Ultrastructural and functional studies have revealed a third zone between the fetal and definitive zones, referred to as the transitional zone, the cells of which have intermediate characteristics between the fetal and adult zones (Fig. 12.10). After midgestation, transitional zone cells have the capacity to synthesize cortisol and thus may be analogous to cells of the zona fasciculata of the adult adrenal. By week 30 of gestation, the definitive zone and transitional zone begin to take on the appearance of the zona glomerulosa and the zona fasciculata, respectively. Thus, by late gestation, the fetal adrenal cortex resembles a rudimentary form of the adult adrenal cortex.

The postnatal remodeling of the primate adrenal cortex involves a complex wave of differentiation such that the inner portion of the fetal zone atrophies and the zonae glomerulosa and fasciculata develop.[213] Fetal zone remodeling in the human is an apoptotic process.[214] It has generally been thought that the adult cortical zones develop from the persistent definitive zone. However, there is no evidence of adrenal cortical insufficiency during the neonatal period when the postnatal remodeling process is at its peak. It is more likely that the nascent adult cortical zones are present and functional before birth. Indeed, morphologic and

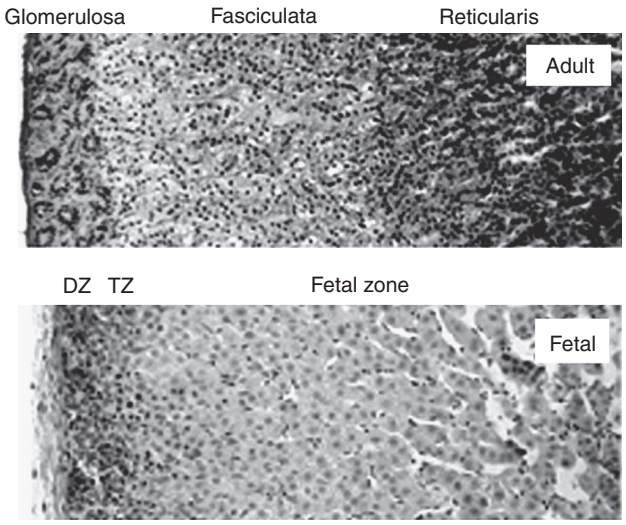

FIGURE 12.10 Morphology of the human adult and fetal adrenal cortex. DZ, definitive zone; TZ, transitional zone.

functional studies have identified rudimentary zonae glomerulosa and fasciculata during late gestation.[215] This lends support to the notion that the postnatal remodeling of the primate adrenal cortex involves apoptosis of a portion of the fetal zone and the simultaneous expansion of pre-existing and functional zonae glomerulosa and fasciculata.

ACTH secreted from the fetal pituitary is the principal trophic regulator of the fetal adrenal cortex. However, ACTH may not be acting directly. During the last two thirds of gestation, the fetal zone grows rapidly and produces large amounts of steroids, even though circulating ACTH concentrations do not rise significantly. Soon after birth the fetal zone rapidly involutes but exposure to ACTH continues, albeit at lower concentrations. Other factors, possibly specific to the intrauterine environment, appear to play a role in the regulation of fetal adrenal cortical growth and function. Substances produced by the placenta (e.g., hCG) have been implicated, and peptide growth factors produced locally within the fetal adrenal[216,217] appear to influence fetal adrenal cortical growth and function by mediating or modulating the trophic actions of ACTH.

Evidence of fetal adrenal steroidogenesis is first seen at 6 to 8 weeks, when the cells in the developing adrenal differentiate and acquire steroidogenic characteristics. At around week 12 of gestation, estriol concentrations in the maternal circulation rapidly increase (approximately 100-fold). This increase coincides with the initiation of fetal zone enlargement and ACTH secretion by the fetal pituitary gland.[209] Production of DHEA-S by the fetal adrenal cortex continues for the remainder of pregnancy and increases considerably during the second and third trimesters. By term the human fetal adrenal produces around 200 mg DHEA-S/day. Thus, placental production of estriol directly reflects the steroidogenic activity of the fetal HPA axis. For this reason, maternal estriol previously was used as an endocrine marker to evaluate fetal well-being.

The point at which the fetal adrenal cortex begins producing physiologically relevant amounts of cortisol has yet to be determined definitively. This question has been partially answered, however, by observations of infants with congenital adrenal hyperplasia (CAH). In CAH due to a deficiency of the 21-hydroxylase (P450c21) enzyme, the fetal adrenals cannot synthesize cortisol.[218] As a result, excess ACTH is produced due to loss of glucocorticoid-negative feedback. Female infants with CAH often are born with urogenital sinus defects and virilization primarily caused by exposure of the urogenital sinus to excessive amounts of adrenal androgen. Because this condition derives from adrenal glucocorticoid deficiency, the observations imply that the adrenal produces enough cortisol in female fetuses before 10 weeks of gestation to regulate ACTH levels and to prevent overproduction of adrenal androgens that may masculinize the female urogenital sinus. Expression of key steroid metabolizing enzymes suggests that the human fetal adrenal cortex does not produce cortisol *de novo* from cholesterol until around week 30 of gestation.[215] However, this does not preclude the possibility that cortisol is produced by using progesterone as a precursor early in gestation.[219]

Because the fate of pregnenolone metabolism is initially determined by the branch point steroidogenic enzymes P450c17 and 3β-HSD, the steroidogenic potential of cells may be inferred by the pattern of expression of these two enzymes (Fig. 12.7). Expression of 3β-HSD by the human fetal adrenal cortex is a critical step in the metabolism of pregnenolone, because it confers on cells the ability to convert Δ5-3β-hydroxysteroids to Δ4-3 ketosteroids essential for mineralocorticoid and glucocorticoid production. Between 12 and 22 weeks of gestation, the human fetal adrenal cortex does not express 3β-HSD. After 22 weeks, 3β-HSD expression can be detected first in the definitive zone cells and later in gestation in the definitive and transitional zone cells. At no time in gestation is 3β-HSD expression detected in the fetal zone. In contrast, expression of P450c17 is highly abundant in the transitional and fetal zones and is lacking in the definitive zone at all gestational ages.[215,220]

The persistent lack of 3β-HSD and expression of large amounts of P450c17 in the fetal zone is consistent with this cortical compartment producing only C19/Δ5 steroids, particularly DHEA. The lack of P450c17 in the definitive zone, and the eventual expression of 3β-HSD in this compartment, is consistent with this zone producing mineralocorticoids late in gestation. The coexpression of 3β-HSD and P450c17 in the transitional zone indicates that this zone has the capacity for glucocorticoid production (Fig. 12.11).

Steroidogenic enzymes downstream of P450c17 and 3β-HSD also have been examined.[221] Their localization and ontogeny are consistent with the concept that the definitive zone develops to form the zona glomerulosa, the transitional zone is analogous to the zona fasciculata, and the fetal zone is analogous to the zona reticularis.

Mineralocorticoid production by the primate fetal adrenal cortex is low early in gestation but increases during the third trimester. At term, 80% of the aldosterone in human and rhesus monkey fetal blood appears to originate from the fetal adrenal.[222] In 18- to 21-week human fetal adrenals, the mineralocorticoid metabolic pathway is localized to the definitive zone, but its activity is low and unresponsive to secretagogues.[223,224]

The angiotensin II receptors, AT1 and AT2, are present on human fetal adrenal cortical cells after 16 weeks.[225] The AT2 receptor is localized mainly on definitive zone cells,

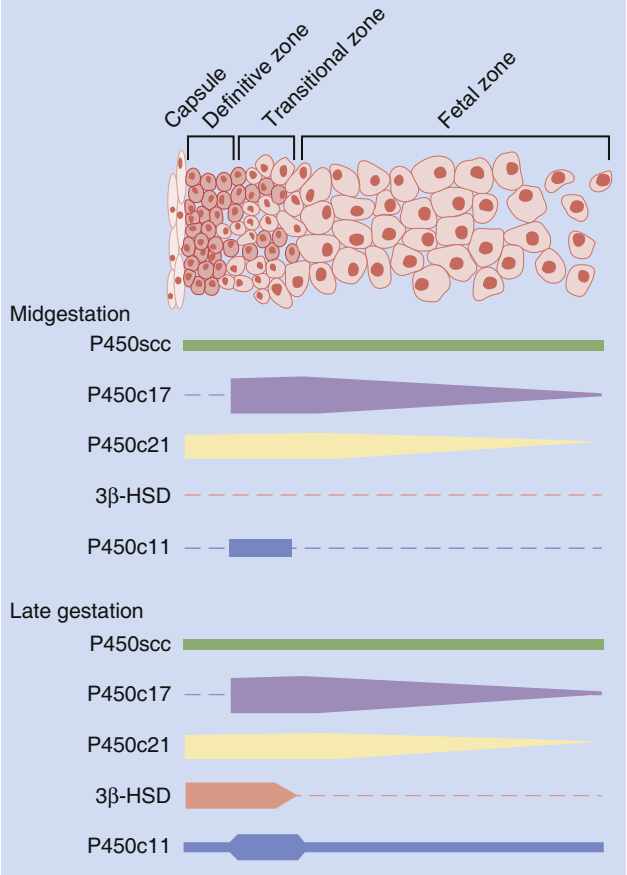

FIGURE 12.11 Schematic representation of the localization of expression of P450scc, 3β-hydroxysteroid dehydrogenase (3βHSD), P450c17, P450c21 and P450c11 in the primate fetal adrenal cortex during midgestation and late gestation. Thickness of the line indicates relative abundance of expression. Dashed line indicates lack of expression. Note the lack of P450c17 expression in the definitive zone at all stages of gestation and the ontogenetic expression of 3βHSD only in the definitive and transitional zones late in gestation. *(From Mesiano S, Jaffe RB. Developmental and functional biology of the primate fetal adrenal cortex.* Endocr Rev *18:378–403).*

whereas the AT1 receptor is detectable to a lesser extent in cells from both fetal and definitive zones. Thus, during the first and second trimesters, the ability of the human fetal adrenal cortex to synthesize mineralocorticoids is minimal even though the cells express AT receptors.

