population prevalence is unknown as descriptive epidemiology has only been done at referral centers involving patients undergoing hip arthroscopy.

Diagnosis

There is an insidious onset of pain typically at the groin but can also manifest at the buttock, lateral or anterior thigh, and low back. Common complaints include a reduced range of motion and /or pain in internal rotation and flexion with activity or trying to sit. Patients will state that they need to frequently change positions to alleviate pain. Diagnosis is usually delayed by years because of the vague nature of the complaints and the lagging radiographic changes.

Young athletic males more commonly are affected by cam lesions. Cam-type deformities can lead to chondral damage, labral tears, and early OA due to abnormal abutment forces on the acetabular labrum.

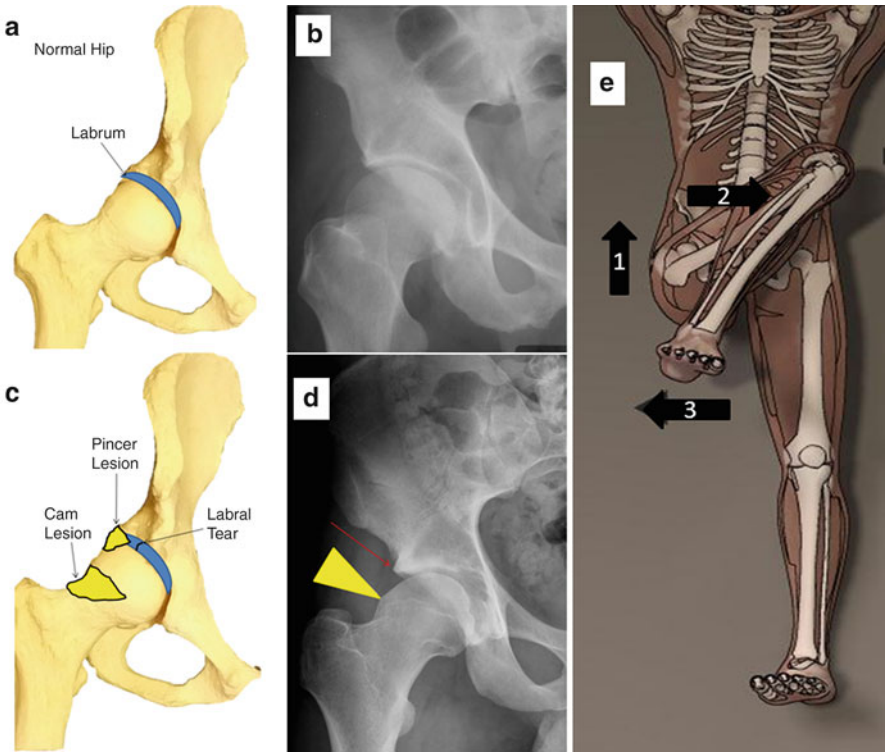

Fig. 2 Femoroacetabular impingement and FADIR test. (**a**) Normal hip anatomic model. (**b**) Normal hip AP radiography. (**c**) Hip anatomic model with cam and pincer lesion and labral tear. (**d**) AP radiography with cam lesion (*yellow arrowhead*) and pincer lesion (*red arrowhead*). (**e**) FADIR test: flexion (*arrow #1*), adduction (*arrow #2*), internally rotate (*arrow #3*) (FADIR image adapted with permission from fpnotebook.com)

DOI 10.1007/978-1-4939-0779-3_118-1

Middle-aged active women are more likely to present with pincer lesions. Their pain results from the over-coverage of the femoral head or acetabular retroversion which appears on plain films as an anterior osteophyte from the superior lateral acetabulum [7]. As mentioned earlier, a mixed cam and pincer deformity is the most common presentation (see Fig. 2). Patients with concomitant labral tears may present with mechanical symptoms of clicking and catching.

Evaluation should include a complete lumbar and lower extremity physical exam specifically assessing for obvious anatomic malalignments (leg length discrepancy, lower limb valgus/varus position, pes cavus/planus), decreased range of motion, and hip weakness. The tests most consistent with FAI include a painful supine impingement test (hip **f**lexion to 90°, **ad**duction, and **i**nternal **r**otation or FADIR; see Fig. 2) along with a painful resisted straight leg raise. (The pattern of inspection, palpation, range of motion, motor strength, and special tests constitutes the essential elements of all musculoskeletal physical examinations and will be repeated throughout the chapter.)

If FAI is suspected, radiographic confirmation is required. Plain radiography includes both a standing pelvis AP and a lateral view (frog leg, cross-table lateral) and possibly a Dunn view (AP pelvis with the hip at 20° abduction and either 45° or 90° flexion) to evaluate femoral head/neck morphology. Plain MRI has little role in FAI evaluation, but MR arthrogram can serve two purposes. The contrast material can help identify chondral and labral lesions which have important treatment implications. In addition the intra-articular anesthesia injected for the procedure can serve a diagnostic role in elucidating if the hip joint is the source of pain. CT is better at defining the three-dimensional bony abnormalities but should be ordered by the treating surgeon for surgical planning. The differential diagnosis includes tendinopathies and chondral or labral pathologies (see Table 1).

Treatment

A trial of nonoperative activity modification, hip strengthening, and pain control either orally or via intra-articular injections may be beneficial. Exercises directed at strengthening the hip abductors, pelvic stabilizers, and abdominal core muscles as well as correcting any contractures of the hamstrings, iliopsoas, quadriceps, or iliotibial band are recommended regardless whether nonsurgical or surgical options are pursued [8]. (This reference contains examples of home exercise handouts for a variety of conditions and is suggested for prescribing home rehabilitation therapy.) Nonoperative management is usually unsatisfactory for active adults as they often are not willing to discontinue/modify pain producing activities. Delayed intervention may also lead to degenerative joint disease which portends a poor prognosis and limits surgical options; therefore, referral is warranted once the diagnosis is made [7].

Greater Trochanteric Pain Syndrome (GTPS) or Trochanteric Bursitis

General Principles

GTPS is a common overuse syndrome involving the gluteus medius and minimus muscles, tendons, and bursa (see Fig. 1). These muscles' primary action is hip abduction. There are at least two involved bursas, the gluteus medius and trochanteric bursa. Bursas are small synovial lined structures that help tissues glide over one another, as when a tendon slides over another tendon or bone.

Overuse syndromes usually involve a victim and a culprit. The victim represents the presenting pain complaint which is the result of the culprit, the biomechanical dysfunction that created the victim. Successful treatment comes from correcting the culprit, not just treating the symptoms of the victim. In the case of GTPS, weakness of the gluteus medius and minimus muscles (the culprit) leads to abnormal hip and knee kinematics concentrated over the greater trochanter [9]. The body tries to alleviate this

DOI 10.1007/978-1-4939-0779-3_118-1

abnormal force by enlarging the bursas as a cushion. Bursa enlargement causes irritation and pressure and thus a painful trochanteric bursopathy develops (the victim). This similar pattern is seen with almost all overuse syndromes and the construct of victims and culprits should serve for treatment recommendations: alleviate the pain of the victim but search for and correct the culprit [10].

Diagnosis

GTPS is characterized by painful swelling and tenderness over the bony prominence of the posterior lateral thigh. Patients of all ages are affected, but the peak incidence is those aged 40–60. Pain may start after a specific trauma or have an insidious onset. Patients will complain of pain in the lower buttocks and the lateral aspect of the thigh when lying on the hip, walking, running, climbing stairs, or when standing on the affected leg. Pain may radiate occasionally down to the calf and is exacerbated by prolonged standing, leg crossing, or single-legged activities. Repetitive hip internal or external rotation can also exacerbate symptoms [9].

Evaluation of a patient with GTPS should include a full history and physical exam of the back, pelvis, and lower extremities. The presence of weakness, contractures, asymmetry, and pain in other areas such as the lower back, groin, knees, ankles, and feet can contribute to the syndrome.

The physical exam should assess for malalignments of the lower extremity as mentioned earlier, gluteus medius weakness, and inflexibility of the iliotibial band. Pain on direct palpation is the most sensitive and specific finding. Often the culprit is a gluteal insertional tendinopathy (a disease of the tendon). Active abduction, engaging of the gluteus medius/minimus muscles, and passive adduction, stretching of the involved muscle, are painful and can exacerbate this lateral hip pain. Reproduction of index pain with a 30 s single-leg stance test is highly suggestive of a gluteal tendinopathy and is also used to detect a positive Trendelenburg sign. A positive or abnormal Trendelenburg sign is when the patient demonstrates an abnormal lateral pelvic tilt while assuming a single-legged stance on the affected side in an effort to overcome hip weakness on the painful limb (see Fig. 3).

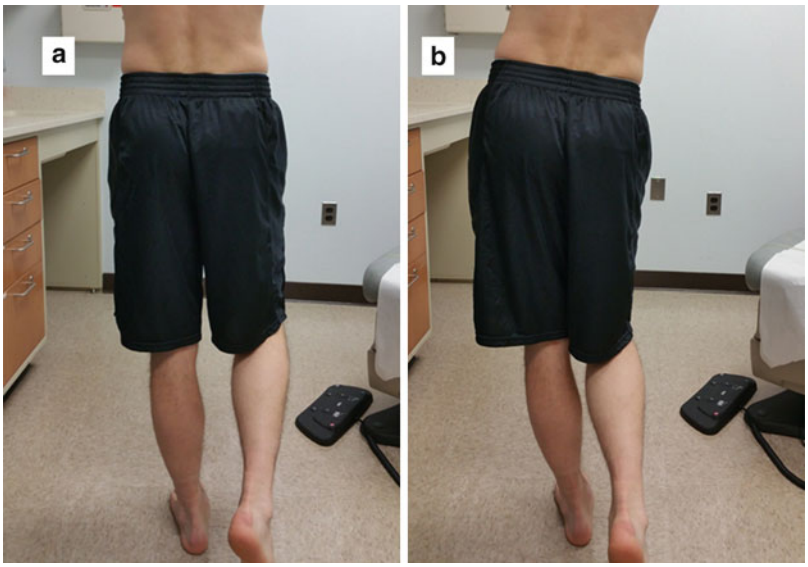

Fig. 3 Trendelenburg sign – patient stands on affected leg and lifts the unaffected leg from floor. (**a**) Normal response – ability to maintain pelvis in neutral position. (**b**) A positive or abnormal sign manifested by inability to maintain neutral posture when standing on the affected leg (non-weight-bearing hip will drop below the weight-bearing hip)

DOI 10.1007/978-1-4939-0779-3_118-1

GTPS is a clinical diagnosis. Imaging is pursued when the diagnosis is unclear or the patient is not responding to appropriate therapy. Plain film radiography may show trochanteric exostoses or osteophytes suggesting calcific tendinopathy or bursopathy in long-standing cases of GTPS. MRI may show degenerative changes to the gluteus medius and minimus tendons. Ultrasonography is emerging as a cost-effective, readily available, and easily applied imaging modality that can show the same features. In addition, it can be used for dynamic assessments and to guide diagnostic and therapeutic procedures [9].

Treatment

GTPS typically responds to conservative measures, such as activity modification, physical therapy (PT) aimed at strengthening the hip (specifically the gluteal muscles – see Ref. [8] for home exercises), and correction of any contractures. Weight loss is appropriate if indicated and can dramatically improve pain. (This holds true for all lower extremity conditions.) Interventions to relieve pain are required if pain precludes daily activities, sleep, and/or participation in rehabilitative exercises. Ice massage may suffice but the short-term use of acetaminophen or NSAIDs may be warranted. If these modalities do not provide adequate symptomatic relief, corticosteroid injection into the associated bursa can be entertained. Long-term studies have shown steroid injections alone to be inferior to PT and they should not be used as sole treatment. (This concept also holds true for most overuse conditions.) While studies on the effectiveness of regenerative (platelet-rich plasma – PRP) and proliferative (prolotherapy) injection therapies have lacked consistency, their use in treating various tendinopathies is growing in popularity and use [9]. They should be considered when pain and dysfunction persist despite appropriate rehabilitation. These treatments should be done in conjunction with strengthening and stretching. Low-frequency shock wave therapy has shown conflicting results but may be an option [11]. Surgical treatment consisting of bursectomy is an option for the rare patient who is compliant with multiple courses of conservative therapy but who still is symptomatic.

Acetabular Labral Tear (ALT)

General Principles

The acetabular labrum is a fibrocartilaginous structure lining the acetabular socket (see Fig. 1). It is vascularized only in the outer third and pain-sensing nerve fibers parallel the blood supply. The lack of robust blood supply explains why the labrum has a poor potential to heal; a similar concept will be discussed in the knee meniscus. The hip labrum serves to aid in stability and force disbursement. ALTs are both common as well as frequently asymptomatic. A cadaveric study found that 93–96 % of hips [12].

An ALT can result from an acute injury or abnormal force pattern stemming from femoral acetabular incongruities (e.g., FAI). Symptomatic ALTs can present suddenly after a traumatic event but much more often present with an insidious onset of groin, lateral, anterior, and posterior hip pain. ALT are undiagnosed for an average of 2 years owing to their vague pain pattern and lack of distinct physical exam techniques [12].

Diagnosis

The signs and symptoms of an ALT include anterior groin pain that worsens with anything that loads the joint such as prolonged periods of standing, sitting, or walking. Sharp pain often accompanied by mechanical symptoms such as clicking or catching is frequently described. Patients often state that they have trouble with sitting positions or when donning their socks and experience an exacerbation of their symptoms with sporting activities [12]. When patients are asked to point to the spot that hurts, they will cup the hip with their forefinger and thumb, dubbed the “C” sign.

DOI 10.1007/978-1-4939-0779-3_118-1

Hip examination must include a visual inspection for lower extremity malalignments, points of tenderness, range of motion, motor strength, and special tests. The special test for ALT with the most substantiating evidence the supine impingement test (FADIR test) described earlier (see Fig. 2). Other tests have been described but lack the supporting evidence of utility.

Imaging of the painful hip should begin with radiographs, including at a minimum a weight-bearing AP (whenever possible radiographs should be weight bearing for any lower extremity conditions) and a lateral projection of the symptomatic hip. In patients with a suspected ALT, radiographs should be analyzed for abnormal morphology of the acetabulum and femoral head, including anatomy predisposing to FAI (see Fig. 2) [13].

MRI with contrast is the imaging modality of choice and can demonstrate a displaced labral flap or irregular labral morphology. A paralabral cyst (a small collection of fluid communicating with the labrum or the cartilage-labral junction) when noted is pathognomonic of a labral tear. Intra-articular anesthetic hip injection can also be helpful in the diagnosis of intra-articular pathology. This injection can be done at the time of MR arthrogram or separately via ultrasound-guided injection or fluoroscopy. Just as in FAI, if intra-articular anesthesia alleviates the pain, the hip joint can be assumed to be the source of the pain. Arthroscopy remains the gold standard for the diagnosis of ALT.

No single patient history or clinical examination findings are "stand alone" in their ability to diagnose ALT. An emphasis on the summative patient history, clinical examination findings, imaging modalities, and intra-articular anesthetic injection response is needed to diagnose a symptomatic ALT [13]. The differential diagnosis (Table 1) includes tendinopathies and chondral lesions.

Treatment

A trial of conservative management, including relative rest and oral analgesic medications, combined with a focused PT protocol for 10–12 weeks is recommended. Therapy should focus on strengthening the hip, pelvis, and abdominal core musculature in addition to addressing flexibility deficits (see Ref. [8] for home exercises). A trial of intra-articular injection with steroid, prolotherapy, or PRP can be offered, but there is insufficient evidence to make a definitive recommendation at this time. In the case of steroids, repeated injections may damage chondral surfaces and are not recommended [11]. When conservative measures do not control the patient's symptoms or when functional limitations remain unsatisfactory, a referral for orthopedic surgery is appropriate [12].

Quadriceps and Hamstring Injuries

General Principles

Injuries to the anterior and posterior thigh are extremely common and can be a source of long-term morbidity especially for the high-level athlete. Injury prevalence is 15–20 % for soccer and football players and 50 % for dancers [14]. The quadriceps muscles are the primary knee extensors and are made of the rectus femoris and vastus lateralis/intermedius/medialis. The hamstring muscles are the primary knee flexors and consist of the bicep femoris, semimembranosus, and semitendinosus. The quadriceps have different origins but a common insertion point, while the hamstrings are the opposite (see Fig. 1). Both muscle groups are prone to acute injuries (avulsions, tendon tears/strains, muscle contusions/tears) and chronic tendinopathies. The rectus femoris and bicep femoris are biarticular muscles (span two joints) and thus are more prone to injury. The onset of injury is critical in differentiating between acute and chronic injury and likewise treatment recommendations.

DOI 10.1007/978-1-4939-0779-3_118-1

Diagnosis

Contusions will be the result of a direct blow or fall while tears/strains usually occur with bursts of speed/kicking/stretching and both can have significant bruising and swelling. A chronic poorly localized pain pattern should raise suspicion of a stress fracture or referred pain (see Table 1). Direct palpation and knowledge of muscle/tendon locations elucidate the structures injured. Pain at the bony origin raises the suspicion of an avulsion injury, while most strains occur at the tendo-muscular junction. Range of motion should be gently assessed and, in the acute setting, passive range of motion should not be attempted. Strength testing of the involved muscle unit will usually be diminished, and the degree of pain and weakness is a predictor of injury severity and thus recovery time. Special tests for referred pain (i.e., radiculopathy or sacroiliac dysfunction) are reserved for those cases that are not straightforward or are not responding to appropriate treatment.

Imaging with ultrasound or MRI is needed for refractory cases or when the diagnosis is in question. Large contusions can lead to the development of myositis ossificans (MO), a calcification of a hematoma. MO presents as a hardening mass. Currently, there is no adequate therapy to treat once present. If there is no history of trauma to explain the calcified mass, a workup for a tumor should be undertaken.

Treatment

The first 24 h is the most critical time for quadriceps contusions. The goal is to maintain maximal flexion and minimize bleeding. This is accomplished by having the patient flex the knee as much as possible and maintaining this position for 24 h with the use of an elastic bandage and the almost continuous use of ice over the tender area [14]. Soft tissue therapy (i.e., massages) is contraindicated acutely for risk of rebleeding. After the first 24 h, patients can begin a gentle stretching program to tolerance and progress as symptoms dictate. Local control of pain can be accomplished with oral (acetaminophen, NSAIDs) and topical (lidocaine, NSAIDS) analgesics or ice. NSAID use has not been found to decrease the incidence of complications, specifically MO [14]. Once full range of motion is achieved, then strengthening should commence (see Ref. [8] for home exercises). Symptom-based progression is discussed in greater detail under the treatment section of calf injuries. Symptom-based progression serves as a template for rehabilitation principles for quadriceps and hamstring injuries as well.

Hamstring tears can be divided into types 1 and 2. Type 1 occurs at the proximal portion of the long head of the bicep femoris and is the result of sprinting, and type 2 occurs at the ischial tuberosity at the origin of the semimembranosus [15] (see Fig. 1). The rehabilitation is similar but type 1 injuries recover quicker compared with type 2 injuries and patients should be advised as such. Rehabilitation begins with restoring full range of motion and then progresses to regaining strength and then ultimately activity- or sport-specific drills (see Ref. [8] for home exercises). The use of a thigh compression sleeve is recommended in the acute, chronic, and rehabilitative setting. These injuries are very prone to recurrence and the high-level athlete may be best served with a referral to a specialist for rehabilitation recommendations.

Chronic hamstring and quadriceps tendinopathies are treated similar to GTPS and are also discussed in the "► Athletic Injuries" chapter. They require addressing risk factors (see Table 2), biomechanical assessment, and strengthening of the involved muscle groups as well as the core muscles.

DOI 10.1007/978-1-4939-0779-3_118-1

Knee Injuries

Meniscal Injuries

General Principles

While its use has decreased over the last 15 years, arthroscopic partial meniscectomy (APM) is still the most common orthopedic surgical procedure in the United States with reported annual incidence rates of 66/100,000 [16]. The medial and lateral menisci are semicircular fibrocartilage structures with perfect congruity between the femur and tibia (see Fig. 4). This perfect congruity allows the menisci to dissipate force and provide joint stability as well as lubrication. Similar to the acetabular labrum, the adult menisci are only vascularized on the periphery, which leads to the concept of red and white zones (red zone with blood supply and white zone without blood supply). In general, red zone injuries have the potential to heal, while white zone injuries cannot heal. This is an important concept in treatment recommendations.

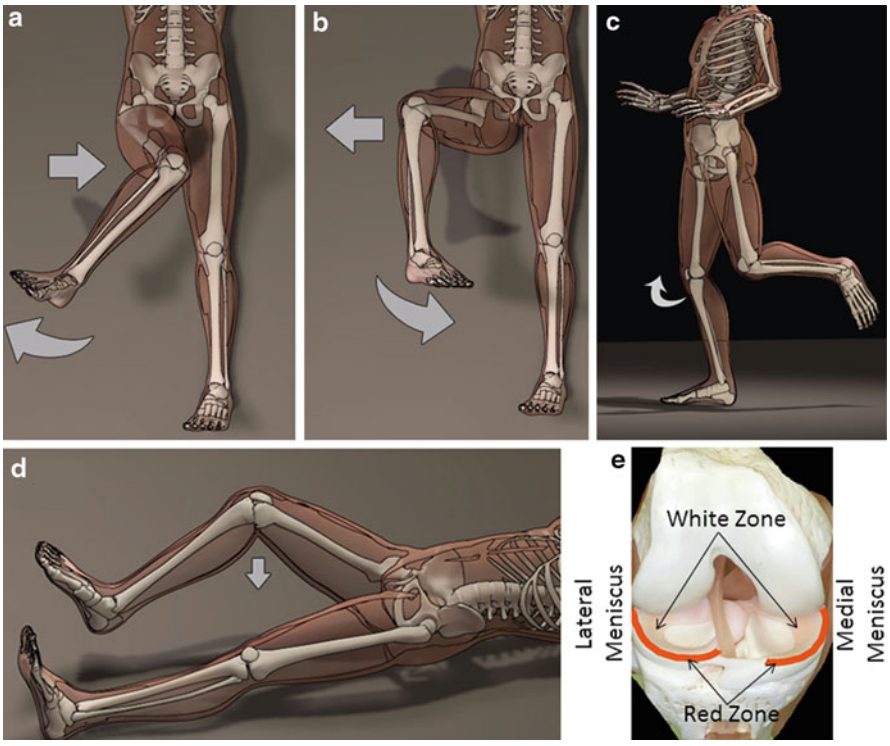

Fig. 4 Meniscal signs and anatomy. (**a**) McMurray test for medial meniscus – with fingers on medial and lateral joint line, flex the hip and knee maximally. Apply a valgus force (in direction of *straight arrow*) to the knee while externally rotating the foot (in direction of *curved arrow*) and passively extending the knee. A positive test is pain (with or without an associated click/snap) located on a respective joint line during movement (sensitivity ~ 65 %; specificity ~ 65 %). (**b**) McMurray test for lateral meniscus – with fingers on medial and lateral joint line, flex the hip and knee maximally. Apply a varus stress (in direction of *straight arrow*) during internal rotation of the foot (in direction of *curved arrow*) and passive extension of the knee. A positive test is pain (with or without an associated click/snap) located on a respective joint line during movement (sensitivity ~ 65 %; specificity ~ 65 %). (**c**) Thessaly test – hold patient's outstretched hands while he or she stands flat-footed on the floor, internally and externally rotating three times with the knee flexed 20°. A positive test is pain in respective joint compartment with movement (sensitivity ~ 85 %; specificity ~ 90 %). (**d**) Bounce home test – flex knee to 45 degrees and allow knee to fully passively extend (direction of *arrow*). A positive test is pain with passive extension (sensitivity ~ 45 %; specificity ~ 75 %). (**e**) Anatomic model of lateral and medical meniscus of right knee showing *red zone* (vascularized) and *white zone* (nonvascularized) (Figures **a**, **b**, **c**, **d** adapted with permission from fpnotebook.com)

DOI 10.1007/978-1-4939-0779-3_118-1

Pain fibers parallel the vascularity and thus are located around the periphery as well. Loss of function leads to abnormal joint forces and accelerates cartilage damage and ultimately osteoarthritis [17].

Diagnosis

Acute meniscal injuries present after a traumatic event. This can be a sudden noncontact twisting event (the most common mechanism) or through contact as in a football tackle. The presence of an acute effusion varies; an effusion generally denotes an injury to the vascularized red zone. Pain is the predominant feature. Other important historical elements are catching or locking, defined as a mechanical symptom of "something" inside the joint not allowing full pain-free range of motion. Physical examination findings can include a variable amount of intra-articular swelling (it is important to differentiate between soft tissue and intra-articular swelling), pain to palpation along the relevant joint line (anterior and posterior medial, anterior and posterior lateral), and pain with one or more of the meniscal tests (see Fig. 4). A thorough assessment for other ligamentous injuries (cruciate, collateral, patellar) is required as their injury has an impact on treatment recommendations.

Plain films consisting of an AP, lateral, and patellar view should generally be ordered if one is considering an acute meniscal tear in order to rule out a fracture, but other than showing an effusion, they are not diagnostic. Despite being able to adequately diagnose an isolated meniscal injury with history and physical exam in >90 % of patients, an MRI is almost always ordered to confirm an acute meniscal tear [16]. In addition to confirming the clinical suspicion, MRI is invaluable at detecting concomitant ligamentous injury and the presence of osteoarthritis or cartilage damage which have treatment recommendation implications.

Chronic (usually degenerative) injuries present with pain along the relevant joint line, intermittent swelling, and possible mechanical symptoms of locking and catching but lack the acute history of a traumatic event (although a careful history may reveal an antecedent event years previous that may have initially damaged the meniscus). Physical examination is similar as in the evaluation for acute injuries (see Fig. 4). The decision to image depends on the patient's symptoms and treatment preferences. A weight-bearing AP and lateral radiograph should be ordered as well as a patellar view (sunrise or merchant) to evaluate the presence and degree of OA which may affect treatment options. If the patient complains of true locking (a mechanical block to range of motion), then an MRI is warranted to confirm the diagnosis. Caution must be taken in interpreting meniscal tears on MRI though as they are present in approximately 20 % of people without knee symptoms <40 years of age and up to 70 % >65 years of age [18]. The differential diagnosis includes OA, chondral lesions, and patellofemoral pain syndrome (see Table 4).

Treatment

In general, patients under 40 and those without significant OA or cartilage damage are ideal candidates for meniscal repair. Acute meniscal tears warrant referral and should be repaired within 8 weeks of the injury [17].

In chronic, degenerative tears, unless the patient has true mechanical symptoms (locking or catching), a discussion of treatment outcomes and joint decision making is warranted. Since repair is generally not possible and once meniscal tissue is removed its function is lost permanently, symptom management becomes the treatment goals.

A randomized clinical trial showed no significant differences in terms of knee pain relief, improved knee function, or patient satisfaction between APM and lower extremity strengthening exercises over 2 years of follow-up [19]. Similar results have been found by other researchers and support the option of conservative management of degenerative tears without true mechanical symptoms.

DOI 10.1007/978-1-4939-0779-3_118-1

Table 4 Knee and calf differential diagnosis disorders of the lower extremity

Very common	Common	Infrequent	Referred
Knee			
• Ligamentous injury (ACL, PCL, MCL, LCL) • Patellofemoral syndrome • Bursitis[a] • Patellar tendinopathy • Osteoarthritis • Chondral lesions • Iliotibial band syndrome (distal) • Meniscal injury	• Osteochondrosis (Sinding-Larsen-Johansson and Osgood-Schlatter) • Less common tendinopathy (quadriceps, proximal hamstring, popliteus) • Patellar instability (can be all directions) • Popliteal cyst	• Plica syndrome • Fat-pad syndrome (Hoffa syndrome) • Osteochondritis dissecans • Crystal induced arthropathy • Stress fracture • Nerve entrapments (common peroneal, saphenous)	• Pigmented villonodular synovitis • Popliteal artery entrapment syndrome • Fabella syndrome
Calf			
• Gastrocnemius[b] • Stress fracture • Medial tibial stress syndrome[c] • Achilles tendinopathy	• Soleus[b] • Plantaris[b] • Fracture • Anterior tibial stress syndrome[d]	• Compartment syndrome (exertional and acute) • Nerve entrapment[e] • Achilles tendon rupture	• Infection • Tumor • Deep vein thrombosis
Differential diagnosis for acute hemarthrosis			
• Ligamentous injury • Meniscal injury • Patella injury • Extensor mechanism injury • Osteochondral injury • Fracture • Avulsion			

[a]Suprapatellar, prepatellar, deep infrapatellar, gastrocnemius, semimembranosus, sartorius, pes anserine, MCL bursa, distal iliotibial band, fibular collateral ligament, popliteus tendon
[b]Includes muscle strain/tears and tendinopathies
[c]Pain along posterior medial aspect of tibia believe to be periostitis of posterior tibial muscle, flexor digitorium longus and/or the solues attachment on tibia
[d]Pain along the anterior aspect of tibia believe to be periostitis of anterior tibial muscle attachment on tibia
[e]Peroneal, sural, tibial

Baker's Cyst (Popliteal Cyst)

General Principles

Named after Dr. William Baker who first described the condition in 1877, a Baker's cyst is more properly termed a popliteal cyst. It is a fluid-filled mass generally resulting from the distention of a preexisting bursa in the popliteal fossa, most commonly the medial gastrocnemius-semimembranosus bursa(see Fig. 1). Unlike other bursa, this one is connected via a valvular opening in the joint capsule posterior to the medial femoral condyle [20].

DOI 10.1007/978-1-4939-0779-3_118-1

Diagnosis

Patients generally complain of fullness behind the knee and a mass can usually be seen and palpated in the prone patient with the knee fully extended. With knee flexion to around 45°, the cyst usually disappears or decreases in size. Confirmation can be obtained via ultrasound or MRI and should be performed if any doubt exists about the masses' etiology. A ruptured popliteal cyst can present with acute pain and signs of inflammation. An evaluation for a deep vein thrombosis (DVT) should be considered in this setting. The differential diagnosis includes tumors both benign and malignant as well as meniscal cysts and DVTs (see Table 4).

Treatment

Management is not dictated by the cyst but rather by the pathology that causes the cyst. OA with or without concomitant meniscal injury is usually the underlying cause in the majority of patients [21]. In those patients having mechanical symptoms due to a large cyst, ultrasound-guided aspiration can provide temporary relief, but the cyst will invariably return if the underlying pathology is not remedied.

Knee Bursitis

General Principles

There are multiple bursas around the knee that can become symptomatic (see Fig. 1 and Table 4). Irritation of any of these bursas can cause knee pain. Definitive treatment lies in treating the underlying cause of the bursa irritation and not the irritation itself (see discussion on victims and culprits under GTPS). Local control of pain can be accomplished with oral (acetaminophen, NSAIDs) and topical (lidocaine, NSAIDS) analgesics or ice massages. Injections can be performed with steroids, switch order as it reads funny with the editing/line justification. Due to the great variability in bursa location, ultrasound-guided injections are recommended. It must be emphasized though that these are temporary measures and the underlying cause must be elucidated and corrected. Pes anserine bursitis will be discussed as it is prototypical and extremely common. Prepatellar bursitis will be mentioned as it has some unique features that must be taken into account.

Pes Anserine Bursitis

The diagnosis is easily made by tenderness at the pes anserine area and an appropriate history. The pes anserine bursa is generally located on the proximal medial portion of the tibia just superficial to the distal tibial insertion of the superficial medial collateral ligament (MCL) of the knee (see Fig. 1). This is the site for the common insertion point for the conjoined tendons of the sartorius, gracilis, and semitendinosus muscles [22]. There is great individual variability in its exact location with most bursas lying between the three conjoined tendons and the tibia, less frequently between the MCL and the tendons, or between the tendons themselves. Because of the close approximation to the distal portion of the MCL, any history of a twisting injury or contact preceding the pain would warrant valgus loading of the knee in 0° and 30° to ensure the MCL is not sprained. In addition, medial meniscal tears can sometimes be confused or coexist with pes anserine bursitis (see Table 4). Treatment of pes anserine bursitis pain should include the local therapies mentioned in the "General Principles" section of knee bursitis and most importantly a search for and correction of the contributing factors: [22]

- OA of the knee – as many as 75 % of patients with OA have symptoms of pes anserine bursitis; knee and hip strengthening are the mainstays for OA treatment.
- Obesity – even a modest weight loss of ∼ 5 % may alleviate the pain.
- Valgus knee deformity, alone or in combination with collateral instability – bracing may be beneficial.

DOI 10.1007/978-1-4939-0779-3_118-1

- Pes planus (i.e., flat foot) – consider foot orthoses.
- Diabetes mellitus (DM) – common comorbidity in a variety of bursitis. It is unclear if it is the obesity that accompanies DM or if it is the DM itself which causes the bursitis, and it is also unclear if good glycemic control will minimize musculoskeletal complaints.
- Medial meniscal tear – loss of stability increases the forces over the pes anserine; see discussion on meniscal injuries for treatment recommendations.
- Saphenous nerve injury (from surgery, trauma, or mass effect) – needs a high index of suspicion for diagnosis and then must treat the cause.

Prepatellar Bursitis

Special note should be made concerning prepatellar bursitis, as an infectious etiology can be the cause. The following in declining order can be responsible for prepatellar bursitis [23]:

- Direct trauma (e.g., a fall on the patella or direct blow to the knee)
- Recurrent minor injuries associated with overuse (e.g., repeated kneeling)
- Septic or pyogenic process
- Crystal deposition (e.g., gout, pseudogout)

If there is any concern for an infection (erythema, warmth, fluctuance), then at a minimum, an aspiration is required to analyze fluid content (white blood cells, protein, lactate, glucose, crystals, Gram stain, culture).

Fortunately, even if the bursa is infected, conservative treatment is warranted with aspiration of as much material as possible and oral antibiotics that are narrowed once laboratory results are known (always consider methicillin-resistant *Staphylococcus aureus* and local antibiotic resistance patterns). Incision and drainage or bursectomy is reserved for patients with severe, refractory, or chronic/recurrent disease [23].

Fractures and Dislocations of the Knee

General Principles

Acute fractures of the knee are the result of trauma and are associated with an acute hemarthrosis. The differential diagnosis for an acute traumatic hemarthrosis in order of precedent is ligamentous injury (ACL being #1), peripheral meniscal injury, or a fracture (see Table 4). Quadriceps and patellar tendon tears are extra-articular structures but are associated with a large amount of soft tissue swelling. Their diagnoses are generally not difficult to make. Patients are unable to extend the knee and, because of their immediate loss of function, almost always present to the emergency room.

An acute fracture will present with focal tenderness over the involved bony area. Range of motion is usually limited by pain and unless there is a concomitant ligamentous/meniscal injury, special tests for the knee are normal. Plain radiography, at a minimum AP and lateral, is usually adequate to confirm the diagnosis, but if negative and clinical suspicion is high, an MRI would be warranted. Although CT is the imaging modality of choice for bony abnormalities, MRI will be able to diagnose the fracture as well as any other soft tissue abnormality that might be missed on CT. All fractures of the knee, which invariably are intra-articular, should be managed in conjunction with an orthopedist or a sports medicine physician in a timely fashion. (i.e., 48 h) In the interim depending on the degree of swelling, a compression wrap or hinged knee brace can be applied. Knee immobilizers are particularly painful and uncomfortable for patients and should never be left on for an extended period of time. If an in-person consultation cannot be

DOI 10.1007/978-1-4939-0779-3_118-1

achieved in an adequate timeframe, a telephone consultation to a specialist for treatment recommendations is warranted. Adequate pain control can generally be achieved with acetaminophen and/or NSAIDs.

Osteochondral defects and stress fractures can present more subtly and subacutely; therefore, a high index of suspicion is required. Osteochondral defects are focal areas of articular injury with damage to both the cartilage and the adjacent subchondral bone. Trauma is the leading cause of a focal osteochondral defect in a previously normal bone in the skeletally mature. The term osteochondral defect encompasses the entity known as osteochondritis dissecans (OCD). The acronym OCD is sometimes applied both to osteochondral defects and osteochondritis dissecans but technically should be reserved for the latter and will be the case in this chapter. The cause of OCD remains unknown but may include one or all of the following factors: genetic predisposition, defective skeletal development, vascular insult, and trauma [24]. OCD usually begins in adolescents although its sequelae, premature OA, may not become apparent until adulthood. Knee OCD frequency is reported to be 20/100,000 in 10–20-year-olds [24]. Symptoms of any osteochondral defect include activity-related pain, catching or locking of the affected joint, and/or a transient effusion. OCD is often misdiagnosed as patellofemoral syndrome. Plain radiography includes AP view, lateral view, sunrise or merchant view, and a notched view, but an MRI is often required for diagnosis and is essential for staging. Adult osteochondral defects may present as an acute fracture or insidious as in an OCD.

When discovered, osteochondral defects should be at a minimum comanaged with an orthopedist or a sports medicine provider. Prognosis and treatment is dependent primarily on the stability of the lesion and the age of the patient. Adolescents with stable lesions can heal, but the skeletally mature are very unlikely to heal on their own [25].

Stress fractures of the knee are not common and require a high index of suspicion. Plain radiography can be suggestive, but generally an MRI is needed to confirm diagnosis. Management involves decreasing force loads and correcting any mitigating factors (see previous discussion on stress fractures).

Patella dislocations occur almost always laterally with the medial patellofemoral ligament tearing. As in other ligamentous injuries, it can occur due to direct trauma or from sudden change in direction or muscular contractions. It is not unusual for the patella to spontaneously relocate. After radiographs are obtained to document fractures and if the patella remains dislocated, administering an adequate amount of intra-articular anesthesia and gently elevating the patella while providing a medially direct force accomplish the reduction. Postreduction radiographs are recommended. There is invariably an injury to the lateral femoral condyle and medial facet of the patella. After knee bracing with a patellofemoral brace, all patients should be referred to orthopedics for management as primary repair is recommended for some patient populations.

A complete knee dislocation is a major traumatic event that should be managed in an emergency room/hospital setting similar to a hip dislocation. In addition to the ligamentous and potential osteochondral abnormalities associated with the injury, the integrity of the popliteal artery must be evaluated radiographically in all cases.

Lower Leg/Ankle/Foot Injuries

Calf Injuries

General Principles

Injuries to the posterior lower leg (calf) are very common especially in the 40–60 year age group [26]. The muscles involved are the gastrocnemius and soleus (also known as the triceps surae as some anatomists believe, this is one muscle with three heads and a common insertion point on the posterior calcaneus, the

DOI 10.1007/978-1-4939-0779-3_118-1

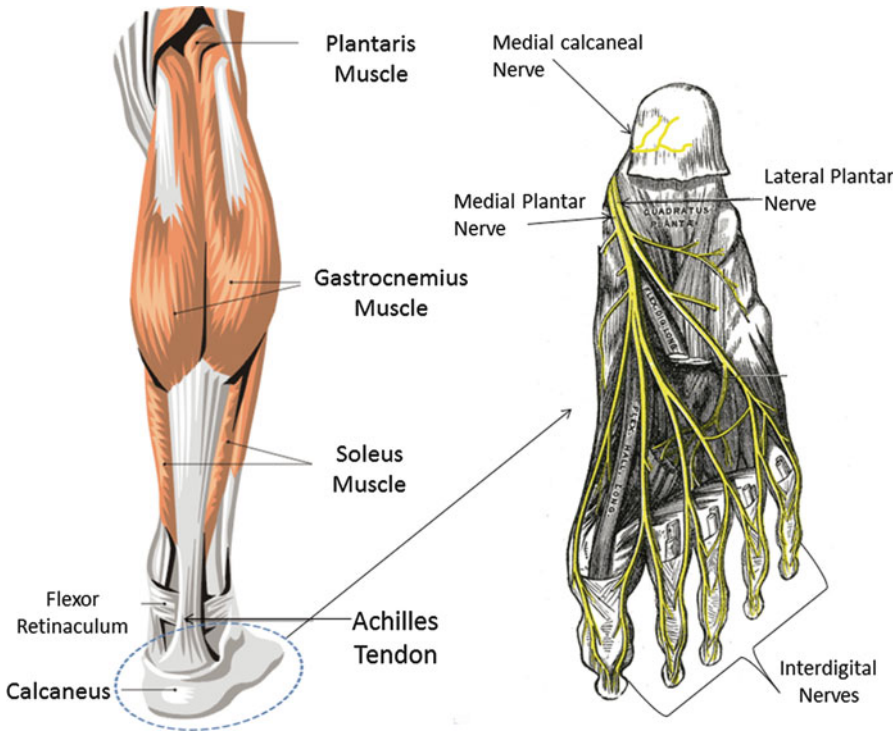

Fig. 5 Posterior distal leg and plantar foot anatomy (distal leg image adapted with permission from fpnotebook.com). Plantar foot adapted from Gray's Anatomy 20th edition from 1918 (Lewis) in the public domain following expiration of its patent. Available online at http://bartleby.com/107/)

Achilles tendon) and the plantaris (see Fig. 5). Together these muscles are the primary plantar flexors of the ankle. Most injuries occur with sudden explosive movements or prolonged running activity. The gastrocnemius is another biarticular muscle of the lower extremity and is composed of a medial and lateral head originating on the respective femoral condyles. The soleus has a broad origin on the proximal tibia and fibula. Over 90 % of injuries involve only the gastrocnemius muscle (medial head 80 % and lateral head 14 %). The plantaris muscle is highly variable in its actual presence and exact location. When present, it originates just medial to the lateral head of the gastrocnemius and is situated just between the gastrocnemius and popliteus muscles proximally and the gastrocnemius and soleus muscles distally. Although its function is debated, it is important to note as injury to the muscle/tendon must remain in the differential of calf pain. The popliteus muscle originates from the lateral posterior complex of the knee and inserts on the posterior aspect of the proximal tibia. Although not a traditional calf muscle, it is included for discussion as it can be a source of pathology in the proximal calf area either due to a tendinopathy or compression of the neurovascular bundle that lies in close approximation to the muscle tendon [27].

Diagnosis

Gastrocnemius injuries are generally of acute origin as when sprinting or jumping such as a tennis player trying to return a shot (hence the moniker "tennis leg"). Pain can be described as a tearing or popping sensation and most will have difficulty bearing full weight on the injured leg. As mentioned earlier, the site of the injury is usually the medial head of the gastrocnemius. There may be a variable amount of swelling or bruising depending on the degree of muscle injury. Active plantar flexion will be painful as this engages the muscle, while passive dorsiflexion will be painful as this stretches an already damaged muscle. The most immediate condition to rule out is an Achilles tendon tear. Both have similar mechanisms of injury but are readily differentiated by physical exam and imaging when necessary. The integrity of the Achilles

DOI 10.1007/978-1-4939-0779-3_118-1

tendon should be assessed with careful palpation. With a tear, there will be considerable swelling at the tear site and a defect can usually be appreciated. There may be lack of passive plantar flexion with the squeezing of the proximal calf musculature while the patient is prone, also known as the calf or Thompson squeeze test. The nomenclature can be confusing as a negative squeeze test is when there is plantar flexion indicating an intact muscle-tendon complex and a positive test is when there is no plantar flexion, indicating a disruption of the muscle-tendon complex. It is less confusing to describe the motion observed when squeezing the posterior calf as opposed to saying a negative or positive test [28]. Due to the plantaris muscle/tendon and deep toe flexors, some passive plantar flexion may still be present even in up to 10 % of complete Achilles tendon ruptures [27]. Likewise, the lack of any passive plantar flexion does not always mean a complete tear either. Two case reports are documented where a positive calf squeeze test (no movement of the ankle) was noted, and upon surgical evaluation, only a tear of the gastrocnemius component of the Achilles tendon was identified with an intact soleus component [29]. Should clinical suspicion still exist for an Achilles tendon tear, imaging either with ultrasound or MRI should be pursued. Ultrasound is quicker and less expensive but is operator dependent, and occasionally an intact plantaris tendon can be mistaken for an intact Achilles tendon, and a large hematoma may obscure complete examination. Both modalities can also be used to evaluate for other clinical entities.

Plantaris injuries, to include muscle or tendon tears, are also of acute origin with the same mechanism as gastrocnemius injuries. Symptoms are similar but not as severe. Due to the plantaris muscle tendon lying underneath the gastrocnemius, swelling and bruising are not as apparent. In addition, these injuries are more distal than the typical medial head gastrocnemius injuries and are usually located mid-calf. The Achilles tendon will be non-tender and intact along its length. As the plantaris usually does not contribute to the Achilles tendon, the calf squeeze test will show ankle plantar flexion (a negative test).

Contrary to gastrocnemius and plantaris muscle injuries, soleus muscle injuries are usually chronic in nature. This may be due to their muscle fiber type. The gastrocnemius is comprised of both fast and slow twitch fiber type while the soleus is comprised almost solely of slow twitch muscle fibers. Distance runners and those who engage in hill running are especially vulnerable to soleus injuries. There is no significant swelling or bruising and palpation only reveals deep muscle soreness. A clue to the diagnosis is to functionally test the soleus muscle. This can be accomplished by having the patient do multiple heel raises on a step (active plantar flexion) with the knee bent to 20–30° of flexion. The gastrocnemius is tested with the knee in full extension. Pain while the knee is flexed but reduced or absent with knee extension is highly suggestive of a soleus muscle injury.

A complete evaluation should include an examination of the entire kinetic chain as mentioned earlier in GTPS by specifically looking for leg length discrepancies, foot abnormalities (pes cavus or pes planus), or hip weakness as evidenced by a positive Trendelenburg sign (see Fig. 3). Table 4 provides a differential diagnosis for lower leg complaints.

Treatment

Treatment is undertaken in a phased approach similar to the majority of all muscle-tendon injuries. (A detailed description will follow and will serve as a model for other muscle-tendon injuries, i.e., groin, quadriceps, and hamstring injuries.) The initial phase is centered on protecting the injury from further damage while trying to restore range of motion. Calf compression can be helpful and is accomplished with commercial compression sleeves or elastic bandages; the latter may be more prudent acutely if a large amount of swelling is present in order to adjust tightness as needed to avoid compression of neurovascular structures. Ice is generally suggested for acute injuries and pain medication (acetaminophen or NSAIDs) can be used as necessary. Severe injuries occasionally require immobilization either with a posterior splint or a commercial walking boot. The continued need for immobilization should be revisited every 3–5 days as normal range of motion is one of the early treatment goals. Some advocate a heel lift to shorten the

DOI 10.1007/978-1-4939-0779-3_118-1

muscle-tendon unit and relieve pain. If a heel lift is used for acute pain management, it should be removed as soon as pain allows (usually 3–5 days) avoiding a permanently contracted muscle-tendon unit.

Once the patient can walk without a limp, the ability to do a heel lift should be tested. If this can be done with minimal pain, the patient may begin active rehabilitation that consists of strengthening the gastrocnemius-soleus complex with repetitive heel raises and progressive loads (see Ref. [8] for home exercises). Sport-/activity-specific training can begin after the patient can tolerate multiple sets of heel raises. Every patient is variable and rather than exact timeframes, functional assessments should be used to guide treatment advances: 1, ability to walk without a limp; 2, ability to do heel lifts without significant pain; and 3, pain-free functional activity.

The continued use of a calf compression sleeve is an option and patient dependent. To prevent recurrences, patients should maintain a strengthening program of the lower extremity. The use of foot orthosis can be considered for leg length abnormalities or pes cavus/planus.

Achilles Tendon Rupture

General Principles

The Achilles tendon, the attachment point of the gastrocnemius-soleus muscles to the posterior calcaneus, has poor vascularity 2–6 cm prior to its insertion (see Fig. 5). This area is most at risk for both tendinopathies and rupture. The annual incidence of rupture is 8/100,000 in the general population but up to 8/100 in the athletic population [30]. Males in their 40s represent the largest cohort. The mechanism of injury is the same as for acute calf injuries described above: a quick change of direction while the ankle is dorsiflexed and the calf muscles contract vigorously either in sporting events or from a fall/misstep. Approximately 10 % of patients who sustain an Achilles tendon rupture had preexisting Achilles tendon problems. The use of fluoroquinolones only slightly increases the risk of tendon ruptures (and tendinopathy) from an unknown mechanism [31]. This risk exists only with the first exposure and is highest for the initial 30 days. Subsequent use does not seem to carry any increased risk. Corticosteroid use also increases the risk for all tendon injuries; the exact increase is unknown.

Diagnosis

An oft-heard complaint is “someone kicked me in the back of the leg.” An audible snap is not uncommon. Plantar flexion is greatly diminished while dorsiflexion is maintained [32]. Most complain of intense pain, but a case series reported that up to one third of patients had no pain with the acute rupture [33]. It is speculated that these patients had chronic tendinopathy and the rupture actually relieved some of the discomfort from the tendinopathy. There is usually a great deal of swelling and ecchymosis in the acute setting. Careful palpation of the tendon will reveal a gap but can be obscured due to the inflammation. In addition to palpation of the tendon, the entire calf musculature should be examined as above because the differential diagnosis is gastrocnemius, soleus, or plantaris injury (see Table 4).

Strength testing demonstrates markedly decreased plantar flexion. The calf squeeze test described above usually shows no plantar flexion (a positive test). As mentioned earlier, even in the face of a complete rupture, there may still be some plantar flexion, and on the corollary, loss of plantar flexion is not 100 % sensitive or specific for a complete rupture. For these reasons and others, it has been estimated that ruptures are missed up to 25 % of the time. Note that these estimates were made prior to the widespread availability of ultrasound and MRI. These advanced imaging studies should be done whenever there is any doubt about the integrity of the tendon, as missed ruptures have high morbidity.

DOI 10.1007/978-1-4939-0779-3_118-1

Treatment

The treatment of Achilles tendon ruptures was traditionally surgical for the active population and nonoperative for the elderly or those with major comorbidities. Recent studies have challenged this notion, and coupled with modern rehabilitation techniques, nonoperative treatments remain a viable option even for the active patient. Joint decision making is paramount. Nonoperative treatment includes a progression from non-weight-bearing casting to a walking boot to a heel wedge with clinical and radiographic assessment of tendon integrity along the way [34]. Physical therapy is performed in conjunction. Unless the physician has considerable experience in managing Achilles tendon ruptures, to include serially casting/splinting, referral to an orthopedic surgeon is recommended. Most authorities still advocate surgical repair for the very active population though [35]. To avoid recurrence regardless of intervention, patients should maintain proper strength and flexibility and consideration should be made to avoid sudden ballistic movements in at-risk population.

Plantar Fasciopathy (PF)

General Principles

Plantar fasciopathy (also known as plantar fasciitis) is the most common cause of heel pain in adults affecting more than two million annually in the United States. The peak incidence is between the ages of 40 and 60 [36]. Those at higher risk include runners and occupations that involve prolonged standing. Physical factors that predispose patients to PF include limited ankle dorsiflexion and obesity.

A complicated fibrous network richly invested with small nerves connects the plantar fascia to the many structures of the foot. Originating on the planar aspect of the calcaneus, the plantar fascia consists of medial, central, and lateral bands. The central portion is most often involved in PF and divides into five bands inserting on to the metatarsophalangeal joints. Its main function is to provide both static and dynamic support of the longitudinal arch.

Biomechanical dysfunction leading to micro-tears at the calcaneal enthesis is thought to be the etiology. The histopathology of PF reveals degenerative tissue and a lack of inflammatory cells which is why the term fasciitis is incorrect. This lack of inflammatory cells also has implications on treatment as well [37]. Enthesopathic conditions such as the seronegative spondyloarthropathies can also present with pain at the plantar fascia. In these cases, inflammation is present due to an autoimmune inflammatory process and not a degenerative process and truly does represent a true plantar fasciitis.

Diagnosis

The classic history is pain which is worst upon the first steps after sleeping or prolonged sitting, improving or at least diminishing in severity after a few minutes of ambulation. There usually is no radiation and if present should alert one to an alternative diagnosis, such as a nerve compression. An inspection of the entire lower extremity should be done as mentioned previously looking for any mal- or misalignments but specifically for leg length abnormalities (true or functional) and foot abnormalities (pes cavus or planus) (see Table 2). There generally is no appreciable swelling or bruising, and their presence would suggest another entity other than PF. Physical exam findings include sharp pain and tenderness over the medial plantar calcaneal region that is accentuated with great toe extension or ankle dorsiflexion. Ankle dorsiflexion may be limited and one must try to deduce if this is from pain or if the Achilles tendon complex is the cause of the limited dorsiflexion which leads to greater stress on the plantar fascia. Palpation and percussion of the posterior tibial nerve, especially the media calcaneal and lateral plantar branch, should be done to ensure they are not the source of the pain (see Fig. 5).

PF is a clinical diagnosis and imaging is reserved to rule out other conditions. The presence of a bony heel spur is fairly meaningless. It is not the cause of the symptoms, although it may be the result of the

[d]Calcaneal (Sever), navicular (Köhler), metatarsal head (Freiberg)

body reacting to the stresses at the calcaneal plantar fascia origin [36]. The most common mimickers are fat-pad syndrome and neuropathies, but it is possible to have multiple concurrent pathologies and one may beget the other [38] (see Table 5 for differential diagnosis).

Treatment

The natural history of PF is self-limited resolution in >95 % of patients but may take up to 12 months [37]. There are a myriad of potential treatments with limited evidence as well as conflicting and mixed results. Therefore a conservative, least invasive, least costly approach is prudent. Obesity is an extrinsic risk factor for all musculoskeletal conditions and should be addressed. If training errors are revealed, these should be corrected. If clues to biomechanical dysfunction are discovered, these should be corrected as well (i.e., lower extremity/core weakness, leg length abnormality, pes cavus/planus; see Table 2). The use of foot orthoses is recommended by many. Unless the patient has true pes cavus, a prefabricated foot insert will suffice for the majority of patients [39]. Initial treatment is aimed at controlling pain to allow normal activities of daily living (ADLs) and then progressing to meet the patient's desired activity goals. In the acute setting, pain relief is the main goal. This can be accomplished with ice massage, pain medications (oral, topical, or injections), and foot orthoses. As soon as tolerated, the stretching and strengthening of the foot and lower extremity complex should proceed. In addition to stretching the plantar fascia itself, the Achilles tendon complex should be stretched repeatedly throughout the day (see Ref. [8] for home exercises). Dropping below the parallel while standing on a step with just the toes can stretch both structures and is also a form of eccentric strengthening exercise [40]. (Eccentric strengthening is when the muscle tendon is contracting while lengthening as in deceleration or lowering a weight.) Orthoses for PF can be heel cups/cushions, counterforce braces, sock-like sleeves, shoe inserts, or dorsiflexion splints. No good evidence-based recommendations can be made, but some patients improve dramatically with their use [39]. They should not be used in isolation but as part of a comprehensive treatment regimen that must include stretching, strengthening, and correcting any extrinsic risk factors discovered.

For refractory cases, injections can be pursued. Corticosteroid/anesthesia injections can provide immediate relief and help to confirm the source of pathology. Their repeated use is discouraged for risk

DOI 10.1007/978-1-4939-0779-3_118-1

of fat-pad atrophy or plantar fascia rupture. In general, they should be employed when severe pain limits ADLs or prohibits rehabilitation. Prolotherapy, PRP, and botulinum toxin are advocated by some and remain an option for recalcitrant cases. Low-frequency shock wave therapy treatments are also employed when other measures fail, but results of trials are mixed [11]. Surgery is a last resort and the diagnosis must be revisited if the patient is not responding to appropriate treatment.

Metatarsalgia

General Principles

Metatarsalgia literally means pain at the metatarsals. It is a nonspecific term applied to any painful condition around the forefoot, generally the metatarsal heads. It is more of a symptom rather than a condition and treatment rests in elucidating and ameliorating the cause of the symptom (victims and culprits concept discussed in GTPS). Forty percent of impact forces are born by the first digit; any condition that alters this normal force distribution is a contributor to the condition. Although any and all of the distal metatarsals can be involved, the second metatarsal head is affected more often due to its relative inflexibility compared with the other digits, its proximity to the main force absorber (the first digit), and the not uncommon anatomic variation of a shortened first metatarsal (the so-called Morton's toe or Morton's foot) [41]. The following section will discuss in greater detail the more common entities that the family physician will encounter that cause metatarsalgia. A more extensive list of causes is provided in Table 5.

Diagnosis

The history is one of gradual pain without overt trauma. An occupational history is paramount as this may be a major modifiable risk factor. As in all musculoskeletal examinations, inspection of the entire kinetic chain should take place looking for any obvious abnormalities. Stress fractures are in the differential diagnosis so inquiring about recent change in exercise pattern is required (see Table 2 for risk factors).

Local tenderness to palpation over the plantar metatarsal heads is present. Weight-bearing plain radiographs may be ordered to assess for additional bony pathology. Advanced imaging with ultrasound and MRI can be used to evaluate for other entities (stress fractures, nerve impingement, etc.). Salient findings for specific diagnosis will be discussed under their respective section.

Treatment

Successful long-term treatment resides with elucidating the cause of the symptoms. For generalized metatarsalgia without a specific etiology, a metatarsal pad or bar can be used to off-load the metatarsal heads. If the patient has obvious anatomic changes, a custom foot orthoses can be pursued [41].

Interdigital Nerve Compression

A variety of conditions can cause compression with subsequent swelling of the interdigital nerves of the toes (see Fig. 5). Morton's neuroma (note there is no true nerve tumor and as such this is a misnomer) specifically refers to nerve compression between the third and fourth digits and is the most common site. Typical nerve paresthesia symptoms are present in the involved nerve distribution and can be accentuated with direct palpation. Compression of the metatarsal heads by squeezing both sides of the forefoot can cause the affected interdigital nerve to have a painful click or snap between the two opposing bones and is called the Mulder's sign.

Symptomatic relief with an anesthesia block can be diagnostic and if combined with corticosteroid can be therapeutic as well. A dorsal approach is highly recommended to avoid complications and ultrasound guidance is advocated to ensure precise delivery under direct visualization [41]. Recurrence can be treated with either nonsurgical (i.e., alcohol) or surgical nerve ablation techniques, but successful long-term

DOI 10.1007/978-1-4939-0779-3_118-1

management also includes correction/management of the biomechanical deformities causing the nerve compression.

Sesamoiditis

Sesamoiditis is also a generic term for pain located around the sesamoid complex. The sesamoid complex is the main force absorber for the first ray. There are two sesamoid bones embedded respectively in the lateral and medial heads of the flexor hallucis brevis at the first MTP joint. They function to improve flexion power of the MTP joint and to absorb the majority of weight bearing along the medial aspect of the foot. Either sesamoid can be bipartite and patients with pes cavus are at higher risk for sesamoid injuries [42].

Patients will present with pain directly over the involved sesamoid upon palpation and great toe dorsiflexion. Various types of padding (i.e., dancer's pad) and foot orthoses are used for treatment but the basic concept is to redistribute the force. Imaging is not required unless it will change management as treatment is centered on correcting any biomechanical dysfunction in order to off-load the force at the sesamoid. If the diagnosis is in question or the patient is not responding to conservative treatment, plain films including an axial sesamoid view should be ordered but can be difficult to interpret. An MRI is more definitive as it will reveal the presence of stress fractures, soft tissue swelling, or other concomitant pathology. The differential diagnosis for the athletic population includes first MTP joint sprain (turf toe). Turf toe is an acute injury that can be recalcitrant to healing as it is difficult to fully unload. It is treated with rest and custom orthoses.

Distal Tibia/Fibula/Ankle/Foot Fractures

Acute fractures of the ankle are common but usually present with the same mechanism as an ankle sprain which is discussed in "► Athletic Injuries" chapter. The foot and leg are the most common locations for stress fractures because of the high, repetitive force loads imparted. As mentioned earlier, they are preceded by new mechanical stresses for which the body has not had time to accommodate. See Table 3 for low- and high-risk stress fractures and management.

Osteoarthritis

Natasha J. Pyzocha[a]* and Douglas M. Maurer[b]
[a]Family Medicine, Army Medcom Madigan Army Medical Center US, Tacoma, WA, USA
[b]Joint Base Lewis-McChord, Madigan Army Medical Center, Tacoma, WA, USA

1 General Principles

1.1 Definition/Background

Osteoarthritis (OA) is a degenerative joint disease characterized by cartilage deterioration and hypertrophy of bone. OA can present in almost any joint in the body, but the knee is the most common location to develop this condition [1]. Other common locations include the fingers, hips, and spine. OA develops when degeneration exceeds chondrocyte remodeling leading to cyst formation, further cartilage loss, and decreased joint use that further decreases the physiologic stimulation of chondrocyte activity. OA threatens patients' ability to participate in healthy physical activity, thereby predisposing them to increased cardiovascular disease, weight gain, diabetes, and potential loss of independence [2].

1.2 Epidemiology

OA is one of the most common chronic medical conditions and the most common type of arthritis [1]. In 2005, the Centers for Disease Control reported that 13.9 % of adults aged 25 and older and 33.6 % (12.4 million) of those 65+, an estimated 26.9 million, US adults have OA [3]. OA accounts for 69.9 % of all arthritis-related hospitalization, and in 2006 approximately 814,900 hospitalizations were for OA as the principal diagnosis [3]. Estimated costs from hospital expenditures of total knee and hip joint replacements are approximately $28.5 billion and $13.7 billion, respectively, in 2009 [3]. The annual direct and indirect cost of OA per patient in 2000 was $5700 [3]. Risk factors include genetics, acute or recurrent trauma, advancing age, female gender, and obesity [4].

1.3 Classification

In 1981, the American College of Rheumatology (ACR) organized a subcommittee to develop criteria to better define OA [5]. The committee developed two methods of classification: traditional inclusion criteria and classification trees. A superior approach according to the ACR is using the tree model in which the appropriate tree is utilized based on patient data. Although clinical data is sufficient to diagnose OA, laboratory and radiographic data may improve sensitivities and specificities. The three joints evaluated were the knee, hip, and hands.

1.4 Osteoarthritis of the Knee

Traditional inclusion criteria of the knee developed in 1989 include knee pain plus at least three of the following six clinical characteristics: greater than 50 years of age, morning stiffness for less than 30 min, crepitus on active motion of the knee, bony tenderness, bony enlargement, or no palpable warmth (Table 1). Using these criteria, there is a sensitivity of 95 % and specificity of 69 % in diagnosing OA [5].

DOI 10.1007/978-1-4939-0779-3_119-1

Table 1 Knee osteoarthritis classical clinical criteria [5]

Knee pain
Plus at least three of the following
Greater than 50 years old
Morning stiffness for less than 30 min
Crepitus on active motion of the knee
Bony tenderness
Bony enlargement
No palpable warmth

Table 2 Hand osteoarthritis classical clinical criteria [6]

Hand pain (including hand aching or stiffness)
Plus at least three of the following
Hard tissue enlargement of two or more of ten selected joints (second and third distal interphalangeal joints, second and third proximal interphalangeal joints, first carpometacarpal of both hands)
Hard enlargement of two or more distal interphalangeal joints
Fewer than three swollen metacarpophalangeal joints
Deformity of at least one of the ten selected joints

Using the classification and regression tree technique (CART), three trees were formed for knee OA. The first tree was based on clinical features alone, clinical features with laboratory findings, and combined clinical, laboratory, and radiographic features. Sensitivities for these trees were 89 %, 88 %, and 94 %, respectively, and specificities were 88 %, 93 %, and 88 %, respectively [5].

1.5 Osteoarthritis of the Hip

The traditional inclusion criteria for diagnosing OA of the hip developed in 1991 include hip pain plus at least two of the following features: erythrocyte sedimentation rate (ESR) of less than 20 mm/h, radiographic osteophytes (femoral or acetabular), or joint space narrowing on radiography (superior, axial, or medial) (Table 2). These criteria accurately diagnose OA with a sensitivity of 89 % and specificity of 91 % [6].

Two classification trees were developed for the hip. The trees were made with and without radiographs. The tree that did not incorporate radiographic features included internal rotation of less than 15°, pain on internal rotation, morning stiffness, age, ESR, and flexion of less than 115°. This tree had a sensitivity and specificity of 86 % and 75 %, respectively. With the addition of radiographs assessing for radiographic osteophytes and axial space narrowing, the sensitivity and specificity improved to 91 % and 89 %, respectively [6].

1.6 Osteoarthritis of the Hands

Traditional inclusion criteria for OA of the hands developed in 1990 include hand pain (including hand aching or stiffness) plus at least three of the following: hard tissue enlargement of two or more of ten selected joints (second and third distal interphalangeal (DIP) joints, the second and third proximal interphalangeal (PIP) joints, and the first carpometacarpal (CMC) joint of both hands), enlargement of two or more DIP joints, fewer than three swollen metacarpalphalangeal (MCP) joints, and deformity of at least one of the ten selected joints (Table 3). These traditional inclusion criteria yielded a sensitivity of 94 % and specificity of 87 % [7].

DOI 10.1007/978-1-4939-0779-3_119-1

Table 3 Hip osteoarthritis classical clinical criteria [7]

Hip pain
Plus at least two of the following
Erythrocyte sedimentation rate of less than 20 mm/h
Radiographic osteophytes (femoral or acetabular)
Joint space narrowing on radiography (superior, axial, or medial)

Classification trees with and without radiographic features were created and found to be identical in that there was no statistical difference in the inclusion criteria. The sensitivity and specificity of the two trees were 92 % and 98 %, respectively. As a result, hand OA is often classified by only clinical features [7].

2 Approach to the Patient

OA is most likely seen in the older patient with insidious onset of pain, swelling, and morning stiffness in the affected joints. History and physical exam can guide a primary care provider's suspicion for OA. Consider an alternate diagnosis in the presence of acute pain, swelling, erythema, fever, or rash. Radiologic and laboratory studies may also be necessary if an alternate diagnosis is suspected.

3 Diagnosis

3.1 History

OA is often diagnosed by an overall clinical picture using the patient's age, history, physical examination, and radiographic findings. No single clinical feature is absolutely sensitive or specific in making the diagnosis. Patients initially present with symptoms to include pain, limited morning stiffness, and reduced function [8].

3.2 Physical Examination

Some common signs include crepitus, joint swelling, restricted movement, and bony enlargement [8]. In later stages, joint deformity may be present [8]. Erythema, fever, severe local inflammation, and progressive pain may suggest another diagnosis [8]. In the presence of an effusion, consider aspiration and fluid analysis.

3.3 Laboratory and Imaging

According to the European League for Rheumatism, three symptoms (persistent knee pain, limited morning stiffness, and reduced function) and three signs (crepitus, restricted movement, and bony enlargement) in a patient with risk factors for OA can make the diagnosis, and imaging may not be necessary [8]. Laboratory tests and radiographs are not needed to accurately diagnose OA, but testing may rule out the likelihood of another process occurring. Radiographic findings may be misleading and disproportionately severe when compared to pain or the clinical examination.

Laboratory tests are typically normal for uncomplicated osteoarthritis. White blood cell count derived from synovial fluid would be expected to be less than 2,000 per mm^3 (2.0×10^9 per L) [9].

Radiologic abnormalities that are often present include joint space narrowing, osteophytes, and subchondral sclerosis [10]. For the evaluation of knee OA, a weight-bearing anteroposterior, lateral, and sunrise views should be ordered. For the evaluation of hip/pelvis OA, an anteroposterior weight-

DOI 10.1007/978-1-4939-0779-3_119-1

Table 4 X-rays for osteoarthritis [11]

Knee	Anteroposterior weight bearing, lateral, sunrise
Hip/pelvis	Anteroposterior weight bearing
Spine	Anteroposterior, lateral
Hand	Anteroposterior, oblique, magnified view
Foot	Anteroposterior, lateral, oblique, magnified view

bearing film should be ordered. For the evaluation of spine OA, an anteroposterior and lateral film should be ordered. For the evaluation of hand OA, an anteroposterior and oblique film should be ordered. A magnified view of the specific joint may also be beneficial. For the evaluation of foot OA, an anteroposterior, lateral, and oblique film should be ordered. A magnified view of the specific joint may also be beneficial (Table 4) [11].

3.4 Differential Diagnosis

The differential diagnosis for OA includes crystal-induced arthritis, gout, pseudogout, rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, septic joint, and Lyme disease.

4 Treatment

The treatment of OA is directed towards reduction of symptoms and preventing disability. To manage the symptoms of OA, patients and healthcare providers often consider multiple approaches [1]. Although there are no pharmacologic therapies that prevent the progression of joint damage due to OA, many medications may help alleviate the symptoms. The goal of therapy is to control pain and swelling, minimize disability, and improve quality of life.

4.1 Lifestyle Modifications

Symptoms of OA are typically relieved with rest; however, resting the affected joint may lead to muscle atrophy and decreased joint mobility. Rest is only recommended for a short period of time (typically 12–24 h for acute pain) after which active and passive joint motion and exercises should resume.

Alternatively, high and low intensity aerobic exercises are beneficial for improvements in functional status, pain, gait, and aerobic capacity [12]. Exercising also decreases the incidence of obesity which is strongly associated with the development of OA. The relative risk of developing knee OA in patients with a high BMI (no specific BMI) was 1.5 for men and 2.1 for women [13]. In a follow-up study using the same population, the risk of developing OA was reduced following weight loss. A 10 lb weight loss over 10 years reduced the probability of developing knee OA by 50 % [14].

5 Medications

5.1 Acetaminophen and Anti-inflammatories

Oral medications are the mainstay treatment used to treat OA [1]. Acetaminophen is the first-line treatment in patients older than 65 years and the preferred agent due to the greater safety profile when compared with the use of nonsteroidal anti-inflammatory drugs [15]. Acetaminophen should be started initially on an as-needed basis, but in patients with persistent symptoms, regular use may be initiated at doses up to 3 g/day [16]. Acetaminophen is generally safe but hepatotoxicity can occur at high doses, especially in patients who concurrently are at risk for hepatic function impairment due to lifestyle choices,

DOI 10.1007/978-1-4939-0779-3_119-1

polypharmacy, or underlying pathophysiology. In patients who take acetaminophen on a chronic daily basis, consider laboratory testing to assess for hepatotoxicity.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are recommended when acetaminophen does not adequately relieve pain. NSAIDs work by preventing inflammation and controlling pain by blocking cyclooxygenase (COX-1 and COX-2 enzymes) [1]. The side effect profile of NSAIDs is not always favorable, and each year, more than 100,000 patients are hospitalized for gastrointestinal complications resulting from NSAID use with 15 % of these patients dying from these complications [1]. NSAIDs should be avoided in patients with prior gastrointestinal ulcers or bleeding and in patients who are taking anticoagulants [17]. Inhibition of the COX-1 enzyme is responsible for the associated gastrointestinal toxicity [17]. The choice of an NSAID is based upon a variety of factors, and there is no convincing evidence that any of the available NSAIDs are more effective than any other for OA of the knee or hip [18]. A short to medium acting NSAID is generally used on an episodic basis in patients with noninflammatory OA. In inflammatory OA, longer therapy at a higher dosage may be required to control symptoms. If one NSAID is not effective after 2–4 weeks on a maximal dosage, then consider the use of a different NSAID.

COX-2 inhibitors were developed to provide relief of pain without associated gastrointestinal complications; however, COX-2 inhibitors have a similar risk of serious adverse gastrointestinal effects as other NSAIDs in long-term users [17]. Chronic use of COX-2 inhibitors has also been associated with an increased cardiovascular risk [17]. Consider treating gastrointestinal symptoms associated with NSAID use with antacids, H2 blockers, or proton pump inhibitors. In patients being treated chronically with daily NSAIDs, consider obtaining a complete blood count, blood urea nitrogen, creatinine, and aspartate aminotransferase.

5.2 Topical Medications

Topical NSAIDs or capsaicin can be used as an alternative treatment in patients who cannot tolerate oral agents, have contraindications to oral agents, or those that may have an increased risk of adverse side effects. Topical NSAIDs typically provide only modest or short-lived benefit and capsaicin may cause local irritation. There are no trials that directly compare topical therapies. Topical NSAIDs may be helpful for the treatment of OA of the hand or knee [19]. Capsaicin has shown mild to moderate efficacy in randomized trials in hand and knee OA in comparison with placebo [20].

5.3 Intra-Articular Injections

Intra-articular injections are common treatments for OA patients with moderate to severe pain that is not adequately controlled by oral medications. Clinical evidence suggests that the benefit is short lived, and usually patients report symptoms returning after 1–4 weeks [21]. Corticosteroids are proven to be effective at reducing pain in knee OA, although duration and exact efficacy of these treatments is controversial [2]. Corticosteroids decrease pain by roughly one third but provides that benefit for approximately 1 week [2, 21]. A dose equivalent to 50 mg of prednisone may be required to show benefit at 16–24 weeks [21]. The ACR suggests that a dose of 40 mg triamcinolone be used for injections to provide adequate pain relief [21]. Triamcinolone appears to be more efficacious than either methylprednisolone or betamethasone [2]. There is concern that long-term treatment could promote joint destruction and tissue atrophy; however, studies tend to suggest that changes are more likely due to the underlying disease than the steroid injection [21]. It is recommended that the same joint not be treated more than four times a year. Intra-articular glucocorticoid injections are generally well tolerated and septic arthritis is rare.

Hyaluronic acid is a secondary medication option for intra-articular injections. In long-term studies of patients with symptomatic hip degenerative joint disease, however, intra-articular injection of hyaluronic acid was no better than placebo [22]. In a Cochrane review, hyaluronic acid and hylan products were

DOI 10.1007/978-1-4939-0779-3_119-1

found to be superior to placebo in efficacy; however, the sample size was small and many different types of viscosupplementation were used. The study found beneficial effects on pain, function, and patient global assessment especially at the 5- and 13-week postinjection period. In some analyses, viscosupplements were comparable in efficacy to systemic forms of treatment but with more local reactions and fewer systemic side effects [23]. The use of these medications remains controversial.

5.4 Opioids

In patients with significant OA symptoms not adequately treated with acetaminophen, NSAIDs, or joint injections, a low potency opioid analgesic may be considered. Tramadol is a weak opioid that does not produce gastrointestinal bleeding or renal problems. A Cochrane review showed that tramadol or tramadol/paracetamol decreased pain intensity, produced symptom relief, and improved function, but these benefits were small [24]. Adverse events were not shown to be life threatening, and the drug may have had some synergistic effect with acetaminophen [24]. It is recommended that non-tramadol opiates not be routinely used due to the increased risk for adverse events [25].

5.5 Referrals

Consider referring patients for assistive devices or braces if patients have restrictions of their activities of daily living. Occupational therapy may be helpful for hand-related or specific work issues. Physical therapy may be helpful for all other patients with the exception of hip osteoarthritis. A recent study in 2014 showed that physical therapy was no more effective than sham therapy in reducing pain and improving function in adults with hip osteoarthritis [26].

5.6 Complementary and Alternative Therapy

Controversy exists about the effectiveness of glucosamine. In some studies, glucosamine was found to reduce the pain of moderate to severe OA of the knee to improve function and slow the progression of joint space narrowing with an onset of benefit at 4 weeks [27, 28]. A Cochrane review found that some formulations of glucosamine (as a Rotta brand pharmaceutical preparation) were effective in improving OA symptoms but non-Rotta preparations were shown to be ineffective [27].

Other complementary therapies such as chondroitin, ultrasound therapy, acupuncture, magnet therapy, ginger, avocado/soybean unsaponifiables, leaches, laser light therapy, platelet-rich plasma, dextrose prolotherapy, tai chi, balneotherapy, and ice massage may be helpful in treating OA but there is limited evidence [29–41].

5.7 Surgical Options

Surgical options are often last-line therapy for OA. Joint replacement should be considered for patients with restriction of joint mobility, weekly exertion-induced pain that restricts exercising, or severe OA; however, the final treatment decision should be made individually [42]. Arthroscopy with arthroscopic debridement and lavage is not an effective treatment for OA of the knee [43]. In one randomized control trial (RCT), arthroscopic surgery plus medical and physical therapy was no more effective than medical and physical therapy alone [44]. Obese patients with BMI >30 are no longer considered as great a risk of hardware failure after total joint replacement as previously thought [42].

Special consideration and optimization of medical therapy should be considered prior to surgical options. Refer to an orthopedic surgeon if pain persists despite continued medical management.

5.8 Patient Education and Activation

Patients should be educated on this chronic condition that worsens over time. They should know common symptoms of OA and those symptoms that may lead to a different etiology. Patients should try to control

DOI 10.1007/978-1-4939-0779-3_119-1

pain primarily with oral medications and may need to escalate care depending on the severity of their symptoms. They should be given references on where to obtain more information.

5.9 Prognosis

Further degeneration of the joint is likely to progress with aging. Obesity and weight gain will lead to further stress and destruction of the joint. Progression is most strongly associated with age, joint space width, femoral head migration, femoral osteophytes, bony sclerosis, Kellgren/Lawrence hip grade 3 (x-rays with moderate multiple osteophytes, definite narrowing of joint space, some sclerosis, and possible deformity of the bone contour), baseline hip pain, and Lequesne index score $\geq$10 (a scoring system developed to assess severity of OA, $\geq$10 is considered severe) [45].

[b]Associate Dean for Medical Education, F. Edward Hebert School of Medicine, Uniformed Services, University of the Health Sciences

Joint pain is a common complaint in primary care. Pain can be considered acute (days), subacute (weeks), or chronic (generally lasting more than 6 weeks). Accurately diagnosing the cause of joint pain, encouraging continuity of care, and working with multidisciplinary teams using the right blend of therapeutic modalities gives patients the best chance for good long-term outcomes. This chapter will focus, in particular, on diseases that commonly present with joint pain.

Differential Diagnosis of Joint Pain

Step 1: A Thorough Medical History

The key step in diagnosing any of the arthritides is a careful history. By definition, arthritis is acute or chronic inflammation of a joint often accompanied by swelling, erythema, and warmth within any individual joint. Most commonly, arthritis presents with some degree of joint pain. A careful medical history allows for determination of inflammatory and mechanical (degenerative) joint disease.

The history should pinpoint the exact location of the pain. Is the problem limited to one joint (monoarticular), several joints (oligoarticular), or many joints (polyarticular)? Is the problem limited to small joints, large joints, or both? Is the pain truly within the joint? If the pain surrounds the joint (periarticular), this leads to suspicion for soft tissue inflammatory conditions (tendionopathy, bursopathy, enthesopathy). If the pain is more diffuse, systemic disorders come to mind. Is the pain symmetric? Rheumatoid arthritis, systemic lupus erythematosis, polymyositis, Sjögren's syndrome, and scleroderma are commonly polyarticular and symmetric. Other conditions that tend to be polyarticular and asymmetric include psoriatic arthritis, ankylosing spondylitis, and other spondyloarthropathies. Joint stiffness, reduced joint range of motion, swelling, constitutional symptoms (fever, chills, sweats, weight loss), local or generalized weakness, a history of trauma or injury, and the presence of fatigue are other important elements of the medical history. It is important to also define exacerbating and alleviating factors as well as the extent, timing, and waxing/waning nature of symptoms.

The history will help determine to what degree joint complaints are associated with rest and physical activity. Symptoms that are exacerbated by physical activity suggest a mechanical component (particularly when combined with locking or a "give-way" sensation). Morning stiffness describes joint stiffness after a period of generalized inactivity (e.g., overnight sleep). While many individuals can be "slow to get going" in the morning, stiffness lasting for more than an hour is not normal and suggests a systemic inflammatory disease. Patients with degenerative disease, such as osteoarthritis, will more commonly complain of stiffness as the day progresses. Noninflammatory joint pain typically increases with physical activity. Other historical features supporting an inflammatory component to the joint pain include midday fatigue and joint swelling. A sleep history is important as many patients describe significant interruptions to their sleep habits associated with many of the arthritides. Assessing activities

*Email: mark.stephens@usuhs.edu

DOI 10.1007/978-1-4939-0779-3_120-1

of daily living provides good insight into functional limitations. Asking about tasks such as standing from a chair without assistance, showering, washing, or combing hair and the ability to climb stairs is helpful. Determining how the pain has limited the patient's overall ability to function helps to establish a baseline and determine realistic treatment goals. A thorough past medical, surgical, travel, and occupational history provides additional clues into the source and etiology of the joint pain.

Step 2: Physical Examination

Everyone presenting with joint pain should have a thorough physical examination that focuses on the musculoskeletal system while looking for systemic clues in all major organ systems such as the skin. The vital signs should be reviewed. Observe the patient's gait. Look for obvious deformities or muscular atrophy. Palpate individual joints for synovial thickening, fluctuance, or laxity. Note passive and active ranges of motion, particularly of the affected joints. Passive range of motion (ROM) is often greater than active ROM in arthritic joints. Test strength and sensation. While time consuming, an accurate documentation of the physical examination, particularly the musculoskeletal exam, is important to assess changes over time. Fortunately, many electronic medical record systems have embedded templates for just this purpose. Formal dynamometry can be used to track changes in strength over time (e.g., grip strength). A general physical exam can provide clues to systemic illness. Skin lesions, organomegaly, lymphadenopathy, pulmonary or cardiac auscultatory changes, and neurological findings all point to different etiologies of joint pain.

A thorough history and physical examination should lead (in most cases) to a short list of diagnostic possibilities. Based on the history and examination, laboratory and radiographic studies help pinpoint the final diagnosis and guide appropriate treatment.

Rheumatoid Arthritis (RA)

Background and Pathophysiology

Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory disease that affects synovial joints in a symmetric distribution. In most patients without proper therapy, RA is chronic and progressive. Early diagnosis and treatment is important to improve long-term outcomes and potential remission. Early treatment, optimally within 12 weeks of symptom onset, with disease-modifying antirheumatic drugs (DMARDs) gives the best chance of achieving remission [1]. RA occurs in all racial and ethnic groups and is seen more commonly in women (3:1) [2]. Prevalence estimates suggest 1.5 million US adults are affected by RA [3]. First-degree relatives have a twofold to threefold higher risk for developing RA. The disease occurs in all age-groups but is more common with increasing age and peaks between the fourth and sixth decades of life. The leading cause of death in RA is cardiovascular disease, and overall mortality is 2.5 times higher in patients with RA as compared to the general population [4].

The definitive cause of RA is unknown. In susceptible individuals, an external trigger, such as infection or trauma, triggers an autoimmune cascade that results in joint inflammation, synovial hypertrophy, joint destruction, and potentially other extra-articular manifestations. A history of parental substance abuse has recently been associated with an increased risk for developing RA in adulthood [5]. Sixty percent of patients with RA in the United States share an epitope on the HLA-DR4 cluster, suggesting some element of genetic risk [6]. Following an environmental insult, synovial cell hyperplasia and endothelial activation lead to progressive inflammation with articular damage and bony destruction. Abnormal cytokine and inflammatory mediator production along with activation of both T-cell and B-cell lineages contribute to the pathophysiology of RA. The proliferation of synovial cells and subsynovial vessels leads to synovial proliferation, pannus formation, and articular destruction.

DOI 10.1007/978-1-4939-0779-3_120-1

Clinical Presentation

The hallmark presentation of RA involves a persistent, symmetric small joint polyarthritis of the hands, wrists, and feet. In decreasing frequency, the knee, shoulder, ankle, cervical spine, hip, and elbow can also be involved (as can, theoretically, any synovial joint). Most patients have an insidious onset over weeks to months. Morning stiffness is common, and patients report increasing difficulty with routine activities of daily living such as personal hygiene, dressing, and combing their hair. Constitutional symptoms (low-grade fever, malaise, fatigue) are common as well. Large joints often become symptomatic later in the course of the disease. The small joints of the hands and feet should be carefully examined for swelling, warmth, tenderness, and changes in range of motion (ROM). Interosseous muscular atrophy is a common early finding. With progressive joint destruction, characteristic joint deformities (such as boutonniere, swan neck, ulnar deviation, or hammertoe) develop. Rheumatoid nodules can develop particularly along the extensor surface of the ulna. Knee effusions are relatively common in RA and may contribute to progressive muscular atrophy of the quadriceps with resulting instability. The hips and cervical spine are also commonly involved in RA. Atlantoaxial instability is more common in patients with early and severe arthritis of the hands and in those on high doses of corticosteroids.

Because RA is a systemic inflammatory process, most patients will exhibit extra-articular manifestations of the disease. Malaise and fatigue are the most common systemic symptoms. Rheumatoid nodules occur in 25 % of RA patients. Cardiovascular disease is more prevalent in RA patients. RA is also associated with pericardial effusions, pericarditis, myocarditis, and coronary arteritis. Hematologic malignancies such as non-Hodgkin's lymphoma are more common in patients with RA. Pulmonary complications include pleural effusions, pulmonary fibrosis, nodular lung disease, and bronchiolitis obliterans. RA is also associated with secondary Sjögren's syndrome.

Diagnosis

The diagnosis of RA is based upon the combination of clinical, laboratory, and radiographic findings. In 2010, the American College of Rheumatology (ACR)/European League Against Rheumatism (EULAR) developed classification criteria to assist in the early detection of RA [7]. This classification represents an update to the 1987 ACR classification criteria as an attempt to better identify patients early in the course of the disease and initiate effective treatment. According to the ACR/EULAR guidelines, patients who have one joint with definitive synovitis that is not explained by another disease process should be tested for RA (Table 1).

Laboratory and Imaging Studies

Selected laboratory tests, undertaken after a careful history and physical examination, can help confirm the diagnosis of RA. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels are markers of inflammation. Both are typically elevated in RA. CRP also corresponds over time to radiographic progression of RA. Common complete blood count (CBC) findings associated with RA include an anemia of chronic disease (normochromic, normocytic) and thrombocytosis. Autoantibodies, including rheumatoid factor (RF), antinuclear antibody (ANA), and anticitrullinated protein antibodies (ACPA; tested commonly as anti-CCP), are normally the most helpful laboratory tests to aid in the diagnosis of RA. Anti-CCP antibodies have a sensitivity and specificity equal to (or better than) RF for the diagnosis of RA [8]. The presence of both anti-CCP and RF is highly specific for the diagnosis of rheumatoid arthritis. As with RF, the presence of anti-CCP antibodies indicates a worse disease prognosis.

Plain radiographs are the preferred initial images in RA. Plain films can show erosions and can be followed serially to mark disease progression. Magnetic resonance imaging (MRI) provides more accuracy and allows for earlier detection of joint changes. MRI is much more costly and is typically used to assess abnormalities of the cervical spine. While ultrasonography is rapidly growing in use for

Table 1 2010 ACR-EULAR classification criteria for rheumatoid arthritis

	Score
A summative score of ≥6/10 from elements A through D is consistent with RA	
(A) Joint involvement	
1 large joint	0
2–10 large joints	1
1–3 small joints (with or without involvement of large joints)	2
4–10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint)	5
(B) Serology (at least 1 test result is needed for classification)	
Negative RF *and* negative ACPA	0
Low-positive RF *or* low-positive ACPA	2
High-positive RF *or* high-positive ACPA	3
(C) Acute-phase reactants (at least 1 test result is needed for classification)	
Normal CRP *and* normal ESR	0
Abnormal CRP *or* abnormal ESR	1
(D) Duration of symptoms	
<6 weeks	0
≥6 weeks	1

musculoskeletal imaging, its role in RA is evolving. Ultrasound can identify joint effusions in deep joints such as the hip or shoulder and can identify synovial vascularization. As an office-based technology, ultrasonography offers promise in the evolving care for RA patients [9].

Treatment

Successful treatment of RA includes a multidisciplinary, interprofessional team employing a variety of modalities including diet, exercise, stress management, physical therapy, behavioral health, medications, and (potentially) surgery. Patient-centered care focusing on specific treatment goals, patient and family education, and long-term expectations facilitates success.

Nonpharmacologic Treatment

Multiple nonpharmacologic modalities are available to help relieve pain, improve function, and maintain (or enhance) strength and range of motion in patients with RA. The application of heat is effective to relieve pain and stiffness. Hot packs, paraffin baths, ultrasonography, and other modalities may provide relief and also help to prepare affected joints for range-of-motion and strengthening exercises. Orthotic devices and splints also play an important role in managing patients with RA. These devices can reduce pain, enhance function, reduce deformity, and provide proper mechanical joint alignment. Since most RA patients complain of fatigue and reduced cardiorespiratory endurance, a program of therapeutic exercise is important to maintain aerobic capacity and muscular strength. Involving occupational therapists, physical therapists, and exercise scientists can help provide individualized programs of splinting and exercise prescription to optimize physical function while mitigating the risk of injury.

Pharmacologic Therapy

Multiple medication options exist for the treatment of RA. These include nonsteroidal anti-inflammatory drugs (NSAIDs), disease-modifying antirheumatic drugs (DMARDs) including biologics, corticosteroids, and biologic agents. Selecting the right therapy for the right patient to optimize outcome while minimizing toxicity can be challenging.