The Fetal Pituitary-Gonadal Axis

The foundation for normal puberty and adult reproductive function is established during fetal life. Intrauterine gonadal development is essential for normal sexual development. The consequence of impairment of this system can be irreparable loss of germ cells and reproductive potential. The development of the fetal testis is described in Chapter 17 and that of the fetal ovary in Chapters 9 and 17.

Studies of anencephalic fetuses indicate that embryonic sexual differentiation and early gonadal development do not depend on fetal pituitary gonadotropes. In anencephalic male fetuses, there is a reduction in Leydig cell number, whereas a reduction in the number of spermatogonia is uncommon.[226] There is also a similar time of appearance of seminiferous tubules in anencephalic and normal fetuses. In female anencephalic fetuses, the ovary appears to develop normally until 32 weeks. At term, ovaries of anencephalic fetuses are smaller than normal, central follicles are absent, and proliferation of oogonia with progression through meiosis until development of primordial follicles is not initiated.[226] Thus, pituitary gonadotropins are necessary for granulosa cell-follicular proliferation near term; they are also needed to a lesser extent, via granulosa cell regulation, for oocyte survival. On the basis of studies in fetal rhesus monkeys, fetal pituitary gonadotropins appear necessary for granulosa cell proliferation and follicular fluid formation during the latter part of pregnancy.[227]

In contrast to the ovary, fetal testes exhibit steroidogenic activity and synthesize testosterone *de novo*.[228] Testosterone secretion by Leydig cells is necessary at different stages of pregnancy for adequate growth of internal and external genitalia. In the fetal rhesus monkey *in utero*, testosterone production can be elicited by hCG injection and by stimulating the fetal pituitary-testicular axis with GnRH.[202,229] Low-density lipoprotein cholesterol can serve as a precursor for steroid synthesis in the fetal testis and may also function as an inducer of testicular steroidogenesis.[230] Levels of aromatase activity, necessary for estrogen formation, are low in the fetal testis.[231]

In contrast to the male, ovarian steroid production is not essential for female phenotypic development. Furthermore, meiosis in the ovary begins relatively early, but significant estrogen production does not occur until late in fetal life, although the capacity for aromatization exists by the eighth week.[232] The preponderance of data indicates that although certain enzymatic activity can be demonstrated in the fetal ovary, it cannot form estrogen *de novo* and is probably steroidogenically quiescent through most of pregnancy.

As with the fetal adrenal cortex, locally produced growth factors, acting in an autocrine-paracrine manner, may play critical roles in controlling the growth and development of the fetal gonads.[233]

The Fetal Pituitary-Thyroid Axis

In the human fetus, the thyroid gland acquires its characteristic morphological appearance and the capacity to concentrate radioiodine and to synthesize iodothyronines by 10 to 12 weeks of gestation. Coincidentally, hypothalamic TRH is detectable at 10 to 12 weeks; by this stage, thyrotropes can be detected in the fetal pituitary and TSH can be found by radioimmunoassay in the fetal pituitary and serum. Thyroxine (T4) has also been found in the fetal circulation.[234]

Thyroid function remains in a basal state until mid gestation. At this time, secretory activity of the thyroid gland and serum T4 concentrations begin to increase. This rise is likely to be related to the establishment of continuity between the hypothalamic and pituitary portions of the portal vascular system. Pituitary and serum TSH concentrations begin to rise shortly before the rise in T4 levels. Maximal TSH concentrations are reached early in the third trimester and do not increase further until term.

In the rhesus monkey, a TSH response to TRH administration is present early in the equivalent of the third trimester.[235] In contrast to the adult, triiodothyronine (T3) administration to the fetus does not suppress the pituitary

TSH response to TRH in primates.[235] The human infant born after 26 to 28 weeks of gestation responds to exogenous administration of TRH with an increase of circulating TSH levels similar to those seen in adults.[236]

At term, TSH secretion by the human fetus can be inhibited by the administration of T4.[236,237] In addition, the elevated cord T4 is associated with marked suppression of the neonatal TSH surge.[237] This inhibitory effect of T4 is presumably mediated through pituitary conversion of T4 to T3. Human fetal serum T4 and free T4 levels increase progressively during the last trimester, although serum TSH levels do not.[237]

Serum T3 concentrations are usually not measurable in the human fetus until approximately the 30th week of gestation.[237] Thereafter, concentrations rise to a mean level of approximately 50 ng/dL at term. The prenatal increase in serum T3 concentration occurs during several weeks and may be related to increased cortisol concentration.[238] Immediately after birth (during the first 4 to 6 hours), circulating T3 levels increase still further to concentrations three to six times those occurring *in utero*.[238,239]

Reverse T3 (3, 3′, 5′-triiodothyronine) reaches concentrations in the human fetus greater than 250 ng/dL early in the third trimester; then decreases progressively until term.[237,239,240] In contrast with T3 levels, serum reverse T3 concentrations remain virtually unchanged during early neonatal life in term infants.

An acute increase in pituitary TSH levels occurs when the term fetus is exposed to the extrauterine environment. This, in turn, stimulates thyroidal iodine uptake and evokes release of thyroid hormones. The maximal TSH concentrations are attained 30 minutes after birth. Thereafter, there is a rapid decrease in serum TSH during the first day of extrauterine life and a slower decrease during the succeeding 2 days. Serum T4 and free T4 levels reach a peak at 24 hours and then decrease slowly during the first weeks of life.[241]

Binding of iodothyronine and maturation of thyroid hormone receptors have not been reported in the human fetus. In the rat, hepatic nuclear T3 receptors mature during the first few weeks after birth.[242] T3 receptor capacity, and possibly affinity, increases during the first 3 to 4 weeks. In the brain (in contrast with the liver) T3 nuclear receptor binding develops early, is comparable with that in the adult brain, and increases still further in the first 3 days of neonatal life.[243]

However, there appears to be a discrepancy between T3 nuclear receptor binding and brain tissue responsiveness in both the neonate and the adult. Neither appears to respond to exogenous T3 administration with an increase in oxygen, α-glycerophosphate dehydrogenase, or malic enzyme consumption.[243] Of interest is the observation that thyroid hormones increase nerve growth factor concentrations in adult and newborn mouse brain[244]; it has been postulated that this nerve growth factor may mediate the effects of thyroid hormones on brain development.[243]

Fetal Pituitary-Growth Hormone

GH is produced and secreted by the human fetal pituitary from around 8 to 10 weeks of gestation.[245] Levels of GH in the fetal circulation peak at around 6 nmol/L at midgestation, then gradually decrease for the remainder of gestation to around 1.5 nmol/L at term. The peak in GH at midgestation is thought to be due to unrestrained secretion because cultured pituitary cells from 9- to 16-week fetuses respond to GHRH with increased GH secretion; they are far less responsive to inhibition by SS.[246] Alternatively, negative feedback pathways for the regulation of GH secretion may develop later then GHRH stimulation. The physiological control of pituitary GH production and secretion is mature by term.

The role of fetal pituitary GH is unclear. Anencephalic fetuses on average are of normal size and weight, suggesting that fetal growth is controlled by factors other than fetal pituitary GH. Placental GH and PL are likely candidates. Clearly, pituitary GH is required for postnatal growth and development, and therefore this system must be mature at birth. However, it likely plays a minimal role in the control of fetal somatic growth.

Fetal Pituitary-Prolactin

Levels of PRL in the fetal circulation are very low during the first half of human pregnancy. The pituitary begins secreting PRL at 25 to 30 weeks, gradually secreting more for the remainder of gestation and reaches a peak at term.[247] The level of PRL expression by the fetal pituitary increases progressively from around 15 weeks. In anencephalic fetuses, pituitary PRL content is within the normal range, indicating that its production by the pituitary is independent of hypothalamic control during most of gestation.[247]

Control of PRL secretion by TRH and dopamine matures late in pregnancy and during the first few months after birth.[245,247] In cultured pituitary cells obtained from midgestation human fetuses, estrogen stimulates and dopamine inhibits PRL secretion.[245] Interestingly, the increase in fetal PRL levels with ongoing gestation coincides with increases in estrogen levels, indicating that its production by the fetal pituitary is influenced by estrogen during most of pregnancy. The role of PRL in fetal development remains uncertain.

Long-Term Effects of Fetal Neuroendocrine Maturation

The appropriate functional maturation of neuroendocrine systems during fetal life has profound effects on long-term health into adulthood. This phenomenon, referred to as developmental origins of adult disease, arose through epidemiological observations that show an association between perturbations of intrauterine nutritional status and the development of hypertension, insulin resistance, and obesity that predispose to cardiovascular disease, diabetes, and the metabolic syndrome in adulthood.[248]

The developmental origins model predicts functional plasticity in the development of fetal neuroendocrine and organ systems such that a single genotype gives rise to multiple "normal" phenotypes in response to environmental cues (e.g., extent of maternal nutrition and stress) mediated through the maternal organism. Thus, the fetus prepares itself for the extrauterine environment by modulating its physiological set points to match the anticipated environment based on maternal cues. Interestingly, the period of neuroendocrine plasticity is limited and the physiological changes appear to be permanent; plasticity does not

continue later in life. For example, studies in animals show that changes in basal and stress-induced fetal HPA activity induced *in utero* by maternal starvation persist after birth. The altered stress-response pathway may underpin pathophysiological conditions that develop during adulthood.[249] Remarkably, studies in sheep indicate that maternal nutrition status before conception influences fetal growth and length of gestation, suggesting that the pre-implantation blastocyst and/or the endometrium are programmed by nutritional status.[250]

The physiological, biochemical, and genetic mechanisms that mediate the reactive plasticity of fetal neuroendocrine development are not clearly defined. The placenta is thought to play an active role, although it remains uncertain how information regarding the environment is transmitted from the mother, through the placenta and to the fetus. As described above, the placenta produces a plethora of hormones that could influence the developmental trajectories of fetal neuroendocrine axes. For example, placental CRH may modulate the responsiveness of the fetal adrenal cortex to ACTH and therefore contribute to the establishment of the HPA set-point.[251]

It is also possible that perturbations in the gestational milieu induce static changes in chromatin structure, referred to as epigenetic modification, in the embryo and fetus that alters gene expression that persist into adult life.[252] The most common epigenetic modifications (also known as marks) are methylation of cytosines in CpG dinucleotides and post-translational modifications (e.g., acetylation) of histones. Methylation in gene promoter regions generally inhibits downstream gene expression and histone modifications alter the chromatin secondary structure affecting activity of the transcriptional machinery.[253] These chemical modifications do not involve changes in the primary DNA sequence and are heritable by mitosis from one cell generation to the next.[254] Importantly, during the preimplantation period embryonic cells undergo waves of demethylation that effectively deprogram all epigenetic marks to generate cells with broad developmental potential. The DNA is then remethylated as the embryo develops. This provides an opportunity for environmental influences to affect the epigenome (genome-wide pattern of epigenetic marks).[255] Thus, epigenetic modification during development is proposed as the main mechanism for environment-induced phenotypic plasticity and provides a mechanistic explanation for the effects of prenatal and perinatal environmental exposures (e.g., malnutrition) on the subsequent disease risk in later life.[256-259]

Fetal Maturation and Timing of Parturition

Fetal Organ Maturation and Preparation for Extrauterine Life

At birth the fetus is abruptly required to establish and maintain physiological homeostasis independently of the placenta and in a markedly altered environment. Survival of the neonate is therefore dependent upon the functional maturation of organ systems essential for extrauterine life. Critical among these are organs that interface with the environment and extract resources (e.g., lungs, gut, and immune system) and those that maintain homeostasis (e.g., the HPA axis, kidneys, liver, and pancreas). The coordination of fetal maturation and the timing of parturition such that birth occurs when the fetus is sufficiently mature to survive as a newborn is therefore critical for neonatal survival.

Many studies in multiple species have demonstrated that glucocorticoids promote the functional maturation of fetal organ systems.[260] Critical processes induced by glucocorticoids include surfactant production by the fetal lungs; activity of enzyme systems in the fetal gut, retina, pancreas, thyroid gland, and brain; and deposition of glycogen in the fetal liver. In sheep, fetal organ maturation is induced by a prepartum surge in cortisol secretion by the fetal adrenals.[261] The cortisol surge also triggers the onset of labor (discussed later in the chapter). Thus, in sheep, the fetal HPA axis, via cortisol, mediates a physiological link between the timing of birth and fetal organ maturation.

The effect of glucocorticoids on the maturation of the fetal lungs is especially important. The inability to exchange gases due to pulmonary immaturity (respiratory distress syndrome) is the leading cause of neonatal morbidity and mortality among preterm infants. Synthetic glucocorticoids that readily cross the placenta are a standard form of therapy administered to women in preterm labor. This treatment significantly increases survival rates among preterm infants mainly by promoting lung maturation and decreasing the severity of respiratory distress syndrome.

The extent to which cortisol from the fetal adrenals regulates fetal organ maturation is uncertain. Experiments of nature suggest that maturation of the human fetus during late gestation is independent of fetal adrenal cortisol production. Fetuses with CAH due to P450c21 deficiency, produce markedly reduced levels of cortisol, yet these infants are usually born at term without any apparent signs of organ immaturity.[262] This observation suggests that cortisol produced by the fetal adrenal gland is not essential for fetal organ maturation; another source of glucocorticoid, possibly from the maternal adrenals, could contribute to the stimulation of fetal organ maturation at the end of human gestation; or maturation of the human fetus is not dependent upon glucocorticoids alone and other factors may be involved.

Although cortisol stimulates maturation of fetal organ systems, it also can have adverse effects on fetal development. To protect the fetus from these negative effects the human placenta prevents maternal cortisol from entering the fetal compartment throughout most of human pregnancy by expressing the 11β-HSD-2 enzyme that converts cortisol to the inactive cortisone.[193] Thus, for most of pregnancy the placenta forms a biochemical barrier to maternal cortisol.

Late in human pregnancy (around 34 to 35 weeks), however, the placental barrier to maternal cortisol weakens. The evidence for this is that estriol levels in the maternal circulation during late pregnancy are inversely related to the circadian changes in circulating maternal cortisol levels.[263] Thus, when maternal cortisol goes up, estriol goes down. This implies that, late in gestation, some maternal cortisol crosses the placenta to the fetal compartment and suppresses ACTH production by the fetal pituitary gland that leads to decreased DHEA-S production by the fetal adrenals and in turn decreased estriol production by the placenta. Increased transfer of maternal cortisol to the fetus

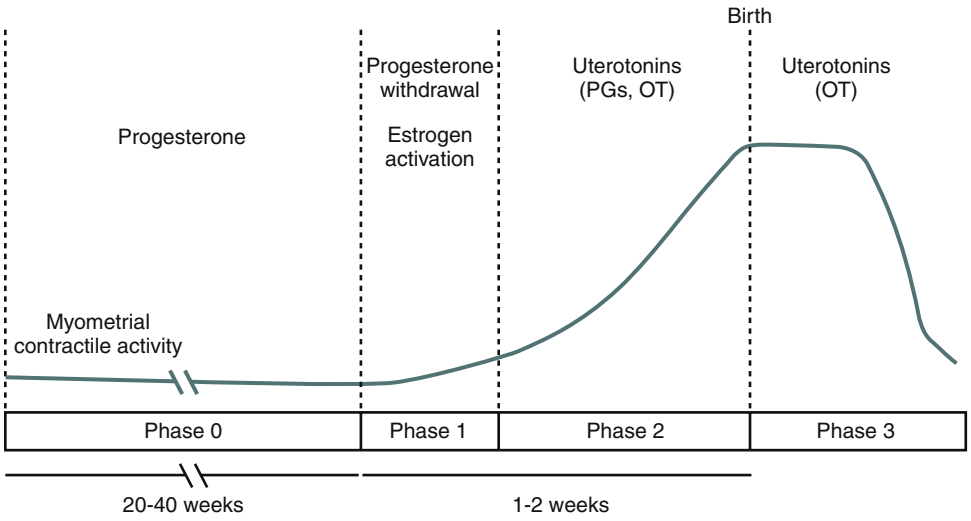

FIGURE 12.12 Phases of human parturition based on myometrial contractile activity and the principal regulatory uterotropins and uterotonins involved. *(Adapted from Casey ML, Macdonald PC. Endocrine changes of pregnancy. In Williams Textbook of Endocrinology, Wilson, JD, Foster, DW, Kronenberg, HM, Larsen, PR, editors. 1998, W.B. Saunders Co: Philadelphia. p 1259.)*

may represent a back-up mechanism to ensure fetal lung maturation. This may explain why fetuses with glucocorticoid deficiency are born without overt signs of organ system immaturity.

The Process of Human Parturition

The process of parturition involves: (1) transformation of the myometrium from a quiescent to a highly contractile phenotype; (2) remodeling of the uterine cervix such that it softens and dilates to allow passage of the fetus; and (3) rupture of the fetal membranes. These temporally coordinated events can be divided into distinct phases based on the contractile activity of the myometrium (Fig. 12.12).[264]

Phase 0 (quiescence): For most of pregnancy the myometrium is in a state of relaxation and relatively insensitive to stimulatory uterotonins (factors that affect uterine contractions); e.g., PGs and OT. In addition the uterine cervix remains closed and rigid. This period, referred to as Phase 0 or quiescence, is controlled by propregnancy relaxatory uterotonins such as β-adrenergic agents, PGI_2, relaxin, CRH, parathyroid hormone-related peptide and nitric oxide, and uterotropins (factors that modulate uterine function and growth), especially progesterone. In general, factors that activate adenylate cyclase or guanylyl cyclases and increase intracellular cAMP and cGMP, respectively (e.g., via $G_{\alpha s}$-protein-coupled receptors) promote myometrial relaxation.

Phase 1 (transformation): As an essential prelude to active labor, the myometrium undergoes a phenotypic transformation, referred to as Phase 1, whereby it gains the capacity to contract forcibly and rhythmically and becomes more responsive to uterotonins. The awakening of the quiescent uterus is initiated by progesterone withdrawal and increased estrogenic effects on gene expression leading to distinct biophysical changes in the myometrium and cervix.

Transformation of the myometrium involves the increased expression of a specific cohort of genes, collectively referred to as *contraction-associated proteins* (CAPs).[265] Some important CAPs include connexins (e.g., connexin-43), which form gap-junctions between myometrial cells, allowing rapid electrical and chemical signaling between adjacent cells to permit coordinated contractions; ion channels (e.g., calcium channels), which determine the resting membrane potential and excitability; uterotonin receptors (e.g., OT and PG receptors); and enzymes that determine the rate of local uterotonin synthesis (e.g., PG endoperoxide synthase-2 [PTGS2]). Concurrently, the uterine cervix gradually softens and becomes more elastic due to increased expression of collagenase and metalloproteinase enzymes. In addition, intrauterine production of PGE_2 and $PGF_{2\alpha}$ increases.