DOI 10.1007/978-1-4939-0779-3_120-1

NSAIDs and Corticosteroids

NSAIDs and corticosteroids are typically used to provide pain relief and reduce inflammation as a "bridge" for the 3–6 months before DMARD therapy takes effect [10]. NSAIDs do not alter or slow joint destruction and are insufficient monotherapy for RA.

DMARDs

Once the diagnosis of RA has been made, the goal is to control the disease activity, slow joint damage, provide symptomatic relief, and improve overall patient function. The DMARDs and biologic agents are most effective in accomplishing these goals. Vaccination requirements should be discussed with patients who are being considered for therapy with DMARD or biologic therapy. The recommendations vary slightly depending on the drug being considered. It should be noted that while patients on prednisone and other immunosuppressive agents can and should receive inactivated vaccines, their protective antibody response might be blunted.

DMARDs can be classified as biologic and nonbiologic agents. Common nonbiologic DMARDS include hydroxychloroquine (HCQ), sulfasalazine (SSA), azathioprine (AZA), methotrexate (MTX), and leflunomide. For treating RA, MTX and SSZ are generally recognized to be the most active with the best risk-benefit ratios. MTX is typically used alone, or in combination with other medications, for moderate to severe RA and can be administered either orally or subcutaneously. The biologic DMARDS include five tumor necrosis factor (TNF) inhibitors etanercept, infliximab, golimumab, certolizumab, and adalimumab. Biologic DMARDs are typically reserved for use when nonbiologic DMARD (e.g., MTX) has not induced a remission or as initial therapy if a patient has many poor prognostic indicators to include erosive disease, positive serological markers, and extra-articular manifestations. Patients on anti-TNF therapy should avoid live viral vaccines and should be screened for latent tuberculosis infection before initiating therapy.

Other non-TNF biologic DMARDs are available. These include rituximab (most often used in combination with MTX), anakinra, abatacept, tofacitinib, and tocilizumab. Recent guidelines have been published to guide changes in medication doses, combinations, and switching agents [11], Table 2.

Surgery

Surgery can provide pain relief, correct deformities, and improve function. Joint fusions, joint replacement, myofascial release, and other techniques are based on patient age, joint(s) involved, functional disability, and disease stage. Patients with cervical spine instability and refractory pain or neurological compromise are candidates for surgical intervention as well.

Clinical Course and Disease Activity 2011 ACR/EULAR guidelines provide a definition of remission of RA for use in clinical trials [12]. Patient activity scales, clinical disease activity indices, and composite scores are combined to determine low, moderate, or high disease activity. To assess progression, patients are generally categorized into four stages: I (early RA), II (moderate progression), III (severe progression), and IV (terminal progression). Similar scales are available to quantify patients' functional capacity: Class I – able to perform activities of daily living; Class II – able to perform self-care and vocational activities, limited in other activities; Class III – able to perform self-care but limited in vocational activities; Class IV – limited in ability to perform self-care. Using established scales and scoring criteria allows for clear communication between patients and multiple members of the health care team to determine the best treatment strategies for each individual patient.

Differentiating Rheumatoid Arthritis from Osteoarthritis

RA and OA are both relatively common clinical conditions. Since the treatment is different, early recognition and differentiation of the two conditions is clinically important. Patients with RA typically

DOI 10.1007/978-1-4939-0779-3_120-1

Table 2 Indications for initiating and switching DMARDs [11]

Disease activity	Recommendation
Early RA (<6 months)	Provide DMARD combination therapy in patients with moderate or high disease activity and poor prognostic features (functional limitation, extra-articular disease, positive RF or anti-CCP antibodies, bony erosions on x-ray) Use anti-TNF agent ± MTX in those with high disease activity and poor prognostic features – *except* for infliximab, which is used in combination with MTX only (i.e., do not use infliximab as monotherapy)
Established RA If prognosis is not mentioned, use or switch to a nonbiologic or biologic DMARD regardless of prognostic features	Initiating and switching among nonbiologic DMARDs In patients who deteriorate after 3 months of DMARD monotherapy from low to moderate/high disease activity, add MTX, hydroxycholoroquine, or leflunomide if no poor prognostic features For patients with persistent moderate/high disease activity after 3 months of MTX or MTX-DMARD combination therapy, add or switch to a different non-MTX DMARD
	Switching from nonbiologic to biologic DMARDs In patients with persistent moderate/high disease activity after 3 months of MTX monotherapy or MTX-DMARD combination therapy, add or switch to an anti-TNF biologic agent, abatacept, or rituximab In patients with persistent moderate/high disease activity after 3 months of intensified DMARD combination therapy or after a second DMARD, add or switch to an anti-TNF biologic agent
	Switching among biologic agents because of lack or loss of benefit In patients with persistent moderate/high disease activity not benefitting after 3 months of anti-TNF biologic therapy, switch to another anti-TNF biologic agent or a non-TNF biologic agent In patients with persistent moderate/high disease activity not benefitting after 6 months of non-TNF biologic therapy, switch to another non-TNF biologic agent or an anti-TNF biologic agent
	Switching biologic agents due to adverse effects In patients with high disease activity and serious event associated with anti-TNF biologic therapy, switch to a non-TNF biologic agent In patients with moderate or high disease activity after failure of non-TNF biologic therapy because of either a serious or a non-serious adverse event, switch to another non-TNF biologic agent or an anti-TNF biologic agent

ACR American College of Rheumatology, *CCP* cyclic citrullinated peptide, *DMARD* disease-modifying antirheumatic drug, *MTX* methotrexate, *RA* rheumatoid arthritis, *RF* rheumatoid factor, *TNF* tumor necrosis factor

complain of morning stiffness, whereas the pain associated with OA increases through the day and with use. The small joints of the hands and feet are symmetrically involved in RA and the distal interphalangeal joints rarely involved. OA often is less symmetric and typically impacts larger weight-bearing joints (hips, knees), However, distal and proximal interphalangeal joints of the hands are commonly symmetrically

DOI 10.1007/978-1-4939-0779-3_120-1

involved in OA. Soft tissue swelling and warmth are more common in RA. Plain films in RA show periarticular osteopenia and marginal erosions. OA patients often have bony osteophytes on physical examination or radiography. Laboratory findings in OA are normal, whereas RA shows elevations of ESR and CRP along with elevations in RF, anti-CCP, and characteristic CBC changes (anemia, thrombocytosis).

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) has a wide range of presentations in children. JIA was formerly known as juvenile rheumatoid arthritis (JRA) and is one of the most common chronic inflammatory diseases of childhood. The etiology is unknown, and multiple subtypes exist. Recent evidence suggests that antibiotic exposure in childhood potentially increases individual risk for JIA [13].

The diagnosis of JIA is based on history and physical examination. Arthritis must be present for at least 6 weeks before the diagnosis of JIA can be considered definitive. Onset occurs before the age of 16. The primary complaint is joint pain (which may manifest as a limp). Children often complain of pain less than adults, however, and in such cases, there is typically cessation of normal joint use such as refusing to stand in a toddler or infant. Onset can be either insidious or abrupt. Morning stiffness is common as is the "gelling phenomenon" (stiffness after periods of rest). An evanescent rash or psoriasis are the most common dermatologic findings. Physical examination is characterized by the presence of arthritis manifested by swelling, warmth, and erythema. Synovitis is common, and children will often hold joints in a position of maximal comfort (e.g., hip in flexion, abduction, and external rotation or knee in partial flexion). Range of motion is limited depending on the degree of pain and swelling. Complications resulting from any of the subtypes of JIA include joint contractures, muscular atrophy, uveitis, and leg length discrepancies.

Clinically, the International League of Associations for Rheumatology has subdivided JIA into multiple categories [14]. These categories include Systemic-onset JIA, Oligoarticular JIA, Polyarticular JIA, psoriatic arthritis, enthesis-related JIA, and undifferentiated arthritis. In systemic-onset JIA, children appear systemically ill and often complain of myalgias and arthralgias. An evanescent rash of the trunk and extremities is common. Organomegaly and lymphadenopathy may occur. Complaints of chest pain or shortness of breath should raise concern for serositis and a careful examination for rubs, rales or gallop rhythms. Complications include hemolytic anemia, pericarditis, and (rarely) macrophage activation syndrome.

In oligoarticular JIA, fewer than four (and often only one) joints are involved. Oligoarticular JIA typically impacts weight-bearing joints (knees and ankles). Affected children do not look systemically ill and often walk without a limp despite obvious joint swelling. Anterior uveitis is present in up to 20 % of children with oligoarticular (and polyarticular arthritis), and slit-lamp screening is important in these subtypes to exclude ocular disease [15]. Children with polyarticular JIA have five or more joints affected. Small and large joints can be affected, and rheumatoid nodules can be seen in active disease. Children with rheumatoid nodules generally are positive for rheumatoid factor.

Psoriatic arthritis in children is typically milder in children than in adults. It is monoarticular and involves the distal interphalangeal joints in 50 % of cases. Nail pitting is present in over two-thirds of cases. Enthesis-related arthritis involves inflammation of the insertion of tendons and ligaments into bone. Pain and tenderness of periarticular structures is common. Additional diagnostic criteria include sacroiliac tenderness, positive HLA-B27 antigen screening, male gender, age over 6 years, the presence of anterior uveitis, and a first-degree relative with related spondyloarthropathies. Rare complications of enthesis-related JIA additionally include restrictive lung disease and aortic insufficiency. Children with undifferentiated arthritis often have manifestations in multiple JIA categories.

DOI 10.1007/978-1-4939-0779-3_120-1

The diagnosis of JIA is clinical. There are no diagnostic laboratory studies. Laboratories are helpful to rule out other disorders, help classify the type of arthritis, and determine the presence of any extra-articular manifestations of disease. Laboratory markers are also used to follow renal or hepatic function in children on various JIA treatment regimens.

The goal of treatment in patients with JIA is to control pain, maximize function, and minimize disability [16]. Current treatment regimens are available based on the following criteria: (a) history of arthritis in $\leq$4 joints, (b) arthritis in $\geq$5 joints, (c) active sacroiliac arthritis, (d) systemic arthritis (inactive), (e) systemic arthritis (active). The first group ($\leq$4 joints) generally includes patients with psoriatic arthritis, enthesis-related arthritis, and undifferentiated arthritis. In this group, nonsteroidal anti-inflammatory drugs (NSAIDs) are often useful for monoarticular disease. Intra-articular steroids and methotrexate are the next-line agents followed by treatment with TNF-α inhibitors. For patients with disease in $\geq$5 joints (RF-negative/RF-positive polyarthritis, psoriatic arthritis, enthesis-related arthritis, and undifferentiated arthritis), NSAIDs have less of a role. Methotrexate and intra-articular steroids are used more commonly. Leflunomide and IL-6 inhibitors (tocilizumab) are alternatives to methotrexate. TNF-α inhibitors are next-line therapy as is abatacept or rituximab. Patients with active sacroiliac arthritis frequently respond to TNF-α inhibitors if they fail to respond to NSAIDs and/or methotrexate.

Patients with active systemic arthritis are treated with corticosteroids after a brief (2-week) NSAID trial. For patients with systemic JIA, anakinra is effective. Tocilizumab has recently been approved for use in systemic JIA as well. Patients who have active arthritis, but no signs of active systemic disease, are treated with NSAIDs, intra-articular injections, and methotrexate. Anakinra or TNF-α are typically used as second-line therapy.

Successful management of children with JIA is best served with an interprofessional and multidisciplinary approach. In addition to rheumatology, patients often benefit from consultation with physical therapy, occupational therapy, behavioral health, and social services to help manage this complex disease.

Reactive Arthritis (Reiter Syndrome)

Reactive arthritis (formerly known as Reiter's syndrome) is an autoimmune response to infection associated with multiple gastrointestinal (GI) and genitourinary (GU) species [17]. *Shigella* sp., *Salmonella, Campylobacter,* and *Chlamydia trachomatis* have been most commonly implicated, but many others have also been associated with this syndrome. Clinically, reactive arthritis typically presents with uveitis/conjunctivitis ("can't see"), noninfectious urethritis ("can't pee"), and arthritis ("can't bend my knee"). Other symptoms include malaise, fatigue, and fever. Physical findings include an asymmetric oligoarthritis that typically involves the weight-bearing joints of the lower extremity and the fingers or toes, so-called sausage digits. While conjunctivitis is the most common eye disease associated with Reiter's syndrome, more worrisome eye diseases such as scleritis, uveitis, episcleritis, and corneal ulceration may be found on ocular exam. Urethral discharge, vulvovaginitis, balanitis circinata, and cervicitis are common genitourinary findings. Although uncommon, keratoderma blennorragicum, a psoriaform rash, may be seen on the palms and soles. Other skin and nail findings include erythema nodosum and onychodystrophy.

Reactive arthritis typically follows 2–4 weeks after an antecedent GU/GI infection. Reactive arthritis is most common in young men [18]. The frequency of reactive arthritis relates to population rates of HLA-B27. The diagnosis of reactive arthritis is based on history and physical examination. There are no specific laboratory tests. CBC, ESR, CRP, HLA-B27, HIV, tuberculin skin testing, urinalysis, and serologies/cultures (particularly for sexually transmitted infections) can rule out associated disease. There is no curative therapy for reactive arthritis. Treatment is symptomatic or targeted toward the underlying disease [19]. While NSAIDs are frequently used as initial therapy, sulfasalazine, methotrexate, and anti-

DOI 10.1007/978-1-4939-0779-3_120-1

TNF agents are useful second-line agents for patients with persistent symptoms and no relief from NSAIDs. Any underlying disease that is identified should be treated accordingly.

Systemic Lupus Erythematosus

Background and Pathophysiology

Systemic lupus erythematosus (SLE) is a chronic inflammatory disorder affecting multiple organ systems. SLE can impact any organ system but most commonly involves the skin, musculoskeletal system, renal system, hematopoietic system, and nervous system. While the exact cause is unknown, SLE is an autoimmune disorder that is characterized by autoantibody formation and inflammation. T cells have traditionally been implicated as playing a central role in SLE pathogenesis, but other inflammatory cells clearly are implicated. Circulating immune complexes interact with native tissues and activate complement and the inflammatory cascade. Genetic defects in lymphocyte signaling, apoptosis, and the clearance of immune complexes have been identified. Interferon regulatory factor 5 (IRF-5) genetic polymorphisms associated with SLE have been identified in different ethnic populations.

The annual incidence of SLE is roughly 5 cases per 100,000 individuals. Higher rates of SLE are reported in blacks and Hispanics. Most cases (90 %) occur in women, particularly after reaching childbearing age. Male cases are described in individuals with Klinefelter syndrome (XXY), suggesting a hormonal contribution to the pathogenesis of SLE. Survival rates for SLE patients have improved markedly over the past several decades. Ten-year survival rates currently exceed 90 %.

Clinical Presentation

One of the characteristic manifestations of SLE is a malar rash that spares the nasolabial folds. Other common features include other mucocutaneous abnormalities, joint pain, fever, neurological events (seizures or stroke), proteinuria/cellular casts in urine sediment/renal insufficiency, lymphadenopathy, sicca symptoms, and pleuritis. Abnormalities in hematologic indices are common as well. Clinically, the mnemonic "SOAP BRAIN MD" has been applied to the 11 ACR classification criteria for SLE (Table 3): **S** (serositis) **O** (oral ulcers) **A** (arthritis) **P** (photosensitivity) **B** (blood disorders) **R** (renal involvement) **A** (antinuclear antibodies) **I** (immunologic data dsDNA) **N** (neurologic findings) **M** (malar rash) **D** (discoid rash). The presence of 4 of the 11 ACR criteria has a 95 % specificity and 85 % sensitivity for the diagnosis of SLE [20].

History and physical examination. Fever, fatigue, and weight loss are the most common constitutional complaints in patients presenting with SLE (new-onset or with flare of active disease). Joint pain is the most common musculoskeletal complaint, followed by myalgias and arthritis. The arthritis is typically symmetrical, and pain may be out of proportion to the degree of joint swelling. Avascular necrosis is more common in patients with SLE, especially those taking corticosteroids. Malar rash, discoid rash, and photosensitivity are the most common cutaneous features. Other associated cutaneous findings include Raynaud's phenomenon, telangiectasia, livedo reticularis, alopecia, discoid lesions, and urticaria. CNS involvement is common in SLE. The most common are seizures, stroke, and mental status changes (psychosis). The ACR has developed case definitions for multiple neuropsychiatric syndromes associated with SLE [21]. Pulmonary findings associated with SLE include pleurisy, pneumonitis, interstitial lung disease, pulmonary hypertension, and an exudative pleural effusion. Corresponding physical findings would include pulmonary rubs, rales, and dullness to percussion. Complaints of chest pain in patients with SLE should not be ignored. Pericarditis is the most common cardiovascular complication of SLE. Patients with pericarditis typically complain of chest pain that is relieved by leaning forward. Pulmonary hypertension can present with progressive dyspnea.

DOI 10.1007/978-1-4939-0779-3_120-1

Table 3 1997 update of the 1982 American College of Rheumatology revised criteria for classification of SLE [20]

Criterion	Description
Four or more of the following 11 criteria (serial or simultaneous)	
Malar rash	Fixed erythema, flat or raised, over the malar prominences, tending to spare the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a results of unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by physician
Arthritis	Involving two or more peripheral joints characterized by tenderness, swelling, or effusion
Serositis	(A) Pleuritis: convincing history of pleuritic pain or rubbing heard by a physician or evidence of pleural effusion *or*
	(B) Pericarditis: documented by electrocardiogram or rub of evidence of pericardial effusion
Renal disorder	(A) Persistent proteinuria >0.5 g/day or >3+ on dipstick *or*
	(B) Cellular casts: RBC, hemoglobin, granular, tubular, or mixed
Neurologic disorder	(A) Seizures: no potentially inciting drugs or known metabolic abnormality (electrolyte imbalance, renal failure) *or*
	(B) Psychosis: no potentially inciting drugs or metabolic abnormality
Hematologic disorder	(A) Hemolytic anemia- with reticulocytosis *or*
	(B) Leukopenia: <4,000/mm^3 total on 2+ occasions *or*
	(C) Lymphopenia: <1,500/mm^3 on 2+ occasions *or*
	(D) Thrombocytopenia: <100,000/mm^3 (no offending drugs)
Immunologic disorder	(A) Anti-DNA *or*
	(B) Anti-Sm *or*
	(C) Antiphospholipid antibodies (i) abnormal IgG or IgM anticardiolipin antibodies, (ii) positive lupus anticoagulant or (iii) a false-positive serologic test for syphilis
Antinuclear antibody	An abnormal antinuclear antibody (ANA) titer in absence of offending drugs

Laboratory Findings

Patients with suspected SLE should have a complete blood count (with differential), basic metabolic profile (creatinine and glomerular filtration rate), and formal urinalysis (microscopy). The CBC may reveal leukopenia, anemia, lymphopenia, and/or thrombocytopenia. Abnormalities in urine sediment may include proteinuria or casts. The metabolic profile examines renal function (changes in glomerular filtration rate), looking for signs of lupus nephritis. Erythrocyte sedimentation rates and C-reactive protein levels are often elevated in SLE. Complement levels (C3, C4, and CH50) are commonly depressed consumption in active lupus nephritis.

There are multiple autoantibody tests available to aid in the diagnosis of SLE. Antinuclear antibody (ANA) testing is 95 % sensitive for SLE but is not specific. Anti-dsDNA is highly specific but has a lower sensitivity. Levels vary with disease activity. Anti-Sm is the most specific antibody test for SLE but has a very low sensitivity. Anticardiolipin antibodies and lupus anticoagulant testing are laboratory tests that can identify antiphospholipid antibodies that may be associated with the antiphospholipid antibody syndrome.

Treatment

The updated European League Against Rheumatism (EULAR) recommendations provide sound guidance for the treatment of SLE [22]. For patients who do not have major organ involvement, corticosteroids and antimalarials are helpful. Traditionally, hydroxychloroquine has been the cornerstone therapy for SLE

DOI 10.1007/978-1-4939-0779-3_120-1

to prevent flares and reduce disease mortality. Nonsteroidal anti-inflammatory drugs can be used for short periods as well if there is not risk of exacerbating underlying organ disorder, particularly renal disease. For cases refractory to steroids and antimalarials, immunosuppressive agents such as azathioprine and methotrexate are also useful for certain manifestations and control of systemic disease. Recently, the FDA has approved the monoclonal antibody belimumab in combination with standard therapy for treatment of SLE. Additional guidelines for the management of lupus nephritis were published by the ACR in 2012 [23].

As with many of the rheumatic diseases, an interprofessional, multidisciplinary team is helpful to maximize clinical outcomes for patients with SLE. Consultations with multiple specialties including rheumatology, neurology, nephrology, pulmonology, cardiology, dermatology, hematology, and maternal fetal medicine may be necessary. Patient education is also important. Patients should avoid any known triggers for SLE flares. Patients should wear sunscreen and minimize ultraviolet light exposure to reduce photosensitivity reactions. Patients with SLE often require vitamin D supplementation. Exercise is important to maximize functional capacity, avoid muscular atrophy, and maximize bone mineralization. Patients with SLE should not smoke or use tobacco products. Patients should receive annual influenza vaccine and should also receive the pneumococcal and meningococcal vaccines [24].

Raynaud's Disease (Primary Raynaud's Phenomenon)

Primary Raynaud's phenomenon, or Raynaud's disease, is a reactive vasospasm of the fingers and toes typically in response to stress or cold exposure. Primary Raynaud's phenomenon is not associated with any other systemic illness. Secondary Raynaud's phenomenon is associated with some other form of clinical illness typically autoimmune in nature with scleroderma, SLE, and mixed-connective tissue disorder being the most common. The cause of Raynaud's disease remains unknown. The disease is slightly more common in women and has no racial predilection unless it is associated with an autoimmune disorder. It most commonly occurs in the second and third decades of life. Raynaud's disease is characterized clinically by pallor (white), followed by cyanosis (blue), and erythema (red) on rewarming. The fingers are most commonly affected followed by the toes and ears [25].

When evaluating patients for Raynaud's disease, a careful history is important. This should particularly include a prior history of frostbite and prior repetitive use of vibrating tools, which predispose to vasospasm. Occupational exposures to organic solvents have also been associated with Raynaud's disease. Secondary Raynaud's phenomenon has been associated with autoimmune diseases (scleroderma, SLE), infectious syndromes (hepatitis B and C), neoplastic syndromes (leukemia, lymphoma), environmental exposures, medications (beta blockers, methylphenidate, oral contraceptives), and hematologic (polycythemia) and metabolic syndromes (diabetes, pheochromocytoma). Historically, the color demarcation between affected and unaffected areas of skin is remarkable. The digits should be examined for sclerodactyly, ulceration, and capillary blush. Nail fold microscopy can reveal abnormalities in capillary loops. Immersing the patient's affected extremity in ice water can often reproduce the symptoms but is typically not necessary for diagnosis. Laboratory testing is helpful in ruling out potential causes of secondary Raynaud's phenomenon, in particular antinuclear antibodies. Diagnostic criteria for primary Raynaud's phenomenon have been established [24] and include trigger by exposure to cold/stress, bilateral (symmetric) involvement, no necrosis, no underlying systemic cause, normal capillary findings on microscopy, and no laboratory evidence of inflammation or antinuclear factors.

The mainstay of treatment for Raynaud's disease centers on patient education and lifestyle change. Patients should be instructed to wear warm socks, gloves, or mittens and avoid unnecessary cold exposure. Tobacco cessation is important (nicotine is a potent vasoconstrictor). If conservative strategies fail, calcium channel blockers are the traditional pharmacological treatment [26]. Nifedipine (30–120 mg

DOI 10.1007/978-1-4939-0779-3_120-1

of extended-release) is typically the agent of choice. Topical nitroglycerin (1 %) and the prostaglandin analogue (Iloprost) have shown promise in limited numbers of studies.

Systemic Sclerosis

Systemic sclerosis (SSc; scleroderma) is a systemic autoimmune disorder, which results in abnormal collagen deposition in the skin and internal organs resulting in progressive fibrosis of the skin, lungs, heart, gastrointestinal tract, and kidneys. Systemic sclerosis represents a broad spectrum of disease with multiple clinical forms. CREST syndrome (*c*alcinosis, Raynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasias) is a form of scleroderma characterized by cutaneous systemic sclerosis typically involving regions distal to the elbows and knees. Diffuse cutaneous systemic sclerosis is more severe and often involves the internal organs to some degree. Diffuse systemic sclerosis has a more fulminant course with organ involvement and rapid progression. The ACR/EULAR criteria for classification of systemic sclerosis were revised in 2013 [27], Table 4.

Three important processes are involved in the pathophysiology of SSc: (1) alterations in cellular and humoral immunity, (2) excessive collagen deposition, and (3) fibroproliferative disease of small arteries/arterioles. The resulting vasculopathy and tissue fibrosis results in organ dysfunction and clinical disease. While the exact etiology is not known, exposure to silica, solvents, and/or radiation in genetically susceptible individuals have all been hypothesized to trigger the disease [28]. Viruses (herpesvirus, cytomegalovirus, parvovirus) have also been proposed to accelerate the disease in genetically susceptible individuals. SSc is more common in women. There appears to be a higher incidence rate in blacks as compared to whites. In the USA, the highest prevalence of SSc is in the Choctaw Indian tribe. The peak incidence is 30–50 years of age.

Patients with SSC present with signs and symptoms involving many different organ systems. Skin complaints include tightness and induration (edema), sclerodactyly, pruriitis, and pigmentary change. Vascular phenomena typically present as secondary Raynaud's phenomenon. Telangiectasias are also common. Gastrointestinal complaints include reflux, dyspepsia, and altered bowel habits (constipation, diarrhea, incontinence). Respiratory manifestations include dyspnea and cough. Musculoskeletal complaints include myalgias, arthralgias, weakness, and decreased joint range of motion. Common physical findings include sclerodactyly, microstomia, telangiectasia, rales, and an accentuated P2 (pulmonary hypertension).

The diagnosis of SSc is based on history and physical examination. Baseline laboratory studies (CBC, CPK, ESR, B-NP, autoantibody profiles) can help exclude other causes and follow disease progression. Endoscopy, echocardiography, and pulmonary function tests can provide further insight to track target organ function.

There is no cure for scleroderma. Treatment is designed to optimize function of involved organ systems, prevent complications, and provide symptomatic relief. Patients should routinely be encouraged to stop smoking [29]. Investigational therapies are under way to treat skin fibrosis. Pruritus is best managed with moisturizers and antihistamines. Raynaud's phenomenon can be managed with lifestyle changes and calcium channel blockers. Sildenafil has been approved to treat pulmonary hypertension. Bosentan (an endothelin receptor antagonist) has been approved to treat SSc-related pulmonary hypertension and may decrease digital ulcer formation. Antacids, histamine blockers (H2), and proton pump inhibitors can treat common reflux symptoms associated with SSc. Cyclophosphamide has been used to treat pulmonary fibrosis in patients with SSc.

As with other conditions, the broad spectrum of SSc may require input and guidance from a range of consultants. Coordinating care and communication in patients with extensive disease can be a challenge. Rheumatology, pulmonology, cardiology, gastroenterology, surgery, nephrology, physical therapy,

DOI 10.1007/978-1-4939-0779-3_120-1

Table 4 ACR/EULAR revised systemic sclerosis classification criteria [27]

Item	Sub-item(s)	Score[a]
Skin thickening of the fingers of both hands extending proximally to the metacarpophalangeal joints (*presence of this criterion is sufficient criterion for SSc classification*)	None	9
Skin thickening of the fingers (*count the higher score only*)	Puffy fingers	2
	Sclerodactyly (distal to the metacarpophalangeal joints but proximal to the proximal interphalangeal joints)	4
Fingertip lesions (*count the higher score only*)	Digital tip ulcers	2
	Fingertip pitting scars	3
Telangiectasia	None	2
Abnormal nail fold capillaries	None	2
Pulmonary arterial hypertension and/or interstitial lung disease (*maximum score is 2*)	Pulmonary arterial hypertension	2
	Interstitial lung disease	2
Raynaud phenomenon	None	3
Systemic sclerosis–related autoantibodies (*maximum score is 3*)	Anticentromere	3
	Anti–topoisomerase I	3
	Anti–RNA polymerase III	3

[a]The total score is determined by adding the maximum score in each category. Patients with a total score equal to or greater than 9 are classified as having definite systemic sclerosis

occupational therapy, and other services may need to be involved. Developing a robust patient-centered team with clear lines of communication is important to reduce morbidity and improve outcomes.

Sjögren's Syndrome

Sjögren's syndrome is a chronic inflammatory autoimmune disorder. It involves lymphocytic infiltrates within exocrine organs and is characterized by the combination of keratoconjunctivitis sicca or xerophthalmia (dry eyes), xerostomia (dry mouth), and parotid enlargement. Extraglandular features include arthralgias, myalgias, arthritis, lymphadenopathy, neuropathy, and Raynaud's phenomenon. The American-European Consensus Group (AECG) criteria [30] for classification of Sjögren's syndrome include (a) ocular symptoms: dry eyes for >3 months; (b) oral symptoms: xerostomia, swollen salivary glands; (c) ocular signs: Schirmer's test <5 mm in 5 min); (d) oral signs: abnormal salivary scintigraphy, sialography, or sialometry; (e) positive salivary biopsy; (f) positive anti-SSA or anti-SSB antibodies.

Sjögren's syndrome is more common in patients with HLA-DR52 and affects women nine times more often than men [31]. Sjögren's syndrome is more common in older adults, with an average age of onset in the fourth and fifth decade of life. It is hypothesized that Sjögren's syndrome is triggered by viral disease, though proof remains inconclusive. Many medications (antidepressants, antihistamines, anticholinergics, diuretics, beta blockers) can also cause xerostomia but should not be confused with Sjögren's syndrome. Outside of sicca symptoms (dry eyes and dry mouth), patients most commonly present with parotitis and cutaneous complaints such as dry skin and pruritis. Dryness of the aerodigestive tract can result in a chronic cough, dysphagia, and a globus sensation. Common physical findings relate to ocular and oral dryness. Angular cheilitis; dental caries; a dry, erythematous, smooth tongue; and chapped lips are common. Parotid gland enlargement occurs in 20–60 % of Sjögren syndrome patients.

The diagnosis of Sjögren's syndrome is based on clinical history (sicca symptoms) and physical examination. Laboratory testing to quantify salivary (sialometry) and lacrimal (Schirmer's test) function are supportive of the diagnosis. Autoantibodies are common in Sjögren's syndrome with anti-SSA and

DOI 10.1007/978-1-4939-0779-3_120-1

anti-SSB being the most common. Treatment options for Sjögren's syndrome patients are limited and primarily focus on symptom relief. Liberal use of ocular lubricants, skin lubricants, and vaginal lubricants can help mitigate dryness. Humidifiers and frequent sips of water can help alleviate dry mouth. Pilocarpine, artificial saliva, and cevimiline have been used for more severe cases of xerostomia [32]. If major organs are involved, the use of immunosuppressive therapy (cyclophosphamide), rituximab, or systemic corticosteroids is appropriate [33]. Such cases are best managed in the context of a multidisciplinary team including rheumatology, pulmonology, and nephrology depending on the extent of extraglandular disease. Sjögren's syndrome patients should have appropriate eye health and oral health professionals as part of this team.

Polymyalgia Rheumatica (PMR)

Polymyalgia rheumatica (PMR) is a chronic inflammatory disorder that typically affects individuals over the age of 50. The cause of PMR is not known. Pathophysiologically, it is similar to giant cell arteritis or temporal arteritis. The disease appears to be polygenic in origin, perhaps triggered by an environmental factor (likely a virus) that results in cytokine production due to macrophage and T-cell activation. Polymyalgia rheumatica has an annual incidence of approximately 53 cases per 100,000 persons over age 50 annually in the United States. PMR is more common in white patients (rare in blacks) and more common in women [34]. The median age at the time of diagnosis is 72 years. One in three patients with polymyalgia rheumatica also have temporal arteritis.

The predominant clinical features of PMR are pain or weakness of the hips and shoulders that are usually associated with morning stiffness. Patients may also complain of constitutional symptoms including fatigue, weight loss, and low-grade fever. In 2012, EULAR/ACR published new scoring criteria [35] for patients with PMR: (a) morning stiffness >45 min (2 points), (b) hip pain and limited ROM (1 point), (c) rheumatoid factor (RF) and anticitrullinated protein antibody (CCP) negative (2 points), (d) no peripheral joint pain (1 point). Patients with four or more points are likely to have PMR (compared to other spondyloarthropathies or inflammatory arthritides). On physical examination, patients may have a low-grade temperature. They often appear fatigued. Patients have normal muscle strength and no atrophy. There is tenderness to palpation, particularly of the hip and shoulder girdles, but many investigators feel that this is due to synovitis. ROM is often reduced due to the pain. The erythrocyte sedimentation rate is the most sensitive (but not specific) laboratory test for PMR. ESR is almost always >40 mm/h and characteristically exceeds 100 mm/h. Creatine phosphokinase levels are normal as are ANA, complement, RF, and anti-CCP levels.

Corticosteroids are generally the cornerstone of treatment for patients with PMR. Patients generally respond well to a prednisone dose of 15 mg/day. If a patient does not respond quickly to corticosteroids, other diagnoses should be considered. Patients often require steroids for a prolonged period (1–2 years). Patients on chronic steroid therapy should receive calcium and vitamin D supplementation and regular DEXA scans to assess bone health [36]. When attempts are made to wean a patient off prednisone, the dose is decreased by only 1 mg/month. Methotrexate and TNF-α inhibitors have also been used as steroid-sparing treatments for PMR [37].

Giant Cell Arteritis (Temporal Arteritis)

Giant cell arteritis (GCA; temporal arteritis) is a cell-mediated inflammatory systemic vasculitis. GCA is the most common systemic vasculitis in adults. Pathophysiologically, GCA is characterized by inflammation of the vascular wall of affected arteries (e.g., the temporal artery) resulting in endothelial injury, luminal narrowing, and distal ischemia. Like polymyalgia rheumatica, GCA typically presents in patients over 50 [38]. The incidence of disease peaks in the eighth decade of life. GCA is more common in women (3:1) and in whites of Northern European descent.

DOI 10.1007/978-1-4939-0779-3_120-1

The onset of GCA is variable. Some patients have an insidious onset, while for others it is abrupt. Often there is a constitutional prodrome with patients complaining of anorexia, malaise, myalgias, night sweats, and weight loss in the preceding days to weeks. Headache is the most common symptom associated with GCA (present in three quarters of patients) [39]. The headache is most commonly tempuraoccipital in location and described as "throbbing" and "continuous." Many patients are tender to palpation over the temporal artery. Jaw claudication and shoulder and/or hip/pelvic girdle pain are often present as well (as in PMR). Some patients with GCA report visual symptoms. Symptoms are often transient, but sudden loss of vision is a poor sign and can be permanent without immediate treatment. The most common visual symptoms included blurring, visual loss, diplopia, hemianopia, or amaurosis fugax.

Patients with GCA (as in PMR) typically have an elevated ESR (50 mm/h to over 100 mm/h). Definitive diagnosis requires a temporal artery biopsy (TAB). Treatment should not be withheld pending biopsy results, and specimens are more likely to be positive if obtained within 24 h of beginning treatment. Recently, the use of color duplex ultrasonography has shown promise as a diagnostic complement to TAB. High-resolution MRI has been used for a similar purpose. The ACR [40] and others [41] have developed diagnostic criteria for GCA including (a) age over 50, (b) new-onset localized headache, (c) temporal artery tenderness to palpation (or decreased pulsation), (d) ESR $\geq$ 50 mm/h, (e) positive TAB (vasculitis with mononuclear infiltration). High-dose corticosteroid therapy is the cornerstone of therapy for GCA. Patients with visual symptoms have a markedly increased chance of visual improvement if steroid therapy is initiated within 24 h. Oral prednisone (40–60 mg/day; some sources suggest 80–100 mg/day in patients with visual or neurological symptoms consistent with GCA) should be started immediately while arranging for TAB. Intravenous methylprednisolone (250–1,000 mg/day for 3 days) is an alternative to oral prednisone. Once symptoms have improved, steroids should be tapered to the lowest dose necessary to suppress symptoms. Patients often require prolonged treatment with corticosteroids. Symptoms and measurement of acute-phase reactants serve as a guide to tapering the dose of corticosteroids. Methotrexate and TNF-α antagonists have been used as steroid-sparing agents in patients requiring higher doses of prednisone (5–10 mg/day) for prolonged periods of time. GCA is best managed in consultation with a rheumatologist in the context of high-dose steroids and surgery consultation required to assist with TAB. Ophthalmology consultation in the context of visual changes should be entertained if the diagnosis is uncertain.

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is a chronic inflammatory seronegative spondyloarthropathy primarily involving the spine (sacroiliac joint and axial skeleton). The disease is more common in men (3:1) and typically presents during adulthood. More than half of the patients with ankylosing spondylitis present complaining of low back pain. Features distinguishing AS from mechanical low back pain include morning stiffness, pain that is unrelieved with rest, and pain that awakens patients from sleep [42]. The pain associated with AS often radiates to the buttocks but rarely below the knee (as seen with sciatica). The onset of pain is often insidious and tends to improve with exercise. Fatigue is reported in 65 % of patients. Extra-articular manifestations of AS include uveitis, pulmonary disease, renal disease, gastrointestinal disease, and metabolic bone disease. Patients may also have peripheral joint involvement (large joints are more commonly involved than small joints). Patients may also complain of other sites of enthesopathic pain (e.g., Achilles tendon, plantar fascia). Onset after the age of 40 is unusual. Over 90 % of Caucasian patients with AS are HLA-B27 positive. However, only 1–2 % of patients who are positive for HLA-B27 develop ankylosing spondylitis, suggesting a role of other factors in the onset of disease [43].

Early diagnosis of AS is important to maximize functional outcomes. The diagnosis of AS is based on a combination of clinical and radiographic findings [44, 45], Table 5. The insidious onset of low back pain

DOI 10.1007/978-1-4939-0779-3_120-1

Table 5 New York and Rome criteria for diagnosis of ankylosing spondylitis

New York criteria	Rome criteria
Low back pain with inflammatory characteristics Limitation of lumbar spine motion in sagittal and frontal planes Decreased chest expansion Bilateral sacroiliitis grade 2 or higher* Unilateral sacroiliitis grade 3 or higher*	Low back pain and stiffness that is not relieved by rest for >3 months Thoracic pain and stiffness Limited motion in the lumbar spine Limited chest expansion History of uveitis
*Diagnose ankylosing spondylitis if patient presents with any clinical criteria	Diagnosis ankylosing spondylitis when any clinical criteria present with bilateral sacroiliitis grade 2 or higher Radiographic sacroiliac (SI) grades Grade 0 – Normal Grade 1 – Suspicious Grade 2 – Minimal sacroiliitis Grade 3 – Moderate sacroiliitis Grade 4 – Ankylosis

that is worse in the morning, relieved with activity, lasting for more than 3 months in patients under the age of 40 should raise the suspicion for AS [46].

Physical examination should include documentation of lumbar range of motion in particular. The two most commonly used tests to assess spinal flexion are Schober's test and Moll's flexion test. Schober's test is performed with the patient standing. Identify the top of the sacrum, and mark a spot on the spine 10 cm above and 5 cm below. In normal individuals, this distance increases by at least 5 cm with forward flexion. The Moll's lateral flexion test is performed by marking a point 20 cm above the iliac crest at the midaxillary line. This distance increases by at least 3 cm with lateral flexion in normal individuals. Uveitis (typically unilateral) is the most common extra-articular manifestation of AS [47], but the cardiopulmonary, renal, gastrointestinal, and neurovascular systems can all be involved.

Radiographic studies help to confirm the diagnosis of AS [48]. Involvement of the sacroiliac joint is required to diagnose AS. Radiographic signs of AS include vertebral "squaring" (erosions of the margins of the vertebral bodies) and sclerosis of the vertebral margins (Romanus lesion). Sacroiliac disease is usually bilateral in AS. If the disease has progressed, patients develop a characteristic "bamboo spine" appearance on x-ray. Power Doppler ultrasonography, MRI, and CT also reveal characteristic signs of sacroiliitis. The ESR is elevated. It is easy to measure the flexibility of the spine, which is decreased in most patients.

The goals of treatment of ankylosing spondylitis are to decrease pain and maintain functional status. No specific disease-modifying treatment currently exists for patients with AS. NSAIDs are the initial drugs of choice to control inflammation and decrease pain. Sulfasalazine is helpful in patients who are unresponsive to NSAIDS. TNF-α antagonists are effective in the treatment of AS [49]. Infliximab, adalimumab, golimumab, certilizumab pegol, and etanercept have all been approved by the FDA as therapy for AS when NSAID therapy has failed. Patients should be screened for Hepatitis B, HIV, and latent tuberculosis before initiating TNF-α antagonist therapy. Complex cases are best managed in the context of a multidisciplinary team including rheumatology, pulmonology, ophthalmology, cardiology, physical therapy [50], and orthopedic surgery depending on the extent of disease.

Psoriatic Arthritis

Psoriatic arthritis is a seronegative inflammatory arthritis that is variable and ranges from 7 % to 42 % in studies (chapter "► Psoriatic arthritis is a seronegative inflammatory arthritis"). Psoriasis typically precedes the appearance of arthritis by several years. The onset is typically insidious with patients primarily

DOI 10.1007/978-1-4939-0779-3_120-1

complaining of stiffness and pain. Psoriatic arthritis is also associated with enthesopathy (inflammation at the insertion of ligament/tendon into bone). The Achilles tendon and plantar fascia are commonly involved. One-third of patients will exhibit dactylitis, or sausage digit. Skin findings are consistent with psoriasis and include scaly erythematous plaques, guttate lesions, and erythroderma. Psoriatic nail changes (pitting, hyperkeratosis, Beau's lines, transverse ridging) are common. With the exception of skin disease, extra-articular findings are less common in psoriatic arthritis patients than in other inflammatory arthritides. Guidelines for diagnosis [51] include the Classification Criteria for Psoriatic Arthritis (CAPSAR) scoring system (3 points total from the following):

- Active psoriasis (2 points)
- History of psoriasis – no active psoriasis (1 point)
- Family history of psoriasis – no active psoriasis (1 point)
- Dactylitis (1 point)
- Juxta-articular new bone formation (1 point)
- Serum RF negative (1 point)
- Nail dystrophy (1 point)

There are no diagnostic laboratory tests for psoriatic arthritis. ESR and CRP are often elevated. X-rays often show joint-space narrowing of the interphalangeal joints with periostitis and may shoe the characteristic "pencil-in-cup" deformity. NSAIDs are the initial treatment of choice, and several disease-modifying antirheumatic drugs have been approved for the treatment of psoriatic arthritis including methotrexate, sulfasalazine, cyclosporine, leflunomide, and TNF-α antagonists [52]. Recently, apremalist (a phosphodiesterase-4 inhibitor) has been approved by the FDA for treatment of psoriatic arthritis in adults [53].

Problems of the Soft Tissues

Fibromyalgia

Definition/Background

Fibromyalgia is a common syndrome characterized by generalized pain present for greater than 3 months, joint stiffness, fatigue, mood disorders, cognitive dysfunction, nonrestorative sleep, and tender points.

First described in the ninth century in Germany, fibromyalgia continues to remain a poorly understood condition that is difficult to diagnose and manage. In early 1900s, the term fibrositis was used to describe the condition since it was thought that inflammation of the connective tissue caused it. However, further systematic scientific studies in the mid-1970s revealed that inflammation was not the contributing factor and the term "fibromyalgia" was coined as a pain syndrome without any specific organ disease [1]. In 1980, a multicenter study was conducted, and two criteria emerged, commonly referred as the American College of Rheumatology (ACR) criteria, for diagnosing fibromyalgia [2]. The first is a history of widespread pain of 3 months or longer duration, and the second is the presence of pain responses at least 11 of 18 designated tender points (TP) (Fig. 1). A newer ACR criterion was formulated in 2010; this criterion is described later in this chapter.

Epidemiology

Fibromyalgia is the third most common rheumatic disorder after osteoarthritis and back pain. The prevalence has been estimated to range from 2 % to 8 % of the population in North America [3]. In 2005, it was estimated that 5 million adults were suffering from fibromyalgia. It is more prevalent in females than in males; using the 1990 ACR criteria, the female–male ratio was 7:1, but the newer ACR diagnostic criteria from 2010 put the ratio at 2:1, similar to other chronic pain conditions.

While it can develop at any age, including childhood, prevalence usually increases with age, with symptoms commonly presenting between 35 and 60 years of age. Genetic predisposition is likely, evidenced by the increased prevalence of fibromyalgia and chronic pain conditions, in family members of fibromyalgia patients. Environmental factors, certain infections, and psychosocial stressors have also been implicated as being likely triggers of risk factors for fibromyalgia. These factors include trauma, poor sleep, obesity, physical inactivity, viral infections, Q fever, Lyme disease, poor job/life satisfaction, or deployments to a war zone.

Other chronic pain conditions are also commonly associated with fibromyalgia. These include but are not limited to headaches, chronic fatigue, restless leg syndrome, irritable bowel syndrome, interstitial cystitis, dysmenorrhea, endometriosis, temporomandibular joint disorder, rheumatoid arthritis, and low back pain [4].

DOI 10.1007/978-1-4939-0779-3_121-1

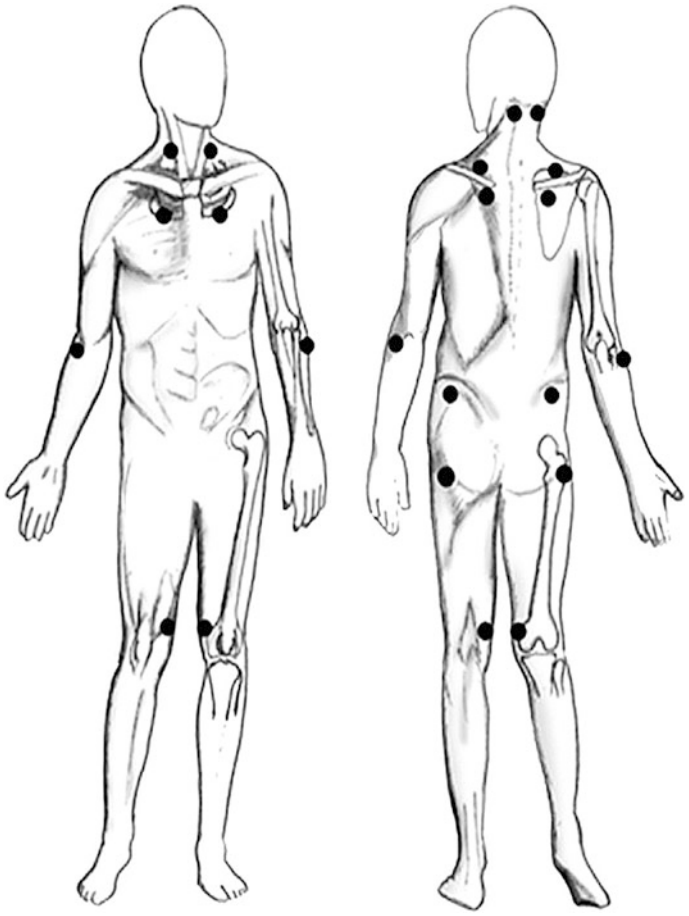

Fig. 1 Tender points location in fibromyalgia (Adapted from Pain Res Treat. 2012; 2012: 426130. © 2012 Enrico Bellato et al., open access article distributed under the Creative Commons Attribution License)

The economic burden of this condition is also significant both on the individual patient as well as the society in general. It has been estimated to be, on average, $35,000 per patient per year, which accounts for both direct costs and indirect expenses. The costs have been estimated to be, on average, medications, treatment costs, and rehabilitation expenses; indirect costs include lost wages, disability, and lost productivity resulting from absenteeism and presenteeism.

Etiopathogenesis

Though fibromyalgia was originally thought to be an inflammatory condition (fibrositis), this has been refuted with later studies. While the exact etiology is still unknown, the general consensus over the past few decades has been that several factors contribute to this process with central sensitization being considered as one of the primary mechanisms. Central sensitization is described as the increased response to stimulation as a consequence of spontaneous nerve activity, enlarged receptive fields, and augmented stimulus responses transmitted by afferent fibers [5].

Other mechanisms include hypothalamic-pituitary-adrenal (HPA) axis dysfunction, sleep disruptions, genetic factors, neurotransmitter imbalances, peripheral pain modulations, psychiatric conditions, and trigger factors. While multiple mechanisms have been attributed, it is important to note that a majority of the patients might not have any precipitating factors.

DOI 10.1007/978-1-4939-0779-3_121-1

Clinical Features

Widespread pain and tenderness remain the hallmark of fibromyalgia. The pain is often described as diffuse, multifocal, deep, gnawing, and burning. It is frequently migratory and often waxes and wanes. Other systemic symptoms such as fatigue and disruptive sleep patterns are quite common. Nonspecific symptoms such as chronic headaches, tingling and numbness, stiffness – especially in the mornings – weight fluctuations, heat and cold intolerance, restless legs, and paresthesias are also reported. Decline in cognitive functions and mood disturbances such as depression and anxiety can also occur at a higher rate in patients with fibromyalgia than the general population. The symptoms appear to worsen with changes in weather, stressful situations, during menstrual cycles, and physical exertion.

Diagnosis

The diagnosis is predominantly made from eliciting the typical history of generalized pain over three months and presence of tender points on physical examination.

In 1990, the ACR criteria were published as a standard for diagnosing fibromyalgia for research proposes, but since then, it has been widely used to clinically diagnose the condition. The pain must affect both sides of the body; it must affect areas above and below the waist; and it must be axial. Tender points are considered positive if pain is elicited with digital palpation with about 4 kg (8.8 lb) of pressure (thumbnail bed blanches). There should be at least 11 of the 18 specified tender points shown in Fig. 1.

Although being widely accepted as the standard for diagnosis, there were many shortcomings in these criteria. Most notably among them was that the primary care provider rarely performed tender point examination even though it was diagnosed most commonly in the primary care setting. The importance of symptoms, based on which the diagnosis was made, was not considered in the 1990 ACR criteria.

In 2010, ACR developed a new diagnostic criteria which include widespread pain index (WPI) and symptom severity scale (SS) [6] (Table 1). The new case definition and diagnostic criteria for fibromyalgia (which includes WPI $\geq$7 and SS $\geq$5 or WPI3-6 and SS $\geq$9) capture 88 % of cases classified by the ACR 1990 classification criteria and do not require a physical or tender point examination.

Basic laboratory tests including complete blood count, erythrocyte sedimentation rate, C- reactive protein, thyroid panel, vitamin D levels, and routine serum chemistries are done primarily to rule out the differentials rather than to rule in fibromyalgia.

Differential Diagnosis

The differential diagnosis for fibromyalgia includes hypothyroidism, rheumatoid arthritis, adrenal dysfunction, systemic infections, and mental health disorders.

Treatment

The goal of treatment should be a multidisciplinary approach to alleviate pain, improve sleep and functioning, and reduce associated symptoms (Fig. 2).

Patient Education. Patient education is essential in aiding understanding, acceptance, and self-management of the condition. There is evidence that educational sessions to explain the condition and set treatment expectations are effective [7]. Various resources such as the Fibromyalgia Impact Questionnaire (FIQ; www.myalgia.com), Patient Global Impression of Change (PGIC), and support groups online and in person are useful tools.

Pharmacological Therapies. The US Food and Drug Administration (FDA) has approved the following medications for fibromyalgia:

Pregabalin.This is a gamma-aminobutyric acid (GABA) analog and an antiepileptic agent that has been found to be effective in pain reduction and improvement in sleep and quality of life measures. The

DOI 10.1007/978-1-4939-0779-3_121-1

Table 1 ACR 2010 fibromyalgia diagnostic criteria (Reprinted with permission from Arthritis Care and Research, 62 (5) May 2010, pp 600–610)

Criteria			
A patient satisfies diagnostic criteria for fibromyalgia if the following three conditions are met:			
1) Widespread pain index (WPI) ≥7 and symptom severity (SS) scale score ≥5 or WPI 3-6 and SS scale score≥9			
2) Symptoms have been present at a similar level for at least 3 months			
3) The patient does not have a disorder that would otherwise explain the pain			
Ascertainment			
1) WPI: note the number areas in which the patient has had pain over the last week. In how many areas has the patient had pain? Score will be between 0 and 19			
Shoulder girdle left	Hip (buttock trochanter) left	Jaw, left	Upper back
Shoulder girdle right	Hip (buttock trochanter) right	Jaw, right	Lower back
Upper arm, left	Upper leg, left	Chest	Neck
Upper arm, right	Upper leg, right	Abdomen	
Lower arm, left	Lower leg, left		
Lower arm, right	Lower leg, right		
2) SS scale score:			
Fatigue			
Waking unrefreshed			
Cognitive symptoms			
For each of the three symptoms above, indicate the level of severity over the past week using the following scale			
0 = no problem			
1 = slight or mild problems, generally mild or intermittent			
2 = moderate, considerable problems, often present, and/or at a moderate level			
3 = severe, pervasive, continuous, life-disturbing problems			
Considering somatic symptoms in general, indicate whether the patient has[a]			
0 = no symptoms			
1 = few symptoms			
2 = a moderate number of symptoms			
3 = a great deal of symptoms			
The SS scale score is the sum of the severity of the three symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general. The final score is between 0 and 12			

[a]Somatic symptoms that might be considered: muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms

starting dose is 75 mg BID and can be titrated up to 300–450 mg/day. Adverse effects include dizziness, dry mouth, blurred vision, weight gain, somnolence, peripheral edema, and concentration problems.

Serotonin Norepinephrine Reuptake Inhibitors (*SNRIs*). Duloxetine and milnacipran reduce pain by increasing activity of noradrenergic antinociceptive pathway [8]. There is also significant improvement in other subjective ratings of fibromyalgia symptoms (PGIC; FIQ total score).

Duloxetine should be considered in patients presenting with significant depression symptoms. The starting dose is 30 mg/day and can be titrated up to 60 mg/day. Adverse effects include nausea, somnolence, dry mouth, fatigue, constipation, and increased sweating.

DOI 10.1007/978-1-4939-0779-3_121-1

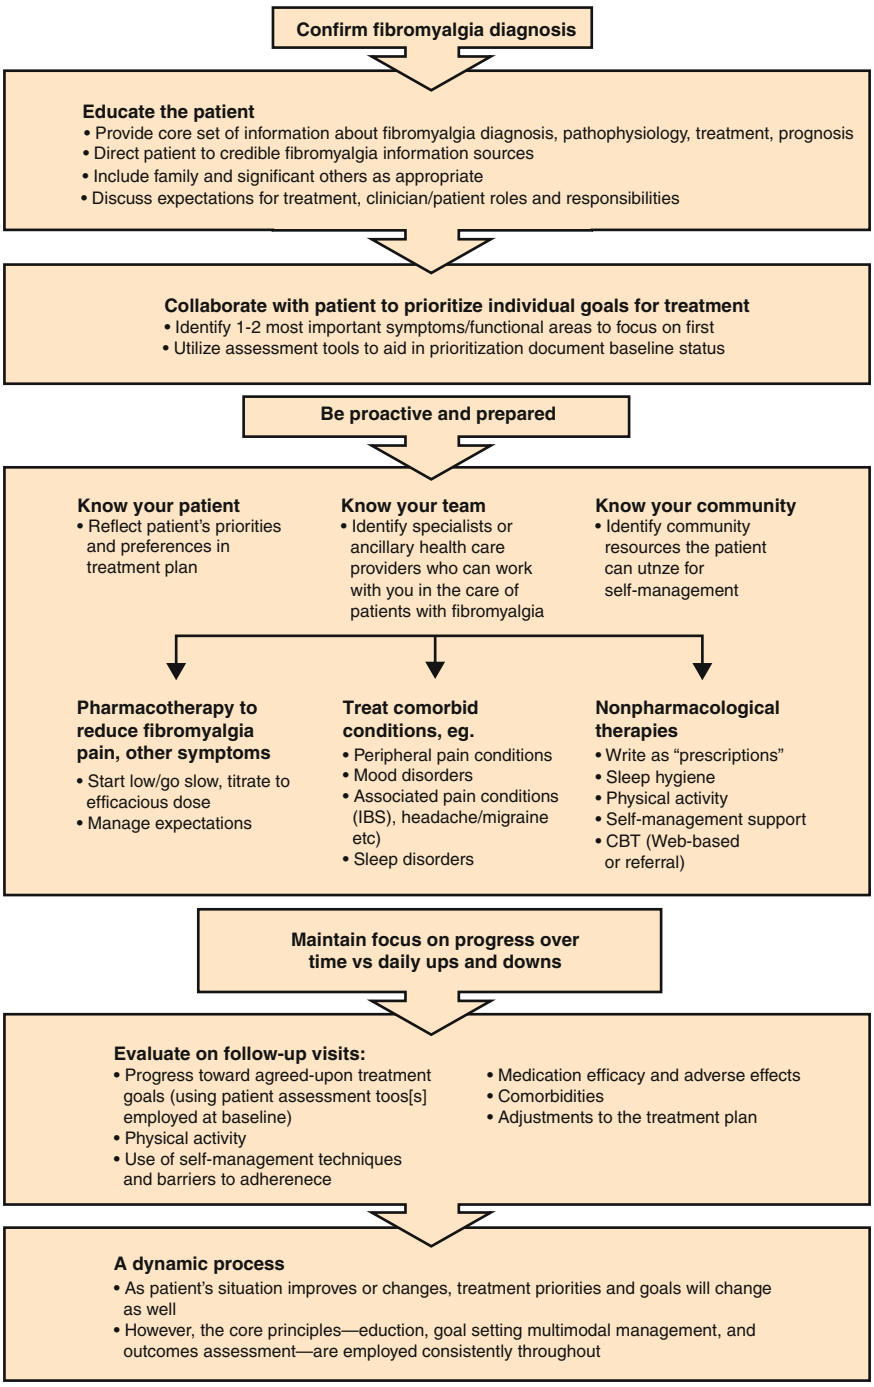

Fig. 2 Multidisciplinary approach for fibromyalgia management (Reprinted from Ref. [43], Copyright (2012), with permission from Elsevier)

Milnacipran is helpful in patients with significant fatigue or cognitive dysfunction. The starting dose is 12.5 mg/day and can be titrated up to 50 mg BID. Adverse effects include nausea, headaches, palpitation, hot flushes, and hypertension.

Other medications, although not approved by FDA, that continue to be used in the management of fibromyalgia include tricyclic antidepressants, specifically amitriptyline and cyclobenzaprine in low doses. Gabapentin, tramadol, fluoxetine, and sodium oxybate are also used for symptomatic relief with

DOI 10.1007/978-1-4939-0779-3_121-1

some efficacy. NSAIDs have not been found to be effective in the management of fibromyalgia but continue to be used in the management.

Exercise/Physical Activity. Aerobic exercise and strength training have been consistently linked to improvement in symptoms. Moderate intensity aerobic training for 12 weeks may improve overall well-being and physical function, but it offers little or no difference in pain or tender points. Strength training for 12 weeks may result in large reductions in pain, tender points and depression, and large improvement in overall well-being but may not lead to any difference in physical function [9].

The most effective recommendation is to start with low impact activity such as walking for 10 min/day and build up to 30–60 min of activity 2–3 times for week.

While various physical activity modalities such as tai chi, yoga, and balneotherapy have been described in the literature, effectiveness is yet to be conclusively demonstrated for management of fibromyalgia.

Cognitive Behavioral Therapy. Cognitive behavioral therapy (CBT), especially pain-based CBT, has been shown to be effective [10]. It is also effective in improving mood, quality of life, and cognitive functioning, especially when included as a part of a multidisciplinary treatment program. CBT can be offered in individual session, small groups, and also online. The Internet-based programs offer more convenience and flexibility to the patients.

Complementary and Alternative Medicine (*CAM*) *Therapies*. Therapies such as acupuncture, hypnotherapy, and mindfulness-based stress reduction (MBSR) are increasingly being used in the management of fibromyalgia, but due to limited number of good quality studies, the clinical benefit of these modalities cannot be determined at the current time.

Myofascial Pain Syndrome

Definition/Background

Myofascial pain syndrome (MPS) is a specific syndrome characterized by a complex of sensory, motor, and autonomic symptoms that are caused by myofascial trigger points [11]. Trigger points are spots of exquisite tenderness and hyperirritability in muscles or their fascia, localized in taut, palpable bands, which mediate a local twitch response of muscle fibers under a specific type of palpation and give rise to pain, tenderness, and autonomic phenomena. This is a common pain condition that is frequently underdiagnosed due to a lack of validated diagnostic criteria and overlap of symptoms with those of other musculoskeletal pain disorders.

Clinical Features

MPS typically presents as a deep somatic pain that is described as constrictive or cramping in nature. It is fairly well discriminated, varies in intensity, and usually prevalent in the head, neck, shoulders, hips, or low back, as these muscles work consistently against gravity or repetitively. Often a history of muscle trauma can be elicited which could be overload, excessive stretching, or overuse. Altered motor functions such as weakness, decreased work tolerance, and loss of coordination are also present. Autonomic disturbances include cooling, sweating, persistent lacrimation, imbalance, dizziness, and tinnitus.

The affected muscles are palpitated to search for the taut bands and to localize the trigger points within the identified band. A *jump sign* is elicited as a pain response when digital pressure is applied on the trigger point resulting in the patient wincing and suddenly moving the limb segment activated by the affected muscle group [12].

DOI 10.1007/978-1-4939-0779-3_121-1

Diagnosis

Diagnosis is predominantly based on clinical findings. There are no established diagnostic laboratory tests or examinations. According to Simon et al., MPS can be diagnosed if five major criteria and at least one minor criterion are satisfied [13].

The major criteria are (1) localized spontaneous pain, (2) spontaneous pain or altered sensation in the target area, (3) taut palpable band in an accessible muscle, (4) exquisite localized tenderness in a precise point along the taut band, and (5) reduced range of motion.

Minor criteria include (1) reproduction of spontaneously perceived pain and altered sensations by pressure on the trigger points, (2) elicitation of a local twitch response, and (3) pain relived by muscle stretching or injection of the trigger point.

Management

Medications such as ibuprofen in combination with sedatives, topical analgesics, and amitriptyline have demonstrated some beneficial effects in clinical studies. Other modalities of treatment include trigger point release, which can be achieved by muscle stretch, and trigger point injections (with anesthetic or dry needling). Trigger point injections are effective in providing prompt relief of symptoms. Injections of botulinum toxin are also used although there is no strong evidence for their clinical effectiveness. Therapeutic ultrasound and laser therapy are other emerging treatment modalities.

Complex Regional Pain Syndrome (CRPS)

Definition/Background

Complex regional pain syndrome is a disabling pain condition with sensory, motor, and autonomic manifestation. Initially termed as Sudeck's dystrophy in 1900, this was considered to be acute inflammatory bone atrophy. As growing evidence revealed an inflammatory as well as sympathetic pathogenesis, it was renamed reflex sympathetic dystrophy. Finally, in 1993, the International Association for the Study of Pain (IASP) introduced the current descriptive term CRPS. It is further subdivided into CRPS I, if there is no obvious nerve injury, or CRPS II, if associated with nerve injury [14]. The pathogenesis, while not conclusive, can be attributed to facilitated neurogenic inflammation, autonomic dysfunction, and neuroplastic changes within the CNS.

Clinical Features

Clinical features include a characteristic triad of autonomic, sensory, and motor disturbances. Distal edema is present in over 80 % of cases and this is worsened by orthostasis and physical strain. Skin temperature changes and trophic changes of the skin, hair, and nail are also noticed. In prolonged cases, atrophy of the skin and muscle is also evident. Burning or stinging pain is commonly reported and this is worsened by anxiety, temperature changes, and orthostasis at night. Glove and stocking distribution of sensory changes, mainly hyperalgesia, is also present. Motor weakness is also reported in a majority of patients.

Diagnosis

Diagnosis is made based primarily on clinical history, examination, and exclusion of other causes. There are various diagnostic criteria established such as IASP criteria, Budapest criteria, and Veldman criteria [15]. Objective testing such as thermography, Doppler, x-ray, and bone scans can be helpful in certain situations. The differential diagnoses include rheumatic disease, inflammatory conditions, compartment syndromes, and nerve injury syndromes.

DOI 10.1007/978-1-4939-0779-3_121-1

Management

Management includes both pharmacotherapeutics and nonpharmacological therapies.

Glucocorticoids especially in the initial phase of edema and hyperthermia have demonstrated positive effects. The dose recommended is prednisone 100 mg/day titrated down by 25 mg every 4 days.

Bisphosphonates were found to be effective in decreasing pain when compared with placebo in patients with bone abnormalities. The medications studied were IV pamidronate (60 mg, intravenous) and alendronate (40 mg PO daily for 8 weeks).

Ketamines intravenously in low doses have moderate evidence for effectiveness in longstanding CRPS.

Physiotherapy and occupational therapy in conjunction with a variety of interventional pain management techniques (discussed below) are described as evidence-based guidelines for management of CRPS I. Activities such as active range of motion, water-based exercises, stress loading, sensorimotor treatment, education, graded exposure to activities, and mirror box therapy have been found to be effective.

Interventional pain management approaches include stellate ganglion blockade, lumbar sympathetic blockade, spinal cord stimulation, and repetitive transcranial magnetic stimulation (rTMS).

Prognosis

Every patient should be treated early and aggressively in the hope of preventing chronicity. In a substantial number of patients, resolution occurs spontaneously, while in others, it may cause ongoing intense pain.

Neuroma

Neuroma is a benign mass that occurs secondary to nerve irritation or injury. Following a partial or complete injury, the nerve tries to establish continuity with its distal end, resulting in a proliferation of disorganized axons, myofibroblasts, endothelial cells, and Schwann cells, leading to a neuroma [16]. Neuromas can present with disabling pain or loss of motor functions. A history of sharp trauma, crush, or stretch injury is often present along with pain related to a single peripheral nerve distribution with or without accompanying numbness or diminished sensation. Tinel's sign (sensation of tingling when an injured nerve is stimulated via light percussion) indicates regeneration of axons and can be elicited from a terminal neuroma. Other diagnostic measures including anesthetic injection and imaging procedures such as ultrasound and MRI may be useful.

In the upper extremity, the most common locations for a neuroma are in the thumb (bowler's thumb). This a pathologic condition associated with bowlers because of the impingement of the bowling ball on the thumb, resulting in repeated minor trauma to the ulnar digital nerve of the thumb. In the lower extremity, Morton's neuroma is the most common type. It is a painful neuropathy resulting from compression of the plantar interdigital nerve between the metatarsal heads and is a common cause of forefoot pain.

Oral analgesics may have some efficacy in the medical management of neuropathic pain. Antidepressants, anticonvulsants, and opioids are used, but their effectiveness is not well studied [17]. When conservative methods fail, operative techniques include resection of the neuroma, use of nerve grafts to reconnect the severed proximal and distal stumps, containment of the neuroma, and translocation of the nerve. A majority of the patients respond favorably to surgery.

Dupuytren's Contracture

Dupuytren's contracture is a benign connective tissue disorder affecting the palmar fascia, which leads to progressive hand contractures resulting in restricting a person's ability to undertake daily activities. This deterioration in hand function is the main reason for seeking treatment. This is most commonly seen in older men of northern European descent (e.g., Celtic, Scandinavian) and is a disorder of autosomal

DOI 10.1007/978-1-4939-0779-3_121-1

dominant inheritance. It is commonly seen in association with diabetes, HIV, epilepsy, alcoholism, and cigarette use [18].

Clinical Features

These features include nodule formation near the MCP joint on the palm of the hand or skin pitting and thickening at that site. The advanced stage may present with cord formation, with the ring and small finger being affected first and gradually progressing to the other fingers. A positive (or failed) tabletop test has been shown to correlate with a MCP joint contracture of 40°. Here the patient is unable to lay his palm and fingers simultaneously flat on a hard surface. This is often used as a screening test for Dupuytren's contracture.

Treatment

Operative intervention remains the gold standard for treatment in cases of advanced disease with contractures. Procedures include needle aponeurotomy, open or percutaneous fasciotomy, and open fasciectomy [19]. Numerous nonoperative modalities, including splinting, physical therapy, and corticosteroid injections, have not been found to be beneficial with regard to long-term outcome.

Collagenase clostridium histolyticm is a minimally invasive, nonsurgical option that has recently been approved by the US FDA. Collagenase is injected directly into Dupuytren's cord leading to lysis of the collagen followed by joint manipulation in an attempt to rupture the cord. Both the injection and subsequent cord rupture can be safely conducted in a medical office. Long-term results and recurrence rates of this procedure are currently being studied.

Ganglion Cysts

This is the most common soft tissue swelling in the hand and wrist. These are benign cysts that are found near a joint capsule, tendon, or tendon sheath. They are more common in women and typically present between the third to sixth decades of life. They can develop suddenly or gradually and can resolve spontaneously in almost half of the cases. While they are usually painless, pain can sometimes be the presenting symptom, especially when the cyst is exerting pressure on a nerve or underlying structure. On palpation, they are typically smooth, mildly tender masses, and may be single or multilobular. Transillumination helps to differentiate between solid and cystic masses. Advanced imaging such as magnetic resonance imaging or ultrasonography is sometimes needed for diagnosis. Treatment includes reassurance, aspiration, and excision [20]. As a majority of the ganglion cysts are asymptomatic, small, and often resolve spontaneously, reassurance that these are not malignant is often sufficient. Aspiration alone is one of the simplest ways to treat ganglion cyst and can be done in the office setting. Caution needs to be exercised when aspirating volar wrist ganglion cyst due to the close proximity of the radial artery. Aspiration is associated with a high recurrence rate. Other conservative methods of management include steroid or hyaluronidase injections, sclerotherapy, and immobilization, but these are not widely adopted. Surgical excision remains the most effective treatment of symptomatic ganglion cysts with a low recurrence rate of 1–4 %.

Abnormalities of Bone

Benign Tumors

There are multiple types of benign bone tumors: bone forming, cartilage forming, and fibrous tumors. These tumors do not metastasize. Important factors in the diagnosis of a bone tumor includes patient's age and gender, the bone involved, location of the tumor on the bone, lesion margin, and periosteal reaction

DOI 10.1007/978-1-4939-0779-3_121-1

Table 2 Skeletal abnormalities by age and common presentation site

Skeletal abnormality	Age at peak incidence	Common locations
Benign tumors		
Osteochondroma	10–30	Metaphysis of long bones
Osteoma	Any	Skull
Osteoid osteoma	5–25	Long bones, spine
Chondroma	20–50	Hands, metaphysis of long bones
Giant cell tumor	20–45	Epiphysis and metaphysis of long bones
Malignant tumors		
Ewing's sarcoma	5–30	Marrow sites (vertebrae, ribs, sternum, pelvis) and proximal long bones at the diaphysis (femur, humerus)
Osteosarcoma	10–40, 60+	Proximal long bones metaphysis (humerus, femur) and pelvis
Primary chondrosarcoma	50–80	Pelvis, hips, shoulder, skull, facial bones
Chordoma	30–80	Base of skull or sacrum
Metastatic malignant tumors	40+	
Non-ossifying fibroma	10–20	80 % occur metadiaphysis of tibia and diatal femur
Paget's disease of bone	50–90	Skull, spine, pelvis, lower appendicular skeleton

(Table 2) [20]. As comprehensive inclusion of all types of tumors is beyond the scope of this chapter, some of the most common benign bone tumors are discussed here.

Osteochondroma

Osteochondroma, also known as exostosis, is a relatively common developmental lesion that forms when fragments of the epiphyseal growth plate or cartilage herniate through the periosteal covering of bones [21]. It is composed of lamellar bones covered by a cartilage cap. The cartilage cap is covered by perichondrium and usually less than 2 cm in thickness. While most of the osteochondromas occur spontaneously, cases following prolonged radiation treatments have also been described. The metaphysis of long bones are the preferred site, but it can arise in flat bones like the ilium and scapula and also in the spine, with cervical spine being the most common location. There is a male preponderance, and majority of the patients are younger than 20 years of age. Painless swelling and cosmetic deformity are the most common presenting symptoms.

Osteoma

This asymptomatic, slow growing tumor is usually an incidental finding. It is most commonly found in the skull and occasionally in the long bones. Osteomas may occur at any age and on rare instances can cause obstructive symptoms especially in the sinuses resulting in headaches and sinusitis. On imaging, they appear as a sharply defined bony surface lesion arising from the cortex [22]. Multiple osteomas are associated with Gardner syndrome and tuberous sclerosis.

Osteoid Osteoma

Osteoid osteoma is a benign lesion of the young and that is two to three times more likely to occur in males than females. It often presents as joint pain, worse at night, and may have an associated effusion. It is the most common cause of painful scoliosis in children. Symptomatic presentation may be difficult to

DOI 10.1007/978-1-4939-0779-3_121-1

distinguish from stress fractures or osteomyelitis. On plain films, cortical thinning and sclerosis are often present in the affected long bones. These lesions are often sensitive to nonsteroidal anti-inflammatory medications. More definitive treatment has been achieved with surgical excision and more recently radiofrequency ablation. Osteoid osteomas greater than 2 cm are pathologically identified as osteoblastomas [20, 22].

Chondroma

Chondromas are benign cartilaginous tumors subdivided by the area of bone affected, those in the medullary region labeled as enchondroma and those more superficial as periosteal chondromas. They are often found incidentally in asymptomatic patients between the ages of 20–50. Areas commonly involved include the hands and long bones. When patients present with pain or atypical radiographic findings, the diagnosis of low-grade chondrosarcoma must be excluded. Surgical excision is often unneeded unless patients are symptomatic. Younger patients who have several chondromas may present with bony abnormalities or pathologic fractures as part of Ollier's disease and Maffucci's syndrome. These patients are also at increased risk of developing chondrosarcomas [20, 22, 23].

Giant Cell Tumor

Giant cell tumors are a benign rare form of aggressive lesions that affect the epiphyseal long bones of adults 20–45 years old. Symptoms often present as pain, tenderness, swelling, and limitations of joint motion. Left untreated significant localized destruction and joint immobility occur. Plain films are often characterized with an enlarging radiolucent lytic lesion with minimal sclerosis. These lesions can extend into the metaphysis and surrounding soft tissues. Systemic metastasis is very rare; however, secondary lesions of the lung have been recorded. Patients treated solely with surgical excision have an 18–50 % rate of relapse, with reoccurrence within 2 years [20, 22, 24].

Malignant Tumors

As a subset, malignant skeletal tumors are uncommon. They usually occur in patients under 30 years of age, affecting bones with the highest rate of growth with the distal femur and proximal humerus most commonly affected. These lesions often have aggressive clinical patterns and may spread systemically. Patient age and tumor location often relate to the likely type of skeletal malignancy (Table 2) [25, 26]. The goal of treatment of most primary malignant bone tumors is a negative surgical margin via resection. This treatment often causes a large boney defect that requires reconstruction. Most often, however, it is the deficiencies in the soft tissue that create the major obstacles to limb salvage [25, 27].

Evaluation and diagnosis of any skeletal abnormality begins with plain radiography followed by MRI and/or CT. For lesions in the extremities, images must include the entire long bone as well as the adjacent joints. Biopsies will be required to conclusively determine diagnosis and direct subsequent therapies. Referral to the necessary specialists is therefore required for diagnosis and treatment [26].

Ewing's Sarcoma

Epidemiology Ewing's sarcoma (EWS) and osteosarcoma (OS) are the most common malignant bone tumors of childhood accounting for 6 % of pediatric malignancies. The skeletal variant of EWS is most likely to occur in younger patients and has been more commonly found in Caucasians and males [27, 28].

Clinical Features EWS may present with nonspecific symptoms such as pain, swelling, and palpable mass. In the case of advanced disease and marrow involvement, systemic symptoms such as fever, anemia, and weight loss may occur. This diagnosis may be mistaken for osteomyelitis especially in the

DOI 10.1007/978-1-4939-0779-3_121-1

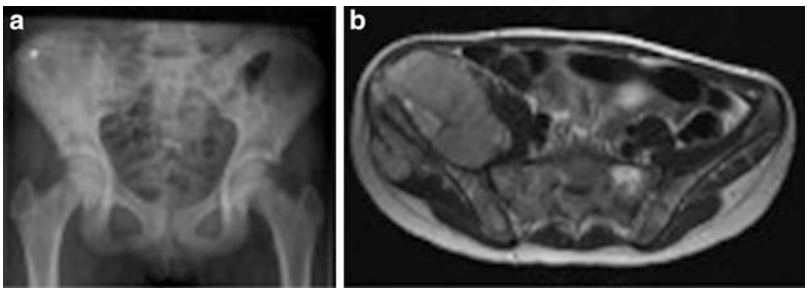

Fig. 3 Ewing's sarcoma. (**a**) AP radiograph of an 11-year-old child shows a destructive lesion of the right iliac bone (*asterisk*) with a permeative and moth-eaten appearance with no obvious soft tissue mass. (**b**) Axial T2-weighted MRI image shows that the radiographic abnormality was associated with a heterogeneous signal intensity large soft tissue mass, which extended anterior and posterior to the right iliac bone. Extensive metastatic disease was also seen within the sacrum and the spine (Reprinted from Clinical Radiology, 68/11, N. Jain, M. Sah, J. Chakraverty, A. Evans, S. Kamath, Radiological approach to a child with hip pain, 1167–1178, 2013, with permission from Elsevier)

setting of systemic symptoms [26]. Appearance of the lesion on x-ray is often described as "moth-eaten" with an "onion peel" appearance of the periosteum (Fig. 3).

Treatment/Prognosis Care often begins with chemotherapy and wide resection when possible. The presentation of tumors in the axial skeleton often affects the ability to achieve wide margins without substantial morbidity. In these cases, adjuvant radiotherapy may be used as EWS is highly sensitive to radiation with a 5-year localized control rate of 53–86 % when radiotherapy is used without surgical intervention [26, 29].

Osteosarcoma

Epidemiology Osteosarcoma affects all age groups and is the most common primary bone tumor [25, 26]. OS and EWS both reach their highest incidence rate during adolescence; however, OS is rarely seen in the very young and has been noted to have a secondary increased incidence in patients 60 years and older [26, 30]. OS is most often seen in males, young blacks, and older white patients. Development of a secondary OS has been primarily linked to prior radiation exposure and/or chemotherapy with anthracycline [26, 27, 31]. OS has also been linked to several cancer-related syndromes such as Werner syndrome, Li-Fraumeni syndrome, and hereditary retinoblastoma [26].

Clinical Features OS often presents with localized pain and swelling, which may be cyclical in nature, and may be accompanied by a tender palpable mass. Systemic complaints are not common and the nonspecific presentation may be mistaken for activity-induced injuries [26]. Laboratory evaluation may reveal elevated alkaline phosphatase, erythrocyte sedimentation rate, and lactate dehydrogenase [32, 33]. Radiographic evaluation of the affected site may present with a mixture of radiodense and lucent areas and a lifting of the cortex forming Codman's triangle (Fig. 4).

Treatment/Prognosis The outcomes of osteosarcoma are most often dependent on the location and grade of the disease, with lesions in the axial skeleton and higher levels of lactate dehydrogenase often indicating worse outcomes. Currently treatment consists of resection and chemotherapy with radiation therapy recommended as an adjuvant treatment [26, 33]. Factors affecting the presence of metastases at diagnosis include older age, involvement of the axial skeleton, greater tumor size, and lower

DOI 10.1007/978-1-4939-0779-3_121-1

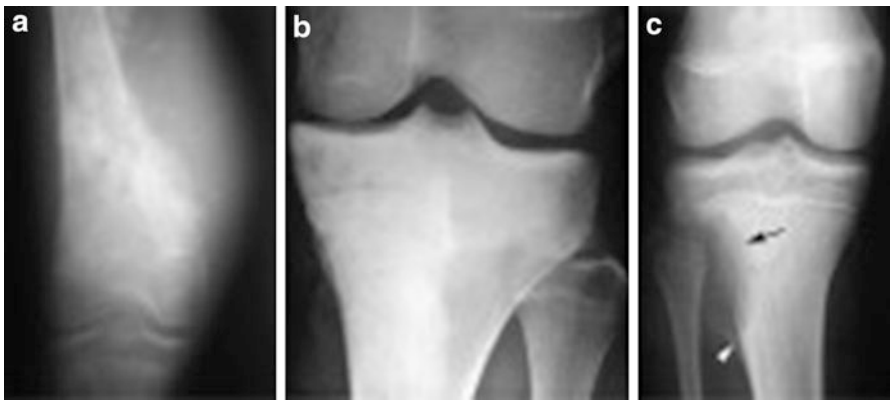

Fig. 4 Osteosarcoma. The varied radiographic appearances of conventional central OS. (**a**) AP radiograph of the distal femur showing a permeative, lytic, and sclerotic lesion with a large soft tissue mass containing immature bone matrix. (**b**) AP radiograph of the proximal tibia showing a predominantly osteoblastic OS, appearing as an area of poorly defined medullary sclerosis with subtle periosteal reaction. (**c**) AP radiograph of the proximal tibia showing a lytic OS (*black arrow*) with a Codman's triangle (*white arrowhead*) demarcating the distal extent of extraosseous tumor (Reprinted from Clinical Radiology, 62/4, Suresh S, Saifuddin A, Radiological appearances of appendicular osteosarcoma: a comprehensive pictorial review, 314–23, 2007, with permission from Elsevier)

socioeconomic status [34]. The 5-year survival rates for osteosarcoma varies drastically by age at presentation with elderly adults having worse prognosis of 24 % versus 62 % [30].

Primary Chondrosarcoma

Chondrosarcomas are rare, slow growing tumors that originate from cartilaginous cells. They occur most commonly between the ages of 20–60. Due to slow progression, prognosis is usually favorable and patients often present with a mass that has been present for years [35]. Patients may complain of pain and tenderness at the site without a palpable mass. Plain films often reveal a defined lytic lesion with associated endosteal scalloping [36]. Treatment of low-grade (Grade-1) cartilaginous lesions includes wide resection, intralesional resection, or curettage and cryosurgery. In patients with more advanced disease, the negative margin resection ± radiation is the treatment of choice. Histopathological stage at the time of diagnosis is the best indicator of outcome in patients with chondrosarcoma, with higher stage linked to worse prognosis. Tumor site has also been associated with worse outcome in patients with pelvic lesions as opposed to those with disease in the extremities [25, 27].

Chordoma

Chordomas are rare tumors affecting the axial skeleton and arise from residuals of the notochord [37]. They are most often located in the sacrum and followed by the base of the skull. Clinical presentation is usually nonspecific and is often diagnosed as pain from disk or other nonspecific musculoskeletal pathologies [38]. The course is often indolent with subsequent metastasis in late disease. Surgery is often the treatment of choice with a high rate of reoccurrence at the treatment site. Recent research has supported the use of high-dose radiation therapy especially for lesions at the base of the skull; however, this method of treatment continues to be controversial [25, 27, 37].

Metastatic Malignant Tumors

Metastasis to the axial skeleton is common in breast, prostate, thyroid, kidney, and lung cancers. Patients may present with pain, hypercalcemia, pathologic fractures, and spinal compression syndromes. Plain radiographs may show lytic or sclerotic lesions. Bone scintigraphy is considered the best method for the

DOI 10.1007/978-1-4939-0779-3_121-1

detection and monitoring of skeletal metastasis. Conclusive determination of tumor origin is determined via biopsy. Treatment of metastatic disease is often specific to the primary disease [39, 40].

Non-ossifying Fibroma

Non-ossifying fibroma (NF), also known as a fibrous cortical defect, is a benign lesion most common in the metaphyseal long bones of children and adolescents. They are often found incidentally as up to one third of healthy children have one or more of these cortical defects. Most NFs are asymptomatic; however, large lesions may cause pain and pathologic fractures. On plain radiograph, the lesion appears ovoid and multiloculated with thinning and expansion of the cortex. Treatment usually consists of observation, especially of asymptomatic lesions, as most resolve without intervention [41].

Paget's Disease of Bone

Epidemiology Paget's disease of bone, also known as osteitis deformans, is a disease of the elderly defined by an excessive breakdown and remodeling of the osseous matrix leading to progressive bony abnormalities. Genetic components and possible links to the paramyxoviruses, canine distemper virus, and respiratory syncytial virus have been identified [42].

Clinical Features Many patients are asymptomatic; however, those with progressive disease may complain of pain. The sequelae of Paget's disease are related to tumor location causing bowing bone deformities, pathologic fractures, osteoarthritis, deafness, headaches, neurologic deficits, and the development of malignant sarcomas. Laboratory analysis reveals elevated levels of alkaline phosphatase, with normal levels of calcium and phosphate. Bone scintigraphy is performed to determine the extent of the disease. On plain radiographs, lytic lesions are often seen in the early phase of the disease (Fig. 5) [42].

Treatment/Prognosis Symptomatic treatment often involves the use of nonsteroidal anti-inflammatory drugs, analgesics, and calcitonin. More targeted therapies may include use of highly potent bisphosphonate drugs shown to improve the extent of osteolytic lesions [42].

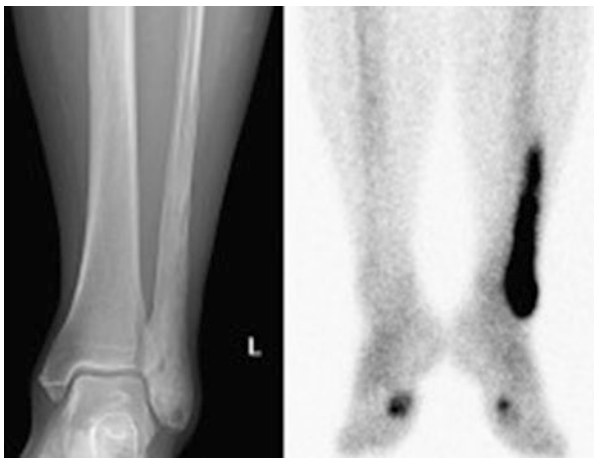

Fig. 5 Paget's Disease. Significant expansion and sclerosis of the distal left fibula with obliteration of the medullary cavity (*left*) is evident on this anteroposterior radiograph. A corresponding solitary region of homogeneous markedly increased uptake is seen on isotope bone scintigraphy (*right*) (Reprinted from Clinical Radiology, 66/7, Cortis K, Micallef K, Mizzi A, Imaging Paget's disease of bone –from head to toe, 662–72, 2011, with permission from Elsevier)

Common Dermatoses

Alex Verdieck Devlaeminck[a]* and Paul Paulman[b]
[a]Oregon Health and Science University, Portland, OR, USA
[b]Department of Family Medicine, University of Nebraska College of Medicine, Omaha, NE, USA

General Principles

Dermatologic conditions are very common and will affect most individuals at some point in their lifetime, accounting for many family physician office visits. Acute conditions may require treatment or can be self-limited. Others are chronic needing daily treatment or recurring in episodes. Some conditions may require assistance of a dermatologist for immunosuppressive treatment to prevent complications such as conditions seen in patients with psoriatic arthritis.

Patients presenting history, age, length of time of condition, previous episodes, and family history can be useful in diagnosing recurring immune conditions. Records of previous treatments attempted by the patient whether they were helpful or not are also useful in managing skin conditions. Chronic skin conditions can be disruptive to the well-being such as the sleep problems associated with itching all night in atopic dermatitis. Disfiguring conditions, extensive psoriasis, and hidradenitis can result in isolation and depression, and the physician should be mindful of these comorbidities.

Physical Exam

Elements of the physical exam should include a good description of the lesion located in the epidermis or dermis, parts of the body affected (i.e., only sun-exposed areas or areas reachable by scratching), and areas of perspiration. Ideally, getting a good idea of the type of lesion, scale or plaque, bulla, vesicle, papules, and nodules, can help determine the diagnosis. Wood's lamp can assist in the diagnosis of fungal elements.

Laboratory

KOH prep can be helpful in either confirming the presence of fungal elements or eliminating the possibility of a tinea infection. Blood tests can assist in cases where the skin condition may be reflective of a rheumatologic illness or infection. The physician should consider ordering labs such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), rapid plasma reagin (RPR) and B12, and vitamin C for possible nutritional deficiencies, inflammatory conditions, or syphilis. Biopsy can be used to confirm a diagnosis when attempted treatment has not been fruitful or to rule out dysplastic lesions.

Chronic Recurring Dermatitis

Atopic Dermatitis aka Eczema

General Principles

Definition Atopic dermatitis (AD) is a chronic skin condition characterized by recurrent pruritus and inflammation. It is now known to be due to a mutation on the FLG gene [1], which encodes for pro-filaggrin, a precursor of filaggrin, the substance that forms the natural skin barrier of the epidermis.

*Email: verdieck@ohsu.edu

DOI 10.1007/978-1-4939-0779-3_122-1

This results in the dysfunction of epidermal hydration and immune reactions. Additionally, patients with AD have exaggerated inflammatory responses to minor skin irritations and skin infections.