Phase 2 (activation): The increased myometrial exposure to PGs and its augmented responsiveness to PGs and OT eventually initiate Phase 2, which is defined by the onset of active labor. During Phase 2, uterotonic drive induces coordinated rhythmic contractions that eventually become more forceful. At the peak of active labor the myometrium is one of the strongest muscles (on a per weight basis) in the human body. As the cervix effaces and becomes more compliant, the contractions progressively move the fetus towards the birth canal. As contractions become more pronounced the force of the fetus against the lower uterine segment dilates the softened cervix enough for it and the placenta to pass through the birth canal.

Phase 3 (hemostasis and involution): Phase 3 begins after the placenta, fetal membranes and decidua are expelled. Importantly, myometrial contraction is sustained (mainly in response to OT) during this time, which helps constrict the spiral arterioles to facilitate postpartum uterine hemostasis. During the following weeks the uterus gradually reverts back to the menstrual state through a combination of myometrial cell apoptosis and atrophy. In addition, the cervix remodels and reverts to the closed and rigid state.

The Hormonal Control of Human Parturition

The hormonal control of parturition involves mainly progesterone and estrogens that have opposing effect on uterine contractility. For most of pregnancy, progesterone actively blocks parturition by promoting uterine quiescence and at the end of pregnancy labor is initiated by the withdrawal of progesterone's relaxatory effects. In contrast, estrogens (mainly estradiol) oppose the actions of progesterone by stimulating biochemical and physical changes in the uterus

and fetal membranes that facilitate labor. Thus, uterine contractility during pregnancy is determined by the balance between relaxatory actions of progesterone and stimulatory actions of estrogens. During most of pregnancy the relaxatory actions of progesterone (i.e., the progesterone block to labor) prevail. Parturition is initiated by progesterone withdrawal, which permits the stimulatory estrogenic actions to increase myometrial contractility and excitability and promote cervical softening.

Progesterone Withdrawal and Estrogen Activation

A major physiological trigger mechanism for parturition is progesterone withdrawal. In all viviparous species studied so far, parturition can be initiated by any intervention that interferes with progesterone synthesis or action and in most species normal parturition at term is triggered by a prepartum decrease in circulating progesterone levels, referred to as systemic progesterone withdrawal.[266]

The mechanism for progesterone withdrawal and how it is controlled differs between species. In some animals (e.g., rodents) progesterone is supplied by the CL during pregnancy and progesterone withdrawal at parturition is caused by hormonal signals from the uterus that induce luteolysis. In other species (e.g., ovine, bovine) progesterone is produced by the placenta and progesterone withdrawal at parturition is caused by hormonal signals from the fetus that decrease placental progesterone secretion. In sheep, this is induced by a surge in cortisol production by the fetal HPA axis 1 to 2 weeks before term,[267] which stimulates expression of the P450c17 enzyme in the placenta which converts progesterone to androstenedione leading to a dramatic decrease in placental progesterone secretion.[268] This also leads to concomitant increase in placental estrogen production due to increased availability of androstenedione for aromatization (Figure 12.7). The fall in circulating progesterone levels, coupled with a rise in circulating estrogens, transforms the uterus and cervix to the laboring state. As cortisol is the principal stimulator of fetal organ system maturation, the prepartum fetal cortisol surge ensures that parturition is coordinated with fetal maturation.

Although cortisol promotes the functional maturation of fetal organ systems in preparation for extrauterine life in the human, as it does in sheep, its production by the fetal HPA axis does not appear to be necessary for normal human parturition.[262,269] As described above, parturition occurs normally at term in pregnancies where the fetuses has CAH due to the inability to produce cortisol.[262] Transfer of cortisol from the maternal to the fetal compartment may compensate for the lack of fetal adrenal cortisol in CAH pregnancies, but whether it plays a role in triggering parturition is unlikely since administration of glucocorticoid to women in threatened preterm birth does not appear to advance the parturition process.

A distinguishing feature of parturition in humans and some nonhuman primates is that circulating levels of progesterone and estrogens are high for most of pregnancy and during labor and delivery (Figure 12.9).[270] Thus, in human parturition the uterus transitions to the laboring state despite being exposed to high levels of progesterone and for most of pregnancy the uterus remains quiescent despite being exposed to high levels of estrogens. Nonetheless, labor in women can be induced at any stage of pregnancy by interventions (e.g., administration of mifepristone, a progesterone receptor antagonist) that inhibits progesterone action.[271] An explanation for this conundrum is that human parturition involves functional—rather than systemic—progesterone withdrawal, whereby uterine cells become refractory to progesterone actions; and functional estrogen activation, whereby uterine cells become sensitive to the stimulatory prolabor actions of estrogens. The physiological control of human parturition therefore mainly involves hormonal interaction that control progesterone and estrogen responsiveness in uterine target cells (mainly myometrial cells).

Functional Progesterone Withdrawal

Progesterone responsiveness is primarily determined by the extent of expression and transcriptional activity of the nuclear progesterone receptor (nPR) that belong to a family of ligand-activated nuclear transcription factors.[272] Transcription of the human nPR gene is controlled by two promoters that produce two major nPR isoforms, PR-A (83 kD) and PR-B (99 kD). PR-A is a truncated (by 165 N-terminal amino acids) form of PR-B. Other nPR transcripts generated by alternate translational start sites, exon splicing, intronic insertions, and exon deletions have also been described, but their levels of expression in most tissues are low and their physiological significance is uncertain.[273]

All progesterone target tissues examined so far coexpress PR-A and PR-B in varying relative amounts depending on tissue type and pathological condition, and as such genomic responsiveness to progesterone is dependent on the combined actions of PR-A and PR-B. Initial studies examining the transcriptional activities of PR-A and PR-B using the canonical progesterone responsive DNA element, showed that upon exposure to progesterone, PR-B has strong transcriptional activity, whereas PR-A on its own has minimal transcriptional activity and, depending on its amount relative to PR-B, represses the transcriptional activity of PR-B.[274] Those observations led to the concept that PR-A and PR-B comprise a dual system for the control of progesterone responsiveness whereby the genomic action of progesterone is inversely related to the PR-A/PR-B ratio. According to this model, progesterone responsiveness is predominantly mediated PR-B whereas PR-A acts as an endogenous repressor of PR-B.

This concept led to the PR-A/PR-B hypothesis for functional progesterone withdrawal which posits that progesterone withdrawal in human parturition is mediated by an increase in the myometrial cell PR-A/PR-B ratio.[275] Consistent with this hypothesis several studies found that PR-A represses the transcriptional activity of PR-B in human myometrial cells and that the onset of labor is associated with a significant increase in myometrial PR-A expression and a rise in the PR-A/PR-B expression ratio (Fig. 12.13).[275-279] Functional progesterone withdrawal could also be mediated by other mechanisms that inhibit the transcriptional activity of PR-B.[280-283] Thus, current data indicate that functional progesterone withdrawal in human parturition is mediated by a variety of processes that abrogate the capacity for ligand activated PR-B to promote relaxation.

Functional Estrogen Activation

In most species, maternal estrogen levels rise prior to delivery. In humans, this rise begins at midgestation and increases gradually during the remainder of pregnancy and

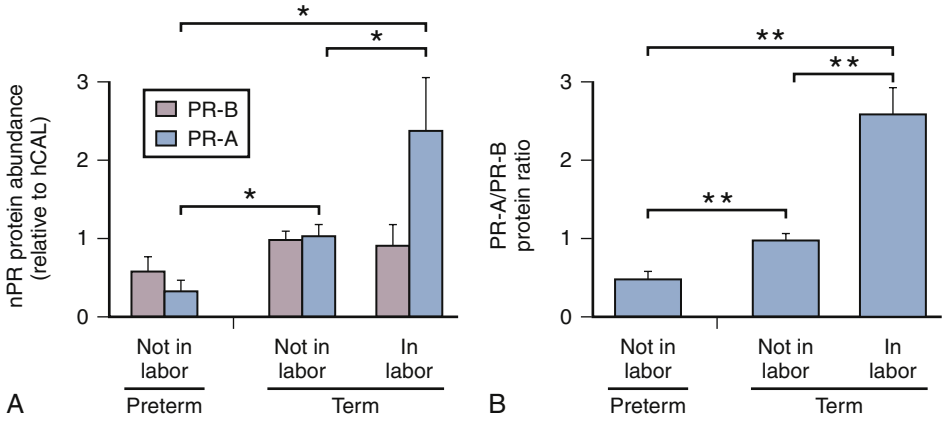

FIGURE 12.13 Relative abundance of PR-A and PR-B proteins **(A)** and the PR-A/PR-B protein ratio **(B)** in lower uterine segment myometrium obtained from term and pre-term c-section deliveries. Nuclear progesterone receptors in the human pregnancy myometrium: evidence that parturition involves functional progesterone withdrawal mediated by increased expression of progesterone receptor-A.* The Journal of Clinical Endocrinology and Metabolism *92:1927, 2007.)*

is dependent mainly on the increased DHEA-S availability to the placenta due to increased activity of the fetal HPA axis (previously discussed in the chapter). The role of placental estrogens in the human parturition process, however, is equivocal because congenital abnormalities affecting estrogen production by the fetal-placental unit, such as anencephaly, congenital adrenal lipoid hyperplasia, placental aromatase deficiency, and placenta sulfatase deficiency, do not affect the timing of birth. It appears that relatively little estrogen is required for normal human pregnancy and parturition.

Increased placental estrogen synthesis also appears to have little effect on the timing of parturition. In pregnancies in which the fetus has CAH due to P450c21 deficiency, cortisol production by the fetal adrenals is markedly reduced, leading to abnormally high ACTH production by the fetal pituitary. This in turn increases production of DHEA-S, which is converted by the placenta to estrogens. Despite markedly elevated placental estrogen production throughout most of pregnancy, individuals with CAH generally do not deliver before term.[262] Thus, increased estrogen synthetic activity by the human fetal-placental unit beyond the already high level does not appear to be a trigger for human parturition. Clearly, the role of estrogens in human parturition is not solely controlled by estrogen levels in the maternal circulation. As with progesterone action, estrogenic activity in the human pregnancy uterus appears to be controlled by changes in estrogen responsiveness.

Functional estrogen activation at parturition could be mediated by changes in estrogen receptor (ER) expression and transcriptional activity in target cells. The human ER exists as two major subtypes, ERα and ERβ (see Chapter 5).[284] Expression of ERα by the human pregnancy myometrium increases significantly at term in association with the onset of labor, whereas ERβ expression in the human myometrium is very low and not affected by the onset of labor.[275] The rise in ERα expression is directly associated with increased expression of connexin-43, a key estrogen-responsive CAP gene. This suggests that the increase in ERα expression at parturition mediates functional estrogen activation by increasing myometrial cell responsiveness to circulating estrogens.

Coordination of Functional Progesterone Withdrawal and Estrogen Activation

Numerous studies in a variety of species have demonstrated functional interaction between the ER and PR systems such that progesterone decreases uterine estrogen responsiveness by decreasing ERα expression, and estrogen increases uterine progesterone responsiveness by increasing PR-B expression. Levels of ERα expression in quiescent (i.e., before labor) term human myometrium correlate positively with the PR-A/PR-B expression ratio,[275] suggesting that myometrial cell expression of ERα increases as progesterone responsiveness decreases. Studies in the rhesus monkey have shown that progesterone inhibits ERα expression in the pregnancy myometrium.[285] Thus, progesterone may decrease uterine estrogen responsiveness by inhibiting myometrial ERα expression. This would explain why the myometrium is refractory to the prolabor actions of estrogens for most of pregnancy. Such a system, in which hormone action is principally controlled by target cell responsiveness, requires circulating hormone to be present; however, the level is not critical, provided that there is sufficient hormone for activation of cognate receptors. This would explain why inhibition of progesterone action alone (e.g., with mifepristone) is sufficient to initiate the full parturition cascade. In addition, suppression of estrogen responsiveness by progesterone may explain why parturition is not initiated prematurely by naturally occurring conditions in which estrogen levels are increased above normal.

Control of Progesterone Withdrawal

The general paradigm regarding the physiological control of human birth timing is that the induction of functional progesterone withdrawal is a pivotal integrative step in the hormonal control of human parturition. Thus, multiple probirth signals converge on the pregnancy uterus to trigger the parturition process by first inducing functional progesterone withdrawal. In particular, proinflammatory stimuli on the myometrium and cervix play a major role in the human parturition cascade.

Multiple studies have shown that human parturition is an inflammatory process and that labor is secondary to inflammation within the myometrium and cervix.[165,286-289] A significant proportion of preterm births are associated with intrauterine infection,[290,291] clinically silent upper genital tract infection, and bacterial vaginosis.[292-296] In the rhesus monkey, activation of the inflammatory system in the gestational tissues, including the myometrium, precedes the onset of labor[297,298] and studies in rhesus monkeys and mice have shown that administration of proinflammatory

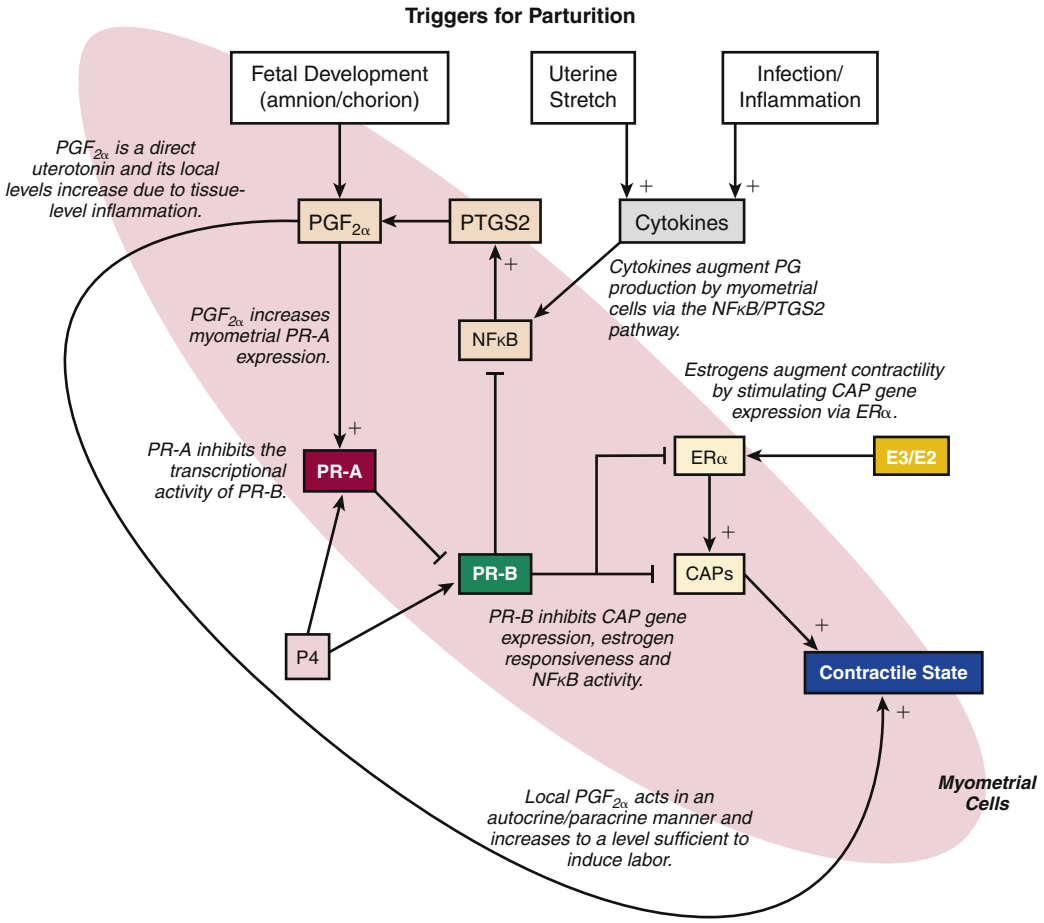

FIGURE 12.14 Theoretical model for how various physiological pro-birth inputs initiate the human parturition cascade by augmenting exposure of myometrial cells to $PGF_{2\alpha}$ which in turn induced functional progesterone withdrawal by increasing PR-A expression which inhibits the anti-inflammatory and anti-estrogenic actions of PR-B. Eventually a NFκB/$PGF_{2\alpha}$-mediated pro-inflammatory state develops in the myometrial compartment which increases local $PGF_{2\alpha}$ to levels that induce labor.

stimuli initiates preterm labor.[299,300] Labor is also associated with, and possibly preceded by, increased PG production by the fetal membranes,[301] which may be an important fetal signal for the induction of human parturition. Studies in human myometrial cell lines showed that $PGF_{2\alpha}$ stimulates PR-A expression and increases the PR-A/PR-B expression ratio.[302] Those findings suggest that $PGF_{2\alpha}$ produced by the gestational tissues in response to proinflammatory stimuli induces functional progesterone withdrawal. In women, administration of $PGF_{2\alpha}$ induces labor and delivery at all stages of pregnancy.[303,304] However, in contrast to its potent and rapid induction of uterine contraction when administered to women in active labor (Phase 2), the induction of labor by $PGF_{2\alpha}$in a quiescent uterus (Phase 0) occurs after a latency of 15 to 20 hours. This likely represents the time needed to augment PR-A expression and induce functional progesterone withdrawal and the downstream transformation of the myometrium to the laboring state.

Implicit in the hypothesis that the uterus transitions to the laboring state as a result of tissue-level inflammation, is the concept that uterine quiescence ensues if proinflammatory pathways in uterine cells are repressed.[162] Recent molecular studies have indeed suggested that this is a principal mechanism by which progesterone promotes myometrial relaxation.[161,305] Progesterone via PR-B inhibits the responsiveness of myometrial cells to proinflammatory stimuli by inhibiting activity of the nuclear factor -κB (NFκB) transcription factor complex, a major mediator of proinflammatory stimuli and regulator of proinflammatory gene expression.[306-308] In human myometrial cells, progesterone via PR-B inhibits the capacity for interleukin-1β (IL-1β) to activate NFκB and induce expression of PTGS2, the key rate limiting and inducible enzyme for the synthesis of $PGF_{2\alpha}$.[305] Importantly, PR-A inhibits the anti-inflammatory effects of PR-B, consistent with the PR-A/PR-B hypothesis.[305] Based on those observations it is possible that with advancing gestation or in response to pathophysiological conditions (e.g., intrauterine infection) $PGF_{2\alpha}$ levels increase in the myometrial compartment and increase PR-A to levels that completely abrogated the anti-inflammatory activity of PR-B leading to a tissue-level positive-feedback proinflammatory state whereby increased local production of $PGF_{2\alpha}$ exerts an autocrine-paracrine effect that further increases inflammation and $PGF_{2\alpha}$ production. Eventually the local $PGF_{2\alpha}$ levels become high enough to exerts potent uterotonic actions to induce labor. This may explain why labor is difficult to stop once it is initiated. A proposed model that integrates myometrial inflammation with functional progesterone withdrawal and local $PGF_{2\alpha}$ production is outlined in Figure 12.14.