Epidemiology AD may affect as much as one in four children and 2–3 % of adults [1]. It is more common in families with a history of atopy, African-American race, and those living in urban areas. Diet modifications do not appear to decrease the risk of developing AD; cat ownership appears to increase the risk although dog ownership is protective.

Classification No specific classification exists, but there are several variants.

Nummular eczema – lesions in papules or around plaques.

Dyshidrotic eczema (pompholyx) – a variant of hand eczema with scaling of hands and small vesicles between fingers [2].

Approach the Patient

It is important to consider how symptoms are affecting the patient. Over 50 % of children have severe itching that is correlated with decreased quality-of-life ratings [1]. Poor sleep impacts on daily activity, potentially school progress, and can affect the family. In addition, pediatric compliance can be variable as daily treatments can be tedious and some parents may just assume their child is doing it. When performing follow-up, care should be taken to determine if the types of medications are tolerable to the patient, for example, some ointments may be so uncomfortable/greasy that these pts may do better with creams. Cost consideration/insurance coverage is important in selecting treatment, as some of the newer agents are expensive.

Diagnosis

Criteria required for a diagnosis include pruritus and chronic or recurrent eczematous skin findings [1].

History Patients will complain of recurrent itchy dry patches, which tend to improve with treatment and then relapse. Pruritus can be severe, disrupting sleep and the quality of life, and worsen during seasons with low humidity. Supporting history includes early age of onset, atopy in patient or family members, immunoglobulin E reactivity, and dry skin. There are several associated conditions the family practitioner may also be treating such as rhinitis, asthma, food allergies, and depression. Family history often includes allergies, allergic rhinitis, and asthma.

Physical Exam The skin can have different appearances, but typically patients will have dry skin with patches of thickened skin with erythema and edema. Vesicles and papules may be present. Excoriations can lead to lichenification. Secondary infections can appear as oozing over crusty skin patches. There are findings that are more common in AD patients: keratosis pilaris, pityriasis alba, cheilitis, dry skin, follicular enlargement, and hyperlinearity. AD typically is located on the face in infants, extensor areas in children, and flexural involvement in both adults and kids. Groin and axillary regions are usually spared.

Laboratory Tests Laboratory tests are not typically indicated; however, a KOH test might be helpful in ruling out fungal infection. Total or allergen-specific serum IGE may be elevated but is not present in all patients or routinely tested.

Special Testing Punch biopsy is rarely needed but may be used when the diagnosis is uncertain.

DOI 10.1007/978-1-4939-0779-3_122-1

Differential Diagnosis Seborrheic dermatitis (especially in infants), scabies, contact dermatitis, ichthyosis, cutaneous T-cell lymphoma, psoriasis, neurodermatitis, tinea.

Treatment

Behavioral The mainstay of treatment includes daily moisturizers and avoidance of itching. Moisturizers should be applied soon after bathing. Emollients are agents that lubricate and occlude the skin to form a barrier layer; liberal and frequent reapplication should be done to avoid dry skin. Patients should be given a choice in the type of vehicle of moisturizer to improve compliance. Studies have not consistently shown any clear benefit related to frequency or duration of bathing, but it is recommended that once-daily bathing of 5 min or less can remove crusts and should be followed immediately by application of moisturizer [3].

Patients should be instructed to avoid known allergens. Cleansers should be limited to neutral or low pH types, hypoallergenic, and fragrance free. Regular soaps are not recommended.

Medications Treatments typically consist of topical steroid creams and/or calcineurin inhibitors.

Topical steroids (TSs) decrease pruritus and acute and chronic inflammation [3]. Low-potency TS or calcineurin inhibitors (CI) are agents used over thin-skinned sites such as the face, neck, and other skinfolds (see Table 1). Moderate- to high-potency steroids are used over moderate and thick skin. TS should be applied daily during outbreaks or when inflammation is severe for up to several weeks. When outbreaks resolve, TS should be used once to twice weekly for maintenance over sites of recurrent inflammation [3]. Twice-daily application is prescribed most often, but once-daily application of potent steroids is also effective. Systemic absorption is only seen when large amounts of very high-potency steroids are used for extended periods of times or inappropriately in young children. Side effects can include telangiectasias, acneiform eruptions, and skin atrophy. Many of these side effects are reversible [4]. Undertreatment can occur as physicians and patients may be worried about side effects of steroids. Patients may be wary of using steroids due to the knowledge of side effects; they should be reassured that when used correctly, they are effective and unlikely to cause problems. Topical calcineurin inhibitors (CI) decrease inflammation by altering the abnormal cellular response. They are used for moderate to severe disease in areas where high-potency steroids would be contraindicated such as the face and

Table 1 Commonly used steroids

Group I ultrahigh strength – superpotent		
Vehicle	Generic	Brand
C, O, G, So, F, Sh	Clobetasol propionate 0.05 %	Temovate, Cormax
G, L, O	Betamethasone dipropionate 0.05 %	Diprolene
C	Fluocinonide 0.1 %	Vanos
T	Flurandrenolide 4 mcg/m2	Cordran tape
C, O	Halobetasol propionate 0.05 %	Ultravate
O	Diflorasone diacetate 0.5 %	Psorcon
Group II high strength – potent		
Vehicle	Generic	Brand
O	Amcinonide 0.1 %	Cyclocort
L, O	Betamethasone dipropionate 0.05 %	Diprosone
C, O	Desoximetasone 0.25 %	Topicort
G	Desoximetasone 0.05 %	Topicort
C, G, O	Fluocinonide 0.05 %	Lidex
C, O, So	Halcinonide 0.1 %	Halog

C cream, *O* ointment, *G* gel, *L* lotion, *Sh* shampoo, *F* foam, *So* solution, *Sp* spray, *T* tape

skinfolds. Tacrolimus (Protopic) 0.03 % ointment bid is approved for age 2 and older, 0.03 % and 0.1 % for age 15 and older. Pimecrolimus (Elidel) 1 % cream is approved for mild to moderate AD; it is applied twice daily for outbreaks or two to three times weekly to sites of recurrent disease. Side effects include burning. There is a black box warning regarding rare cases of malignancy that have been reported, but recent surveillance data of long-term users has not supported this finding [3]. Infected areas may require treatment with antibiotics such as oral cephalexin (Keflex) and topical mupirocin (Bactroban) and/or the use of diluted bleach baths to help decrease colonization of *Staph aureus*.

Referrals Referral to dermatology may be necessary for severe cases.

Patient Education It should revolve around having patients understand that AD is a relapsing condition that will likely require chronic therapy ranging from moisturizers to increases in intensity of treatment during exacerbations and potentially physician visits for complications. Risks of steroids should be

DOI 10.1007/978-1-4939-0779-3_122-1

discussed with patients, and they should be reassured that research has shown that topical steroid is safe when used appropriately.

Seborrheic Dermatitis (SD)

General Principles

Definition SD is a recurrent inflammatory condition characterized by redness and scaling of the skin that surrounds sebaceous glands. It is thought to be caused by colonization of the *Pityrosporum* (*Malassezia*) yeast [2, 5, 6], which thrives in the setting of an altered composition of sebaceous gland secretions. The inflammation then occurs due to an altered immune response.

Epidemiology SD is more common in males and may start at puberty but more commonly after age 20. There is a variant that occurs in infancy, and SD is more common in patients with HIV and Parkinson's disease [6].

Classification Infantile SD is a self-limited variant that resolves by 3–4 months of age. Severe cases may be due to other underlying medical conditions.

Diagnosis

History Patients will typically report flaking and scaling over a time often starting around puberty. The symptoms may improve and worsen due to stress, fatigue, or new medications. Most patients will have mild itching especially in the scalp.

Physical Examination The physician will see greasy scaling plaques or macules over red inflamed skin. Crusting is common and may be white yellow to brown, thin to very thick. The scaling will appear oily as affected areas have a high concentration of sebaceous glands. Common sites are the face typically eyebrows, eyelashes, nasolabial fold, anterior hairline, posterior ears, glabella, and beard. Groin and axilla may be affected.

Laboratory and Imaging Testing is not routinely needed, but fungal cultures may be helpful in resistant cases.

Special Testing Biopsy may be done when the diagnosis is uncertain.

Differential Diagnosis Psoriasis, atopic dermatitis, rosacea, pityriasis versicolor, tinea, contact dermatitis, lupus.

Treatments

Behavioral Thick scales (such as in infantile SD) may be loosened by application of oil to loosen the crust then shampoo to rinse off. In adults, lid and facial hygiene should be performed with antidandruff shampoos.

Medications Medications for SD include antifungals, steroid agents, and keratolytic agents [6].

Face: ketoconazole 2 % cream or foam bid × 4 weeks, ciclopirox (Loprox) 1 % cream, metronidazole (Metrogel) 0.75 % gel. Low-potency topical steroids (Table 1) are used to decrease inflammation: Hydrocortisone 1 % cream/lotion, desonide (DesOwen) lotion twice daily for several days, and calcineurin inhibitors such as tacrolimus 0.1 % ointment and pimecrolimus 1 % cream bid × 8 weeks also decrease inflammation.

DOI 10.1007/978-1-4939-0779-3_122-1

Scalp (antifungal): ketoconazole 2 % shampoo (1 % is over the counter (OTC)), selenium sulfide shampoo 2.5 % (1 % OTC), ciclopirox 1 % shampoo.

Topical steroids: clobetasol 0.05 % shampoo/foam twice weekly for 1 month, fluocinonide (Derma-Smoothe) 0.05 % solution, desonide (DesOwen) 0.05 % lotion.

Oral antifungals may be needed in resistant cases: itraconazole 200 mg daily, ketoconazole 200 mg daily, or fluconazole 150 mg daily for 1–2 weeks.

Keratolytics: Lipohydroxy acid and 1 % salicylic acid shampoos have been effective.

Tea tree oil has also been shown to be more effective than placebo in studies [3].

Referrals Consultation with dermatology may be needed in resistant cases, which are more common with coexisting medical conditions such as HIV and neurologic disease.

Counseling Patients should be warned of the need to contact their provider if infectious symptoms occur.

Patient Education Physicians must explain to patients that SD is a chronic recurring condition and maintenance is often necessary with increases in frequency or strength of treatment when exacerbations occur. Treatment failures are often due to short length and insufficient frequency of treatment.

Papulosquamous Disease

Psoriasis

General Principles

Definition Psoriasis (PS) is an immune-mediated inflammatory genetic disease of dysregulated inflammation. Susceptibility genes have been mapped on several different chromosomes [7]. The skin condition is variable in severity. In addition, psoriasis may have systemic manifestations with the possibility for destructive seronegative arthritis that is independent of skin disease severity. Arthritis usually develops 12 years after the skin manifestations and affects up to 60 % of psoriasis sufferers [7]. Nail disease affects 50 % of psoriasis sufferers and is difficult to treat. Use of biologic and immunosuppressive agents has been a great advancement in the treatment and prevention of complications of psoriasis.

Psoriasis has been associated with other autoimmune conditions such as Crohn's disease and ulcerative colitis. Recent research has found associations with metabolic syndrome and cardiovascular disease. Common comorbidities are obesity, diabetes, coronary artery disease, hypertension, and an atherogenic lipoprotein profile [7].

Epidemiology PS affects 2 % of the population and is more common in patients that are overweight [7]. Genetic and environmental factors influence its development. The prevalence is increasing likely due to the increasing incidence of obesity. The age of onset is usually between 15 and 30 years of age, and the clinical course can be varied. There is another peak of diagnosis in the 55–60 age range.

Classification **Plaque psoriasis** is the most common form of PS and can vary from several hidden lesions to numerous plaques that may be difficult to hide and can lead to social isolation [2, 5, 7]. Plaques are typically one to several centimeters in size, round or oval shaped with a scale upon a red base. They most commonly occur on the extensor surfaces of arms and legs and can affect the buttocks and trunk.

Erythroderma is widespread erythema and is associated with systemic symptoms such as fever, chills, potentially a more severe hypothermia, and dehydration.

DOI 10.1007/978-1-4939-0779-3_122-1

Pustular psoriasis is a variation with pustular psoriatic lesions containing collections of neutrophils. There's also a localized variant with pustules confined to the palms and soles.

Guttate psoriasis is subcentimeter papules on the trunk or proximal extremities; it typically affects patients under 30 and often occurs after an upper respiratory strep infection.

Inverse psoriasis occurs on flexural and skinfold areas.

Diagnosis

History Patients will typically report seeing areas of skin that appear inflamed and scaly on the scalp, elbow, or knees and do not resolve with time. Plaques and pustules may be painful. Some patients may complain of joint pain from associated arthritis. Lymphoma and melanoma have an increased prevalence as well as squamous cell carcinoma with patients that have extended UV treatment [7]. Depression and suicidal ideation are common among psoriasis sufferers. Psoriasis is increased among those who abuse alcohol, but it is unknown if this is a cause or an effect.

Physical Exam Classic psoriasis consists of 1–6 cm round or oval plaques of silvery scaling skin on a red base often over extensor surfaces. The Auspitz sign is pinpoint bleeding which occurs after peeling back the scale. Guttate psoriasis presents with very small plaques 1–10 mm in diameter. Pustular psoriasis will present with pustules over the body or palms and soles. Erythrodermic psoriasis presents with generalized erythema over the entire body; scaling may or may not be present. Nail disease can include pitting, onycholysis, and subungual hyperkeratosis. The majority of patients with psoriasis will have some nail involvement during their lifetime more commonly in the fingers.

Lab and Imaging Studies do not add to diagnosis or prognosis.

Special Testing Punch biopsy can verify the diagnosis if it is uncertain.

Differential Diagnosis Atopic dermatitis, lichen planus, contact dermatitis, T-cell lymphoma, pityriasis rosea, scalp seborrheic dermatitis, tinea.

Treatment

Medications Limited disease (less than 5 % of the skin) can generally be treated with topical medications [8]. Topical steroids (TSs) can be quite effective when tailored toward the patient including thought to vehicle delivery depending on the body part affected and patient preference. Low-potency steroids should be reserved for areas with thin skin such as the face and intertriginous areas. Mid- or high-potency steroids are the typical choice for initial therapy, and underdosing with a lower strength is more likely to lead to treatment failure. These treatments should be limited to 4 weeks of use with reduction in frequency as response occurs. Calcipotriene 0.005 % (Dovonex) [8], a vitamin D analog, works by inhibiting keratinocyte proliferation; it is available in cream and lotions and in combination with steroids. The most common side effect is local irritation and dryness, and its use is inactivated by UVA light. Calcitriol and tacalcitol are newer formulations that will likely be available in the United States soon. Combination treatment with calcipotriene and steroid ointment can also be helpful.

Topical calcineurin inhibitors, tacrolimus and pimecrolimus, alter the inflammatory cascade [8] and can be useful especially for treatment in thin-skinned areas and when used under occlusion. Tazarotene (Tazorac) 0.1 % qhs can also be helpful but can be limited by local irritation.

Topical coal tar also affects keratinocyte proliferation [8] and is commonly prescribed in other countries; however, its use is not well tolerated due to the odor and potential staining of clothes.

DOI 10.1007/978-1-4939-0779-3_122-1

Extensive disease affecting greater than 5 % of the skin typically requires a combination of topical therapy, light therapy, and systemic therapy [8].

Systemic therapy can prevent or halt the progression of complications such as psoriatic arthritis. Acitretin (Soriatane) and isotretinoin are oral retinoids that are effective, but both are teratogenic. Immunosuppressive agents such as methotrexate and cyclosporin (CyA) have been useful. Biologic agents are FDA approved for psoriasis; there are multiple agents that are currently in use and many in the pipeline. Prescribers must be familiar with side effects of each medication as they work through immunosuppression. The physician should understand pretreatment screening tests, vaccinations needed for patients undergoing immunosuppressive treatment, pregnancy prevention, and lab surveillance. Discussion of biologics is beyond the scope of this chapter and rapidly changing.

Phototherapy with narrowband UVB can be effective but requires treatment several times a week [8]. Psoriatic ultraviolet A (PUVA) is very effective and can lead to long-term remission in some people. However, this may be associated with photoaging and potential increased risk of skin cancer.

Referral Dermatology consultation is highly recommended in psoriasis that is extensive (>5 % of skin) or has been difficult to treat. The physician should keep in mind that complications of psoriasis are independent of skin disease severity.

Counseling The physician who prescribes systemic therapy should warn the patient of increased risk of infection if immunosuppressive therapy is used.

Patient Education The physician should impress upon the patient that they have a chronic disease that will require maintenance therapy. Patients should be screened for social complications such as isolation and depression.

Acne

General Principles

Definition Acne is a recurrent inflammatory condition that often starts in preadolescence or adolescence. It is typically more severe in adolescents but can continue on into adulthood. Acne is thought to be a combination of variations in skin oiliness, hormonal changes, increased testosterone levels, and bacterial colonization [9]. Although diet is often blamed, it has not been shown to be a factor in the severity of the disease [10].

Epidemiology Acne occurs in all ages but is much more common in adolescents. Most people will have acne at some point in their lifetimes. It occurs in all races.

Classification Acne can be classified according to age or predominant skin findings [10].

Preadolescent acne occurs between the ages of 7 and 12 generally preceding puberty and most commonly occurs in the forehead and midface areas.

Adolescent acne occurs between the ages of 12 and 19 and can vary in intensity and area affected. This is usually the time of the most severe acne.

Adult acne occurs at any age; it is usually milder and distinctly different from rosacea. Women may experience varying acnes throughout their menstrual cycle which is often referred to as hormonal.

Lesion classifications include **comedonal** with closed comedones (whitehead) or open comedones (blackheads).

DOI 10.1007/978-1-4939-0779-3_122-1

Mixed comedonal/inflammatory will have a combination of each.

Cystic nodular acne consists of deep painful cyst that may lead to scarring.

Acne fulminans is a rare condition with sudden onset of severe crusting acne and systemic illness [2] (Photo 1).

Approach to the Patient

Diagnosis and treatment will often include counseling the patient and parents. Treatment may be a combination of parental assistance and adolescents independently being responsible (or irresponsible) for their own treatment. Assessments of treatment failures should include these realities.

Diagnosis

History Most patients will come to the physician after having acne for some time. History should include type of acne lesion they have seen, OTC product use, soap use, hygiene habits, and which areas have been affected. Family history of scarring acne may be a clue to the potential severity and need for close follow-up.

Physical Exam Inspection of the skin may show closed comedones, open comedones, cysts, and inflammation. Physical exam should include examination of the chest and back.

Differential Diagnosis Rosacea, folliculitis.

Treatment

Behavioral Patients should be instructed to wash their face twice daily and not to use very astringent products.

Medications Treatment choices are aimed at the type of acne and should include a stepwise approach starting with topical antibiotics such as benzoyl peroxide, adding a topical tretinoin or considering change of topical therapy, then adding oral antibiotics, and then Accutane.

Photo 1 Closed comedonal acne in a preadolescent

DOI 10.1007/978-1-4939-0779-3_122-1

Table 2 Adolescent acne treatment

Severity	Initial	Inadequate response
Mild	BP or TR or Combo Tx, BP + TAbx or TR + TAbx + BP	Add BP or retinoid or increase TR strength
Moderate (comedonal/mixed/inflammatory)	TR + BP or TP + BP + oral Abx	Increase TR strength/type or add/change OAbx or OCP^{female}
Severe (inflammatory/nodular)	Oral Abx + topical retinoid + topical Ab	Change OAbx or isotretinoin or OCP^{female}

See Refs. [2, 5, 9, 10]
TR topical retinoids: tretinoin, adapalene, tazarotene
TAbx topical antibiotics
BP benzoyl peroxide, clindamycin, erythromycin, sulfacetamide
OCP oral contraceptives
OAbx doxycycline, minocycline, tetracycline

Topical antibiotics (TAbx) work by decreasing the colonization of *Propionibacterium* acnes [10], benzoyl peroxide (BP) 2.5–10 % (cream, gel OTC) with stronger concentrations being more irritating and sodium sulfacetamide (Sulfacet-R). Clindamycin (solution, gel, lotion) and erythromycin (solution, gel) should not be used alone as they can create bacterial resistance. Combination of topical antibiotics containing BP may cause less resistance.

Topical retinoids (TR) reduce follicle obstruction [10] and can cause irritation so dosing strength and vehicle should be gradually increased: tretinoin 0.025 %, 0.05 % (Retin A, gel, cream), adapalene 0.1 %, 0.3 % qhs (Differin, gel, cream).

Tazarotene 1 % cream qhs (Tazorac) – stronger, more irritating.

Comedolytic agents: salicylic acid (Clearasil, Clean and Clear OTC), azelaic acid (Azelex) 20 % cream 15 % gel (comedolytic/antibacterial).

Systemic antibiotics are indicated in resistant cases [9] but have been overused in the past without trying topical therapies initially (doxycycline 100 mg daily/bid, minocycline (Minocin) 100 mg daily, tetracycline 500 mg daily/bid, erythromycin 250–500 mg bid, trimethoprim/sulfamethoxazole bid); bacterial resistance is common with oral antibiotic use, and most cannot be used in pregnancy.

Oral retinoids: Isotretinoin (Accutane) 5–2.0 mg/kg/day [9, 10] is very effective. Isotretinoin (Accutane) can be a helpful addition to the acne arsenal in resistant cases or severe nodular acne; however, it is vital that providers familiarize themselves with the standard of care when consenting, monitoring, and prescribing this medication. Common side effects include severe dry skin, dry mucous membranes and eyes, and headaches. Complications are depression, liver and cholesterol abnormalities, and severe birth defects if a fetus is exposed. Currently, prescribing isotretinoin to females of childbearing age requires a physician to register themselves and the patient in the iPLEDGE system [11]. iPLEDGE is a manufacturer-supported FDA-approved risk management system that strives to prevent fetal exposure to isotretinoin in female patients [12]. It is vitally important that one is familiar with lab surveillance: lipids, LFTs, CBC, and birth control use.

Oral contraceptives: Norgestimate/ethinyl estradiol (Ortho Tri-Cyclen) and norethindrone acetate/ethinyl estradiol (Estrostep) have been FDA approved, but almost any OCP will work.

Antiandrogens: Spironolactone 50–200 mg/day antiandrogen is also used.

Intralesional Steroids Triamcinolone 10 mg/ml (Kenalog) 0.1 ml injected directly into nodule can reduce the size of the nodule.

Referral Referral to dermatology should be considered in treatment failures and in patients with cystic scarring acne, as they may be good candidates for Accutane. Endocrinology referral may be

DOI 10.1007/978-1-4939-0779-3_122-1

indicated in cases where endocrine dysfunction is suspected, very young age, or unexpected increase in severity.

Counseling Patients taking acne medications that are teratogenic should be counseled on proper birth control.

Patient education Acne sufferers should be instructed in proper hygiene and need for daily treatments to ensure response. Clinicians should monitor mood in teenagers and people with severe acne which is associated with depression.

Rosacea

General Principles

Definition Rosacea is a chronic inflammatory condition of the oil glands of the face thought to be due to bacterial colonization and skin susceptibility [2]. It is characterized by flushing of the skin due to capillary reactivity. Rosacea causes chronic redness of the face, adult acne-like lesions, and sensitivity to temperature change. Ocular involvement can occur.

Epidemiology It is more common in Caucasians of Irish, English, or German descent and more prevalent in females [13]. The symptoms typically start after age 30.

Classification **Erythematotelangiectatic** Classic type with redness and telangiectasias.

Papulopustular Pustules are predominant.

Rhinophymatous More common in males; the nose and face develop thickened skin.

Ocular rosacea A variant with eye redness and sensitivity.

Diagnosis

History Patient will typically complain of gradual onset of sensitive skin characterized by flushing and stinging. They may report redness and worsening acne that does not resolve over time. Patients with long-standing rosacea may have noticed a thickening and distortion of the skin.

Ocular rosacea typically causes a feeling of foreign body sensation and photophobia, and some patients have recurrent hordeolum.

Physical Examination The most common finding is general redness over the cheeks, nose, forehead, and chin. Lesions can include papules and pustules but are not comedonal. Telangiectasias can be seen on close inspection. Phymatous rosacea will have thickened skin, enlarged pores, and telangiectasias. Ocular findings can include eyelid inflammation, conjunctivitis, and telangiectasias on the eyelids. Corneal ulcers can occur in severe cases.

Differential Diagnosis Acne, systemic lupus erythematosus (SLE), polymyositis, sarcoidosis, photodermatitis.

Ocular: bacterial conjunctivitis.

Treatment

Behavioral Treatments include avoidance of triggers such as alcohol, spicy food, or hot beverages. Exposure to the sun or extreme temperature changes can worsen symptoms. Patients should avoid astringents or substances that contain alcohol, menthol, peppermint, witch hazel, and eucalyptus. Cleansers should be fragrance free with a neutral pH. Patients should be urged to use sunscreen and cover the skin. Moisturizers help to restore the normal skin barrier.

DOI 10.1007/978-1-4939-0779-3_122-1

Medications Topical therapies [5, 13] include metronidazole (Metrogel, Noritate) 0.75–1 % daily and sulfacetamide with sulfur (Sulfacet-R) once daily.

Azelaic acid 1 % (Azelex) is used for papules, pustules, erythema, and nodules.

Oral tetracyclines are helpful for controlling inflammation in more severe cases: doxycycline 100 mg bid, minocycline 100 mg bid, and tetracycline 500 mg bid. They may be tapered after 1 month of treatment.

Isotretinoin (Accutane) may be effective.

Brimonidine tartrate (Mirvaso) 0.33 % topical gel [14] is a selective alpha-2 agonist aimed at decreasing erythema that works by decreasing blood vessel dilation.

Ocular rosacea is primarily treated with oral antibiotics, eyelid hygiene, and the use of metronidazole gel.

Lasers are effective for removing vascular telangiectasias.

Rhinophyma can be treated with a CO_2 laser or dermabrasion.

Referrals Dermatology consultation is recommended for patients that do not respond to therapy or have more severe cases or those requiring treatment with laser. Ophthalmology referral may be useful to confirm the diagnosis and necessary for proper treatment of ocular rosacea.

Patient Education Patients should be instructed about avoidance of triggers such as astringent soaps and fragrances.

Hidradenitis Suppurativa (HS) aka Acne Inversa

General Principles

Definition Hidradenitis is a chronic condition characterized by recurrent painful cysts in the armpit and groin areas. It is caused by intermittent hair follicle occlusion in areas with high numbers of apocrine glands [2]. The follicle becomes inflamed and may drain; severe cases will result in fistula and scar formation.

Epidemiology HS is more common in women typically starting after puberty.

Diagnosis

History Most patients will report recurrent painful lumps in the armpit or groin. The cysts may persist for some time or resolve some time after draining spontaneously.

Physical Exam The physician will be able to palpate tender nodules beneath the skin 5 mm to 2 cm in size. The skin overlying the lumps may be erythematous or warm; drainage may be seen. Advanced cases may show sinus tracts with thickened skin and hypertrophic scar formation.

Differential Diagnosis Acne, abscess, ruptured epidermal cyst.

Treatment

Large acute lesions should be incised and drained to give symptomatic relief.

Behavioral Patients should be instructed to bathe regularly and quit smoking.

DOI 10.1007/978-1-4939-0779-3_122-1

Medication Oral tetracyclines [5] are helpful for controlling inflammation in more severe cases: doxycycline 100 mg bid, minocycline 100 mg bid, tetracycline 500 mg bid. Cephalexin 500 mg tid is also helpful if overlying skin is infected.

Triamcinolone 10 mg/ml (Kenalog) 0.1 ml injected directly into a nodule can reduce the size of the nodule.

Referral Consultation with a dermatologist or general surgeon should be considered in complicated cases.

Counseling Patients should be warned of potential scarring for surgical procedures.

Patient Education Patients should be encouraged to lose weight if obese.

Contact Dermatitis

General Principles

Definition Contact dermatitis is a common skin problem that actually encompasses two distinct conditions: allergic contact dermatitis (ACD) and irritant contact dermatitis (ICD) [15]. The two conditions may be difficult to distinguish from each other on physical exam. History may be helpful in differentiation, or skin testing may be necessary.

Epidemiology Allergic contact dermatitis is slightly more common in females. Irritant contact dermatitis is common in occupations where exposures to irritants are likely to occur; these include the use of solvents and cutting fluids in machinery jobs and exposure to irritants in gardening, painting, photography, hairdressing, food processing, health, and beauty professions [16].

ICD is the second most common work-related reason for needing medical attention after trauma.

Classification **Allergic contact dermatitis (ACD)** is an allergic reaction to an antigen that becomes immunogenic after contacting proteins in the skin [16]. It is a delayed hypersensitivity reaction that typically occurs several days after an exposure. Reexposure leads to sensitization and quicker onset of rash. The reaction occurs only when the substance came in direct contact with the skin or was transferred to another part of the body by touch. Common causes are *Toxicodendron* (rhus) plants – their urushiol sap is found in poison ivy, oak, and sumac – and nickel, a common component of cheaper jewelry and metal belt buckles. Fragrances, balsam of Peru, and cosmetics commonly cause ACD on the face and thin skin of the neck and arms. Adhesive tape, topical medicines, lanolin, neomycin, and nonsteroidal anti-inflammatory drug (NSAID) creams are also frequent offenders. Latex found in toys and balloons can also cause ACD.

Irritant contact dermatitis (ICD) is caused by repetitive exposure to a substance that chemically irritates or damages the skin [16]. Subsequently, a chemical exposed to already damaged skin will cause a subsequent immune reaction. Chemicals found in the workplace or in repeated exposure in the home during hobbies are most likely to cause these reactions. Reactions most often occur on the hands. Common causes are solvents, cutting fluids, photography chemicals, and detergents. Specific substances the physician may ask about when investigating the cause include chromium, rubber additives, nickel, food ingredients, latex gloves, and bisphenol A in vinyl gloves. Lip licking and repeated handwashing can damage the skin and predispose patients to becoming irritated by chemicals.

Eyelid dermatitis (ED) [16] is a subset of contact dermatitis that can be caused by direct exposure of a substance to the eyelid or commonly transfer of an allergen or irritant chemical. Frequent offenders are cosmetics and manicuring products. ED can also be caused by allergens in the air or cosmetics applied to other areas then transferred to the eyes as they are often touched throughout the day.

DOI 10.1007/978-1-4939-0779-3_122-1

Table 3 Common contact allergens

Area	Allergen source	Substance
Eye	Cosmetics, nail polish, and hair product components	Acrylic, formaldehyde multiple chemicals in hair treatments
Scalp	Hair dye	Paraphenylenediamine
Hands	Fragrance work/hobby chemicals	Chromium, nickel, rubber additives, latex – natural rubber vinyl gloves – bisphenol A
Lips	Lip balm	Cinnamon, peppermint
Genitals	Topical meds, lubricants	Latex – condom/diagram
Neck	Jewelry, hair dye, perfumes	Nickel
Axilla	Shaving, depilatory agents	Aluminum hydroxide
Face	Fragrance, sunscreen, rubber, balloons, toys, sponges	Latex, balsam of Peru, nickel (ears)
Legs	Depilatories, topical medications	Topical steroids/neomycin, thimerosal/caines (with chronic stasis)

Allergic contact cheilitis[16] occurs in patients that are prone to chapped lips wherein the dry fissured lips allow antigen exposure. Common sources are lip balm, cinnamon, and peppermint (Table 3).

Diagnosis

History The ACD rash typically follows exposure within 24–96 h. Subsequent exposure results in a quicker onset of rash. The rash typically starts with a mild itch or burn, and then pruritus increases and can be very intense. A complete history of potential exposures to the affected areas within the week prior is helpful. Even with a good history, patients often do not recall all exposures. If ICD is suspected, a thorough work history is important. Common professions that predispose patients to ICD are health professionals, food industry workers, beauticians, hairdressers, machinists, construction workers, agricultural workers, foresters, and fishers. A home history of hobbies such as photography should also be investigated including all chemicals and what area of the body is exposed.

Physical Exam ACD will typically appear like scaly, red well-demarcated patch. Clustered papules and vesicles or bulla may be present. Plant dermatitis is typically a linear vesicular rash (Koebner reaction). Early stages of ACD are more likely to be characterized as papular vesicular eruptions, while a chronic contact will include the later stages of hyperkeratosis, lichenification, fissuring, and scaling. The dorsum of the hand is a common site as well as any area that may have come in contact with the irritant. It is unusual to have ACD on the palms or soles as the skin is thick and not easily penetrated by an antigen. ICD can appear similar but is more likely to be lichenified and not as well demarcated.

ACD will typically resolve within 2–4 weeks but may last as much as 1–2 months. In ICD, skin changes can persist as long as the irritants are repeatedly in contact with the skin.

Laboratory Tests They are not usually needed; however, a KOH test may be helpful to rule out a fungal infection.

Special Testing Biopsy may be required to diagnose the condition. ACD typical pathology will show spongiotic edema and perivascular inflammation with a histiocytic infiltrate. ICD may show necrosis, acantholysis, and pustulosis.

Patch testing[16] is indicated when the cause is not obvious or recurrent symptoms occur. It is very important in occupational exposures where the patient may have to use a special equipment to keep from coming in contact with the irritant. Patch testing cannot be done when a patient is on more than 20 mg of

DOI 10.1007/978-1-4939-0779-3_122-1

prednisone or on an area that has been treated with a potent topical steroid or calcineurin inhibitor within 1 week of testing. It is subject to false positives especially in atopic patients.

Differential Diagnosis Atopic dermatitis, lichen simplex, neurodermatitis, psoriasis, impetigo, erythrasma, scabies, nummular dermatitis, mycosis fungoides, cutaneous drug reaction.

Treatment

Behavioral Avoidance of allergic agents is the mainstay of ACD treatment, when this is not practical protecting the area from direct exposure through creating a barrier such as sewing a piece of fabric over the nickel metal on jeans snaps or belt buckles. Treatment of the skin rash commonly starts with cool compresses to soothe the symptoms. Burow's solution, calamine, and oatmeal solution can also be helpful.

Medications Small areas of the skin can be treated with mid- or high-potency topical steroids; thinner skin areas should be treated with lower-potency TS.

Oral steroids [16] are a reasonable option when an extensive area is involved. It will offer relief within 12–24 h. The typical starting dose is 0.5–1 mg/kg for 5–7 days then decrease to 50 % of the dose for an additional 5–7 days.

Antihistamines can help by sedating patients but have not been shown to ease symptoms. Topical steroids are not as effective in ICD.

Emollients are the main treatment for ICD as a secondary prevention to repair the skin barrier and decrease the drying and cracking of the skin that aids or worsens the skin irritation.

Referrals Dermatology consultation is helpful when patch testing is needed.

Patient Education Physicians should instruct patients in avoidance of substances and help them understand where they may be able to find substances.

Urticaria

General Principles

Definition Urticaria is a condition characterized by wheals and hives that appear intermittently and are associated with severe itching. It can be caused by IgE-mediated allergic reactions and non-IgA-mediated mechanisms [17]. Both will cause mast cell and basophil activation. A hive is consists of superficial edema of the epidermis. Severe reactions may include systemic symptoms such as fatigue, malaise, and gastrointestinal disturbances. Angioedema may also occur. In many cases, no cause can be found [18].

Common causes: medications such as antibiotics, opioids, NSAIDs, ACE inhibitors, and radiocontrast agents

Children and adults: viral infections, rotavirus, rhinovirus, mycoplasma group A strep, antibiotics, and IgE-mediated reactions to food such as milk, eggs, and wheat

Adults: tree pollen, peanuts, seafood, vaccinations, insect stings, inhalant allergens

Epidemiology Urticaria is most common in young adults aged 20–40 [17]; in chronic urticaria, there is a female preponderance.

Classification **Acute urticaria** Duration is <6 weeks. It is more likely to be associated with a virus and responsible for 2/3 of urticaria.

DOI 10.1007/978-1-4939-0779-3_122-1

Chronic urticaria (**CU**) Duration is >6 weeks of recurrent hives and in most cases, a cause cannot be found. Etiology can be hepatitis B, Epstein Barr virus (EBV), HSV, *Helicobacter pylori*, and parasite infections [17]. There are medical conditions associated with CU – such as cryoglobulinemia, hepatitis C virus, lymphoproliferative disorders – Chronic Lymphocytic Leukemia (CLL), connective tissue disease, SLE, Juvenile Rheumatoid Arthritis (JRA), serum sickness, thyroid disease, hormone therapies (OCPs, neoplasms, ovarian tumors).

Types of Urticaria **Physical urticaria** (dermatographic urticarias) – can persist for years [18].

Vibratory urticaria – itching and swelling after the skin is exposed to vibration.

Solar urticaria – patients will have urticaria within several minutes of exposure to sunlight.

Delayed pressure urticaria – swelling several hours after exposure to a skin pressure. Common causes are tight garments, working with tools.

Cold urticaria – development of hives in response to a cold contact.

Heat urticaria – development of hives in response to ambient heat.

Aquagenic urticaria – rare, appearance of hives after direct contact of the skin with water.

Cholinergic urticaria – small hives that occur as body temperature rises; it can be caused by exercise, sweating, hot baths or showers, or embarrassment/flushing.

Exercise-induced anaphylaxis (EIA) – pt develops itching with hives and angioedema after exercise; in some patients, this is related to ingestion of a specific food or medication and exercising afterwards; in others, exercise alone may cause it.

Contact urticaria – latex, stinging nettle.

Diagnosis

History The physician should take a thorough history of recent exposure to medications, food, acute infectious symptoms, and aeroallergens. One should inquire as to whether the rash appears transient, the history of previous similar rash, and the timing of symptoms. Symptoms of anaphylaxis may be present such as difficulty of breathing, light-headedness, or gastrointestinal (GI) symptoms. Angioedema should be ruled in or out, and symptoms consistent with recent exposure to physical urticarias should be elicited. Past medical history should be taken with attention to the history of autoimmune or inflammatory disorders.

Physical Examination The typical hives will be 1–4 cm in size, various shaped, and pink or red in color and will blanch with pressure. A hive/wheal will consist of raised skin that is erythematous and firm; dermatographism is often present. The wheals will usually appear and resolve in minutes to hours, but some may remain and then regress within 24–48 h; in the meantime, new ones may form. The physician should examine for angioedema, a more diffuse swelling of the mucous membranes. Lung exam should be done to rule out stridor or wheezing.

Lab and Imaging Testing for causes of acute urticaria is generally not indicated unless there is a compelling reason [18]. In chronic urticaria, it is recommended that testing be done if disease is severe or persistent although it is unlikely to find a cause.

Recurrent urticaria with angioedema may be a sign of hereditary angioedema, and testing for acquired C1 inhibitor deficiency or angiotensin-converting inhibitor should be done.

Common labs are complete blood count (CBC) to detect eosinophilia; ESR (erythrocyte sedimentation rate) can be elevated in autoinflammatory disorders or vasculitis, *H. pylori*, thyroid autoantibodies.

Complement screening – C1 inhibitor deficiency.

DOI 10.1007/978-1-4939-0779-3_122-1

Special Testing Skin testing immunoassays may help to determine the cause in acute cases. Biopsy is typically not needed but if performed will show a lymphocytic infiltrate or a mixed cellular infiltrate of lymphocytes and inflammatory cells. Biopsy should be done if the diagnosis is unclear and if vasculitis is in the differential. Food challenge testing can be done for specific urticarias.

Cold urticaria – ice cube to the forearm for 5 min.

Delayed pressure urticaria area – 15 lb of weight suspended over the patient's shoulder for 15 min then should be recorded if whether a reaction develops minutes to several hours later.

Dermatographia – can be brought about by stroking the skin with a firm object and seeing if a skin reaction is evoked.

Aquagenic can be diagnosed by applying a wet compress for 20 min.

Differential Diagnosis Cutaneous drug reaction, anaphylaxis, erythema multiforme, viral exanthem, Stevens-Johnson syndrome, urticarial vasculitis.

Treatment

Behavioral Avoidance of known allergies.

Medications Second-generation antihistamines for 4–6 weeks [18] then tapered: cetirizine (Zyrtec) 10 mg daily, fexofenadine (Allegra) 180 mg daily, loratadine (Claritin) 10 mg daily. Doubling or quadrupling the usual dose can be helpful for patients who do not respond to initial dosing.

First-generation antihistamines may be limited because of sedation: diphenhydramine (Benadryl) 25–50 mg qid prn, hydroxyzine 25–50 mg qid prn.

Oral steroids may be effective: prednisone 40–60 mg daily 1–3 weeks.

H_2 antagonist: ranitidine (Zantac) 150–300 mg bid, famotidine (Pepcid) 20–40 mg bid, montelukast (antileukotrienes) (Singulair) 10 mg daily.

Biologics: Omalizumab 150–300 mg subQ for chronic urticaria is FDA approved for patients with CU that are not improved with other treatments.

Referrals Consultation with an allergist or dermatologist may be necessary for refractory or persistently recurring urticaria.

Patient Education Physicians should counsel patients in avoidance of triggers and that NSAIDs may worsen symptoms.

Pityriasis Rosea (PR)

General Principles

Definition PR is a self-limited acute exanthem that is thought to be caused by infection; however, no specific virus or bacteria have ever been found [19]. Outbreaks have occurred in clusters, and PR will not typically recur.

Epidemiology It most commonly affects children and young adults.

Diagnosis

History Patients will typically complain of a rash that started on their trunk and can spread variably to the limbs. Some patients will complain of mild itching and in some cases will remember a prodromal illness.

DOI 10.1007/978-1-4939-0779-3_122-1

Physical Examination Inspection of the skin will typically show oval raised patches 5–10 mm in size with a dry collarette of scale on the periphery. Coloring can be mild pink and appear lighter than the natural skin color in darker-skinned individuals. The rash typically begins over the torso and is aligned in a typical Christmas tree pattern that will spare the hands. A herald patch may precede the diffuse rash by days to weeks in 50 % of the cases; it will measure 2–10 cm. The physical exam should include auscultation of the lungs to rule out wheezing or stridor which may also be seen in allergic drug reactions.

Laboratory KOH testing is not necessary but if done will be negative.

Special Testing Biopsy is rarely needed as patients can typically be reassured but can be done at a later date if the rash does not resolve as expected. Histology will show nonspecific inflammation.

Differential Diagnosis Tinea corporis, secondary syphilis, eczema, guttate psoriasis, other viral exanthems, cutaneous drug reaction.

Treatment
Behavioral The mainstay of therapy is reassurance as in the majority of patients the rash will recede within 5 weeks and in some it may last as long as 3 months.

Medications In some patients, pruritus is bothersome and treated with topical steroids. Calamine lotion and zinc oxide oral antihistamines may be helpful. Systemic steroids may be used in cases where itching is severe.

Referral This should not be needed.

Patient Education Physicians should reassure the patient that the rash will resolve, not scar, and not recur.

Cutaneous Drug Reaction (CDR)/Cutaneous Drug Eruptions

General Principles

Definition Eruptions comprise a group of immune- and nonimmune-mediated reactions that manifest as several different cutaneous reactions.

Epidemiology Cutaneous reactions are more common in older patients and women. Certain comorbidities, for instance, renal insufficiency, lupus, hepatic disease, cystic fibrosis (CF), and human immunodeficiency virus (HIV), may predispose patients to reactions. UV light can increase the adverse reaction as well as infections like mononucleosis, herpes simplex virus (HSV), or mycoplasma [20].

Classifications Allergic reactions are of the following types: IgE-mediated hypersensitivity Type I, cytotoxic antibody Type II, vasculitis immune complex reaction Type III, and delayed hypersensitivity Type IV [20].

Exanthem maculopapular rashes – most common reaction with macules and papules more commonly concentrated on the torso.

Urticaria – intermittent hives.

Erythema multiforme (EM) – skin rash with targetoid lesions.

Angioedema – swelling of the lips and mucous membranes.

Drug-induced vasculitis – petechial rash.

DOI 10.1007/978-1-4939-0779-3_122-1

Fixed drug eruption – recurring skin reaction that is limited on the body geographically and recurs with repeated use of a medication.

Pigment changes – induced by some medications and can vary from melanotic to blue, silver, yellow, or red.

Photodermatitis drug + UV light – phototoxicity drug acts to concentrate UV in the skin and cause sunburn like rash.

Stevens-Johnson syndrome (**SJS**) 5 % mortality – a hypersensitivity reaction with blistering and desquamation.

Toxic epidermal necrolysis (**TEN**) 20–30 % mortality – blistering rash with significant desquamation.

Warfarin skin necrosis – rare hemorrhagic bulla while heparin necrosis is a more localized reaction with purpuric plaques near injection sites.

Diagnosis

History The physician should be concerned about any new rash in a patient who does not have a preexisting skin condition and who takes medication. Rashes are more likely to occur with topical application and oral ingestion and with chronic or repeated prescription. Exanthems typically start within 1–2 weeks of starting a new drug, but the range can be 1 week–1 month in medication-naive patients [21]. Repeated exposures to medications will result in a shorter time to onset of rash. Urticarial reactions can be immediate or within days of starting medication. The physician should review medication history, herbal history, previous reactions, and any improvement after discontinuation of the drug. Common drug offenders are carbamazepine, phenytoin, antibiotics, anti-inflammatory drugs, and allopurinol.

Physical Examination Presentation can be varied from exanthems that are maculopapular, morbilliform, or erythrodermic. Exanthems often occur first symmetrically on the torso and may be worse in areas under pressure like the back or buttocks in bedbound patients. Urticarial reactions can present with papules or large hives. EM presents with macules, papules, or vesicles that resemble a target. SJS will consist of blistering more extensively in multiple mucous membranes. TEN blistering and bulla will affect the skin and mucous membranes. Angioedema will present with swelling of the mucous membranes and possibly lips and if severe respiratory excursion may be difficult. Contact dermatitis will show erythematous urticarial plaques in areas of topical medication application.

Laboratory and Imaging For skin rashes, labs are not necessary, as CBC will generally not show eosinophilia. In more severe cases of TEN or SJS, laboratory testing is important to determine how ill a patient may be.

Special Testing Skin biopsy may be helpful, as the histology will show eosinophilia, edema, and inflammation. In erythema multiforme, vasculitis is seen and necrosis will be present. Biopsy will confirm the diagnosis if concern for SJS or TEN is present. Patch testing is helpful in contact dermatitis. Photopatch testing where exposure to UV light is added to patch testing is needed for photoallergic reactions. Skin prick test can confirm IgE-mediated allergic reactions; however, it should be done with proper precautions in patients with a history of severe reactions.

Differential Diagnosis Viral exanthem, pityriasis rosea, scalded skin syndrome.

DOI 10.1007/978-1-4939-0779-3_122-1

Treatment

Behavioral Exanthems are self-limited; however, many patients will request relief from symptoms. Discontinuation of the offending medication as well as documentation of the allergic reaction in the medical record is important.

Medications Treatment of symptoms includes antihistamines to help pruritus, topical steroids, and oral steroids. Second-generation antihistamines are cetirizine (Zyrtec) 10 mg daily, fexofenadine (Allegra) 180 mg daily, and loratadine (Claritin) 10 mg daily [20, 21]. First-generation antihistamine effectiveness may be limited by sedation: diphenhydramine (Benadryl) 25–50 mg qid prn, hydroxyzine 25–50 mg qid prn.

Oral steroids [21] may be effective: prednisone 40–60 mg daily 1–3 weeks.
Topical steroids may help in cases of contact dermatitis of discrete skin rash.
Hospitalization is necessary for SJS and TEN to perform fluid resuscitation.
Epinephrine may be necessary for angioedema and in cases of anaphylaxis.

Referral Consultation with an allergist or dermatologist may be needed when the specific causative medication cannot be found.

Patient Education Patients must be told that they are allergic to the medication and possible related medications; they must refrain from taking the medication again and should never take an unknown medication.

Bullous Diseases

Bullous Pemphigoid (BP)

General Principles

Definition Bullous pemphigoid (BP) is a chronic autoimmune disorder in which patients have recurrent bullous lesions on the skin. It is IgG mediated where autoantibodies bind to specific antigens causing a complement cascade resulting in blisters [22].

Epidemiology BP is more common in men over 60 years old [5].

Diagnosis

History Most patients will recall having itching prior to the formation of bulla, which, once formed, will take a long time to heal.

Physical Examination Lesions will have tense bulla/small blister overlying normal or erythematous skin. BP does not typically affect mucous membranes.

Special Testing Biopsy is necessary for diagnosis.

Differential Diagnosis Pemphigus vulgaris, scalded skin syndrome.

Treatment

Medications Oral steroids like prednisone 60–80 mg daily [2] then tapered after a few weeks may take 2–10 months for remission.

DOI 10.1007/978-1-4939-0779-3_122-1

IV immunoglobulin.

Immunosuppressive medications have been used for severe disease or when a patient has been unable to wean off of steroids.

High-potency topical steroids are applied topically for local disease.

Referral Dermatology consultation is necessary for patients who do not achieve an adequate response with systemic steroids or are unable to wean off steroids.

Counseling Patients on long-term steroids should be warned of the side effects of the treatment.

Patient Education Patients should be counseled of the chronicity of the condition and need to follow up with their physician.

Pemphigoid Vulgaris (PV)

General Principles

Definition PV is an autoimmune chronic bullous disease that affects the oral mucosa, skin, and mucous membranes. There is a high mortality rate of 10 % with treatment and higher without. It is caused by an autoantibody formed against the adhesive molecule that holds epidermis together; subsequent separation of keratinocytes then occurs [2, 5].

Epidemiology Age 30–50.

Classification **Pemphigus vulgaris** – common type

Pemphigus foliaceus – superficial form, more common in South America

Paraneoplastic pemphigus – a form associated with hematologic malignancies

Diagnosis

History Patients will report the appearance of painful blisters that typically start in the mucous membranes of the mouth, and then several weeks later, skin lesions will develop on the scalp, face, and upper torso.

Physical Examination Examination will reveal blisters that are of varying sizes, which easily shear off and leave painful erosion and then post-lesion hyperpigmentation. The Nikolsky sign is present when skin will shear off after lateral pressure is applied to the skin near a blister.

Laboratory and Imaging **Special testing** Two biopsies should be done via punch or shave that includes the epidermis. One biopsy should be sent for direct immunofluorescence, which will show desmoglein antibodies.

Differential Diagnosis Bullous pemphigoid, linear IgA dermatosis, dermatitis herpetiformis.

Treatment

Medications Oral steroids: prednisone 60 mg daily.

Referrals Consultation with multiple specialties may be needed: dermatology for treatment and gastroenterology for endoscopy if esophageal disease is suspected.

DOI 10.1007/978-1-4939-0779-3_122-1

Table 4 Amount of steroid to treat body surface area

Area	Fingertip unit
Hand	.5
Arm	3
Leg	6
Torso	8
Foot	2
Face	2

Counseling Patients on long-term steroids should be warned of the side effects of the treatment.

Patient Education and Activation Patients should be counseled of the chronicity of the condition and need to follow up with their physician.

Topical Steroid (TS) Treatment Principles

Steroid creams work by decreasing inflammation and hyperproliferation and altering immune reactions [4] (Table 1). They improve symptoms of itching and burning. TS is typically applied one to two times daily initially until response has begun, then decreasing the frequency of application.

Patients should be instructed in the amount of steroid to use. The fingertip unit [23] is the amount of steroid squeezed from a tube from fingertip to the first crease (Table 4).

Selection of the type of treatment and likelihood of it benefiting the patient should always be considered, as it will affect compliance [23]. Patients may prefer certain vehicles [3] so the physician should ask the patient whether they would prefer an oily substance versus cream or foam. In general, ointments are most useful for areas that are dry or where the skin is thickened or when its occlusive properties are beneficial. In these areas, creams may be rubbed off too easily; however, some patients may not like ointments due to their greasiness. Occlusion can be achieved by wrapping the area in plastic. Tape such as flurandrenolide (cordran tape) impregnated with steroid ointment is often used to treat areas such as the fingers. Creams are more useful in intertriginous areas and exudative lesions where they will not add too much moisture. Lotions are more easily applied to hair-bearing areas; they often contain alcohol. Gels can be drying which helps with exudative lesions. Foams and shampoos are more useful in hair-bearing areas like the scalp.

Undertreatment with low-potency steroid when a high-potency steroid is indicated (i.e., psoriasis) may lead to treatment failure [8] and affect adherence. In general, lower-potency steroids are used on areas with thinner skin such as the face and neck and in children. Moderate-potency topical steroids are used chronically in severe disease or thick skin such as the palms and soles.

High-potency TS is used in shorter durations and never on the face or intertriginous areas.

Side effects happen on occasion and comprise the following: tachyphylaxis, hypopigmentation, contact dermatitis to other ingredients in the vehicle, telangiectasia, striae, rosacea, and acne-like eruptions.

Adrenal suppression is possible when very high-potency steroids are used over extended periods of time. Skin atrophy is the most common effect of overuse which typically resolves after cessation of steroid.

Skin Infections and Infestations

Thomas Golemon*
University of Illinois College of Medicine at Peoria, Peoria, IL, USA

Pyodermas and Bacterial Skin Infections

Impetigo

General Principles

Impetigo is a common, contagious superficial skin infection seen most often in infants and children.

Epidemiology It is caused by *Staphylococcus aureus* and Group A streptococci and presents in two major types: bullous and nonbullous. Bullous impetigo is caused by staphylococci that produce an epidermolytic toxin.

Diagnosis

Physical Examination Impetigo begins with small, thin-walled blisters that rapidly coalesce into round or oval-shaped bullae containing a cloudy fluid. The central area of the bullae then collapses, leaving a honey-colored thin layer surrounded by a rim of crusty tissue that continues to expand. In the untreated individual, these will reach 2–8 cm-sized patches that can remain for months. Nonbullous impetigo appears to be more related to Group A streptococcal infection, although staphylococci can also be found. Clinically, the lesions begin most often around the mouth or nose with small vesicles that rupture, producing a serious discharge that dries into a honey-colored crust. The lesions have a red, moist base and often extend by satellite lesions over adjacent skin.

Treatment

Treatment with topical 2 % mupirocin ointment is safe and as effective as oral antibiotics in patients with a limited number of lesions. Oral antibiotics are recommended for patients with numerous lesions or for infections that occur during community outbreaks of post-streptococcal glomerulonephritis to help eliminate nephritogenic strains of *Streptococcus pyogenes* [1].

Erysipelas and Cellulitis

General Principles

In contrast to impetigo, cellulitis and erysipelas are deeper skin infections manifested by distinctly painful, red, swollen skin.

Epidemiology The causative agents are predominantly Group A streptococci and *Staphylococcus aureus*, the latter presenting as either methicillin-sensitive (MSSA) or methicillin-resistant (MRSA) strains. Erysipelas is usually caused by Group A streptococci. It is a more superficial form of cellulitis.

*Email: longhorn@uic.edu

DOI 10.1007/978-1-4939-0779-3_123-1

Fig. 1 Cellulitis in a patient with chronic edema and dry skin. Note the sharp inferior margin and streaking up the medial lymphatics. The skin was red, hot, and tender to touch

Diagnosis

Physical Examination Erysipelas has the clinically distinctive feature of a clear-cut margin that visibly demarcates the infected tissue from uninvolved adjacent skin. Lymphatic involvement is common and progression of the infection through the lymphatic chains causes linear "streaks," especially apparent on the extremities (Fig. 1). It is often associated with a fever of 101–104°, chills, and malaise.

Treatment

Treatment consists of oral or intravenous antibiotics active against streptococci, depending on the severity and location of the infection.

Cellulitis

General Principles

Cellulitis differs from erysipelas by involving deeper skin and subcutaneous structures.

Epidemiology

The past decade has witnessed a significant increase in the number of skin and soft tissue infections (SSTIs) reported worldwide from community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA). The development of such an infection can lead to cellulitis with or without abscess formation.

Diagnosis

Cellulitis is not clearly demarcated visually, as is erysipelas, but presents with pain, fever, and leukocytosis, usually with a demonstrable portal of entry. Lacking such a portal of entry, patients may report the initial tender papule was thought to be a "spider bite."

Laboratory Neither blood analysis (WBC, CRP) nor cultures of blood or skin aspirates has been found to be clinically useful or cost-effective in determining abscess presence [2].

Treatment

Treatment of cellulitis has become the subject for many studies related to CA-MRSA. The most recent recommendations are that empiric treatment of outpatient non-purulent cellulitis be initiated with

DOI 10.1007/978-1-4939-0779-3_123-1

β-lactam antibiotics (cephalexin, dicloxacillin, amoxicillin/clavulanate), finding no significant difference in clinical failure rates between these and non- β-lactam alternatives. The Infectious Disease Society of America (IDSA) has recently updated their guidelines (June 2014) for management of SSTIs. Their recommendations include the adoption of oral β-lactam antibiotics for the mild, non-purulent category and moving to intravenous antibiotics of similar nature for a moderate infection [3]. Individual community susceptibility data should always be considered in antibiotic choices.

Chemoprophylaxis The use of prophylactic antibiotics (benzathine penicillin or erythromycin or clindamycin) has been proven effective.

Prevention

Prevention of recurrent episodes of cellulitis is important, including physical inspection of the feet for interdigital maceration, cracks, or fissures.

Folliculitis, Furuncles, and Carbuncles

General Principles

Folliculitis is an inflammatory condition of the hair follicle, either from infection or superficial mild trauma, such as friction from clothing.

Epidemiology The bacterial etiology of infection is usually staphylococcal in nature. "Hot tub folliculitis" is a subset of folliculitis caused by *Pseudomonas aeruginosa,* which may be found in unclean hot tubs or jacuzzis.

Diagnosis

Physical Examination The condition presents as small white pustules at the site of hair follicles on almost any surface of the body. There is often a small ring of erythema around the infected follicle, and the lesion may be painless or variably painful depending on its size and depth. In skin that is repeatedly shaved, spread of the infection can occur quickly to multiple follicles from microtrauma and bacterial implantation.

Treatment

Treatment is effective with topical mupirocin ointment or with oral antibiotics in more extensive involvement. Razors must be changed frequently and shaving may need to be interrupted during treatment of the lesions. Hot tub folliculitis is usually self-limited and requires only antiseptic care.

Prevention

Decolonization techniques using mupirocin in the nares may help eliminate reservoirs of staphylococci.

Furuncles ("Boils")

General Principles

Furuncles ("boils") are localized infections that extend from a follicular site into a deeper, walled-off subcutaneous abscess. They are often found in areas of friction from clothing, such as the belt-line, groin, thighs, or bra-line, but also may occur near the nares or on the face [4].

DOI 10.1007/978-1-4939-0779-3_123-1

Diagnosis

Physical Examination Furuncles are characterized by an initially firm, tender erythematous nodule that subsequently enlarges and develops a fluctuant surface that erodes with spontaneous drainage.

Treatment

Treatment of furuncles is drainage, which may be encouraged spontaneously by warm compresses or may be accomplished by incision and drainage (I&D) under local anesthesia in the office. Oral anti-staphylococcal antibiotics are useful in the early stages of infection.

Carbuncles

General Principles

Carbuncles are multiple furuncles clustered together, characterized by larger areas of involvement and multiple drainage sites.

Treatment

Oral antibiotics and drainage procedures usually suffice, but surgical consultation may be required for extensive debridement.

Hidradenitis Suppurativa

General Principles

Hidradenitis suppurativa is a suppurative process affecting the follicles and apocrine glands in the axillae, groin, and below the female breasts that can seem to be a simple folliculitis early in its course. This disease progresses inexorably with gradual spread to adjacent follicles. After years, areas of scarred remnants remain scattered over the axillae, groin, and inframammary skin (Fig. 2).

Fig. 2 Hidradenitis suppurativa

DOI 10.1007/978-1-4939-0779-3_123-1

Treatment
Treatment for individual drainage sites is similar to that of folliculitis, but the chronicity of the disease usually requires surgical removal of the affected areas.

Behavioral The impact of hidradenitis suppurativa on the emotional and psychological well-being of patients may require counseling and psychological support [5].

Abscess of Skin

General Principles
A skin abscess is the result of the accumulation of pus in the skin or subcutaneous tissues. Recent studies have shown that bedside ultrasonography improves diagnostic accuracy and decision-making regarding the presence of abscess fluid [6].

Diagnosis
Clinically, an abscess presents as an exquisitely tender, swollen, red, fluctuant mass. The diagnoses may be simple, but if accompanied by significant cellulitis, the indurated, tender tissue may make palpation of the fluctuant area difficult.

Treatment
The treatment of choice for skin abscesses is incision and drainage (I&D). The Infectious Disease Society of America (IDSA) recommends addition of non-beta-lactam empiric antibiotics only in moderate or severe categories of purulent skin and soft tissue infections (SSTIs) [3]. However, incision and drainage is a painful procedure, and a common mistake is to create an incision of insufficient depth to fully drain the abscess.

Referrals If local or regional anesthesia is inadequate, further sedation or anesthesia should be considered, especially for children or adults with abscesses that are unusually large or are in sensitive sites.

Prevention
Prevention of recurrent skin abscesses follows the rationale for that of recurrent cellulitis. Efforts at decolonization have not been shown in large studies to be statistically reliable. However, if attempted, a 10-day course of twice-daily intranasal mupirocin, daily hexachlorophene washes, and oral antibiotics (TMP/SMX or minocycline) aimed only at the index patient was shown to reduce the rate of methicillin-resistant *Staphylococcus aureus* (MRSA) reinfection in a small study in California [7].

Necrotizing Fasciitis

General Principles
Necrotizing fasciitis is an uncommon to rare life-threatening, rapidly progressive infection of the subcutaneous tissues and fascia.

Epidemiology It is most often polymicrobial (Type I), although a smaller proportion of patients will have only a single organism, usually group A streptococcus (Type II). A third type, recently described, is caused by vibrio species and is associated with salt water-related minor injuries (fish fin stings or handling raw sea food) in areas with warm seawater [8]. Predisposing factors include diabetes mellitus, cirrhosis, pulmonary disease, end-stage renal disease, immune suppression, or drug injection.

DOI 10.1007/978-1-4939-0779-3_123-1

Diagnosis

Clinical presentation is typically that of a presumed cellulitis. The only indicator that this may be more than a simple cellulitis is the finding of unrelenting pain that is out of proportion to the clinical findings. Without a high index of suspicion, the diagnosis may initially be missed and the patient sent home. As the disease progresses, the affected skin develops yellowish bullae, which become violaceous in color (a strong clue to the diagnosis of necrotizing fasciitis), and the skin becomes "woody" in texture, with loss of sensation. Crepitus may occur. Confusion and sepsis are frequent findings. The fatality rate is 25–70 % from sepsis and multiorgan failure.

Laboratory and Imaging Ancillary testing is nonspecific. Demonstration of gas or deeper tissue infection should prompt surgical consultation and immediate exploration to confirm or exclude necrotizing fasciitis.

Erythrasma

General Principles

This uncommon skin infection is characterized by brownish pigmentary change in a plaque-like area, usually in the groin, interdigital toe spaces, or inframammary areas.

Epidemiology The infection is caused by the bacteria *Clostridia minutissimum*, but is often confused with tinea, especially in the groin. It may remain for years if not treated appropriately. It can be distinguished by virtue of its less inflammatory presentation, relative lack of symptoms, and its coral red fluorescence with Wood's lamp [9].

Treatment

Treatment can be accomplished with oral erythromycin, or clarithromycin.

Cutaneous Leishmaniasis

General Principles

Cutaneous leishmaniasis is one of three forms of disease caused by an intracellular protozoa of the *Leishmania* species.

Epidemiology Leishmaniasis is transmitted by the sandfly, which is only 1/3 the size of a mosquito. Because it makes no sound, is small, and the bite may not be painful, patients often do not realize they have been bitten. Over 90 % of the cutaneous leishmaniasis originates in countries that are most often visited by military personnel, missionaries, or tourists. While the infection is rare in the United States, a persistent nodule or plaque on the torso, extremities, or face should prompt questions about exposure by travel to the Middle East, or to Central or South America.

Diagnosis

Physical Examination The patients present several weeks (or in some cases up to several months) after exposure with one or more non-pruritic nodules. The lesions progress to a nodular plaque and then often ulcerate with raised circular borders and a central depression. The lesions last for months and are usually painless.

DOI 10.1007/978-1-4939-0779-3_123-1

Differential Diagnosis Diagnosis can be made by a combination of clinical presentation and smears or biopsies from the active edge of a lesion [10].

Treatment

Treatment decisions should involve consultation with CDC and infectious disease consultants.

Viral Diseases of the Skin

Herpes Simplex

General Principles

Herpes simplex virus (HSV) is a neurotropic virus causing infections of the mucous membrane and skin.

Epidemiology The virus enters the tissues through a portal of entry on the skin or mucous membrane, replicates in the local site, and by retrograde axonal flow reaches the dorsal root ganglia, establishing a lifelong latency state. The primary infection can range from completely asymptomatic to a syndrome with significant pain and tissue change. Recurrent infections, always occurring at the same anatomic site, recapitulate the primary infection in a much-shortened course of about 1 week. The recurrences appear when the latent virus is reactivated by some stimulus, such as illness, fever, chapping, menses, or UV light exposure. Herpes simplex in wrestlers is called *Herpes gladiatorum* and is transmitted by direct contact during wrestling bouts. *Ocular herpes* is a rare cause of keratoconjunctivitis and can cause blindness. Emergent ophthalmologic referral is indicated if it is suspected. *Herpetic whitlow* is the infection by HSV of the distal phalanx around the nail or on the pulp of the finger tip. It occurs when the digit involved is exposed to HSV, either by thumb-sucking or digital-oral or digital-genital contact, in the presence of a portal of entry. *Eczema herpeticum* occurs when an atopic individual, often just recovering from an episode of herpes labialis, develops widespread HSV lesions over an area of recent eczema. This constitutes a dermatological emergency [11].

History The initial symptoms are a tingling pain or burning sensation at the site of infection, followed within days by local swelling and the appearance of uniform-sized groups of vesicles on a red base. These progress to umbilicated pustules, which then rupture and form crusts. The entire site is often very tender to touch.

Diagnosis

Physical Examination Herpes simplex labialis ("cold sore") is very common, and patients often do not seek the physician's care for recurrences (Fig. 3). Initial infections, particularly in infants and children, may cause enough oropharyngeal pain on swallowing to make fluid intake difficult.

Treatment

Treatment of primary and recurrent episodes on skin surfaces can be undertaken with topical creams such as acyclovir cream or n-docosanol cream (OTC Abreva) or with oral medications such as acyclovir, valacyclovir, or famciclovir.

DOI 10.1007/978-1-4939-0779-3_123-1

Fig. 3 Recurrent herpes on upper lip

Genital Herpes

Diagnosis

Physical Examination Genital herpes in the female can cause pain, itching and burning, dysuria, and discharge. In the male, pain and burning of the lesions may be associated with local lymphadenopathy.

Treatment

Treatment regimens are similar to that for oral lesions, but in pregnant females, the presence of an active HSV infection at or near delivery prompts concerns about vertical transmission to the fetus.

Prevention

A Cochrane review has shown that prophylaxis which begun with acyclovir or valacyclovir at 36 weeks gestation significantly reduces herpetic recurrences at delivery as well as reducing viral shedding [12].

Herpes Zoster

General Principles

Herpes zoster, commonly known as shingles, is a viral infection of the skin along the dermatome served by a dorsal root ganglion which was infected during a childhood episode of chicken pox. The virus remains latent until reactivated and then travels back down the sensory nerve and prompts the rash, which can occur anywhere along the dermatome.

History Clinically, the patient reports an initial sense of the skin itching or burning in the affected dermatome 4 or 5 days prior to the onset of the rash. Occasionally the area is so painful it can mimic more serious, internal diseases such as pleurisy, myocardial ischemia, or an intra-abdominal process, causing diagnostic confusion.

Diagnosis

Physical Examination The appearance of the classic erythematous rash, associated with the formation of variably sized blisters, along the course of the affected dermatome resolves any diagnostic dilemmas. The rash can continue to be painful in varying degrees as crops of blisters occur for a week. The thin-walled blisters rupture and form a crust, which gradually heals in 2–3 weeks [4].

DOI 10.1007/978-1-4939-0779-3_123-1

Treatment

Treatment of zoster is most successful when begun within 72 h of the onset of symptoms. Good results have been obtained with three oral medications: acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex). Acetaminophen and nonsteroidal anti-inflammatories are useful for mild to moderately severe pain, whereas narcotic analgesics may be required in others. For postherpetic neuralgia, which occurs in a minority of patients but can be a serious problem, treatment options include tricyclic antidepressants, tramadol, long-acting opioids, or pregabalin (Lyrica). Topical capsaicin (Zostrix) or a lidocaine patch (Lidoderm) may also be of benefit.

Prevention

Prevention of herpes zoster by vaccination is indicated for patients over age 60 years [13].

Viral Warts

General Principles

Warts are caused by infection of the epidermis by the human papilloma virus (HPV), creating a variety of benign neoplasms. Most warts resolve spontaneously within months, but recalcitrant ones can last years. Cell-mediated immunity response is a key element in wart resolution, as witnessed by the more frequent and longer-lasting occurrences of warts in patients with AIDS, lymphomas, or immune suppressive drugs. There are a variety of treatments available, signaling that no single treatment regimen is always effective for cure.

Diagnosis

Physical Examination Common warts (*verruca vulgaris*) occur mostly on the hands and present as smooth, round papules that develop into typical dome-shaped round or ovoid lesions with hyperkeratotic, dry surfaces and loss of skin lines. Black dots, representing thrombosed vessels, may be seen on the surface or when exposed by paring down the keratinaceous surface with a #15 knife blade. Plantar warts occur on the soles of the feet in large, hyperkeratotic lesions that cause pain with walking. Trimming the thick keratin accumulation with a #15 knife blade relieves much of the discomfort. Condylomatous warts are found in moist, intertriginous inguinal tissues and on mucous membranes, especially in the vaginal area. These warts are sexually transmitted and may occur on the urethra, penile shaft, and rectum in males. Untreated lesions enlarge, developing cauliflower-like vegetation that can become quite large. They may remain for years and can be difficult to treat.

Treatment

Topical salicylic acid applied at home or cryotherapy at the physician's office are the most reliable and cost-effective treatments for common and plantar warts. Imiquimod may be a useful agent for facial lesions or for recalcitrant common warts. Injection of candida antigen (immune-modulation) intralesionally also appears to be an effective option. Pulsed dye laser therapy may be reserved for recalcitrant or hard to reach (periungual) warts [14]. Treatment options for condylomas include patient-applied therapies such as imiquimod and podofilox, along with cryotherapy and surgical excision [15].

DOI 10.1007/978-1-4939-0779-3_123-1

Hand-Foot-Mouth Disease

General Principles

Epidemiology Hand-foot-mouth disease (HFMD) is a contagious, usually benign, enterovirus disease caused mainly by Coxsackievirus A16 in the United States. It is most common in children, but can be seen in adults. HFMD is spread by contact with saliva, mucus, blister fluid, or fecal material from an infected person.

History and Physical Examination There may be a prodrome of malaise, loss of appetite, fever, and sore throat. One or two days later, tender aphthous sores appear in the mouth and a rash follows within 24 h. The self-limited rash is found especially on the palms and soles, but may occur on the face, buttocks, and legs. The skin lesions begin as small red macules, but develop into white 3–5 mm vesicles with a red periphery.

Treatment
Treatment of HFMD is supportive and symptomatic care. Cool fluids in small amounts help alleviate pain and swallowing in the eruptive phase. Infected patients should be kept at home until the rash clears and careful personal hygiene observed to prevent spread [16].

Fungal Infections and Yeast Infections

Dermatophytoses

General Principles
The group of dermatophytes includes fungi (tinea, ringworm) that are the most common fungal infections seen by primary care physicians. They survive in superficial keratin found on the skin, hair shafts, and nails. At times, they may be confused with eczema or other skin disorders.

Epidemiology Tinea capitis is most often seen in children, presenting as one or more round patchy areas of hair loss. These grow larger untreated and in some instances may cause an inflammatory reaction deeper into the scalp called a kerion. Kerions are boggy and indurated and can cause scarring alopecia. "Black dot tinea," the appearance of tinea in the scalp when the infected hair shaft breaks off at the scalp surface, is usually caused by *Trichophyton tonsurans*.

Diagnosis
Tinea barbae is a less common hair infection than tinea capitis. It may occur in those who work with or milk animals and thus lay their face on the side of the animal (such as dairy farmers). The hairs of a fungal-infected beard can be plucked painlessly and examined for hyphae. Tinea corporis and tinea faciei are common in children and adults. These are the classic "ringworm" appearing lesions, with the annular shape, clearing center, and a superficial active border. Untreated, they can achieve a large area with an irregular, serpentine border. In wrestlers, this form of infection is called tinea gladiatorum. Tinea cruris, or "jock itch," occurs mostly in adult males, and is more common in the warm summer months (Fig. 4). Like tinea pedis, this lesion can be extremely pruritic. Tinea pedis, also known as "athlete's foot," most classically presents in the toe web between the fourth and fifth toes in a young adult male, although any interdigital spaces can be affected. The warm, moist environment in the toe webs, the common

DOI 10.1007/978-1-4939-0779-3_123-1

Fig. 4 Tinea cruris

exposure to locker room floors and communal baths, and the tightly fitting shoes over a sweating foot all combine to create this most common of tinea infections. Intense itching is most noticeable when the socks and shoes are removed. "Two feet-one hand" syndrome is occasionally noted, when both feet and the dominant hand the patient uses to scratch or pick at the infected site become infected [17]. Tinea incognito is the name given to any tinea infection which has been treated erroneously or inadvertently with topical steroids. The steroid blunts inflammation and disguises the usual active border. A careful history and review of medications will suggest the correct diagnosis, and KOH examination and culture will confirm the diagnosis.

Treatment

For small areas of infection, topical antifungal creams are effective and available over the counter. These should be continued for at least 1 week after apparent resolution to prevent recurrence. Larger areas are more efficiently treated with oral antifungals. For children, griseofulvin is the drug of choice [18]. In adults, fluconazole (Diflucan), itraconazole (Sporanox), or terbinafine (Lamisil) are recommended. In Athlete's Foot, treatment is aimed at drying the moist areas with cool Burrow's solution soaks and use of over-the-counter topical antifungal creams. In severe cases, oral antifungals can be used as for tinea corporis.

Prevention

Tinea gladiatorum in high school wrestlers can be prevented by use of prophylactic fluconazole [19].

Nail Infections

General Principles

Tinea unguium (onychomycosis) is an infection of the nails by dermatophytes, most often Trichophyton species. Patients may complain of discomfort walking due to the distorted nail and may suffer social embarrassment or loss of self-esteem from the cosmetic appearance [20].

Epidemiology The fungus may attack the nail proximally (less common, except in immune deficiency patients), distally (most commonly), or from a superficial surface invasion (white superficial onychomycosis) (Fig. 5).

DOI 10.1007/978-1-4939-0779-3_123-1

Fig. 5 Onychomycosis of nail plate beginning at the distal subungual area. Note characteristic streaks toward proximal nail matrix as channels

Diagnosis

Diagnosis can be made with KOH of subungual scrapings and histologic exam of distal nail clippings. Culture to confirm the species of fungus is desirable to guide treatment choices.

Treatment

Treatment of nail infections is more difficult than other tineas, requiring longer treatment intervals and accompanied by a higher failure rate. For toenails, terbinafine (Lamisil) given in a continuous dose of 250 mg/day for 12 weeks yields 70–88 % cure rate and is inexpensive in generic form. Pulse dosing at 500 mg/day 1 week per month for 3 months is less effective at 58.7 % cure rate [4]. Fingernails need be treated only 6 weeks at the same dose. Fluconazole and itraconazole have also been used with lesser success. For prolonged treatment options, baseline CBC and liver function tests with rechecks every 4–6 weeks are recommended.

Yeast

General Principles

Yeast organisms thrive in moist, warm environments, and infections are therefore most common in the interdigital spaces of those who work around water (dishwashers, cooks, bartenders) or in areas of the body where skin overlap provides warmth and moisture. These include the oral mucosa (especially in infants), the groin and genetalia, and inframammary or sub-pannus skin areas.

Epidemiology *Candida albicans* and other species of Candida live within the normal skin and mucous membrane flora, but cause infection with triggers such as pregnancy, oral contraceptives, topical or oral steroid use, oral antibiotics, diabetes, skin maceration, or any process interfering with cell-mediated immunity.

Thrush is oral candidiasis in infants or children. It is frequently seen in healthy newborns, where it may be asymptomatic or may cause some fussiness.

Diagnosis

Physical Examination Thrush in place of it appears as a creamy exudate or white adherent plaques from the accumulation of desquamated superficial epithelium. If removed, a raw, reddened tender epithelium is

DOI 10.1007/978-1-4939-0779-3_123-1

found. Candidal vulvovaginitis is a common infection in women, causing itching, burning, dysuria, and vaginal discharge. The vaginal tissues are red, swollen, and tender, and often a whitish curdy discharge is found. The vaginal pH is normal (pH < 4.5), distinguishing this discharge from other common causes of vaginitis. Candidal balanitis in the male presents with raw, red skin over the glans penis and skin of the shaft, especially in uncircumcised men. Candidal intertrigo is common, especially in warm climates and in obese or diabetic patients. Overlapping skin surfaces are ideal for monilial growth, and the resultant infection causes an area of bright red, superficially raw skin that is moist and confluent with peripheral "satellite" colonies. Candidal diaper rash causes red, raw, macerated, or fissuring skin in the diaper area of infants (or adults).

Treatment

Thrush is treated in children with nystatin oral suspension. In adults this is most efficiently accomplished by oral fluconazole. For patients with cancer or HIV, prophylactic dosing can help prevent relapses. Treatment of vulvovaginitis with oral fluconazole (150 mg PO, one dose only) is usually effective. Alternatively, vaginal and intravaginal creams and troches are available (terconazole and miconazole). As in the female, a single oral dose of fluconazole 150 mg is as effective as topical antifungal creams applied daily for 7 days (clotrimazole and miconazole) for treatment of balanitis in the male. Treatment of intertrigo is aimed at removing the moist environment using Domeboro's solution for soaks several times a day and at eliminating the actively growing yeast with antifungal creams. For candida diaper rash, excess moisture can be addressed by frequent diaper changes or intervals of open-air exposure without a diaper. Antifungal creams are applied twice daily for 7–10 days. Avoidance of formulations containing both antifungal and steroid creams is usually prudent, as the steroid component may cause prolonged duration of the moniliasis [4].

Tinea Versicolor

General Principles

Tinea versicolor is a commonly encountered infection of the skin, whose name originates from the fact that the affected skin has a different color in the summer than in the winter.

Epidemiology It is caused by dimorphic lipophilic yeast, *Pityrosporum ovale* and *Pityrosporum orbiculare*, together previously called *Malassezia furfur*, that thrives best in the stratum corneum and hair follicles of sebaceous-rich skin.

Diagnosis

History and Physical Exam The characteristic appearance of the rash is an area of cape-like confluence, usually over the shoulders and upper chest, with a reticular border of multiple oval macules of varying size. In the winter months, Caucasians will be found to have a slightly scaly, light brown rash; in the summer, the same individual will present with white oval to circular patches that stand out against the tanned skin – hence the name "versicolor." While the upper chest is most often involved, the rash may extend to the upper arms, neck, and abdomen. The rash may be slightly itchy, but is usually asymptomatic.

Laboratory The clinical diagnosis can be confirmed by lightly scraping the lesions with a #15 knife blade, producing a powdery scale (Fig. 6). A potassium-hydroxide preparation of the scale will demonstrate the classic "meatball and spaghetti" appearance of the hyphae and spores.

DOI 10.1007/978-1-4939-0779-3_123-1

Fig. 6 Powdery scale noted on scraping with #15 knife blade. KOH shows "meatballs & spaghetti"

Treatment

For limited disease, topical antifungals, such as ketoconazole 2 %, are highly effective and still the treatment of choice. For extensive rashes or failures of topical treatments, oral antifungals of the azole class have proven to be effective.

Infestations

Lice/Pediculosis

General Principles

Lice are obligate human ectoparasites that feed by piercing the skin with their claws and ingesting the blood, causing an itchy reaction in the skin of the patient. They live at the border of skin and hair and are visible as a 1–2-mm mobile insect. Females lay 0.8-mm eggs (nits) that are glued firmly to the hair shaft. After an 8–10 day incubation, the larvae hatch and mature. Live nits will be found within the first ¼ inch of a growing hair, but empty nits will remain attached to hairs for months.

Epidemiology There are three main species of lice: *Pediculosis capitis* or head lice, *Pediculosis corporis* or body lice, and *Pthirus pubis* or pubic lice. Pubic lice are the most contagious of sexually transmitted diseases, with a 90 % chance of acquisition with only one exposure. Head lice are most commonly seen in school children and are the focus of greatest attention by parents, school nurses, and physicians.

Diagnosis

The diagnosis is made by demonstrating lice or by combing the hair with a fine-toothed "nit comb."

DOI 10.1007/978-1-4939-0779-3_123-1

Treatment

Growing resistance of lice has occurred to the most commonly used chemicals, permethrin 1 % (Nix) and pyrethrins 0.3 % and piperonyl butoxide 4 % shampoo (RID). These over-the-counter preparations are now often effective in only about 45 % of patients. Permethrin is considered the first choice, can be used in patients 2 months and older, and is least expensive. Malathion (Ovide) 0.5 % lotion is used in treatment failures but is much more expensive and cannot be used in children under 6 years of age [21]. Parents uneasy with insecticide use can utilize the nonpharmacologic techniques of wet-combing or application of Cetaphil in a dry-on suffocation-based treatment plan. While questions have been raised about study design, Pearlman reported a 95 % eradication rate in patients who had failed other treatments using this simple and inexpensive technique [22]. Treatment for body and pubic lice is similar. Ivermectin (Stromectol) 200 mcg/kg orally with a second dose repeated in 10 days is also effective for all types of lice and can be used on patients $\geq$ 15 kg at a cost of approximately $10–$30 per dosage [23].

Scabies

General Principles

Scabies is an intensely pruritic infestation caused by the mite *Sarcoptes scabiei*. It is the most common of infestations and is highly contagious. Close personal contact, as within households or nursing homes, will result in rapid spread. The initial symptoms begin insidiously with one or two mildly itchy sites. The fertilized female mite burrows into the stratum corneum and, through her 30-day life cycle, continues to burrow up to several centimeters. Along the way, she leaves a path strewn with eggs (at a rate of 1–3 per day) and fecal pellets (scybala). The eggs hatch and the larvae mature within 2 weeks. The adult forms mate, and the cycle is repeated. Meanwhile, the discarded scybala and egg casings prompt an extremely pruritic allergic rash at the sites of infestation. The deceptively slow start of the disease, lasting up to a month, is rapidly replaced by a widespread, intensely itching rash as the mites multiply exponentially causing papules, vesicles, and burrows.

Diagnosis

The diagnosis can be confirmed by scraping a burrow and finding egg casings, eggs, scybala, or mites (Fig. 7). Mites are less frequently seen in the usual cases of scabies. Only in crusted (Norwegian) scabies

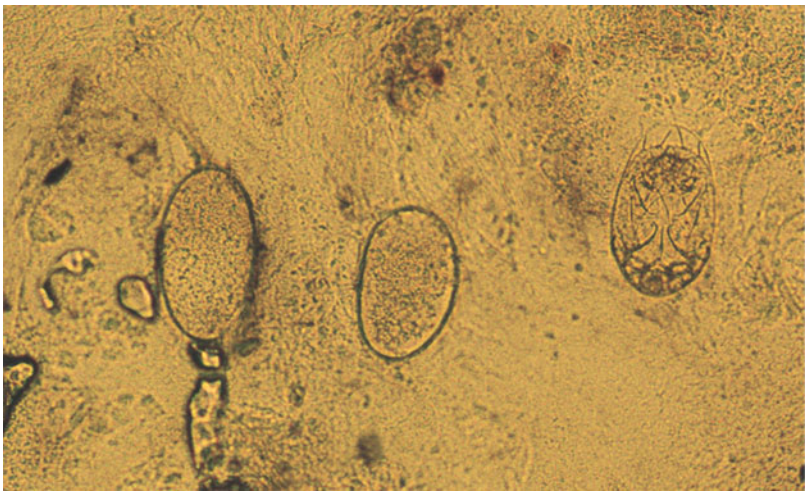

Fig. 7 *Sarcoptes scabiei*, wet mount of KOH prep

DOI 10.1007/978-1-4939-0779-3_123-1

are there hundreds or thousands of mites. It is an uncommon form and is found in patients with immune deficiencies, mental disorders, or the elderly.

Physical Examination Sites of infestation are classically the hands, feet, wrists, axilla, waistline/abdomen, and genetalia. Infants and children may have greater number on the palms and soles. Nocturnal itching is classic, and if left untreated, the infestation can last for years.

Treatment

Scabies is treated with permethrin 5 % (Elimite) cream, the drug of choice. All members of the household should be treated, regardless of symptom presence. One application is considered curative, although many practitioners repeat the treatment in 1 week. Oral Ivermectin (Stromectol) is another first-line treatment option. It is usually chosen for treatment failures, the elderly, or those unable to complete topical therapy. Treatment for crusted scabies requires dual regimens of topical permethrin and oral Ivermectin as well as special environmental measures [21].

Patient Education All clothing and personal items should be washed in hot water and dried in a hot dryer. It is important to inform patients that itching usually improves shortly after treatment, but persists for 3–4 weeks thereafter.

Chiggers

General Principles

Chiggers, also known as the harvest mite or red bug, are bites from the barely visible Trombicula mites causing an irritating and very itchy rash.

Diagnosis

History and Physical Examination Bite sites are most often near the ankles and legs, but can occur in skinfolds, especially in the groin, axilla, or waistline. The itching is most severe for the first 1–2 days and resolves spontaneously in 1–2 weeks afterwards.

Prevention

Bites can be prevented by use of proper clothing and any DEET-containing repellants.

Delusional Parasitosis

General Principles

Delusional parasitosis is a psychodermatologic condition in which the patient is firmly convinced of an infestation with some type of organism and uses destructive measures (scratching, gouging, shaving) on the skin to combat the problem. The condition may last for years, and others within the patient's orbit (spouse, child) may also become convinced of its existence (termed *folie à deux*).

DOI 10.1007/978-1-4939-0779-3_123-1

Diagnosis

History and Physical Examination The patient classically presents to their PCP with symptoms of a crawling or itchy sensation for months or years. They usually bring with them "evidence" of the infestation, called the "matchbox sign," in which pieces of skin and debris they have removed are placed in tissue paper and placed in a container, such as a matchbox or plastic baggies. Skin exam reveals numerous active and healing excoriations in reachable anatomic sites and no lesions in unreachable areas.

Treatment

Treatment requires the investment of time to listen attentively and empathetically to the patient's complaint to establish rapport. A systematic evaluation is required to ensure there really is no infestation. Often the symptoms persist, and the use of low-dose atypical antipsychotic medications is required for resolution [24].

Referrals Referral to psychiatry may be a useful adjunct, but the patients often refuse the referral as unnecessary and an implication of the physician's lack of belief in their symptoms and needs.

Cat Scratch Disease (CSD)

General Principles

Cat scratch disease is an illness caused by *Bartonella henselae* and characterized by unilateral adenopathy, malaise, anorexia, aches, and a moderate to low-grade fever. It is most often seen in children, but can be present in adults. It is usually a benign, self-limited disease, although rarely it can cause ophthalmic complications or neurologic symptoms. Over 90 % of patients have a history of contact with a cat or kitten. The bacteria is passed from pet to owner by scratches or bites.

Diagnosis

The diagnosis of cat scratch disease can be confirmed by the combination of a history of exposure to cats, lymphadenopathy, and elevated antibodies to *B. henselae*.

Physical Examination A red papule or vesicle is often found on the hand, which, in contrast to insect bites, is non-pruritic. As the vesicle heals, regional adenopathy (usually ipsilateral) occurs. Persistent lymphadenopathy, which is often the presenting symptom, usually resolves in 1–6 months.

Treatment

Treatment is usually unnecessary [4].

Bedbugs

General Principles

Bedbugs (*Cimex lectularius*) are small, light-aversive insects that hide near beds and obtain blood meals from humans while they sleep. They are found worldwide and have undergone a significant resurgence in the past decade, most likely due to expanded travel and increasing resistance to current insecticides. Cimex saliva, which incites the post-bite rash and evokes a wide variety of responses from their victims, is injected into the skin at the bite site. The host reaction is usually an intensely pruritic maculopapular rash, although papules, wheals, and vesicles have been reported.

DOI 10.1007/978-1-4939-0779-3_123-1

Diagnosis

Confirmation requires a careful examination of the sleeping premises. Molted exoskeletons, dark granular feces, eggs, and debris all can be found within a few feet of the sleeper. These sites are often in mattress seams, headboards, wall hangings, peeling wallpaper, or other similar sites [25].

Physical Examination Bite sites are found on exposed skin. The classic linear three-bite presentation, "breakfast, lunch, and dinner," should suggest the diagnosis of bedbugs.

Treatment

Bite treatment is aimed at relief of the itching with topical steroids or oral antihistamines. The rash is self-limited, resolving in 1–2 weeks.

Patient Education Eradication of an infested site can be frustrating and costly. An integrated pest management strategy is recommended by the Centers of Disease Control and Prevention (CDC) as well as the Environmental Protection Agency (EPA) to eliminate infested sites. The EPA and CDC have web sites with features that answer frequently asked questions (FAQs) as well as information on the life cycle of the insects and methods of control.

Myiasis (Botfly)

General Principles

Cutaneous myiasis (botfly infestation) occurs when eggs of a human botfly, *Dermatobia hominis*, are deposited into the skin of the host. The botfly itself does not bite, but uses other biting insects to transmit its eggs by a process called phoresis. Infestation is most commonly seen in late summer or fall, frequently in travelers who have visited Central or South America.

Diagnosis

History and Physical Examination Clinically, the patient presents with a red papule that can appear on any exposed skin surface. As the larvae grows in the subcutaneous tissue, an air vent into the skin is created and the larvae rise up every minute or so for oxygen, causing a sensation of movement within the skin.

Treatment

Treatment consists of recognition of the condition and removal of the larvae [4].

Skin Tumors

Alexandra Verdieck-Devlaeminck*
Oregon Health and Science University, Portland, OR, USA

General Principles

Skin tumors encompass both benign and malignant entities; some tumors will self-resolve, while others may require treatment. Currently there is no overwhelming recommendation for universal screening for skin cancer. The United States Preventive Services Task Force (USPSTF) [1] concludes that "the current evidence is insufficient to assess the balance of benefits and harms of using a full body skin exam by a primary care clinician or patient self examination for the early detection of cutaneous melanoma, basal cell cancer, or squamous cell skin cancer in the adult general population." Grade I. The USPSTF was unable to detect any harm of screening. Many physicians perform a skin exam during the regular physical examination, and others will ask patients if there has been a history of a mole change or other skin concerns and tailor their exam to the patient's history. The patients most likely to benefit from screening are those that would be considered high risk. High-risk patients tend to be fair-skinned individuals over age 65, patients with atypical moles, and patients with more than 50 moles, personal history of excessive sun exposure, tanning bed use, or skin cancer in the family. Most screening is aimed at early detection of melanoma as early detection can alter the course of the disease.

Approach to the Patient

History

The important aspects of history include duration of the lesion, change in appearance, symptoms, and history of trauma. Patients' pertinent past medical history may include history of sun exposure, medications (including immunosuppressives), and family history of certain skin tumors.

Physical Examination

The physical examination should include observation for all characteristics of a lesion. Pigment components can range from tan to brown to black. Vascular characteristics may include different shades of red, purple, or black, the shape of the blood vessels (such as branched atypical vessels in basal cell carcinomas), and the ability of the lesion to blanch with pressure. Skin tumors can differ by location of the lesion in relation to the epidermis such as it is atop the skin (seborrheic keratosis), within the skin (junctional nevus), or under the skin (lipoma). Furthermore, some skin tumors are more common in damaged skin, and examining the surrounding skin for sun damage or scarring is an important aspect of the exam. Using a dermoscope to further elucidate surface characteristics such as vascular formations and pigment distribution can be very helpful in diagnosing skin tumors. In some cases photographing a low-risk skin lesion and providing surveillance can be helpful.

Biopsying a skin tumor may be necessary to determine diagnosis, while at other times diagnosis may be obvious with a good physical examination. Alternatively patients may request removal or biopsy for

*Email: verdieck@ohsu.edu

DOI 10.1007/978-1-4939-0779-3_124-1

reassurance or cosmetic reasons. Referral may be the wise choice in lesions that are difficult to diagnose or when biopsy may require specialized skills like Mohs surgery.

Keratosis

Seborrheic Keratosis (SK)

General Principles

Definition SKs occur as a focal proliferation of epidermal cells; there can be varying amounts of hyperpigmentation, and keratinocytes secrete substances that increase pigmentation (Fig. 1). Leser-Trelat sign [2] is when a patient develops numerous SKs suddenly; it is associated with internal malignancy such as carcinoma of the GI tract.

Epidemiology SKs are commonly found only in patients over 30, equally in male and female patients. Incidence increases with older age.

Classification Irritated SK is a variant that appears redder and histologically looks irritated.

Diagnosis

History Most patients will describe a slow-growing lesion that has become progressively larger and darker over time. Some patients record being able to scratch it off but it will recur. They typically cause no symptoms; however, they can become irritated by friction.

Physical Examination SKs are 4 mm to 2 cm oval lesions, and color can range from pink to the more common tan and dark brown. They typically appear as rough and dry stuck-on lesion on the top of the skin. Commonly they have a waxy or oily feel. Patients may have multiple lesions especially on the chest and back. Inflamed lesions can have a redder color. When examined with a dermoscope, the surface characteristics of retained keratin cysts can be seen that look like milia and comedo-like openings or a cerebriform (brainlike) appearance [3].

Special Testing Atypical SKs should be removed by shave or elliptical excision. On occasion biopsy may be necessary for lesions that appear irritated or scabbed.

Differential Diagnosis Solar lentigo, malignant melanoma, squamous cell carcinoma, pigmented actinic keratosis, and pityriasis rosea.

Treatment

Therapy is generally not needed for most lesions, and reassurance is typically adequate. Cryosurgery can be used for shallow lesions but may result in hypopigmentation. For patients who want them removed, a shave biopsy, cautery, or curettage can be done but may result in scarring.

Referrals Dermatology consultation can be useful for patients who want extensive treatment.

Counseling Patients who request treatment should be warned of possible hypopigmentation or scarring.

Patient Education Reassurance can help patients understand that these are benign lesions, but they will likely remain or may grow.

Sunscreen should be recommended to prevent further skin damage.

DOI 10.1007/978-1-4939-0779-3_124-1

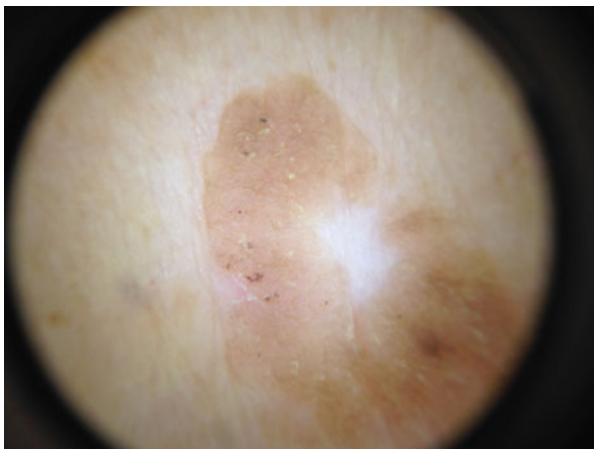

Fig. 1 Early seborrheic keratosis with typical stuck-on appearance and developing milia and comedo-like openings commonly seen under dermoscopy

Actinic Keratosis (AK) aka Solar Keratosis

General Principles

Definition Actinic keratosis are very common nonpigmented lesions (Fig. 2). They consist of atypical keratinocytes that have partially invaded the epidermis. AKs occur after repeated or prolonged sun exposure in susceptible patients leading to skin damage and inability for the body to repair. They are considered premalignant as some may develop into squamous cell carcinoma (SCC) at a rate of 6 % over a 10-year duration [4].

Epidemiology AKs occur in patients over the age of 40, more common in males and patients with fair skin and outdoor occupations. Seventy-five percent of people over 80 are affected. They can develop in younger patients who get a lot of sun exposure.

Approach to the Patient

Diagnosis

History Patients will complain of a red or scaly spot that has been present for months to years. They often will pick or attempt to scratch it off, but it will always reform. Rarely they will cause pruritus or burning.

Physical Examination Lesions are typically found in sun-damaged skin or areas of sun exposure. AKs are generally 3–10 mm in size and may be red or yellow in color with an adherent scale. They will feel rough to the touch. Commonly affected areas are the face, ears, scalp, neck, forearms, and hands.

Special Testing Biopsy should be done in thicker lesions when the diagnosis is unclear and SCC is in the differential.

Differential Diagnosis SCC, seborrheic keratosis, eczema, basal cell carcinoma.

Treatment

Therapy is usually recommended to prevent progression to SCC [5].

Cryotherapy applied for 5–10 s will cure over 75 % of lesions. Surgical curettage and electrodesiccation are more effective for thicker lesions.

DOI 10.1007/978-1-4939-0779-3_124-1

Medications

Topical fluorouracil (5FU) 5 % cream is applied twice daily for 2–4 weeks. Patients will experience local irritation at the site during treatment [5]. Topical imiquimod 5 % cream is applied once daily up to three times a week for 16 weeks and will also cause local irritation. Topical diclofenac applied twice daily for three months is effective in approximately 50 % of subjects but is limited by local side effects. Chemical peels are also effective.

Photodynamic therapy with sensitizing agents is also effective.

Referrals Dermatology consultation may be needed in extensive cases.

Counseling Patients should be counseled that hypopigmentation, scarring, and hair loss may occur with cryotherapy. Topical therapies may have a lot of irritating side effects during treatment.

Patient Education Patients should be advised to protect themselves from the sun through clothing and sunscreen. Regular skin exams should be performed as patients with AKs may be more likely to get other types of skin cancer.

Pigmented Lesions

Nevus (Common Mole)

General Principles

Definition A nevus is a confined nest of melanocytes within the skin.

Epidemiology Nevi are acquired in childhood and young adulthood, and new moles that develop in later adulthood should be viewed with caution.

Classification

Dermal/Intradermal A nevus that is raised above the epidermis; it may be flesh colored or pigmented.

Junctional A nevus with cells at the dermoepidermal junction.

Compound A nevus with raised pigmented cells in the dermis and dermoepidermal junctions.

Dysplastic (Clark's Nevus) Nevi that are irregular-appearing moles with an uneven distribution of melanocytes giving them a nonuniform appearance. Histologically they are compound nevi with

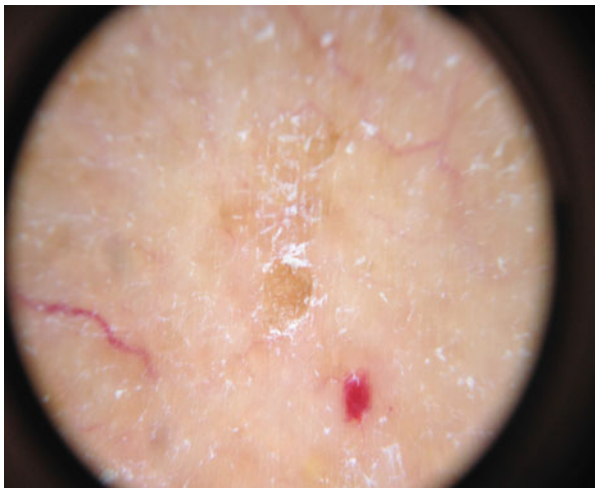

Fig. 2 Actinic keratosis seen centrally through polarized dermoscopy; the surrounding skin is sun damaged and cherry angioma also visible at 5 o'clock

DOI 10.1007/978-1-4939-0779-3_124-1

Table 1 Three-point checklist – dermoscopy

Nevus	Melanoma
Regular pigment network	Irregular pigment network
Symmetry of color/structure	Asymmetry of color or structure
No blue or white coloring	Blue or white coloring

melanocytes that are irregularly distributed. The familial atypical mole and melanoma syndrome (FAMM) [4] is a condition occurring in patients with many nevi – some atypical – and first or second degree relative with melanoma; FAMM vastly increases a patient's risk of developing melanoma.

Congenital Nevus A mole that is present at birth and may be very large. There is a small increased risk of melanoma especially in larger or nonuniform lesions (Fig. 3).

Blue A nevus having a blue or black appearance as the melanocytes are concentrated deep in the dermis.

Halo Nevi A growing nevus surrounded by an area of hypopigmentation which is an inflammatory response. They are typically found in adolescents and the halo resolves with time.

Spitz Nevus/Spindle Cell Nevus A reddish papule found in children; development in adults is a concern for melanoma.

Nevus Spilus A group of speckled darker brown spots within a larger tan/brown macule.

Approach to the Patient

Diagnosis

History The physician should inquire about any recent changes in moles. Sun exposure history and family history of melanoma should be asked.

Physical Examination Nevi can be quite variable in appearance. Color can vary from flesh colored to pink, tan, dark brown, blue, or black.

The physician should visually inspect the skin to see if there is a regular identifiable pattern that defines one of the benign nevus types. In addition many patients have similar characteristics to their moles and a different-looking mole commonly termed the "ugly duckling" should raise suspicion. Dermoscopy is helpful in reassuring the patient that the skin lesion looks very regular. The three-point checklist [3] can help the physician determine if a lesion is more likely to be a nevus versus a melanoma (Table 1).

If 2 of 3 or 3 of 3 melanoma criteria are present, the physician should biopsy the lesion.

Special Testing A biopsy should be performed on any suspicious lesion. Shave biopsy is acceptable in a low-risk thin lesion or likely dermal nevus. Excisional biopsy is recommended if melanoma is in the differential.

Differential Diagnosis Melanoma, seborrheic keratosis, solar lentigo.

Treatment

Therapy typically consists of observation and reassurance. Patients may request removal due to recurrent irritation (dermal nevi) or for cosmetic reasons. Depending on the type of nevus, biopsy methods will differ. A shave biopsy may be useful for a dermal nevus that is growing above the skin surface or for a thin nevi. Punch biopsy is appropriate for small lesions 5 mm or less.

DOI 10.1007/978-1-4939-0779-3_124-1

Behavioral

Medications Prescription and over-the-counter creams are not indicated nor effective in removing nevi.

Referrals Dermatology consultation is indicated for very large nevi or patients that may have multiple dysplastic nevi or suspicious nevi that the physician may feel uncomfortable biopsying.

Counseling Patients should be warned that removal may result in scarring or keloid formation in susceptible patients.

Patient Education and Activation Patients should be reminded to protect their skin with sunscreen and clothing. Moles that are changing or bleeding should be brought to the attention of the physician; the ABCDE rules [6] are a good guide:

ABCDE

(A) **Asymmetry**
(B) **Border irregularity**
(C) **Multiple colors**
(D) **Diameter greater than 5 mm/quarter inch**
(E) **Evolving – change in size, shape, or color**

Solar Lentigo/Actinic Lentigo (Liver Spot)

General Principles

Definition Lentigines are acquired pigmented skin lesions caused by sun damage. They are commonly found on sun-exposed areas such as the face, neck, and extremities [4]. Histologically there is an increase in melanocytes and keratinocyte hyperpigmentation [2]. They are considered an adult variant of the freckle. However, they do have the capacity to change and undergo malignant transformation to the melanoma form lentigo maligna melanoma.

Epidemiology Lentigines typically occur in patients over the age of 40 and are more common in Caucasians who have had significant sun exposure and on sun-exposed areas.

Classification

Inkpot Lentigo Uniformly dark black-pigmented lesion with irregularly dispersed pigment.

Peutz-Jeghers Syndrome Multiple mucus membrane lentigines – associated with intestinal polyps.

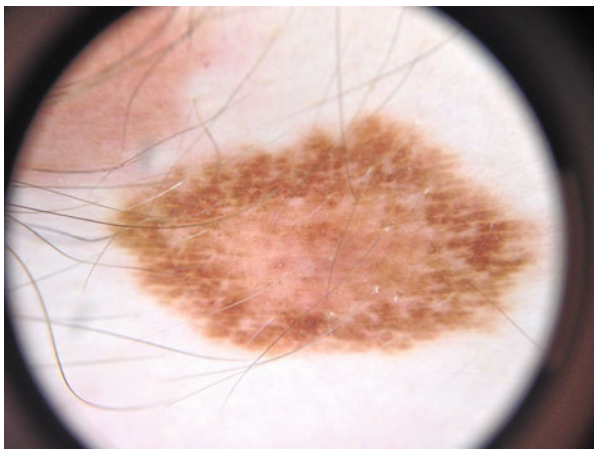

Fig. 3 This congenital nevus in a 45-year-old male measured 2 cm and had never changed

DOI 10.1007/978-1-4939-0779-3_124-1

Lentigo Maligna (LM) It is the in situ malignant variant – a lentigo that has transformed to a superficial spreading melanoma/melanoma in situ.

Approach to the Patient

Diagnosis

History Most patients will report noticing brown spots on sun-exposed areas; the spot becomes darker upon sun exposure and may lighten during the winter months. Patients typically report developing more of the spots as they age.

Physical Examination The physician will see a tan to dark brown to black blotchy macule ranging in size from 2 to 20 mm. Common affected areas are the sites of most frequent sun exposure: the back, face, lips, dorsum of hands and forearms, and anterior legs in women. Dermoscopy can be helpful to see if the pigment is evenly distributed within a lesion or abnormally concentrated which can be a sign of developing malignancy [3].

Special Testing Biopsy should be performed on a lesion that is changing or has a large variation in color. Punch biopsy can be performed in an irregular area of large lesions, while elliptical excision is desirable when possible.

Differential Diagnosis Melanoma, nevi, lentigo maligna, lentigo maligna melanoma, pigmented actinic keratosis, flat seborrheic keratosis.

Treatment

Cryotherapy may be done on small lesions; it works variably and can lead to hypopigmentation.

Medications Treatment is not necessary, but if desired, medications to bleach the skin can be used but typically take many weeks to work. Hydroquinone 4 % cream bid, azelaic acid 20 % cream bid for 2–4 weeks, and glycolic acid peels are all somewhat effective.

Referrals Dermatology consultation may be warranted in lesions that are undergoing rapid change or have very irregular borders that the physician does not feel comfortable biopsying.

Counseling Patients should be warned that some treatments may result in uneven bleaching or thus skin or temporary irritation.

Patient Education and Activation Patients should observe lesions for change. Sunscreen, hats, clothing, and sun avoidance can prevent lentigines from forming.

Malignant Skin Lesions

Melanoma

General Principles

Definition Melanoma is the type of skin cancer characterized by irregular melanocytes growing in an irregular pattern. Melanomas may arise in preexisting nevi or arise de novo. They can spread locally through lymphatic extension or by hematogenous dissemination to the lungs, liver, and other organs.

Epidemiology Melanomas account for but cause 5 % of skin cancers and most skin cancer deaths. Its incidence is increasing with 76,000 new cases per year with almost 10,000 deaths per year [7]. Most cases are in elderly males; however, it is the most common cancer in young adults. There is a slight female predominance in superficial spreading types and lentigo maligna melanoma in elderly patients. In males the most commonly affected areas are the trunk, head, and neck and in females the extremities.

DOI 10.1007/978-1-4939-0779-3_124-1

Classification

Superficial Spreading The most common type; the melanoma is slowly growing horizontally usually originating from a preexisting nevus.

Nodular They are raised brown/black rapidly growing lesions, often with red elements and hemorrhage or ulceration.

Lentigo Maligna Melanoma A thin horizontally spreading lesion arising from a lentigo in a sun-exposed area.

Acral Melanoma A palmar or sole melanoma more common in African Americans and Asians.

Nail Melanoma A rare type of melanoma arising from the nail matrix causing an irregularly pigmented streak in the nail.

Amelanotic Melanoma A nonpigmented melanoma, these should be suspected in a growing lesion that is not easily identifiable as another type of skin lesion (i.e., dermatofibroma); the common saying is "if it's pink stop and think."

Approach to the Patient

Diagnosis History The patient may note that a lesion has changed in appearance over time. Symptoms may include itching, scabbing, or bleeding. Medical history may include certain risk factors such as advanced age, sun exposure, sunburns at young age, pale pigmentation, sun-tanning bed use, immunosuppression, multiple nevi, atypical nevi, or family history of melanoma.

Physical Examination Melanomas usually have visible discoloration, multiple colors, uneven pigment, or ulceration. Areas of uneven pigment can include darker black coloring or loss of coloring (regression). Dermoscopy can be a valuable tool for assisting the physician and differentiating between nevi and melanoma by magnifying the lesion further revealing pigment pattern characteristics, asymmetry, and recession. Area lymph nodes should be palpated when melanoma is suspected.

Laboratory and Imaging Ancillary testing is generally not recommended unless the tumor has metastasized in which case chest x-ray (CXR) and CT scan may help with staging.

Special Testing Suspected melanoma should be biopsied preferably with an excisional biopsy typically with 2–4 mm margins. On extremities the biopsy should be oriented along the longitudinal axis. Lesions suspicious for nail melanoma should include the nail matrix and may be best left to a physician with experience in biopsying the nail bed. Deep shave biopsy may be acceptable in cases where there is a low suspicion for melanoma, and complete removal will take place with the shave, e.g., a thin lesion. A punch biopsy may be acceptable in cases where the entire lesion cannot be removed, rapid diagnosis is needed, or in a sensitive area such as in facial or acral locations. In case a large partial biopsy is necessary, it should be performed on the most atypical portion of the lesion, and the physician should understand that there will not be reliable depth reporting from the biopsy report.

Pathology guides treatment and further workup [7, 8]. Staging depends upon several characteristics of the lesion. The Breslow maximum tumor thickness measures how deep the malignant cells invade the dermis. The mitotic rate – mitoses per mm squared – and presence or absence of ulceration are all reported in the pathology report and are important prognostic indicators. The Clark level of anatomic invasion and microsatellite tumor is also important. Sentinel node biopsy is often recommended for melanomas greater than 1 mm thickness and its results may determine prognosis.

Differential Diagnosis Nevi, dysplastic nevi, seborrheic keratosis, solar lentigo, inflamed SK, pyogenic granuloma, pigmented BCC, dermatofibroma, hemangioma.

Treatment Therapy after biopsy usually includes further excision; it is guided by tumor thickness (Table 2).

DOI 10.1007/978-1-4939-0779-3_124-1

Table 2 Breslow thickness and re-excision margin

	Breslow depth	Re-excision margin
Melanoma in situ	Only involving epidermis	0.5 cm
Melanoma	<1.0 mm	1 cm
Melanoma	1.01–2.0 mm	1–2 cm
Melanoma	>2.0 mm	2 cm

Medications Melanoma vaccines have been developed and may be used by oncologists as adjuvant therapy.

Referrals Consultation with a dermatologist or oncologist who treats malignant melanoma is recommended, especially if such treatments with interferon and other immunotherapy are considered.

Lentigo maligna melanoma lesions can be difficult to excise in total due to their large size, so off-label treatments such as topical imiquimod and radiation therapy are often employed by specialists.

Counseling Prior to biopsy and re-excision, patients should be warned of the possibilities of poor healing and scarring as well as the possibility of incomplete removal.

Patient Education Patients should be reminded to assess skin lesions for change and schedule regular skin exams. They should be encouraged to limit sun exposure and protect themselves with the use of sunscreen and clothing.

Basal Cell Carcinoma

General Principles

Definition Basal cell carcinoma (BCC) is the most common type of skin cancer. It originates in the keratinocytes of the basal layer of the epidermis. It can locally invade but rarely metastasizes.

Epidemiology BCC occurs in older patients typically on sun-exposed skin, more commonly in Caucasians with fair skin.

Classification

Nodular These are the most common and can be pigmented or nonpigmented.

Superficial BCC These are oval thin flat scaling lesions.

Sclerotic/Morpheaform These are rare and appear flat/scar-like and can be difficult to treat.

Approach to the Patient

Diagnosis

History Most patients will report a slowly growing lesion that may ulcerate or scab.

Physical Examination BCCs are commonly pink or white pearly nodules 3 mm to 1 cm in size, with crusting or bleeding. They are most frequently on sun-exposed areas such as the head and neck. The surrounding skin typically shows evidence of chronic sun exposure. Dermoscopy can be useful in identifying BCC as commonly one will see branching blood vessels on the surface (Fig. 4).

Special Testing Biopsy through an excisional or shave biopsy is needed for diagnosis. For excisional biopsy 1–3 mm margins are preferred in areas where there's sufficient skin to close the wound. Shave biopsy may be necessary on areas of the face or scalp where skin preservation is important. However, if performing a shave biopsy, the physician must prepare the patient that if the pathology returns as a BCC another procedure may be necessary.

Treatment If the lesion is excised in total, no further treatment is necessary [9]. Curettage and electrodessication can be performed on incompletely removed BCC. Mohs surgery is a treatment typically

DOI 10.1007/978-1-4939-0779-3_124-1

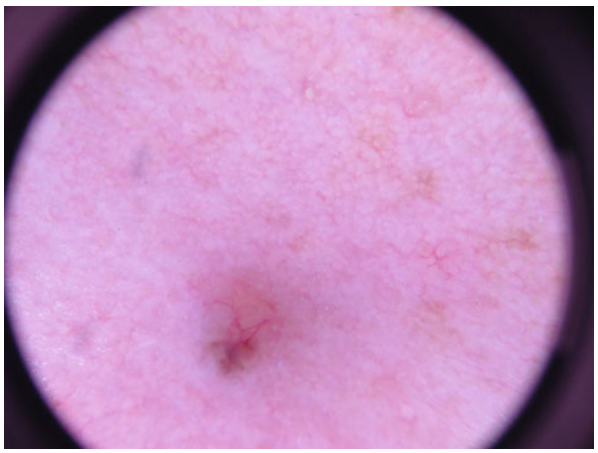

Fig. 4 Pigmented BCC under dermoscopy; branched vessels and irregular blotches of pigment seen

done at a specialist's office where successive layers of tumor are removed then immediately examined under the microscope until the last layer is free of all tumors. The procedure may be necessary in cosmetically sensitive areas such as the face or when tumors have recurred in the same area. Mohs is expensive and time consuming and may not be available in all areas. Surveillance for all removed BCCs should be performed as 5 % of treated lesions will recur.

Radiation therapy may be done in difficult-to-treat lesions such as large extensive lesions or as a palliative treatment when surgery is unlikely to occur. Photodynamic therapy can also be used in which topical photosensitizing agents are applied to the tumor followed by light therapy.

Cryotherapy has been used to treat very thin lesions.

Medications 5FU can be used to treat superficial BCCs; it causes an inflammatory response which destroys the BCC.

Imiquimod (Aldara) 5 % applied daily for 6 weeks can be used to treat superficial BCC. It causes severe inflammation which in turn destroys the BCC.

Counseling Patients should be counseled that biopsy may result in scarring and there is a small change of recurrence even with complete removal.

Patient Education Patients should be advised to protect themselves from the sun with sunscreen, UV-obstructing clothing, and hats.

Squamous Cell Carcinoma (SCC)

General Principles

Definition Squamous cell cancer is a skin cancer that arises when atypical keratinocytes invade the epidermis [10]. Most SCCs are highly curable with appropriate treatment, but certain types have a predilection to metastasize through lymph channels [11]. The rate of metastasis is 2–6 % [10].

Epidemiology SCC tends to occur in Caucasians with fair skin and occur on the face, neck, head, and hands. SCCs are also common in transplant patients who are on immunosuppressants. They tend to develop in areas of preexisting damage to the skin from sun, radiation, arsenic, burns, scars, and presence of the HPV [12]. Actinic keratoses are the precursors of SCC where the atypical keratinocytes have partially invaded the epidermis.

DOI 10.1007/978-1-4939-0779-3_124-1

Classification

Bowen's Disease SCC in situ that has not invaded past the epidermis.

Keratoacanthoma These are a low-grade variant of SCC that develop suddenly and have a central core of keratin.

Oral SCC It is a more aggressive type of SCC.

Erythroplasia of Queyrat Penile SCC It often appears ulcerated and is related to the HPV virus.

Vulvar SCC Vulvar SCC is a variant that arises from the HPV virus. It is more common in immunocompromised hosts.

Approach to the Patient

Diagnosis History Most patients will report a nonhealing scab or flaky area of several months or more duration.

Physical Examination Most lesions will appear as a thin pink plaque or nodule with an adherent scale. The surrounding skin will often show sun damage. The nearby area and lymph nodes should also be examined.

Laboratory and Imaging CT of the area may be necessary to image lymph nodes in high-risk lesions such as oral SCC.

Special Testing An excisional biopsy of the lesion with a 4 mm margin is the gold standard as the specimen can be assessed for complete removal of the cancer. This can be accomplished during the original excisional biopsy. High-risk SCCs may have microscopic spread and Mohs surgery may need to be performed to assess for invasion.

Differential Diagnosis Actinic keratosis, superficial BCC, lichen planus.

Treatment Therapy for small well-defined SCC is complete with the original excisional biopsy if pathology reveals clear margins. High-risk SCCs may have microscopic spread, and Mohs surgery may need to be performed to assess for invasion [12]. If a low-risk SCC extends to the margin of a biopsy specimen, a repeat excision or curettage + electrodessication must be performed.

Mohs surgery is indicated for high-risk lesions or SCC that would be difficult to remove completely by traditional surgical excision. Mohs is ideal for difficult-to-treat areas, such as the eyes, lips, nose, and ears.

Curettage and electrodessication alone can be used to remove small well-defined SCCs less than 1 cm in size.

Cryosurgery can also be used for small well-defined low-risk tumors by experienced physicians; it is not acceptable for high-risk or recurrent tumors.

Radiation treatment is used to decrease tumor size in areas where resecting the lesion would be technically difficult. Cosmetic problems such as telangiectasia can occur, so it is not recommended in younger patients.

Photodynamic therapy is under investigation as a potential treatment.

Medications 5FU is being tested for treatment of superficial SCC.

Referrals Dermatology consultation is prudent for high-risk lesions, large lesions, or those requiring Mohs surgery.

Counseling Patients should be advised of scar potential prior to removal of tumor.

Patient education Patients should be advised that SCCs may recur, and they should have follow-up exams. Sun avoidance and protection with sunscreen and clothing should be done.

DOI 10.1007/978-1-4939-0779-3_124-1

Keratoacanthoma

General Principles

Definition Keratoacanthomas are thought to be variants of squamous cell carcinoma that arise from the hair follicle of the skin. They are made up of atypical keratinocytes that form a central plug. They can develop quite rapidly but are considered a nonaggressive form of skin cancer in that they rarely go on to spread local damage [13]. Their development is related to sun exposure.

Epidemiology Keratoacanthomas occur more commonly after age 50 and in people with fair complexions. The lesions typically develop in areas of the skin that have been previously damaged by sun or injury like the face, neck, and extremities.

Approach to the Patient

Diagnosis History A patient may report a tender nodule forming over a period of weeks to months typically starting as a small pimple then enlarges.

Physical Examination The tumors are 5 mm to 2 cm flesh-colored dome-shaped nodules with a central appearing keratin plug or necrosis.

Special Testing Biopsy is recommended to determine if the lesion is a keratoacanthoma or a more aggressive type of squamous cell carcinoma.

Differential Diagnosis Aggressive SCC, sebaceous cyst, molluscum, epidermal inclusion cyst, dermatofibroma.

Treatment Removal of the entire lesion is warranted and is typically done best by excisional biopsy. If a lesion is large, a partial shave may be acceptable with complete excision necessary if pathology shows a squamous cell carcinoma. An incomplete excision will require follow-up curettage and electrodesiccation.

Referrals Dermatology or general surgeon consultation is advisable with a very large lesion or one in a technically difficult area.

Counseling Patients should be warned of potential scarring or incomplete removal prior to performing excision.

Patient Education and Activation Patients should be advised to use sun protection with sunscreen and clothing.

Vulvar SCC

General Principles

Definition Vulvar SCC is a variant of SCC that typically arises from the HPV virus [14]. It is often discovered late in its course and has the potential to metastasize.

Epidemiology Vulvar SCC occurs in females over 35, more commonly in patients exposed to HPV, immunocompromised, or with preexisting skin conditions of the vulva area.

Classification

Keratinizing Non-HPV-associated SCC that is more likely to have ridges or crusts on physical examination.

Bowenoid HPV-associated flat thickened SCC.

Vulvar Intraepithelial Neoplasia (VIN) In situ vulvar SCC.

DOI 10.1007/978-1-4939-0779-3_124-1

Approach to the Patient

Diagnosis History Many patients may report no symptoms or itching, pain, and bleeding. They may notice ulcers, vaginal discharge, or dysuria. Patients may be reluctant to discuss symptoms or bring lesions to the attention of the physician.

Physical Examination Appearance of vulvar SCC and vulvar intraepithelial neoplasia (VIN) can be quite variable. Lesions may take on a whitish, red, or hyperpigmented appearance with patches of thickened skin. Other lesions may have a crusty, verrucous, or even ulcerated appearance. Often there are multiple lesions.

Laboratory and Imaging Special staining of p53 and MIB-1 protein can be done on biopsy specimens to predict aggressiveness [14].

Special Testing Colposcopy with the use of diluted acetic acid or toluidine blue to enhance lesions can be done on the vulva and nearby areas. Multiple biopsies are recommended and should be done via punch or excision. The physician who is comfortable performing a punch biopsy on other parts of the body should be able to do one with the same methods used on regular skin.

Differential Diagnosis Lichen sclerosis, lentigo, mucous cyst, acrochordon, tinea cruris, condyloma.

Treatment Therapy is based on the extent of dysplasia. Vulvar epithelial neoplasia II and III and SCC in situ are often treated with surgery. Adjuvant treatment is often needed for and is beyond the scope of this chapter. Radiotherapy, chemotherapy, and topical therapies are also used.

Medications 5FU cream is used for VIN lesions, but its use is limited by side effects.

Referrals Consultation with a dermatologist or gynecologic oncologist is necessary for complex or complicated lesions.

Counseling Patients undergoing biopsy should be counseled on potential need for multiple biopsies.

Patient Education and Activation Patients should be instructed to return to the physician if they have any recurrent symptoms.

Kaposi's Sarcoma (KS)

General Principles

Definition Kaposi's sarcomas are opportunistic malignant vascular neoplasms consisting of endothelial cells proliferating within the tumor. They are associated with human herpes virus 8 – HHV8 [2, 15] – which has a receptor that promotes endothelial cell proliferation. HHV8 has been found in all lesions. Lesions can be found on the skin, oral cavity, gastrointestinal tract, lymph nodes, or respiratory tract.

Epidemiology The incidence and type of KS varies by country; in the USA it is more common in males and HIV-positive patients.

Classification

Classic KS These are most often found on the legs of men of Italian or Eastern European descent.

African KS This is an endemic type of KS involving the lymph nodes most common in equatorial Africa most often in young men and children.

Immunosuppressed KS These occur in patients with HIV or organ transplant patients.

DOI 10.1007/978-1-4939-0779-3_124-1

Approach to the Patient

Diagnosis History Patients will typically report the appearance of a purple painful lesion that appeared over time.

Physical Examination The classic lesion is a red or purple nodule 3–15 mm in size. However, KS lesions can also be in the form of patches or macules and are often multiple. Oral lesions may be flat or nodular. The entire skin should be examined for other lesions as well as palpation of the nearby lymph nodes.

Laboratory and Imaging Biopsy is necessary for diagnosis. Chest x-rays are sometimes performed after the diagnosis is made as well as GI evaluation or bronchoscopy if disease is suspected elsewhere. HIV testing should be considered in patients presenting with KS.

Special Testing Biopsy is necessary to make the diagnosis.

Differential Diagnosis Pyogenic granuloma, nodular melanoma, hemangioma, hematoma, purpura, bacillary angiomatosis.

Treatment Therapy varies depending on the type of Kaposi's sarcoma. Initial treatment includes excision by excisional biopsy. Curative treatment includes electrodessication and curettage, cryosurgery, or radiation therapy [15].

Medications Complex cases may require intralesional or systemic chemotherapy. Patients should be treated for reversible immunosuppression such as the case of HIV disease. Removing immunosuppressants may improve disease if medically feasible.

Referrals Consultation with a dermatologist or oncologist is necessary for treatment.

Counseling Patients should be warned of potential scarring with biopsy.

Patient Education Patients should be educated on the signs and symptoms of recurrent disease.

Vascular Lesions

Hemangioma (HM) aka Strawberry Hemangioma

General Principles

Definition Hemangiomas are benign vascular growths made up of blood vessels. They can grow quite rapidly in the first month of life, and they can continue to grow up until six months and then recede by the elementary school age [2, 4].

Epidemiology They occur in infants within the first month of life; there is a slight female predilection.

Classification

Infantile aka Strawberry Hemangiomas These are superficial, typically first noticed as an area of red pigmentation on an infant's skin some time after birth. They proceed to grow up from the surface up until about two years of age and then recede. Thirty percent are present at birth, while the remaining appear within the first few weeks of life.

Cavernous Hemangiomas aka Deep Hemangiomas These occur in infancy and are typically of a deeper color. They are larger than strawberry hemangioma, often multiple, and may involve deeper tissue levels. Cavernous HM tend to persist over time.

DOI 10.1007/978-1-4939-0779-3_124-1

Approach to the Patient

Diagnosis **History** Parents will typically report seeing a red area on the skin that appears to be growing over time. Parents may report bleeding in lesions that are prone to friction.

Physical Examination In the early phase of hemangioma development, the physician may only see a flat red spot. After several weeks, the HM will feel more like a red spongy mass. Deeper lesions can take on purple coloring.

Laboratory and Imaging MRI may be considered in large, deep, or spinal hemangioma to delineate the extent of the lesion.

Special Testing Hemangiomas that lay on the midline of the spine may be related to neural tube defects and referral to a specialist is recommended.

Differential Diagnosis Pyogenic granuloma.

Treatment Most hemangiomas can be left alone to spontaneously recede. Irritated lesions or ones that obstruct vision or impede function should be considered for treatment. Pulsed dye laser treatment and surgery have been used for larger lesions or those affecting function; however, newer medical treatments have enjoyed success.

Behavioral Parents should be reassured that most HMs cause no symptoms to the patient; on occasion larger ones prone to friction should be protected.

Medications Oral propranolol is a newer very successful treatment in shrinking HMs [16] and should be prescribed by a provider with experience in dosing. Prednisone given orally can also be used to shrink HMs but often causes side effects.

Referrals Pediatric dermatology or pediatric surgeon consultation should be done when a lesion is large, ulcerating, or compromising function.

Counseling Physicians should review side effects of oral treatments and surgical treatments with patients prior to treatment.

Patient Education and Activation Parents should be reassured that most hemangiomas will recede over time resulting in a much smaller lesion.

Cherry Angioma

General Principles

Definition Angiomas are very small acquired vascular neoplasms made up of proliferating capillaries [2]. They are found in most adults.

Epidemiology They typically occur in patients over the age of 30 and increase in number as patients age.

Approach to the Patient

Diagnosis **History** Most patients will report a painless red bump or bumps on their skin.

Physical Examination Angiomas are 0.5–5 mm round vascular papules. Color can range from cherry red to deep purple, and they are most often found on the torso.

Special Testing Shave biopsy may be needed for larger lesions if there is a concern for malignancy.

Differential Diagnosis Telangiectasia, pyogenic granuloma, petechiae, bacillary angiomatosis, melanoma.

DOI 10.1007/978-1-4939-0779-3_124-1

Treatment Therapy is typically unnecessary; however, if patients desire for cosmetic reasons, there are several options.

Pulsed dye laser therapy, cryotherapy, and electrocautery are all quite effective [17].

Counseling Patients should be warned of the risks of scarring or depigmentation prior to treatment.

Patient Education and Activation Patients should be reassured that these are benign entities and adults tend to acquire more as they age.

Angiokeratoma

General Principles

Definition Angiokeratoma are vascular papules arising from dilated blood vessels with epidermal hyperkeratosis. They more commonly appear as multiple lesions clustered in one area, often on the scrotum or vulvar areas. Increased venous pressure has been implicated in their formation [4].

Epidemiology They may appear during childhood or adulthood depending on the type.

Classification

Angiokeratoma of Fordyce Multiple angiomas on the scrotum or vulva.

Solitary Angiokeratoma Single lesions.

Angiokeratoma of Mibelli An autosomal dominant disorder with painful lesions on the dorsal surfaces of the digits.

Fabry's Disease An X-linked inborn error that leads to formation of angiokeratomas in a bathing-suit distribution around puberty.

Approach to the Patient

Diagnosis History A patient will report a typically painless dark spot/spots.

Physical Examination Angiokeratomas are 0.5–5 mm papules that can be red, purple, or black. Dermoscopy examination reveals obvious vascular lacunae within a papule.

Special Testing Biopsy is not typically required but if performed will show blood vessel dilatation with hyperkeratosis.

Differential Diagnosis Hemangioma, melanoma, Kaposi's sarcoma, pyogenic granuloma.

Treatment Therapy is typically only necessary for cosmetic reasons. Electrocautery and laser therapy are effective.

Referrals Consultation with a dermatologist may be necessary for laser treatment. Treatment associated with Fabry's disease is directed at the underlying disease.

Counseling Patients should be warned of potential scarring from treatment.

Patient Education and Activation Patients should be reassured that genital angiokeratomas are not sexually transmissible.

Venous Lake

General Principles

Definition Venous lakes are made up of a dilated portion of a vein on previously damaged skin.

Epidemiology They are more common in older patients on sun-damaged skin. The face, lips, and ears are common sites.

DOI 10.1007/978-1-4939-0779-3_124-1

Approach to the Patient

Diagnosis History Most patients will not be seeing a very dark spot on their skin or lips. Raised lesions may cause symptoms of itching or soreness especially if they become thrombosed.

Physical Examination Venous lakes are typically 3–10 mm in size. Coloring can be purple, red, or black. Dermoscopy examination will show the telltale grapelike congregation of vascular lacunae [3].

Special Testing Biopsy is not necessary.

Differential Diagnosis Malignant melanoma, venous varicosity, melanoma, Kaposi's sarcoma.

Treatment Therapy is generally not indicated unless the lesion is repeatedly traumatized. Laser can be effective as well as surgically unroofing the lesion and cauterizing the base.

Referrals Dermatology consultation may be needed for laser treatment or changing lesions.

Counseling Patients should be warned of potential scarring from treatment.

Patient Education and Activation Patients should be warned to avoid the sun and protect their skin with sunscreen and clothing.

Pyogenic Granuloma (PG)

General Principles

Definition These benign lesions are vascular growths that arise in the skin or oral mucosa in reaction to small trauma. Histologically, they contain proliferating endothelial cells and fibroblasts [2].

Epidemiology Most often PGs occur in young adults and children, and they affect both genders equally.

Approach to the Patient

Diagnosis History Patients will commonly give the story of a new onset yellow or red lump that bleeds easily with just minor pressure. Occasionally patients will be able to give a history of preceding trauma and a lesion forming during the healing process. Patients may report mild soreness. If the patient's medical history includes immunosuppression or HIV, Kaposi's sarcoma should be considered.

Physical Examination Pyogenic granulomas tend to appear as moist red/rust-colored papules 4–15 mm in size. Some will have yellow discharge overlying the papule (Fig. 5). There may be a surrounding collarette of the skin at the narrowed base. PGs are friable with contact bleeding with only minor trauma.

Special Testing A lesion should be sent for pathology if there's any question that it may be something other than a pyogenic granuloma.

Differential Diagnosis Nodular melanoma, Kaposi's sarcoma, bacillary angiomatosis, angiosarcoma.

Treatment PGs should be removed surgically with a shave-type procedure followed by electrodesiccation or curettage of the base of the granuloma. PGs may bleed quite a bit during removal; however, when the lesion is completely removed, the bleeding typically slows down. Silver nitrate or aluminum chloride applied to the base will stop further bleeding. Occasionally adequate treatment or failure to remove all of the granuloma will lead to its recurrence, which can be treated with repeat curettage.

Referrals Consultation with dermatology is helpful for multiple or recurring PGs or if the diagnosis is in doubt.

Counseling Patients should be warned of the possibility of a small scar after removal.

Patient Education and Activation Patients can be reassured this is a benign lesion; however, if it does not heal completely and act as expected after removal, they should be urged to follow up.

DOI 10.1007/978-1-4939-0779-3_124-1

Fig. 5 This large pyogenic granuloma formed within 2 days

Nonpigmented Nonvascular Lesions

Dermatofibroma aka Fibrous Histiocytoma

General Principles

Definition Dermatofibromas are skin lesions made up of dendritic histiocyte cells. They may arise in reaction to a minor injury such as an insect bite or develop spontaneously [18].

Epidemiology They are more common in women especially on the lower legs or arms.

Approach to the Patient

Diagnosis History Most patients will not recall any trauma and some will have symptoms of mild itching. Typically the lesion will have been present for several months to years, grown to a certain size and remained stable.

Physical Examination Inspection will reveal a 3–8 mm firm, rubbery papule fixed within the skin. They are usually pink, tan, or brown in color often with a central pale area and darker red or brown toward the periphery. The skin will dimple over the lesion when the dermatofibroma is pinched on both sides. Dermoscopy will reveal a large central pale to white patch [3].

Special Testing Biopsy is not required to make the diagnosis; however, on some occasions, it may be necessary to reassure the patient and/or provider.

Differential Diagnosis Amelanotic melanoma, dermatofibrosarcoma, keloid.

Treatment It is not required; however, some patients may want removal for cosmetic reasons. Cryotherapy can be attempted to decrease the size, but it may result in hypopigmentation of the area. Punch or excisional biopsy can be performed for removal but may result in scar.

Medications Creams are not effective in decreasing the appearance or size of a dermatofibroma.

Referrals Consultation with a dermatologist can be done if there is doubt to the diagnosis.

Counseling Patients who request removal should be counseled that the scar may be of similar size to the original dermatofibroma.

Patient Education and Activation Patients should be told that the lesion will likely persist indefinitely, but if unexpected change in size occurs, they should return to their physician.

DOI 10.1007/978-1-4939-0779-3_124-1

Keloid/Hypertrophic Scar

General Principles

Definition A keloid is a fibroproliferative response to a skin injury. The subsequent keloid will be larger than the original injury. True keloids will not regress with time unlike hypertrophic scars which are of different etiology and may regress [4, 19]. Hypertrophic scars are an exaggerated response to healing that does not extend beyond the scars' original size.

Epidemiology Keloids occur with equal frequency in men and women. They are more common before age 30, in darkly pigmented skin and over the chest and back where the skin is under more tension while healing. Hypertrophic scars do not show a racial difference.

Approach to the Patient

Diagnosis **History** Patients will typically recall an event of skin disruption such as a piercing, surgery, or burn within one year of keloid formation. There may be itching or mild pain.

Physical Examination Coloring can range from flesh colored to red. They can range from soft to very firm to the touch.

Special Testing Biopsy is not necessary for diagnosis.

Differential Diagnosis Hypertrophic scar, dermatofibroma, sarcoidosis, dermatofibrosarcoma.

Treatment Surgical removal or correction should only be attempted by experienced surgeons as adjunctive treatments to limit reformation will likely be necessary. Laser has shown promise for very vascular scars.

Behavioral Silicone gel sheets applied during healing may prevent formation of keloids in susceptible patients but research is not entirely convincing.

Medications Injecting a keloid with intralesional triamcinolone 10–40 mg/ml can decrease the size and symptoms but may need to be repeated every 2–4 weeks. Imiquimod may be marginally effective.

Referrals Dermatology, plastic surgery, or general surgery consultation may be necessary for treatment of large keloids.

Counseling Patients should understand that any surgical treatment may result in subsequent scarring.

Patient Education and Activation Due to the nature and difficulty of treating keloids, the physician should be understanding of the distress a patient may feel in becoming scarred. Patients at risk of keloids should also consider not having elective cosmetic procedures due to the risk of keloid formation.

Lipoma

General Principles

Definition A lipoma is a benign growth composed of grouping of adipocytes in a fibrous capsule [2, 20].

Epidemiology They most often occur in adulthood on areas of the body that contain more fat.

Classification

Hereditary Multiple Lipomatosis An autosomal dominant condition of multiple lipomas in males.

Pleomorphic Lipomas that contain adipocytes and giant cells.

Angiolipoma A lipoma variant with adipocytes and vascular proliferation.

Spindle Cell Lipoma A variant containing spindle cells.

DOI 10.1007/978-1-4939-0779-3_124-1

Approach to the Patient

Diagnosis History Most patients will report a slowly growing lump under their skin that is nonpainful.

Physical Examination A mild swelling may be seen under the skin. Palpation typically reveals a soft to medium firm lump that is not fixed to the overlying skin.

Special Testing MRIs can be used to determine if fast-growing lesions are more consistent with liposarcomas.

Differential Diagnosis Epidermal cyst, liposarcoma.

Treatment No treatment is necessary for most lipomas; however, patients may desire removal secondary to discomfort from large lipomas or for cosmetic reasons. Surgical excision is the most common treatment and several different techniques exist [20]. Enucleation can be performed by cutting a 5 mm incision, freeing the underlying lipoma from the surrounding tissue and extruding it through the incision. Excision can be also performed via traditional surgical excision or by cutting an ellipse of the skin overlying the lipoma then dissecting the lipoma from the surrounding tissues and suturing the defect closed. Liposuction can be used to decrease the size of a lipoma.

Medications Injection with triamcinolone 10 mg/ml with lidocaine may be repeated monthly several times to shrink a lipoma.

Referrals Consultation with a dermatologist or general surgeon may be necessary in the case of large lipomas or those overlying sensitive structures.

Counseling Patients should be warned of potential for scarring or damage to underlying tissues during removal.

Patient Education and Activation Patients can be reassured that these are benign, and if they grow quickly or become symptomatic, they should follow up with their physician.

Epidermal Inclusion Cyst (EC)/Sebaceous Cyst

General Principles

Definition Epidermal cysts are collections of keratin within a cyst felt under the skin. They arise from hair follicles within the epidermis.

Classification

Milia One to two millimeter epidermal cysts typically on the face are typically very firm and will stay solid when extruded.

Wen/Pilar Cyst Cysts in hair-bearing areas, they have thick walls that line the cyst.

Ruptured Sebaceous Cyst Due to the thin-walled nature of ECs, they commonly rupture under the skin and produce a severe inflammatory reaction.

Gardner's Syndrome Multiple sebaceous cysts may be related to Gardner's syndrome, which is an autosomal dominant condition associated with colon polyps and potentially colon cancer.

Epidemiology ECs typically occur after puberty or in adulthood most commonly on the face, neck, posterior ears, or trunk.

Approach to the Patient

Diagnosis History Patients typically will complain of a small bump in their skin sometimes knowing of its presence for several months or they may have just discovered it. Occasionally with an inflamed cyst a

DOI 10.1007/978-1-4939-0779-3_124-1

patient will report that they had a small bump that suddenly grew overnight to a hard red painful area resembling an abscess.

Physical Examination It typically reveals a hard nonpainful lump 0.5–5 cm in size. There may be a pore over the cyst with plugged keratin underneath. Ruptured cysts are typically red, warm, and very tender. At times they will be oozing inflammatory products.

Laboratory and Imaging Culture of ruptured cysts is not recommended as they are not infected.

Special Testing On occasion an abnormal-appearing cyst may be sent to pathology if the diagnosis is uncertain.

Differential Diagnosis Lipoma, keratoacanthoma, abscess.

Treatment Small asymptomatic cysts do not need to be removed. However, cysts typically will enlarge over time, so in areas where they are likely to be traumatized, are symptomatic, or affect cosmesis, removal is recommended.

Ruptured cysts should be incised and the contents drained. However, complete removal of the cyst may be difficult due to adherence or scarring of the cyst wall, and removal may be best done after inflammation resolves.

Excision [21] of the cyst can be done through a minimally invasive technique of making a 3–4 mm incision (or punch biopsy), removing the cyst contents, and then pulling the cyst out through the incision and removing it. Alternatively a larger incision can be made, the cyst freed from the surrounding tissues and removed in total.

Behavioral Medications Antibiotics are not indicated in the case of a ruptured cyst as these are not infected.

Referrals Consultation with plastic surgery or dermatology may be necessary in cysts over cosmetically vulnerable areas.

Counseling Patients should be warned of possible scarring or incomplete removal of cyst prior to removal.

Patient Education and Activation Patients should be advised that cysts may increase in size or rupture.

Oral Lesions

Leukoplakia

General Principles

Definition It is a term used to describe a white lesion of the oral mucosa that cannot be wiped off [22]. Most lesions are due to hyperkeratosis or irritants and will resolve in a short time; however, 25 % of lesions contain dysplastic cells and may progress to SCC/oral cancer. Lesions on the floor of the mouth or ventral tongue or nodular in appearance are more likely to be premalignant.

Epidemiology Leukoplakia typically occurs after age 40. It is more common in males, tobacco users, and those exposed to HPV.

Classification

Erythroplakia A focal red area within a leukoplakia patch [23].

Oral Hairy Leukoplakia EBV-associated variant often on the lateral tongues of patients with HPV [2].

DOI 10.1007/978-1-4939-0779-3_124-1

Approach to the Patient

Diagnosis History Patients may have seen the lesion and occasionally will have soreness or noticed mild bleeding, but they typically have no symptoms.

Physical Examination It will show a white patch or plaque in oral mucosa most commonly seen in the buccal mucosa, floor of the mouth, or lower lip. Red areas (erythroplakia) may also be seen. Lymph node examination should be performed. Lesions may appear verrucous, and these lesions are higher risk for malignancy.

Laboratory and Imaging There is currently no recommendation for HPV swabbing for lesions although research is in progress.

Special Testing Biopsy should be performed in tobacco users if a lesion is thick, is changing, or has any erythroplakia. Biopsy should also be performed if the lesion does not resolve after 14 days of observation or after removing potential irritants. Toluidine blue is a substance that can be applied to a leukoplakia; it binds preferentially to areas of high DNA concentration and may guide the practitioner to biopsy a more concerning area.

Differential Diagnosis Thrush, lichen planus, oral hairy leukoplakia, squamous cell carcinoma, frictional keratosis.

Treatment Therapy depends on the degree of dysplasia on a biopsy sample [22]. Mild dysplasia can be observed with follow-up to assess for clinical change. Removal is indicated in moderate-to-severe dysplasia, and excision with scalpel or CO2 laser can be performed. Cryosurgery and electrosurgery are also used for treatment. Patients should be encouraged to follow up to assess for clinical recurrence.

Behavioral Patients should be encouraged to refrain from irritating substances and tobacco products.

Medications 5FU is used in treatment.

Referrals Consultation with an experienced oral surgeon or otolaryngologist may be necessary for biopsy or treatment.

Counseling Patients should be warned of the malignant potential of lesion and those that will become cancerous can do it within 6 months to several years.

Patient Education and Activation Patients should be encouraged to quit tobacco products if used and if a lesion persists patients should have a follow-up with their physician.

Erythroplakia

General Principles

Definition Erythroplakia is an oral lesion with red qualities that cannot be wiped off. Malignancy potential is high, as 90 % will contain premalignant cells [22].

Epidemiology It is similar to leukoplakia with a higher incidence in smokers and males.

Approach to the Patient

Diagnosis History Patients often have no symptoms, but pain and bleeding can occur.

Physical Examination Erythroplakia have a flat or velvety appearance, and color can range from pink to red, typically heterogenous with areas of hyperkeratosis. Lymph nodes should also be examined.

Special Testing. Biopsy should be performed expediently by the physician or specialist. If a partial biopsy is to be done, getting a sample of the thickest part of the lesion is more likely to show pathology.

Differential Diagnosis Mucocele, lichen planus, SCC.

Treatment Excision should be performed surgically or with CO2 laser.

DOI 10.1007/978-1-4939-0779-3_124-1

Behavioral Patients should refrain from irritating substances or tobacco products.

Referrals Consultation with an otolaryngologist or oral surgeon may be necessary for biopsy or removal of some lesions.

Patient Education and Activation Patients should be counseled to avoid tobacco products and alcohol as well as monitoring for reoccurrence.

Surgical Techniques

Physicians will find themselves removing lesions that are malignant, potentially malignant, and benign. The decision to remove benign lesions should be done only after careful consideration and discussion with the patient of possible complications. Areas of potential for poor healing such as the lower leg should be done with caution. Scarring can occasionally be worse than the original lesion especially on areas that heal poorly or are prone to form keloids (chest/back).

Presumed malignant lesions should be removed in total whenever possible depending on the size of lesion and location [17]. Elliptical excision is the desired method of removing cancerous lesions including a 2 to 3 mm margin of normal skin. Punch biopsy may be an accepted course when lesion can be completely removed with a punch or in the case of a very large lesion where waiting for an excision may delay diagnosis or a patient may be unable to travel to get a more difficult biopsy done.

A **shave excision** is typically done on bumpy lesions such as pyogenic granuloma, dermal nevi, and skin tags. It may be acceptable on lesions such as squamous cell carcinoma or basal cell carcinoma in areas where removal of excessive skin would be difficult and the patient understands that another treatment may be necessary if pathology reveals an incomplete excision. One should be very hesitant to perform a shave biopsy on a suspected melanoma, as bisecting the depth of a melanoma would highly affect the ability to stage the melanoma accurately. The shave biopsy procedure [17] includes marking the lesion and landmarks prior (as epinephrine may cause blanching and disappearance of vascular landmarks) to numbing the lesion with lidocaine with or without epinephrine, prepping the skin with ChloraPrep or Betadine, and removing the lesion to the level of the mid-dermis. A shave may be performed with a scalpel, razor blade, or DermaBlade. Hemostasis can be achieved by application of aluminum chloride, pressure, or silver nitrate.

Shave biopsies offer the benefit of removing less skin and in most cases providing the patient with a diagnosis without cutting through to the dermis which enables improved healing and less bleeding.

Excisional biopsy is most commonly done to remove a suspected melanoma, BCC, SCC, or dermatofibroma. The lesion and ellipse should be marked prior to anesthesia as epinephrine may cause a lesion to blanch and borders may become indistinct prior to excision. The area should be anesthetized with lidocaine with or without epinephrine. The area should then be cleansed with alcohol, ChloraPrep, or povidone-iodine. The lesion should be removed with a 2 to 4 mm margin. Care must be taken to the scalpel perpendicular to the lesion so as not to partially bisect the lesion while removing it. Also orienting the ellipse longitudinally on extremities or in the area of the skin lines can be helpful with healing. The biopsy site should be close with interrupted sutures and left in for 7–21 days depending on the site.

Punch biopsy is most often used to assist in diagnosis or remove small lesions. The area is first anesthetized with lidocaine with or without epinephrine. The skin should be cleansed with alcohol and a sterile punch tool is used to enter the skin and rotated clockwise and counter clockwise through the dermis to the subdermal fat. The specimen is then cut free from the underlying fat and sent to the lab. A 2–3 mm punch can often be closed with just an adhesive tape such as Steri-Strips, while a 4–6 mm punch may require a suture.

DOI 10.1007/978-1-4939-0779-3_124-1

Table 3 Biopsy methods for skin cancers

Shave	Excisional	Electrodessication	Cryotherapy
SCC	Malignant melanoma	SCC	Thin SCC
BCC	SCC	BCC	Actinic keratosis
Nevus	BCC	Pyogenic granuloma	Dermatofibroma
	Lipoma	Cherry angioma	Seborrheic keratosis
	Sebaceous cyst	Sebaceous hyperplasia	Leukoplakia
	Pyogenic granuloma	Actinic keratosis	

Curettage and **electrodesiccation** [17] can be used to destroy small benign lesions or as a complementary procedure to treat an incompletely removed small or superficial SCC or BCC. The area is anesthetized with lidocaine and then a curette is used to scrape away the remaining lesion. This is done by sight and touch as malignant lesions are often softer. The area is then curetted until firm normal/gritty skin can be felt underneath. The site is then desiccated/burned to the base with electrocautery. This is repeated two more times. The electrocautery has the advantage of achieving hemostasis.

Cryotherapy can be used for treatment of superficial lesions but can cause hypopigmentation or potentially incomplete treatment. Shorter freezing times of 5–15 s can be used for thin lesions like actinic keratosis. Longer freezing times for two cycles of 30 s each are required for thin BCC or SCC (Table 3).

Principles of Sun Exposure Protection/Sunscreen

UVA light is generally stronger and more damaging and penetrates deeply to the mid-dermis. There is no seasonal variation, it is found in tanning beds, and it causes aging of the skin, photo eruptions, and skin cancer.

UVB light is stronger in the summer and at midday; penetration increases with higher altitudes, and UVB causes sunburn, skin cancer, and cataracts.

Exposure to sun during midday and at altitude increases sun damage.

Sunscreen

Sunscreens work by either absorbing or reflecting the sun's rays.

Absorbing "organic" sunscreens contain the active ingredients benzophenones, anthranilates, oxybenzone, or PABA.

Reflecting sunscreens contain zinc oxide and titanium dioxide.

Broad-spectrum sunscreens provide UVA and UVB protection in turn reducing sunburn, skin cancer, AKs, SCC, and melanoma.

SPF protection denotes that higher numbers limit greater amounts of UVB exposure; SPF $>$ 30 or 50 is considered protective.

Most patients use less sunscreen than needed and do not reapply often enough. Adult face requires one tsp for coverage and the body two to three tablespoons. Sunscreens should be applied 30 min prior to sun exposure and reapplied every 2 h. Most water-resistant sunscreens will be useless after 30 min of water activity.

Disorders of Hypopigmentation

Vitiligo

Vitiligo is an acquired loss of pigmentation characterized by the absence of epidermal melanocytes. The destruction of melanocytes may be autoimmune in nature, but the pathogenesis is not understood. Approximately 1 % of the population is affected with no propensity in either gender. There is a positive family history in 30 % of cases, lending to a relatively strong genetic component, and half of all cases of vitiligo occur prior to the age of 20 [1]. Vitiligo is further classified as type A or type B. Type A is three times more common, more generalized, and more associated with immunologic diseases. Type B is less common, more rapidly progressive, but less generalized in appearance and follows a dermatomal appearance [2]. Lesions are milk-white hypopigmented macules and patches with discrete margins, which are symmetrically distributed [3]. Commonly affected areas for both types include the face, backs of hands, axillae, and genitalia. The scalp, lips, and mucous membranes may also be affected. Vitiligo can also occur at sites of trauma, such as the elbows or knees, and in previously sun-damaged skin [2]. Vitiligo is associated with thyroid disorders in up to 30 % of cases, and there are also reported associations with alopecia areata, adrenal insufficiency, pernicious anemia, and type I diabetes [2]. Laboratory examination to exclude these associated systemic disorders should include thyroid studies, basic chemistry labs, fasting glucose, and a complete blood count. The diagnosis of vitiligo is made by physical exam. A Wood's lamp can be used in fair-skinned individuals, to accentuate hypopigmented areas. Skin biopsy and histologic examination reveal the absence of epidermal melanocytes.

Available literature does not show a higher predilection in dark-skinned individuals, but easier recognition of skin manifestations may increase perceived disfigurement and social stigmata in these patients. It can have a major impact on feelings of stress, self-consciousness, and sexual relationships leading to low self-esteem and depression.

Management

The goal of treatment is to restore melanocytes to the skin, which requires activation and migration of melanocytes located in the hair follicles. Therefore, skin with little hair, such as the hands or feet, responds poorly to treatment. Treatment usually takes 6–12 months and should be started early in the course of disease. Narrowband ultraviolet B (UVB) is more effective than psoralen plus ultraviolet A radiation (PUVA) and is recommended as the first-line treatment for generalized vitiligo [2]. Moderate-potency topical steroids, or topical calcineurin inhibitors (tacrolimus and pimecrolimus), for 6–9 months are preferred for localized vitiligo [2]. In patients with extensive generalized depigmentation who do not respond to phototherapy, depigmentation of the surrounding skin should be considered. All patients with vitiligo should minimize sun exposure and apply broad-spectrum sunscreens to help minimize the contrast between tanned skin and hypopigmented skin.

Pityriasis Alba

Pityriasis is a common hypopigmentation skin disorder in prepubescent children with a history of atopic dermatitis. The most common sites affected are the face, neck, and arms [4]. The lesions begin as a nonspecific erythema but gradually become scaly and hypopigmented. It is often confused with vitiligo, but vitiligo lesions do not scale. Potassium hydroxide preparation is negative in pityriasis, distinguishing it from tinea infections. The condition is benign and improves after puberty, which can help reassure patients and their families. Treatment consists of topical emollients, which have shown to be just as effective as any medicated topical treatment [3]. High-potency topical steroids can be used on erythematous inflammatory lesions, but the depigmentation is not affected by any treatment. Pimecrolimus cream 1 % and tacrolimus ointment (0.03 % or 0.1 %) are nonsteroidal alternatives for treatment.

Tuberous Sclerosis

Tuberous sclerosis (TS) is the second most common neurocutaneous syndrome, affecting 1 in 6,000 newborns, and is marked by childhood seizures and mental retardation but can affect several organ systems [5]. Congenital hypopigmented macules are generally oval or ash leaf shaped located on the arms, legs, and trunk. However, adenoma sebaceum is the most common cutaneous manifestation of TS. The lesions are small (1–5 mm), smooth, firm, yellow-pink papules with telangiectasia [6]. Skin manifestations may be the earliest sign of TS and occur in 80 % of patients by 1 year of age [7]. Skin biopsy shows normal melanocytes which excludes vitiligo as the diagnosis. TS is an autosomal dominant disease, and genetic counseling should be offered in persons with a family history of TS. There is no treatment for the skin manifestations, but they offer an early window for diagnosis and referral, for the management of other clinical manifestations of TS.

Disorders of Hyperpigmentation

Pityriasis Versicolor (Tinea Versicolor)

Tinea versicolor is not truly a hyperpigmentation disorder, but involved skin may appear darker than normal, and it is a common presenting complaint for family physicians. Increased sebum production during puberty allows the proliferation of *Pityrosporum ovale* or *Malassezia furfur*, which causes brown, pink, or reddish skin discoloration that may be scaly and pruritic [8]. Potassium hydroxide preparation is positive for fungal elements, and Wood's lamp examination can reveal yellow to yellow-green fluorescence. Both topical and oral antifungal treatments are effective. Topical therapy is preferred for localized disease and systemic therapy for recurrent or widespread lesions. Topical selenium sulfide 2.5 % applied for 10 min daily for 7 days and 2 % ketoconazole shampoo applied to affected areas for 5 min prior to showering for three consecutive days are effective regimens [9]. Topical antifungal agents are also effective but require daily use for approximately 14 days. Oral ketoconazole and itraconazole, both at doses of 200 mg/day for 5 days, are also effective and appropriate for patients with a large surface area burden for topical treatment [10]. Oral terbinafine and griseofulvin are not effective in treating tinea versicolor. Hypo- or hyperpigmentation can be present even after successful treatment. The presence of scale and positive KOH preparation confirms treatment failure.

Photosensitivity Dermatitis

Phototoxic reactions are nonallergic and induced by the use of systemic or topical medications or by contact with certain plants and foods in combination with sun exposure. Skin manifestations are generally confined to sun-exposed areas and result in erythema within minutes to hours of sun exposure [11]. Reactions can range from imperceptible erythema followed by prolonged hyperpigmentation to a

DOI 10.1007/978-1-4939-0779-3_125-1

sunburn-like reaction, edema with vesicles, and bullae [12]. Common medications associated with photosensitivity include antibiotics (fluoroquinolones, sulfonamides, tetracyclines), diuretics (furosemide, hydrochlorothiazide), diltiazem, nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, and topical retinoids. Common foods include lemons, limes, celery, dill, and carrot juice [11]. Treatment is removal of the offending agent. When this occurs, the eruption generally resolves spontaneously. Oral steroids may be needed for severe cases with a significant inflammatory response. Avoidance of the offending agent (medication or food), direct sunlight, and tanning facilities is paramount. The use of clothing with ultraviolet filters and sunscreen can minimize the risk of a photosensitivity reaction.

Lichen Planus

Lichen planus (LP) is an inflammatory skin and mucous membrane reaction of unknown etiology. Mean age of onset for men and women is in the fifth decade of life, and it is rare in children younger than 5 years of age. A positive family history is found in 10 % of patients. In the past, it has been thought that liver disease is a risk factor for cutaneous LP, specifically hepatitis C infection [13]. However, this association is based on studies showing weak associations and prevalence rates that range from 0 % to 63 %. Therefore, screening for hepatitis C in patients with diagnosed lichen planus is also controversial.

Clinical Presentation

Clinical features are characteristic and follow the five P's of lichen planus: pruritic, planar, polyangular, purple, and papules. The planar surface reveals a lacy, reticular pattern of crisscrossing whitish lines (Wickham's striae). Patterns can include annular, diffusely papular, or linear and most commonly affect the flexor surfaces of the wrists, forearms, and legs [14]. The clinical course is unpredictable as spontaneous remission can occur in a few months, but most commonly, LP lasts for approximately 4 years. Mucosal LP can occur with or without cutaneous eruptions; oral lichen planus is associated with concomitant vulvovaginal lesions 25 % of the time [14]. Cutaneous manifestations can be erosive or nonerosive and can arise on the tongue, lips, buccal mucosa, glans penis, and anus. While a skin biopsy is the gold standard for diagnosis, the diagnosis usually can be made clinically by history and characteristics on physical exam.

Treatment

High-potency topical steroids are used as initial treatment for cutaneous and oral LP. Intralesional (triamcinolone acetonide 5–10 mg/ml every 3–4 weeks) and oral steroids (4 week course and taper of prednisone) can also be used for hypertrophic and generalized severely pruritic LP, respectively [13]. Azathioprine can be used as an alternative to steroids. Phototherapy with narrowband UVB or PUVA can also be used for generalized disease. Cyclosporine (6 mg/kg/day) is reserved for patients with severe disease. Calcineurin inhibitors, such as topical tacrolimus and pimecrolimus, and aloe vera gel have all been shown to be effective in treating mucous membrane LP if topical steroids are not tolerated [13]. Antihistamines can be used as adjunctive therapy for intense pruritus.

Cutaneous Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic multisystem inflammatory disorder that is potentially fatal. The disease has no single diagnostic marker and is diagnosed using a combination of clinical and laboratory criteria [15]. Diagnosis and treatment can prevent significant morbidity and mortality. The prevalence of the disease is higher in African American females and persons of Hispanic and Asian descent.

DOI 10.1007/978-1-4939-0779-3_125-1

Clinical Presentation

Patients with SLE will present with myriad of symptoms; however, cutaneous manifestations are the most common sign. General symptoms such as fatigue and fever (in the absence of infection) are also common. There are three subsets of cutaneous SLE: chronic (discoid), subacute, and acute lupus erythematosus [16]. Chronic type lesions are sharply demarcated erythematous raised lesions that can be round (discoid) and may have a scale. Lesions are normally found distributed asymmetrically on the face and scalp and can last for months. Rheumatologic lab tests such as antinuclear antibody (ANA), anti-double-stranded (ds) DNA, and erythrocyte sedimentation rate (ESR) are usually normal. Subacute lesions can be induced by medications such as hydrochlorothiazide and calcium channel blockers. They can be papulosquamous or annular-polycyclic and occur on the trunk, sparing the knuckles, axillae, and lateral part of the trunk. Subacute lesions are rarely noted below the waist; ANA, ds-DNA, and ESR are usually positive, and lesions are likely to recur [16]. Classically, acute lesions present as a superficial, non-pruritic, erythematous plaques on sun-exposed areas of the body. The face (butterfly rash), chest, shoulders, extensor surfaces of the arms, and dorsal aspect of the hands are the most common areas. Both non-scarring and scarring alopecia occur in more than 20 % of cases of SLE [16].

Treatment

Photosensitivity is present in all types of cutaneous SLE, and ultraviolet rays from the sun can both induce or exacerbate cutaneous symptoms. Patients should avoid exposure to direct sunlight and use a daily broad-spectrum sunscreen with a sun protection factor (SPF) of 15 or higher [16]. Topical corticosteroids are first line for the treatment of all forms of cutaneous SLE and are used up to three times a day if needed, even on the face. It is common to start with a low- to medium-potency steroid and advance to high potency in those who do not respond. If topical steroids fail, antimalarial medications such as hydroxychloroquine or chloroquine are indicated [16]. Dapsone can be used when antimalarials fail or are not tolerated. Third-line therapies include azathioprine, methotrexate, and isotretinoin. Oral corticosteroids should be reserved for patients that fail topical steroid treatment and antimalarial treatment.

Corns and Calluses

Corns and calluses result from hyperkeratosis associated with stimulation of the epidermis secondary to chronic pressure or friction on the skin [17]. Risk factors include poorly fitting shoes and anatomical pathology (bunions, hammer toes, claw toes, elevated metatarsals, and varus or valgus inverted hindfoot) leading to abnormal pressure points on the foot. Hyperkeratosis is a normal protective physiologic response; however, it becomes pathologic when the corn or callus becomes large enough to cause symptoms.

Clinical Presentation

Because structural abnormalities are an important risk factor, a thorough examination of the foot and ankle is paramount in the evaluation of corns and calluses. Corns are distinguished from calluses often by location as well as the presence of a central conical core of keratin. They are usually located over non-weight-bearing surfaces and are painful when direct pressure is applied. Two subtypes of corns exist: the hard corn and the soft corn. Hard corns are typically located on the dorsolateral aspect of the fifth phalanx or the dorsum of the interphalangeal joint of the lesser toes [17]. The absorption of an extreme amount of moisture from perspiration between the toes leads to soft corns. They most commonly occur between the fourth and fifth web space and are caused by wearing a shoe that is too tight across the toes. Calluses typically form at sites of friction, pressure, and irritation such as the heel or under metatarsal

DOI 10.1007/978-1-4939-0779-3_125-1

heads. In contrast to corns, calluses do not possess a conical core and have undefined margins [17]. Both entities can be painful and interfere with daily activities.

Corns and calluses are of particular concern for individuals with peripheral arterial disease or diabetes. These patients classically have significantly reduced sensation and pain perception in the distal extremities leading to an increased risk of tissue breakdown, ulceration, and infection.

Management

Removal or redistribution of pressure is the first-line treatment for corns and calluses. Orthotic devices or changing footwear can be helpful in patients with foot abnormalities, such as pes planus. Symptomatic relief of a hard corn can often be achieved through debridement of the lesions and removal of the keratin plug [17]. Patients with a soft corn should be advised to wear shoes with a roomy toe box, low heels, and soft upper portion. Keratinolytic medications (40 % salicylic acid plaster) should be used to remove the excessive keratin. Paring down the lesion with a sharp blade is also an option. Appropriate patients (nondiabetics) can be instructed to use a pumice stone or emery board, after soaking the foot in warm water, to help reduce the size of the lesion.

If conservative treatments do not achieve symptomatic relief, corrective surgery may be necessary. A number of procedures exist to correct the underlying cause rather than simply excise the hyperkeratotic area.

Nail Abnormalities

Physical examination of the nails is often overlooked by family physicians, but may reveal localized abnormalities that should be treated or offer a window to an underlying systemic disease requiring further workup. The three most common conditions of the nails the family physician encounters are onychomycosis, ingrown toenails, and subungual hematomas.

Tinea Unguium (Onychomycosis)

Although occurring in 10 % of the general population, onychomycosis is much more common in the older adult occurring in 20 % of those older than 60 years and 50 % of those older than 70 years [18]. Toenails are affected more often than fingernails and are most often caused by dermatophytes of the *Trichophyton* genus. There are five classes of onychomycosis based on morphologic appearance [19]. Distal onychomycosis is the most common and, as its name implies, affects the distal aspect of the nail. Proximal subungual infections invade the nail plate from below and cause the nail to separate. This pattern is the most common form in patients with human immunodeficiency virus infection (HIV). Superficial infection pattern appears to have powder-like patches of transverse striae on the surface of the nail. The nail plate is not thickened as is seen in other infection patterns. Psoriatic nail changes and trauma-related dystrophy can mimic onychomycosis [20]. Histologic examination of distal nail clippings with periodic acid-Schiff (PAS) staining is the best way to diagnose onychomycosis and differentiate it from dystrophic changes resulting from psoriasis. In contrast, potassium hydroxide (KOH) testing, or nail culture procedures, yields many more false negative results (poor sensitivity). If KOH or culture methods are used, it is important to collect distal nail particles as well as subungual debris with a curette. The diagnosis of onychomycosis should be confirmed because the treatment is long and potentially expensive; however, the involvement of multiple toes or concomitant tinea pedis may justify treatment without confirmation [20]. Fingernail infections are generally caused by the *Candida albicans* species and are associated with chronic mucocutaneous candidiasis.

DOI 10.1007/978-1-4939-0779-3_125-1

Management

Onychomycosis can negatively affect patient's lives via social stigma and disruption of daily activities or prevention of leisure activities. Treatment is often difficult with a 5-year recurrence rate of approximately 30–50 % [21]. Some common poor prognostic factors include >50 % areas of nail involvement, significant lateral nail disease, subungual hyperkeratosis, white/yellow/brown streaks in the nail, and patients with poor peripheral circulation or immunosuppression. Oral antifungals are the treatment of choice. Terbinafine is the first-line treatment with a higher cure rate, lower relapse rate, and fewer side effects than itraconazole. Continuous dosing (terbinafine 250 mg/day for 12 weeks) has been shown to be superior to intermittent treatment, but pulse dosing of itraconazole (200 mg twice a day for 1 week per month × 3 months) is an alternative to continuous dosing [19]. Complete resolution takes time (12–18 months to replace a diseased nail), and the nail surface is likely to still look infected after the 12-week treatment course. The use of oral antifungals is discouraged in patients with liver, renal, or heart disease. Liver function testing should occur prior to, and one month after, initiating therapy. Although topical antifungals are not used to treat active onychomycosis, they can be used to help prevent recurrence. A twice-weekly application of terbinafine cream in the nail area, and between the toes, has been suggested for prevention [21]. Painful or extremely infected nails can be surgically removed.

Ingrown Toenails

Ingrown toenails are common and most commonly affect the large toe. Ingrown toenails occur when the periungual skin is penetrated by the nail, entering the dermis and causing a foreign body reaction which results in a painful toe [22]. Risk factors include tightly fitted shoes, trauma, hyperhidrosis, poor foot hygiene, or excessive trimming of the lateral nail plate. Characteristic signs and symptoms include pain, edema, exudate, and excessive granulation tissue. Indications for treatment include significant pain or infection or recurrent paronychia. Conservative therapy can be used when there is minimal inflammation and pain without purulent drainage. Frequent warm water soaking for 10–20 min, followed by application of a topical antibiotic or topical steroid several times daily, can be tried initially [23]. Other conservative methods include placing wisps of cotton, dental floss, or a gutter splint under the lateral nail edge. There is no evidence to suggest that any of these methods increases the risk of infection. The most common surgical procedure to treat an ingrown toenail is partial avulsion of the lateral edge of the nail followed by matricectomy using 80–88 % phenol. Phenolization after partial avulsion is more effective at preventing recurrence than partial avulsion alone, although there is an increase in postoperative infections [23]. The regular use of post-procedure antibiotics is not indicated.

Subungual Hematoma

Trauma to the nail and bleeding of the underlying nail bed cause immediate pain secondary to increasing pressure and separation of the nail plate. Puncturing the nail with an electrocautery device, or a red-hot paperclip, is the quickest and most effective method of draining the blood [24]. It is important to avoid the lunula (white crescent part of the nail), and its underlying nail matrix, during the procedure. No anesthesia is required for this procedure. It is important to tell patients that nail discoloration may persist until the nail has completely grown out.

Alopecia

Alopecia is defined as the absence of hair where it is supposed to be present. Growing hairs are termed anagen hairs and make up approximately 85 % of all hair. They are securely anchored to the scalp and generally remain in this phase for 3 years. The resting, or telogen phase, lasts about 100 days and makes

DOI 10.1007/978-1-4939-0779-3_125-1

up the other 15 % of all hair (with some in a catagen or transition phase). Normal shedding of hair occurs daily; however, abnormal hair loss can be pathologic or physiologic.

Pathologic Hair Loss

There are four main types of pathologic hair loss. They are categorized according to the degree of scalp involvement (focal or diffuse), as well as the presence of or absence of scarring. Physical exam and a thorough history will yield the correct categorization of hair loss for the majority of patients. Early recognition and diagnosis are important to aid in timely treatment, which may help to prevent further hair loss.

Telogen Effluvium

Telogen effluvium is the most common form of pathologic hair loss and typically follows a major life stressor such as a serious illness or injury, childbirth, or excessive dieting/rapid weight loss. Physiological causes include anemia, thyroid disorders, and several medication classes (beta-blockers, anticoagulants, oral contraceptives) [25]. Whatever the etiology, the hair follicle enters into the resting phase (telogen phase) and causes diffuse, non-scarring hair loss, without causing complete baldness. The hair follicle, in essence, resets its biological clock and undergoes a normal involutional process [26]. This process takes approximately 100 days, so hair loss is typically seen 2–3 months after the inciting event. Conversely, when the precipitating event is removed, hair loss corrects itself in about 100 days [26]. Physical examination typically reveals generalized hair loss as well as a positive hair pull test [25]. Taking 40–60 hairs between your thumb and forefinger and sliding down the length of the hair while holding a steady traction on the hairs complete the test. The test is considered positive if greater than 10 % of the hairs are removed. Treatment consists of stress reduction or identifying a medical cause [26]. Although difficult at times, patients should be reassured that no medication is needed for treatment. As stress wanes, the hair follicles regain normal physiologic activity, hair loss subsides, and regrowth occurs naturally.

Anagen Effluvium

Anagen effluvium is a sudden loss of hair follicles in their growing phase and can cause 80–90 % hair loss. Chemotherapy, radiation, or toxic chemicals typically cause this, though inflammatory diseases such as alopecia areata and pemphigus are also culprits [27]. Anagen effluvium can manifest as either patchy or diffuse hair loss. Hair shedding typically begins 1–3 weeks after starting chemotherapy and is usually complete after 1–2 months. Hairs of the scalp are the most largely effected, though there can be hair loss of the eyebrows, eyelashes, pubic hair, and axillary hair as well [28]. Hair follicle stem cells are spared from destruction; therefore, the hair loss from anagen effluvium is not permanent [29]. No medication has been shown to prevent anagen effluvium.

Alopecia Areata

Alopecia areata is characterized by rapid hair loss in a sharply defined area. Its incidence is about 0.1–0.2 % of the population of the United States. The etiology is unknown, but genetic factors may play a role. The association of alopecia areata with thyroid disorders and vitiligo suggests an autoimmune etiology; however, the significance of this association is unknown. Alopecia areata manifests as a non-scarring form of focal hair loss that can occur in a single patch or multiple patches. The affected skin shows smooth, circular, discrete areas of complete hair loss. The periphery of the circular areas may have short stubs of hair that remain (exclamation point hair). The hair loss can occur at any age, but it is more common in children and young adults, with up to 66 % of people affected being less than 30 years of age [25]. The onset of the

DOI 10.1007/978-1-4939-0779-3_125-1

hair loss is typically rapid (a few weeks) and can potentially affect the entire body (alopecia universalis) but the scalp remains the most commonly affected. Overall, as many as 50 % of patients with alopecia areata will recover within 1 year; for those with 1–2 patches of focal hair loss, recovery is as high as 80 % [30]. Factors associated with a high likelihood prolonged hair loss or relapse are onset in childhood, severe disease affecting scalp and the body, duration of more than a year, associated nail disease (pitting of the nail plate), or a family history of alopecia areata [31]. Unfortunately, there are currently no curative treatments for alopecia areata. Treatments help to control but do not cure or prevent the spread of alopecia areata. Intralesional injection of corticosteroids is the first-line treatment in patients with less than 50 % of the scalp affected. Injection of triamcinolone acetonide (5–10 mg per ml) into the hairless patch every 2–6 weeks stimulated hair growth in 60–67 % of cases. The use of high-potency topical corticosteroids has been controversial in the past; however, clobetasol propionate, 0.05 %, applied to the area in a thin layer for 6 weeks and then off 6 weeks, has been found to be both highly effective and safe in children [32]. Topical minoxidil 5 % concentration can also be used in individuals with greater than 50 % of the scalp affected. It is best used in combination with other treatments, such as topical corticosteroids or anthralin. Other treatments include topical immunotherapy such as dinitrochlorobenzene, and tars, which induce an irritant or allergic contact dermatitis that promotes hair growth during healing [26].

Cicatricial (Scarring) Alopecia

Cicatricial alopecia causes permanent hair loss due to the destruction of hair follicles by inflammatory, autoimmune, or non-follicular process. It can be widespread or localized and can be classified as primary or secondary. In primary scarring alopecia, the follicle is the target of inflammation and common causes include discoid lupus, folliculitis decalvans, lichen planopilaris, acne keloid, and dissecting cellulitis of the scalp. In secondary scarring alopecias, the follicles are destroyed by a non-follicular process such as neoplasm, radiation, infection, surgery, and physical or chemical burns [31]. A biopsy is recommended to help support the diagnosis and determine the etiology. Scarring alopecia is an indication for dermatologic referral. Treatment depends upon the level of activity of the disease causing the scarring. Certain causes such as discoid lupus and lichen planopilaris may respond to topical, intralesional, or systemic steroids. Folliculitis decalvans will often respond to long-term antibiotic treatment with doxycycline, minocycline, erythromycin, Bactrim, or rifampin. If scarring is severe, surgical treatments including scalp stretching (removal of bald area and stretching the adjacent scalp over the removed area) or hair transplantation will be needed for treatment.

Traumatic Alopecia

Traumatic alopecia results from hair being forcefully extracted from the head or the breaking of hair shafts by friction, traction, pressure, or other physical trauma. Typical causes include cosmetic practices, trichotillomania, and pressure on the head as occurs on the occiput of infants who lie on their back. Common cosmetic practices that can cause traumatic alopecia include tight braiding (traction alopecia), use of hair extensions, frequent brushing with nylon bristles, as well as most hair-straightening practices. Traction alopecia from braids or hair weaves can be detected along the frontal and temporal hairlines. Longstanding traction can lead to cicatricial alopecia and permanent hair loss. Treatment is removal of the practice that caused the hair trauma.

Trichotillomania is consciously or habitually plucking, cutting, or pulling hair in a bizarre manner and is a self-induced form of traumatic alopecia. Although it can be normal in children, it is closely related to obsessive-compulsive disorder in some children and adults. The mainstay of treatment is helping the patient find a different way to express their emotional needs. Psychiatric referral may be necessary.

DOI 10.1007/978-1-4939-0779-3_125-1

Fungal Infection (Tinea Capitis)

Fungal infections can lead to scarring and non-scarring alopecia. Black dot tinea capitis is the most common form in the United States and preferentially affects African American children between 3 and 9 years of age [20]. Similar manifestations in adults should lead one to consider other diagnoses or consider a concomitant immunocompromised condition. Hair, within the scaly patches of hair loss, break off flush with the scalp and appear as a black dot. Diagnosis of tinea capitis can be confirmed with a wood's lamp, fungal culture, or 10 % KOH examination, but most physicians treat tinea capitis if the presentation is typical. First-line treatment of tinea capitis in children has traditionally been with 6–12 weeks of griseofulvin. Newer studies have shown that terbinafine and Diflucan have equal effectiveness and safety and shorter treatment courses [20]. Topical antifungals are not effective as they do not penetrate the hair shaft. However, concomitant treatment with 1 % or 2.5 % selenium sulfide shampoo or 2 % ketoconazole shampoo should be used in the first 2 weeks of treatment to help decrease the risk of transmission [20]. There should be consideration of treating all close contacts with one of the aforementioned shampoo regimens for 2–4 weeks.

Physiologic Hair Loss

Androgenic alopecia (male pattern baldness) affects greater than 50 % of men by 50 years of age and 40–50 % of women by 60 years of age. It manifests as bitemporal hair thinning followed by loss of hair over the crown. Symptoms for women are not as severe as in men. Rapid hair loss or hair loss accompanied by pruritus, burning, or tenderness should lead one to consider other diagnoses. An association between male pattern baldness with cardiovascular disease and prostate cancer has been reported; however, the strength of the associations, if any, needs to be clarified. Treatment of androgenic alopecia includes both surgical and nonsurgical options. Medical options include topical minoxidil and oral finasteride. Topical minoxidil prolongs the anagen phase of hair follicles and pushes resting hair follicles into the growing phase. Minoxidil, at 5 % concentration, has been found effective for both hair preservation and regrowth in both men and women, but is much more effective in the preservation of existing hair. It should be applied twice daily, and benefits may take up to a year to be noticed [33]. Discontinuation of the medication results in continued hair loss and use should be indefinite. There are minimal side effects associated with topical minoxidil. Finasteride is an oral type II 5a-reductase inhibitor that blocks the conversion of testosterone to DHT. At treatment dosing (1 mg per day), it has been found to decrease circulating DHT by two thirds. When used for 2 years, the medication was able to prevent further hair loss in 83 % of men between the ages of 18 and 41 [33]. As with minoxidil, treatment should continue for 12 months to assess the drug's efficacy and must be continued indefinitely to maintain that efficacy. Finasteride can cause decreased libido, erectile dysfunction, and ejaculatory dysfunction and is a pregnancy category X medication. Finasteride can also significantly decrease serum levels of prostate-specific antigen. There is weak evidence showing that combination of finasteride and minoxidil works better than either alone, and this may be an option. Possible surgical approaches for androgenic alopecia include follicle transplant, scalp reduction, and a transition flap.