Role of Uterine Stretch in Human Parturition

Uterine stretch has also been proposed as a signal for the induction of parturition. Such a mechanism would ensure that the fetus does not grow larger than the pelvic opening. In general, gestation is shorter in twin pregnancies,[309,310] presumably due to the increased stretch imposed on the uterine wall. Studies in rats have shown that distention of a nonpregnant uterine horn induces changes in CAP gene expression similar to those in the pregnant horn and that progesterone inhibits stretch-induced CAP gene expression.[311-313] The stimulatory effect of stretch on CAP gene expression was also observed in cultured human myometrial cells.[314-318] Stretch of cultured uterine myocytes also increased expression and release of IL-8, a potent proinflammatory chemokine that promotes the infiltration of activated macrophage and neutrophils.[315] The human uterus is subjected to a significant amount of distention, especially late in the third trimester. A likely scenario is that a threshold of uterine stretch exists above which the induction of CAP and proinflammatory gene expression contributes to the parturition cascade.

Role of Fetal Lung Maturation in Human Parturition

Studies in rodents have indicated that the fetal lungs contribute to the parturition process.[319] In this species, surfactant protein -A (SP-A), a critical lung surfactant protein, produced by the fetal lung epithelium is secreted into the amniotic fluid where it activates fetal macrophages and causes them to migrate to the myometrium. In the myometrium the increased production of cytokines by the fetal macrophages induces NFκB activation in the myometrial cells leading to functional progesterone withdrawal (discussed later in the text). This interaction ensures that fetal lung maturation, indicated by SP-A production, and birth timing is coordinated. However, evidence for a similar system is not apparent in the human and the trafficking of fetal macrophages in the myometrium in humans and mice differs substantially. However, some studies suggest that SP-A interacts directly with myometrial cells via a specific receptor to increase prostaglandin production and contractile capacity.[320] Thus, SP-A produced by the human fetal lungs may directly affect myometrial contractility and the capacity for the development of an inflammatory response in the gestational tissues. This may impact on the sensitivity of the gestational tissues to inflammation-induced parturition. An interesting twist to this paradigm is the observation that the fetal membranes express SP-A in response to glucocorticoid and that SP-A induces prostaglandin synthesis by chorionic trophoblasts.[321] This may represent an important interaction to coordinate birth timing with fetal lung maturation.

Role of Placental CRH and Urocortins in Human Parturition

A unique feature of primate pregnancy is that the placenta produces CRH in increasing amounts during gestation.[322] Studies of maternal CRH levels during human pregnancy suggest that placental CRH plays a role in the physiology of parturition. Concentrations of CRH in the maternal circulation and the rate of change as gestation progresses are predictive of the gestation length.[97] The trajectory of maternal CRH levels at mid gestation are indicative of whether parturition will occur at term, preterm, or postterm (Fig. 12.15).

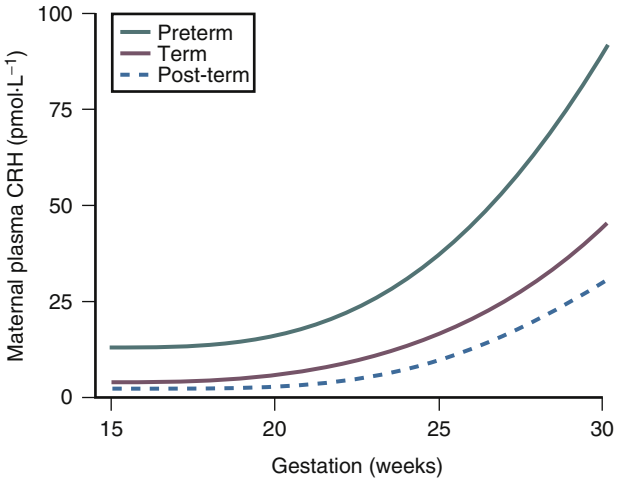

FIGURE 12.15 Schematic representation of the association between changes in maternal plasma CRH levels between 15 and 30 weeks gestation and the timing of birth. *(From McLean M, Bisits A, Davies J, et al. A placental clock controlling the length of human pregnancy.* Nature Med *1:460, 1995.)*

Interestingly, the exponential rise in maternal plasma CRH concentrations with advancing pregnancy is associated with a concomitant fall in the concentrations of the CRH-binding protein in late pregnancy (Fig. 12.5).[97] The implication of these reciprocal concentration curves is that there is a rapid increase in circulating levels of bioavailable CRH concurrent with the onset of parturition.

CRH may be involved directly in the regulation of human parturition by modulating myometrial contractility. Receptors for CRH have been identified in the human myometrium and fetal membranes.[323-326] *In vitro* studies have shown that CRH stimulates the release of PGs from human decidua and amnion,[327,328] and augments the action of OT and $PGF_{2\alpha}$ on myometrial contractility.[329-331] During most of pregnancy, CRH increases adenylate cyclase activity in the quiescent myometrium, leading to an increase in intracellular cAMP, which promotes relaxation. In contrast, at around the time of parturition the capacity for CRH to increase cAMP decreases; especially in laboring myometrium.[332] Thus, for most of pregnancy CRH contributes to the maintenance of myometrial relaxation and this effect decreases as part of the parturition process. Whether changes in CRH receptor signaling contribute to the onset of labor remains unknown.

As previously mentioned, the existence of an extrahypothalamic source of CRH may have profound effects on the activity of the fetal-placental unit. In particular, a positive feedback endocrine loop may develop between placental CRH and the fetal adrenal cortex as a consequence of the direct action of CRH on the fetal adrenal cortex and the stimulation of placental CRH expression by cortisol. In addition, CRH may increase ACTH responsiveness in fetal adrenal cortical cells (especially cells in the transitional zone) by increasing ACTH receptor expression in fetal

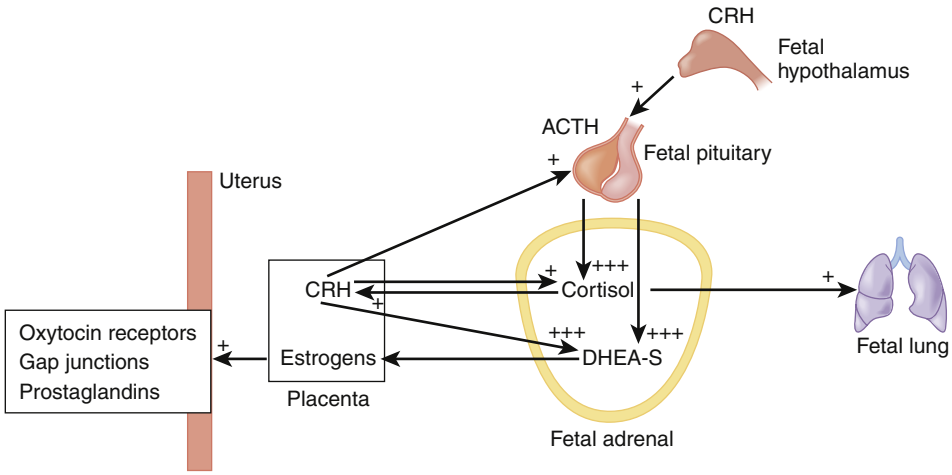

FIGURE 12.16 Schematic model of how placental corticotropin-releasing hormone (CRH) modulates activity of the fetal-placental unit. An increase in bioactive placental CRH at term has effects on both the fetus and the mother. In the fetus, CRH stimulates the fetal adrenal directly, to stimulate production of DHEA-S, which is converted by the placenta to estrogen, which in turn, drives expression of CAPs necessary for uterine contractions and parturition. The placental CRH may also act on the fetal adrenal cortex by up-regulating ACTH receptor expression and increasing responsiveness to ACTH, which evokes fetal adrenal cortisol production from the definitive zone and DHEA-S production from the fetal zone. A feed-forward loop is thus started as fetal adrenal cortisol production, in turn, stimulates CRH production by the placenta. *(From Smith R, Mesiano S, Chan EC, Brown S, Jaffe RB. Corticotropin-releasing hormone directly and preferentially stimulates dehydroepiandrosterone sulfate secretion by human fetal adrenal cortical cells.* J Clin Endocrinol Metab *83:2916–2920, 1998.)*

adrenal cortical cells.[251] As a result, fetal adrenal cortisol and placental estrogen synthesis increase through a positive feedback loop involving placental CRH (Fig. 12.16).

Urocortins, and especially urocortin-II, may also regulate myometrial contractility and the process of human parturition via their interaction with the type-II CRH receptor in myometrial cells.[121,129,333] Other studies have suggested that urocortin augments PG production by the placenta.[334]

Role of Uterotonins in Human Parturition

Uterotonins are substances that modulate myometrial tone and contractility (see also Chapter 28). The main uterotonins involved in human labor are OT and PGs (mainly PGE_2, PGI_2, and $PGF_{2\alpha}$). In addition, PGs (especially PGE_2) also promote cervical ripening. The physiological actions of PGs and OT are thought to be terminal events in the human parturition cascade and occur downstream of progesterone withdrawal and estrogen activation. Therefore, disruption of PG and OT action has attracted considerable attention as tocolytical strategies for the treatment of preterm labor.