Dyslipidemias

Cezary Wójcik*
Oregon Health Sciences University, Portland, OR, USA

1 General Principles

1.1 Definition of Dyslipidemias

Dyslipidemias are disorders encompassing abnormal function and/or levels of plasma lipoproteins. In routine clinical practice, they are detected by altered plasma lipid levels, which can be elevated (hyperlipidemia) or decreased (hypolipidemia). Normal lipid levels are not synonymous to desirable (optimal or physiological) levels. Dyslipidemias are of extreme clinical importance due to their association with atherosclerosis and rates of heart attack and stroke. The desirable level of low-density lipoprotein cholesterol (LDL-C) is <100 mg/dL, while the non-HDL-C desirable level is <130 mg/dL. High-density lipoprotein cholesterol (HDL-C) is considered low when <40 mg/dL in men and <50 mg/dL in women. Triglycerides (TGs) are above normal when >150 mg/dL after a 12 h fast [1].

1.2 Lipids and Lipoproteins

Lipoproteins are particles composed of lipids (C, cholesterol; TGs, triglycerides; phospholipids) and proteins (apolipoproteins, Apo). The standard lipid panel (LP) measures total TG and cholesterol content in a particle (-C), but not particle count (-P), which can be measured directly (e.g., NMR LipoProfile™) or by surrogate markers (e.g., ApoB or ApoA1 levels). Chylomicrons are synthesized in the intestinal epithelium (TG:C ratio 10:1). The liver synthesizes very low-density lipoprotein VLDL-P (TG:C ratio 5:1), hydrolyzed in circulation to intermediate (IDL-P), and then low-density lipoprotein (LDL-P), which hardly contain any TG. LDL-P and other ApoB-containing lipoproteins (e.g., chylomicron remnants, VLDL-P, and IDL-P) may penetrate the arterial intima, promoting the development of atherosclerotic plaques. High-density lipoprotein (HDL-P, measured by surrogate markers HDL-C or ApoA1) participates in reverse cholesterol transport from the plaque to the liver and therefore is thought to be beneficial. Circulating LDL-P is bound to LDL receptors on hepatocytes. This complex is endocytosed. LDL-P is degraded, while the LDL receptor is recycled to the cell surface to bind more LDL-Ps. However, PCSK9 (proprotein convertase subtilisin/kexin type 9), a protein secreted by hepatocytes, binds to LDL receptors preventing their recycling and leading to their degradation. Cholesteryl ester transfer protein (CETP) mediates the exchange of cholesteryl esters from LDL-P and HDL-P for TG from VLDL-P. In patients with metabolic syndrome and type 2 DM, VLDL-P is overloaded with TG, and CETP activity is increased. This leads to the formation of small, dense, cholesterol-poor LDL-Ps, which remain longer in the circulation. It also leads to the formation of small, cholesterol-poor HDL-Ps, which are unstable and release ApoA1, which is lost in the urine leading to decreased HDL-C [2, 3].

DOI 10.1007/978-1-4939-0779-3_126-1

1.3 Epidemiology

Western lifestyle increases the prevalence of dyslipidemia worldwide. In the USA, an estimated 53 % of adults have less than perfect lipid levels: 27 % have high LDL-C, 23 % have low HDL-C, and 30 % have high TG. 21 % of US adults have mixed dyslipidemia (high LDL-C with either low HDL-C and/or high TG). Nearly 6 % have all three abnormalities [4].

1.4 Screening for Dyslipidemias in Adults

Screening for dyslipidemias is recommended by the US Preventive Services Task Force (USPSTF) with Grade A recommendation in (1) men aged ≥35 years; (2) men aged 20–35 years, if at increased risk for coronary heart disease (CHD); and (3) women aged ≥45 years, if at increased risk for CHD. Screening women aged 20–45 years at increased risk for CHD has a Grade B recommendation. No recommendation is made for or against screening in men aged 20–35 years or women aged ≥20 years, not at increased risk for CHD (Grade C). Increased risk for CHD includes diabetes mellitus (DM), previous personal history of CHD or noncoronary atherosclerosis, tobacco use, hypertension, obesity, and family history of CHD in males aged <50 and females aged <60. The preferred screening method is total cholesterol (TC) and HDL-C on fasting or non-fasting samples. The optimal interval for screening is uncertain. Every 5 years is reasonable, with shorter intervals for people with dyslipidemia. An age to stop screening has not been established [5]. The National Lipid Association (NLA) recommends screening all adults (≥20 years) with a fasting or non-fasting lipid profile (LP) every 5 years [1].

1.5 Screening for Dyslipidemias in Children

According to the USPSTF, evidence is insufficient to recommend for or against routine screening for dyslipidemias in infants, children, adolescents, and young adults until the age of 20 years [5]. The NIH Heart, Lung, and Blood Institute Expert Panel recommended universal screening in children aged 8–11 years and adolescents aged 17–21 years with either fasting LP or non-HDL-C [6]. The American Heart Association (AHA) recommends cholesterol screening every 4–6 years for all adults ≥20 years, but does not endorse universal screening in pediatric populations. The American Academy of Pediatrics recommends testing of children with a fasting LP or a non-fasting non-HDL-C once between age 9 and 11 [6]. Screening starting at age 2 should be considered in children with a family history of premature cardiovascular disease or elevated cholesterol [7].

1.6 Classification

Dyslipidemias can be divided into primary (genetic) and secondary. Fredrickson's classification distinguishes the following:

- *Type I (hyperchylomicronemia)*: TG to TC ratio ~10:1, TG >1,000 mg/dL; presentation often in children with abdominal pain (recurrent pancreatitis) and eruptive xanthomas. No elevated atherosclerotic cardiovascular disease (ASCVD) risk. Prevalence ~1:1,000,000.
- *Type IIa (familial hypercholesterolemia, FH)*: LDL-C usually ≥190 mg/dL, in homozygous FH (hoFH) often up to 500 mg/dL and above. Subjects with mild mutations and heterozygous FH (heFH) may have LDL-C <190 mg/dL. Early ASCVD, sometimes in children, is present. Tendon xanthomas and corneal arcus are frequent findings. FH phenotype is classically caused by LDL receptor mutations, but can be seen with mutations of ApoB or PCSK9 (gain of function). Prevalence: hoFH 1:1,000,000, heFH 1:200–1:500.
- *Type IIb (familial combined hyperlipidemia, FCH):* LDL-C, TG elevated, low HDL-C, TG to TC ratio ~5:1, atherogenic, frequent with metabolic syndrome. Prevalence ~1:100–1:200.

DOI 10.1007/978-1-4939-0779-3_126-1

- *Type III (dysbetalipoproteinemia):* IDL-P elevated, TC ∼ 300 mg/dL, TG ∼ 300 mg/dL, tuberoeruptive xanthomas, orange palmar xanthomas, atherogenic. Caused by ApoE2/E2 genotype or rare ApoE mutations, often silent, unmasked by environmental factors in <20 % of ApoE2/E2 homozygotes. Prevalence ∼1:200.
- *Type IV (hypertriglyceridemia)*: TC ∼250 mg/dL, TG 400–1,000 mg/dL, low atherogenicity, exacerbated by alcohol and poor diet. Prevalence ∼1:100–1:200.
- *Type V (familial mixed hyperlipidemia)*: TC ∼250 mg/dL, TG >1,000 mg/dL, both chylomicrons and VLDL-P elevated, can present in childhood similar to type I, or later in life with type 2 DM, gout, and metabolic syndrome. Prevalence ∼1:100–1:200.

Dyslipidemias not included in the Fredrickson classification:

- Elevated *lipoprotein (a):* Lp(a) is a prothrombotic and atherogenic lipoprotein, with a specific Apo (a) covalently bound to ApoB, often found in families with early ASCVD [8].
- *Inherited low HDL-C*: hypoalphalipoproteinemia is usually associated with increased ASCVD. Rare forms include Tangier's disease and lecithin-cholesterol acyltransferase (LCAT) deficiency, which in its heterozygous form is known as fish-eye disease. It is unclear whether they are associated with higher ASCVD risk. Very rare forms of low HDL-C (such as with ApoA1 Milano) are cardioprotective.
- *Inherited high HDL-C*: very high HDL-C levels (>100 mg/dL) may not be cardioprotective, as they often reflect deficient function of HDL-P.
- *Inherited low LDL-C*: hypobetalipoproteinemia, autosomal dominant, heterozygote patients have LDL-C of 20 and less, decreased ASCVD risk. Moderate LDL-C decrease (40–60 mg/dL) and decreased ASCVD risk are seen with loss of function and PCSK9 mutations. Abetalipoproteinemia, autosomal recessive, presents in childhood (homozygotes only) with symptoms of deficiency of fat-soluble vitamins; LDL-C and VLDL-C are undetectable. Patients are at increased risk of hemorrhagic stroke.
- *Familial combined hypolipidemia*: caused by mutations of the ANGPTL3 gene; all lipid levels are very low, including HDL-C, decreased ASCVD risk.
- *Sitosterolemia*: with or without elevated LDL-C, caused by accumulation of toxic plant stanols and sterols, normally not absorbed into systemic circulation, increased risk of ASCVD, tendon xanthomas. Prevalence ∼1:1,000,000.
- *Cerebrotendinous xanthomatosis (CTX)*: rare, normal LDL-C levels, resulting from accumulation of cholestanol, increased ASCVD risk, mimics hoFH plus neurological abnormalities. Prevalence ∼1:50,000.
- *Cholesteryl ester storage disease aka LAL (lysosomal acid lipase) deficiency*: high LDL-C and TG, very low HDL-C, elevated LFTs, unexplained hepatosplenomegaly and hepatosteatosis. *Wolman's disease* is caused by complete LAL absence, fatal ∼ 1 year of age, due to anemia, liver failure, and cachexia. Prevalence ∼1:50,000.

Secondary dyslipidemias can be subdivided by causative condition into lifestyle induced (high cholesterol/high fat diet, sedentary lifestyle, alcohol), endocrine (metabolic syndrome/DM, hypothyroidism, Cushing, polycystic ovarian syndrome), drug induced (cyclosporine, progestins, thiazides, beta-blockers, retinoids, estrogens, steroids, atypical antipsychotics, protease inhibitors), pregnancy, renal

DOI 10.1007/978-1-4939-0779-3_126-1

(chronic renal disease, nephrotic syndrome), infectious (HIV, hepatitis), hepatic (obstructive liver disease, cholestasis), storage disease (Gaucher's), and others (anorexia nervosa, cancer, transplant patients). Atherogenic dyslipidemia associated with metabolic syndrome, obesity, and/or type 2 DM is characterized by high TG, low HDL-C, and normal or only slightly elevated LDL-C. However, there is a significant increase in LDL-P, which can be measured directly or as increased non-HDL-C or ApoB. It correlates with increased ASCVD risk [2, 3].

2 Diagnosis of Dyslipidemias

2.1 History

Patients with dyslipidemia often have signs and symptoms of atherosclerosis in different locations; therefore, it is important to inquire about exertional chest pain, history of abnormal EKG, stress test, intermittent claudication, erectile dysfunction, diagnosed CAD, or stroke/TIA. High TG level may cause recurrent pancreatitis in adults and children. History of intermittent abdominal pain and skin eruptions characterizes children with chylomicronemia. Infants with hypo- and abetalipoproteinemia present with failure to thrive, steatorrhea, and developmental delay. Recurrent Achilles tendonitis in a child or adolescent may indicate FH. Family history should focus on premature ASCVD, early death, unusual skin/tendon lesions, pancreatitis, or known lipid disorders. It is important to review dietary habits, smoking history, alcohol use, exercise, and use of any medications or dietary supplements.

2.2 Physical Examination

Many physical findings are present in patients with dyslipidemias. Excess cholesterol and/or TG form deposits in different tissues. Xanthelasmas are flat, demarcated cholesterol deposits in subcutaneous tissue usually in or close to eyelids. Xanthelasmas are common and nonspecific, often a familial trait unrelated to dyslipidemia, never related to TG elevation. Larger and more tuberous cholesterol deposits are called xanthomas. Tendon xanthomas, specifically Achilles tendon xanthomas, are found in FH, CTX, and sitosterolemia patients, often at an early age. Tuberoeruptive xanthomas on elbows and knees as well as palmar xanthomas are found in dysbetalipoproteinemia. Arcus senilis is a grayish/white C/phospholipid deposit in the corneal margin. When found that at <40 years of age is associated with dyslipidemia, later in life is a nonspecific finding. Clouding of the entire cornea from cholesterol deposits is characteristic of fish-eye disease. Eruptive xanthomas are TG accumulations in the form of small papules often with an inflammatory base, found in hyperchylomicronemia and severe hypertriglyceridemia. Fundoscopic eye exam in children suspected to have hoFH may reveal nonarteritic ischemic optic neuropathy. Lipemia retinalis is a creamy white appearance of retinal vessels associated with high TG levels. Orange tonsils are characteristic of Tangier's disease. Hepatosplenomegaly can be found in patients with type I or type V dyslipidemia, as well as with LAL deficiency. A systolic ejection murmur at the right upper sternal border can be auscultated in patients with hoFH, reflecting aortic stenosis (AS) resulting from xanthomatous infiltration of aortic valves (valvular AS) and root (supravalvular AS). Patients with CTX show cataracts and various neurological symptoms: ataxia, dysarthria, dementia, and seizures [2, 3].

2.3 Laboratory and Imaging

It is important to distinguish measured C levels within lipoprotein particles (-C) from the actual levels of particles themselves (-P). LP provides information about TC, LDL-C, HDL-C, VLDL-C, as well as TG. Non-HDL-C is calculated by subtracting HDL-C from TC. When LP is collected, non-fasting TG levels can be 20–40 % higher than fasting. When LDL-C is calculated by the Friedewald formula [LDL-C $=$ TC$-$(HDL-C $+$ TG/5)], it becomes inaccurate with TG >200 mg/dL and unreliable

DOI 10.1007/978-1-4939-0779-3_126-1

with >400 mg/dL. In such case, direct LDL-C measurement is obtained. Non-fasting TC and HDL-C can be used to calculate non-HDL-C. TSH and proteinuria screen will rule out two common secondary causes of dyslipidemia. In anticipation of statin therapy, obtaining baseline LFTs, A1C, and CK levels is advised [2, 3].

Extent of preclinical atherosclerosis is measured by two noninvasive methods: carotid intima-media thickness (CIMT), obtained by US, and coronary calcium score (CCS), obtained by a limited CT scan. CCS has a higher grade of recommendation for the purpose of risk restratification in intermediate risk individuals [9].

2.4 Special Testing

Advanced lipid tests are offered by several companies (Cleveland HeartLab, Atherotech, LipoScience, Boston Heart, Berkeley HeartLab, etc.). They include combinations of measurements, obtained by different proprietary techniques, which are often discrepant. Caution is advised when using those tests, as many of them lack high-level evidence for their use, especially in the general population.

LDL-C and LDL-P can be discordant in up to 30 % of individuals, especially those with metabolic syndrome. LDL-P is a better predictor of CV risk than LDL-C [10, 11]. Increasing accuracy of surrogate markers to estimate CV risk reflects the direct association of LDL-P with atherosclerosis (LDL-P > ApoB > non-HDL-C > LDL-C > TC). LDL-P can be measured directly by tests such as NMR LipoProfile™, also providing measurement of other lipoproteins and the insulin resistance index (predicting the risk of developing type 2 DM). Canadian and NLA guidelines recommend measuring ApoB as the secondary target of therapy. Measurement of Lp(a) is reasonable in patients with family history of early ASCVD. Evaluation of two different inflammatory markers, high-sensitivity CRP and Lp-PLA2, aids in the potential restratification of patients at intermediate risk. Evidence is lacking to use HDL and LDL subfractions as well as more comprehensive inflammatory panels [2, 3, 12].

Genotyping ApoE helps diagnose dysbetalipoproteinemia (Apo E2/E2), and it can also disclose increased risk of Alzheimer's disease (Apo E4/E4). Cholestanol measurement evaluates the proportion of cholesterol from intestinal absorption vs. synthesis in order to potentially guide therapeutic decisions [2, 3].

2.5 Differential Diagnosis

Treatable, secondary causes of dyslipidemia need to be ruled out before concluding that it is a primary, i.e., genetic problem. Most cases of dyslipidemia reflect a combination of genetic and environmental factors.

3 Treatment

Dyslipidemias, especially secondary to poor lifestyle choices, are amenable to therapeutic lifestyle modifications (TLMs). However, pharmacologic therapy is often required. According to the 2013 American College of Cardiology (ACC)/AHA recommendations, statin therapy is based on a global assessment of risk and potential benefit of treatment evidenced in randomized controlled trials (RCTs) without the need of using targets of therapy (Fig. 1). The 2013 ACC/AHA guidelines emphasize statin treatment in four statin benefit groups: (1) patients with established ASCVD, (2) patients with LDL-C ≥190 mg/dL, (3) patients aged 40–75 with DM and LDL-C 70–189 mg/dL, and (4) patients aged 40–75 with 10-year ASCVD risk ≥7.5 %, as calculated by pooled cohort equations (http://my.americanheart.org/professional/StatementsGuidelines/Prevention-Guidelines_UCM_457698_SubHomePage.jsp) [9].

In contrast, the NLA, International Society for Atherosclerosis, Canadian Cardiovascular Society, and other organizations still focus on attaining specific lipid targets [1, 13, 14]. NLA recommends the use of

DOI 10.1007/978-1-4939-0779-3_126-1

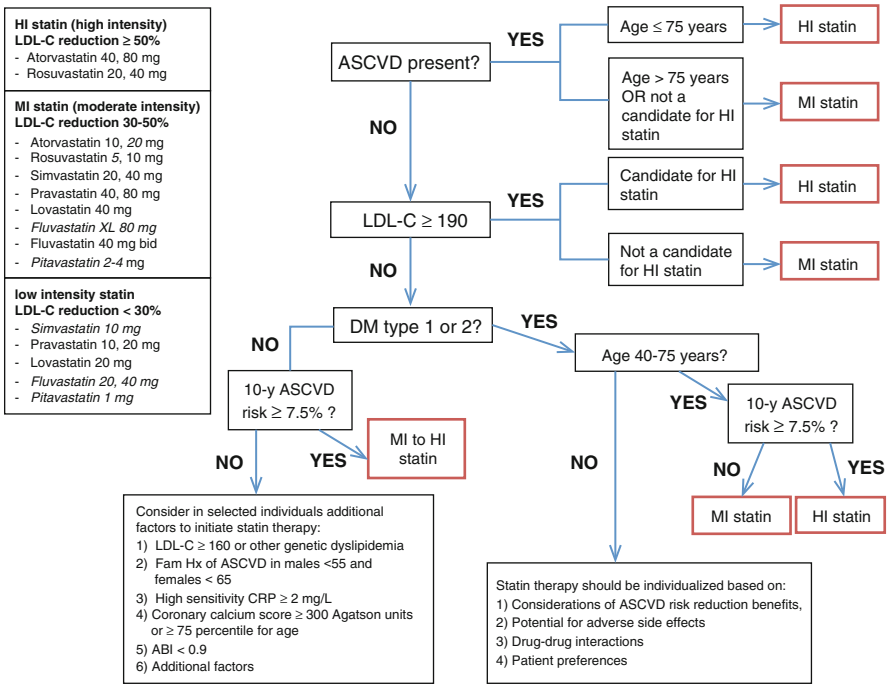

Fig. 1 Algorithm of major recommendations for statin therapy for ASCVD prevention based on 2013 ACC/AHA guidelines. Heart healthy lifestyle is the foundation for prevention. In individuals aged 40–75 without ASCVD, without DM, and with LDL-C 70–189 mg/dL, pooled cohort equations should be used to recalculate risk every 4–6 years. Initial evaluation prior to initiation of statin therapy should include fasting LP, ALT, A1C (if DM status is unknown), and CK (if indicated) and possible evaluation for secondary causes of dyslipidemia. TG ≥500 mg/dL and unexplained ALT elevation >3 × the upper limit of normal should be further evaluated and treated. Patients with LDL-C ≥190 should be evaluated for secondary causes. If dyslipidemia is primary, family should be screened for FH. Adherence to therapy should be tested initially by fasting LP in 4–12 weeks, thereafter every 3–12 months. Lack of anticipated response with good adherence may require increase of statin intensity and/or consider adding non-statin therapy. Statin intolerance requires considering non-statin therapy. In the table showing statin doses for different intensities of therapy, italic font means particular doses or statins were not tested in RCTs

pooled cohort equations, as well as Reynolds or Framingham scoring for risk assessment, in order to establish desired goals. NLA recommends the use of non-HDL-C as the primary target of therapy. In low-, moderate-, and high-risk patients, the non-HDL-C goal is <130 mg/dL (LDL-C goal <100 mg/dL, ApoB goal <90 mg/dL), while in very high-risk patients, the non-HDL-C goal is <100 mg/dL (LDL-C goal <70 mg/dL, ApoB goal <80 mg/dL). Decreased HDL-C (<40 mg/dL in men and <50 mg/dL in women) is not considered a target of therapy, but a marker of cardiovascular risk. TG >500 mg/dL are treated to prevent pancreatitis. TG 150–500 mg/dL is are not a target of therapy, but a marker of cardiovascular risk [1].

3.1 Therapeutic Lifestyle Modifications (TLMs)

TLMs constitute the foundation of management of dyslipidemias. Moderate aerobic physical activity 30–45 min at least 5 × per week improves CV health, leading to decrease in TG and LDL-C, with increase of HDL-C. Diets high in saturated fats raise LDL-C and HDL-C. In addition, trans fats increase Lp(a) levels. High-carbohydrate low-fat diets lower LDL-C and HDL-C, but increase TG and LDL-P, and therefore should be avoided by patients with metabolic syndrome/type 2 DM. Mediterranean diet decreases LDL-C and raises HDL-C. Nut consumption decreases LDL-C and TG. Alcohol consumption raises TG and HDL-C. Patients with type I and V dyslipidemias require very low-fat diets [2, 3].

DOI 10.1007/978-1-4939-0779-3_126-1

3.2 Medications

There are various classes of drugs used to treat dyslipidemias (Table 1). Statins inhibit hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme of cholesterol synthesis. This leads to increased removal of LDL-P from plasma by upregulation of liver LDL receptors. Statins decrease LDL-C (18–55 % reduction), non-HDL-C (15–51 %), and TG (7–30 %), while increasing HDL-C (5–15 %). They also exert additional pleiotropic effects, unrelated to LDL-C lowering (e.g., anti-inflammatory, antithrombotic, and plaque stabilizing). Their benefits have been confirmed in multiple RCTs.

Statins are generally well tolerated, but up to 10 % of patients may show statin intolerance. Choice of different statins is mostly based on their potency, side effects, drug interactions, and cost (Table 1). Myalgias and myopathy are the main reason of switching statin, nonadherence, and discontinuation of therapy. Severe rhabdomyolysis is very rare (1:100,000). However, patients initiating statins should be

Table 1 Lipid-lowering medications

Medication	Dose range	LDL reduction (%)	Cost	Side effects and special considerations	Pregnancy category
Statins (HMG-CoA reductase inhibitors)					
Atorvastatin (Lipitor)	10 mg qd min 80 mg qd max	31–35 50–60	$$–$$$	CYP3A4 metabolized, long half-life, avoid erythromycin, azoles, protease inhibitors, cyclosporine, and grapefruit juice	X
Rosuvastatin (Crestor)	5 mg qd min 40 mg qd max	40–48 58–64	$$$$	Minimal CYP2C9, long half-life	X
Fluvastatin (Lescol)	20 mg qhs min 80 mg XL max	20–25 27–32	$$	CYP2C9, least chance of myopathy, short half-life	X
Lovastatin (Mevacor)	10 mg qhs min 80 mg qhs or 40 mg bid max	25–30 35–40	$–$$	CYP3A4 metabolized, short half-life, avoid erythromycin, azoles, protease inhibitors, cyclosporine, and grapefruit juice. Best absorbed with food	X
Pitavastatin (Livalo)	1 mg qd 4 mg qd	32–46	$$$$	Minimal CYP2C9 and 2C8, long half-life	X
Pravastatin (Pravachol)	10 mg qhs min 80 mg qhs max	25–32 17–32	$–$$	Minimal CYP metabolism, short half-life, avoid erythromycin	X
Simvastatin (Zocor)	10 mg qhs min 40 mg qhs max	27–32 38–43	$–$$	CYP3A4 metabolized, short half-life, avoid erythromycin, azoles, protease inhibitors, cyclosporine, and grapefruit juice. Decrease dosing of diltiazem, verapamil, amlodipine, and amiodarone	X
Cholesterol absorption inhibitors					
Ezetimibe (Zetia)	10 mg qd	20	$$$$	Well tolerated; when combined with statin, it can raise LFTs and contribute to myalgia/myopathy. Available in combination with simvastatin (Vytorin) and atorvastatin (Liptruzet)	C
Bile acid sequestrants					
Colestipol (Colestid)	2–16 g qd or divided (start low and titrate up)	10–25	$$	Do not use when TG >300; constipation; decreased absorption of many drugs and vitamins. Contraindicated when hx of bowel obstruction	B

(*continued*)

DOI 10.1007/978-1-4939-0779-3_126-1

Table 1 (continued)

Medication	Dose range	LDL reduction (%)	Cost	Side effects and special considerations	Pregnancy category
Cholestyramine (Questran)	4–16 g divided bid (start low and titrate up)	10–25	$$	Do not use when TG >300; constipation; decreased absorption of many drugs and vitamins. Contraindicated when hx of bowel obstruction	C
Colesevelam (Welchol)	3.75 g qd or divided bid	10–25	$$$	Easier to use, less interactions. Do not use when TG >300; constipation; decreased absorption of many drugs and vitamins. Lowers A1C 0.5 %. Contraindicated when hx of bowel obstruction	B
Niacin (nicotinic acid – not nicotinamide)					
Niacin immediate release, crystalline (Niacor, etc.)	100–3,000 initial dose qd, then divided bid/tid, titrate up slowly	5–25	$	Flushing, dry skin, rash, glucose intolerance/new onset type 2 DM, hyperuricemia, dyspepsia/PUD, afib, infections. May enhance side effects of statins	C
Niacin sustained release (Endur-Acin, etc.)	500–2,000 mg qhs, titrate up slowly	5–25	$	Flushing, dry skin, rash, glucose intolerance/new onset type 2 DM, hyperuricemia, dyspepsia/PUD, afib, infections. May enhance side effects of statins. Monitor LFTs due to potential hepatotoxicity	C
Niacin extended release (Niaspan)	500–2,000 mg qhs, titrate up slowly	5–25	$$–$$$	Flushing, dry skin, rash, glucose intolerance/new onset type 2 DM, hyperuricemia, dyspepsia/PUD, afib, infections. May enhance side effects of statins. Monitor LFTs due to potential hepatotoxicity	C
Fibrates					
Gemfibrozil (Lopid)	600 mg bid	6–20 when TF <400, increase when TG >400	$$	Avoid combination with statins due to increased risk of myalgia/myopathy	C
Fenofibrate (Tricor, Trilipix, Lofibra, Fenoglide, Lipofen, Triglide, etc.)	43–200 mg qd	6–20 when TF <400, increase when TG >400	$–$$$	May be combined with statins. Avoid in kidney disease. Multiple formulations make dosing confusing	C
ω3 polyunsaturated fatty acids					
DHA/EPA (Lovaza)	4 g qd or 2 g BID	increase up to 40 %	$$$	Well tolerated, may increase ALT, may increase bleeding time	C
EPA (Vascepa)	2 g BID	0	$$$	Well tolerated, may increase ALT, may increase bleeding time	C
Microsomal triglyceride transfer protein inhibitors					
Lomitapide (Juxtapid)	Start 5 mg qd, titrate up as tolerated up to 60 mg qd	40–50	$$$$$$$	Use restricted to hoFH, REMS required; risk of hepatotoxicity. Requires strict low-fat diet. GI side effects	X

(*continued*)

DOI 10.1007/978-1-4939-0779-3_126-1

Table 1 (continued)

Medication	Dose range	LDL reduction (%)	Cost	Side effects and special considerations	Pregnancy category
ApoB antisense oligonucleotide					
Mipomersen (Kynamro)	200 mg Subq injection, q week	40–50	$$$$$$$	Use restricted to hoFH, REMS required; risk of hepatotoxicity	B
PCSK9 inhibitor antibodies					
Alirocumab, evolocumab, bococizumab, and others	75–200 mg Subq injection q2 weeks or q month	49–51 %	$$$$?	In phase 3 trials, likely to be on the market soon. Alirocumab reported 54 % RRR in CV events vs. placebo	?

warned of signs and symptoms of this adverse reaction (tea-colored urine, oliguria, severe muscle pain, nausea, vomiting, confusion). Following liver function tests (LFTs) is no longer recommended in asymptomatic patients after the initiation of statin therapy. Mild elevation of LFTs (<3 × upper limit of normal) is observed in 1–2 % of patients taking statins and should not lead to discontinuation of therapy. Statins very rarely if at all cause liver disease/failure. Liver disease is not a contraindication of their use. Statins confer a small, dose-dependent risk of developing type 2 DM in predisposed individuals (up to 9–12 %). However, CV benefits from their use greatly outweigh this risk. While data from RCTs do not show any adverse effects of statins on cognition, several observational studies reported memory problems and cognitive impairments with statin use, which lead to their discontinuation [13, 15].

According to 2013 ACC/AHA recommendations, treatment with statins aims for a >50 % reduction of LDL-C with high-intensity statins and >30 % reduction with moderate-intensity statins. When following NLA recommendations, achieving the non-HDL-C goal (representing LDL-P) <130 mg/dL or <100 mg/dL (very high-risk patients) becomes more important.

Statin-intolerant patients, as well as patients who fail to achieve goals on statins alone, can benefit from add-on therapy, such as the intestinal cholesterol absorption blocker ezetimibe (LDL-C reduction of 13–20 %, non-HDL reduction 14–19 %, TG reduction 5–11 %, HDL-C increase 3–5 %) or bile acid sequestrants (LDL-C reduction 15–30 %, non-HDL reduction 4–16 %, HDL-C increase 3–5 %, TG increase up to 10 %).

TG >500 mg/dL are treated with fibrates, niacin, and/or prescription strength omega-3 fish oils (ω3PUFAs), which lower TG 20–50 %. Niacin also lowers LDL-C (5–25 %) and non-HDL-C (8–23 %), raises HDL-C (15–35 %), and decreases LDL-P. European guidelines recommend niacin to lower Lp(a) in patients with levels >50 mg/dL [8]. Fibrates and high-dose ω3PUFAs decrease LDL-P as reflected by the non-HDL decrease 5–19 %, while they either do not affect LDL-C (TG <400 mg/dL) or increase LDL-C 20–25 % (TG >400 mg/dL). Fibrates do increase HDL-C 10–20 %, while the effect of ω3PUFAs on HDL-C is variable.

CETP inhibitors (torcetrapib, dalcetrapib, etc.) were once promising drugs, which failed in clinical trials: they either caused increased mortality or lack meaningful effects despite raising HDL-C levels. An emerging therapy, likely soon to be approved by the FDA, is the use of monoclonal antibodies binding PCSK9. Blocking PCSK9 increases the number of LDL receptors and therefore LDL-P clearance. New drugs approved for hoFH patients include mipomersen and lomitapide, which by different mechanisms prevent VLDL-P synthesis in the liver [2, 3].

3.3 LDL Apheresis

In severe hoFH, often multiple drugs are used to achieve the therapeutic goal of lowering LDL-C at least 50 %. When maximally tolerated pharmacotherapy fails (LDL-C >200 mg/dL in subjects with CAD,

DOI 10.1007/978-1-4939-0779-3_126-1

>300 mg/dL in those without CAD), patients are treated with LDL apheresis. The procedure lasts 2–4 h and it is performed every 2–4 weeks in special facilities. Each apheresis session leads to a 49–75 % decrease in LDL-C [1, 7].

3.4 Diet Supplements

Red rice yeast contains natural lovastatin (2–10 mg). However, red rice yeast produced in the USA may not contain any lovastatin, as mandated by the FDA. Plant sterols/stanols lower LDL-C by 5–20 %. Soluble dietary fiber lowers LDL-C by 5–10 %. Soy protein has a marginal benefit on lowering LDL-C. There is no evidence supporting the use of garlic, guggulipid, policosanol, or tocotrienols in lowering LDL-C. Over-the-counter fish oil (ω3PUFA) lowers TG and LDL-P, while raising HDL-C and LDL-C. Statins lower CoQ10 levels; therefore, CoQ10 supplementation may prevent myalgias associated with statin use [2, 3, 14].

3.5 Referrals

Difficult to manage patients with dyslipidemias, especially patients with extreme LDL-C and TG elevations, and those who do not respond appropriately to therapy should be referred to clinical lipidologists. This is an emerging subspecialty, open to family physicians (http://www.lipidboard.org).

4 Prevention

Physical activity, weight loss, and a diet low in cholesterol and saturated fat (for patients with high LDL-C) and/or carbohydrates (for patients with atherogenic dyslipidemia) form the basis of prevention of secondary dyslipidemias [2, 3].

5 Family and Community Issues

Cascade screening of family members is advised, especially in the case of FH and elevated Lp(a). Prevalence of FH is elevated in some ethnic groups (French Canadians, Ashkenazi Jews, Afrikaners, Lebanese Christians). The FH Foundation provides resources, support, and cascade registry (http://thefhfoundation.org).

Diabetes Mellitus

Charles Kent Smith[a]*, John P. Sheehan[b] and Margaret M. Ulchaker[b]
[a]School of Medicine, Case Western Reserve University, Cleveland, OH, USA
[b]North Coast Institute of Diabetes and Endocrinology, Inc., Cleveland, OH, USA

Diabetes mellitus (DM) affects over 29 million individuals or 9.3 % of the United States (US) population. Twenty-one million are diagnosed; 8.1 million are undiagnosed. Estimated total costs of diabetes in the US in 2012 were $245 billion, with $176 billion in direct costs and $69 billion in indirect costs. Prediabetes affects 37 % of the US population and 51 % of individuals over age 65 years. The most prevalent form of DM, type 2 DM, has racial preponderances, female predilection, and strong associations with obesity. The rates of type 2 DM in individuals under aged 20 years is increasing especially in minority populations [1]. Published national and international standards of care have been disseminated directly to patients and physicians, heightening the importance of adequate care and glycemic control to minimize devastating long-term complications [2, 3]. Table 1 describes diagnostic criteria for diabetes mellitus and impaired glucose tolerance [4].

Heightened clinical awareness of the genetics and predisposing factors should foster early diagnosis and adequate metabolic control of the type 2 patient. In contrast, the type 1 DM patient generally presents with a more precipitous clinical picture of ketoacidosis. Declining islet β-cell secretory function is more gradual, however, and can evolve over a 10-year period. Occasionally, there is diagnostic confusion owing to a lack of a family history, the absence of significant ketosis, and the absence of significant obesity and other diagnostic hallmarks. The measurement of C-peptide levels, glutamic acid decarboxylase antibodies (GAD), islet cell antibodies, and insulin autoantibodies provides useful diagnostic clarification. C-peptide is the fragment produced when proinsulin, produced by the islets of Langerhans, is cleaved to produce insulin. For every molecule of insulin produced, a molecule of C-peptide has to exist; therefore, C-peptide is a marker of endogenous insulin production. Measurement of a C-peptide level is very useful in documenting insulin secretory capacity in the insulin-treated individual, in whom an insulin level would measure both endogenous and exogenous insulin. Careful clinical follow-up can clarify evolving absolute insulin deficiency even in the absence of these laboratory markers. Latent autoimmune diabetes of adulthood (LADA) is characterized by positive GAD antibodies and has a more indolent nature. Patients may remain on non-insulin-based pharmacotherapy for years before requiring insulin therapy [5].

Pathophysiology

Previously, type 1 DM was considered to be an acute event. Viral associations were invoked with regard to the seasonal trends in its incidence. However, patients can have markers of islet destruction in the form of GAD antibodies, islet cell antibodies, and/or insulin autoantibodies for up to 10 years prior to the development of overt DM. Positive antibodies along with the loss of first-phase insulin secretion in response to an intravenous glucose tolerance test are highly predictive of evolving type 1 DM. Immunomodulation in type 1 DM with immunosuppressive or stem cell therapy has proved elusive despite studies demonstrating short-term success.

Table 1 Diagnostic criteria for diabetes mellitus, impaired glucose tolerance, and gestational diabetes

Nonpregnant adults
Criteria for diabetes mellitus: diagnosis of diabetes mellitus in nonpregnant adults should be restricted to those who have one of the following
Fasting plasma glucose ≥126 mg/dl. Fasting is defined as no caloric intake for at least 8 h
Symptoms of diabetes mellitus (such as polyuria, polydipsia, unexplained weight loss) coupled with a random plasma glucose level of ≥200 mg/dl. Random is defined as any time of day without regard to time interval since the last meal
2-h postprandial plasma glucose ≥200 mg/dl during an oral glucose tolerance test. The test should be performed by World Health Organization criteria using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water
Hemoglobin A1c (HbA1c) ≥ 6.5 % by a National Glycosylated Hemoglobin Standardization Program (NGSP)-certified or traceable method
Note: In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a second occasion. The oral glucose tolerance test is not recommended for routine clinical use
Criterion for impaired glucose tolerance: 2-h postprandial plasma glucose ≥140 mg/dl and ≤199 mg/dl during an oral glucose tolerance test. The test should be performed by World Health Organization criteria using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water
Pregnant women – see chapter "12"

In contrast, type 2 DM is associated with genetic predispositions, advancing age, obesity, and lack of physical fitness. The importance of appropriate caloric intake and energy expenditure has been clearly established. The Twin Cycle Hypothesis of glucose and lipid defects involves lipid accumulation in the liver and worsening hepatic insulin resistance. Additionally, lipid accumulation in the β-cell worsens β-cell function and promotes β-cell apoptosis. Hence, caloric restriction will reduce hepatic and β-cell lipid accumulation [6]. Although type 2 DM is a syndrome of insulin resistance and β-cell secretory defects, in any given individual it is not possible to define the degree of insulin resistance versus secretory defects with any precision. The earliest metabolic defect found in first-degree relatives of individuals with type 2 DM is defective skeletal muscle glucose uptake with later increased insulin resistance at the level of the liver and resultant uncontrolled hepatic glucose output. The ensuing hyperglycemia can have a toxic effect called glucotoxicity on the islets, resulting in worsening secretory defects with declining insulin secretion and self-perpetuating hyperglycemia. Hyperglycemia can also downregulate glucose transporters. To become hyperglycemic, insulin secretion must be insufficient to overcome the insulin resistance; it has been estimated that insulin secretory capacity is reduced by 50–80 % at the time of diagnosis of type 2 DM. It is unclear whether secretory defects or insulin resistance is the primary defect even for type 2 DM. Patients may exhibit many abnormalities, including loss of first-phase insulin secretion and loss of the pulsatility of insulin secretion. Additionally, both men and women tend to have abdominal obesity, which is associated with hyperinsulinemia and insulin resistance. Type 2 DM is a syndrome not only of disordered glucose metabolism but also of lipid metabolism; many patients have a concurrent dyslipidemia manifesting as elevations in serum triglycerides, reductions in high-density lipoprotein (HDL) cholesterol, and marginal increases in total cholesterol. This dyslipidemia results from uncontrolled hepatic very low-density lipoprotein (VLDL) secretion and defective clearance of lipoprotein molecules. The associations of hyperinsulinemia and insulin resistance with essential hypertension are well documented along with the marked tendency for patients with essential hypertension to develop DM and the converse – patients with type 2 DM developing essential hypertension. A central unifying hypothesis focuses on hyperinsulinemia and insulin resistance being primary metabolic aberrations that result not only in hyperglycemia but also hypertension and dyslipidemia. Defronzo's original triumvirate of liver, β-cell, and skeletal muscle dysfunction has been expanded and replaced by the concept of the ominous octet which is now regarded as the basis of the pathophysiology of type 2 DM [7]

DOI 10.1007/978-1-4939-0779-3_127-1

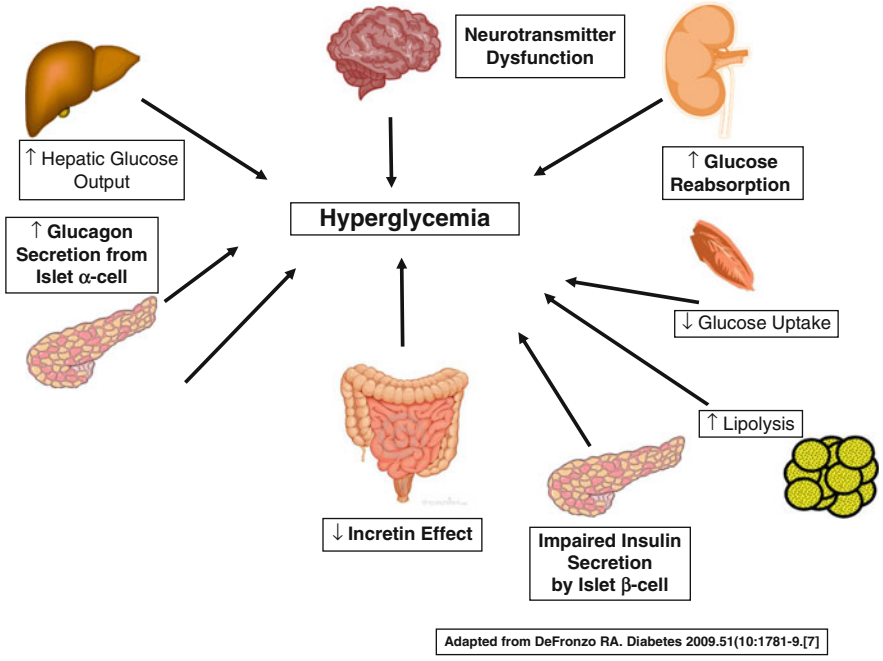

Fig. 1 The ominous octet (**Adapted from DeFronzo [7]**)

(see Fig. 1). Other aspects of the cardiometabolic syndrome include polycystic ovarian syndrome (PCOS), obstructive sleep apnea, and hyperuricemia [8].

Importance of Glycemic Control

The Diabetes Control and Complications Trial (DCCT) in individuals with type 1 DM proved the profound impact of intensive therapy on reducing the risk of microvascular complications. The EDIC trial (Epidemiology of Diabetes Intervention on Complications), the extension of the DCCT through 18 years, has continued to demonstrate that prior good glycemic control provided reduced future risk of microvascular and macrovascular complications – the concept termed "metabolic memory"[9]. A potential negative aspect of attempts to achieve optimum glycemic control by intensive insulin therapy is the potential for severe hypoglycemia. An educated and motivated patient working with a multidisciplinary healthcare team can significantly reduce the risk of this. Glycemic goals may need to be modified in the individual with poor hypoglycemia awareness. The United Kingdom Prospective Diabetes Study (UKPDS), a 20-year prospective study in newly diagnosed type 2 DM patients, demonstrated that both intensive glycemic control and intensive blood pressure control reduced the risk of microvascular and macrovascular complications of DM. The 10-year follow-up of the UKPDS showed reduced complications from earlier good glycemic control, a concept that was termed the "legacy effect"[10]. Excellent metabolic control is defined by normal hemoglobin A1c (HbA1c) levels without significant hypoglycemia as an achievable goal.

Defining Control

The definition of DM control has varied throughout the decades. The HbA1c, the marker of long-term glycemic control, measures the degree of glycosylation of the A1c subfraction of hemoglobin and reflects

DOI 10.1007/978-1-4939-0779-3_127-1

the average blood glucose over the preceding 60–90 days. The HbA1c allows for identification of possible patient falsification of, or errors in, home blood glucose monitoring (HBGM) results. It is a useful motivating tool for patients; it often becomes a perceived challenge to reduce the result within the constraints of hypoglycemia. The National Glycosylated Hemoglobin Standardization Program (NGSP) is responsible for standardizing and correlating various assays to the DCCT methodology. Hemoglobinopathies can skew HbA1c results and can be detected via inspection of the chromatograms in the laboratory. The American Diabetes Association recommends that the HbA1c be performed at least two to four times per year in all patients. Given that the DCCT demonstrated a linear relation between the HbAlc (all the way into the normal, nondiabetic range) and microvascular complication risk, the ideal is therefore normalization of the HbA1c within the constraints of hypoglycemia. The Action to Control Cardiovascular Risk Reduction (ACCORD) study in individuals with type 2 DM of 10 years duration and preexisting cardiovascular disease however showed increased cardiovascular events and mortality in the intensively treated group [11]. This increase is believed by many experts to be due to the hypoglycemia risks with the use of insulin and other secretagogues in this high-risk population. A recent meta-analysis showed a disturbing association between sulfonylurea/insulin combination and cardiovascular risk and mortality [12]. Measurement of 1,5 anhydroglucitol reflects glucose control in postprandial states but is typically utilized in research settings as opposed to use in clinical practice. Fructosamine assays as a marker of glycemic control over the preceding 2–3 weeks are rarely used in clinical practice.

Glycemic Goals

Glycemic goals should be individualized based upon age, diabetes duration, complications of diabetes, comorbid conditions, and life expectancy. The ADA's goals are for most nonpregnant adults to have an HbA1c <7.0 % (with a view to <6.5 % in selected individuals) and <8.0 % in less healthy individuals. ADA's preprandial capillary glucose goal is 80–130 mg/dl with peak postprandial capillary glucose goal of <180 mg/dl [13]. The American Association of Clinical Endocrinologists (AACE) recommends tighter glycemic goals of an HbA1c <6.5 % for most individuals with less stringent goals for less healthy individuals such as those with a limited life expectancy. AACE's glycemic goals are a fasting plasma glucose <110 mg/dl with 2-h postprandial goals <140 mg/dl [3].

In addition to markers of glycemic control, it is critical to monitor other clinical parameters. Annual lipid profiles are an integral part of overall DM care in view of the high prevalence of dyslipidemia especially in the patient with type 2 DM. In type 1 DM patients, lipid disturbances are uncommon unless patients are in poor glycemic control, have a familial dyslipidemia, or have renal insufficiency. Markers of nephropathy are also important to measure. The earliest marker, microalbuminuria, is not only a forerunner of overt clinical nephropathy but is also a marker for greatly increased cardiovascular risk in both type 1 DM and type 2 DM patients. Microalbuminuria can be conveniently measured in spot urine specimens or by an overnight albumin excretion rate, rather than the more cumbersome 24-h urine collection.

Patient Education

Patient attention to management principles decidedly affects short-term metabolic control and ultimately has an impact on long-term complications. Interactions of patients with registered nurses and dietitians (preferably certified diabetes educators) are critical. The presence of family members and significant others during the educational sessions is vital to a successful outcome. Education must encompass a

DOI 10.1007/978-1-4939-0779-3_127-1

comprehensive understanding of the pathophysiology of DM and its complications and the importance of attaining and sustaining metabolic control.

Home Blood Glucose Monitoring

Accurate HBGM is a key to successful diabetes management. In type 1 DM patients, the minimum safe and efficacious schedule is premeal and *hs*. For optimum safety and efficacy, individuals should also monitor BG levels 2-h postprandially and prior to driving. Periodic overnight monitoring is also helpful to assess nocturnal glycemic issues. In individuals with type 2 DM, performing HBGM daily at varying times of the day is a good start. Pending the pharmacotherapy regimen, individuals with type 2 DM may need to monitor BG levels up to that ideally recommended for the individual with type 1 DM. Results stored in the memory of meters can be downloaded to a computer via a meter-specific computer program. However, the traditional written log actually provides more information when an educated, motivated patient records HBGM results, times of day, medication administered, carbohydrate intake, and notes regarding activity and other variables.

Continuous glucose sensors which measure interstitial glucose levels are approved by the US Food and Drug Administration for trend detection only and do not replace HBGM for insulin dosing or for confirmation of hypoglycemia. Calibrations must be done at least every 12 h and should ideally be performed when glucose levels are in steady state (fasting or 3–4 h postprandially) to ensure best correlation. One insulin pump has a "threshold suspend" feature whereby when the individual's interstitial glucose level reaches a predefined glucose level, the insulin pump will suspend insulin delivery.

Medical Nutrition Therapy

Education must also focus on dietary principles. Many patients still perceive that "sugar-free" implies carbohydrate-free and that "sugar-free" foods cannot affect blood glucose control. This belief fails to recognize the monomer/polymer concept and the fact that carbohydrates are ultimately digested into glucose. Achieving a high degree of dietary education generally requires several sessions with a dietitian/nutrition specialist. Dietary principles are an ongoing exercise, and eradication of myths and misconceptions is a major task.

For individuals with diabetes, the macronutrient distribution must be individualized although the total dietary fat intake should be 20–30 % of kcal. Caloric requirements are based on ideal body weight (IBW) – not actual body weight [14]. We calculate IBW by the Hamwi formula.

Women
100 lb for 5 ft
5 lb for every additional inch
Example: woman $5'3'' = 115$ lb IBW
Men
106 lb for 5 ft
6 lb for every additional inch
Example: man $5'8'' = 154$ lb IBW

Based on anthropometric measures, 10 % may be subtracted or added based on small body frame or large body frame, respectively.

Basal caloric requirements can then be calculated as follows.

$$\text{Woman } 5'3'' : \text{IBW} = 115 \text{ lb}$$
$$115 \times 10 \text{ kcal} = 1,150 \text{ kcal/day}$$

DOI 10.1007/978-1-4939-0779-3_127-1

Add 300–400 kcal/day for moderate to strenuous activity. Subtract 500 kcal/day to achieve 1 lb per week of weight loss.

Because individuals with DM type 2 are generally hyperinsulinemic, diet prescriptions for weight loss and maintenance require a lower caloric level than previously mentioned. The activity factor in kilocalories (300–400 kcal/day) can be modified in these individuals. For the overweight type 2 DM patient, caloric restriction is of major importance. A hypocaloric meal plan that is acceptable to the patient, regardless of the macronutrient composition, is the key [15]. Patients tend to underestimate caloric intake and overestimate energy expenditure. Consumption of an extra 100 kcal daily over and above metabolic needs, which seems trivial, will result in a 10 lb weight gain over 1 year; conversely, subtraction of 100 kcal daily will result in a 10 lb weight loss over 1 year. In individuals with type 2 DM, the Look AHEAD trial showed a reduction in HbA1c with diet and exercise [16] equivalent to many forms of pharmacotherapy.

In contrast, diet for the type 1 DM patient should involve careful counting of carbohydrate grams via weighing and measuring food and accurate matching of rapid-acting analog insulin (RAA) to carbohydrate planned to be consumed. In addition to precise carbohydrate gram counting to match RAA insulin to planned carbohydrate intake, patients must learn about carbohydrate augmentation for physical activity. Patients also need instruction on carbohydrate strategies for dealing with intercurrent illness when the usual complex carbohydrate may be substituted with simple carbohydrate. Although it has long been said that diet is the cornerstone of DM management, effective DM dietary education is still problematic owing to time constraints and reimbursement problems.

Exercise

Aerobic exercise combined with resistance training can have a profound beneficial effect on diabetes control. The benefits of exercise include improved control of glucose, lipids, and blood pressure; improved cardiorespiratory capacity; reduction in body fat with an increase in muscle mass; reduced fall risk; and an overall increase in well-being. Exercise needs to be tailored to each individual's physical capacity, DM complications, comorbid medical conditions, and personal preferences regarding the type of exercise and location. Exercise needs to become a priority rather than an option. An easy start can be wearing a pedometer and walking with a view to reach the ADA's goal of 10,000 steps per day. The ultimate goal is engaging in aerobic exercise 5 days per week for 45 min daily.

Insulin

Insulin-treated patients must be aware of the many facets of insulin therapy. The use of insulin pen devices has replaced the traditional vial and syringe for most individuals; however, many insulin users fail to follow manufacturers' recommendations for "the 2-unit air shot" prior to each insulin injection. Site selection, consistency, and rotation remain crucial. Insulin absorption is most rapid from the upper abdomen; the arms, legs, and buttocks, respectively, are next. We find that administering the premeal RAA insulin in the abdomen optimizes postmeal control. In contrast, the buttocks, as the slowest absorption site, is not a good choice for premeal injections. However, the lower buttocks is an ideal site for bedtime injections of the intermediate-acting insulin [neutral protamine Hagedorn (NPH)] to minimize nocturnal hypoglycemia in patients still using this less physiologic insulin. Haphazard site selection and rotation can lead to erratic glycemic control. Because of the variability in absorption among sites, we suggest site consistency – using the same anatomic site at the same time of day (all breakfast injections in the abdomen, all dinner injections in the arms, all bedtime injections of NPH in the lower buttocks). Broad rotation within the sites is important to eliminate local lipohypertrophy which is less common with the use of human analog insulins. Injecting into lipohypertrophic sites delays the absorption of insulin. The RAAs with earlier peaks at 60–90 min postinjection improve postprandial glycemic control. This facilitates

DOI 10.1007/978-1-4939-0779-3_127-1

insulin injection timing as it is injected 0–10 min premeal. In contrast, regular insulin requires premeal timing of insulin injections (generally at least 30 min) to optimize postprandial glycemic control, as its peak effect is 2–3 h after injection. Patients need a comprehensive perspective on insulin adjustments for hyperglycemia, altered physical activity, illness management, travel, and alcohol consumption.

Patients need education on the pathophysiology, prevention, and treatment of microvascular complications. Education on macrovascular risk factors and their modification for prevention of cardiovascular, cerebrovascular, and peripheral vascular disease is also critical. Patients can have a considerable impact on decreasing foot problems and amputations with simple attention to hygiene (avoidance of foot soaks), daily foot inspection, and the use of appropriate footwear. These measures can greatly reduce the incidence of trauma, sepsis, and ultimately amputations.

Diabetic Complications

Complications of DM include those that are specific to DM and those that are nonspecific but are accelerated by the presence of DM. The microvascular complications of DM are diabetes specific – the triad of retinopathy, neuropathy, and nephropathy. Macrovascular disease – atherosclerosis – a common complication in patients with DM, is not specific to DM but is greatly accelerated by its presence. A major misconception among patients and even physicians is that the complications of DM tend to be less severe in patients with type 2 DM. Patients with type 2 DM or impaired glucose tolerance have greatly accelerated macrovascular disease and also suffer significant morbidity from microvascular complications.

Retinopathy

Retinopathy, the commonest cause of new-onset blindness during middle life, is broadly classified as nonproliferative (background) and proliferative. Macular edema is characterized by the collection of intraretinal fluid in the macula, with or without lipid exudates (hard exudates). In nonproliferative retinopathy, ophthalmoscopic findings may include microaneurysms, intraretinal hemorrhages, and macular edema. In more advanced nonproliferative retinopathy, cotton wool spots reflecting retinal ischemia can be noted. In proliferative retinopathy, worsening retinal ischemia results in neovascularization, preretinal or vitreous hemorrhage, and fibrous tissue proliferation. Macular edema can also occur in proliferative retinopathy. Early diagnosis and treatment with laser therapy has been shown to be vision sparing in patients with macular edema and/or proliferative retinopathy. Treatment with injectable anti-vascular endothelial growth factor (VEGF) products has been demonstrated to reduce hemorrhage and macular edema. Studies clearly document the importance of annual examinations by an ophthalmologist for all patients. The use of optical coherence tomography (OCT) to assess retinal thickness enhances diagnosis and treatment of retinal disease. Good visual acuity does not exclude significant retinal pathology; unfortunately, many patients, and healthcare providers alike, believe good visual acuity implies the absence of significant retinal disease.

Neuropathy

Diabetic neuropathy is discussed in chapter “74.”

Nephropathy/Hypertension

Diabetic nephropathy first manifests as microalbuminuria, detected by a spot urine microalbumin-to-creatinine ratio or by an elevated timed overnight albumin excretion rate. The presence of microalbuminuria should alert the patient and physician to the need for stringent glycemic control; such

DOI 10.1007/978-1-4939-0779-3_127-1

control has been shown to decrease the progression from microalbuminuria to clinical proteinuria and attendant evolution of hypertension. Hypertension increases the rate of deterioration of renal function in patients with DM, and aggressive treatment is mandatory. The Captopril Diabetic Nephropathy Study demonstrated that treatment with the angiotensin-converting enzyme inhibitor (ACEi) captopril was associated with a 50 % reduction in the risk of the combined end points of death, dialysis, and transplantation in macroproteinuric (>500 mg/24 h) type 1 DM patients. Overall, the risk of doubling the serum creatinine was reduced by 48 % in captopril-treated patients. The beneficial effects were seen in both normotensive and hypertensive patients such that captopril at a dose of 25 mg po tid is approved for use in normotensive proteinuric (>500 mg/24 h) type 1 DM patients [17]. In light of this and other studies in both type 1 and type 2 DM patients, the use of ACEI for prevention of progression of microalbuminuria and macroalbuminuria is recommended, unless there is a contraindication. For antihypertensive therapy, ACEi is the antihypertensive of choice, unless contraindicated, given the data not only in nephropathy but also in retinopathy.

Given the macrovascular benefits alone, we should probably be looking for reasons not to prescribe ACEis in individuals with type 2 DM, rather than reasons to prescribe them. In patients intolerant of ACEis due to cough, angiotensin receptor blockers (ARBs) are good alternative. The use of prophylactic ACEis or ARBs in normotensive normoalbuminuric individuals with type 1 DM is not justified by clinical trial data. Calcium channel blockers are good alternatives in light of data that show decreasing proteinuria with many of these agents over and above that achievable with conventional antihypertensive therapy. Avoidance of excessive dietary protein intake is also important, as excessive dietary protein may be involved in renal hypertrophy and glomerular hyperfiltration.

Patients with DM in general are salt sensitive, having diminished ability to excrete a sodium load with an attendant rise in blood pressure; therefore, avoidance of excessive dietary sodium intake is important. Hyperinsulinemia and insulin resistance are also important in the genesis of hypertension, with insulin-resistant patients having higher circulating insulin levels to maintain normal glucose levels. Associated with this insulin resistance and hyperinsulinemia is the occurrence of elevated blood pressures even in nondiabetic individuals. Insulin is antinatriuretic and stimulates the sympathetic nervous system; both mechanisms may be important in the genesis of hypertension. Hypertension exacerbates retinopathy, nephropathy, and macrovascular disease and must be diagnosed early and managed aggressively. When lifestyle modifications fail to control blood pressure, the pharmacologic agent chosen should be not only efficacious but kind to the metabolic milieu. The ACCORD blood pressure trial showed no cardiovascular risk reduction benefit in achieving the epidemiologic ideal blood pressure of 115/75 mmHg versus 130/80 mmHg [18]. Monotherapy of hypertension is frequently unsuccessful, especially in the setting of nephropathy, such that combination therapy is frequently needed with special attention to underlying concomitant medical problems (see chapter “77”).

Diuretics are very useful in edematous states. Beta-blockers have an important role in the post-myocardial infarction/anginal patient and in the heart failure patient. The benefits of beta-blockade in these patients outweigh the theoretical problems of masking of hypoglycemia, delay in recovery of hypoglycemia, and the worsening of insulin resistance. ACEIs or angiotensin receptor blockers (ARBs) are generally the preferred initial antihypertensive therapy in individuals with DM; calcium channel blockers are a good choice for the angina patient. Alpha-blockers are a good choice in the patient with benign prostatic hyperplasia; however, they are generally not used as monotherapy given the data suggesting increased risk of congestive heart failure. Coadministration of aliskiren (Tekturna) with ACEis or ARBs is contraindicated based on the Aliskiren Trial in Type 2 Diabetes Using Cardiovascular and Renal Endpoints (ALTITUDE). The results demonstrated similar systolic and diastolic blood pressure control with an increased risk of significant hyperkalemia and hypotension in the aliskiren-treated patients [19].

DOI 10.1007/978-1-4939-0779-3_127-1

Macrovascular Disease

Macrovascular disease is the major cause of premature death and considerable morbidity in individuals with DM, especially those with type 2 DM. Conventional risk factors for macrovascular disease warrant special attention in DM; they include smoking, lack of physical fitness, excessive dietary fat intake, obesity, hypertension, and hyperlipidemia. Smoking cessation and appropriate antiplatelet therapy are important. Correction and control of hyperlipidemia through improved metabolic control and the use of diet or pharmacotherapy are mandatory for the DM patient. LDL cholesterol lowering has been demonstrated to confer greater coronary event risk reduction and mortality reduction in diabetic patients than in nondiabetic patients. DM is one of the few diseases in which women have greater morbidity and mortality than men, especially in terms of macrovascular disease, with African-American women bearing the greatest load. There are now two competing guidelines in regard to lipid therapy. The Adult Treatment Panel III guidelines [20], which are most familiar to clinicians, were developed based on the analysis of many decades of research (randomized clinical trials, epidemiologic trials, in vivo studies, and in vitro studies) and focus on the atherogenicity of lipoproteins and utilize goal low-density lipoprotein (LDL-C) targets. In contrast, the American College of Cardiology/American Heart Association ATP IV, based only on randomized clinical trial evidence, does not utilize LDL goals and in fact focuses solely on the use of the drug class of statins in various populations [21]. These new guidelines result in many more individuals being recommended for statin treatment. They are more cumbersome in application and do not provide information on monitoring safety and efficacy [22]. A meta-analysis of high-dose versus moderate-dose statin therapy showed that high-dose statin therapy was associated with increased risk of new-onset type 2 DM. However, moderate-dose therapy conveyed less cardiovascular protection [23]. The ACCORD trial demonstrated that routine use of fibrates is not justified [24]. The use of extended-release niacin for increasing high-density lipoprotein (HDL-C) and reducing triglyceride levels remains controversial in terms of reducing cardiovascular events without untoward side effects [25]. Extended-release niacin may still be beneficial in selected patients [26].

Foot Problems

Foot problems in the diabetic are a major cause of hospitalization and amputations. They generally constitute a combination of sepsis, ischemia, and neuropathy. The presence of significant neuropathy facilitates unrecognized repetitive trauma without appropriate pain that can result in ulceration and ultimately nonhealing. Additionally, neuropathy may mask manifestations of peripheral vascular disease (PVD) (e.g., claudication and rest pain) such that patients may have critical ischemia with minimal symptoms. Therefore, PVD may be difficult to diagnose on the usual clinical grounds alone. Not only may neuropathy mask clinical symptoms, the clinical signs may be somewhat confusing. Patients with less severe neuropathy may exhibit cold feet related to arteriovenous shunting, and patients with more severe neuropathy may exhibit cutaneous hyperemia related to autosympathectomy. Noninvasive vascular testing along with clinical evaluation is helpful for the diagnosis and management of PVD. Calcific medial arterial disease is common and can cause erroneously high blood pressure recordings in the extremities, confusing the assessment of the severity of PVD. Severe ischemia with symptoms and nonhealing wounds generally requires angioplasty/stenting or formal surgical intervention. Milder symptoms and disease may respond favorably to enhanced physical activity and the use of one of the hemorheologic agents – pentoxifylline (Trental) or cilostazol (Pletal). Appropriate podiatric footwear and management are important to both ulcer healing and prevention of repetitive trauma. Early PVD can readily be detected by ankle-brachial indices using a handheld Doppler. A reduced ankle-brachial index at the posterior tibial artery in isolation has been demonstrated to be an important marker for PVD and also confers a 3.8-fold increased risk of cardiovascular death.

DOI 10.1007/978-1-4939-0779-3_127-1

Achieving Glycemic Control

Type 1 DM

Optimal management of type 1 DM requires an educated, motivated patient and a physiologic insulin regimen. The major challenge is physiologic insulin replacement matched to dietary carbohydrate with appropriate compensation for variables such as exercise. The three major factors in glycemic control are carbohydrate intake, insulin, and physical activity. If one variable changes, a second variable must change to compensate. Physiologic insulin replacement is the standard of care and involves intensive insulin basal-bolus therapy with multiple injections or the use of insulin pump therapy. The key to successful insulin therapy is individualization. Several regimens have been utilized to achieve glycemic control. In the individual with type 1 DM, the total daily dose (TDD) is typically 0.5–0.8 units/kg of body weight. However, the TDD can be very low in very insulin-sensitive individuals and in the post-pancreatectomy patient due to glucagon deficiency. Basal insulin requirements are typically between 40 % and 50 % of the TDD. A common mistake is to keep increasing the basal insulin dose to compensate for postprandial hyperglycemia. The net result to this flawed strategy is severe hypoglycemia with delayed meals and weight gain while "eating up" to the basal insulin.

Insulin pump therapy utilizes only RAA insulin and delivers basal insulin in minute amounts every few minutes to control hepatic glucose output and disposal in the fasting state. The rates are preprogrammed in 0.025 unit increments. Insulin pumps have the ability to titrate doses to accommodate individual dawn hormonal surges and activity levels. Pumps also have preprogrammed individualized algorithms for RAA to carbohydrate ratios and correction factors for hyperglycemia. They also have the ability to deliver dual wave boluses which can be used for meals with slowly digested complex carbohydrate and higher fat meals or in cases of gastroparesis. Boluses can be split to deliver a specified percentage for immediate delivery (i.e., 70 %) and then the remainder over a number of hours (i.e., 30 % over 3.5 h).

Modern injection-based regimens revolve around the use of a true basal insulin such as insulin glargine (Lantus), insulin glargine U-300 (Toujeo), or insulin detemir (Levemir) to control hepatic glucose output and disposal in the fasting state. RAA should be injected prior to ingestion of carbohydrate at meals and snacks. Patients need to be educated and engaged in accurate carbohydrate counting for safety and efficacy. Patients need to have established RAA to carbohydrate ratios, such as 1 unit of RAA for every 10 g of carbohydrate to be consumed, so that as the planned carbohydrate intake varies the RAA dose varies. Insulin-sensitive individuals may have a ratio of 1 unit of RAA for every 40 g of carbohydrate, whereas the more insulin-resistant patient, such as a type 1 DM patient with a family history of type 2 DM, may have a ratio of 1 unit of RAA for every 3 g of carbohydrate. Insulin-to-carbohydrate ratios often vary throughout the day with many individuals requiring more insulin at breakfast due to the dawn hormonal surge lasting until 10–11 AM. Timing of RAA injections to 10–15 min premeal/pre-snack optimizes postprandial glycemic control. Routine postprandial RAA administration is discouraged except in such situations as unknown/unpredictable carbohydrate intake as in toddlers, the extreme elderly patient, or in situations of illness. Fixed doses of RAA are typically not useful as individuals do not consume the same amount of carbohydrate at each meal. Patients need to have an insulin algorithm for guidance in administration of additional RAA insulin in response to hyperglycemia. For example, in the individual taking 0.5 units TDD/kg body weight, prior to meals and at bedtime, for every 50 mg/dl elevation in blood glucose above 100 mg/dl, take 1 additional unit of RAA to reduce the blood glucose level by 50 mg/dl. In patients with a lower TDD/kg body weight, the reduction may be 70 mg/dl per additional unit of RAA, while in those taking a higher TDD/kg body weight, the reduction may be 30 mg/dl per additional unit of RAA.

Use of a premixed insulin or split-mixed insulin regimen should be rare for the type 1 DM patient as they are unphysiologic. Such regimens are antiquated and have inherent risks of nocturnal hypoglycemia

DOI 10.1007/978-1-4939-0779-3_127-1

Table 2 Hypoglycemia management strategies

Causes	Signs and symptoms	Treatment
Insulin/secretagogue overdose	Sympathomimetic	Conscious – 15 g
Carbohydrate omission Missed/late meal Missed/late snack	Coldness Clamminess Shaking Diaphoresis Headaches	Simple carbohydrate Juice 4 oz Regular soda 6 oz 3-4 glucose tablets
Uncompensated activity/exercise	Neuroglycopenic Confusion Disorientation Loss of consciousness	Unconscious Glucagon SC[a] D_{50} 50 cm^3 IV

[a]We do not recommend the use of gel products for treatment of unconscious hypoglycemia, as aspiration is a potential hazard

from the pre-supper intermediate-acting insulin when stringent control of the fasting blood glucose is sought. This regimen was one of those used in the conventional group in the DCCT and was inferior at reducing the risk of complications.

Patients also need a plan for RAA/carbohydrate adjustment for physical activity and illness. Many episodes of severe hypoglycemia occur in the context of unplanned physical activity and dietary errors; likewise, many episodes of ketoacidosis occur during episodes of minor intercurrent illness. Physical activity has a major impact on glycemic control. In general, every 20–30 min of physical activity, pending intensity, over the patient's baseline activity level will result in a 50 mg/dl decrement in blood glucose. For physical activity, a proactive reduction in RAA dosage of 1–2 units per 20–30 min of activity generally suffices pending the intensity of the activity. The other option is to augment carbohydrate intake (i.e., 15 g carbohydrate prior to every 20–30 min of activity). It is not recommended to inject RAA into an exercising extremity such as the leg due to enhanced absorption and risks of hypoglycemia. Patients must fully understand that illness is a situation of insulin resistance and that at all of the routine insulin doses should be administered. Carbohydrate from meals and snacks may be substituted as simple carbohydrate in the form of liquids such as juices and regular ginger ale.

Inhaled human insulin (Afrezza inhalation powder) has recently been approved as an alternative to subcutaneous injections of RAA or regular insulin. It must be used in combination with basal insulin. Acute bronchospasm is a risk in patients with asthma or chronic obstructive pulmonary disease and is therefore contraindicated in these patients. A decline in pulmonary function can be seen even in patients without preexisting chronic lung disease. Spirometry should be performed at baseline, at 6 months, and then annually even in patients who exhibit no pulmonary symptoms. Long-term studies of its safety, including cardiopulmonary effects, are pending.

Severe hypoglycemia in the well-educated, adherent, motivated patient on a physiologic insulin regimen is uncommon. Most severe hypoglycemic episodes are explained on the basis of diet, exercise, and/or insulin-adjustment errors. The individual who is attempting to achieve true euglycemia, however, is at risk for periodic easily self-treated hypoglycemia. See Table 2 hypoglycemia for management strategies. For the individual with type 1 DM who has been educated thoroughly, is on a physiologic insulin regimen with carbohydrate counting precision, and has algorithms for illness and physical activity, failure to attain the desired degree of glycemic control is largely related to psychosocial variables or, occasionally, altered and unpredictable insulin kinetics.

DOI 10.1007/978-1-4939-0779-3_127-1

Type 2 DM

In most instances, type 2 DM is a syndrome of insulin resistance coupled with variable secretory defects, both of which can be compounded by glucotoxicity. As insulin resistance is related to genetic factors, obesity, and sedentary lifestyle, the mainstay of treatment for the type 2 DM patient is reduction of insulin resistance through diet and exercise and reversal of glucotoxicity acutely through reestablishment of euglycemia. Many patients still perceive themselves to be more absolutely insulin deficient than insulin resistant and are willing to accept insulin therapy as a compromise in the context of failed weight loss efforts. Additionally, many patients perceive pharmacotherapy to be equivalent to a diet and exercise regimen alone, assuming the desired degree of glycemic control is achieved. Chronic nonadherence to a diet regimen with resultant failure of weight loss or progressive obesity frequently leads to mislabeling the patient as a "brittle diabetic." It is important to avoid premature and unnecessary insulin therapy in these individuals and to stress to them the importance of diet and exercise as the most physiologic approach to controlling their metabolic disorder. Premature insulin therapy can lead to excessive weight gain with resultant progressive increasing insulin doses and a vicious cycle of weight gain, frequently without improvement in glycemic control.

Pharmacotherapy for Type 2 DM

To achieve HbA1c goals, the vast majority of type 2 DM patients will require combination therapy. Pharmacotherapy for type 2 DM should be directed at addressing the pathophysiologic components of the ominous octet [7] (see Fig. 1).

Decreasing Insulin Resistance/Increasing Insulin Sensitivity

Metformin hydrochloride and the thiazolidinediones work via different mechanisms. Metformin mainly inhibits the uncontrolled hepatic glucose production, while the thiazolidinediones mainly enhance skeletal muscle glucose uptake and decrease free fatty acid efflux from adipocytes.

Metformin IR (Glucophage) and metformin ER (Glucophage XR, Glumetza) are true insulin sensitizers, decreasing hepatic glucose production and enhancing peripheral glucose utilization. They are antihyperglycemic and do not stimulate insulin secretion; hence, when used as monotherapy, they cannot induce hypoglycemia. Lipid levels may improve. Ideal candidates for treatment are overweight or obese type 2 DM patients. For a 70 kg man, the usual starting dose is metformin IR 500 mg bid or metformin ER 500 mg qpm; maximum dose metformin IR is 850 mg tid or metformin ER 2,000 mg qpm. In the UKPDS, despite similar levels of glycemic control, the subset of obese type 2 DM patients treated with metformin had a statistically significantly lower cardiovascular event and death rate than the other groups. Thus, metformin must be modulating other aspects of the cardiometabolic syndrome. The potentially fatal side effect of lactic acidosis generally occurs only when metformin is used in contraindicated patients: those with renal insufficiency, liver disease, alcohol excess, or underlying hypoxic states (congestive heart failure, chronic obstructive pulmonary disease, significant asthma, acute myocardial infarction). Metformin should be discontinued in the morning of (1) elective surgery that may require general anesthesia and (2) elective imaging procedures using contrast materials (e.g., intravenous pyelogram, cardiac catheterization) and should not be restarted for 48–72 h after the surgery/procedure, pending documentation of a normal serum creatinine. Adjustments in the patient's diabetes regimen will have to be made for this time period to maintain glycemic control. Metformin is contraindicated in women with a serum creatinine $\geq$1.4 mg/dl, in men with a serum creatinine $\geq$1.5 mg/d, significant hepatic dysfunction, type 1 DM, and acute and chronic conditions associated with hypoxia. Metformin therapy has been associated with malabsorption of vitamin B12; hence, monitoring of vitamin B12 levels is recommended [27]. Metformin should be used as the foundation of pharmacotherapy for type 2 DM assuming no contraindications.

DOI 10.1007/978-1-4939-0779-3_127-1

Metformin can enhance fertility in premenopausal women with PCOS; appropriate contraception should be used to prevent unwanted pregnancy.

Thiazolidinediones [pioglitazone (ACTOS) and rosiglitazone (Avandia)] are antihyperglycemic insulin-sensitizing agents that bind to the peroxisome proliferator-activated receptor (PPAR) and amplify the insulin signal. Insulin levels decline. In addition to glucose-lowering properties, they have purported beneficial effects on the other components of the cardiometabolic syndrome. These agents may also assist in the preservation of β-cell function via reduction in lipid deposition within the islets of Langerhans – a concept called lipotoxicity, a finding documented in animals. There is no hypoglycemia when used as monotherapy. LDL-C concentration rises but with less small dense LDL. Triglycerides decline and HDL-C levels rise. Weight gain can occur with these agents. These agents can be safely used in patients with renal insufficiency without the need for dosage adjustment. A contraindication to their use is liver disease or elevations in hepatic transaminases. Edema is the commonest clinical adverse effect and is worsened by concomitant insulin therapy. Although the risk of transaminase elevation is rare, monitoring should be done prior to initiation of therapy and then periodically thereafter. These agents are contraindicated in patients with type 1 DM and in patients with New York Class III or Class IV congestive heart failure. Clinically, glucose lowering is very gradual with these agents, such that individualized downward titration in insulin dosage in insulin-treated type 2 DM patients may not be needed for at least 2 weeks, and the maximum effect may not be seen for up to 12 weeks. Pioglitazone was associated with an increased bladder cancer risk consisting of four extra cases per 10,000 patients treated. A recent meta-analysis found no increased risk of bladder cancer [28], confirming the findings of the Proactive Prospective Clinical Trial in macrovascular events trial (PROactive) 10-year follow-up. Rosiglitazone prescribing was restricted in the US based on a flawed meta-analysis showing increased cardiovascular deaths. A reevaluation of the Rosiglitazone Evaluated for Cardiovascular Outcomes and Regulation of Glycaemia in Diabetes (RECORD) trial failed to show increased cardiovascular risk [29]. Rosiglitazone can be prescribed only via a risk evaluation mitigation strategies (REMS) program. In regard to pioglitazone, the usual starting dose of pioglitazone is 15 mg qd, and the maximum dosage is 45 mg qd; however, in most patients, to reduce the risk of pedal edema, the maximum dose should not exceed 30 mg qd. In regard to rosiglitazone, the usual starting dose is 4 mg qd, either as a single daily dose or in divided doses. The maximum dose is 8 mg qd, but edema and heart failure risk is increased. Thiazolidinediones can enhance fertility in premenopausal women with PCOS; appropriate contraception should be used to prevent unwanted pregnancy.

α-Glucosidase Inhibition

α-Glucosidase inhibition by acarbose (Precose) and miglitol (Glyset) has a primary mode of action of decreasing postprandial blood glucoses via direct interference with the digestion and absorption of dietary carbohydrate and thus reduces postprandial glucoses. There is no hypoglycemia as monotherapy and no weight gain. Both insulin levels and lipid levels decline. These agents are most commonly used as adjunctive therapy rather than monotherapy. Both agents need to be dosed with the first bite of the meal. Increased intestinal gas formation, the most common side effect, is minimized with slow dose titration and does decrease with continued administration. They are contraindicated in type 1 DM, inflammatory bowel disease, bowel obstruction, cirrhosis, and conditions associated with maldigestion or malabsorption. In a 70 kg man, the starting dose of both acarbose and miglitol is 25 mg tid with a maximum dose of 100 mg tid.

Augmentation of Insulin Secretion

Sulfonylureas enhance insulin secretion and action. First-generation sulfonylureas should no longer be used as they have high risks of side effects, such as sustained hypoglycemia, the chlorpropamide flush

DOI 10.1007/978-1-4939-0779-3_127-1

(an Antabuse-like reaction), protein-binding interference with certain medications, and syndrome of inappropriate diuretic hormone secretion. The second- and third-generation sulfonylureas are preferred owing to their increased milligram potency, shorter duration of action, and better side-effect profile.

Prior concerns about possible cardiotoxicity of sulfonylureas related to the University Group Diabetes Program (UGDP) study have generally disappeared, given the emergence of data to support the safety of these agents from the cardiovascular prospective in the UKPDS. Glimepiride (Amaryl), a third-generation sulfonylurea, has theoretical benefits in terms of reduced risk of hypoglycemia, potentially lower risk of adverse cardiovascular effects, and perhaps reduced potential for secondary failure. Sulfonylureas are contraindicated in type 1 DM. In a 70 kg male, the usual starting dose of glimepiride is 2 mg daily with a maximum dose of 4 mg bid; the usual starting dose of glipizide ER (Glucotrol XL) is 5 mg qd with a maximum dose of 20 mg qd.

The insulin secretagogue in the glinide class, repaglinide (Prandin), is dosed prior to meals, producing an abrupt secretion of insulin secretion, designed to assist in the control of postprandial glucose levels. There is potential, although unproven, for a reduction in weight gain that is so frequently seen with sulfonylureas. Theoretical potential to reduce secondary failure rates is also a purported benefit. In a 70 kg man, the usual starting dose of 0.5 mg prior to each meal with a maximum dosage of 16 mg daily in divided doses premeal. Coadministration with gemfibrozil can result in an increase in repaglinide exposure. It is contraindicated in type 1 DM.

Nateglinide (Starlix), a phenylalanine derivative, is an insulin secretagogue, the effects of which are more glucose dependent. Nateglinide dosed prior to meals produces an abrupt spurt of insulin. However, in contrast to repaglinide, nateglinide restores early insulin secretion that is lost as β-cell function declines prior to the development of type 2 DM. Early insulin secretion is important, shutting off hepatic glucose production in preparation for the prandial glucose rise. Weight gain is attenuated, and hypoglycemia is very rare. Switching from a sulfonylurea to nateglinide can result in a slight rise in fasting plasma glucose; however, as postprandial glucose is significantly improved, the HbAlc may be maintained or lowered. This is due to the fact that postprandial glucose contributes more to the HbA1c than fasting or preprandial glucoses do when the HbA1c is <8.0 %. In a 70 kg male, the usual starting dose and maximum dose are 120 mg with each meal; in individuals with an HbA1c close to normal, the starting dose can be 60 mg tid. Use with caution in moderate to severe hepatic impairment. It is contraindicated in type 1 DM.

Dipeptidyl Peptidase IV (DPP-IV) Inhibitors

DPP-IV inhibitors inhibit the enzyme DPP-IV which degrades native glucagon-like peptide-1 (GLP-1) resulting in a return of reduced GLP-1 levels to normal and resulting in glucose-dependent insulin secretion and decreased glucagon levels. Their effects are mainly postprandial, as monotherapy does not cause hypoglycemia and is weight and lipid neutral. DPP-IV inhibitor dosing varies according to creatinine clearance (CrCl) with the exception of linagliptin (Tradjenta). In a 70 kg male, starting and maximum doses are as follows with sitagliptin (Januvia): 25 mg qd for CrCl $<$ 30 ml/min, 50 mg qd for CrCl 30–49 ml/min, and 100 mg qd for CrCl $\geq$ 50 ml/min. In 70 kg male, starting and maximum doses for saxagliptin (Onglyza) are 2.5 mg qd for CrCl $\leq$ 50 ml/min or with coadministration of a strong inhibitor of CYP3A4/5 and 5 mg qd for CrCl $>$ 50 ml/min. For linagliptin, in a 70 kg man, both starting and maximum doses are 5 mg qd due to the mainly fecal excretion of the drug, regardless of CrCL. Linagliptin should not be coadministered with medications that are strong inducers of either CYP3A4 or *P*-glycoprotein as its efficacy will be decreased. For alogliptin (Nesina), in a 70 kg man, both starting and maximum doses are 6.25 mg qd for CrCl $<$ 30 ml.min, 12.5 mg qd for CrCl 30–59 ml/min, and 25 mg qd for CrCl $\geq$ 60 ml/min. Side effects of DPP-IV inhibitors include upper respiratory infections, nasopharyngitis, headache, and urinary tract infections. Early on, an association of increased risk of pancreatitis and pancreatic cancer was noted in post-marketing reports; however, this has been negated by findings of the US Food and Drug

DOI 10.1007/978-1-4939-0779-3_127-1

Administration (FDA) and the European Medicines Agency (EMA). They are contraindicated in type 1 DM.

Bromocriptine Mesylate

Once daily bromocriptine mesylate (Cycloset), a dopamine agonist, increases the level of bromocriptine for 4–5 h. It is generally used as a second- or third-line agent. It reduces fasting glucose levels without increasing insulin levels, does not cause hypoglycemia as monotherapy, and is weight and lipid neutral. The precise mode of action is unknown. In a 70 kg man, the starting dose is 0.8 mg qam within 2 h of awakening and should be dosed with food. It can be titrated weekly to a maximum dose of 4.8 mg qd with the same dosing considerations. Side effects are the rate-limiting step and include nausea, anorexia, dyspepsia, emesis, dizziness, fatigue, and asthenia. There are multiple potential drug interactions when it is coadministered with strong inhibitors/inducers/substrates of the CYP3A4 pathway and medications that are highly protein bound. It is contraindicated in type 1 DM and in patients with syncopal migraine as it may precipitate hypotension.

Colesevelam

Colesevelam's (Welchol's) mode of action regarding glucose lowering is unknown; it is not approved as monotherapy. Fasting glucose levels are reduced without increasing insulin levels. It is weight neutral. LDL-C levels are reduced; however, triglyceride levels are increased in insulin-treated patients. In a 70 kg man, the usual starting dose is three 625 mg tablets with lunch and dinner or six 625 mg tablets at dinner. Colesevelam can cause constipation. It reduces levels of many medications such as cyclosporine, levothyroxine, oral contraceptives that include ethinyl estradiol/norethindrone, and the second- and third-generation sulfonylureas. Reports also show reduced levels of phenytoin and lower international normalized ratio (INR) levels in warfarin-treated patients. The main side effect is constipation. It is contraindicated in type 1 DM.

Sodium-Glucose Cotransporter-2 (SGLT-2) Inhibitors

Although the renal threshold for glucose in the individual without DM is 180 mg/dl, in the individual with DM, the renal threshold is closer to 240 mg/dl, thereby causing increased reabsorption of glucose. The SGLT-2 receptors transport approximately 90 % of filtered glucose from the proximal tubule in the kidney into the interstitial cells for reabsorption. SGLT-2 inhibitors reduce the glucose reabsorption and increase urinary glucose excretion by approximately 70 g/day resulting in a 280 kcal caloric purge and in improved fasting and postprandial glycemic control, weight loss, and reduced systolic blood pressure. As monotherapy, they do not cause hypoglycemia. A slight increase in LDL-C is seen. In a 70 kg man, the usual starting dose of canagliflozin (Invokana) is 100 mg qam with an estimated glomerular filtration rate (eGFR) of $\geq$45 ml/min; the dose can be titrated to 300 mg qam if eGFR is $\geq$60 ml.min. With dapagliflozin (Farxiga), the usual starting dose is 5 mg qam if eGFR is $\geq$60 ml/min and can be up-titrated to 10 mg qam if eGFR is maintained at $\geq$60 ml/min. With empagliflozin (Jardiance), the usual starting dose is 10 mg qam with a maximum dose of 25 mg qam if the eGFR is maintained at $\geq$45 ml/min. The most common side effect is genital mycotic infections in women and uncircumcised men. Urinary tract infections, thirst, constipation, hypovolemia, and a transient reduction in creatinine clearance can be seen. When initiating therapy or increasing dosage, it is prudent to review diuretic and antihypertensive therapy and reduce doses in anticipation of the blood pressure-lowering effects. Patients should be counseled on maintaining good oral fluid intake of at least 64 oz daily of non-caffeinated beverages. As monotherapy, they do not cause hypoglycemia. Hypoglycemia can occur when used concurrently with insulin or secretagogues such that down-titration of insulin and/or secretagogues is appropriate early on. They are contraindicated in type 1 DM.

DOI 10.1007/978-1-4939-0779-3_127-1

Injectable Incretin Therapy

GLP-1 receptor agonists bind to the GLP-1 receptor and raise GLP-1 levels to pharmacologic levels resulting in suppression of glucagon hypersecretion, restoration of first-phase insulin secretion, enhancement of glucose-dependent insulin secretion, delayed gastric emptying, and promotion of both the physical sensation of gastric fullness and central satiety. They are resistant to degradation by DPP-IV. When used as monotherapy, they do not cause hypoglycemia; they facilitate weight loss. They are favorable agents to use as monotherapy in metformin-contraindicated patients as they do not promote weight gain. Side effects include nausea, dyspepsia, emesis, diarrhea, and constipation. The agents with longer half-lives generally have fewer gastrointestinal side effects. They are contraindicated in patients with either a personal or family history of either medullary thyroid cancer or multiple endocrine neoplasia syndrome 2 (MEN2) due to studies demonstrating C-cell hyperplasia in mice and rats and the association of medullary thyroid cancer to C-cell hyperplasia. In primates and humans, there has been no sustained elevation in calcitonin levels. Additionally, there have been no cases of C-cell hyperplasia. If a thyroid nodule is noted on physical examination or radiologic study, the patient should be referred to an endocrinologist for evaluation (see Table 3 for specifics of individual medications). GLP-1 receptor analogs are approved only for use of type 2 DM. Post-marketing reports indicated a potential association with an increased risk of pancreatic cancer and pancreatitis, but the US FDA and the EMA have not found such a relationship in the clinical trial data.

Pramlintide (Symlin), an analog of the neuroendocrine hormone amylin, is secreted by the ß-cells in response to the intake of food. Pramlintide suppresses the hypersecretion of glucagon and results in delayed gastric emptying and decreased food intake and increased central satiety thus improving postprandial glucose levels. It is approved for use in both type 1 and type 2 DM patients. In type 1 DM patients, pramlintide should be initiated at a dose of 15 mcg sc prior to major meals with gradual titration to 30–60 mcg premeal if tolerated. In type 2 DM patients, the starting dose is 60 mcg prior to major meals with up-titration to 120 mcg as tolerated. Nausea is the rate-limiting step in dosage titration. Extreme caution must be used when using in conjunction with insulin as there is an increase in the risk of hypoglycemia. Reduction in premeal RAA by 50 % is recommended in insulin users with increased HBGM needed for both safety and efficacy.

Insulin Therapy

Insulin therapy in type 2 DM patients is indicated in situations where patients are acutely decompensated and are more insulin resistant due to intercurrent illnesses. Clearly, short-term insulin therapy can reestablish glycemic control acutely in many individuals. However, reevaluation of endogenous insulin production with C-peptide determinations is important. Most obese patients with type 2 DM have normal or fairly elevated C-peptide levels, assuming they are not glucotoxic from antecedent chronic hyperglycemia. The initiation of insulin therapy in a type 2 DM patient remains controversial in terms of indications and the optimal insulin regimen. The dilemma revolves around the obese C-peptide-positive patient who was achieving good glycemic control in the short term with insulin. This individual often suffers progressive obesity and worsening glycemic control owing to worsening insulin resistance, thereby increasing requirements for exogenous insulin. Thus, frequently insulin therapy in an obese C-peptide-positive patient fails to achieve its primary goal of sustained improved glycemic control. Additionally, perpetuation of the obese state, or indeed worsening thereof, in conjunction with progressive hyperinsulinemia raises concerns about the impact of this worsened metabolic milieu on hypertension, dyslipidemia, and the atherosclerotic process. Initiation of insulin therapy should therefore be undertaken cautiously in most patients and progress carefully monitored in terms not only of glycemic control but also of hypertension, dyslipidemia, and obesity.

Many insulin regimens have been used to treat type 2 DM, most being similar to those used in the type 1 DM setting. Trends have focused on the use of bedtime basal insulin therapy in these individuals on the grounds that it can maximally affect the dawn hepatic glucose output/disposal and peak insulin resistance, thereby achieving the best possible fasting blood glucose and minimizing glucotoxicity. Minimizing glucotoxicity facilitates daytime β-cell secretory function and minimizes the need for daytime insulin therapy. Combination therapy with insulin-sensitizing agents and insulin is theoretically sound, reducing the need for exogenous insulin. One such regimen has been the use of a bedtime dose of basal insulin such as insulin glargine insulin glargine U-300, or insulin detemir at a dose of 0.2 units/kg of body weight coupled with daytime oral agents/GLP-1 receptor agonists. An alternative dosing is to use insulin glargine insulin glargine U-300 or insulin detemir starting at a dose of 10 units and titrating accordingly. Several titration regimens have been demonstrated to be both safe and successful [30]. Although hypoglycemia is relatively uncommon in type 2 DM patients owing to their fundamental insulin resistance, it can occur in those on insulin or sulfonylureas. Sulfonylureas should be used with caution in combination with insulin, especially in patients with hepatic or renal impairment and in the elderly. The Outcomes Reduction with Initial Glargine Intervention (ORIGIN) trial with insulin glargine showed a neutral effect on cardiovascular events and cancer risk in patients with cardiovascular risk factors plus impaired fasting glucose, impaired glucose tolerance, or overt type 2 DM [31].

Weight-Based Approaches

Pharmacotherapy for obesity is an ever-changing environment with available medications as an adjunct to diet and exercise. Approved oral medications include phentermine/topiramate extended-release (Qsymia), lorcaserin (Belviq), and naltrexone HCL/bupropion HCL (Contrave). The injectable GLP-1 analog liraglutide has been approved at higher doses than that approved for treatment of type 2 DM (Saxenda). The rate-limiting step for most individuals is cost with health insurance plans frequently carving out pharmacotherapy coverage for obesity. Bariatric surgery, despite claims, is a treatment, not a cure, for type 2 DM. Careful medical nutrition therapy and exercise is important. Recidivism rates remain high in bariatric surgery patients.

Prevention of type 2 DM

Can type 2 DM be prevented? The Diabetes Prevention Program in type 2 DM showed a 58 % risk reduction in the development of type 2 DM in patients treated with diet and exercise versus a 31 % risk reduction in patients treated with metformin. A Finnish lifestyle modification study demonstrated a similar 58 % risk reduction in developing type 2 DM in patients with impaired glucose tolerance who were randomized to a program of intensive diet and exercise. There is also data suggesting thiazolidinediones may prevent type 2 DM.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is the ultimate expression of absolute insulin deficiency resulting in uncontrolled lipolysis, increased free fatty acid delivery to the liver, and ultimately accelerated ketone body production. Insulin deficiency at the level of the liver results in uncontrolled hepatic glucose output via gluconeogenesis and glycogenolysis. With insulin-mediated skeletal muscle glucose uptake being inhibited, hyperglycemia rapidly ensues. The attendant osmotic diuresis due to hyperglycemia results in progressive dehydration and a decreasing glomerular filtration rate. Dehydration may be compounded by

DOI 10.1007/978-1-4939-0779-3_127-1

gastrointestinal fluid losses (e.g., emesis from ketones or a primary gastrointestinal illness with concurrent diarrhea). Insensible fluid losses from febrile illness may further compound the dehydration.

Diagnosis of DKA is fairly characteristic in the newly presenting or established type 1 DM patient. The history of polydipsia, polyuria, weight loss, and Kussmaul's respirations is virtually pathognomonic. Physical examination is directed at assessing the level of hydration (e.g., orthostasis) and the underlying precipitating illness. Measurement of serum ketones, urine ketones, and blood glucose levels can rapidly confirm the clinical suspicion, with arterial pH, serum bicarbonate, and ketones validating the diagnosis. A thorough search for an underlying precipitating illness remains axiomatic (e.g., urosepsis, respiratory tract infection, or silent myocardial infarction). Treatment is directed at correcting (1) dehydration/hypotension, (2) ketonemia/acidosis, (3) uncontrolled hepatic glucose output/hyperglycemia, and (4) insulin resistance of the DKA/underlying illness. Of course, specific treatment is directed to any defined underlying illnesses.

Dehydration and hypotension require urgent treatment with a 5- to 6-L deficit to be anticipated in most individuals. Initial treatment is 0.9 % NaCl, with 1–2 L/h being given for the first 2 h and flow rates thereafter being titrated to the individual's clinical status. Potassium replacement at a concentration of 10–40 mEq/L is critical to replace the usual deficits of more than 5 mEq/kg once the patient's initial serum potassium level is known and urine output is documented. Giving 50 % of the potassium as KC1 and 50 % as KPO_4 appears theoretically sound, but routine phosphate replacement has not been shown to alter the clinical outcome. Bicarbonate therapy is generally reserved for patients with a pH of less than 7.0, plasma bicarbonate less than 5.0 mEq/L, severe hyperkalemia, or a deep coma. Bicarbonate is administered by slow infusion 50–100 mEq over 1–2 h with the therapeutic end point being a pH higher than 7.1 rather than normalization of the pH. Overzealous use of bicarbonate can result in severe hypokalemia with attendant risk of arrhythmias, paradoxical central nervous system acidosis, and possible lactic acidosis due to tissue hypoxia. Intravenous insulin therapy is initiated at a dose of 0.1 U/kg/h with rapid titration every hour should a 75–100 mg/dl/h decrease in blood glucose not be achieved. Insulin therapy at this relatively high dose is needed to combat the insulin resistance of the hormonal milieu of DKA (i.e., high levels of glucagon, cortisol, growth hormone, and catecholamines). Given that hepatic glucose output is more rapidly controlled than ketogenesis, the insulin infusion rate can be maintained by switching the intravenous infusion to dextrose 5–10 % when the blood glucose is less than 250 mg/dl. The insulin infusion is continued until the patient is ketone-free, clinically well, and able to resume oral feeding. It is of paramount importance that subcutaneous insulin be instituted promptly at the time of refeeding.

Flow sheets should be generated documenting the following:

1. Patient admission weight relative to previous weights with serial weights every 6–12 h, urine ketones, and fluid balance
2. Vital signs and mental status every 1–2 h
3. Bedside glucose monitoring every 1–2 h
4. Urine ketones every 1–2 h
5. Fluid balance
6. Blood gases and arterial pH on admission, repeating until pH is over 7.1
7. Serum potassium on admission and then every 2–4 h
8. Serum ketones on admission and then every 2–4 h
9. Complete blood count, serum chemistries, chest roentgenogram, electrocardiogram, and appropriate cultures on admission
10. Abnormal chemistries other than potassium repeated every 4 h until normal

Thyroid diseases are common endocrine disorders that may seriously affect patients' health and often require lifelong treatment and monitoring. This chapter reviews the most common thyroid problems, with emphasis on clinical presentation, diagnosis, treatment, and follow-up.

Screening for Thyroid Disease

The American Academy of Family Physicians, American College of Physicians, US Preventive Services Task Force, and the Royal College of Physicians all concluded there is not enough evidence to recommend screening in the general population. However, the American Thyroid Association recommends measuring a thyroid-stimulating hormone (TSH) level in all patients at age 35 and every 5 years thereafter, even though they note a serious lack of efficacy data, especially in men and younger women [1]. Laboratory measurement of thyroid function is recommended in certain patient groups who are at higher risk for thyroid disease. The American Association of Clinical Endocrinologists recommends TSH measurement in women of childbearing age before pregnancy or during the first trimester [2]. Patients with atrial fibrillation or hyperlipidemia should have their TSH measured at least once. Annual laboratory measurement of thyroid function is recommended for patients with diabetes or Down syndrome. Patients taking certain medications such as amiodarone and lithium require periodic TSH measurement as these medications may alter thyroid function.

Hyperthyroidism

Thyrotoxicosis is caused by excess thyroid hormone. The prevalence of hyperthyroidism in community-based studies has been estimated at 2 % for women and 0.2 % for men [3]. As many as 15 % of cases of hyperthyroidism occur in patients older than 60 years, of which a large percentage was taking thyroid home preparation [4]. Excluding excess thyroid hormone ingestion, approximately 90 % of hyperthyroidism is caused by Graves' disease. Thyrotoxic nodules and thyroiditis account for almost all other cases [5]. Women are more commonly affected by hyperthyroidism than men, with reported ratios varying from 4:1 to 10:1 [5, 6].

Health Risks

Hyperthyroidism causes or exacerbates several other health problems, with cardiovascular complications being most important. Atrial fibrillation is the most common complication, occurring in 8–22 % of

*Email: TDAVIS2@lsuhsc.edu

DOI 10.1007/978-1-4939-0779-3_128-1

thyrotoxic patients, and these patients are at increased risk of stroke from atrial thromboembolism [7]. Cardiac failure, angina, myocardial infarction, and sudden death have been associated with thyrotoxicosis [8]. Thyroid storm causes multisystem involvement and carries a high risk of mortality (10–75 %) [5]. Calcium and bone metabolism are affected by thyrotoxicosis, leading to osteoporosis and an increased risk of bone fracture. Atrial fibrillation and osteoporosis may occur with even subclinical hyperthyroidism [9]. Certain ethnic groups may suffer less common complications. Periodic paralysis may occur as a result of thyrotoxicosis and is observed mostly in Oriental populations [10].

Family Impact

As with any chronic disease, hyperthyroidism may place stress on the family system. The affected family member may experience emotional labiality, heat intolerance, and fatigue, all of which strain relationships within the family. Hyperthyroidism may be especially stressful prior to diagnosis as the patient and family may not attribute their symptoms to a physiologic illness versus psychological. Symptoms of hyperthyroidism may adversely affect job performance and subsequently produce additional stress and loss of income.

Clinical Presentation

Symptoms of thyrotoxicosis, arranged in order of frequency, are listed in Table 1, and the chief complaint can be any one of these symptoms. A directed history usually reveals up to eight symptoms, although some patients, especially in the geriatric age group, may report only a few [5, 11].

Patients often report weight loss, even with a history of increased appetite. Heat intolerance is usually described as preferring room temperatures cooler than do other family members or preferring winter to summer. Fatigue and weakness of proximal muscles can be reported as difficulty climbing stairs.

It is of note that abdominal symptoms of vomiting, nausea, and abdominal pain, although previously thought to be rare or present only preceding thyroid storm, may be relatively common [11]. Patients who present with these abdominal symptoms as their chief complaint may be at higher risk of missed diagnosis. Vomiting can occur without nausea and tends to be postprandial. Abdominal pain is usually epigastric or left upper quadrant in location, unrelated to meals, and described as sharp or cramping [11].

Physical findings of thyrotoxicosis are listed in Table 1, and five or more are typically present. Goiter is the most frequent sign, but the enlargement may be only mild or difficult to appreciate, especially when it occupies a substernal location. The skin tends to be warm, moist, and velvety smooth. A fine tremor of outstretched hands is usually present, and deep tendon reflexes are often brisk with a rapid relaxation phase. Lid lag may be present with any cause of thyrotoxicosis; exophthalmos is specific to Graves' disease. Onycholysis may be present, typically of the ring fingers, causing separation of the nail from the distal nail bed and difficulty cleaning the nails (Plummer's nails) [5, 10, 16].

Laboratory Evaluation

Confirmation of clinical thyrotoxicosis is accomplished by measuring thyrotropin (TSH) by a highly sensitive assay and is further substantiated with measurement or estimate of free thyroxine (T_4) and sometimes free triiodothyronine (T_3). These hormones are clinically active only when they are not protein bound. A diagnostic approach to the patient with thyrotoxicosis is shown in Fig. 1. Along with the TSH,

initial tests are usually free T_4 and free T_3. Although the reliability of some methods has been questioned in the past, newer assays of free T_4 and free T_3 are more dependable [5, 12]. Euthyroid patients may have an elevated total T_4 due to excess thyroid-binding proteins, such as found in pregnancy, use of estrogens, or some inherited disorders.

DOI 10.1007/978-1-4939-0779-3_128-1

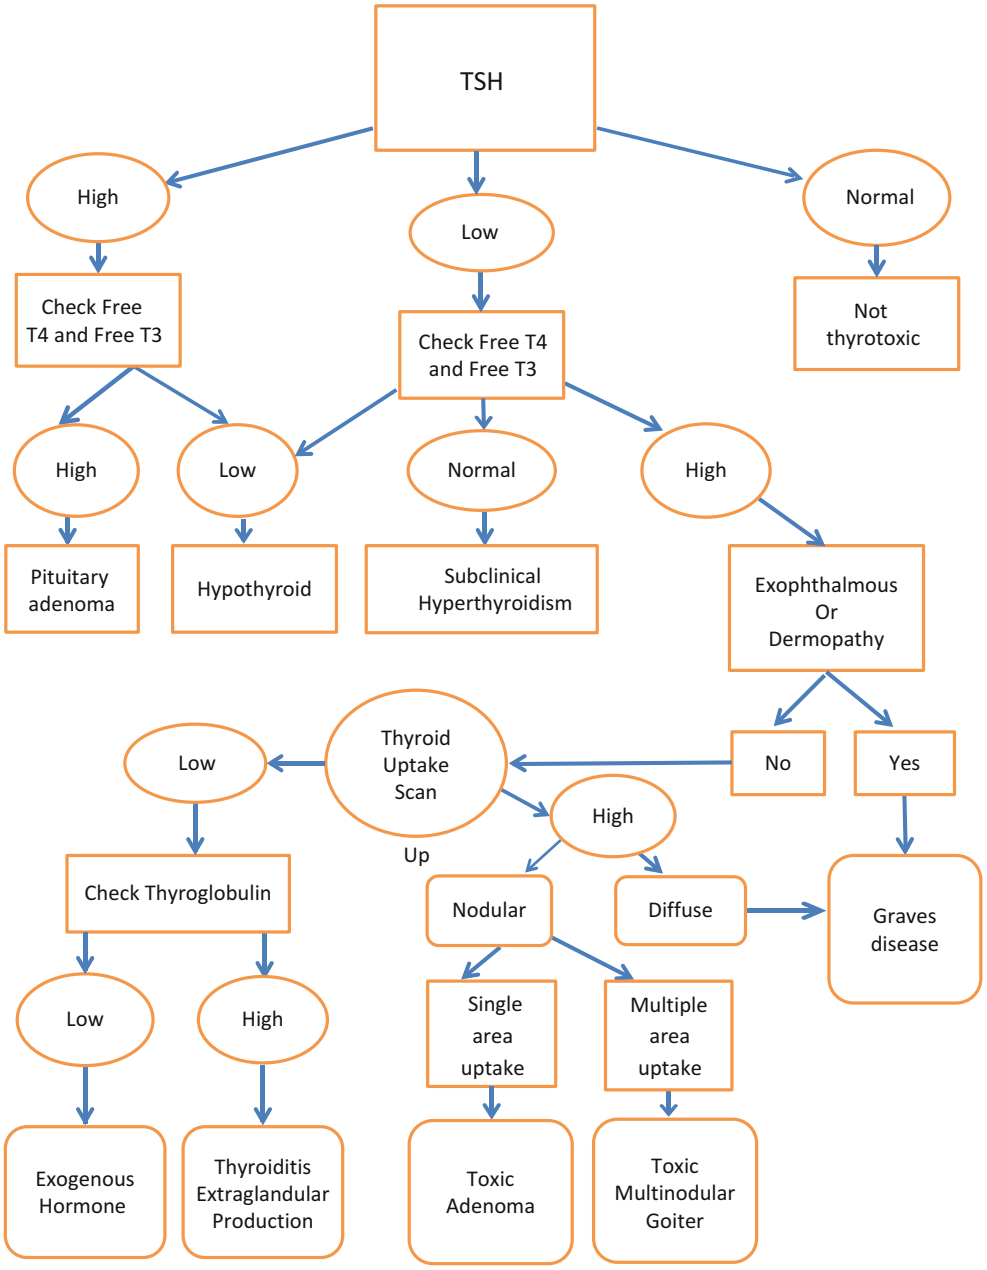

Fig. 1 Diagnostic approach to the patient with thyrotoxicosis (see attached document)

Through pituitary feedback mechanisms, TSH levels inversely follow free T_4 levels. Measurement of TSH by a highly sensitive assay in patients with hyperthyroidism yields a value far below the normal range and helps confirm the diagnosis. The sensitive TSH is especially useful in patients with concomitant illnesses or on medications that can alter T_4 [12]. Because TSH is a more sensitive measure of thyroid status, patients may have an abnormally low TSH with a normal free T_4. They are considered to have subclinical hyperthyroidism [5, 9]. TSH can also be moderately low as a result of nonthyroidal illness or medications (glucocorticoids and dopamine) and is occasionally low in healthy people, particularly the elderly [13]. The TSH level in these settings is usually not less than 0.1 μU/mL. When the TSH level is less than the lower limit of a sensitive assay (undetectable), thyrotoxicosis is usually present [5]. Rarely, a TSH-secreting adenoma causes hyperthyroidism with an elevated TSH.

DOI 10.1007/978-1-4939-0779-3_128-1

When TSH is low but free T_4 is normal, measurement of free T_3 should be obtained and, if elevated, confirms clinical thyrotoxicosis. This condition, known as T_3 toxicosis, occurs occasionally in patients with early Graves' disease or a thyrotoxic nodule [5, 10].

Nuclear medicine scans of the thyroid are useful for assessing thyroid size to determine if thyroid nodules are functioning (hot) or nonfunctioning (cold) and to measure the level of thyroid function (thyroid uptake). Of the radionuclides available for thyroid scans, iodine 123 (^{123}I) is optimal. Technetium may also be used for thyroid imaging, but measurement of function is less reliable, as a nonfunctioning nodule by the ^{123}I scan may demonstrate function with technetium [5].

Graves' Disease

The disease described by Robert Graves in 1835 is the most common cause of hyperthyroidism [5]. It is caused by an autoimmune process, closely related to chronic lymphocytic (Hashimoto's) thyroiditis. The onset of Graves' disease may follow some physical or psychological stress, and a family history of thyroid disease is often present [5, 10].

Signs and Symptoms

All the clinical manifestations of thyrotoxicosis may be present in Graves' disease, with additional specific findings of ophthalmopathy and dermopathy. A diffuse goiter occurs in most patients and may cause neck swelling or dysphagia. On palpation, the thyroid is nontender and somewhat soft. Eye problems occur in more than 50 % of patients and include pressure sensation, irritation, gritty feeling, lacrimation, a change in appearance, and occasional blurred vision or diplopia. The exophthalmos occasionally causes marked eye irritation or even blindness. Dermopathy occurs in 1–2 % of patients and causes raised, firm, nontender, intradermal nodules on the anterior surfaces of the lower legs. Clubbing of the nails (acropachy) is a rare manifestation of Graves' disease [5, 10].

Diagnosis

Graves' disease is diagnosed by confirming hyperthyroidism with thyroid function tests (free T_4), along with one or more physical findings specific to the disease. If a goiter is present without exophthalmos or dermopathy, Graves' disease may be difficult to distinguish from subacute painless thyroiditis or postpartum thyroiditis. A reliable history of chronic hyperthyroid symptoms strongly suggests Graves' disease, and an elevated thyroid uptake confirms this diagnosis when it remains in doubt [5, 10]. Thyrotropin receptor (TSH-R) antibodies are present in most patients with Graves' disease, but they are of limited diagnostic value. High titers of these antibodies may identify those patients who are unlikely to go into remission. Measurement of TSH-R antibodies in pregnant patients with thyrotoxicosis may be useful [5].

Treatment

Therapy of Graves' disease is directed toward controlling the effects of excess thyroid hormone and reducing the production of additional hormone [13]. Beta-blockers are especially effective in controlling the tachycardia, tremor, and other symptoms related to excess hormone. Atenolol is often preferred because it has the advantages of single daily dosing and beta-1 selectivity. Alternatively, propranolol is begun at 20–40 mg 2–4 times daily and increased every few days until the heart rate is within the normal range [10]. When beta-blockers are contraindicated, diltiazem or clonidine may be effective [14, 15]. Controlling hormone production may be accomplished with antithyroid medications, radioiodine ablation, or

DOI 10.1007/978-1-4939-0779-3_128-1

surgery. Choice of treatment is influenced by the clinical presentation, the age of the patient, and the patient's ability and willingness to comply with a treatment regimen [5, 10].

Antithyroid medications available in the United States to control thyroid hormone production are the thionamides, methimazole, or propylthiouracil. In addition to blocking production of thyroid hormone, these medications may alter the course of the disease via their immunosuppressive effects [16]. Reported remission rates vary widely and are probably higher in patients with less severe hyperthyroidism, short duration of illness, and small goiter. The duration of treatment is usually 6 months to 2 years. The remission rate can be as high as 60 % if treatment is continued for 2 years. Failure to achieve remission after 2 years of treatment is an indication for alternate therapy [5, 10, 16].

Initial adult dosage of methimazole is 20–30 mg/day divided into two doses. In patients with severe hyperthyroidism and a large goiter, the higher dose is warranted. Euthyroid status, determined clinically and with thyroid function tests (T_4 and T_3), is usually achieved within 4–6 weeks, and the dosage is reduced incrementally every 4–6 weeks to a maintenance dose of 2.5–10 mg/day given in a single dose. TSH is not useful for following the response to treatment, as it may remain suppressed for months after T_4 and T_3 normalize. The initial dose of propylthiouracil is usually 300 mg/day, and maintenance is 50–100 mg/day. Both must be divided into three doses [5, 10]. Either of these drugs may cause rash, leukopenia, and (rarely) agranulocytosis. Patients should be cautioned about these side effects. Methimazole has the advantages of lower risk of agranulocytosis, a longer half-life allowing usage on a once-a-day schedule, and more rapid return to euthyroid status. Propylthiouracil is preferable during pregnancy, lactation, or thyroid storm [5, 10]. Patients with mild hyperthyroidism and small goiters or those with goiters that shrink during antithyroid medication therapy may go into remission with a prolonged course of antithyroid medications.

Iodine 131 ablation may be used for definitive treatment for patients with more severe hyperthyroidism and large goiters to permanently destroy thyroid tissue sufficiently to reduce hormone production to normal levels. This option has the advantage of low cost and low complication rate. This treatment may be used initially in patients with mild thyrotoxicosis. Patients who are elderly or have severe thyrotoxicosis should first be treated with antithyroid medications because ^{131}I ablation can induce a temporary exacerbation of thyrotoxicosis or thyroid storm [10]. The amount of radiation used can be calculated based on the patient's weight, gland size, and thyroid uptake. A major disadvantage of this treatment is the high prevalence of hypothyroidism (>90 %), which continues to increase with the passage of time [5]. Therefore, a patient's ability to comply with lifelong replacement therapy should be considered when choosing this treatment. Pregnancy is a contraindication to ^{131}I.

Subtotal thyroidectomy is an alternate method of permanently controlling thyroid hormone production. This treatment is indicated when the goiter is large, particularly if obstructive symptoms are present. Surgery is also indicated in children who fail a trial of antithyroid medication. The disadvantages of surgery include the cost and risk of surgical complications. Following surgery for Graves' disease, hypothyroidism has been reported in 53 % of patients and recurrence of hyperthyroidism in 3.4 % [10].

Follow-Up

Regardless of the treatment used, Graves' disease requires lifelong monitoring. Patients treated with antithyroid medications who go into remission must be followed for possible relapses and are at a small risk of late hypothyroidism. After treatment with ^{131}I ablation or surgery, patients require chronic periodic monitoring for development of hypothyroidism. Once hypothyroidism occurs, lifelong hormone replacement is necessary [5, 10].

DOI 10.1007/978-1-4939-0779-3_128-1

Thyrotoxic Nodule

An autonomously functioning thyroid nodule may cause thyrotoxicosis with typical hyperthyroid symptoms. Physical examination reveals a thyroid nodule, and findings specific to Graves' disease are absent. The diagnosis is confirmed with an elevated free T_4, low TSH, and a hot nodule on radioiodine scan. Fine-needle aspiration is indicated if the nodule is not hot on nuclear medicine scan, as with other nontoxic nodules.

Treatment is with ^{131}I ablation or occasionally surgery. Antithyroid medications may be used but are not typically prescribed for thyrotoxic nodules. Hypothyroidism following ^{131}I ablation is less common than with Graves' disease, although a 40 % long-term prevalence of hypothyroidism has been reported [17]. Indications for surgery include a thyrotoxic nodule that is very large or progressively enlarging or other signs suggestive of thyroid cancer [5].

The nodule may persist after ablation treatment, and ongoing monitoring by physical examination is needed to identify any increase in size. Should the nodule or adjacent tissue enlarge, further evaluation for possible thyroid cancer is required. Periodic monitoring for possible hypothyroidism also is necessary.

Thyroiditis

Thyroiditis is defined as an inflammatory process involving the thyroid gland. This inflammation may cause thyrotoxicosis due to unregulated release of thyroid hormone from an injured gland. There are several types of thyroiditis, each with a different clinical picture; three are discussed below. Hashimoto's thyroiditis is discussed in the next section, and postpartum thyroiditis is discussed in the section on pregnancy. Measurement of ^{123}I thyroid uptake is useful in any patient with thyrotoxicosis and suspected thyroiditis. Elevated free T_4 with diminished thyroid uptake confirms thyrotoxicosis due to thyroiditis.

Subacute painful (granulomatous) thyroiditis is probably caused by a viral infection and is the type of thyroiditis that most commonly results in thyrotoxicosis. Patients present with an exquisitely tender, firm, asymmetric nodular thyroid gland. They have symptoms of neck pain, a flu-like syndrome, and symptoms of thyrotoxicosis. The erythrocyte sedimentation rate is elevated, and antithyroid antibodies are absent. These patients usually go through four phases: (1) hyperthyroidism lasting 3–6 weeks, (2) euthyroid status for a few weeks, (3) hypothyroidism lasting weeks to months, and (4) euthyroid state again. The clinical diagnosis is usually made during the hyperthyroid phase and is confirmed with an elevated free T4 and decreased uptake on ^{123}I scans. Treatment of inflammation is accomplished with aspirin, other nonsteroidal anti-inflammatory agents, or corticosteroids (prednisone 20 mg twice daily for 1 week then tapered over 2–4 weeks). Patients may require β-blocker therapy to control symptoms and tachycardia initially, but there are usually no long-term sequelae requiring treatment or monitoring [5, 18].

Subacute painless (lymphocytic) thyroiditis is an autoimmune process that may cause thyrotoxicosis. Physical examination usually reveals a mildly enlarged thyroid gland that is somewhat firm and nontender, although nearly 50 % of patients have no goiter. Antibodies to thyroid peroxidase are present in about 50 % of patients. These patients may go through the same four phases as subacute painful thyroiditis, but the euthyroid phase preceding hypothyroidism may be brief or absent. Some patients do not return to euthyroid status after hypothyroidism occurs and require chronic thyroid hormone replacement [5, 18].

Acute thyroiditis, caused by a bacterial infection, is a rare condition in developed countries because of the availability of antibiotic therapy. Patients present with acute thyrotoxicosis, fever, and a tender, enlarged thyroid gland. Treatment is directed toward controlling effects of excess thyroid hormone with

DOI 10.1007/978-1-4939-0779-3_128-1

beta-blockers and treating the infection with broad-spectrum antibiotics. Needle aspiration for culture is indicated, and abscess drainage may be necessary [5, 18].

Subclinical Hyperthyroidism

Subclinical hyperthyroidism is defined by low or undetectable serum thyroid-stimulating hormone (TSH) levels, with normal levels of free T4 and free T3. Subclinical hyperthyroidism can be divided into two categories: low but detectable TSH levels (0.1–0.4 mIU per L) and suppressed TSH levels (less than 0.1 mIU per L) [19]. Subclinical hyperthyroidism may be exogenous as a result of intentional administration of thyroid hormone to suppress thyroid malignancy or unintentional excessive hormone therapy in patients with hypothyroidism. It may also result from endogenous overproduction of thyroid hormone such as from Graves' disease, autonomous functioning thyroid adenoma, toxic multinodular goiter, and subacute/painless/postpartum thyroiditis. Subclinical hyperthyroidism should be differentiated from other causes of low TSH levels that are not related to relative thyroid overactivity, such as the use of certain drugs (dopamine and glucocorticoids), nonthyroidal illness (euthyroid sick syndrome), pituitary causes (TSH deficiency), hypothalamic causes (thyrotropin-releasing hormone deficiency), and psychiatric conditions, especially affective disorders [20].

Most patients with subclinical hyperthyroidism will not progress to overt hyperthyroidism. Cardiovascular effects of subclinical hyperthyroidism include an increase in average heart rate, increased risk of atrial arrhythmias, increased left ventricular mass, and reduced heart rate variability [20–22]. Subclinical hyperthyroidism may reduce bone mineral density (BMD), particularly in cortical bone. Patients with subclinical hyperthyroidism may experience increased signs and symptoms of adrenergic overactivity, particularly those younger than 50 years [20]. Possible associations between subclinical hyperthyroidism and quality of life parameters, cognition, and increased mortality rates are controversial [20]. The effectiveness of treatment in preventing these conditions is unknown. There is no consensus regarding screening for subclinical hyperthyroidism in the general population.

Hypothyroidism

Hypothyroidism, a deficiency of thyroid hormone, can be caused by several conditions that result in the same clinical picture. The most common causes of hypothyroidism are autoimmune thyroid diseases, including Hashimoto's thyroiditis, and previous treatment for Graves' disease. Other causes of thyroiditis, congenital hypothyroidism, and central (secondary) hypothyroidism are uncommon.

Approximately 1–2 % of the general population has spontaneous hypothyroidism: 1.9 % of the female population and 0.1 % of the male population [6]. Hypothyroidism is more common with advancing age, affecting 6.9–7.3 % of patients aged 55 or over [23, 6]. Women are affected 10 times more frequently than men. Congenital hypothyroidism occurs in 1/3,000 to 1/4,000 live births in the United States [24].

The US Preventive Services Task Force and the American Academy of Family Physicians do not recommend routine screening for hypothyroidism in asymptomatic adults [25].

Health Risks

Severe hypothyroidism may lead to coma and death if untreated. Hypothyroidism can cause bradycardia, hearing impairment, carpal tunnel syndrome, and hypercholesterolemia with increased risk of

DOI 10.1007/978-1-4939-0779-3_128-1

atherosclerotic heart disease. Dementia, depression, and suicide can be sequelae of hypothyroidism. Hashimoto's thyroiditis may be associated with primary thyroid lymphoma [19]. Elderly patients are at increased risk because concomitant illnesses are common and because the symptoms of hypothyroidism may remain unrecognized [23].

Family Issues

The depression associated with hypothyroidism may have a devastating effect on the family. Withdrawal, vegetative disturbances, apathy, and loss of motivation can affect the entire family unit. This situation is especially a problem when the diagnosis is delayed.

Clinical Presentation

The most common symptoms of hypothyroidism are cold intolerance and fatigue [25]. Other symptoms include generalized weakness, fatigue, memory loss or slowed thinking, intolerance to cold, dry skin, hair loss, hoarseness, dyspnea, anorexia, deafness, chest pain, arthralgia, and facial or peripheral edema. A modest weight gain of approximately 10 pounds is typical, but patients may actually lose weight early in the disease process due to anorexia [1]. Constipation is a common complaint. Depression is often the presenting symptom, and hypothyroidism must be considered during any depression work-up [26, 27] (see chapter ► Anxiety Disorders). Women may have heavy, prolonged menstrual periods that can lead to severe anemia [5].

Periorbital edema, peripheral edema, and pale, thick, dry skin are often the first physical signs noted. Hyperkeratosis of the knees and elbows is also common. Diastolic hypertension may be present. Delayed relaxation phase of deep tendon reflexes is common but may be subtle. When hypothyroidism is severe, mucopolysaccharides deposit in subcutaneous tissue, causing the nonpitting edema known as myxedema. Pleural and pericardial effusions, cardiomegaly, bradycardia, and prolonged QT interval are possible cardiac manifestations [5].

Laboratory Evaluation

Primary hypothyroidism is diagnosed by finding an elevated TSH and a low free T_4 [25] (Fig. 2). Patients may have other lab abnormalities including elevated C-reactive protein, hyperprolactinemia, hyponatremia, increased creatinine kinase, increased serum lipids, proteinuria, and normocytic anemia [25]. Secondary hypothyroidism is characterized by a normal or low serum TSH and a low serum T4 (Fig. 2).

Treatment

Oral synthetic L-thyroxine is the treatment of choice for hypothyroidism [12] [19, 25, 28]. The usual starting dosage is approximately 75 μg/day, but patients older than 50 years and patients with heart disease are started at a much lower dose (25 μg/day). The patient should be instructed to take the medication on an empty stomach (1 h) and should not be taken with other medications such as bile acid resins, proton pump inhibitors, calcium carbonate, and ferrous sulfate [25]. The TSH is measured every 6 weeks, and the

DOI 10.1007/978-1-4939-0779-3_128-1

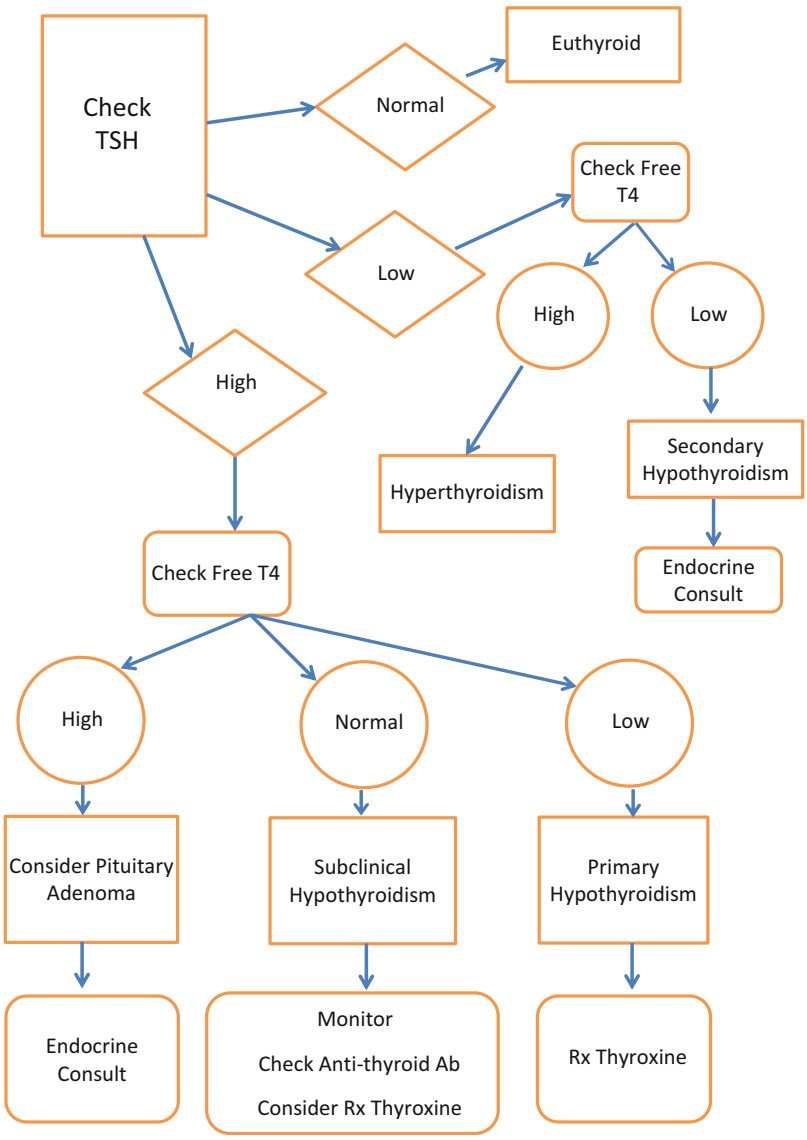

Fig. 2 Evaluation for hypothyroidism [11]

dosage of thyroxin is adjusted upward by 25 μg/day until the TSH is within the normal range, indicating the patient has returned to a euthyroid state. The target dose for most patients is approximately 1.6–1.7 μg/kg/day. Most forms of hypothyroidism are lifelong problems, and continued replacement is necessary. Once the patient is on a stable dose, the TSH level should be assayed annually to monitor appropriateness of replacement therapy [12]. Overreplacement with T4 can cause hyperthyroidism and its complications. Noncompliance with levothyroxine therapy is the most common cause of difficulty in obtaining and maintaining a patient's TSH in the therapeutic range [25].

The majority of evidence does not demonstrate a benefit of combination T4 and T3 therapy [28]. Temporary treatment with T3 may be appropriate in some patients; however, further studies are needed before that can be recommended.

DOI 10.1007/978-1-4939-0779-3_128-1

Subclinical Hypothyroidism

Subclinical hypothyroidism is defined as the presence of a high TSH with a free T_4 in the normal range. Some authors feel these patients are functionally hypothyroid relative to their own bodily requirements [12, 28] [29]. There is still some debate about whether to treat subclinical hypothyroidism. Patients often feel better with therapy, and treatment is usually indicated, especially if antithyroid antibodies are present [3]. Asymptomatic patients who have mild TSH elevation (<10 μU/mL), negative antithyroid antibodies, and no goiter may be followed without replacement [5, 19]. Since subclinical hypothyroidism may be associated with reversible hypercholesterolemia, depression, and atherosclerosis, treatment is warranted for patients with these conditions as well as infertility or pregnancy [25, 26, 30, 31].

Hashimoto's Thyroiditis

Hashimoto's thyroiditis was first described in 1912 in four patients with lymphocyte infiltration, fibrosis, and follicular cell degeneration. It causes most cases of adult-onset hypothyroidism in iodine-sufficient areas of the world [6, 18]. The etiology of the disease is autoimmune, with high serum concentrations of antibodies to thyroid peroxidase and thyroglobulin usually present [18, 29]. Like most autoimmune diseases, there is a genetic predisposition. It is most common in women (8:1) and is usually diagnosed between the ages of 30 and 50. Its incidence is increasing in developing countries [18].

Signs and Symptoms

Patients usually present with a painless, diffuse, firm goiter. Patients may complain of tenderness or fullness of the anterior neck. Dysphagia and hoarseness are occasionally present. Although hyperthyroidism is found in up to 5 % of patients during the acute stages of the disease, hypothyroidism with its various signs and symptoms is more common [19]. The presence of pain suggests the development of a primary B-cell lymphoma, a cancer associated with chronic autoimmune thyroiditis [5].

Diagnosis

The diagnosis is suspected in patients with a characteristic goiter and is confirmed in 90 % of cases by finding antibodies to thyroid peroxidase. Antithyroglobulin antibodies are also present in up to 70 % of patients, but they are rarely present alone. Therefore, this latter assay is not usually necessary for diagnosis [29]. Free T_4 and the TSH level should be obtained to determine thyroid function [18, 29]. If the goiter is very large, lobulated, or painful, fine-needle aspiration or biopsy may be indicated [5].

Treatment

Treatment of hypothyroidism is described above and requires lifelong replacement. Thyrotoxicosis usually does not occur with this type of thyroiditis, and if present is of short duration requiring only symptomatic treatment. Graves' disease may precede or follow this illness and require additional treatment.

Congenital Hypothyroidism

Thyroid dysgenesis is the cause of congenital hypothyroidism in 80 % of patients, and various problems with thyroid hormone production and regulation account for the rest. Severe growth and mental retardation (cretinism) can occur, but these sequelae are avoided if replacement therapy with levothyroxine is

DOI 10.1007/978-1-4939-0779-3_128-1

started within the first 3 months of life. Undiagnosed congenital hypothyroidism has become rare in industrialized countries owing to neonatal screening. Transient perinatal hypothyroidism may result when mothers are given iodine or iodine-containing contrast agents [24].

Euthyroid Sick Syndrome

Many severely ill patients without signs or symptoms of thyroid dysfunction have a low T_3 level or have T_3 and T_4 levels below normal range. Free T_4 is usually normal if measured by a reliable, sensitive assay, and TSH is also usually normal. This so-called euthyroid sick syndrome is not indicative of true tissue hypothyroidism, and replacement is unnecessary unless the TSH level becomes markedly elevated (>20 μU/mL) [32].

Thyroid Nodules and Thyroid Cancer

Benign thyroid nodules are frequently encountered in primary care. They are estimated to occur in 4–8 % of the adult population. In contrast, clinically significant thyroid cancer is infrequent, comprising only 1 % of all malignancies and ranking 35th among causes of cancer death. Clinically insignificant thyroid cancers are more common, with American autopsy studies revealing a prevalence of 6–13 % [33].

Health Risks and Family Issues

Providing cost-effective yet thorough management for patients with thyroid nodules represents a distinct challenge to family physicians (Fig. 3). Although thyroid nodules carry a low risk of mortality due to thyroid cancer, patients and their families must struggle with the knowledge that a potentially malignant growth is present. The anxiety produced by this fear not only causes stress in the patient but also has major implications for the family. Therefore, the evaluation should reveal adequate information not only to satisfy the physician but to alleviate the fears of patients and their family members.

Evaluation

Table 2 lists the findings that indicate high and moderate risks of cancer. When two or more of these factors are found, the probability of thyroid cancer is high. Laryngoscopy to evaluate vocal cord function is indicated, especially if any hoarseness or voice change has occurred. A history of neck irradiation increases the risk of both benign and malignant thyroid nodules. Multiple thyroid nodules suggest a benign process.

Laboratory Studies

Thyroid function tests and the TSH assay are useful for confirming the clinical impression of thyroid status. Thyrotoxic nodules are only rarely malignant [5, 34]. Measurement of antibodies to thyroid peroxidase is useful for identifying autoimmune thyroiditis when there is also diffuse enlargement of the gland. A calcitonin assay is important in patients with a family history of multiple endocrine neoplasia type II (MEN-II) or medullary carcinoma, as calcitonin is usually elevated under these conditions. Genetic

DOI 10.1007/978-1-4939-0779-3_128-1

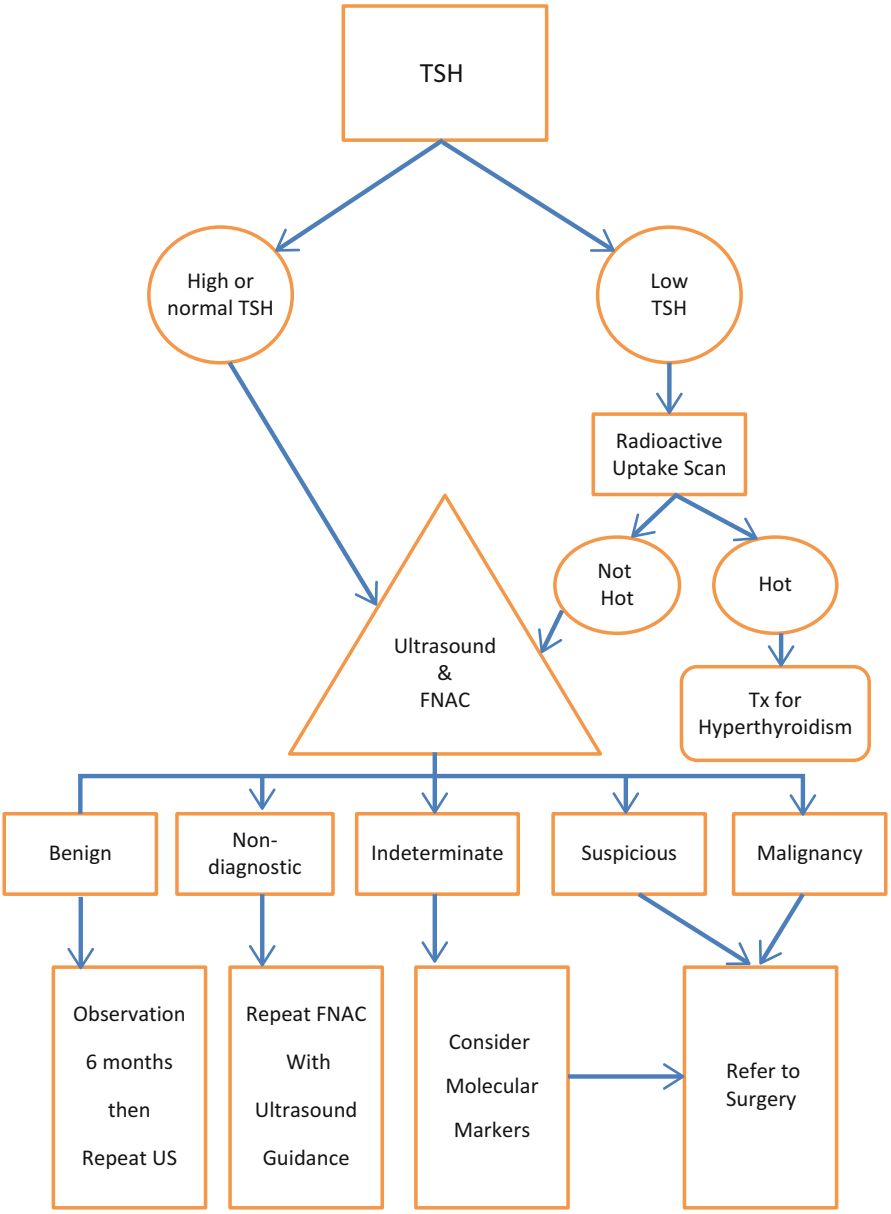

Fig. 3 Evaluation of thyroid nodule (palpable or incidental)

testing and calcitonin elevation may identify family members with this type of thyroid cancer before clinical manifestations appear [5, 29, 33].

Work-Up

The work-up of a solitary nontoxic thyroid nodule is outlined in Fig. 3. The evaluation begins with a TSH. Patients with a low TSH need a radionuclide thyroid scan. A palpable nodule that corresponds to an area of tracer uptake requires no cytologic evaluation; however, a thyroid ultrasound may be considered. According to the American Thyroid Association (ATA) Guidelines, all thyroid nodules or suspected thyroid nodules in patients with an elevated or normal TSH should have ultrasonography to document location, number, size, and appearance of the nodule(s) followed by fine-needle aspiration and cytology (FNAC) [34]. Other experts maintain that all nodules should be examined through ultrasound, regardless of the TSH [35]. FNAC has become the initial procedure of choice because it is the most accurate and

Male sex and solitary nodule

most cost-effective [34]. The FNA technique is relatively simple and low risk [5, 33], and its sensitivity is reported to be more than 90 % [36, 37]. The most worrisome limitation of FNAC is a false negative that may cause a malignancy to be missed, although the false-negative rate has been less than 10 % in most studies and in one study as low as 0.7 %. There is particular difficulty differentiating follicular adenoma from follicular carcinoma with FNAC, as finding evidence of invasion is required to diagnose the latter. A skilled and experienced cytopathologist is required for reliable results.

Results of FNAC are classified into five categories: (1) malignant when malignant cells are identified, (2) benign when adequate benign glandular tissue is present, (3) nondiagnostic when the biopsy tissue does not meet specific criteria for cytologic adequacy, (4) indeterminate which can be a follicular neoplasm (Hurthle cell neoplasm) or atypia, and (5) suspicious for papillary thyroid cancer. Results read as nondiagnostic require the FNAC to be repeated using ultrasound guidance [36].

Ultrasonography can be used to determine if a thyroid nodule is solid or cystic, but this finding does not completely differentiate benign from malignant nodules. Studies have demonstrated that 9–14 % of cystic nodules contain cancer compared to 10–20 % of solid nodules being cancerous [34]. Cystic degeneration occurs in 25 % of papillary carcinomas; therefore, the characteristic appearance of the nodule on ultrasonography does not determine whether or not a biopsy is indicated. Ultrasonography may be used to monitor and follow the characteristics and size of a nodule and to evaluate for metastasis.

Management

The decision regarding when to remove a thyroid nodule surgically should take into account several factors, including clinical findings, availability of FNAC with cytopathologic support, degree of anxiety of the patient and family, and ability to have reliable long-term follow-up. ATA Guidelines are as follows: (1) Surgery is recommended for patients with FNAC results demonstrating malignant cells or suspicion for malignant cells. (2) Observation and serial ultrasound examinations 6–18 months are recommended for nodules with benign FNAC. Should the nodule increase in size, repeat FNAC or surgery is indicated. (3) Repeat the FNAC if the initial results are nondiagnostic. Consider surgery if the second FNAC is also nondiagnostic. (4) Consider surgery or repeat the FNAC for a persistent nodule after aspiration of a cyst. (5) Recurrent cystic nodules with benign cytology should be considered for surgery or percutaneous ethanol injection [34].

DOI 10.1007/978-1-4939-0779-3_128-1

Routine suppression of benign thyroid nodules with thyroid hormone replacement is not recommended in iodine-sufficient populations. Thyroid nodules associated with Hashimoto's thyroiditis have been shown to respond to suppression [5].

Thyroid Cancer

Thyroid cancer is divided into two main types: differentiated thyroid cancer (DTC) and poorly differentiated thyroid cancer. DTC arises from thyroid epithelial cells and accounts for the vast majority of thyroid cancer and is associated with a more favorable prognosis. Surgery is the treatment of choice for all thyroid carcinomas when excision is possible [34, 36].

Differentiated Thyroid Cancer Cell Types

1. Papillary carcinoma accounts for 85 % of all thyroid cancers. The tumor is slow growing, and there is good long-term survival if surgical removal is performed while the cancer is still confined to the thyroid gland. Papillary carcinoma spreads by lymphatic means.
2. Follicular carcinoma accounts for about 10 % of all thyroid cancers. It is slightly more aggressive than the papillary variety and spreads by the hematogenous route. A subcategory of follicular carcinoma is the Hurthle cell type, which is more aggressive and more common in iodine-deficient countries [34].
3. Medullary carcinoma accounts for only 2–5 % of thyroid cancers. Most of these lesions are sporadic, but some are familial; 20 % are part of the MEN-II syndrome, which has an autosomal-dominant inheritance pattern. The latter can be identified early with elevated calcitonin levels and genetic testing. Screening with these tests should be performed on all family members if MEN-II or familial medullary carcinoma is diagnosed. If medullary carcinoma is not diagnosed prior to a palpable mass being present, the cure rate is less than 50 % [33, 34, 38].

Undifferentiated Thyroid Cancer Cell Type

1. Anaplastic thyroid carcinoma is the most aggressive type but accounts for only 2–7 % of cases. It has the worst prognosis of any thyroid cancer, with a median survival time of 4–7 months and a 5-year survival rate of only 4 %.

Near-total or total thyroidectomy is the procedure of choice if the thyroid cancer is greater than 1 cm. Lobectomy may be appropriate for less than 1 cm, low-risk carcinomas in some patients [34]. Radioiodine ablation is recommended for patients with known residual tumor and probably also for those at high risk of recurrence. Some patients with anaplastic thyroid cancer will respond to combined radiation and chemotherapy after thyroidectomy [5].

Thyroid Disease During Pregnancy

Both hypothyroidism and hyperthyroidism can complicate pregnancy (see chapter ▶ Medical Problems During Pregnancy). Hypothyroidism causes anovulation and rarely coincides with pregnancy. When hypothyroidism occurs, it is associated with gestational hypertension, premature labor, and low birth

DOI 10.1007/978-1-4939-0779-3_128-1

weight. Monitoring and management of the pregnant patient with thyroid disease requires the use of trimester-specific reference ranges for TSH and serum free T4 [39].

Thyroid-binding globulin increases during pregnancy, and so total T_3 and T_4 increase as well. Her dose of L-thyroxine should be adjusted to maintain the TSH level in the normal range on a sensitive assay [39]. In general, the pregnant patient with prepregnancy hypothyroidism will require an increase in her L-thyroxine of about 30 %. A convenient way to increase her L-thyroxine dose is for her to take nine doses per week rather than seven. Her TSH should be monitored 4 weeks after a dosage change and every 4 weeks during the first half of her pregnancy. The TSH should be rechecked at least once between 26 and 32 weeks gestation. After delivery, the patient should resume her prepregnancy dose and have her TSH assessed 6 weeks postpartum [39].

Hyperthyroidism during pregnancy is relatively uncommon and caused by the same etiologies as in nonpregnant patients, with Graves' disease being the most common cause. Thyrotoxicosis may lead to spontaneous abortion, stillbirth, neonatal death, and low birth weight [39]. All patients with a suppressed TSH should have their serum free T4 determined. Antithyroid drugs, usually propylthiouracil during the 1st trimester, followed by methimazole during the 2nd and 3rd trimester are recommended for treatment in pregnant patients. In addition, propranolol and occasionally thyroid resection may be used for treatment [39]. Any use of radioactive iodine is contraindicated during pregnancy.

Postpartum thyroiditis is a transient autoimmune thyroid dysfunction that occurs within the first postpartum year (see chapter ▶ Postpartum Care). It is probably an exacerbation of a preexisting subclinical autoimmune thyroiditis [5, 40]. The true incidence is 5–10 %, although it is frequently underdiagnosed [37]. The most common complaints are depression, poor memory, and impaired concentration. The clinical course consists of a hyperthyroid phase (which may be absent), followed by a hypothyroid phase and eventually a return to euthyroid status. The diagnosis is usually made with a TSH measurement. Patients with antibodies to thyroid peroxidase and thyroglobulin are at increased risk of developing this syndrome [41]. Patients who have one episode of postpartum thyroiditis are at increased risk for recurrence with future pregnancies and may develop permanent hypothyroidism [40].

Osteopenia and Osteoporosis

Katherine Reeve and Ryan West

Contents

Osteoporosis is a major health concern worldwide and within the United States. Approximately 9 % of U.S. adults over the age of 50 have osteoporosis, and up to 50 % have some degree of low bone density [1]. Osteoporosis causes more than two million fractures per year with $19 billion in associated costs in the United States alone [2]. The clinical costs of an osteoporotic fracture are equally great and include increased mortality, increased disability, and an increased need for long-term nursing care. The most common sites of fracture are the hip, vertebrae, and wrist. Hip fractures are particularly deadly, carrying a 26 % 1-year mortality rate for patients over the age of 69. Of those who survive, functional skills are significantly decreased with decreased fine motor and mobility scores [3]. Vertebral fractures lead to chronic back pain and deformity in up to 30 % of patients. These fractures may have a long-term impact on overall quality of life and the ability to carry out activities of daily living (ADL).

Osteoporosis is defined as decreased bone mineral density leading to increased fragility and an increased risk of fractures. Symptoms are usually not present early on, and an osteoporotic fracture is often the first sign of disease. The lifetime risk of an osteoporotic fracture is 44 % [4].

Osteoporosis can be primary or secondary. Primary osteoporosis is bone loss as a result of aging alone. Secondary osteoporosis refers to bone loss as a result of chronic conditions that lead to accelerated bone loss. It can be caused by endocrine

disorders such as hyperparathyroidism or hyperthyroidism. Other causes include malignancy, renal failure, and nutritional deficiencies [5].

Risk Factor Assessment

Risk factor assessment begins with taking a detailed history and performing a physical exam. Risk factors for developing osteoporosis include family history, lifestyle, and contributing medical conditions.

Risk Factors for Osteoporosis

Lifestyle	Family history	Genetic/Medical
Poor diet Low activity level Tobacco use Alcohol use	History of osteoporosis History of fractures	Menopause Caucasian or Asian ethnicity Endocrine disorders Certain medications

Lifestyle

Lifestyle choices can affect bone density. Excessive use of alcohol may decrease bone formation by suppressing osteoblastic function, which increases the risk of osteoporosis. Cigarette smoking has been associated with an increased risk for osteoporosis, although the direct link is not well established [6].

Regular physical activity early in life is associated with higher peak bone mass, and continued activity leads to lower rates of hip fractures in postmenopausal women [7]. Maintaining healthy eating habits is necessary to obtain the required nutrients to build healthy bone mass. Calcium and Vitamin D are two of these essential nutrients.

Genetics

Several genetic factors can increase the risk of developing osteoporosis. Those of northern European or Asian descent have higher rates of osteoporosis and osteopenia. Women are at a much higher risk of developing osteoporosis than men due to accelerated bone loss after menopause. Certain genetic conditions such as Turner's syndrome increase risk of osteoporosis due to decreased estrogen production.

Endocrine Factors

There are several endocrine disorders that can increase risk of osteoporosis. Any disorder that decreases estrogen production will increase risk. This includes early menopause, surgical menopause, or premature ovarian failure. Risk is also increased by endocrine disorders that disrupt normal bone metabolism, such as hyperthyroidism, hyperparathyroidism, Addison's disease, and Cushing's syndrome.

Medications

Certain medications can have a negative effect on bone metabolism, including anticoagulants, corticosteroids, thyroid hormone, chemotherapeutic agents, anticonvulsants, loop diuretics, proton pump inhibitors, antidepressants, and medroxyprogesterone aceteate (MDA). Chronic use of any of these medications may increase the risk of developing osteoporosis and suffering osteoporotic fractures.

There are a few medications associated with increased bone mass and decreased rate of factures, including thiazide diuretics, statins, and beta blockers [8].

Laboratory Assessment

If the history and physical exam suggests secondary causes of osteoporosis, laboratory testing should be considered and must be guided by the patient presentation. Useful initial testing may include thyroid-stimulating hormone (TSH), parathyroid hormone (PTH), calcium, vitamin D, complete blood count (CBC), complete metabolic panel, 24 h urinary calcium, and testosterone in men [9].

Bone Densitometry Assessment

Arguably the most important evaluation for osteoporosis is determining the bone mineral density (BMD). The diagnosis of osteoporosis it made

Table 1 Indications for bone mineral density (BMD) screening

US Preventive Services Task Force[a]
Women ≥65
Women <65 with fracture risk equal to or greater than 65 year old white female
Men: insufficient evidence to determine benefit vs harm
International Society for Clinical Densitometry[b]
Women ≥65
Women 60–64 with fracture risk equal to or greater than 65 year old white female
Women on prolonged hormone replacement therapy
Men ≥70
Anyone with a fragility fracture
Anyone receiving or considering treatment for osteoporosis

[a]United States Preventive Services Task Force. Osteoporosis: Screening, 2011
[b]International Society for Clinical Densitometry. Osteoporosis Screening Guidelines, 2012

primarily based on the BMD and is defined as a BMD 2.5 standard deviations (SD) below the mean for young Caucasian females.

It is important to determine the BMD of patients who are at increased risk of osteoporosis to identify, prevent, and treat osteoporosis. Using the BMD we can estimate future fracture risk, guide treatment decisions, and monitor response to treatment. Both the US Preventive Services Task Force (USPSTF) and the International Society for Clinical Densitometry (ISCD) have issued recommendations on who should be screened for osteoporosis with BMD testing (see Table 1).

The mostly widely used and universally accepted method of measuring BMD is the dual-energy x-ray absorptiometry (DXA) scan. It has been accepted as the gold standard for determining the BMD of the hip and spine. It has replaced the quantitative computed tomography (CT) scan, which requires significantly greater radiation exposure. The DXA generates a report that is interpreted by a radiologist, endocrinologist, or other physician that has been certified to interpret the results. In the report both a T score and a Z score are given. The T score is defined as the number of standard deviations above or below the mean BMD. It is important to note that the T score is not adjusted for age, gender, or race and is instead compared to the mean BMP for a young Caucasian female. The Z score, however, is the number of standard deviations above or below the mean and is adjusted for age, gender, and race.

Although there has been some disagreement in the past, currently both the World Health Organization (WHO) and the ISCD recommend using T-scores as the standard to evaluate all postmenopausal women and men older than 50 [10]. Based on their T-score, patients can be classified into three categories: normal BMD, osteopenia, or osteoporosis. A different classification is recommended for premenopausal women, men under 50, and children. In these cases the Z score, which is adjusted for age, gender, and race, should be used instead [11]. Based on their Z score, patients can be classified into two categories: below expected range or within expected range for chronological age with a Z score below or above −2.0 respectively.

Alternative studies exist to evaluate for fracture risk and include quantitative ultrasonography (QUS) and peripheral DXA (pDXA). These modalities are generally less expensive and more portable and may be used in settings where DXA is not available. Both of these may help predict future fractures. However, they cannot be used to reliably determine BMD and should not be used for diagnosis or tracking disease progression if DXA or quantitative CT is available.

FRAX Score

The Fracture Risk Assessment tool (FRAX) was developed in 2008 by the WHO to estimate 10-year probability of hip fracture and major osteoporotic fracture. These estimates are based on untreated patients between 40 and 90 years of age. The calculation is based of several risk factors including age, fracture history, steroid use, body mass, smoking, alcohol use, rheumatoid arthritis, parental history of hip fracture, and having secondary causes of osteoporosis. Femoral neck bone mineral density (BMD) can also be factored in as well if available but is not needed to generate the 10 year risk. There is a calculator

available online at www.shef.ac.uk/FRAX. It is often included on DXA reports [12]. This information can help guide management and may indicate the need for earlier treatment in patients with osteopenia (see Pharmacological Treatment section below).

Diagnosis

The diagnosis of osteoporosis is made primarily from bone mineral density using the DXA as the gold standard for assessment. Osteoporosis in postmenopausal women and in men greater than 50 is defined as bone mineral density 2.5 standard deviations below normal as reflected by a T score of less than −2.5. In premenopausal women and men less than 50 they are considered to be below the expected range for age if the bone mineral density is less than 2.0 standard deviations below normal adjusted for age as reflected by a Z score of less than −2.0 [10]. Osteopenia is defined as a bone mineral density of 1–2.5 standard deviations below normal with a T score of −1 to −2.5.

World Health Organization (WHO) Diagnostic criteria for osteoporosis

Diagnosis	Bone Mineral Density (BMD) T score[a]
Normal	≤1
Osteopenia	1–2.5
Osteoporosis	≥2.5

[a]Standard deviation (SD) below the mean in healthy young females

Prevention and Treatment

Nonpharmacological

There are several nonpharmacological measures that can be taken to help prevent and treat osteoporosis. These measures include an active lifestyle with weight bearing exercises, fall precautions, avoidance of tobacco and excessive alcohol use, and adequate intake of calcium and vitamin D. These measures should be started early in life and continued. BMD peaks around age 35 and then is slowly lost. This loss is accelerated in women after menopause when estrogen levels drop.

Calcium

The recommended daily intake of calcium for postmenopausal women is 1,200 mg/day. For adult men, it is slightly lower at 1,000 mg/day [13]. Calcium supplementation is recommended if a sufficient amount cannot be obtained by diet alone. There are different formulations of calcium supplements, citrate and carbonate. Calcium citrate is best absorbed when taken between meals. Conversely, calcium carbonate is best absorbed when taken with meals. No form of calcium should be taken with iron as iron decreases intestinal absorption of calcium. Studies have shown that calcium in combination with Vitamin D can increase BMD and may or may not decrease fracture risk in postmenopausal women [14]. Given its mild effect on BMD and fracture risk, supplementation alone is not recommended as monotherapy for osteoporosis.

Vitamin D

Vitamin D assists with calcium absorption. The recommended daily intake of vitamin D needed for adequate calcium absorption is 600–800 IU according to the National Institutes of Health (see Table 2). The National Osteoporosis Foundation (NOF) differs slightly. NOF recommends 400–800 IU for those under age 50 and a higher intake of 800–1,000 IU for those over age 50 [15]. Patients with a documented Vitamin D deficiency should be treated with 50,000 IU of Vitamin D2 (ergocalciferol) for 8 weeks followed by a maintenance dose of 1,000 IU of Vitamin D3 (cholecalciferol) daily. The treatment goal is a serum vitamin D level greater than 30 ng/ml.

Physical Activity

Maintaining an active lifestyle with adequate physical activity, particularly weight-bearing exercise is important in maintaining musculoskeletal health. Exercise has been shown to slightly increase BMD and slightly reduce the risk of having a fracture. Maintaining a healthy and

Table 2 Optimal Calcium[a] and Vitamin D intake[b]

Population	Calcium	Vitamin D
Infants, children, and young adults		
0–6 Months	200	400
6–12 Months	260	400
1–13 years	700–1,300	400–600

71+ years	1,200	800

Adapted from the National Institutes of Health Recommendations on Calcium and Vitamin D 2011
[a]Calcium recommendations in mg/day
[b]Vitamin D recommendations in IU/day

active lifestyle may also reduce the risk of falls, which in turn may reduce the risk of fractures. Exercise is recommended as a safe and effective way to reduce bone loss [16].

Fall Prevention

Falls cause the majority of osteoporotic fractures. Risk factors for falls are numerous and include visual or hearing impairments, musculoskeletal disorders, cognitive disorders, and increased age. Many medications can also increase the risk of falls. These include antidepressants, antipsychotics, benzodiazepines, diuretics, beta blockers, and antihypertensives. A detailed history should be obtained on each patient to document fall risks and identify any potentially concerning medications. It may be appropriate to start patients in an exercise program or physical therapy to improve balance and strength or adjust medications to prevent future falls.

Pharmacological Treatment

Pharmacological treatment is the mainstay of osteoporosis management. Available agents for treatment and prophylaxis of osteoporosis include bisphosphonates, calcitonin, hormone therapy, estrogen agonists/antagonists, parathyroid hormone (PTH), and the RANK Ligand inhibitor Denosumab.

Indications for treatment:

Diagnosis of osteoporosis
Diagnosis of osteopenia plus >3 % risk of hip fracture or >20 % risk of major osteoporotic fracture in 10 years based on FRAX score
A history of vertebral or hip fractures

The optimal duration of treatment has not been determined. The decision of when to stop treatment or consider a drug holiday remains controversial and will depend on the agent used and the severity of disease.

Bisphosphonates

Bisphosphonates are considered first-line therapy for the treatment and prevention of osteoporosis. They are available in both oral and intravenous preparations. All of the agents listed below are FDA approved for both the prevention and treatment of postmenopausal osteoporosis except

Ibandronate, which is approved for treatment only. The most common side effect from the oral preparations is acid reflux. Therefore the patient should be advised to take the medication with a full glass of water and remain upright for 30 min.

Alendronate (Fosamax)

Alendronate reduces the incidence of spine and hip fractures by about 50 % over 3 years with or without a history of previous fracture. It is an oral medication.

The recommended starting dose for postmenopausal osteoporosis prevention is 5 mg/day or 35 mg/week. Treatment dose is 10 mg/day or 70 mg/week. The 70 mg dose/week may increase compliance as it is dosed once weekly and also has been shown to have decreased esophageal irritation from acid reflux.

Risedronate (Actonel)

Risedronate reduces the incidence of vertebral fractures by 41–49 % and nonvertebral fractures by 36 % over 3 years. It is an oral medication and has fewer gastrointestinal side effects than alendronate. Dosing options include 5 mg daily, 35 mg weekly, 75 mg twice monthly, and 150 mg monthly.

Ibandronate (Boniva)

Ibandronate has been shown to decrease the incidence of vertebral fractures by about 50 %. However, it has not been shown to significantly reduce nonvertebral fractures. It is an oral medication. The recommended dose is 150 mg taken every month.

Zoledronic Acid (Reclast)

Zoledronic acid is the only IV preparation among the bisphosphonates. It has been shown to decrease vertebral fractures by 70 %, hip fractures by 41 %, and other nonvertebral fractures by 25 % over 3 years in those with osteoporosis. Zoledronic acid is dosed just once yearly.

Hormonal

Hormone Replacement Therapy (HRT)

Hormone replacement therapy is FDA approved for the prevention of osteoporosis in women and has been shown to decrease vertebral and hip fractures by 34 % [17]. It is available in oral and transdermal preparations.

Safety issues continue to be controversial with HRT with possible increased risk of myocardial infarction, stroke, breast cancer, pulmonary embolus, and deep vein thrombosis. Given these risks, it is best to consider nonhormonal treatments for primary treatment of osteoporosis. It may be a reasonable treatment option for patients who also have moderate to severe postmenopausal symptoms. If it is used, it should be used for at the lowest effective dose for the shortest duration possible.

Estrogen Agonist/Antagonists (Formerly Known as Selective Estrogen Receptor Modulators (SERMs))

Estrogen Agonist/Antagonists work by acting on estrogen receptors within the bone to prevent resorption and have been shown to increase BMD and decrease fractures in postmenopausal women. However, they are less effective than bisphosphonates and carry all the risks of HRT. They are therefore considered second-line treatments. They do have one advantage in that they may decrease the risk for breast cancer. Raloxifine is the preferred agent in this category and has been shown to decrease the risk of breast cancer. It is a reasonable alternative for postmenopausal women who cannot tolerate bisphosphonates or who at increased risk of invasive breast cancer. Premenopausal women should not be treated with estrogen agonist/antagonist as they may actually decrease BMD in this population [18].

Calcitonin

Calcitonin is an alternative treatment method for osteoporosis. It inhibits by bone resorption by binding to osteoclasts. It is available in several forms including intranasal, intramuscular, and subcutaneous. The nasal dosing is usually preferred as it can easily be dosed at home without

needing an injection and tends to have a lower side effect profile. One of the benefits of calcitonin is its analgesic effect. Studies have shown that when taken after a vertebral fracture, pain has been significantly reduced at 2, 3, and 4 weeks. However, no benefit has been shown when used for chronic pain [19].

Calcitonin has been shown to increase bone mass and prevent fractures when compared to placebo. However, when compared to bisphosphonates, it is inferior at both increasing bone mass and preventing fractures [20]. For this reason, it is not considered first-line treatment, but is a reasonable alternative if a patient is unable to tolerate bisphosphonates or for short-term analgesic use following an osteoporotic fracture.

Parathyroid Hormone (PTH)

PTH works as an anabolic agent by stimulating osteoblastic activity. It is currently the only anabolic agent that is FDA approved for the prevention and treatment of osteoporosis. It is administered in a daily subcutaneous injection and has been shown to significantly increase BMD and decrease fractures. PTH is not a first-line treatment because it can have more side effects than other agents. It can cause hypercalcemia, hyperuricemia, and increased risk of osteosarcoma. The risk of osteosarcoma is controversial as it has only been shown in animal studies and has not been confirmed in any human trials [21]. However, given the possible risk the FDA currently recommends limiting PTH therapy to 2 years until further longitudinal studies have been completed.

RANK Ligand Inhibitor

Denosumab (Prolia) is FDA approved for the treatment of osteoporosis in postmenopausal women with high risk of fracture. It has been shown to decrease vertebral and hip fractures in similar rates to that of bisphosphonates. It is given as subcutaneous injection every 6 months.

It can decrease serum calcium levels, so any underlying hypocalcemia should be corrected prior to starting treatment [22].

Conclusion

Osteoporosis is a common condition that greatly increases the risk of fracture with subsequent increases in morbidity and mortality. Measures should be taken early in life to prevent the development of osteoporosis including exercise, adequate calcium and vitamin D intake, and avoidance of tobacco and excessive alcohol use. Obtaining a detailed history is essential to identify patients that may be at increased risk of developing osteoporosis. Universal screening guidelines exist for all women greater than 65 and should be considered in other patients at risk. DXA is the gold standard for screening and diagnosis of osteoporosis. Bisphosphonates are first-line therapy for both prevention and treatment of osteoporosis. Other pharmacological options are available for patients who cannot tolerate bisophosphonates or have other special considerations.

Selected Disorders of Nutrition

Douglas J. Inciarte

Contents

Introduction

Nutrition disorders seen in primary care are common in the daily medical practice, either in the inpatient or outpatient setting. The assessment and management of nutritional disorders are linked to intestinal and liver disorders that interfere with the nutrient metabolism, affecting the overall care of the patient. Malabsorption of nutrients in the human body causes multiple symptoms and signs such as diarrhea, musculoskeletal, neurological, skin, and mucous membrane pathology resulting in weight loss, weakness, malnutrition, and electrolyte abnormalities.

This chapter will discuss the most common nutritional disorders by mineral or vitamin deficiency causing neurological disorders and other symptoms.

Vitamin and Mineral Deficiencies

Vitamin D Deficiency

Vitamin D deficiency continues to be fairly common in children and adults. Even though Rickets was considered a disease that was essentially eliminated years ago after milk was fortified with vitamin D, we now know that even in utero and during childhood, vitamin D deficiency can cause growth retardation and skeletal deformities.

Vitamin D deficiency in adults can increase the risk of osteopenia and osteoporosis and can cause

DOI 10.1007/978-1-4939-0779-3_130-1

osteomalacia and muscle weakness, thereby increasing the risk of fracture.

The discovery that most tissues and cells in the body have a vitamin D receptor and that several possess the enzymatic machinery to convert the primary circulating form of vitamin D, 25-hydroxyvitamin D, to the active form, 1,25-dihydroxyvitamin D, has provided new insights into the function of this vitamin. Of great interest is the role it can play in decreasing the risk of many chronic illnesses, including common cancers, autoimmune diseases, infectious diseases, and cardiovascular disease [1].

Vitamin D is not a vitamin. It is a prohormone that is synthesized in the skin simplistic from a metabolite of cholesterol.

It is further metabolized to a family of molecules that principally function in the regulation of intestinal calcium absorption [2].

Solar ultraviolet B radiation (wavelength, 290–315 nm) penetrates the skin and converts 7-dehydrocholesterol to previtamin D3, which is rapidly converted to vitamin D3. Because any excess previtamin D3 or vitamin D3 is destroyed by sunlight, excessive exposure to sunlight does not cause vitamin D3 intoxication.

Few foods naturally contain or are fortified with vitamin D. Vitamin D2 is manufactured through ultraviolet irradiation of ergosterol from yeast, and vitamin D3 through the ultraviolet irradiation of 7-dehydrocholesterol from lanolin. Both are used in over-the-counter vitamin D supplements, but the form available by prescription in the United States is vitamin D2. Vitamin D from the skin and diet is metabolized in the liver to 25-hydroxyvitamin D, which is used to determine a patient's vitamin D status, and 25-hydroxyvitamin D is metabolized in the kidneys by the enzyme 25-hydroxyvitamin D-1α-hydroxylase (CYP27B1) to its active form, 1,25-dihydroxyvitamin D. The renal production of 1,25-dihydroxyvitamin D is tightly regulated by plasma parathyroid hormone levels and serum calcium and phosphorus levels. The efficiency of the absorption of renal calcium and of intestinal calcium and phosphorus is increased in the presence of 1,25-dihydroxyvitamin D [1].

Patients with chronic kidney disease (CKD) are at a higher risk of vitamin D deficiency due to either renal losses or decreased synthesis of 1,25-dihydroxyvitamin D.

Because vitamin D is produced by the actions of sunlight on the skin, its deficiency does not usually represent a dietary deficiency, but is seen in those whose skin exposure to ultraviolet light is inadequate; this group includes individuals who, as a result of illness or frailty, seldom venture outdoors, who live at high latitude (particularly if they have dark skin), and who habitually completely cover their skin (e.g., veiled women). The melanin in pigmented skin absorbs ultraviolet light and reduces vitamin D synthesis. This is a valuable protective mechanism in those living in intensely sunny climates, but becomes a liability when these individuals move to relatively sunless environments, such as the cities of Northern Europe and North America. Low 25-hydroxyvitamin D levels are found in the exclusively breastfed infants of vitamin D-deficient mothers, so supplementation of pregnant women and their infants in high-risk groups is advised [3].

Although there is no consensus on optimal levels of 25-hydroxyvitamin D as measured in serum, vitamin D deficiency is defined by most experts as a 25-hydroxyvitamin D level of less than 20 ng per milliliter (50 nmol per liter) [4–6].

Serum 25-hydroxyvitamin D level is the best indicator to assess overall vitamin D levels due that this measurement reflects total vitamin D from dietary intake and sunlight exposure, as well as the conversion of vitamin D from adipose stores in the liver.

Symptoms of vitamin D deficiency are related to Rickets in children and osteomalacia in adults. It is very common that patients with vitamin D deficiency can present with bone pain, fatigue fractures, muscular cramps, muscle pain, and gait disorders, with an increased incidence of falls in the elderly [7].

Vitamin D deficiency is treated with vitamin D oral supplementation, and the recommended dose of vitamin D depends upon the nature and severity of the vitamin D deficiency.

In patients who do not have problems absorbing vitamin D:

If 25-hydroxyvitamin (25-OH-D) is less than 20 ng/mL (50 nmol/L), treatment includes 50,000 international units of vitamin D2 or D3 by mouth once per week for 6–8 weeks, and then 800–1,000 (or more) international units of vitamin D3 daily thereafter. The vitamin D levels should be retested in 6 weeks after the treatment was started

In patients with a level between 20 and 30 ng/mL (50–75 nmol/L), treatment usually includes 800–1,000 international units of vitamin D3 by mouth daily, usually for a 3-month period. However, many individuals will need higher doses.

Once a normal level is achieved, continued therapy with 800 international units of vitamin D per day is usually recommended.

In infants and children whose 25-OH-D is less than 20 ng/mL (50 nmol/L), treatment usually includes 1,000–5,000 international units of vitamin D2 by mouth per day (depending on the age of the child) for 2–3 months.

In patients who have diseases or conditions that prevent them from absorbing vitamin D normally (e.g., kidney or liver disease), the recommended dose of vitamin D will be determined on an individual basis. When vitamin D level is normal (>30 ng/mL [≥75 nmol/L]), a dose of 800 international units of vitamin D per day is usually recommended [8].

Vitamin D dosing represents the safe boundary at the high end of the scale and should not be misunderstood as amounts people need or should strive to consume. While these values vary somewhat by age, intakes of vitamin D should not surpass 4,000 IUs per day, due to increase risk for harm. Once intakes surpass 2,000 mg per day for calcium, the risk for harm also increases. As Americans take more supplements and eat more of foods that have been fortified with vitamin D and calcium, it becomes more likely that people consume high amounts of these nutrients. Kidney stones have been associated with taking too much calcium from dietary supplements. Very high levels of vitamin D (above 10,000 IUs per day) are known to cause kidney and tissue damage [9].

Vitamin B12 Deficiency

Vitamin $B_{12\ (cobalamin)}$ deficiency was recognized as a health concern nearly 100 years ago and continues to have clinical significance.

It is particularly common in the elderly (>65 years of age), but is often unrecognized because of its subtle clinical manifestations, although they can be potentially serious, particularly from a neuropsychiatric and hematological perspective. In the general population, the main causes of cobalamin deficiency are pernicious anemia and food-cobalamin malabsorption.

Food-cobalamin malabsorption syndrome, which has only recently been identified, is a disorder characterized by the inability to release cobalamin from food or its binding proteins.

Cobalamin malabsorption syndrome is usually caused by atrophic gastritis, related or unrelated to *Helicobacter pylori* infection, and long-term ingestion of antacids and biguanides [10].

Both the clinical recognition of vitamin B12 deficiency and confirmation of the diagnosis by means of testing can be difficult. The patient's history may include symptoms of anemia, underlying disorders causing malabsorption, and neurologic symptoms.

The most common neurologic symptoms are symmetric paresthesias or numbness and gait problems [11, 12].

Physical examination may reveal pallor, edema, pigmentary changes in the skin, jaundice, or neurologic defects such as impaired vibration sense, impaired position and cutaneous sensation, ataxia, and general weakness.

The first test performed to confirm the diagnosis of vitamin B12 deficiency is generally measurement of the serum vitamin B12 level. Both false negative and false positive values are common (occurring in up to 50 % of tests) with the use of the laboratory-reported lower limit of the normal range as a cutoff point for deficiency [11].

Given the limitations of available assays, clinicians should not use a laboratory's reported lower limit of the normal range to rule out the diagnosis of vitamin B12 deficiency in patients with compatible clinical abnormalities; because of this concern, obtaining a methylmalonic acid (MMA) level, total homocysteine, or both is useful in making the diagnosis of vitamin B12 deficiency in patients who have not received treatment. The levels of both methylmalonic acid and total homocysteine are markedly elevated in the vast majority (>98 %) of patients with clinical B12 deficiency [13].

Elevated levels of methylmalonic acid and total homocysteine decrease immediately after treatment, and the levels can be remeasured to document adequate vitamin B12 replacement.

The level of serum total homocysteine is less specific, since it is also elevated in folate deficiency [13], classic homocystinuria, and renal failure.

If the patient consumes sufficient amounts of vitamin B12 and has clinically confirmed B12 deficiency, then malabsorption (pernicious anemia) must be present. Chronic atrophic gastritis and intestinal vitamin B12 malabsorption should be investigated. A positive test for anti-intrinsic factor or anti-parietal cell (both highly specific 100 % and 50–100 %) antibodies is indicative of pernicious anemia; surveillance for autoimmune thyroid disease is reasonable in patients with positive antibody tests.

Chronic atrophic gastritis can be diagnosed on the basis of an elevated fasting serum gastrin level and a low level of serum pepsinogen I [14]. Some experts recommend endoscopy to confirm gastritis and rule out gastric carcinoid and other gastric cancers, since patients with pernicious anemia are at increased risk for such cancers [14].

For the treatment of vitamin B12 deficiency, oral replacement must be considered. Healthy older adults should consider taking supplemental crystalline vitamin B12 as recommended by the Food and Nutrition Board. Unfortunately, most patients with clinical vitamin B12 deficiency have malabsorption and will require parenteral or high-dose oral replacement. Adequate supplementation results in resolution of megaloblastic anemia and resolution of or improvement in myelopathy.

The most recommended treatment is schedules for injections of vitamin B12 (called cyanocobalamin in the United States and hydroxocobalamin in Europe) [15, 16].

Patients with severe disease should receive injections of 1,000 μg at least several times per week for 1–2 weeks, then weekly until clear improvement is shown, followed by monthly injections. Hematologic response is rapid, with an increase in the reticulocyte count in 1 week and correction of megaloblastic anemia in 6–8 weeks. Patients with severe anemia and cardiac symptoms should be treated with transfusion and diuretic agents, and electrolytes should be monitored. Neurologic symptoms may worsen transiently and then subside over weeks to months [12].

The treatment for pernicious anemia is lifelong, and in patients in whom vitamin B12 supplementation is discontinued after clinical recovery, past neurologic symptoms will recur within as short a period as 6 months, and megaloblastic anemia recurs in several years [15].

Folic Acid Deficiency

Folic acid or folate refers to a family of compounds that belongs to the group of vitamin B cofactors that participate in the methylation of homocysteine to methionine and to the conversion of S-adenosylmethionine (SAM), the universal methyl donor, to processes involving DNA, RNA, hormones, neurotransmitters, membrane lipids, and proteins. Food folates are present in animal products as well as green leafy vegetables, fruits, cereals and grains, nuts, and meats.

The most common cause of folic acid or folate deficiency is nutritional, either due to poor diet and/or alcoholism. Normal body stores are small (5–10 mg), and individuals on a folate-deficient diet and/or alcoholics can develop megaloblastic anemia within 4–5 months, even sooner if they have a low folate intake (5–10 weeks) [18].

In child-bearing women, a high dose of folic acid supplement reduces the incidence of recurrent neural tube defects by 70 % [17].

Folate deficiency is also common in the elderly older adults. In one study the age-specific prevalence of folate deficiency was approximately 5–10 % in those ages 65–74 years [19].

Alcohol abuse produces a sharp fall in serum folate within 2–4 days by impairing its enterohepatic cycle and inhibiting its absorption. Alcoholics can develop megaloblastosis within 5–10 weeks. Folate depletion is quicker than the 4–5 months required in normal patients in part because alcoholics often have lower folate stores due to previous dietary habits.

Several drugs interfere with folic acid metabolism including trimethoprim, pyrimethamine, methotrexate, and phenytoin.

The classic clinical presentation of folate deficiency is quite different from that of B12 deficiency; in folic acid deficiency, it is rare to see neurological changes or symptoms.

Exceptions to this general rule are the rare cases of hereditary folate malabsorption and/or metabolism, which are associated with progressive neurologic deterioration early in life [20]. For the diagnosis of folate deficiency, one must obtain assays of serum or red cell folate, serum B12, methylmalonate, and homocysteine to distinguish between folate and vitamin B12 deficiency.

The treatment of folic acid deficiency is 1–5 mg per day of oral folate supplementation, and the duration of the treatment should be for 1–4 months or until complete hematologic recovery occurs.

A dose of 1 mg per day of folic acid is usually sufficient and recommended for disease prevention in normal adults, alcoholics, the elderly, and prevention of neural tube defects in female patients of child-bearing age.

Iron Deficiency

Iron deficiency is a global health problem and continues to be the top cause of anemia affecting more than two billion people worldwide. It is prevalent in pediatrics and in premenopausal women in both low-income and developed countries [21]. The estimated prevalence of iron deficiency worldwide is twice as high as that of iron-deficiency anemia.

The reported prevalence of iron deficiency in the absence of dietary fortification is approximately 40 % in preschool children, 30 % in menstruating girls and women, and 38 % in pregnant women [22, 23].

In developing countries, iron deficiency and iron-deficiency anemia are the results of lack of dietary intake, loss of blood due to intestinal parasite colonization, or both.

In first-world countries, certain eating habits such as vegetarian diet or no intake of red meat and pathologic conditions such as acute gastrointestinal bleeding or malabsorption are the most common causes. Other causes are sprue, atrophic gastritis, *H. pylori* infection, gastrectomy, and gastric bypass procedures.

The diagnosis of iron deficiency is the same as for any suspected anemia: complete blood count, red blood cell indices, and examination of the peripheral blood smear. A low serum ferritin is diagnostic of iron deficiency. If the diagnosis of iron deficiency is suspected, then a therapeutic trial of iron administration to provide both confirmation of the diagnosis and therapy is indicated. The presumptive diagnosis is made if there is a positive response to a trial of oral iron replacement, characterized by a modest reticulocyte count increase after 5–7 days, followed by an increase in hemoglobin until approximately 3 weeks until the serum ferritin and hemoglobin concentration return to normal.

The treatment of iron deficiency consists of oral administration of iron sulfate (which is the most frequent presentation in the United States). A daily dose for adults with iron deficiency is 100–200 mg of elementary iron and that for children is 3–6 mg per kilogram of body weight of a liquid preparation; for both groups, the supplement should be administered in divided doses without food. Vitamin C ingestion may improve iron absorption. Long-term use of oral iron is limited by side effects, including nausea,

vomiting, constipation, and metallic taste; these side effects are frequent and, although not severe, are often worrisome to patients.

In severe cases including malabsorption or blood loss, patients will need intravenous iron or transfusion in the face of acute blood loss. The intravenous route is the preferred route when a rapid increase in hemoglobin level is required when iron replacement cannot be accomplished via the oral route.

Malnutrition

Malnutrition is a very important problem that is encountered more often than expected in medical practice and results from inadequate or poor-quality food intake or from diseases that alter food intake or nutrient requirements, metabolism, or absorption.

Malnutrition can be classified via primary and secondary causes. Primary malnutrition presents in third-world or developing countries where social or political conditions have deteriorated. Secondary malnutrition is seen in first-world or industrialized countries. It presents in populations with adequate food supplies which can become malnourished as a result of acute or chronic diseases that alter nutrient intake or metabolism, particularly diseases that cause acute or chronic inflammation.

In terms of primary malnutrition, the most common diseases are *marasmus* and *kwashiorkor*. Marasmus results from long-term deficit of dietary energy. Kwashiorkor is the result of a poor protein intake diet. Energy-poor diets with minimal inflammation cause gradual erosion of body mass, resulting in classic marasmus. By contrast, inflammation from acute illnesses such as injury or sepsis or from chronic illnesses such as cancer, lung or heart disease, or HIV infection can erode lean body mass even in the presence of relatively sufficient dietary intake, leading to a kwashiorkor-like state. Quite often, inflammatory illnesses impair appetite and dietary intake, producing combinations of the two conditions [24].

The difference between marasmus and cachexia is that marasmus is a starvation-related malnutrition where all available body fat stores have been exhausted due to starvation without systemic inflammation. Cachexia is related to chronic disease malnutrition with loss of lean body mass due to chronic systemic inflammation. The diagnosis is based on fat and muscle wastage resulting from prolonged calorie deficiency and/or inflammation. Diminished skinfold thickness reflects the loss of fat reserves; reduced arm muscle circumference with temporal and interosseous muscle wasting reflects the catabolism of protein throughout the body, including in vital organs such as the heart, liver, and kidneys [24].