Prostaglandins

A considerable body of data has accumulated in the last 30 to 40 years demonstrating that PGs produced by intrauterine tissues are critical regulators of myometrial contractility (see Chapter 6).[335,336] Key among these are following observations: (1) administration of PGE_2 or $PGF_{2\alpha}$ at any stage of human pregnancy will induce uterine contractions and cervical ripening and cause labor and delivery;[337,338] (2) inhibition of PG biosynthesis with aspirin, indomethacin, or specific PTGS2 inhibitors suppresses labor and prolongs gestation,[339,340] and (3) production of PGE_2 and $PGF_{2\alpha}$ by intrauterine tissues (particularly the amnion, chorion, decidua, and myometrium) increases late in gestation and in association with the onset of labor.

PGE_2 and $PGF_{2\alpha}$ stimulate uterine contractions by increasing intracellular calcium, which then triggers the contractile machinery by facilitating myosin light chain phosphorylation. By far the most abundant PG in the gestational tissues, and especially in the myometrium, is PGI_2 which is thought to relax the myometrium by increasing cAMP levels in myometrial cells. However, studies using specific PGI_2 receptor (IP) antagonists have shown that, although activation of IP increases cAMP levels and PK-A activity in myometrial cells, it also increases expression contractile proteins such as connexin-43.[341] This suggests that PGI_2 could contribute to the parturition process even though it is considered to be a relaxatory PG.

The regulation of intrauterine PG production is considered to be a pivotal event in human parturition. The rate-limiting step in PG biosynthesis is catalyzed by two isozymes, PTGS1 and PTGS2 (also known as cyclooxygenase-1 and cyclooxygenase-2) (see Chapter 6). PTGS1 is constitutively expressed in most tissue types, whereas PTGS2 expression is inducible, increasing in response to various physiological conditions and especially in response to proinflammatory stimuli. PGs are metabolized by the prostaglandin dehydrogenase (PGDH) enzyme, which irreversibly converts PGE_2 and $PGF_{2\alpha}$ to inactive forms.

Intrauterine biosynthesis of PGs occurs mainly in the amnion and, to a lesser extent, in the chorion. Both tissues express PTGS2, which increases in association with the onset of term and preterm labor. PGs also are produced in the decidua and in the myometrium, and in both sites, production increases at the time of labor. In the fetal membranes, PTGS2 expression increases during the third trimester and several weeks before the onset of labor.[342] This finding supports the notion that intrauterine PG production rises as part of the parturition process rather than as a consequence of labor.

Exposure of the myometrium to fetal membrane-derived PGs is dependent on the balance between PTGS2

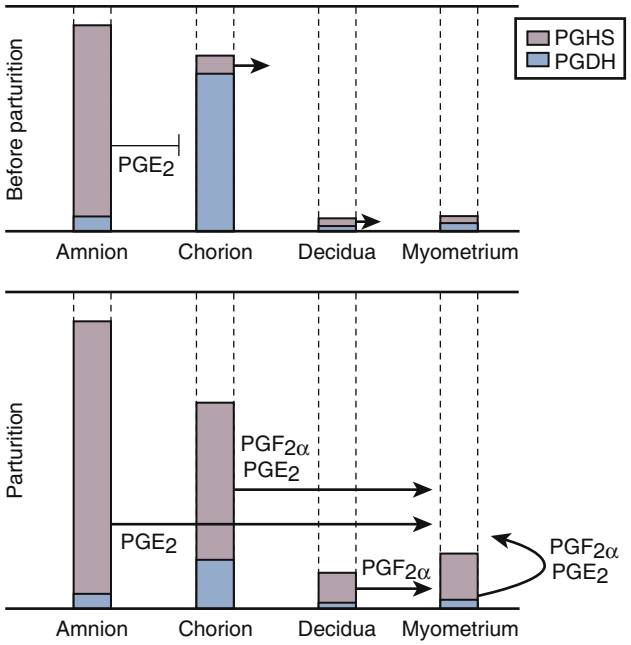

FIGURE 12.17 Changes in prostaglandin endoperoxide H synthase (PGHS) and prostaglandin dehydrogenase (PGDH) activities in the fetal membranes decidua and myometrium associated with the onset of human labor. Parturition is associated with a marked increase in PGHS activity in all tissues. PDGH is predominantly expressed by the chorion and effectively blocks amnion prostaglandins (PGs) from accessing the myometrium. Parturition is associated with decreased PGDH activity in the chorion which could allow more active PG to reach the myometrium.

and PGHD activities in the chorion. PGs produced by the amnion accumulate in amniotic fluid and do not necessarily gain access to target receptors on myometrial cells because the chorion, which lies between the amnion and the maternal tissues of the uterus, expresses high levels of PDGH.[343] Thus, through most of pregnancy the chorion may act as a barrier, preventing amnion-derived PGs from activating the myometrium (Fig. 12.17). Several studies have indicated that propregnancy factors such as progesterone prevent myometrial exposure to PGs by stimulating PGHD and inhibiting PTGS2. In contrast, cortisol, CRH, and several immune cytokines may inhibit PGDH and stimulate PTGS2, leading to a net increase in active PGs accessing the myometrium.[335] Thus, the balance of PG synthesis and metabolizing activities in the fetal membranes may be pivotal in the control of uterine contractility.

During pregnancy, the human myometrium expresses receptors for PGE_2, $PGF_{2\alpha}$, PGI_2, and thromboxane.[344] The pleiotropic actions of PGs in diverse tissue types can be explained by the existence of multiple receptor species linked to different intracellular signaling pathways.[345] For example, PGE_2 interacts with four subtypes of PGE_2 receptors (EPs): EP1, EP2, EP3, and EP4. In addition, eight splice variants of the EP3 receptor have been identified.[346]

With regard to myometrial contraction, the diversity of PGE_2 receptor types may have important physiological ramifications. Interaction of PGE_2 with EP1 and EP3 increases intracellular calcium and decreases cAMP, leading to contraction. In contrast, interaction of PGE_2 with EP2 and EP4 activates adenylate cyclase, leading to increased cAMP and relaxation. Thus, PGE_2 can cause uterine contraction or relaxation depending on the type and cohort of EPs expressed. In contrast, $PGF_{2\alpha}$ interacts with a single $PGF_{2\alpha}$ receptor (FP) that increases intracellular calcium leading to contraction. PGI_2 binds the PGI_2 receptor (IP) that is linked to adenylate cyclase, leading to increased intracellular cAMP and relaxation; although it may also increase CAP gene expression. Thromboxane binds to the thromboxane receptor (TP) and increases calcium and augments contractility.

The regulation and localization of specific PG receptors in the myometrium and cervix is thought to be an important component in the endocrine control of pregnancy and parturition. Studies of EP and FP expression in the term human uterus have shown that EP2 expression is greater than FP before the onset of labor and decreases with increasing gestation and that expression of the FP receptor is low before labor and increases significantly in association with the onset of labor.[347] These findings indicate that myometrial relaxation through most of pregnancy is maintained at least in part by EP2, whereas the onset of labor involves an increase in myometrial FP, allowing $PGF_{2\alpha}$ to stimulate contraction. The balance between PG receptors mediating relaxation and contraction and their distribution in the uterus (fundal or cervical) may determine the net effect of PGs on the process of labor.

Oxytocin

Oxytocin is one of the most potent stimulators of uterine contraction. It is routinely administered to promote labor and treat postpartum hemorrhage. OT is a 9-amino acid peptide secreted by the posterior pituitary and is also produced in a number of peripheral tissues, including the ovary. During pregnancy, OT is produced by the amnion, chorion, and decidua.[348] OT is not generally considered to be involved in the initiation of labor because its circulating levels do not increase until the expulsive phase of labor.[349] This is not unexpected, because vaginal distention is a principal stimulus for the release of pituitary OT in human labor, via a neurologic feedback mechanism known as the Ferguson reflex.

However, as with PGs, OT produced by intrauterine sites may play a significant paracrine role in regulating uterine contractions at parturition. The mechanisms underlying the control of intrauterine OT production and its potential to stimulate uterine contractions remain uncertain. Despite this, it is clear that OT contributes to the uterotonic milieu of human parturition because inhibition of OT action by specific synthetic antagonists disrupts the normal pattern of labor, decreases uterine contractility in women with threatened preterm labor, and significantly prolongs gestation.[350,351]

OT action appears to be regulated at the level of target tissue responsiveness by changes in OT receptor (OTr) expression. In the human, myometrial and decidual OTr content and expression increase gradually toward the end of pregnancy and then rise significantly in association with the onset of labor.[352] Expression of the OTr by myometrial cells is up-regulated by estrogen and is part of the cassette of CAPs thought to transform the myometrium to the laboring phenotype.[353] Thus, induction of OT responsiveness by increased OTr expression may be the principal mechanism

underlying the uterotonic actions of locally produced and pituitary OT in human pregnancy. After birth, pituitary oxytocin contributes to uterine involution and especially the tonic contraction of the myometrium needed for postpartum hemostasis. OT also affects the preparation of the breast for lactation (see Chapters 3 and 10).

CHAPTER 13

The Hypothalamo-Pituitary Unit, Testis, and Male Accessory Organs

Peter Y. Liu
Johannes D. Veldhuis

The function of the hypothalamo-pituitary-testicular-accessory organ axis is to ensure normal androgenization (including embryonic, infantile, pubertal, and adult sexual maturation), male sexual behavior, and reproductively competent sperm output. Thus, the system is important for both the health of individuals and preservation of humankind. All elements in the system acting together as an integrative regulatory network are critical for male reproductive health. Dysfunction may result in ambiguous genitalia, sex reversal, pubertal delay, eunuchism, impaired spermatogenesis, and reduced systemic androgen exposure. Furthermore, partial deficiency of reproductive hormones may contribute to some of the features of male aging, impair recovery from protracted critical illness, and induce visceral adiposity with insulin resistance. This chapter reviews the hypothalamo-pituitary-testicular axis, its components, and their joint regulation. Where practicable, emphasis is on newer discoveries in humans. Hormonal methods to regulate male fertility and to limit age-associated frailty constitute examples of how knowledge of male reproductive physiology is being translated into clinical practice.