Routine laboratory findings in cachexia/marasmus are relatively unremarkable. The creatinine-height index (24-h urinary creatinine excretion compared with normal values based on height) is low, reflecting the loss of muscle mass. Occasionally, the serum albumin level is reduced, but it remains above 2.8 g/dL when systemic inflammation is absent. In kwashiorkor there is a connection with acute, life-threatening conditions such as trauma and sepsis. The physiologic stress produced by these illnesses increases protein and energy requirements at a time when intake is often limited. Physical exam and laboratory findings include increased hair pluckability, edema, skin breakdown, and poor wound healing with severe decrease of albumin ($<$2.8 g/dL) and transferrin ($<$150 mg/dL). Lymphocytopenia ($<$1,500 lymphocytes/μL) can be also encountered.

Other mineral deficiencies such as vitamin C and zinc are relatively common in sick patients. Scurvy is rare in developed countries. Signs of corkscrew hairs on the lower extremities are found frequently in chronically ill and/or alcoholic patients. Scurvy can be diagnosed by determination of plasma vitamin C levels. Low zinc levels are common in patients with malabsorption syndromes such as inflammatory bowel disease, and they present with poor wound healing, pressure ulcer formation, and impaired immunity.

Thiamine deficiency is a common problem of alcoholism and is replaced with oral formulations.

The treatment of vitamin C deficiency is 250–500 mg/d of oral formulations. Patients with zinc deficiencies will need oral supplementation with 220 mg of zinc sulfate one to three times daily.

In the inpatient setting, hypophosphatemia results from rapid intracellular shifts of phosphate in underweight or alcoholic patients receiving intravenous glucose, with numerous complications such as acute cardiopulmonary failure, collectively called refeeding syndrome, and can be life-threatening; in these situations, consulting a clinical nutritionist is necessary.

Nutritional Requirements for Health Maintenance, Gender/Age/Disease, or Activity

Data from the 2007–2008 National Health and Nutrition Examination Survey (NHANES) suggested that nearly half of US adults aged 20–69 reported taking at least one dietary supplement in the past month. The factors that were independently associated with a greater likelihood of supplement use are as follows: being female, older, white race, having higher level of education, non-supplemental nutrition access program (SNAP) participation, and living in a food-secure household. When considering nutrients from food, supplement users tended to consume greater amounts of vitamin A, vitamin C, vitamin E, folic acid, calcium, and iron. There was no association between supplement use and daily intakes of vitamin B12 and zinc from food sources only. Including nutrients from daily supplement use, supplement users consumed greater amounts of all eight nutrients [25].

One research study regarding the use of vitamins did show additional support for the conclusion that the vast majority of consumers recognize that multivitamins and other supplements can be helpful in filling nutrient gaps in the diet but should not be viewed as replacements for a healthy diet or healthy lifestyle habits. This finding suggests that policy makers and health professionals could feel comfortable recommending rational dietary supplementation as one means of improving nutrient intakes, without being unduly concerned that such a recommendation would lead consumers to discount the importance of good dietary habits.

The online tool at http://fnic.nal.usda.gov/interactiveDRI/ allows health professionals to calculate individualized daily nutrient recommendations for dietary planning based on the DRIs for persons of a given age, sex, and weight. To provide guidance for food education a good reference is the U.S. Department of Agriculture (USDA) MyPlate Food Guide for individuals (www.supertracker.usda.gov/default.aspx), to create food-exchange lists for therapeutic diet planning, and as a standard for describing the nutritional content of foods and nutrient-containing dietary supplements [26].

Our conclusion is that a well-balanced lifestyle along with exercise should never be replaced by the use of vitamins; however, the use of daily calcium, vitamin D, and folic acid in child-bearing women has been proven to prevent diseases.

Selected Disorders of the Endocrine and Metabolic System

Stella O. King[a]*, Mohammed A. Mohiuddin[b] and Richard D.Blondell[c]

The endocrine system governs the metabolic activities of the body, affects tissue growth, and regulates the functioning of many organ systems that influence behavior and cognition. Because the endocrine system is involved in an extraordinary range of physiological processes, it is important to consider an endocrine disorder in many clinical situations, especially when a patient presents with vague multisystem complaints.

The Pituitary

The pituitary (hypophysis) has two distinct parts: an anterior lobe (adenohypophysis) and a posterior lobe (neurohypophysis), which have different embryological origins. There is also a vestigial intermediate lobe. The neurohypophysis is not a true gland. Instead, macroneurons of the hypothalamus project to the posterior pituitary and release into capillary beds either oxytocin or vasopressin that are similar 9-amino-acid peptides. Vasopressin is also known as arginine vasopressin (AVP), antidiuretic hormone (ADH), and argipressin. The adenohypophysis is a true gland containing different cell types that secrete several discrete hormones (see Table 1). The production and pulsatile release of these hormones are under the control of neurons of the hypothalamus that secrete regulatory hormones (e.g., gonadotropin-releasing hormone, GnRH) that are transported to the adenohypophysis by a tiny portal vein system. Excess secretion of anterior pituitary hormones may be due to hypothalamic stimulation, loss of hypothalamic inhibition, or a hormone-secreting adenoma. If an adenoma is secretory, usually only one hormone is produced, which is typically prolactin, growth hormone (GH), or adrenocorticotropic hormone (ACTH), which is also known as cosyntropin.

Hyperprolactinemia and Galactorrhea

Prolactin is a 198-amino-acid hormone that is required for lactation but not breast development. Hyperprolactinemia may be noted during the evaluation of breast discharge, menstrual disorders, infertility, or impotence. The hypothalamus inhibits pituitary prolactin release. Any condition which impacts the hypothalamus or the pituitary stalk causing hypopituitarism may lead to hyperprolactinemia.

The pituitary may secrete prolactin in response to stimulation of the nerves innervating the breast. This may be due to trauma, scars, breast implants, neoplasm, herpes zoster, or nipple stimulation secondary to clothing or foreplay. Pregnancy, hypoglycemia, stress, food ingestion, and sleep are physiological causes of prolactin release. Certain medications have been implicated as the cause of hyperprolactinemia, including opioids, estrogens, verapamil, alpha methyldopa, risperidone, selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants, monoamine oxidase inhibitors, cimetidine, metoclopramide, and dopamine receptor antagonists [1, 2]. Chronic diseases such as renal failure, cirrhosis, and hypothyroidism may also lead to increased prolactin secretion.

Table 1 Hormones of the Adenohypophysis (anterior pituitary)

Pituitary cell type (staining characteristics)	Hormone(s) secreted	Target site	Clinical consequence of excess	Clinical consequence of deficiency
Somatotrophs (eosinophilic)	GH	Bones	Gigantism, acromegaly	Dwarfism
		Glucose metabolism	Glucose intolerance	Fasting hypoglycemia
Lactotrophs (eosinophilic)	Prolactin	Breasts	Galactorrhea	Inability to lactate
Corticotrophs (basophilic)	ACTH	Adrenal cortex	Cushing syndrome	Adrenal insufficiency
	β-Lipoprotein	Skin	Hyperpigmentation	Hypopigmentation
Thyrotrophs (chromophobic)	TSH	Thyroid	Hyperthyroidism[a]	Hypothyroidism
Gonadotrophs (chromophobic)	FSH, LH	Females: ovaries Males: testes	Precocious puberty	Delayed puberty, infertility, loss of secondary sexual characteristics

[a]Secondary hyperthyroidism is a rare condition. Chromophobe adenomas are usually nonsecretory
GH growth hormone, *ACTH* adrenocorticotropin hormone, *TSH* thyroid-stimulating hormone, *FSH* follicle-stimulating hormone, *LH* luteinizing hormone

Clinical Presentation

Women frequently present with oligomenorrhea, infertility, galactorrhea, vaginal dryness, and dyspareunia. Men may present with hypogonadism, erectile dysfunction, infertility or gynecomastia, occasionally with galactorrhea. They tend to present with headache and visual symptoms due to increased incidence of macroadenoma [3].

Diagnosis

A complete medical history including medications is important. Information about chronic medical issues such as renal failure, hepatic failure, and hypothyroidism should also be elicited as these conditions may lead to hyperprolactinemia.

In women of childbearing age, pregnancy should be excluded. Other initial laboratory tests include thyroid, renal, and hepatic function studies. Prolactin levels should be obtained. Normal prolactin levels for nonpregnant women are 2–29 mIU/L and 2–18 mIU/L in men. Visual field testing should be performed in patients presenting with complaints of headache or visual disturbance.

Magnetic resonance imaging (MRI) determines tumor size and excludes presence of other sellar and stalk lesions [3]. Pituitary adenomas are the most common cause of hyperprolactinemia [4]. Prolactinomas are the most common pituitary adenomas and are divided into microadenomas (<1 cm) and macroadenomas (>1 cm). There is evidence to suggest that patients who do not have macroadenoma, enlarging microadenoma, infertility, persistent galactorrhea, gynecomastia, testosterone deficiency, oligo/amenorrhea, or acne/hirsutism may not require intervention. Their physicians may opt to monitor symptoms, prolactin levels, and interval MRI. The data are not clear regarding precise MRI intervals for follow-up [3].

Management

Medication-induced hyperprolactinemia should be addressed by removal of the causative agent. The medication should be discontinued for 3–4 days, and an alternative agent should be found. Dopamine agonists are the drugs of choice for treatment of hyperprolactinemia due to macroprolactinomas or to

microadenomas that require intervention [3]. Bromocriptine and cabergoline are derived from ergot and may restore prolactin levels, shrink adenomas, and increase bone density. Recent studies have found that cabergoline produces fewer side effects and is more effective at normalizing prolactin levels than bromocriptine [5]. One risk of cabergoline is an increased association with cardiac valvular disease. Trans-sphenoidal surgery remains the mainstay of treatment for the majority of macroadenomas; however, 10 % of adenomas may recur after surgery [6].

Hypopituitarism

Hypofunction of the pituitary is a rare disorder that may be either partial or complete (panhypopituitarism). It is caused by a number of disorders that disturb the gland directly (primary hypopituitarism) or the hypothalamus (secondary hypopituitarism) (see Table 2).

Clinical Presentation

Children may present with growth failure and delayed puberty. Adults typically present with a confusing array of psychological problems, family or social difficulties, and multisystem somatic complaints that are due to hormonal deficiencies and the underlying disease that causes the hypopituitarism. Common complaints include fatigue, weight loss, dry skin, menstrual abnormalities, and sexual dysfunction. Symptoms may develop abruptly (as in the Sheehan syndrome) or slowly (as with a slow-growing nonsecretory adenoma). Partial loss of pituitary function might mimic primary failure of the target site. Panhypopituitarism is ultimately fatal. Patients appear pale and chronically ill with a loss of secondary sexual characteristics. Galactorrhea can occur in secondary hypopituitarism (e.g., hypothalamic sarcoidosis) because the hypothalamus inhibits pituitary prolactin. Lack of vasopressin produces polydipsia and polyuria of central diabetes insipidus (DI).

Diagnosis

If the patient is viewed as a whole, the diagnosis is suggested by the clinical history and examination and can be confirmed by simultaneously measuring serum pituitary and target gland hormone levels [7]. MRI is the preferred method for evaluating hypothalamic and pituitary anatomy.

Management

Treatment is aimed at the underlying condition and replacement of target gland hormones. A deficiency of glucocorticoids is corrected before thyroid hormone replacement to prevent precipitating an adrenal crisis. Because aldosterone secretion is unaffected, mineralocorticoids are not necessary. Sex hormones can be started once the patient is euthyroid, but gonadotropins are required to restore fertility. In children, GH is required. In adults, replacement of GH reduces body fat, increases muscle mass and bone density, and improves exercise tolerance in the short term; the long-term benefits have not been evaluated. At least one study has suggested that patients affected by traumatic brain injury may demonstrate a higher percentage

DOI 10.1007/978-1-4939-0779-3_131-1

of abnormality in growth hormone production, which may improve after 1 year [8]. These patients should wear a medical identification bracelet or necklace.

Neuroendocrine Disorders of Water Balance

Endocrine diseases may present with abnormalities of water balance: hyponatremia, hypernatremia, polyuria, or polydipsia. Body water and osmotic homeostasis are balanced under physiological conditions by a sensitively regulated vassopressin system essentially depending on two determinants: the serum osmolality and arterial blood volume [9]. Thirst is an important backup mechanism, becoming indispensable in the moment when pituitary and renal mechanisms fail to maintain body fluid homeostasis. Addison disease causes hyponatremia due to excessive sodium excretion. The syndrome of inappropriate secretion of ADH (SIADH) may result from disruption of normal feedback to neurohypophyseal system.

Polydipsia

Primary Polydipsia

Primary polydipsia (PP) results from an excessive fluid intake ingested over an extended period of time and not from deficient vassopressin secretion or activity. An excessive consumption of fluids results in excessive body fluid, decreased serum osmolality, and suppressed vassopressin release. PP comprises patients with a defective thirst mechanism or with increased thirst sensation (dipsogenic DI) and patients with a more unknown motive for polydipsia frequently associated with psychiatric disorders (psychogenic polydipsia). The subsequent increase in water excretion compensates for the high fluid intake, and the tonicity stabilizes at a new set point around the osmotic threshold for vassopressin secretion. Therefore, despite intact pituitary and renal function, patients with PP share essential characteristics of DI. Because dipsogenic DI can be caused by the same hypothalamic lesions as found in central DI, it is essential to perform cranial MRI (cMRI) scans in all patients with PP before idiopathic or psychiatric illness can be diagnosed. PP may also have an iatrogenic origin, either due to drug intake associated with oral dryness of anticholinergic medications or due to the medical advice to increase fluid intake for certain health benefits.

Secondary Polydipsia

Secondary polydipsia is protective in patients with polyuria from any cause. When access to water is limited, dehydration, hypernatremia, and death can result. It is difficult or impossible to determine the underlying cause among psychiatric patients, although a water deprivation test could be helpful. The clinician should also search for some other underlying diseases and should not automatically assume that psychogenic polydipsia is the cause of polyuria or hyponatremia in a psychiatric patient. In such situations, the clinician could evaluate the patient for hypopituitarism biochemically and radiographically. Functional evaluation of the thyroid, adrenals, and kidneys may also prove useful.

Polyuria and Central Diabetes Insipidus

Polyuria may be due to central diabetes insipidus (DI), nephrogenic DI, an osmotic diuresis, or primary polydipsia. Osmotic diuresis of diabetes mellitus resulting in polyuria is also seen with poorly resorbed solutes (e.g., mannitol, sorbitol, and urea).

Central DI is caused by a deficiency of vasopressin either through loss of the large hypothalamic neurons that synthesize vasopressin or via destruction of the capillary beds of the posterior pituitary. Acquired central DI mostly results from trans-sphenoidal surgery of the pituitary or head trauma

DOI 10.1007/978-1-4939-0779-3_131-1

[9]. Central DI may be partial or complete, transient or permanent, associated with other pituitary deficiencies or the sole abnormality. It is produced by the disorders causing hypopituitarism but can also be inherited as an X-linked trait. A transient form is associated with pregnancy.

Clinical Presentation

Polyuria and polydipsia are the only findings in the idiopathic form, but acquired central DI may also present with the symptoms and signs of the associated pituitary lesion. Depending on the underlying etiology, the onset of central DI may be gradual or abrupt. Large volumes (>30 mL/kg) of dilute urine (specific gravity <1.010, osmolality <300 mOsm/L) are excreted over a 24-h period. Nocturia is usually present.

Diagnosis

A water deprivation test is used to distinguish DI from other causes of polyuria. In a controlled setting, water intake is restricted, and the weight and the sodium and osmolarity of the plasma and urine are measured hourly. The patient should not be allowed to lose more than 5 % of body weight. Dilute urine in the face of concentrated serum suggests DI. Then, vasopressin is administered to differentiate central DI from nephrogenic DI. Newly available assay for copeptin, the C terminus of the vasopressin precursor which is surrogate for endogenous plasma vasopressin, holds promise as an easy-to-measure response to an appropriate osmotic stimulus. It offers the potential for higher diagnostic specificity and simplification of the differential diagnostic protocol of DI. T1-weighted MRI studies of the posterior pituitary within the sella turcica may also help to distinguish central DI from PP [9].

Management

The treatment of central DI is directed at diagnosing and treating the underlying cause if possible. Intranasal synthetic analogues of vasopressin are used to treat central DI, though absorption may be erratic with a common cold or allergic rhinitis. Partial central DI may be treated successfully with diuretics (thiazides) or ADH-releasing drugs (e.g., chlorpropamide, carbamazepine). Medical identification should be worn by patients.

Disorders of Secondary Sexual Characteristics

Secondary sexual characteristics are initially expressed at puberty and are maintained in adults by the sex hormones.

Normal Puberty

Puberty is the process leading to physical and sexual maturation that involves the development not only of secondary sexual characteristics but also skeletal growth, alterations in lean body mass, and psychological changes. Normal puberty consists of two main endocrinologic events: adrenarche and gonadarche. Adrenarche is the increased secretion of adrenal androgens that normally occurs in both genders between 6 and 8 years of age, usually preceding gonadarche. It is associated with bone growth and changes in pilosebaceous units. Although the adrenals account for some pubic hair growth, the biological role of adrenarche is not completely understood [10]. Gonadarche is initiated by the hypothalamus. Episodic secretion of GnRH by the hypothalamus results in the pulsatile secretion of the gonadotropin follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by the anterior pituitary.

In boys, LH stimulates testosterone secretion by the Leydig cells, and after spermarche, FSH supports the maturation of spermatozoa. The process of puberty initiates with testicular enlargement and is

DOI 10.1007/978-1-4939-0779-3_131-1

followed by the appearance of pubic hair and enlargement of the penis. Skeletal growth is a late event of male puberty.

In girls, FSH stimulates follicle formation and estrogen secretion. After the onset of ovulation, LH stimulates the development of the corpus within a ruptured graafian follicle. In girls, puberty is heralded by breast development and skeletal growth, followed by the appearance of pubic and axillary hair and then menarche. Recent data suggests that the average age of menarche in the USA, which previously was stable at 12.8 years, has decreased [11, 12]. The change is likely due to the obesity epidemic. Current evidence suggests that pubertal development in girls is associated with body mass index [13].

Precocious Puberty

Precocious puberty may be due to CNS processes or peripheral processes (See Table 3). Central precocious puberty is due to the premature production of gonadotropins. In young children, the process is likely to be pathological. Peripheral precocious puberty is defined by the early appearance of sex hormones. A clinician can distinguish between central and peripheral precocious puberty by order of appearance of sexual characteristics and onset of puberty in family members. Height, weight, Tanner stages of breast development, axillary and pubic hair growth, and genitalia are documented. Radiographs of the left wrist for bone age may be taken. A difference of greater than two standard deviations is considered abnormal.

The treatment of central precocious puberty, which is considered gonadotropin-releasing hormone (GnRH) dependent, is with long-acting GnRH agonists [14]. The agonists maintain constant serum levels of GnRH activity, which supersedes the pulsatility of endogenous GnRH [15]. Options for treatment include depot injections of leuprolide acetate (Lupron Depot-Ped®) administered every 4 weeks, extended depot leuprolide acetate (Lupron Depot-Ped 3 Month®) administered every 3 months, and the annual histrelin subcutaneous implant (Supprelin LA®) [15]. These interventions may be utilized, particularly in girls under age 6 years to preserve adult height potential. GnRH therapy may reduce gonadal sex steroid production within 2–4 weeks in girls and within 6 weeks in boys [14]. The treatment of peripheral precocious puberty depends on the etiology. For example, girls with McCune-Albright syndrome may be treated with the estrogen receptor antagonist fulvestrant (Faslodex®). Boys with familial testotoxicosis have been treated "off-label" with medroxyprogesterone or with flutamide and letrozole [15].

Delayed Puberty

Boys who have not demonstrated testicular enlargement by the age of 14 or for whom 5 years or more have passed between the initial and complete growth of the genitalia have delayed puberty. Girls who have not developed breast buds by the age of 13 or who exhibit primary amenorrhea (passage of 5 years or more between the appearance of breast buds and menarche) have delayed puberty. An appropriate initial assessment consists of a medical history, a complete physical examination with particular attention to the timing of pubertal milestones, and a graph of height and weight. A radiograph of the left wrist for bone age should be obtained. Children with delayed puberty may then be grouped according to the initial assessment: those who appear normal, those who appear to have chromosomal abnormalities (e.g., Turner syndrome in girls, Klinefelter syndrome in boys), and those who appear to have a chronic disease (e.g., hypopituitarism, malignancies, chronic infections, malnutrition, anorexia nervosa). Those who seem normal except for pubertal delay may have a constitutional pubertal delay, primary hypogonadism (e.g., congenital defects, tumors, injuries, infections), or secondary hypogonadism (i.e., gonadotropin deficiency). Appropriate diagnostic tests include serum FSH, LH, estradiol (in girls), or testosterone (in boys); a GnRH stimulation test; and MRI if a CNS lesion is suspected.

DOI 10.1007/978-1-4939-0779-3_131-1

Hypogonadism in Adults

Adults may present to their physicians with infertility and loss of secondary sexual characteristics. In men, primary hypogonadism is most often caused by exposure to physical agents (cytotoxic drugs, radiation, or alcohol), infections (mumps), or trauma requiring castration [16]. Women lose gonadal function following oophorectomy and during menopause, but ovarian failure before the age of 40 is considered premature. The serum pituitary gonadotropins (i.e., FSH and LH) are elevated with gonadal failure. Sex hormone replacement therapy can restore secondary sexual characteristics but not fertility. Unexplained loss of secondary sexual characteristics should prompt an evaluation for secondary hypogonadism (i.e., hypopituitarism) consisting of hormonal studies of the hypothalamic-pituitary axis and possibly MRI of the sella.

Hirsutism and Virilization

Excessive hair growth leads many women to seek medical advice. The significance of this complaint can range from a minor cosmetic issue to the early sign of an adrenal adenocarcinoma. The clinician must determine if the clinical presentation is due to an idiopathic etiology, nonandrogenic factors, or androgen excess. Medications which promote increased hair growth include cyclosporine, minoxidil, diazoxide, dexamethasone, phenytoin, and streptomycin. These often promote vellus hair growth, which is soft and lightly pigmented. Hirsutism is the excessive growth of androgen-dependent hair on the face, axilla, chest, and suprapubic areas of women, and it may be physiological. It is a common presentation of the polycystic ovarian syndrome. The use of androgens for "body sculpting" may lead to hirsutism. Virilization refers to the androgen-dependent masculinization of women and is characterized by clitoromegaly, deepening voice, increased muscle mass, temporal balding, and hirsutism. When virilization is accompanied by defeminization (decrease breast size and vaginal atrophy), it is always pathological.

Diagnosis

A systematic approach should be efficient, safe, and cost effective [17]. A detailed history about onset of hirsutism, weight changes, menstrual history, medications including illicit androgen use, and balding can be helpful as is a family history of similar presentations. The examination should evaluate the presence of terminal hair on cheeks, axillae, chest, and abdomen to determine if the pattern of hair growth is distributed in a male hair pattern and involves terminal hairs which are long, pigmented, and coarse. The Ferriman-Gallwey score identifies hair growth in 11 areas and may be used for continued evaluation. A score greater than 8 confirms the presence of hirsutism. The examination must also determine if the signs of virilization or defeminization are present. The presence of ambiguous genitalia is suggestive of the virilizing forms of congenital adrenal hyperplasia.

Since androgen-mediated hirsutism is almost never associated with a normal menstrual pattern, women with hirsutism and oligomenorrhea should have plasma testosterone measured. If the testosterone result is abnormal ($>$200 ng/dL), MRI examination of the adrenal glands and pelvic organs should be performed to look for a mass. If the testosterone result is mildly elevated but $<$ 200 ng/dL, then an ACTH stimulation test can be performed to differentiate adrenal causes (e.g., 21-hydroxylase deficiency) from other causes (e.g., "obesity-related" insulin resistance).

Management

Cosmetic treatments include shaving, plucking, and waxing. Electrolysis, thermolysis, nonlaser light, and lasers are expensive treatment options. Eflornithine is a topical medication used twice daily to slow hair growth. Patients can expect improvement in 2 months. Cessation of the medication results in regrowth of the hair [18]. The diuretic spironolactone is a potent antiandrogen that has been used off label for hirsutism in doses of 100–200 mg per day [19, 20]. Spironolactone is associated with fetal genital development

DOI 10.1007/978-1-4939-0779-3_131-1

abnormalities. Flutamide, an androgen receptor blocker, has also been used off label and has multiple side effects, including discolored urine and liver enzyme abnormalities. Metformin and troglitazone can reduce insulin resistance among those women with polycystic ovaries [21, 22] but has potential for side effects. Birth control pills and long-acting GnRH agonists may suppress the hypothalamic-pituitary-ovarian axis.

The Parathyroids and Calcium Metabolism

The parathyroids are four tiny glands located in the neck close to the thyroid that secrete parathormone (PTH). PTH and vitamin D (a prohormone) are the principal regulators of calcium and phosphate metabolism. The action of parathormone includes (1) liberation of calcium from the bone through activation of osteoclasts; (2) enhancement of resorption of calcium from the renal tubules, thus decreasing renal calcium loss; (3) stimulation of intestinal absorption of calcium directly and by promoting the production of renal calcitriol; and (4) inhibition of the renal reabsorption of phosphate. Calcitonin produced in response to hypercalcemia by perifollicular cells of the thyroid inhibits bone resorption by a direct action on osteoclasts. Excessive secretion of calcitonin does not usually cause hypocalcemia. It is rare in patients with thyroid medullary carcinoma, which typically secretes large amounts of calcitonin.

Hypoparathyroidism and Hypocalcemia

Characteristic features of hypoparathyroidism are hypocalcemia and hyperphosphatemia. Hypomagnesemia and low or inappropriately normal levels of PTH may also be observed. Hypoparathyroidism usually follows surgical removal of the parathyroids. Target organ unresponsiveness to PTH can be inherited (DiGeorge syndrome) or idiopathic, which occurs sporadically. Intestinal diseases or poor dietary intake are important causes because maintenance of appropriate serum calcium levels requires intestinal absorption of calcium. Vitamin D deficiency, hypomagnesemia, and pancreatitis may also lead to hypocalcemia. Hypocalcemia can occur with renal tubular acidosis or renal failure. Autoimmune polyendocrine syndrome type 1 (APS-1), which is a multiorgan autoimmune disorder, is also an important cause in which autoantibodies are detected against NALP5 (expressed in cytoplasm of parathyroid chief cells) [23].

Clinical Presentation

The symptoms and signs of hypoparathyroidism are primarily neurological: paresthesia, Chvostek's sign, carpopedal spasm, tetany, delirium, and seizures. Symptoms are related to the degree of hypocalcemia. Patients with mild symptoms might mimic psychiatric disorders such as dementia, depression, or psychosis. ECG changes such as prolonged QT interval may be noted.

Diagnosis

In the frail and older adult population, hypoalbuminemia is a common cause of abnormally low serum calcium value. Measured total serum calcium decreases by 0.8 mg/dl for every 1 g/dL decrease in total serum protein. If after this correction is made, the serum calcium is still abnormally low and hypoparathyroidism is suspected, a serum PTH assay should be obtained. Inappropriately elevated PTH values are found with hypocalcemia associated with pancreatitis, hyperphosphatemia, and vitamin D deficiency (secondary hyperparathyroidism).

DOI 10.1007/978-1-4939-0779-3_131-1

Management

Treatment is aimed at the underlying disease if possible. Calcium and vitamin D are the cornerstones of replacement therapy. One gram of calcium carbonate can be taken with each meal and increased to 9–12 g/day (constipation can be a problem). A single administration of vitamin D3 alone with a mean dose of 2.04 μg/day is not only safe but also an easy and cost-effective regimen [24]. Dietary restriction of proteins decreases phosphorus absorption, which is an important factor in management of hypocalcemia. Intravenous calcium is required for acutely ill patients.

Hyperparathyroidism and Hypercalcemia

Primary hyperparathyroidism causes hypercalcemia through increased bone resorption and is due to an autonomously functioning benign adenoma 80 % of the time. Idiopathic or familial parathyroid hyperplasia accounts for most of the rest. Multiple adenomas, carcinoma of the parathyroids, or ectopic production of the PTH by a malignancy are rare causes. Other causes of hypercalcemia due to increased bone resorption of calcium include metastatic cancer, Paget's disease, hyperthyroidism, and prolonged immobilization. Hypercalcemia may also occur because of decreased renal excretion of calcium (thiazide diuretics, lithium) or increased absorption of calcium from the gut (sarcoidosis, vitamin D intoxication). Prolonged tourniquet use can cause measured serum calcium levels to appear elevated.

Clinical Presentation

Hyperparathyroidism may present as hypercalcemia discovered via routine multichemistry testing associated with the subtle psychological symptoms of anxiety, indecision, loss of energy, excessive worry, and irritability. Hypercalcemia may also present as an acute or chronic illness with lethargy, nausea, vomiting, polydipsia, polyuria, impaired renal function, nephrocalcinosis, muscle atrophy, or bradycardia. A short QT interval may be noted on the electrocardiographam (ECG), and severe hypercalcemia can produce ECG changes mimicking an acute myocardial infarction [25]. Thirteen percent (13 %) of the cases of acute pancreatitis during pregnancy are associated with hyperparathyroidism due to a parathyroid adenoma compared to 0.4 to 1.5 % in the general population [26].

Diagnosis

Elevated serum calcium levels are more than 10.5 mg/dL. Because almost half of total serum calcium is protein bound, adjustment may be required if a variation in the serum protein level also exists. An increase of protein by 1 g/dL raises the measured total serum calcium by about 0.8 mg/dL. Because serum calcium levels may fluctuate, results that are minimally elevated (10.5–11.5 mg/dL) should be repeated several times; the average value, not the lowest, is then used for clinical decision-making. If malignancy is suspected, a chest radiograph, a bone scan, and in men the serum prostate-specific antigen (PSA) and alkaline phosphatase levels are useful tests. Patients with Paget's disease have characteristic radiographs of bones, and patients with sarcoidosis or tuberculosis may have abnormal chest radiographs. If hyperparathyroidism is suspected, measuring serum PTH level is essential.

Management

The key to management of hypercalcemia is diagnosis and treatment of underlying disease. For patients with minimal symptoms, maintenance of hydration, dietary restrictions of calcium intake, and loop diuretics are recommended (thiazide diuretics are contraindicated because they enhance renal reabsorption of calcium). Chronic therapy involves oral glucocorticoids in the lowest effective dose for patients with malignancies or sarcoidosis and oral phosphates. Acutely symptomatic patients may require treatment in a hospital setting. Many of these patients can be managed conservatively. Surgical treatment of patients with symptomatic or mildly symptomatic hyperparathyroidism is controversial, but it is

DOI 10.1007/978-1-4939-0779-3_131-1

required for symptomatic patients with parathyroid adenomas or hyperplasia. Emergency treatment of severe tumor-induced malignant hypercalcemia with a combination of calcitonin and the bisphosphonate etidronate is more effective than either alone [27].

Adrenal Dysfunction

The adrenal glands consist of an outer layer (the cortex) and an inner core (the medulla) and play a major role in many endocrine and metabolic activities of the body. The adrenal cortex secretes three main groups of steroid hormones: glucocorticoids, mineralocorticoids, and sex hormones. Glucocorticoid secretion is under pituitary control. The mineralocorticoids are part of the renin-angiotensin system. Control of sex hormone production is not well understood. The adrenal medulla secretes catecholamines (epinephrine, norepinephrine) and is linked to the CNS by the autonomic nervous system.

Adrenocortical Insufficiency

Adrenal insufficiency occurs due to a disruption in the hypothalamic-pituitary-adrenal axis. Adrenal hypofunction may be a primary disorder (Addison disease) or secondary to adrenal insufficiency associated with hypopituitarism or adrenal function suppression by long-term exogenous glucocorticoids. The most common cause of Addison disease is idiopathic autoimmune adrenalitis [28]. Other pathological causes include tuberculosis, amyloidosis, and neoplasia. Adrenal insufficiency may also be congenital or familial.

Clinical Presentation

Chronic onset is very typical of Addison disease. Malaise, fatigue, weakness, and orthostatic hypotension are early symptoms and signs. Hyperpigmentation is also common with early disease; pale skin is typical of hypopituitarism. Late findings include anorexia, nausea, vomiting, diarrhea, hyponatremia, hyperkalemia, and fasting hypoglycemia. Patients may seek medical attention only in an adrenal crisis following some physical stress because early disease may go unrecognized. An adrenal crisis is characterized by muscle weakness, severe abdominal pain, and hypotension followed by shock, renal failure, and death. Since Addison disease is uncommon, affecting only about 1 in 20,000 in the United States and Western Europe, a high clinical suspicion is necessary to prevent the misdiagnosis of an adrenal crisis [29].

Diagnosis

The presence of hyponatremia, hyperkalemia, and a low 8:00 AM serum cortisol level would suggest a diagnosis of adrenal insufficiency. Demonstrating the inability of the adrenal cortex to increase cortisol production during an ACTH stimulation test is key [30]. Synthetic ACTH 0.25 mg is administered intravenously, and serum cortisol levels are determined at baseline and at 30, 60, and 90 min. The peak value should be at least double and 10 μg/dl greater than the basal value, though there is some disagreement over the definition of a normal response. If the test is abnormal, simultaneous 8:00 AM cortisol and ACTH levels can help distinguish primary from secondary adrenal insufficiency. Addison disease diagnosis involves a combination of low serum cortisol levels and persistently elevated levels of ACTH.

Management

Addison disease is treated with glucocorticoid and mineralocorticoid hormone replacement therapy, but the latter is not required for the treatment of adrenal insufficiency secondary to hypopituitarism.

DOI 10.1007/978-1-4939-0779-3_131-1

Hydrocortisone is the drug of choice for treating cases of adrenal crisis or insufficiency because of its glucocorticoid and mineralocorticoid effects [31]. Glucocorticoids are administered if there is a suspicion of an adrenal crisis, which may also require fluid and electrolyte therapy and vasopressors. Traveling patients should carry glucocorticoids for self-administration (injection or per rectum), and they should always wear medical identification. Monitoring for concomitant autoimmune diseases is important; up to 50 % of patients develop another autoimmune disorder during their lifetime [28].

Adrenocorticoid Excess

The stigmata of adrenocorticoid excess (Cushing syndrome) commonly results from the long-term use of exogenous glucocorticoids. Occasionally, it may be caused by an ACTH-secreting pituitary adenoma (Cushing disease), a glucocorticoid-producing adrenal adenoma or carcinoma, or another ACTH-producing neoplasm (usually lung).

Clinical Presentation

Characteristically, affected patients demonstrate rounded "moon facies," truncal obesity with a prominent dorsal cervical fat pad ("buffalo hump"), hypertension, hirsutism, osteoporosis, glucose intolerance, hypokalemia, and psychiatric disturbances. Patients may complain of proximal muscle weakness, menstrual abnormalities, and sexual dysfunction.

Diagnosis

Confirmation of the clinical diagnosis of adrenocorticoid excess and determining the cause may require the performance of a variety of tests [32]. If there is a clinical suspicion of Cushing syndrome, a 24-h urine specimen for free cortisol assay or a rapid low-dose dexamethasone suppression test may be obtained. For the latter, the patient is instructed to take 1 mg of dexamethasone between 11:00 PM and midnight, and a serum cortisol level is obtained at 8:00 AM the next morning. A value ≤ 5 μg/dL is normal. Values ≥ 5 μg/dL require further evaluation with a 2-day dexamethasone suppression test [33].

Management

Therapy is directed at eliminating the source of the excessive glucocorticoids through medication change or surgery for a neoplasm if indicated. Recently developed agents inhibit ACTH secretion from corticotrope tumors or antagonize cortisol action for patients in whom surgery is not possible, for those who decline adrenalectomy, or for those in whom surgery has failed [34].

Hyperaldosteronism

Primary hyperaldosteronism, or Conn syndrome, is a rare condition caused by an aldosterone-secreting neoplasia or hyperplasia of the adrenal gland [35]. Secondary hyperaldosteronism is associated with renin hypersecretion (e.g., renal artery stenosis). Primary hyperaldosteronism is a common secondary form of arterial hypertension with a particularly high prevalence among patients with resistant hypertension. Profound diuretic-induced hypokalemia in a patient with diastolic hypertension is suggestive of hyperaldosteronism. Other patients present with muscle weakness, transient paralysis, paresthesia, tetany, isolated diastolic hypertension, hypernatremia, and hypokalemia. The diagnosis is complicated and involves measuring plasma aldosterone and renin concentrations, conducting imaging studies, and sometimes administrating selective adrenal vein catheterization. The treatment of a unilateral adenoma is surgical. Bilateral adrenal hyperplasia is treated using mineralocorticoid antagonists (e.g., spironolactone). Eplerenone is derived from spironolactone and considered a selective mineralocorticoid receptor antagonist with limited cross-reactivity for the androgen and progesterone receptors, thus lacking

DOI 10.1007/978-1-4939-0779-3_131-1

many of the significant sexually related adverse effects known to be associated with the use of spironolactone.

Hypoglycemia

Hypoglycemia not associated with the treatment of diabetes mellitus is characterized by "Whipple's triad": (1) a low plasma glucose level, (2) symptoms of neuroglycopenia, and (3) relief of these symptoms by carbohydrate intake [36]. Hypoglycemia is defined as a measured plasma glucose concentration <70 mg/dL, and severe hypoglycemia is defined as a blood glucose concentration <50 mg/DL [37]. The symptoms of hypoglycemia are due to two main processes: an adrenergic response (which usually occurs first when serum glucose levels begin to fall) and CNS dysfunction (which usually occurs later at lower glucose levels). Adrenergic symptoms and signs include anxiety, hunger, a feeling of warmth, nausea, palpitations, tremulousness, pallor, and diaphoresis. Neuroglycopenic symptoms and signs include dizziness, diplopia, blurred vision, inability to concentrate, amnesia, confusion, behavior changes, seizures, and coma. Because many patients present with vague symptoms or with a self-diagnosis of hypoglycemia, an important first step is to determine if there is a relation between the relief of hypoglycemia symptoms by carbohydrate intake and the corresponding plasma glucose levels [38].

Diagnosis

Ideally, a plasma blood glucose value is obtained at the time the patient has symptoms, but many times it is not practical. Some patients can be taught how to measure blood glucose levels at home and are asked to keep a diary of symptoms, blood glucose levels, and responses to carbohydrate ingestion. A hypoglycemic disorder is suspected if the patient exhibits Whipple's triad. Patients who have vague symptoms after meals not associated with hypoglycemia are said to have "idiopathic postprandial syndrome." The supervised 72-h fast is the classic diagnostic test for a hypoglycemic disorder; the 5-h glucose tolerance test is not considered to have diagnostic value [36]. During the 72-h fast, the patient is allowed only calorie-free and caffeine-free beverages. All medications are stopped. Levels of plasma glucose, insulin, C peptide, and proinsulin are determined every 6 h until the plasma glucose is 60 mg/dL or lower and then every 1–2 h. The test is ended when hypoglycemic plasma values are noted and the patient has symptoms of hypoglycemia. The absence of typical signs or symptoms precludes the diagnosis of a hypoglycemic disorder. A low plasma glucose level alone is not a sufficient finding for this diagnosis.

Management

Treatment is directed at the underlying cause. Patients who have undergone surgical procedures including gastrectomy, gastrojejunostomy, vagotomy, pyloroplasty are more prone to this condition secondary to enhanced transit of glucose into the intestine, which promotes insulin response. Sometimes, an explanation of the cause and advice to have frequent meals are all that is required. Individuals who exercise intensely may need to "carbohydrate-load" the day before and ingest carbohydrates during exercise. Medications may need to be discontinued or be given in a lower dose. The most commonly reported drugs associated with hypoglycemia are quinolones, pentamidine, quinine, beta blockers, and angiotensin-converting enzyme inhibitors and insulin-like growth factor (IGF); however, the evidence to support this association is of low quality [39]. Patients who have an alcohol use disorder may require specific treatment. Those with factitious hypoglycemia require psychiatric help. Patients with insulinomas are rare (about per million person-years) and may require localization with medical imaging prior to surgical treatment.

DOI 10.1007/978-1-4939-0779-3_131-1

Gout

Gout is a common cause of inflammatory arthritis [40]. Hyperuricemia is a common finding but does not inevitably cause disease. Hypertension, obesity, high alcohol intake, and the use of thiazides and loop diuretics contribute in an additive manner to the risk of gout.

Clinical Presentation

The clinical manifestations of gout are caused by the deposition of monosodium urate crystals in joints, bursae, and soft tissues. Acute gout presents as a self-limited episode of synovitis referred to as a "gout flare." Podagra usually refers to an acute gout attack in the feet, especially a gout flare of the great toe. Acute gout attacks can be debilitating and are the major component of the reported decreased health-related quality of life and decreased work productivity in patients with gout. Classic signs of chronic gout include tophi, deposits of uric acid in periarticular fibrous tissue, the cartilage of the external ear, and the kidneys.

Diagnosis

The diagnosis requires the direct identification of urate crystals in synovial fluid. Serum urate levels are typically normal during episodes of acute gout. An infectious cause may need to be excluded. The diagnosis of gout should prompt a search for associated medical conditions: alcoholism, various nephropathies, myeloproliferative disorders, and hypertension. Gout is also associated with insulin resistance. Certain hereditary disorders of purine metabolism such as hypoxanthine guanine phosphoribosyltransferase deficiency are also worth considering, especially when gout presents in the second or third decade of life.

Management

Options for the management of acute gouty arthritis include nonsteroidal anti-inflammatory drugs (NSAIDs), systemic or intra-articular corticosteroids, and oral colchicine. For best results, treatment needs to be initiated within 24 h of the onset of a gout flare. Established pharmacological urate-lowering therapy should be continued without interruption during an acute attack of gout. Prophylactic therapy is recommended for patients with three or more acute episodes per year with tophaceous deposits, with overproduction of uric acid, or who are on continued cyclosporine therapy. The American College of Rheumatology (ACR) guidelines on managing gout recommend allopurinol or febuxostat as first-line pharmacological urate-lowering therapy with a goal of reducing sUA to <6 mg/dL [41]. Probenecid is an alternative if contraindications exist or if the patient is intolerant to allopurinol and febuxostat. Anti-inflammatory prophylaxis with colchicine or NSAIDs is recommended upon initiation of urate-lowering therapy prophylaxis for acute gout attacks; corticosteroids are a second-line option. Intravenous pegloticase decreases serum uric acid and gout attacks and improves quality of life for those with chronic gout that is refractory to usual treatments. The key principles of nutrition therapy include a restriction of high purine meat, limiting alcohol intake, and reaching the proper body weight. Proponents of alternative therapies advocate a "Mediterranean diet," the intake of low-fat dairy products, and the use of cherry and related extracts [42].

Family and Community Issues

Endocrine and metabolic disorders may be associated with life-threatening crisis. For example, a patient with adrenal insufficiency (Addison's disease) who requires emergency surgery for multiple injuries

DOI 10.1007/978-1-4939-0779-3_131-1

sustained in a motor vehicle accident will need glucocorticoid and mineralocorticoid replacement therapy. The patient and family members need to be educated about the nature of these illnesses in the event of a medical emergency. Patients should be encouraged to wear medical alert identification as appropriate.

Anemia

Daniel T. Lee* and Monica L. Plesa
Department of Family Medicine, David Geffen School of Medicine at UCLA Health System, Santa Monica, CA, USA

Background and Introduction

Anemia is a reduction in blood hemoglobin (Hgb) concentration or hematocrit (Hct). Normal values of Hgb and Hct vary based on age, gender, ethnicity, and other special considerations and have been widely studied over the years. Recent data from large samples selected to represent the population of the USA suggests that the lower limit of normal hemoglobin concentrations be 13.7 g/dL in young white men (ages 20–59 years) and 12.9 g/dL in young black men, 13.2 g/dL in white and 12.7 g/dL in black men ages 60 years and over, and 12.2 g/dL in white women and 11.5 g/dL in black women 20 years and over, including elderly women [1]. The lower limit of normal for children age 1–3 years is 11 g/dL, with the cutoff rising to approach adult values by age 15–19 years.

It can be particularly difficult to diagnose the cause of anemia in the elderly population, and between 30 % and 50 % of anemia in this age group can be considered "undiagnosed anemia of the elderly" after extensive workup [2]. People residing at higher altitudes have higher baseline Hgb and Hct levels than residents at sea level. Smokers and patients exposed to significant secondhand smoke may have higher Hgb and Hct levels as well [3]. Endurance athletes can have a "sports anemia" as a result of increased plasma volume that lowers hematocrit despite stimulated erythropoiesis and higher red blood cells counts (RBCs) compared to sedentary individuals [4]. Gastrointestinal (GI) bleeds, anemia of chronic inflammation (ACI) due to increased cytokine release with exercise, hemolysis of senescent RBCs in contracting or compressed muscles, hematuria, and sweating can further contribute to this "sports anemia," especially in long-distance runners [4, 5]. Additionally, it is always important to evaluate results in the context of previous data. For example, a low "normal" Hgb may be significant if a recent value was higher.

On occasion, the Hgb and Hct may not accurately reflect red cell mass as they are concentrations and depend on the plasma volume. For example, patients with expanded plasma volume, as in pregnancy or congestive heart failure, may have falsely low values, while patients with plasma contraction, as in burns or dehydration, may have falsely elevated values. In the setting of acute blood loss, both RBCs and plasma are lost equally, and the true degree of anemia may not be appreciated until plasma volume has time to expand.

Anemia may be categorized by the RBC size (microcytic, normocytic, or macrocytic) or by cause (RBC underproduction, RBC destruction, or RBC loss). A patient's history, physical exam, and laboratory studies are integral to determine the etiology of the anemia regardless of the diagnostic approach taken.

Clinical Presentation

Symptoms

Symptoms of anemia are highly variable and depend on the degree of anemia and the rapidity of its development. They arise from the effects of decreased oxygen delivery to end organs and can be exacerbated by hypovolemia. In response to a decrease in Hct, the body increases oxygen extraction by

*Email: dtlee@mednet.ucla.edu

DOI 10.1007/978-1-4939-0779-3_132-1

its tissues as well as increases the delivery of oxygen to these tissues by augmenting cardiac output with a faster heart rate and larger stroke volume. Those with mild or gradually developing anemias may be seemingly asymptomatic, although these patients may also demonstrate symptoms that are not yet recognized by the patient and/or physician [6]. Others may present with a range of symptoms including fatigue, weakness, decreased exercise tolerance, dizziness, headache, tinnitus, palpitations, syncope, impaired concentration, and restless leg syndrome (RLS). Some patients experience abdominal discomfort, nausea, and bowel irregularity as blood is shunted from the splanchnic bed. Decreased blood flow to the skin may result in cold intolerance. Patients with preexisting vascular disease are prone to exacerbations of angina, claudication, or cerebral ischemia.

History

Historical clues assist in determining the cause of anemia. Family history of anemia or onset of anemia in childhood suggests an inherited etiology. Chronic medical conditions such as hepatic, renal, endocrine, or inflammatory disorders can lead to anemia of chronic disease (ACD). Malignancies and infections may also cause anemia. Exposure to some medications, alcohol, and toxins (e.g., lead) can lead to anemia due to bone marrow suppression or interference with vitamin absorption. Chronic diarrhea or a history of GI conditions associated with malabsorption suggests a nutritional deficiency anemia. Obesity or a history of bariatric surgery or other GI surgeries can predispose to iron deficiency anemia (IDA). Dietary intake of iron, folate, and vitamin B12 (cobalamin) should be obtained. Paresthesias of the extremities or alteration in mental status may point to vitamin B12 deficiency. A history of gallstones or jaundice points to hemolysis. Pica, especially of ice, suggests iron deficiency. Potential blood loss from the GI tract or heavy uterine bleeding must be ascertained. Frequent blood donations or blood draws in hospitalized patients may lead to an induced anemia.

Physical Examination

Tachycardia and wide pulse pressure may be present in the anemic patient as a result of increased cardiac output. The skin and conjunctiva may demonstrate pallor. In very severe anemias, retinal hemorrhages may be seen. Jaundice may suggest hemolysis or liver disease. Glossitis can be present in vitamin B12 and iron deficiency. Lymphadenopathy may occur in the presence of hematologic malignancies and infections such as HIV and tuberculosis. A systolic ejection murmur and venous hum may be heard. Signs of liver disease and splenomegaly should be sought. The stool should be examined for blood. Proprioception and balance deficits may occur in vitamin B12 deficiency.

Laboratory Data

Complete Blood Count. Once a patient is determined to be anemic by Hgb and/or Hct, a complete blood count (CBC) with differential should be obtained for the RBC indices as well as the platelet and white blood cell (WBC) values. Mean corpuscular volume (MCV) reflects the size of the RBC. The normal MCV for adults is debatable, with the lower limit of normal defined as 80–82 fl and the upper limit of normal as 98–100 fl. MCV in children is lower, starting at 70 fl at 1 year of age and increasing 1 fl/year until adult values are reached at puberty. Table 1 divides common causes of anemia into microcytic (<82 fl), normocytic (82–98 fl), and macrocytic (>98 fl).

The red cell distribution width (RDW) quantitates the variation in size of the RBCs. Normal RDW is less than 14.5 %. An elevation of the RDW may make the MCV by itself less reliable. An example is a patient who has both iron and B12 deficiencies. In this case, the MCV may be normocytic, but the RDW will be elevated [7]. Recent data from ICU and cardiac patients suggests a possible correlation between increased RDW and increased inflammation, oxidant damage, or vascular trauma that may be predictive of poor outcomes irrespective of the presence of anemia [8].

DOI 10.1007/978-1-4939-0779-3_132-1

Table 1 Classification of anemia based on MCV

Microcytic	**Macrocytic**
Iron deficiency	Non-megaloblastic
Thalassemia	Alcoholism
Anemia of chronic disease[a]	Chronic liver disease
Hemoglobin E[a]	Bone marrow disorders
Sideroblastic anemia[a]	Hypothyroidism[a]
Lead poisoning[a]	Sideroblastic anemias[a]
Hereditary[a]	Marked reticulocytosis
Myelodysplastic syndrome[a]	Spurious[a]
Severe alcoholism[a]	Normal variant[a]
Medications[a]	Neonatal period
Normocytic	Megaloblastic
Elevated reticulocyte count	Folate deficiency
Acute blood loss	Poor intake
Hemolysis	Malabsorption
Decreased reticulocyte count	Ethanol
Anemia of chronic disease	Medications
Chronic kidney disease	Pregnancy
Chronic liver failure	Infancy
Endocrine disease	High folate requirement
Iron deficiency	B12 (cobalamin) deficiency
Myelodysplastic syndromes	Pernicious anemia
Aplastic anemia[a]	Gastric or ileal surgery[a]
Pure red cell aplasia[a]	Ileal disease[a]
Myelophthisic anemia[a]	Strict veganism[a]
Sideroblastic anemia[a]	Fish tapeworm infection[a]
	Bacterial overgrowth[a]
	Pancreatic insufficiency[a]
	Medications[a]
	Congenital disorders[a]
	Medications (anticonvulsants, chemotherapy, zidovudine)

[a]Less common

Mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) generally mirror the MCV (i.e., smaller RBCs tend to have lower MCHs and MCHCs, such as in iron deficiency and thalassemias). Larger RBCs tend to have greater MCH and MCHC values, such as in spherocytosis or sickle-cell anemia.

The presence of hypochromic and hyperchromic RBCs is also important in evaluating anemia. Hypochromic erythrocytes (MCHC <28 g/dL) tend to be more prevalent in IDA than in thalassemias, while hyperchromic erythrocytes (MCHC >41 g/dL) can easily identify hereditary spherocytosis [8].

Platelet and WBC counts should be noted. Among other things, decreased platelet levels (thrombocytopenia) and/or decreased WBCs (leukopenia) suggest bone marrow suppression, aplastic anemia, hypersplenism, vitamin B12 deficiencies, infections, or malignancies. Elevated platelet counts (thrombocytosis) are often seen in IDA, trauma, and infections. Increased WBC counts (leukocytosis) can also be seen in infections and malignancies. Severe pancytopenia should prompt a workup for aplastic anemia, hematologic malignancy, or chemotherapy and/or radiation side effects, among other causes.

DOI 10.1007/978-1-4939-0779-3_132-1

Reticulocyte Count. Reticulocytes, which are newly formed RBCs, normally account for about 1 % of circulating RBCs. Reticulocyte formation is increased in a normal individual who loses blood, with the degree of reticulocytosis increasing as anemia becomes more severe. Therefore, a patient's reported reticulocyte percentage should be adjusted for the degree of anemia to determine if the bone marrow response is appropriate:

$$\text{correted reticulocyte } \% = \text{reticulocyte } \% \times \text{patient's Hct/normal Hct.}$$

A corrected reticulocyte percentage (also known as reticulocyte index) greater than 1 % indicates appropriate bone marrow response to anemia. If the value is less than 1 %, causes of hypoproliferative bone marrow should be sought. Increased reticulocyte counts are present in hemolysis and acute hemorrhage and response to treatment in anemias from other causes. An alternative to corrected reticulocyte percentage is the absolute reticulocyte count, which equals the reported reticulocyte percentage multiplied by the RBC count. The absolute reticulocyte count is normally 50,000–75,000/mm^3.

Peripheral Smear. Abnormalities in the peripheral smear, such as burr cells seen in renal failure or teardrop cells found in myelofibrosis, can assist in determining the etiology of anemia.

Other Laboratory Tests. Further laboratory testing may be warranted, depending on the above RBC indices and peripheral smear. Bone marrow biopsy is reserved for situations in which anemia remains unexplained or is suspected to arise from marrow dysfunction. Current research focuses on other RBC indices such as MCH, reticulocyte cell Hgb content, and reticulocyte maturity index and the role of genetics in diagnosing anemia [8]. Algorithms for evaluation of microcytic, normocytic, and macrocytic anemias are provided in Figs. 1, 2, and 3.

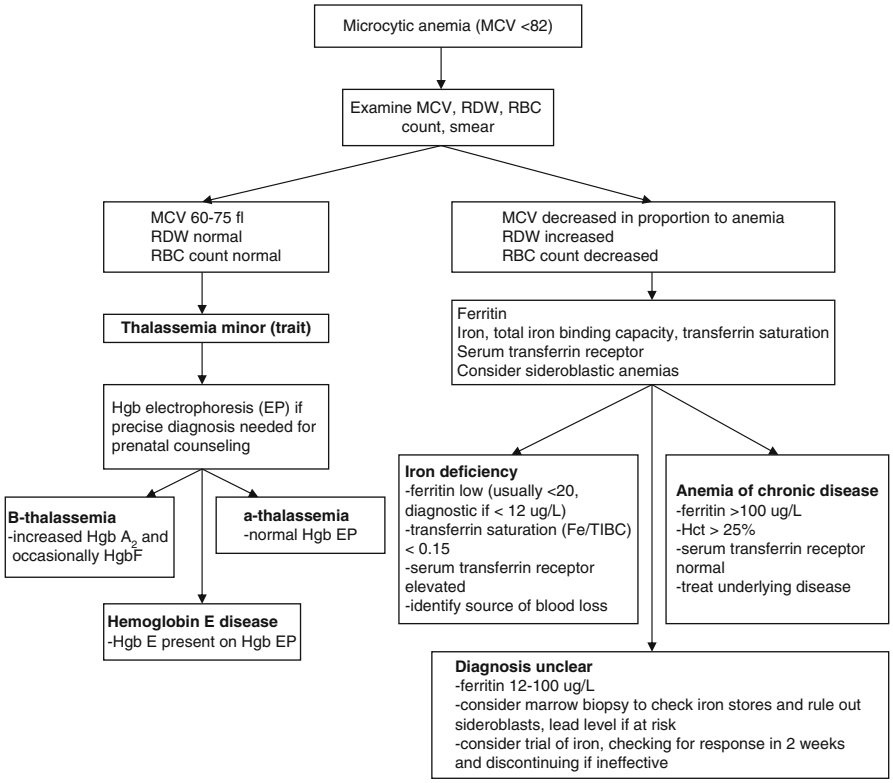

Fig. 1 Evaluation of microcytic anemia

DOI 10.1007/978-1-4939-0779-3_132-1

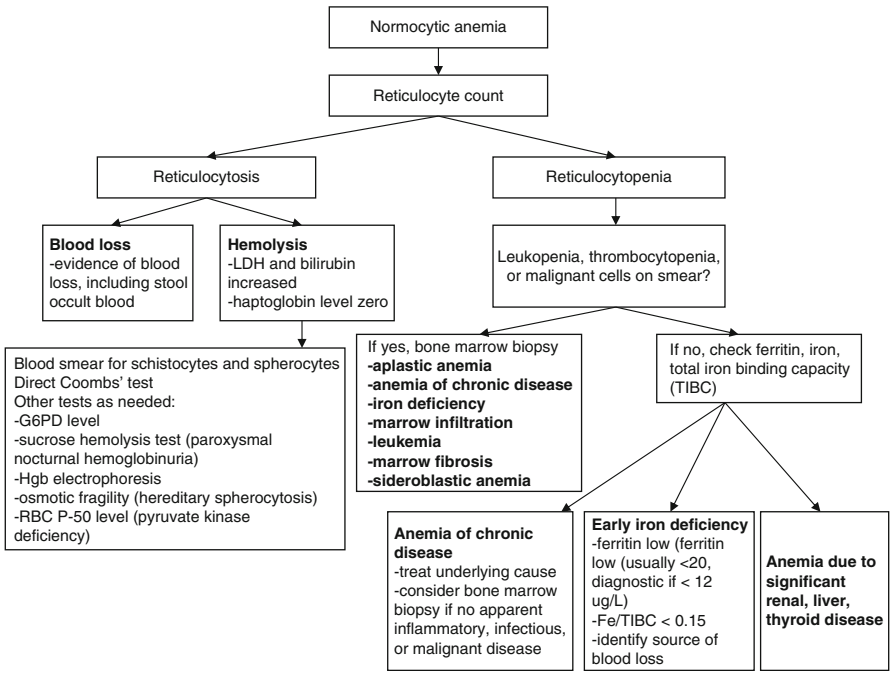

Fig. 2 Evaluation of normocytic anemia

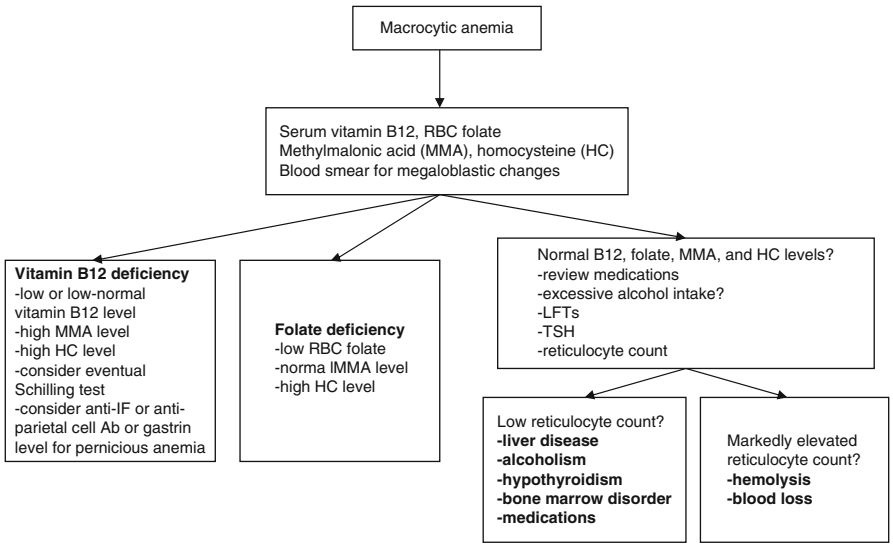

Fig. 3 Evaluation of macrocytic anemia

Microcytic Anemias

Iron Deficiency Anemia

IDA is probably the most common cause of anemia in the USA (Fig. 1). The recommended dietary allowance (RDA) for iron is 8 mg daily for men and 18 mg daily for women [9]. Daily requirements increase during pregnancy, lactation, and adolescence. Meats, eggs, vegetables, legumes, and cereals are principal sources of iron in the American diet, with iron from meats being much more available for absorption than iron from other dietary sources.

DOI 10.1007/978-1-4939-0779-3_132-1

In the USA, IDA accounts for approximately 40 % of anemia in children. Term, healthy infants have sufficient iron stores for at least the first 4 months of life. However, breast milk does not contain as much iron as does formula, so full-term infants who are exclusively or mostly breastfed may become iron deficient around 4–6 months of age until they receive sufficient iron through solid food sources. Therefore, iron supplementation of 1 mg/kg/day may be considered in these infants starting at 4 months of age until appropriate iron-containing complementary foods (including iron-fortified cereals) are introduced into the diet.

IDA may also be seen in older infants fed primarily with cow's milk because the iron content is low and cow's milk may displace other sources of iron in these infants' diets. Furthermore, the high levels of calcium and phosphorous in cow's milk can decrease iron absorption. Thus, the American Academy of Pediatrics recommends screening for anemia in all infants around 12 months of age [10]. A serum ferritin and C-reactive protein level (CRP) should be checked. Elevations of both ferritin and CRP can occur in the setting of inflammation. On the other hand, a low serum ferritin (<10 ug/L) confirms IDA, and these infants should be treated appropriately. Alternatively, infants with mild anemia (10–11 dL/g) can undergo a trial of iron supplementation for 1 month, and a repeat Hgb showing an appropriate rise of 1 dL/g would confirm IDA [10].

Other populations that may develop IDA include children and adolescents whose iron needs are increased due to their rapidly growing bodies in conjunction with poor iron intake. Females lose iron in menstrual blood and can become iron deficient if their bleeding outpaces their iron intake. Pregnancy places additional demands on a woman's iron stores as the placenta and fetus require iron, and blood is lost during childbirth. Obesity can predispose to IDA due to increased inflammation from adipose tissue and subsequent increased production of hepcidin, which directly impairs absorption of iron and iron availability for erythropoiesis. Patients with a history of bariatric surgery are at risk of IDA given their history of obesity and possible malabsorption resulting from the surgery itself [11]. IDA is also seen in decreased absorption states such as celiac disease and gastrectomy.

In men and postmenopausal women, GI blood loss is the most likely cause of IDA. In these patients, a diligent search for occult GI bleeding is imperative when another source of bleeding is not readily appreciated. This should include upper and lower endoscopy with small bowel biopsy. Radiologic tests may substitute if endoscopy is not practical. In over 1/3 of patients with IDA, no source of blood loss will be found despite this evaluation [12]. In these patients, prognosis is good, with anemia resolving in more than 2/3 without recurrence [13]. Further search for source of GI blood loss is required only for persistent bleeding or severe anemia.

Physician examination may reveal glossitis and angular stomatitis. Esophageal webs, splenomegaly, and koilonychias (spoon-shaped nails) rarely occur. Patients may complain of RLS. Although the relationship is unclear, one study showed 24 % of patients with IDA also had RLS [14].

The most sensitive and specific laboratory test for IDA is serum ferritin, which reflects iron stores. While a ferritin below 12 ug/L is diagnostic, a workup for IDA should be considered in patients with ferritins of 13–20 ug/L since a significant number of these patients will have IDA. Since ferritin is an acute phase reactant, falsely normal levels may occur with coexisting inflammatory conditions. Normal ferritin values also increase with age and must be considered when evaluating anemia in an older adult. Nonetheless, a ferritin level above 100 ug/L practically rules out IDA [15]. A decreased serum iron and increased total iron-binding capacity (TIBC) are helpful but less reliable indicators of IDA. The transferrin saturation (iron/TIBC) should be less than 0.15, but this ratio may be reduced in ACD as well. The MCV is usually normal in early iron deficiency and typically decreases after the Hct drops. The MCV then changes in proportion to the severity of anemia. The RDW is often increased. Although not as widely available, soluble serum transferrin receptor (TfR) rises in IDA and may assist diagnosis in difficult cases, although an increase in TfR may also be seen in increased or ineffective erythropoiesis [16, 17]. The transferrin

DOI 10.1007/978-1-4939-0779-3_132-1

receptor-ferritin index (ratio of sTfR to the logarithm of serum ferritin) may also play a role in these difficult cases, with a value >2 suggesting IDA and a value <1.0 indicating ACD [17].

Occasionally, ferritin values fall in the indeterminate range of 12–100 ug/L, and the diagnosis remains uncertain. Bone marrow biopsy is the gold standard to determine iron stores but is rarely necessary. An alternative is a several week trial of iron replacement. Reticulocytosis should peak after 1 week, and the Hct should normalize in about a month. If no response to therapy occurs, iron should be discontinued to prevent potential iron overload and iron therapy side effects.

Oral iron replacement is available in ferrous and ferric forms. Ferrous forms are preferred due to superior absorption and include ferrous sulfate, gluconate, and fumarate. Although most patients with IDA may not need this much, ferrous sulfate 325 mg TID (65 mg of which is elemental iron) is the cheapest and provides the theoretically needed 150–200 mg of elemental iron per day in patients with IDA. Some studies suggest that much less iron supplementation is needed in patients with IDA as their GI tracts absorb more iron after becoming iron deficient. Thus, as little as 60 mg elemental iron once or twice a week may suffice if the patient is unable to tolerate daily dosing [18]. Although Hct should normalize in a few weeks, iron replacement should continue until ferritin reaches 50 ug/L or at least 4–6 months. Many patients experience side effects of nausea, constipation, diarrhea, or abdominal pain as a result of activated hydroxyl radicals released during the oxidation of ferrous compounds within the lumen of the gut or the mucosa [6]. Enteric-coated iron preparations are meant to decrease these symptoms but are not well absorbed and should be avoided. To minimize these effects, iron may be started once a day and titrated up. In addition, iron may be taken with food, although this can decrease absorption by 40–66 % [19]. Taking iron with vitamin C may help increase absorption [20]. Liquid iron preparations may be tried. Despite these measures, 10–20 % of patients will not tolerate oral iron replacement [21]. Bran, eggs, milk, tea, caffeine, calcium-rich antacids, H_2-blockers, proton pump inhibitors, and tetracycline can interfere with iron absorption and should not be taken at the same time. Also, iron supplementation can interfere with the absorption of other medications, including quinolones, tetracycline, thyroid hormone, levodopa, methyldopa, and penicillamine.

Most patients respond well to oral replacement of iron. Treatment failures may result from poor adherence, continued blood loss, interfering substances listed above, or gastrointestinal disturbances limiting absorption. In the rare case where poor absorption or severe intolerance to iron cannot be overcome, parenteral replacement may be needed. Iron dextran may be given IV or as a painful IM injection. The total dose (mg) required to replenish stores equals:

$$0.3 \times \text{body weight (lb)} \times (100 - \text{Hgb [g/dL]} \times 100)/14.8$$

Adverse reactions include headache, flushing, dyspnea, nausea, vomiting, fever, hypotension, seizures, and chest, back, and abdominal pain. Urticaria and anaphylaxis can occur. A test dose (0.5 ml = 12.5 mg) should be given to determine whether anaphylaxis will occur. If tolerated, the remainder of the dose may be given up to a maximum daily dose of 100 mg over 2 min or more. If possible, intravenous iron is preferred over intramuscular due to a lower incidence of local reactions and more consistent absorption.

Thalassemia

The thalassemias are inherited disorders of hemoglobin synthesis that are more common in people from the Mediterranean, Asia, and Africa. The rare thalassemia majors cause severe anemia and are discovered early in life. Family physicians are more likely to encounter thalassemia trait (thalassemia minor) occurring in individuals heterozygous for alpha or beta globin chain mutations.

Thalassemia trait should be suspected in an asymptomatic patient with mild anemia and a disproportionately low MCV (56–74 fl). The RDW is usually normal, and the RBC count is normal or increased by

DOI 10.1007/978-1-4939-0779-3_132-1

10–20 %. Iron studies are normal unless concomitant IDA is present. Blood smear may show target cells, ovalocytes, and basophilic stippling. If a precise diagnosis is required (e.g., for prenatal counseling), hemoglobin electrophoresis may be performed. In beta thalassemia trait, elevated levels of Hgb A2 and occasionally Hgb F will be seen. In alpha thalassemia trait, the hemoglobin electrophoresis will be normal, and the diagnosis is made by exclusion. It is important to determine the etiology of anemia in these patients as treatment with iron therapy is unnecessary and potentially harmful in patients with thalassemia trait who do not have IDA.

Hemoglobin E

Hgb E has a prevalence of 5–30 % in certain groups from Southeast Asia. The heterozygote has mild microcytosis and normal Hct. Homozygotes have marked microcytosis (MCV 60–70 fl) and mild anemia. Target cells may be present on peripheral smear. Hgb electrophoresis reveals the presence of Hgb E, establishing the diagnosis. Patients who have both Hgb E and beta thalassemia develop severe transfusion-dependent anemias.

Sideroblastic Anemia

Sideroblastic anemias are a heterogeneous group of disorders in which ringed sideroblasts are found on bone marrow staining. Sideroblastic anemia may be X linked or due to toxins or medications (lead, alcohol, isoniazid, chloramphenicol, chemotherapy). It may be related to neoplastic, endocrine, or inflammatory diseases or a part of myelodysplastic syndrome. The MCV is usually low but may range from low to high. Iron saturation and ferritin are normal to high. Marrow examination is diagnostic, and treatment is aimed at the underlying cause. In the case of lead poisoning, anemia is microcytic, and basophilic stippling may be seen on peripheral smear. This diagnosis should be suspected and serum lead level tested in high-risk groups such as children ingesting paint, soil, and dust and adults with occupational exposure.

Normocytic Anemias

The absolute reticulocyte count or corrected reticulocyte percentage is important in determining the cause of a normocytic anemia (Fig. 2).

Normocytic Anemia with Elevated Reticulocytes

Acute Blood Loss. Acute blood loss is usually obvious but can be missed in cases such as hip fractures and retroperitoneal or pulmonary hemorrhages. The true degree of anemia may not be revealed in the Hct at first, since RBCs and plasma are lost equally. It may take several days for equilibration of blood volume and Hct to fully reflect the degree of bleeding.

Hemolysis. There are many causes of hemolytic anemia (Table 2). Laboratory values consistent with hemolysis include elevated serum lactate dehydrogenase (LDH) and indirect bilirubin. Haptoglobin, a plasma protein that binds and clears Hgb, drops precipitously in the presence of hemolysis. If hemolysis is suspected, the peripheral smear should be examined for schistocytes (mechanical hemolysis) and spherocytes (autoimmune hemolysis or hereditary spherocytosis). A direct Coombs' test will reveal an autoimmune basis for hemolysis. Further, confirmatory testing may be performed as appropriate (Fig. 2), usually with the guidance of a hematologist. Treatment of hemolytic anemia is directed at the underlying cause and providing supportive care. Corticosteroids and splenectomy may be indicated for specific causes.

DOI 10.1007/978-1-4939-0779-3_132-1

Table 2 Causes of hemolysis

Intrinsic (defect in RBCs)	Extrinsic (defect external to RBCs)
Hemoglobinopathies	Immune
Sickle syndromes	Autoimmune
Unstable hemoglobins	Lymphoproliferative
Methemoglobinemia	Malignancy
Membrane disorders	Collagen vascular disorders
Paroxysmal nocturnal hemoglobinuria	Drug induced (methyldopa, procainamide, quinidine, levodopa, sulfas, penicillin, NSAIDS)
Hereditary spherocytosis	Mechanical
Elliptocytosis	Disseminated intravascular coagulation (DIC)
Pyropoikilocytosis	Thrombotic thrombocytopenia purpura (TTP)
Stomatocytosis	Hemolytic uremic syndrome (HUS)
Enzyme deficiencies	Prosthetic heart valves
Glucose-6-phosphate dehydrogenase (G-6-PD)	Disseminated neoplasms
Pyruvate kinase	Burns
Glucose phosphate isomerase	Malignant hypertension
Congenital erythropoietic porphyria	Vasculitis
	Severe hypophosphatemia
	Physical activity (“march” hemoglobinuria)
	Strenuous exercise
	Hypersplenism
	Infections
	Clostridium, *Plasmodium*, *Borrelia*, *Mycoplasma*, *Babesia*, *Hemophilus*, *Bartonella*
	Bites
	Snakes
	Spiders

Normocytic Anemias with Decreased Reticulocytes

Anemia of Chronic Disease. ACD, also called anemia of chronic inflammation (ACI), results from chronic inflammatory disorders, infections, and malignancies. ACD is the second most common cause of anemia after iron deficiency. It is probably the most common form of anemia in the elderly [22]. The pathogenesis of ACD is multifactorial and not fully understood. Proposed mechanisms include reduction in RBC life span, impaired utilization of iron stores, and a relative erythropoietin deficiency. Although the anemia is customarily normocytic, it can be microcytic in 30–50 % of cases [23]. The degree of anemia is usually mild, with Hgb between 7 and 11 g/dl. The serum iron, TIBC, and transferrin saturation are usually low and not helpful in distinguishing ACD from IDA. More useful is the ferritin level, which is normal or high in ACD. Ferritin greater than 100 ug/L essentially rules out IDA, whereas levels less than 12 ug/L are diagnostic of IDA. In cases of uncertain ferritin levels (12–100 ug/L), a brief therapeutic trial of iron or a bone marrow biopsy may help with the diagnosis. Normal TfR levels may be useful in diagnosing ACD due to the suppression of TfR by inflammatory cytokines [15].

Treatment of ACD is directed toward the management of the underlying disorder. Erythropoietin plus iron supplementation is effective in raising Hct in certain cases. Iron treatment by itself is not indicated for ACD since iron stores are adequate. However, if the anemia is more severe than expected, one should

DOI 10.1007/978-1-4939-0779-3_132-1

search for a coexisting cause. For example, a patient with rheumatoid arthritis may develop concomitant IDA from GI blood loss due to chronic NSAID use.

Chronic Kidney Disease. Anemia occurs frequently in chronic kidney disease (CKD) due primarily to the kidney's inability to secrete erythropoietin. Generally, the creatinine is above 3 mg/dl or the estimated glomerular filtration rate (eGFR) is less than 30 ml/min/1.73 m^2. The peripheral smear is usually normal, but burr cells can be seen. The ferritin is typically increased. If a low to low-normal ferritin is noted, concomitant IDA should be entertained. In fact, many patients with end-stage kidney disease may suffer from "functional iron deficiency." The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI) recommends considering iron repletion in patients with CKD with anemia and serum transferrin saturation <30 % and ferritin <500 μg/L [24].

Therapy consists of ameliorating the renal disease and administering erythropoiesis-stimulating agents (ESAs), namely, erythropoietin and darbepoetin. ESA should be considered for all non-hemodialysis patients with CKD and Hgb < 10 g/dl, with a goal Hgb of 10–11.5 g/dl. Initial dosing of ESA is based on the patient's Hgb concentration, body weight, and clinical circumstances, and it is adjusted based on the patient's response to treatment. The FDA recommends starting epoetin alfa at 50–100 units/kg three times per week; however, more commonly, it is dosed at 10,000 units weekly or 20,000 units every other week. Patients with concomitant IDA should have iron repleted prior to and during ESA therapy in order to prevent worsening IDA and enhance erythropoiesis. Iron stores should be assessed at least every 3 months during treatment [24]. The treatment and dosing of ESA with iron supplementation may be performed in consultation with a hematologist and/or nephrologist. Hemodialysis may improve RBC production, but ESA is the mainstay of treatment, even before dialysis is required. Complications of ESAs include increased blood pressure.

Chronic Liver Disease. Chronic liver disease causes a normocytic or occasionally macrocytic anemia. Target cells can be seen on peripheral smear. Spur cells are seen in severe liver failure. Treatment is directed at improving liver function. Alcoholics with liver disease have additional causes for anemia that are discussed under non-megaloblastic macrocytic anemias.

Endocrine Disease. Various endocrine diseases such as hypothyroidism, hyperthyroidism, hypogonadism, hypopituitarism, hyperparathyroidism, and Addison's disease are associated with anemia. The anemia is corrected with treatment of the underlying endocrine problem.

Aplastic Anemia. Aplastic anemia is due to an injury or destruction of a common pluripotential stem cell resulting in pancytopenia. Bone marrow biopsy reveals severe hypoplasia and fatty infiltration. In the USA, approximately half the cases are idiopathic. Other causes include viral infections (HIV, hepatitis, EBV), drugs and chemicals (chemotherapy, benzene, chloramphenicol), radiation, pregnancy, immune diseases (eosinophilic fasciitis, hypoimmunoglobulinemia, thymoma, thymic carcinoma, graft-vs.-host disease), paroxysmal nocturnal hemoglobinuria, systemic lupus erythematosus, and inherited disorders.

Treatment includes managing the underlying cause and supportive care in conjunction with a hematologist. Judicious use of transfusions may be needed if the anemia is severe. Immunosuppressive therapy and bone marrow transplantation are indicated in certain cases.

Myelophthisic Anemia. Myelophthisic anemias result from bone marrow infiltration by invading tumor cells (hematologic malignancies or solid tumor metastases), infectious agents (tuberculosis, fungal infections), or granulomas (sarcoidosis). Less common causes include lipid storage diseases, osteopetrosis, and myelofibrosis. Treatment is directed at the underlying cause.

Red Cell Dysplasia. Pure red cell dysplasias involve a selective failure of erythropoiesis. The granulocyte and platelet counts are normal. Red cell dysplasias share many causes with aplastic and myelophthisic anemia, including malignancies, connective tissue disorders, infections, and drugs. There is an idiopathic form and a congenital form. One infection that specifically targets red cell production is parvovirus B19. This virus also causes erythema infectiosum ("fifth" disease), an acute polyarthropathy

DOI 10.1007/978-1-4939-0779-3_132-1

syndrome, and hydrops fetalis. Anemia results from parvovirus B19 infection mostly in those with chronic hemolysis, by suppressing erythropoiesis and disrupting a tenuous balance needed to keep up with RBC destruction. In this situation, anemia can be profound but is usually self-limited. Parvovirus B19 infections may become chronic in immunosuppressed individuals who cannot form antibodies to the virus. Treatment concepts for red cell aplasia are similar to treatments for aplastic anemia.

Myelodysplastic Syndromes. The myelodysplastic syndromes (MDSs) are a group of clonal hematologic diseases of unknown etiology that result in the inability of bone marrow to produce adequate erythrocytes, leukocytes, platelets, or some combination of these. Patients are usually over 60 years of age and have an increased risk for leukemia. MDS may account for as much as 15–20 % of anemia in the elderly [2]. Bone marrow biopsy is diagnostic, revealing characteristic dysplastic blood precursor cells. Treatment is largely supportive.

Macrocytic Anemias

Macrocytic anemias may be separated into megaloblastic and non-megaloblastic types, based on peripheral smear findings (Table 1) (Fig. 3). A sensitive and specific sign of megaloblastic anemia is hypersegmented neutrophils, in which neutrophils contain nuclei with more than five lobes. A marked elevation of MCV (>120 fl) is also highly suggestive of megaloblastosis. RBCs of megaloblastic anemias, in addition to being increased in size, are often oval in shape (macroovalocytes).

Most macrocytosis, however, results from non-megaloblastic causes. Drug therapy and alcoholism may account for >50 % of macrocytosis, whereas vitamin B12 and folate deficiencies may be responsible for only 6 % of cases [25].

Megaloblastic Anemias

Vitamin B12 Deficiency. Vitamin B12 (cobalamin) is ingested from primarily animal sources, including meats, eggs, and dairy products. The US RDA of vitamin B12 increases with age and is 2.4 ug daily for adults. A typical Western diet provides 5–30 ug/day. After ingestion, B12 is bound by intrinsic factor, which is produced by gastric parietal cells. Bound vitamin is absorbed in the terminal ileum. Body stores of vitamin B12 total 2,000–5,000 ug. Thus, B12 deficiency takes years to develop and rarely occurs from dietary insufficiency except in strict vegans. The majority of B12 deficiency is due to pernicious anemia, which occurs primarily in the elderly and is most often due to autoimmune atrophy of the gastric mucosa and intrinsic factor deficiency. Less often, pernicious anemia can be due to *H. pylori* infections or Zollinger-Ellison syndrome. Other causes of B12 deficiency include gastric and ileal surgeries, including gastric bypass surgery and ileal absorption problems such as Crohn's disease, sprue, and tapeworm infection.

Signs and symptoms of B12 deficiency include glossitis, sore mouth, and GI disturbances such as constipation, diarrhea, and indigestion. Neurologic symptoms such as paresthesias of the extremities and subacute combined degeneration (loss of lower extremity vibration and position sense) may occur. Dementia and subtle neuropsychiatric changes may be present. Importantly, anemia or macrocytosis is absent in 28 % of patients with neurologic abnormalities due to B12 deficiency [26].

In addition to peripheral smear changes of hypersegmented neutrophils and macroovalocytes, laboratory findings include a low B12 level (<200 pg/ml) and reticulocyte count. However, low-normal B12 levels (<350 pg/ml) are present in many patients with neurologic disease or anemia, so further workup may be indicated if the diagnosis is still suspected. Falsely low B12 levels may be found in folate deficiency, pregnancy, and myeloma. Elevated serum methylmalonic acid (MMA) levels are highly sensitive and essentially rule out B12 deficiency if normal. In one study, elevated MMA levels occurred

DOI 10.1007/978-1-4939-0779-3_132-1

in 98 % of cases of clinically defined B12 deficiency. Falsely elevated levels occur in kidney disease and hypovolemia, and spot urine MMA levels may be superior in this setting. Homocysteine level rises with B12 deficiency (96 % of cases in one study) but is less specific, occurring in folate deficiency and kidney disease as well [27–29]. Occasionally, a mild thrombocytopenia and leukopenia, along with an elevated LDH and indirect bilirubin from ineffective erythropoiesis, are present.

Traditionally, the Schilling test was performed to determine the etiology of B12 deficiency. It measures 24-h urinary excretion of radiolabeled B12 given orally and distinguishes pernicious anemia from bacterial overgrowth and other absorption problems. This test is not commonly utilized as it is expensive, difficult to perform properly, and no longer available in many centers. Antibodies to intrinsic factor may be measured and are the preferred test for diagnosing pernicious anemia. These antibodies are highly specific for pernicious anemia but present in only about 50 % of cases. Antibodies to gastric parietal cells are found in about 85 % of cases of pernicious anemia but also in 3–10 % of healthy persons [29]. Extremely elevated serum gastrin levels and low pepsinogen 1 levels also suggest pernicious anemia.

B12 replacement regimens vary. One common method is 1,000 ug vitamin B12 IM daily for 1 week, then weekly for 1 month, and then every 1–3 months. The Hct should return to normal in 2 months. Failure to normalize should trigger a search for coexisting iron deficiency, which occurs in up to one third of patients. Six months or more may be needed for neurologic improvement, and up to 80 % of patients will have at least partial resolution of neurologic manifestations. An alternative to parenteral B12 is high-dose oral therapy. Patients with pernicious anemia can absorb 1–2 % of oral B12 without the addition of intrinsic factor, so treatment with daily oral B12 1,000–2,000 ug can be considered in adherent patients [30]. B12 maintenance can also be accomplished with an intranasal gel preparation 500 ug once weekly, although this form is more costly than parenteral and oral forms. Treatment should continue indefinitely as the deficiency will likely return unless a reversible cause is identified and addressed.

Folate Deficiency. Folate is found in a wide variety of unprocessed foods. Especially rich sources include green leafy vegetables, citrus fruits, liver, and certain beans and nuts. The RDA for folate is about 200 ug daily and is increased to 400 ug in pregnancy. In contrast to vitamin B12, folate stores remain adequate for only 2–4 months, so folate deficiency anemia is often the result of inadequate dietary intake. The typical Western diet provides only 200–300 ug of folate daily. Persons at risk for folate deficiency include malnourished alcoholics, neglected elderly, and the homeless. Patients who are pregnant or have certain malabsorption disorders are also at risk. Impaired absorption may occur in patients taking oral contraceptives, metformin, or anticonvulsants, such as phenobarbital and phenytoin. Cirrhosis can lead to deficiency through decreased storage and metabolism capabilities of the liver. Dialysis can cause loss of folate and deficiency.

The clinical findings of folate deficiency are similar to B12 deficiency except neurologic symptoms are generally absent. The laboratory findings are similar except that the homocysteine level alone is elevated while MMA remains normal. The serum folate can rise to normal after a recent folate-rich meal, vitamin ingestion, or hemolysis, so serum folate should not be used for diagnosis. Although expensive, RBC folate level is felt to be more accurate. Confirmation with homocysteine levels should be obtained if the diagnosis is suspected.

Treatment is aimed at the underlying problem. Replacement is usually 1 mg orally daily. If present, concurrent vitamin B12 deficiency must be treated as well, because folate replacement can resolve hematologic abnormalities while permitting neurologic damage from vitamin B12 deficiency to progress.

Drugs. Certain drugs cause megaloblastic anemia. Most common causes are chemotherapy agents. Infrequent causes are phenytoin, sulfasalazine, zidovudine, trimethoprim, pyrimethamine, methotrexate, triamterene, sulfa compounds, and oral contraceptives.

DOI 10.1007/978-1-4939-0779-3_132-1

Non-Megaloblastic Anemias

Alcoholism. The most common cause of non-megaloblastic macrocytic anemia is alcoholism. Anemia in alcoholics may arise from multiple causes. Alcohol suppresses erythropoiesis and decreases folate absorption in patients whose diets are often poor. Alcoholics can lose blood from varices and ulcers. Anemia is worsened if liver failure occurs. Moreover, alcoholics are prone to develop sideroblastic or hemolytic anemia. They are also at increased risk for developing infections that can lead to ACD. Comprehensive therapy includes reduction of alcohol intake, folate supplementation, and treatment of complications.

Miscellaneous. The anemia of hypothyroidism, chronic liver disease, postsplenectomy, and primary bone marrow disorders may be macrocytic instead of normocytic. Hemolytic anemia or hemorrhage can result in macrocytosis when reticulocytes, which are larger than normal RBCs, are markedly increased. Certain drugs occasionally cause non-megaloblastic macrocytic anemia. Spurious macrocytosis, although rare, must also be considered due to cold agglutinins causing the RBCs to clump and appear larger to automated counters. Other causes include hyperglycemia causing RBCs to swell when diluted during blood processing or leukocytosis leading to increased blood sample turbidity with a subsequent overestimation in cell size by the machine [31].

Summary

Discovery of anemia should lead the physician to investigate the underlying cause of anemia. Conversely, it may be reasonable to check for anemia in patients who develop certain acute or chronic medical conditions. The history and physical examination combined with the CBC, peripheral smear, and reticulocyte count reveal the etiology in most cases. However, it is not uncommon to find multifactorial causes for a patient's anemia. If the type of anemia remains unclear or there is additional evidence of marrow dysfunction (pancytopenia), a bone marrow biopsy and hematology consultation may be indicated.

Bleeding Disorders

Primary care physicians are often faced with bleeding disorders in several situations. They may be faced with diagnosing a previously unknown bleeding disorder (in both adults and children) but also might be managing or comanaging a patient with a chronic bleeding disorder.

Diagnosis and Evaluation

Adult and pediatric patients with bleeding disorders can present in many ways: many have the complaint of easy bruising (although this is usually not pathologic), excessive bleeding from menses, or postsurgical bleeding. A complete history is the most critical part of the examination and focuses on the "bleeding score" – a risk assessment specifically designed to evaluate for risk of von Willebrand's disease but may be useful in ascertaining risk and severity of many bleeding disorders. See Table 1. Further, questions regarding family history are essential: A positive family history in first-degree relatives (especially regarding menorrhagia) is reason alone to justify a workup. A dietary history can be useful in identifying patients at risk for vitamin K deficiency. Finally, ensure that a full medical reconciliation is completed, as several medications may cause easy bleeding. See Tables 1 and 2 [1].

If the history warrants a further workup, blood work should be done. A PT/PTT, bleeding time versus platelet function assay (preferred), and a mixing study should be used to aid diagnosis. See Table 3 for common patterns of laboratory studies for bleeding diagnoses. It is important to mention that even if the lab workup is normal – if there is enough clinical concern (i.e., high bleeding score) – the patient should be referred to a hematologist for further workup.

Management of Bleeding Disorders

Primary care management of bleeding disorders should be based on comfort level of both the patient and the physician. Due to the significant cost and complexity of management, many primary care physicians refer at diagnosis. However, a patient-centered approach is necessary to deal with the psychosocial disorders associated with bleeding disorders (see Table 4). Referral to an appropriate support group or a family counselor may improve the patient's and family's level of functioning and compliance.

Congenital Bleeding Disorders

Von Willebrand's Disease

Von Willebrand's disease (vWD) is the most common congenital bleeding disorder. The prevalence of vWD may be as high as 1.5 % of the population; the most severe form has a prevalence rate of 1 in 1 million. vWD is an inherited hemorrhagic disorder characterized by deficiency of von Willebrand factor (vWF). vWF is necessary for normal interaction of platelets with vessel walls. vWD is inherited in an autosomal dominant pattern, with males and females equally affected. There are four types and multiple subtypes of vWD. Many patients with vWD also have low levels of factor VIII [3].

Hemorrhage with vWD is highly variable. Epistaxis, gastrointestinal bleeding, easy bruising, and menorrhagia are characteristic of vWD. Hemarthroses are rare. Bleeding following trauma, dental extractions, or operations may be severe. Patients with vWD types I and II platelet type usually have mild or no bleeding problems. Patients with type III disease have severe bleeding problems.

The diagnosis of vWD is confirmed by laboratory findings of prolonged bleeding time, decreased factor VIII levels, decreased vWF activity, and decreased vWF antigen. The PT, APTT, and platelet count are usually normal (Table 3).

The goals of therapy for vWD are to correct coagulation abnormalities, prevent hemorrhage, and return the levels of vWF and factor VIII to normal. For patients with mild vWD, DDAVP administered intranasally or intravenously at a dose of 0.2–0.3 μg/kg body weight can be

Table 1 Bleeding score

Source	Score					
	−1	0	1	2	3	4
Epistaxis	N/A	No/trivial	>5 episodes per year or lasts >10 min	Consultation to specialist but no intervention	Packing, cauterization, or antifibrinolytics	Blood transfusion, replacement therapy, or desmopressin
Cutaneous (bruises)	N/A	No/trivial	>1 cm and no trauma	Consultation to specialist but no intervention	N/A	N/A
Minor wounds	N/A	No/trivial	>5 episodes per year or lasts >5 min	Consultation to specialist but no intervention	Surgical hemostasis	Blood transfusion, replacement therapy, or desmopressin
Oral cavity	N/A	No	Bleeding noted once	Consultation to specialist but no intervention	Surgical hemostasis or antifibrinolytics	Blood transfusion, replacement therapy, or desmopressin
Gastrointestinal	N/A	No	Associated with angiodysplasia, hemorrhoids, portal hypertension, ulcer	Spontaneous	Surgical hemostasis, blood transfusion, replacement therapy, desmopressin, or antifibrinolytics	N/A
Tooth extraction	No bleeding in two extractions	None performed, or no bleeding in one extraction	Bleeding noted in <25 % of all procedures	Bleeding noted in >25 % of all procedures	Resuturing/packing	Blood transfusion, replacement therapy, or desmopressin
Surgery	No bleeding in two surgeries	None performed or no bleeding in one surgery	Bleeding noted in <25 % of all procedures	Bleeding noted in <25 % of all procedures	Surgical hemostasis or antifibrinolytics	Blood transfusion, replacement therapy, or desmopressin

(*continued*)

Table 1 (continued)

Source	Score					
Menorrhagia	N/A	No	Consultation to specialist but no intervention	Antifibrinolytics, pill use	Dilatation and curettage, iron therapy	Blood transfusion, replacement therapy, or desmopressin
Postpartum hemorrhage	No bleeding in two deliveries	None performed or no bleeding in one delivery	Consultation to specialist but no intervention	Dilatation and curettage, iron therapy, antifibrinolytics	Blood transfusion, replacement therapy, or desmopressin	Hysterectomy
Muscle hematomas	N/A	Never	Post-trauma, no therapy	Spontaneous, no therapy	Spontaneous or traumatic, requiring desmopressin or replacement therapy	Spontaneous or traumatic, requiring surgery or blood transfusion
Hemarthrosis	N/A	Never	Post-trauma, no therapy	Spontaneous, no therapy	Spontaneous or traumatic, requiring desmopressin or replacement therapy	Spontaneous or traumatic, requiring surgery or blood transfusion
Central nervous system	N/A	Never	N/A	N/A	Subdural	Intracerebral

A score >4 has a sensitivity of 100 % and a specificity of 87 % for von Willebrand's disease [2]

effective [4]. Oral contraceptives can increase plasma levels of factor VIII and vWF and are useful for women with vWD whose primary problem is menstrual bleeding. Intravenous factor VIII is used to treat patients with more severe bleeding problems. Treatment is titrated to the clinical status of the patient. Surgical and dental procedures can be safely performed in most patients with vWD. Treatment is started (DDAVP or factor VIII) 1 h prior to the procedure and is continued for 2–3 days after the procedure. The goal of perioperative therapy is to keep the bleeding time within the normal range. vWD is preventable only through genetic counseling. It is passed via an autosomal dominant pattern, with 50 % of the children of a parent with vWD at risk to inherit the disease. vWD can be detected in utero via chromosomal analysis. The family and community issues are similar to concerns faced by patients with hemophilia A.

Table 2 Medications that cause bleeding and bruising [1]

Common	Rare
Aspirin	Cephalosporins
Clopidogrel (Plavix)	Ginkgo biloba
Heparin	Gold
Nonsteroidal anti-inflammatory drugs	Interferon
Warfarin (Coumadin)	Metaxalone (Skelaxin)
Other anticoagulants	Penicillins
	Propylthiouracil
	Selective serotonin reuptake inhibitors
	Testosterone replacement
	Tricyclic antidepressants

Hemophilia A

Hemophilia A is an autosomal X-linked recessive deficiency of factor VIII. Because of the mode of transmission and gene expression, males have hemophilia A, and females are usually asymptomatic carriers of the hemophilia A gene. All daughters of a hemophiliac father are carriers of the hemophilia A gene; all his sons are normal. The children of a female hemophilia A carrier have a 50 % chance of being affected by the gene. Hemophilia A affects approximately 1 in 10,000 to 1 in 20,000 males in the United States [5]. Most children with severe hemophilia present within the first year of life due to easy bruising, hemarthrosis, oral bleeding, and post-procedure bleeding.

Hemophilia A usually presents with hemorrhage into a joint or a muscle. Excessive bleeding following minor cuts or abrasions is rare because of normally functioning platelets and normal vessel walls. A common first presentation is either a hemarthrosis or large bruise following a fall during the first 2 years of life or prolonged bleeding following neonatal circumcision. The most common bleeding sites are the joints (knees, elbows, ankles, shoulder, hips, wrists), muscles, renal tract, nervous system, gastrointestinal tract, and oral cavity following tooth extraction.

Screening coagulation tests reveal a normal platelet count, normal bleeding time, normal prothrombin time (PT), and prolonged activated partial thromboplastin time (APTT) (Table 3). The diagnosis is confirmed by obtaining a serum factor VIII assay (normal 1.0 U/mL). The disease is classified as mild, moderate, or severe depending on the serum level of factor VIII activity [3].

Table 3 Laboratory abnormalities seen with bleeding disorders

Disease	Platelet count	Bleeding time	PT	APTT
Hemophilia A and B	Normal	Normal	Normal	Prolonged
von Willebrand's disease	Normal	Prolonged	Normal	Normal
Thrombocytopenia	Low	Prolonged	Normal	Normal
Vitamin K deficiency	Normal	Normal	Prolonged	Normal or prolonged

PT prothrombin time, *APTT* activated partial thromboplastin time
Normal values, platelet count 250,000–500,000/mm^3; bleeding time, Ivy 2–7 min, Duke 1–4 min; APTT 34–54 s; PT 10–14 s

Table 4 Common psychosocial concerns associated with hemophilia (and other bleeding disorders) [1]

Responses of the patient and family to a chronic illness, including overprotection
"Daredevil syndrome" – patient taking risks above those expected for the developmental stage
School and vocational problems
Financial burdens (treatment cost $10,000–$50,000/year)
Concern about infections from blood products (human immunodeficiency virus (HIV) infection prior to 1985, hepatitis B and C)
Peer and sibling relationship problems

Hemorrhage in hemophilia is prevented by intravenous infusion of recombinant factor VIII or human-derived factor VIII concentrates (treated to inactivate or remove viruses). The plasma factor VIII level is maintained at 0.3 U/mL if the patient experiences minor hemorrhage, 0.5 U/mL with severe hemorrhage, and 0.8–1.0 U/mL with life-threatening hemorrhage. Intravenous desamino-γ-D-arginine vasopressin (DDAVP) (desmopressin acetate 0.3 μg/kg) is the treatment of choice for the patient with mild hemophilia; the mechanism of action is unclear [6]. Complications of bleeding are managed conservatively or by drainage depending on the site and severity.

Surgical and dental procedures can be performed for the patient with hemophilia A. The following factors should be considered:

1. The procedure should be done in a facility with an adequate blood bank and surgeons and dentists experienced in treating patients with hemophilia A.
2. No intramuscular medications are prescribed, and no salicylate is given.
3. The factor VIII level should be maintained at 80–100 % of normal (0.8–1.0 U/mL).
4. ∈-Aminocaproic acid (EACA) (4 g PO q4–6 h for 2–8 days) can be used as single or adjunctive postoperative therapy for dental procedures [4]. ∈-Aminocaproic acid is a potent inhibitor of fibrinolysis (inhibits plasminogen activation) and enhances hemostasis in hemophiliacs. Hemophilia A is preventable only via genetic counseling (see chapter "▶ Genetic Disorders"). A family genogram is invaluable for tracking the illness across generations. Women who are at risk for being carriers for hemophilia A can be identified as normal or carriers through factor VIII antibody studies and DNA analysis, with a detection rate of 70–100 % [7]. Hemophilia A can usually be detected in a male fetus using chromosome studies when there is a family history of hemophilia A (i.e., the mother is at risk of being a carrier). Detection of de novo cases, with no family history, is difficult.

Hemophilia B

Hemophilia B is an X-linked recessive factor IX deficiency. It has an incidence of approximately 1 in 30,000 males and is diagnosed by factor IX assay. Hemophilia B is clinically indistinguishable from hemophilia A. Treatment of hemophilia B is intravenous recombinant or human-derived factor IX concentrate. DDAVP has no value in hemophilia B. However, treatment with fibrinolytic inhibitors (i.e., EACA) is indicated [8].

Easy Bruising

Simple, easy bruising (devil's pinches) is an ill-defined condition that presents with bruises on the lower extremities and trunk [9]. In one survey of 500 people, 18 % of healthy individuals reported easy bruising, with women predominant [10]. It may be considered as the underlying etiology only when all other life-threatening causes have been ruled out.

Senile purpura is a characteristic lesion of the elderly [11]. The lesion is caused by progressive loss of collagen in vessels and skin, possibly hastened by ultraviolet (sun) exposure. The lesions of senile purpura usually occur on the upper extremities, especially the back of the hands, wrists, and forearms. The lesions are large, dark, and well demarcated. The diagnosis

is made clinically. Screening coagulation studies are usually normal. There is no specific treatment. Most lesions of senile purpura resolve slowly. Counseling the patient regarding the benign nature of the illness is recommended. Minimizing sun exposure may slow some of the skin changes of aging.

Acquired Bleeding Disorders

Vitamin K Deficiency

Vitamin K is a fat-soluble compound essential to the synthesis of factors II, VII, IX, and X. The sources of vitamin K are dietary (especially green, leafy vegetables) and synthesis of vitamin K by intestinal bacteria. The daily adult requirement of vitamin K is 100–200 μg/day. Deficiency states of vitamin K can be seen in the newborn (hemorrhagic disease), the elderly, and patients with liver disease, after ingestion of vitamin K antagonists (i.e., warfarin), or with long-term antibiotic use (elimination of gastrointestinal flora).

Vitamin K deficiency presents with bleeding in the skin or from mucosal surfaces. Internal bleeding and hemarthroses are rare. The PT is prolonged, the bleeding time and platelet count are usually normal, and the APTT may be prolonged (Table 3).

Vitamin K deficiency is diagnosed by correcting clinical and laboratory abnormalities with vitamin K replacement. A direct laboratory assay for vitamin K is also available [12].

In the case of life-threatening hemorrhage, fresh frozen plasma is given intravenously to return the PT to normal and stop the bleeding. In less urgent situations, vitamin K can be given by the intramuscular, intravenous, or oral route (AquaMEPHYTON 10–15 mg). The goal of therapy is to prevent further bleeding and to return the PT to normal. Treatment with vitamin K usually corrects the PT within 24–48 h.

A diet with adequate amounts of vitamin K-containing foods (especially green, leafy vegetables), avoidance of hepatotoxic agents, and judicious use of long-term antibiotics can prevent vitamin K deficiency. Vitamin K 0.5–1 mg IM should be given to all newborns to prevent hemorrhagic disease of the newborn [13]. Vitamin K supplementation is also recommended during pregnancy for women on anticonvulsant therapy or prolonged treatment with certain antibiotics [14]. Vitamin K deficiency may be a sign of neglect in the elderly patient, whose diet may be deficient.

Thrombocytopenia

Reduction in platelet counts may not always be clinically apparent (manifesting in easy bruising/bleeding) and is often noted incidentally on routine lab work – especially in routine hospital work. Platelets play a crucial role in hemostasis through adhesion, "platelet plug" formation, and release of substances that promote platelet aggregation. Bleeding due to platelet disorders is usually in the skin or from mucosal surfaces. Thrombocytopenia is defined as a platelet count below 100,000/mm^3. Atraumatic bleeding usually is not a problem with a platelet count above 20,000/mm^3. Traumatic bleeding can occur with platelet counts of 40,000–60,000/mm^3. Other routine clotting studies are usually normal except for a prolonged bleeding time.

Diagnosis of thrombocytopenia has a prognostic significance. In one study of 217 persons with platelet counts from 100 to 150 × 10 per μL over a 10-year period, 64 % of patients' platelet counts normalized or remained stable. The probability of developing immune thrombocytopenic purpura or an autoimmune disorder was approximately 7 %. Four cases of myelodysplastic syndrome were diagnosed (2 %), all of which were in older patients [15].

Most surgical and invasive procedures can be performed safely in patients with platelet counts greater than 50 × 10 per μL. Other procedures, such as bone marrow biopsy, bronchoscopy, and endoscopy, can be completed safely in patients with platelet counts greater than 20 × 10 per μL

provided that no other bleeding abnormalities are noted [15].

Diagnosis of Thrombocytopenic Disorders

Thrombocytopenia can result from several mechanisms: decreased platelet production, increased platelet consumption, or sequestration (see Table 5 for etiologies). A systematic approach should be used to evaluate incidental thrombocytopenia. During the patient history, physicians should inquire about easy bruising/petechiae, melena, rashes, fevers, and bleeding. They also should inquire about medication use, immunizations, recent travel, transfusion history, family history, and medical history. A history of acute and chronic alcohol use should be obtained. Any recent hospitalization or heparin exposure should raise the possibility of heparin-induced thrombocytopenia. Pregnant patients with visual symptoms, headaches, abdominal pain, or influenza-like symptoms may have preeclampsia or HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome. The physical examination should include the eyes (e.g., hemorrhage is suggestive of central nervous system bleeding), abdomen (e.g., splenomegaly, hepatomegaly), lymph nodes (e.g., lymphadenopathy), skin (e.g., petechiae, purpura, bruising), and neurologic system. Bleeding (e.g., epistaxis, mucosal,

Table 5 Etiologies of thrombocytopenia [1]

Decreased production	Increased platelet consumption	Sequestration
Bone marrow failure (e.g., aplastic anemia, paroxysmal nocturnal hemoglobinuria, Shwachman-Diamond syndrome)	Alloimmune destruction (e.g., posttransfusion, neonatal, posttransplantation)	Chronic alcohol abuse[a]
Bone marrow suppression (e.g., from medication, chemotherapy, or irradiation)	Autoimmune syndromes (e.g., antiphospholipid syndrome, systemic lupus erythematosus, sarcoidosis)	Dilutional thrombocytopenia (e.g., hemorrhage, excessive crystalloid infusion)
Chronic alcohol abuse[a]	Disseminated intravascular coagulation[a]/severe sepsis[a]	Gestational thrombocytopenia
Congenital macrothrombocytopenias (e.g., Alport syndrome, Bernard-Soulier syndrome, Fanconi anemia, platelet-type or pseudo-von Willebrand's disease, Wiskott-Aldrich syndrome)	Drug-induced thrombocytopenia	Hypersplenism (e.g., distributional thrombocytopenia)
Infection[b] (e.g., cytomegalovirus, Epstein-Barr virus, hepatitis C virus, HIV, mumps, parvovirus B19, rickettsia, rubella, varicella zoster virus)	Heparin-induced thrombocytopenia	Liver disease (e.g., cirrhosis, fibrosis, portal hypertension)
Myelodysplastic syndrome	Immune thrombocytopenic purpura[a]	Pseudothrombocytopenia
Neoplastic marrow infiltration	Infection[b] (e.g., cytomegalovirus, Epstein-Barr virus, hepatitis C virus, HIV, mumps, parvovirus B19, rickettsia, rubella, varicella zoster virus)	Pulmonary emboli
Nutritional deficiencies (vitamin B and folate)	Mechanical destruction (e.g., aortic valve, mechanical valve, extracorporeal bypass)	Pulmonary hypertension
	Preeclampsia/HELLP syndrome	
	Thrombotic thrombocytopenic purpura/ hemolytic uremic syndrome	

HELLP hemolysis, elevated liver enzymes, and low platelet count, *HIV* human immunodeficiency virus
[a]More than one mechanism of action
[b]Thrombocytopenia with infection is usually caused by bone marrow suppression. In some cases, the thrombocytopenia is also immune mediated

Table 6 Clinical considerations to assist with diagnosis of thrombocytopenia [16]

Clinical consideration	Possible diagnosis
Timing	
Acute	Acute infection (primarily viral), acute leukemias, aplastic anemia, chemotherapy or irradiation, drug-induced thrombocytopenia, HELLP syndrome/preeclampsia, heparin-induced thrombocytopenia, ITP, malignancies with marrow infiltration, myelofibrosis, TTP/HUS
Chronic	Chronic alcohol abuse, congenital syndromes, ITP, liver disease, myelodysplastic syndrome
History	
Family history	Congenital thrombocytopenia
Liver disease	Chronic alcohol abuse, chronic liver disease
Pregnancy	Gestational thrombocytopenia, HELLP syndrome/preeclampsia
Recent change in medication	Drug-induced thrombocytopenia
Recent hospitalization	Heparin-induced thrombocytopenia
Recent immunization	MMR, varicella, influenza A (H_1N_1)
Recent transfusion or high-risk behavior	Alloimmune destruction, posttransfusion purpura, viral infection (HCV, HIV)
Recent travel	Dengue fever, malaria, rickettsial diseases
Recent valve replacement surgery	Mechanical destruction
Symptoms	
Abdominal pain	HELLP syndrome/preeclampsia, HUS, platelet sequestration
Recent fever	Viral infections (CMV, EBV, HIV, influenza A (H_1N_1), parvovirus B19), TTP, rickettsial diseases
Weight loss or night sweats	HIV, malignancies (acute leukemias, myelodysplastic syndrome)
Physical examination	
Acute rash	Rickettsial diseases, SLE, viral infections
Generalized lymphadenopathy	Viral infections (CMV, EBV, HIV), SLE, myeloproliferative disorders, lymphoproliferative disorders
Hepatomegaly	Chronic liver disease, acute leukemias, viral infections (CMV, EBV, HBV, HCV)
Neurologic	TTP
Splenomegaly[a]	Autoimmune (SLE, sarcoidosis), hypersplenism, viral infections

CMV cytomegalovirus, *EBV* Epstein-Barr virus, *HBV* hepatitis B virus, *HCV* hepatitis C virus, *HELLP* hemolysis, elevated liver enzymes, and low platelet count, *HIV* human immunodeficiency virus, *HUS* hemolytic uremic syndrome, *ITP* immune thrombocytopenic purpura, *MMR* measles, mumps, and rubella, *SLE* systemic lupus erythematosus, *TTP* thrombotic thrombocytopenic purpura

[a]Ultrasonography may be useful in patients who are obese

gastrointestinal, genitourinary) also should be assessed. Results of the history and physical examination are summarized in Table 6: *Clinical considerations to assist with diagnosis of thrombocytopenia.* A peripheral smear should also be obtained in order to assist with diagnosis, as several findings may assist with diagnosing the underlying etiology.

Treatment is unnecessary in patients with mild thrombocytopenia and is reserved for the patient who is bleeding because of thrombocytopenia or whose platelet count is below 20,000/mm^3. The goal of therapy is to stop the bleeding and return the platelet count to more than 20,000/mm^3. Treatment is summarized in Table 7: *Treatment of thrombocytopenia.*

Emergent Thrombocytopenia

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is caused by interaction of immunoglobulin G (IgG) and other antibodies with megakaryocytes

Table 7 Treatment of thrombocytopenia

Etiology	Severity	Clinical presentation	Evaluation	Treatment	Comments
Bone marrow suppression by irradiation, chemotherapy, or neoplasia	Moderate to severe	History of exposure, comorbid preexisting disease, or malignancy Acute leukemias present with fatigue, weakness, bruising, hepatosplenomegaly	Directed by preexisting diagnosis, specific cancer markers Abnormal blood smear or bone marrow biopsy	Based on underlying etiology	Usually affects all cell lines
Chronic alcohol abuse	Mild to moderate	Findings range from normal to evidence of cirrhosis or hepatic failure	Positive screening questionnaire, abnormal liver function tests (AST/ALT >2, GGT), macrocytosis, folate deficiency, hepatic imaging as clinically indicated	Cessation of alcohol use, vitamin and nutritional replacement	Cessation of alcohol use may lead to platelet rebound (>500 × 10 per μL [500 × 10 per L]) at 1–2 weeks
Chronic liver disease	Mild to severe	Symptoms are variable and based on evidence of cirrhosis, liver dysfunction, gastrointestinal bleeding, ascites, hepatomegaly, and jaundice	Abnormal intrinsic liver function testing, imaging, and liver biopsy as clinically indicated	Based on etiology, often supportive	Hypersplenism often is present contributing to thrombocytopenia
Congenital thrombocytopenia	Mild to moderate	Long history of abnormal platelet count or family history of thrombocytopenia	Many disorders associated with giant platelets, neutrophil inclusions, or other congenital anomalies	Varies depending on primary abnormality	Often asymptomatic when there is no bleeding diathesis
Disseminated intravascular coagulation	Severe	Acute illness; bleeding, acute renal failure, hepatic and respiratory dysfunction, and shock are common clinical manifestations Secondary to other comorbid conditions, such as sepsis, trauma, burns, or malignancy	Prolonged coagulation activation, elevated fibrin markers, and accelerated fibrinolysis (low fibrinogen levels)	Supportive treatment with platelet and clotting factor replacement therapy	Mortality rates exceed 20 %; prognosis is based on treating the underlying disorder
Drug-induced thrombocytopenia	Moderate to severe	Can range from asymptomatic to evidence of clinical bleeding	Detailed history of recent prescription medications, nutritional supplements, and over-the counter agents	Removal of offending agent Serial platelet monitoring until normalization	May be initially indistinguishable from ITP Often resolves within seven to 14 days after agent is discontinued

Heparin-induced thrombocytopenia	Moderate to severe	Thrombocytopenia or a 50 % reduction after exposure to heparin or low-molecular-weight heparin Arterial and venous thrombosis	History of heparin use, erythema or necrosis at site of injection, thrombosis, ELISA test for presence of platelet factor 4 antibodies	Immediate withdrawal of heparin, treatment with nonheparin anticoagulant	Warfarin (Coumadin) monotherapy may induce thrombosis and is contraindicated in the acute setting
Gestational thrombocytopenia	Mild	Asymptomatic with platelet counts rarely $<70 \times 10$ per μL (70×10 per L)	Identified during initial prenatal CBC No associated fetal thrombocytopenia Spontaneous resolution after delivery	No treatment indicated Platelet counts approaching 50×10 per μL (50×10 per L) often are considered ITP and treated with corticosteroids or IVIG	Possible immunologic etiology May be difficult to distinguish from ITP before delivery Up to 15 % of infants with thrombocytopenia are born to women with ITP
Immune thrombocytopenic purpura	Mild to moderate	Often asymptomatic, although symptoms can range from petechiae and easy bruising to severe bleeding diathesis (rare) Secondary ITP may present in patients with autoimmune disorders, infections (e.g., cytomegalovirus, Epstein-Barr virus, *Helicobacter pylori*, hepatitis C virus, human immunodeficiency virus, varicella zoster virus), and lymphoproliferative disorders	Remainder of CBC normal, normal peripheral blood smear, absence of clinically associated conditions Secondary ITP causes should be investigated as clinically indicated	Corticosteroids, IVIG, rituximab (Rituxan), splenectomy Treatment not indicated for platelet counts $> 50 \times 10$ per μL unless active bleeding Secondary ITP also requires treatment of underlying cause	Diagnosis of exclusion Patients older than 60 years should have bone marrow biopsy to rule out myelodysplastic syndrome or lymphoproliferative disorder MMR vaccination causes one case of ITP per 40,000 doses
Infections (viral or rickettsial)	Mild to moderate	Viral: prodrome or asymptomatic; known viruses include cytomegalovirus, Epstein-Barr virus, hepatitis B and C viruses, human immunodeficiency virus, parvovirus B19, varicella zoster virus Rickettsial: Lyme disease, Rocky Mountain spotted fever, ehrlichiosis; tick-borne illnesses present with fever, headache, malaise, arthralgias, and rash	Viral: diagnosis based on viral etiology, directed antiviral titer testing if available Rickettsial: ELISA testing may be useful	Viral: based on viral etiology; most self-limited viral infections are supportive Rickettsial: doxycycline is recommended in symptomatic tick-borne disease	Viral: varicella (live) and influenza A (H_1N_1) vaccinations have been reported to cause mild transient thrombocytopenia Rickettsial: ehrlichiosis causes more severe thrombocytopenia than Rocky Mountain spotted fever and Lyme disease

(*continued*)

Table 7 (continued)

Etiology	Severity	Clinical presentation	Evaluation	Treatment	Comments
Preeclampsia/HELLP syndrome	Mild to moderate	Elevated blood pressure, visual symptoms, headache, right upper quadrant abdominal pain, influenza-like symptoms	CBC, liver function test, urine protein level, increased uric acid level, increased LDH level, basic metabolic panel	Delivering the fetus; intravenous magnesium sulfate	Recovery usually is within 3 days of delivery. If persistent beyond the third day after delivery, presume thrombotic thrombocytopenic purpura
Pseudothrombocytopenia	Factitious	Asymptomatic; in vitro agglutination of platelets	Repeat CBC using non-EDTA anticoagulant	No treatment indicated	Peripheral blood smear will demonstrate clumping
Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome	Moderate to severe	Most common presentation is nonspecific and includes abdominal pain, nausea/vomiting, and weakness; patients with thrombotic thrombocytopenic purpura may have neurologic abnormalities at presentation	Microangiopathic hemolytic anemia, impaired renal function, neurologic abnormalities, proteinuria, increased LDH, increased bilirubin, and decreased haptoglobin levels	Plasma exchange	10–30 % mortality despite treatment; in children, hemolytic uremic syndrome presents with gastroenteritis (bloody diarrhea) and 60 % will have thrombocytopenia

ALT alanine transaminase, *AST* aspartate transaminase, *CBC* complete blood count, *EDTA* ethylenediaminetetraacetic acid, *ELISA* enzyme-linked immunosorbent assay, *GGT* γ-glutamyltransferase, *HELLP* hemolysis, elevated liver enzymes, and low platelet count, *ITP* immune thrombocytopenic purpura, *IVIG* intravenous immunoglobulin, *LDH* lactate dehydrogenase, *MMR* measles, mumps, and rubella

or platelets, resulting in increased platelet destruction. ITP can present as a primary problem or be associated with such condition as malignancies, collagen vascular disease, or viral illnesses. Acute ITP is most common in children, and chronic ITP is more common in adults, with a male/female ratio of 1:3 [16]. Acute ITP occurs most commonly between the ages of 2 and 9 years; chronic ITP occurs chiefly between the ages of 20 and 50 years.

Patients with ITP may be asymptomatic, or they may present with persistent skin bleeding (especially in areas exposed to trauma) or mucosal surface bleeding (i.e., epistaxis, menorrhagia, ecchymoses). Internal hemorrhage and hemarthroses are rare. Intracranial hemorrhage, though rare, can be a serious complication of ITP. There is no lab test for ITP. The diagnosis is purely clinical.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is primarily a disease of adults of largely unknown etiology. The hallmark of TTP is widespread platelet thrombi occurring throughout the microcirculation. Although rare, TTP can be fatal in up to 90 % of untreated patients.

The clinical manifestations of TTP may include hemorrhage, hemolytic anemia, neurologic problems (headache, mental status changes, seizures, coma, and focal neurologic changes), hematuria, renal failure, and fever.

The diagnosis of TTP is made based on the clinical findings and laboratory findings including severe thrombocytopenia, red cell fragmentation, reticulocytosis, elevated indirect serum bilirubin, decreased haptoglobin, and proteinuria. Disseminated intravascular coagulation is usually not associated with TTP. Severe TTP is treated with prednisone (1–2 mg/kg/day) and plasmapheresis.

The hemolytic uremic syndrome (HUS) is clinically similar to TTP [17]. HUS is usually seen in children following infections by viruses, *Escherichia coli*, or *Shigella* species. The clinical picture of HUS includes thrombocytopenia and hemolytic anemia. Neurologic symptoms are less common in HUS than in TTP. The treatment for patients with HUS is plasma exchange. Syndromes resembling TTP/HUS have been seen in patients receiving certain chemotherapeutic agents.

Disorders of the Vascular Wall

The integrity of the vascular wall is essential for maintenance of normal coagulation. Some causes of vascular wall disruption are listed in Table 8. Vascular causes of bleeding (purpura) tend to manifest most often on the lower extremities. Purpura of the head and neck is usually caused by fat emboli, amyloidosis, or mechanical

Table 8 Bleeding from vascular abnormalities

Congenital	Acquired
Hereditary hemorrhagic telangiectasia	*Mechanical*
Angiokeratoma corporis diffusum	Trauma
Ataxia telangiectasia	Increased venous pressure
Cavernous hemangioma	*Decreased supporting tissue*
Ehlers-Danlos syndrome	Senile purpura
Pseudoxanthoma elasticum	Scurvy
Osteogenesis imperfect	Corticosteroids
Marfan syndrome	Amyloidosis
	Chemical agents
	Warfarin (Coumadin)
	Snake venoms
	Infections: meningococcus, rickettsiae, streptococci, shigellae, gram-negative bacteria, measles, rubella, diphtheria
	Vasculitis: Henoch-Schönlein purpura
	Vascular obstruction
	DIC
	Fat emboli
	Leukostasis
	Paraproteinemia
	Proliferative retinopathy
	Idiopathic causes

stresses. Bleeding from vascular causes (with some exceptions) is usually confined to the skin.

Congenital Disorders

Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) is a congenital disorder. Bleeding in patients with hereditary hemorrhagic telangiectasia (HHT) occurs because of malformations of small veins in the skin and mucosa (telangiectases). Transmission of HHT is autosomal dominant, with males and females affected equally (incidence 1/50,000) [18]. Epistaxis and gastrointestinal (GI) tract bleeding are the most common presentations. The lesions of HHT usually become clinically significant during the second or third decade of life. Examination may reveal lesions in the mouth, face, hands, and feet. The lesions are 1–3 mm in diameter, non-pulsatile, red to purplish and flat, round, or spiderlike. HHT lesions are also found in the lungs of 15–20 % of patients and can occur in virtually any organ.

The diagnosis of HHT is established via the history and clinical examination. The family history is often positive. Screening coagulation studies are usually normal. Therapy for HHT is symptomatic. Whenever possible, pressure is applied to bleeding sites. Cautery or surgical therapy of nasal mucosal lesions yields mixed results. GI bleeding can be treated by resection or embolectomy. HHT is not preventable.

The family and community issues are similar to those faced by patients with other bleeding disorders.

Vasculitis

Vasculitis (vascular inflammation) can be caused by many disease processes, including immune causes, infections, drugs, neoplasms, connective tissue diseases, and cold exposure. Henoch-Schönlein purpura (HSP) (allergic purpura) is considered the model for the study of vasculitis. It primarily affects the kidneys, GI tract, and joints. The etiology is unknown. HSP has been seen after viral and streptococcal infections. Drugs (sulfonamides and penicillin) have been implicated as causative agents, and there are data to support an immune mechanism as a cause [19]. HSP is most often seen in children aged 2–10 years (male/female ratio 2:1) but can occur at any age. There is an increased incidence during early spring and early autumn.

HSP presents with fever followed by a macular or urticarial rash on the buttocks, legs, and arms that becomes purpuric. Lesions can occur in crops. Other findings include edema (legs, hands, scalp, eyes), abdominal pain, vomiting, diarrhea, intussusception, arthritis, and hypertension. Kidney involvement is manifested by proteinuria, hematuria, renal failure, or nephrotic syndrome. Iritis, pericarditis, pleurisy, and neurologic disorders are seen less frequently.

Most patients recover spontaneously within 1 month, although relapses are frequent. Treatment is symptomatic. Penicillin is often used because of the association of HSP with streptococcal infections. Glucocorticoids and immunosuppressive agents can be used for the 5–10 % of patients who develop progressive renal failure. Dapsone is being studied as a possible treatment for HSP [20].

Emergent Bleeding Disorders

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a consumptive coagulopathy. Due to a severe underlying cause, there is an acceleration of fibrin deposition in blood vessels and lysis of red blood cells. This disorderly production of fibrin deposition leads to diffuse and damaging fibrin plugs in the microvasculature, further accelerating the process. The fibrin (and procoagulants) is consumed to the point where bleeding occurs. It is a hemorrhagic complication of many serious illnesses (Table 9). Hemorrhage may occur in the skin, central nervous system (CNS), GI system, genitourinary system, or elsewhere. DIC may be

Table 9 Causes of disseminated intravascular coagulation

Tissue injury	Immunologic phenomena
Obstetric problems	**Drugs**
Amniotic fluid embolism	Fibrinolytic agents
Abruptio placentae	Ancrod
Uterine rupture	Warfarin (Coumadin)
Eclampsia	Heparin
Retained dead fetus	Lipid emulsion
Septic abortion	Clotting factor concentrate
Midtrimester abortion	**Other causes**
Malignancies	Liver disease
Infections	Pancreatic disease
Bacterial	Pulmonary disease
Fungal	Neurologic disease
Viral	Envenomation
Protozoal	Transfusions
Cardiovascular disease or injury	

associated with a high mortality rate depending on the nature and severity of the cause. The diagnosis is suspected clinically and confirmed by laboratory findings of elevated fibrin degradation products, prolonged prothrombin and partial thromboplastin times, decreased fibrin levels, and thrombocytopenia.

Treatment of DIC consists of maintaining the vital functions of the patient and treating the underlying disease process. Heparin is used if there is evidence of thrombosis (gangrene of the extremities or digits) [21]. Because DIC depletes coagulation factors, replacement with cryoprecipitate may be considered if there are no evidence of thrombosis and indications of coagulation factor depletion. Platelets are replaced for any patient with a count less than 20,000/mm^3 or any patient with a count less than 50,000/mm^3 with bleeding [22].

Neutropenia

Neutropenia exists when an absolute neutrophil count (ANC) is less than 1500/mm^3 (Table 10):

Table 10 Classifications of neutropenia

ANC	Level of neutropenia	Implication
1000–1500/mm^3	Mild	Increased risk of bacterial infections
500–1000/mm^3	Moderate	Increased risk for opportunistic bacterial infections
<500/mm^3	Severe	Life-threatening bacterial infections common

$$\text{ANC} = \text{WBC} \times (\%\text{Bands} + \%\text{Mature Neutrophils}) \times 0.01$$

This range holds true for both sexes and many ethnicities except in children <12 months of age when neutropenia is defined by an ANC <1000/mm^3. Those of African descent, Jewish Yemenites, and some Arab populations typically have a lower ANC than other nationalities, typically 1400/mm^3, but have very rarely ANC <1000/mm^3 [23, 24]. The diagnosis is confirmed by repeat CBC with manual differential and peripheral smear. Neutropenia can result from decreased production, increased destruction, and margination or shift of neutrophils from blood to tissue. When anemia, thrombocytopenia, and/or abnormal peripheral smear is found in addition to neutropenia, then a bone marrow aspiration could provide evidence of blood cell line disorder or bone marrow failure. Treatment of all causes of neutropenia often requires consultation with hematology. If the patient is febrile in addition to being neutropenic, broad-spectrum antibiotics should be started while awaiting consultation and culture speciation and antibiotic sensitivity. Granulocyte colony-stimulating factor (G-CSF) can be provided to stimulate production of neutrophils acutely to decrease length of neutropenic fever as well as chronically for treatment of neutropenia.

Acquired Neutropenia

Postinfectious Neutropenia

This is the most common cause of acquired neutropenia. Infectious precipitating state can be bacterial or viral. *Staphylococcus aureus* and

Escherichia coli are two common bacteria that can be associated with neutropenia. Common viruses include Epstein-Barr virus, hepatitis B, cytomegalovirus, and influenza which lead to mild or moderate neutropenia. Neutropenia is common among patients with acquired immunodeficiency syndrome (AIDS). When infection is widespread such as in sepsis, neutropenia can be more severe. ANC normalizes as the infection resolves and viremia decreases.

Drug-Induced Neutropenia

Table 11 lists agents associated with neutropenia. Drug-induced neutropenia is the second most common cause, with an incidence of 2.4–15.4 cases per million reported each year. The most common drugs to cause severe agranulocytosis are clozapine, antithyroid drugs (thioamides), sulfamethoxazole-trimethoprim, and sulfasalazine [25]. Treatment is immediate cessation of the medication and consultation with hematology if neutropenia does not improve after the offending drug is discontinued.

Congenital Neutropenia

There are numerous forms of congenital neutropenias, with recessive and autosomal dominant cases, but the most severe is Kostmann syndrome. Kostmann syndrome is diagnosed by persistent ANC $<200/mm^3$ with a history of recurrent infections often of the mouth and perirectal area shortly after birth, fever, organ abnormalities, and short stature. Mutations of the G-CSF receptor are commonly associated with this syndrome. Given the severe nature of the disease, patients are often treated with G-CSF life-long.

Autoimmune Neutropenia

Primary autoimmune neutropenia is the most common cause of neutropenia in children <2 years old [26]. This is often familial and

Table 11 Drugs that cause neutropenia

Nonsteroidal anti-inflammatory drugs	**Antimicrobials (cont)**
Ibuprofen	Capreomycin
Indomethacin	Carbenicillin
Meclofenamate	Cefaclor
Mefenamic acid	Cefadroxil

characterized by the patient's inability to increase WBC count when ill. The patient will still show clinical signs of illness such as tachycardia and fever. Children with this diagnosis will usually have resolution without intervention within 2–3 years, and all patients often recover by 5 years old.

Patients with secondary autoimmune neutropenia will often have positive antineutrophil antibodies (ANA). Common comorbid diagnoses include Crohn's disease, systemic lupus erythematosus, Felty syndrome, antiphospholipid antibody syndrome, and rheumatoid arthritis. Other primary causes of secondary autoimmune neutropenia include infection and malignancy. Those with lupus and Felty syndrome may improve with splenectomy or immunosuppressive therapy.

Alloimmune (Isoimmune Neutropenia)

Isoimmune neutropenia occurs in 3 % of live births and is caused by maternal antineutrophil antibodies to fetal neutrophil antigens. Associated clinical manifestations include neonatal fever; infection within the urinary tract, skin, and lungs; or signs of sepsis. Neutropenia is likely to resolve within 7–15 weeks. Treatment options range from glucocorticoids and/or IgG antibodies to exchange transfusion with maternal neutrophils that may be warranted.

Nutritional Neutropenia

Neutropenia can be caused by deficits of vitamin B_{12}, folate, and copper, all of which are common in patients who abuse alcohol. Neutropenia can resolve with adequate supplementation of vitamin deficits.

Intrinsic Defects Causing Neutropenia

Cyclic neutropenia is associated with periodic bouts of neutropenia and infection, followed by return to normal levels of neutrophils. As in other hereditary neutropenic disorders, the underlying etiology is a genetic mutation affecting neutrophil elastase (ELA2). Counts cycle on average every 21 days. Many are genetically inherited and present in infants and children but can be acquired in adulthood. Treatment is supportive to include antimicrobial mouthwash when neutropenia is mild to daily G-CSF if neutropenia is severe.

Other Hematologic Disorders

Hemochromatosis

Hereditary hemochromatosis (HH) is an autosomal recessive inherited disorder in patients of European origin with an increased prevalence in men. Age at diagnosis is typically 40–60 years old, relatively later in women compared to men due to blood loss associated with menstruation. It is estimated that 1–6 people per 100 in the United States will have elevated transferrin levels, 35–50 % of those will have persistent elevation, and less will have concurrent ferritin elevation and even fewer develop clinical symptoms [28]. Eighty to 90 % of those patients diagnosed with hereditary hemochromatosis are homozygous for the HFE gene C282Y, and 10 % of those will have end-organ damage associated with the disease [29]. Secondary

hemochromatosis is common among anemias that are associated with iron absorption and inefficient erythropoiesis, as well as a requirement of chronic transfusions. Patients are typically asymptomatic if caught early, but as iron overload progresses clinical manifestations include cardiomyopathy, dysrhythmias, cirrhosis of the liver, hepatocellular carcinoma, bronzing of the skin, diabetes, arthralgias, osteoporosis, and hypogonadism.

Non-fasting serum levels of ferritin and transferrin saturation (serum iron concentration divided by total iron-binding capacity in mcg/dL then multiplied × 100) can be used to screen for diagnosis. Per the 2011 guidelines from the American Association for the Study of Liver Diseases, the recommended cutoffs of >45 % transferrin saturation and serum ferritin >300 ng/mL in men and >200 ng/mL in women could indicate disease [30]. An elevated transferrin saturation has greater sensitivity than a plasma ferritin for detecting HH [31]. When transferrin saturation cutoff is increased from >45 % to >50 %, the specificity for recognizing someone homozygous for C282Y increases from 0.96 to 0.98 [32]. Definitive diagnosis is made following pathologic evaluation of a liver biopsy which is needed to stage fibrosis and diagnose nonclassical hereditary hemochromatosis [29].

Treatment of hereditary hemochromatosis entails regular phlebotomy to decrease serum ferritin levels to 50–150 ng/mL while maintaining an Hgb >12.5 g/dL [33]. If secondary hemochromatosis is present, then iron chelation is preferred to phlebotomy given typical levels of anemia already present in those with secondary hemochromatosis. Six percent of individuals with HH and cirrhosis will develop hepatocellular carcinoma; therefore patients should have screening liver ultrasonography every 6–12 months [34]. Intervals of scans are decreased even further if lesions are found on the liver. Screening for disease outside of symptoms or evidence of iron overload is only recommended for those with first-degree relatives with hereditary hemochromatosis [35]. Dietary modifications need not be made but oral iron supplementation and vitamin C should be avoided.

Polycythemia

Polycythemia vera is a chronic myeloproliferative disorder resulting in HCT >52 % in white men and HCT >47 % for women and African Americans [36]. Evidence of portal vein thrombosis and splenomegaly with or w/o thrombocytosis or leukocytosis should increase clinical suspicion of the diagnosis. Low serum erythropoietin (EPO) has a sensitivity of 70 % and a specificity of 90 % for polycythemia vera. The median age at diagnosis is 60 years old, and incidence of disease is 2.3/100,000 persons per year with a slightly higher incidence in men compared to women [36]. Classic clinical symptoms are pruritus after bathing, burning pain in distal extremities, weakness, and gastrointestinal symptoms. It is important to recognize and refer immediately as survival is greater than 10 years if treated with regular phlebotomy and myelosuppressive agents but is 6–18 months without treatment [36]. Mortality from disease is secondary to vascular thrombosis from increased number of RBCs. Goal of phlebotomy is to maintain an HCT <45 % in white males and <42 % in women and African Americans.

Secondary polycythemia can arise from underlying lung or heart disease, living at high altitude, or smoking. If concurrent hypoxia is associated with lung or heart disease, then RBC counts will decrease with supplemental oxygen. There is no way to prevent polycythemia vera, but one can prevent secondary polycythemia by preventing heart and lung disease by things such as tobacco cessation.

Sickle-Cell Disease

Sickle-cell anemia is an autosomal recessive inherited disease caused by a single defect in the beta chain of hemoglobin (Hb A) resulting in sickle hemoglobin molecule (Hb S) that becomes dysfunctional when deoxygenated. Patients who are homozygous for the sickle-cell gene have sickle-cell anemia (Hb SS), and those who are heterozygous have sickle-cell trait (Hb S trait). Sickle-cell disease includes multiple common genotypes (Hb SS, Hb S beta$^{0 \text{ and } +}$ thalassemia,

and Hb SC) and resulting phenotypes. Sickle-cell disease affects 70,000–100,000 people in the United States of predominantly African and Hispanic descent [37]. On average 2000 infants are born with the disease each year [37].

Morbidity and mortality stem from chronic hemolysis, tissue infarction, and painful episodes. Vaso-occlusion episodes not only involve the sickled RBC but also leukocytes, activated vascular endothelium, altered nitric oxide metabolism, hypercoagulability, and ischemia-reperfusion injury [38]. Individuals with Hb SS have marked clinical manifestations with associated morbidity and mortality, while those with Hb S trait are relatively asymptomatic. The other common genotypes of sickle-cell disease detailed above are associated with mild to moderate clinical symptoms.

Mortality from sickle-cell disease fell by 42 % in African American children under 4 years old following addition of pneumococcal vaccination in 2000 [39]. Survival rates have increased from 14 years old to nearly 50 years old within one generation secondary to vaccines and prophylactic antibiotics [40]. Patients are at increased risk for infection from encapsulated organisms secondary to splenic dysfunction. All infants with Hb SS and Hb SB^0 thalassemia should receive daily penicillin starting at 2 months of age. It is more controversial to give daily penicillin for prophylaxis in infants with Hb SC and Hb SB^+ [41]. Erythromycin is the preferred alternative antibiotic, and if there is no history of invasive pneumococcal disease or splenectomy, then prophylaxis can be stopped at 5 years old. Concern for infection requires initiation of broad-spectrum antibiotics and then tailored to organism as appropriate. As detailed below transfusions to maintain Hgb >10 g/dL improve morbidity perioperatively in all but lowest risk surgeries, as do chronic transfusions reduce the incidence of primary stroke by 1.6 % of abnormal transcranial blood flow velocity (TBV) on transcranial Doppler ultrasonography [40]. Other reasons for acute transfusion include: splenic or hepatic sequestration, stroke, multiorgan failure, and worsening acute chest syndrome, while additional reasons for chronic transfusions include prevention of stroke recurrence, chronic heart failure, pulmonary hypertension, or recurrent splenic sequestration. Side effects of recurrent transfusions include iron overload, which can comparably be managed with oral deferasirox as with IV deferoxamine [37].

Acute manifestations of the disease include painful crises, acute chest syndrome (ACS), and multiple organ failure syndrome. Painful crises are managed with opiates to control pain but not over sedate (ketorolac is an ineffective adjunct to narcotics) [37] and meperidine should be avoided [40], oxygen if hypoxic, frequent incentive spirometry and fluid overload avoidance to prevent progression to acute chest syndrome. Patients with acute chest syndrome present with dyspnea, cough, chest pain, fever, and a new infiltrate on chest radiography. Treatment with dexamethasone may limit severity of ACS in children but has been correlated with rehospitalization within 72 h of discharge for severe pain [44]. When conservative management fails to improve hypoxemia or signs of respiratory failure occur, then transfusion of pRBCs is warranted. Fever, worsening anemia, decreased platelets, rhabdomyolysis, and mental status changes are all associated with the onset of multiorgan failure. Rapid referral to a specialist is warranted as exchange transfusion could be lifesaving [46] (Table 12).

As with management of all chronic diseases, physicians should expect both the patient and family to go through significant adjustments to the diagnosis and management of the disease. Many aspects of this adjustment correspond to those typically seen in a grief-loss process. Physicians and families must encourage the patient to be as active and involved as possible, promoting independence and confidence in his or her abilities as well as decreasing withdrawal, regression, and the potential for depression. Independence also minimizes the tendency for anger and resentment to build up if the patient-family relationship becomes overly dependent. Problems can arise when family members try to protect the patient and consistently put the needs of the patient first becoming attentive to their every need. The decision to take on these functions is often made without an overt discussion within the family.

Table 12 Treatment for patients with sickle-cell disease

General treatment
Caloric supplements
Folic acid (5 mg/day) – remains controversial
Prophylactic penicillin, daily starting at 2 months old until 5 years old unless there is h/o invasive pneumococcal disease or splenectomy
Pneumococcal vaccine (7-valent conjugate vaccine prior to 2 years old, 23-valent polysaccharide vaccine when >2 years old, redose in q3–5 years revaccination when <10 years old or in 5 years if initial dose >10 years old)
Haemophilus influenzae B vaccine, annual influenza, and quadrivalent meningococcal after 2 years old
Hepatitis B vaccine
Transfusions to maintain hemoglobin between 10 and 12 g/dL, especially prior to surgery
Chelation therapy as needed for iron overload
Antidepressants for chronic pain
Psychological support
Acute crisis treatment
Hydration (IV hypotonic fluids for maintenance after volume resuscitation achieved)
Oxygen if hypoxic, incentive spirometry, or positive expiratory pressure device for all during waking hours
Antibiotics if fever or infection is present
Analgesia: consider patient-controlled analgesia with narcotics (narcotics preferred over NSAIDS)
Crisis prevention
Hydroxyurea – adults, adolescents, and emerging research in kids with 3+ moderate to severe vaso-occlusive episodes per year (use decreases painful crises, acute chest episodes, and frequency of transfusions)
Transcranial Doppler ultrasonography – screening at 2 years old to identify those with abnormal transcranial blood flow velocity (TBV). If TBV is elevated child has increased risk from stroke, and prophylactic transfusions can prevent primary stroke
Allogeneic hematopoietic cell transplantation – indicated in young patients with multiple sickle-cell disease-related complications; studies have shown that it can be curative

Power struggles can ensue and can manifest in various behavioral-emotional symptoms (i.e., school problems, family dysfunction, caregiver burnout). Pain associated with a chronic, relapsing condition like sickle cell can be one of the most troubling symptoms patients and their families confront and the most difficult for physicians to manage [46–48]. This is because chronic pain is a subjective experience involving the interactions among physiologic, psychological, and sociocultural factors. Chronic pain can have its origins not only in the organic disease but also in the patient's psychological distress (i.e., anxiety, depression, substance abuse), caregiver burnout, and/or secondary gain (i.e., malingering). The diagnostic question that emerges is: How much of this pain is real and how much is psychological? The physician can sort out the issues and answer this question by taking a careful history, paying attention to the patient's affect and caregivers' verbal and nonverbal signals, assessing the patient for psychosocial problems, and maintaining continuity of care.

It is critical that all family members be given adequate and clear information regarding the nature of the disease. Major decisions about caregiving, symptom management, and range of activities should be negotiated, with physician assistance if necessary. Ultimately, families are helped by the physician assisting them to live with and not be consumed or defined by the chronic condition.

Hematologic Malignancies

Multiple Myeloma

Multiple myeloma (MM) is the most common bone malignancy characterized by expansion of plasma cell mass and overproduction of M proteins (IgG, IgM, or IgA or rarely IgE or IgD). The number of new cases diagnosed is 6.1 per 100,000 men and women per year [49]. Median age at diagnosis is 70 years old, and incidence increases with age. The diagnosis is more common among males than females and African Americans more than Caucasians. Clinical symptoms include bone pain, malaise, anemia, recurrent infections, renal insufficiency, and hypercalcemia. Initial workup when diagnosis is suspected includes CBC, CMP, ESR, and serum and urine protein electrophoresis in addition to X-rays of the chest, long bones, pelvis, and skull.

The diagnosis of symptomatic MM is made by presence of characteristic serum and urine M proteins by electrophoresis or immunofixation and

bone marrow clonal plasma cells in addition to end-organ impairment (hypercalcemia, renal insufficiency, anemia, and bone lesions). MRIs are used to assess for spinal cord compression or soft tissue plasmacytomas. A premalignant disorder known as monoclonal gammopathy of undetermined significance (MGUS) also leads to increased monoclonal paraproteins, but unlike those associated with multiple myeloma, they do not cause end-organ damage and do not require treatment. Symptomatic MM is treated with systemic chemotherapy and if they are young and well enough autologous stem cell transplantation. All of those with symptomatic MM should be prescribed a bisphosphonate (IV preferred), level of evidence A, to decrease vertebral fractures and pain [50]. Bone pain is best managed with opiates. Percutaneous vertebroplasty and kyphoplasty improve symptoms associated with comorbid vertebral compression fractures. Relapse is common, and according to the American Cancer Society, median survival is anywhere from 29 to 62 months depending on stage at diagnosis [51].

Myelodysplastic Syndromes

Myelodysplastic syndromes (MDS) are disorders associated with the neoplastic development of stem cells resulting in abnormalities of hematopoiesis. Individual or various cell lines can be affected resulting in symptomatic anemia (most common), increased bleeding secondary to thrombocytopenia, or increased risk of infection secondary to neutropenia. Some patients with MDS will progress to have acute myelogenous leukemia. Many cases are associated with treatment from a previous malignancy, but many arise without etiology. The incidence rate during 2001–2004 within the United States was roughly reported to be 3.3 per 100,000, but the diagnosis is often underreported [52]. Prevalence is higher among males than females and increases with age. Patients are more likely to be found in those of Caucasian or Hispanic origin. The age-adjusted 3-year survival rate for MDS is approximately 60 % [53].

Peripheral blood smears will often demonstrate dysplasia, and % of blasts to determine involvement and specific histologic features of the cells can be determined from a bone marrow biopsy. MDS is commonly diagnosed based upon unexplained cytopenia (Hgb <10 g/dL, absolute neutrophil count $<1.8 \times 10^9$/L, or platelets $<100 \times 10^9$/L), morphologic dysplasia, and blast cells accounting for less than 20 % of total cells on the bone marrow aspirate and peripheral blood smear. Aside from allogeneic hematopoietic cell transplantation, there is no cure for MDS. Systemic chemotherapy, erythropoietin, hematopoietic growth factors, and immunosuppressive therapy are common agents utilized for management of disease. Asymptomatic patients do not necessarily need treatment, and immediate treatment/referral to a hematologist is warranted for symptomatic anemia and/or thrombocytopenia or recurrent infections secondary to neutropenia.

Leukemias

Leukemias are the result of massive proliferation of hematopoietic stem cells. They are categorized as acute or chronic and lymphoblastic or myelogenous. The age-adjusted incidence rate of leukemia within the United States in 2011 (for all races and both sexes) was 13.66 per 100,000 persons [54]. Roughly 1 in 70 persons will develop leukemia in their lifetime [55]. The prevalence of the disease increases with age, and more white males will be diagnosed than females or other ethnicities. Of the four classifications (listed in Table 13), ALL is the most common childhood cancer, and 80 % of leukemias among adults are AML. Predisposing risk factors for the disease include many genetic abnormalities (Down syndrome, neurofibromatosis), immunodeficiency disorders, exposure to ionizing radiation, industrial chemical exposure (i.e., benzene), and previous leukemia or radiation therapy.

Common presenting signs of leukemia are fever of unknown origin, anorexia, pallor, lethargy, and abnormal bleeding or bruising. One-third of all children will present with long-bone or spine pain that wakes them up, and 75 %

Table 13 Leukemias [55]

Disease	Incidence	Treatment	5-year survival rate
Acute			
Acute myeloid leukemia (AML)	Common in elderly; 80 % of acute leukemia in adults	Systemic chemotherapy Bone marrow transplantation (selected patients)	<50 years old = 55 % >50 years old = 14 %
Acute lymphocytic leukemia (ALL)	Common cancer in children, 53 % of new cases <20 years old	Systemic chemotherapy Bone marrow transplantation (selected patients)	<50 years old = 75 % >50 years old = 25 %
Chronic			
Chronic myeloid leukemia (CML)	More common in middle age	Systemic chemotherapy Bone marrow transplantation (selected patients) Splenic irradiation (selected patients)	<50 years old = 84 % >50 years old = 48 %
Chronic lymphocytic leukemia (CLL)	More common in the elderly (>65 years old)	Systemic chemotherapy Radiation therapy (selected patients)	<50 years old = 94 % >50 years old = 83 %

of children with leukemia will have hepato- or splenomegaly. Priapism is a red flag for childhood leukemia [56]. Adults will have the common presenting signs detailed above in addition to weight loss and anemia-related symptoms such as dyspnea or chest pain. If diagnosis is suspected, a CBC is drawn first; a complete metabolic panel and coagulation panel are helpful for any concurrent abnormalities and will give the hematologist/oncologist baseline liver functions. In current level evidence rating of C, all patients with a WBC >20,000 per uL and associated anemia, thrombocytopenia, thrombocytosis, or hepato- or splenomegaly or constitutional symptoms need to have a peripheral smear ordered [55]. Any positive lab findings in light of symptoms require prompt referral to a hematology/oncology specialist.

ALL and AML treatment may include chemotherapy, radiation, monoclonal antibodies, or hematopoietic stem cell transplant. CLL may be just monitored if there are no anemia or thrombocytopenia and less than three areas of nodal involvement, and CML progression can be slowed with tyrosine kinase inhibitors, but definitive treatment is with hematopoietic stem cell transplant [55]. When cranial irradiation is used to treat ALL, growth hormone deficiency and metabolic syndrome are common resulting disorders [57]. As more and more children with leukemia are surviving, it has become important for the family physician to be able to care for these cancer survivors. In addition to any age-appropriate USPSTF cancer screening guidelines, a leukemia survivor should have 1–2 months CBCs for the first 3 years, then every 3–6 months for up to 5 years, and then annually [55]. The most common form of cancer after diagnosis of leukemia is another form of leukemia or lymphoma. From a cohort of 17,000 childhood cancer survivors in North America treated between 1970 and 1986 as part of the Childhood Cancer Survivor Study, the 30-year cumulative occurrence of cancer after leukemia was 5.6 % [58]. Since high-dose steroids are often used with chemotherapeutic regimens, monitoring for osteonecrosis of joints and osteoporosis must be undertaken. All patients having had a hematopoietic stem cell transplant must have an initial bone scan 1 year after transplantation and then serially repeated based on clinical picture. Knowing the chemo agent used is helpful, especially if an anthracycline (such as

doxorubicin) was used as 5–10 % will develop congestive heart failure 20–30 years after treatment [57]. Follow-up care for both acute leukemias includes an echocardiogram every 2–3 years; however, echocardiograms are not routinely monitored for those who had or who have chronic leukemia.

Presenting complaints of eye disorders need to be quickly divided into complaints that are serious and require an emergent or urgent examination and treatment. Urgent symptoms include recent visual loss, double vision, pain, floaters, flashes, and photophobia. Less serious symptoms, which can be evaluated less urgently, include vague ocular discomfort, tearing, mucous discharge, burning, or eyelid symptoms.

The basic eye examination includes testing for visual acuity with the Snellen chart or starting at 3 years old a picture chart or matching chart [3]. Along with visual acuity, confrontation visual fields, ocular motility testing, ophthalmoscopy, corneal staining, pupillary examination, and pressure measurement are essential elements of a complete urgent exam [1].

Pupil

The pupil regulates the amount of light that enters the eye. Normal pupils are round, regular in shape, and nearly equal in size. The pupillary examination is designed primarily to detect neurologic abnormalities that disturb the size of the pupils. Pupillary reflexes include the direct light reflex and the indirect, or consensual, reflex, a response to light falling on the opposite eye. The measurement of pupil size in dim light assesses the motor (efferent) limb of the pupillary reflex arc; the evaluation of pupil response to direct light assesses both the motor and the sensory (afferent) limbs; the swinging light test (testing for the consensual reflex) assesses only the sensory limbs.

Constriction of the pupil to less than 2 mm is called miosis if it does not dilate in the dark. Topical cholinergic-stimulating drops and systemic narcotics are the most frequent causes.

Dilatation of the pupil to more than 6 mm is called mydriasis, with failure to constrict to light stimulation. Topical atropine-like drops, trauma, and oculomotor nerve abnormalities are the most common causes.

Anatomic variation in the diameter of the iris is less than 1 mm. It is best to determine this parameter in the dimmest light possible, measuring with the pupil gauge found on the near vision card. True inequality of pupil size (anisocoria) is caused by drugs, injury, inflammation, angle-closure glaucoma, ischemia, paralysis of the sphincter pupillae muscle (dilated) and dilator pupillae muscles (constricted), Horner syndrome, neuronal lesions (Argyll Robertson pupil), or, most commonly, physiologic variations [2].

Eyelids

The eyelids protect the cornea, aid in the distribution and the elimination of tears, and limit light entering the eye. Abnormalities can occur in the skin, mucous membranes, glands, and muscles [2].

Congenital Abnormalities

The most common congenital variation is an epicanthus, which is a vertical skinfold in the medial canthal region. This may simulate an esotropia (pseudostrabismus) [3].

Positional Abnormalities

Entropion

Entropion is inversion of the lid margin. Etiologies are age related (involutional), cicatricial, spastic, and congenital. Involutional entropion of aging is common, causing misdirected eyelashes (trichiasis) that irritate the eye. Secondary conditions include conjunctivitis, corneal ulcers, keratitis, tearing, and blepharitis. Treatment includes eyelid hygiene, lubricating agents, and topical antibiotics when inflammation is present. Taping or patching can be palliative or temporary while awaiting definitive surgical procedures for symptomatic patients [4].

Ectropion

Eversion of the lid margin, or ectropion, can be age related, cicatricial, spastic, and allergic. Severe cases may follow Bell's palsy (see chapter "▶ Care of the Patient who Misuses Drugs"). Ocular manifestations include chronic

conjunctivitis, keratitis, epiphora, and keratinization of the lid. Treatment options are similar to those for entropion [5].

Blepharoptosis

The etiology of blepharoptosis lies either in the innervation or the structure of the levator palpebrae superioris muscle, leading to a drooping upper eyelid and a narrow palpebral fissure. The congenital type can be unilateral or bilateral. Acquired forms include dehiscence of the levator aponeurosis, neuropathy, intracranial disorders, Horner syndrome, myotonic dystrophy, and myasthenia gravis. Surgical therapy is the only successful management strategy [6].

Inflammation

Blepharitis

Blepharitis is an inflammatory condition of the lid margin oil glands. It may be infectious, usually due to *Staphylococcus aureus*, involving the eyelash roots, glands, or both. It has been described as "acne" of the eyelids. Individuals who have acne rosacea or seborrheic dermatitis of the scalp and face are particularly vulnerable (see chapter "► Selected Disorders of the Female Reproductive System"). Symptoms include swelling, redness, debris of the lid and lashes, itching, tearing, foreign body sensation, and crusting around the eyes on awakening. Management of blepharitis is primarily lid hygiene using warm compresses with baby shampoo or an eyelid cleansing agent applied with a finger, washcloth, or cotton-tipped applicators. Nightly application of bacitracin or erythromycin ointment to the lid margins is helpful when there are signs of secondary infection. For severe or recurrent cases, systemic therapy with tetracycline or doxycycline can be used for several months [7].

Hordeolum

Also known as a stye, an external hordeolum is an inflammation of the ciliary follicles or accessory glands of the anterior lid margin. It is a painful, tender, red mass near the lid margin, often with pustule formation and mild conjunctivitis. An internal hordeolum, which presents in a similar manner, involves an infection of the meibomian gland away from the lid margins. Treatment is usually simple for this self-limited condition: intermittent hot, moist compresses plus topical ophthalmic antibiotics such as tobramycin, bacitracin, erythromycin, gentamicin, or sulfacetamide to prevent infection of the surrounding lash follicles. One method to hasten drainage of the external hordeolum is to epilate (remove a hair and its root) the lash, which effectively creates a drainage channel. Occasionally an incision or puncture for drainage and administration of systemic antistaphylococcal antibiotics are necessary [8].

Chalazion

A chalazion (lipogranuloma) is a chronic granuloma that may follow and be secondary to inflammation of a meibomian gland. During its chronic phase, it is a firm, painless nodule up to 8 mm in diameter that lies within the tarsus and over which the skin lid moves freely. It usually begins as an internal hordeolum. Asymptomatic chalazia usually resolve spontaneously within a month. Treatment options for persistent chalazia include an intralesional long-acting corticosteroid injection, which may cause hypopigmentation, or a surgical incision and curettage with a clamp [8].

Dermatitis

Dermatitis may be either infectious or of contact etiology. Contact dermatitis is common because of exposure to sensitizing irritants such as neomycin, atropine, cosmetics, lotions, soaps, nickel, thimerosal (often in artificial tears), chloramphenicol, poison ivy, and others. Manifestations include erythema, vesiculation, scaling, edema, and itching. Therapy, most importantly, is removal of the offending agent (see chapter "► Selected Disorders of the Female Reproductive System"). During the acute stages, cool compresses, antihistamines, and topical corticosteroids provide relief. Occasionally, systemic steroids are necessary such as for severe poison ivy dermatitis. The most common infectious etiologies are impetigo, erysipelas, and herpes zoster, with treatment the same as indicated for other locations [8].

Conjunctiva

Subconjunctival Hemorrhage

Subconjunctival hemorrhage not caused by direct ocular trauma is usually the result of a sudden increase in intrathoracic pressure, as when sneezing, coughing, or straining to evacuate. Rupture of a conjunctival blood vessel causes a bright red, sharply delineated area surrounded by normal-appearing conjunctiva (Fig. 1). The blood is located underneath the bulbar conjunctiva and gradually fades in 2 weeks. Usually no cause is found, but it is seen with hypertension, with anticoagulation, and in neonates or their mothers as a result of labor and delivery. No treatment is indicated [9].

Pingueculum and Pterygium

A pingueculum is an area of nasal or temporal bulbar conjunctiva that contains epithelial hyperplasia, a harmless yellow-white, plaque-like thickening.

A pterygium is a triangular elevated mass consisting of vascular growth of the conjunctiva, usually nasal, that migrates onto the corneal surface. Environmental factors such as prolonged sunlight exposure and exposure to heat, wind, and dust contribute to its formation. It may be unsightly and uncomfortable, and it may interfere with vision.

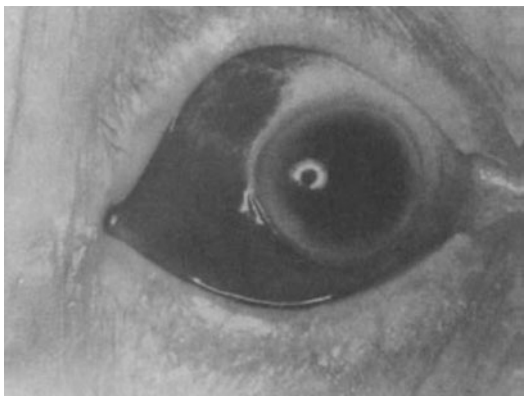

Fig. 1 Subconjunctival hemorrhage

Occasionally inflammatory discomfort of either a pingueculum or pterygium may require a mild topical steroid or nonsteroidal anti-inflammatory drop [2].

Surgical removal may be necessary if vision is impaired or for excessive irritation.

Recurrence may occur, but using a conjunctival autograft or amniotic membrane graft may decrease the recurrence [2, 10].

Lacrimal System

Epiphora

Epiphora is a condition in which tearing occurs because of either hypersecretion or impaired drainage of tears through the lacrimal passages. Causes include muscle weakness, allergy, ectropion, occlusive scarring, glaucoma, dacryocystitis, canaliculitis, and inflammation [2]. In infancy, it is usually due to congenital nasolacrimal duct obstruction, which has a high rate of spontaneous resolution during the first year. Nasolacrimal duct massage may help [3].

Dry Eye

The tear film is a complex, delicately balanced fluid composed of contributions from a series of glands. Alacrima, decreased or absent tears, occurs with keratoconjunctivitis sicca, associated with the autoimmune systemic complex of Sjogren syndrome, most frequently from rheumatoid arthritis or thyroid diseases (see chapters "▶ Benign Breast Conditions and Disease" and "▶ Selected Disorders of the Musculoskeletal System"). Other causes of dry eye can be blepharospasm, blepharitis, allergies, systemic medications, and toxins [10]. Tear film deficiency also causes nonspecific symptoms of burning, foreign body sensation, photophobia, itching, and a "gritty" sensation. Physical findings include hyperemia, loss of the usual glossy appearance of the cornea, and a convex tear meniscus less than 0.3 mm in height. The Schirmer and rose bengal test results do not have a significant

association with symptoms [11]. Treatment is difficult and lifelong with artificial tears containing methylcellulose, polyvinyl alcohol, or 2 % sodium hyaluronate four times a day to hourly. Punctal occlusion with a silicone plug or permanent punctal closure via thermal cautery can produce dramatic symptomatic improvement. Severe cases occasionally require mucolytic agents or autologous serum tears [7, 12].

Dacryocystitis

Dacryocystitis is a painful inflammation of the lacrimal sac resulting from congenital or acquired obstruction of the nasolacrimal duct. Even though congenital nasolacrimal duct obstruction occurs commonly in infants, dacryocystitis is rare and is commonly associated with nasolacrimal duct cysts. In adults it is idiopathic or the result of an obstruction from infection, a facial trauma, or a dacryolith, rarely neoplasm. The medial lower lid location has a domed mass that is tender and painful, with discharge and tearing. Treatment includes hot packs with topical and systemic antibiotics for penicillinase-producing staphylococcal organisms [8].

Dacryoadenitis

Dacryoadenitis, an enlargement of the lacrimal gland, may be granulomatous, lymphoid, or infectious in origin. If acute, this lesion is painful, tender, suppurative, and inflamed; if chronic, it may manifest simply as a swollen, hard mass. Treatment of dacryoadenitis is determined by its etiology and ranges from supportive heat therapy and massage to incision and drainage, followed by the use of systemic antibiotics and, if not responsive, by steroids [8].

Orbit

Preseptal (periorbital) and postseptal (orbital) cellulitis are bacterial infections of the periocular tissue that are serious and potentially vision threatening and lethal. Preseptal cellulitis involves only the lid structures and periorbital tissues anterior to the orbital septum. Postseptal cellulitis involves tissue behind the septum, which children and adolescents have more commonly than adults. Routes of infection include trauma, bacteremia, upper respiratory infection, and sinusitis. Cellulitis should be considered in every patient with swelling of the eye (see chapter "▶ Epstein-Barr Virus Infection and Infectious Mononucleosis"). Critical signs include pain, fever, erythema, tenderness, swelling, and conjunctival injection. With postseptal infection, impaired ocular motility, afferent pupillary defect, proptosis, and visual loss also occur. Cavernous sinus thrombosis may develop. Leukocytosis is usually present, and a peripheral white blood cell count of more than 15,000/mm^3 suggests bacteremia. Computed tomography (CT) of the orbit is indicated to identify the extent of infection [8].

A bacterial pathogen is identified as the cause of periorbital cellulitis in only 30 % of cases. Treatment must cover gram-positive and gram-negative anaerobes and potential methicillin-resistant *Staphylococcus aureus*. Antimicrobial therapy should be intravenous and guidelines suggest amoxicillin/clavulanic or ceftriaxone with metronidazole as empiric treatment. Emergency consultation with hospitalization should be obtained from both an ophthalmologist and an otolaryngologist [8, 13].

Retina

Disorders of the retina often present with complaints of decreased vision. Assessing visual acuity, examining the eye, and looking for underlying medical problems are important to direct appropriate referral and care.

Arterial Occlusive Retinal Disease

Central artery occlusion (CRAO) is a severe sudden loss of vision due to an embolic or thrombotic occlusion, or obstruction, of the central retinal artery. It is usually painless and is usually

monocular. Occasionally it is preceded by symptoms of amaurosis fugax, lasting 5–20 min. A cherry-red spot is often seen in the central macula. Treatment consists of immediate decompression of the eye by pharmacologic or anterior chamber paracentesis. It is important to evaluate for giant cell arteritis as this can cause a CRAO [14].

Branch retinal artery occlusion (BRAO) is a painless, less severe, more peripheral embolic phenomenon in the retinal arterial circulation, where an immediate blank or dark area is noted in the patient's visual field. It is almost always monocular. Treatment is based on finding the systemic source of the problem. Common causes include carotid plaques and cardiac valvular disease [14].

Venous Occlusive Retinal Disease

Central and branch retinal vein occlusions (CRVOs, BRVOs) must be suspected with unilateral loss of vision. A CRVO presents as a sudden loss of vision secondary to compression of the venous return by a retinal artery, causing thrombosis at that location. If an occlusion occurs at the optic nerve head, it is a CRVO; if it is seen more peripherally, it is a BRVO. The CRVO is diagnosed by the presence of flame-shaped and blot hemorrhages throughout the entire retinal field, often obscuring the view of the underlying retina (Fig. 2) [14].

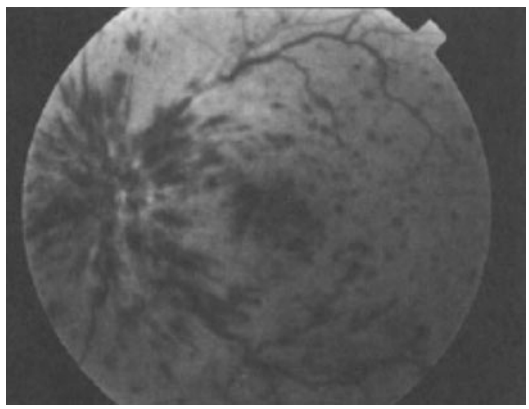

Fig. 2 Central retinal vein occlusion

A BRVO causes less severe visual loss, often not noticed by the patient. It leads to stasis of the venous flow more peripherally, which if it involves the macula causes central loss of vision. Here again, a flame-shaped hemorrhage is present upon examination [14]. Treatment involves intravitreal injections of anti-vascular endothelial growth factor (VEGF) therapies or laser [15].

Retinal Detachment

The annual incidence of retinal detachment is 12.9:100,000. People with high myopia and lattice degeneration of the retina have about a 1 % chance of a retinal detachment. Retinal detachment can occur in about 10 % of patients with vitreous detachment which commonly occurs between the ages of 60 and 80 years. A frequent symptom of retinal detachment is a gray curtain or cloud covering a portion of the visual field. These symptoms may be preceded by a quick flash of light and a new onset of many small black floaters. On physical examination with a dilated pupil, one sees a corrugated bulbous elevation of the retina. If a detachment can be surgically repaired immediately, prior to a macular detachment, the resulting visual acuity is much better [16].

Diabetic Retinopathy

Early detection of diabetic retinopathy is important. Diabetics should have regular ophthalmologic examinations (see chapter "▶ Rheumatoid Arthritis and Related Disorders").

Nonproliferative Diabetic Retinopathy

Nonproliferative diabetic retinopathy is graded as mild, moderate, or severe. With the more severe retinopathy, cotton wool spots are present, and dot and blot hemorrhages and lipid accumulation are seen throughout the retina (Fig. 3). If there is thickening of the retina in the central macular zone, diabetic macular edema is present and can cause profound visual loss. Laser and intravitreal

injections are used to stabilize and improve visual function [14, 17, 18].

Proliferative Diabetic Retinopathy

Proliferative diabetic retinopathy is diagnosed when neovascularization is detected at the optic nerve or elsewhere in the retina. It poses a risk of retinal and vitreous hemorrhage, tractional retinal detachment, fibroglial proliferation, and retinal fibrosis. With a dilated pupil, a lacy network of fine vessels is seen, indicating retinal ischemia (Figs. 4 and 5). Panretinal photocoagulation (PRP) eliminates the mid-peripheral retina. PRP may cause some night and central vision loss but prevents progressive severe visual loss [14, 18, 19].

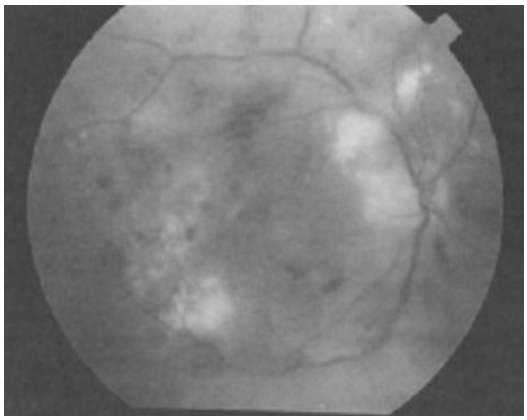

Fig. 3 Nonproliferative diabetic retinopathy

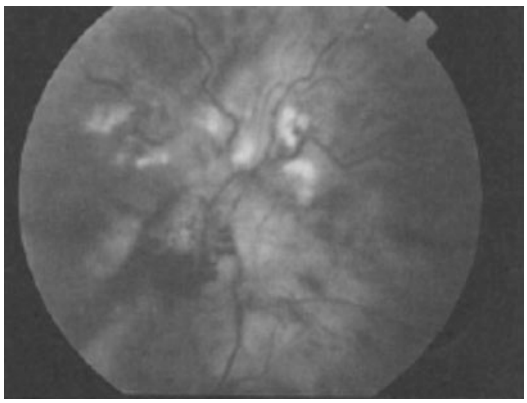

Fig. 4 Proliferative diabetic retinopathy

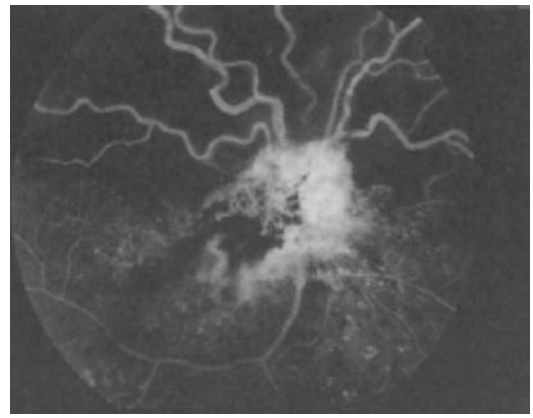

Fig. 5 Angiogram of proliferative diabetic retinopathy

Amaurosis Fugax

Amaurosis fugax is the sudden, painless, monocular loss of vision, described as a curtain or a shade being pulled down or up, blanketing the field of vision. It totally resolves in 5–30 min. A cholesterol plaque in the carotid artery, or rarely, a calcific cardiac valvular condition, is the etiology. Treatment is directed toward anticoagulation or antiplatelet therapy. Based on the patient's risk threshold, surgical intervention, such as carotid endarterectomy, is undertaken [1].

Ocular Migraine

Ocular migraine is a common condition in individuals over age 40. It presents often as a migraine aura, a fortification scotoma of jagged, multicolored lights that expand in a gradual fashion across the entire field of vision, leaving in its wake a darker or blank scotoma (see chapter "► Care of the Patient with a Sleep Disorder"). Often associated with the migraine symptoms is a queasy feeling. If the episode lasts longer than 1 h, the diagnosis is in question. The eye examination at the time is entirely normal. Treatment is directed to the underlying migraine. Neuroimaging may also be considered if the symptoms are not classic or the duration exceeds 1 h [1, 14].

Macular Degeneration

Macular degeneration is an aging phenomenon of the inner retina that results in visual loss due to deterioration of the retinal photoreceptors. There are two types of macular degeneration: dry and wet.

Dry Age-Related Macular Degeneration

Dry age-related macular degeneration presents with slow visual loss in the central field of vision. Often the first signs are reduced reading vision and later scotoma in the central field of vision as the severity increases. There is a loss of photoreceptor function in the central macular zone (Fig. 6) [14].

Neovascular Age-Related Macular Degeneration

Neovascular age-related macular degeneration presents with sudden visual loss and hemorrhage in the central macular zone. The underlying retina develops a defect, allowing the choroidal vessels to grow through the retinal pigment epithelium (Fig. 7). The patient presents with a dark or distorted spot in the central field of vision. As the hemorrhage progresses, the vision deteriorates further. Any sudden change in vision of a patient with macular degeneration should result in immediate referral to an ophthalmologist, as neovascular age-related macular degeneration can be treated by intravitreal injection of anti-vascular endothelial growth factors or in some instances laser therapy [14, 20].

Optic Nerve

Optic Disc Edema

Optic nerve disc edema is a common end point for several ocular disorders that result in swelling of the optic nerve head and hemorrhage in the surrounding peripapillary retina. Blood vessel margins are often blurred as they cross over the optic nerve, and splinter hemorrhages are present, distinguishing this disorder from pseudopapilledema (Fig. 8). The ocular causes of disc edema include the following: optic neuritis, anterior ischemic optic neuropathy (arteritic and nonarteritic), ischemic papillitis as in diabetes, and increased intracranial pressure. When optic disc head edema is secondary to increased intracranial pressure, it is termed papilledema. Papilledema occurs in both eyes but may be asymmetric [21, 22].

Pseudopapilledema

Pseudopapilledema is a benign, anomalous appearance of the optic nerve head due to optic disc drusen, often seen during a normal eye

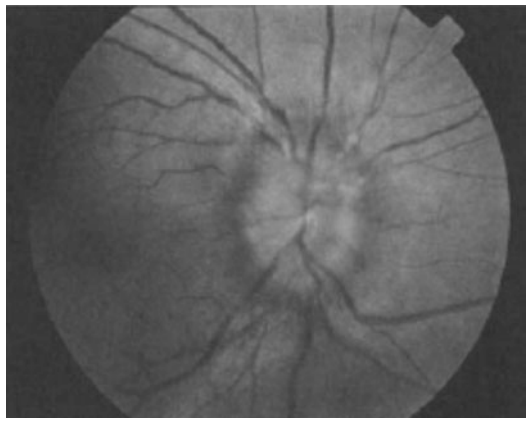

Fig. 8 Optic nerve head edema (papilledema)

examination. The optic nerve head has an elevated, lumpy appearance. No nerve fiber layer edema or splinter retinal hemorrhages are seen, as would be seen with disc edema [22].

Lens

Cataracts, or a clouding of the lens of the eye, are increasingly common among our aged population in the United States. The cataract can be graded in three of the most common varieties, based on the location of the lenticular opacity.

A nuclear sclerotic cataract is hardening of the central nucleus of the lens and leads to gradual yellowing of the nucleus. With further progression, it may turn brown. Frequently this type of cataract is not appreciated at an early stage because of the gradual progression and bilateral aspect of presentation.

Cortical cataract is whitening of the peripheral lens cortex. As the opacity progresses more centrally, more visual deprivation results. Frequently people complain of glare from lights with this type of cataract. Occasionally, double vision is noted, as cortical opacity splits light into different focal points.

Posterior subcapsular cataracts are the most visually disabling and the progression can be rapid. Near vision is more impaired than distance vision. The disorder is often seen in patients on chronic steroids (topical or systemic) or diabetes.

The diagnosis can be easily made by dilating the pupil and using the red reflex test. Examination indicators are a hazing over with a nuclear sclerotic cataract, a spoke-like defect with a cortical cataract, and a central dark opacity with a posterior subcapsular cataract. Treatment normally is surgical, but if the patient is not a surgical candidate, chronic dilation of the pupil improves the vision in some patients. Visual recovery from surgery is frequently rapid [23].

Glaucomas

Primary Open-Angle Glaucoma

Primary open-angle glaucoma (POAG) is a relatively common disorder whose incidence increases with advancing age. There is an obstruction of aqueous outflow at the level of the trabecular meshwork. Predisposing factors include a family history of glaucoma, severe blunt trauma to the eye, and possibly high myopia. In 2004, the prevalence of POAG for adults 40 and older in the United States was estimated to be about 2 % [24].

Glaucoma can occur without elevated intraocular pressure. Computer-based visual field testing can be used to screen for glaucoma, but the US Preventive Services Task Force does not recommend for or is not against screening. Physical exam findings of glaucoma show damage to the optic nerve. Elevated intraocular pressure does tend to raise the risk threshold of developing glaucoma. The diagnosis is based on a triad of findings: increased intraocular pressure, optic nerve head cupping, and visual field defect. A cup/disc ratio of more than 0.60 is often a diagnostic clue, as is asymmetry between the two eyes. When a family history of glaucoma is present, or an enlarged cup-to-disc is seen, referral to an ophthalmologist is indicated (Figs. 9 and 10).

The treatment options are pharmacologic lowering of intraocular pressure, laser trabeculoplasty to attempt to increase the aqueous outflow, or surgical decompression of the eye by trabeculectomy or aqueous shunts [14, 23–26].

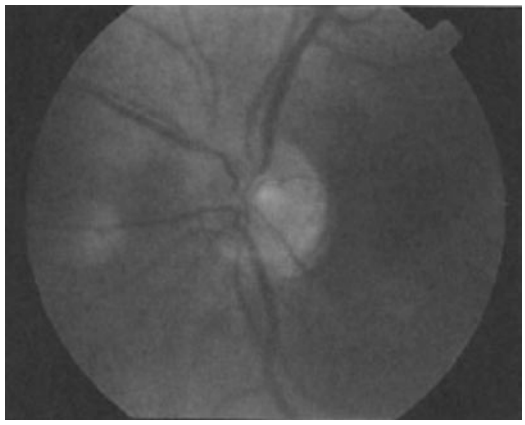

Fig. 10 Normal optic nerve with a healthy, nonexcavated optic cup

Angle-Closure Glaucoma

An acute angle-closure glaucoma attack is precipitated by abrupt closure in the aqueous outflow. The iris, with slight dilation, occludes the trabecular meshwork, resulting in progressively increasing pressure within the eye. The acute symptoms include pain, decreased vision, halos around lights, nausea, and vomiting. Examination reveals a cloudy or "steamy" appearance of the cornea, a nonreactive mid-dilated pupil, an area of injection around the limbus, and elevated intraocular pressure. Immediate referral to an ophthalmologist is mandatory. A laser iridotomy is often necessary, and close monitoring is needed in the uninvolved eye [27].

Oculomotor Motility

Strabismus

Strabismus is commonly defined as a deviation of the visual axis. This ocular misalignment can be found at almost any age. The malalignment of the eyes prevents binocular vision. Examine the eyes of newborns and children for symmetric corneal light reflex and use the cover/uncover test to identify esotropia (in-turning of one eye) or exotropia (out-turning of one eye). At birth most infants have a small degree of exotropia that resolves during the first few months of life. Newborns can reliably fix with both eyes by 4 months old. An abnormal cover/uncover test or caregiver report of deviation after 4 months old needs evaluation for potential amblyopia [3].

The treatment of strabismus is based on first correcting any refractive disorder, patching for amblyopia if present, and, lastly, surgically realigning the eyes. Visual outcome is best when the problem is diagnosed early [3, 28].

Amblyopia

Amblyopia is defined as a poorly sighted eye secondary to some form of visual deprivation at an early age. Treatment is best when started at a younger age. The US Preventive Services Task Force recommends assessing visual acuity at least once between 3 and 5 years of age to detect amblyopia. Amblyopia is seen in association with strabismus and with refraction disorders [28].

Strabismus produces amblyopia by preventing image stimulation in the fovea of the deviated eye. Occasionally, the diagnosis is made using a red reflex test with a direct ophthalmic scope held about 3 ft from the child's eyes. A difference in the red reflex may indicate a refractive error, amblyopia, or an opacity in the ocular media [28].

Anisometropia is a difference in the refractive status between the eyes leading to amblyopia. Treatment of amblyopia is aimed at restoring

the suppressed visual input by occluding the more favored eye with a patch, colored lenses, or pharmacologic intervention. Treatment is more successful when started under 7 years old but older children may benefit from treatment [3, 28].

Optical Defects

Refractive Disorders

A refractive disorder occurs because the focal point of light does not fall on the retina. In addition to glasses, excimer laser surgery has produced safe and accurate correction of refractive disorders. Laser-assisted in situ keratomileusis (LASIK) is the most common refractive procedure performed today. In LASIK the corneal stroma is remodeled with computer-controlled assistance to focus images on the retina of the eye. Recovery is usually within days to weeks. Complications, although rare, include under- and overcorrections, diffuse keratitis, and infection. Phakic intraocular lenses are an emerging option for surgical correction with very high myopia [29].

Accommodation Loss or Presbyopia

Accommodation, the ability to adjust the optic power of the eye, decreases from childhood to about age 75. In the normal human eye, as accommodation occurs, the ciliary body contracts, relaxing the zonules (or fibers) to the lens of the eye, and an active increase in lens curvature occurs, increasing the optical power of the eye. As the eye ages, hardening (sclerosis) of the lens reduces the elasticity of the lens capsule and plasticity of the lens core, resulting in a loss of accommodative amplitude. To correct this loss, reading glasses and monocular vision using contacts are prescribed. Options for surgical treatment include LASIK to achieve monovision and multifocal or accommodating intraocular lenses if cataract surgery is indicated [30].