Physiology of the Male Gonadal Axis

Overview: Ensemble Nature of Reproductive System

Male reproductive hormones consist of hypothalamic decapeptides, gonadotropin-releasing hormones (GnRH), pituitary gonadotropins, luteinizing and follicle-stimulating hormones (LH and FSH), testicular steroids, testosterone and estradiol (Te and E_2), and putatively systemically active gonadal peptides like inhibin B. Integration requires repeated incremental and decremental feedforward (stimulatory) and feedback (inhibitory) signaling among neural and hormonal components of the axis (Fig. 13.1). The negative-feedback system can be exploited to regulate male fertility by suppressing spermatogenesis with exogenous sex hormones. Gonadotropin and Te deficiency can result in infertility or subfertility, impaired sexual maturation, reduced muscle and bone mass, insulin resistance, visceral fat accumulation, diminished erythropoiesis, libido, potency, and general well being.[1]

Essential Roles of GnRH and Upstream KiSS1 Neurons

In the adult, specialized neurons (approximately 1200 in the human) located in the arcuate-nucleus of the mediobasal hypothalamus secrete GnRH in a pulsatile fashion into a portal microvasculature system. GnRH pulses stimulate gonadotropes located in the anterior pituitary to secrete LH and FSH.[2] In the embryo, migration of GnRH neurons from the olfactory placode into the upper diencephalon is essential to establish the anatomical proximity required for effectual hypothalmo-pituitary signaling. Several genes (KAL1, KAL2, and PROK2) are critical for both olfactory-bulb morphogenesis and proper GnRH neuronal migration. KAL1, KAL2, and PROK2 are located on chromosomes X, 8, and 3, and respectively encode anosmin-1, fibroblast growth-factor (FGF) receptor 1, and prokineticin 2.[3] Inactivating mutations of any of these genes, including FGF8 which is the ligand for the FGF receptor 1, and less commonly neuroembryonic LHRH factor (NELF) cause Kallmann syndrome.[4] The syndrome is characterized clinically by hyposmia or anosmia and isolated gonadotropin deficiency.[5] Inheritance patterns are respectively X-linked, autosomal dominant and recessive for defects in anosmin, FGF-receptor 1, and prokineticin or its receptor. Recently identified mutations in the chromodomain helicase deoxyribonucleic acid (DNA) binding protein-7, which cause CHARGE syndrome, may also present with Kallmann syndrome and idiopathic hypogonadotropic hypogonadism.[6,7]

Pulsatile GnRH release is both intrinsic to clusters of GnRH neurons and essential to stimulate LH secretion over the long term. Continuous GnRH delivery downregulates gonadotrope GnRH receptors and signaling pathways, which forms the basis for treating prostatic cancer and precocious puberty with long-acting GnRH agonists.[8] Episodic GnRH secretion begins during fetal development when GnRH neurons first populate the mediobasal hypothalamus. A second surge of high-amplitude LH pulsatility emerges in infant boys during the first several months of

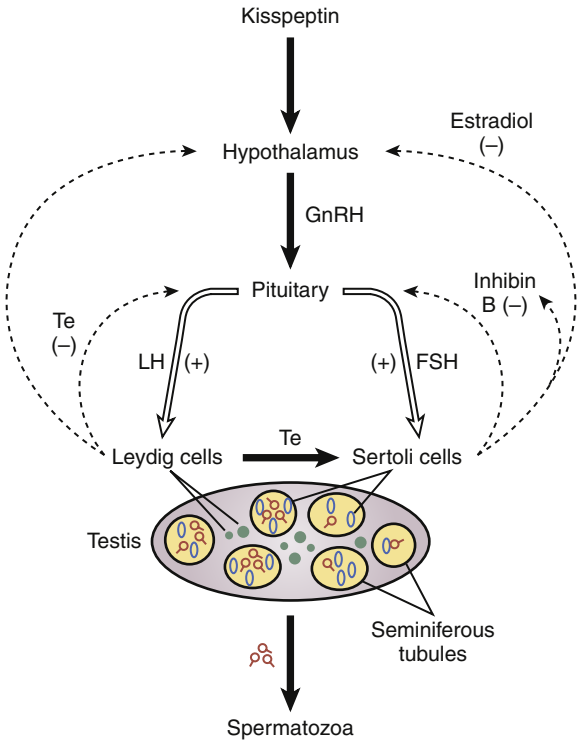

FIGURE 13.1 Schematic representation of the human male gonadal axis. The *left* side highlights feedforward (stimulation) by gonadotropin releasing hormone (GnRH) on luteinizing hormone (LH) secretion and LH on testosterone (Te) secretion as well as feedback (inhibition) by Te onto hypothalamic GnRH and pituitary LH outflow. The *right* side presents GnRH → follicle stimulating hormone (FSH) drive and FSH → inhibin B/estradiol (E_2) feedforward, and conversely feedback by inhibin B and E_2. The inhibin B feedback loop has not been demonstrated directly in men. *(Adapted from Liu PY, Takahashi PY, Nehra AX, et al: Neuroendocrine aging: pituitary-gonadal axis in males. Squire, L. R. Encyclopedia of Neuroscience.* Oxford, Academic Press *6:317–326, 2009, Fig. 6.)*

Table 13.1 Selected Putative Nonsteroidal Regulators of GnRH Neurons

Ligand	Role	Reference
GnRH	Autoinhibit (or stimulate)	316-318
Kisspeptin	Activate GPR54 receptor on GnRH neurons	24,319
Galanin, neuromedin B	Stimulatory of GnRH release	317,320,321
Glutamate	Activate N-methyl-D-aspartate receptor	322,323
Norepinephrine	Excitatory (beta-1 receptor) or inhibitory (alpha-1 receptor)	324-326
GABA*	Inhibit or stimulate	327-331
Nitric oxide	Stimulatory	332,333
Dopamine	Repressor or activator	334,335
Neuropeptide Y	Activate or inhibit via distinct receptor subtypes	336-338
CART†	Stimulate	339,340
Opiatergic peptides	Repress, (e.g., dynorphin)	341
Prolactin	Inhibit via cognate receptor	342
Calcitonin gene-related peptide	Inhibit	343
Ciliary neurotrophic factor	Stimulate	344
Leptin, orexin A/B	Stimulate GnRH outflow fasting	345
Somatostatin	Inhibit GnRH neurons	317
Serotonin	Inhibit or stimulate (via 5HT-1A or 2C and 4)	346
Tachykinins, neurokinin B and Substance P	Stimulatory	347,348

*Gamma-amino butyric acid acts via a type A or type B receptor.
†Cocaine- and amphetamine-regulated transcript.
CRH, AVP, and α-MSH inhibit, whereas melanin-concentrating hormone stimulates, GnRH release.[349,350] (Not shown.)

age.[9] GnRH secretion declines during childhood only to be reinstated at markedly higher amplitude and slightly higher frequency in puberty.[10,11]

The kisspeptin-kiss1R system controls the timing of puberty, and may also regulate GnRH secretion in other epochs of life.[12-14] Kiss1R (formerly known as GPR54) is a G-protein coupled receptor expressed on GnRH neurons.[15] KiSS-1 is the gene that encodes kisspeptin-121, which is proteolytically cleaved to a 54 amino-acid peptide named kisspeptin-54 (also known as metastin) and kisspeptin-14 and -13. Kisspeptin-54 is the natural ligand for the receptor Kiss1R. Inactivating mutations of either KiSS-1 or Kiss1R in mice and of KiSS1 in men result in normosmic hypogonadotropic hypogonadism, thus establishing that kisspeptin and cognate receptor are necessary upstream activators of GnRH neurons.[16] Mutations in the genes tachykinin 3 (TAC3) and TACR3, which encode the peptide neurokinin B and its receptor, respectively, also result in hypogonadatropic hypogonadism.[17] Furthermore, specific neurons (kisspeptin neurokinin B dynorphin [KNDy] neurons) in the arcuate nucleus of the hypothalamus, which coexpress kisspeptin, neurokinin B and the endogenous opioid peptide, dynorphin, are critical for sex-steroid feedback regulation of GnRH secretion. Proximate control of kisspeptin neurons and Kiss1R receptors by sex steroids and neurotransmitters is under intensive study. Table 13.1 highlights some of a myriad of GnRH regulators, whose site(s) of action require more precise definition. Regulators include seasonal, appetitive, anorexigenic, stress-associated, and anabolical (trophic) factors.

Sex steroids, acting in part via estrogen-receptor alpha, regulate KiSS1, neurokinin B, and dynorphin gene expression in a brain region-specific manner.[18] Estrogen and androgen repress both KiSS1 and dynorphin in KNDy neurons in the arcuate nucleus, thereby inferably transducing sex-steroidal inhibition of GnRH outflow.[19-21] This is not true in the anteroventral periventricular nucleus, which directs positive feedback by estrogen in female rodents (Fig. 13.2). The latter site contains few KiSS1 neurons in the male. Other neurotransmitters may be important, since the administration of antihypertensives (particular alpha-adrenergic blockers, selective serotonin-reuptake inhibitors, gamma-aminobutyric acid agonists, and dopamine) can influence LH secretion. However, whether such effects are direct or indirect with respect to KiSS1 and GnRH neurons remains largely unexplored.[22]

Differential Control of LH and FSH Secretion

GnRH preferentially stimulates FSH secretion in childhood and LH secretion in infancy, puberty, and adulthood.[23] Like

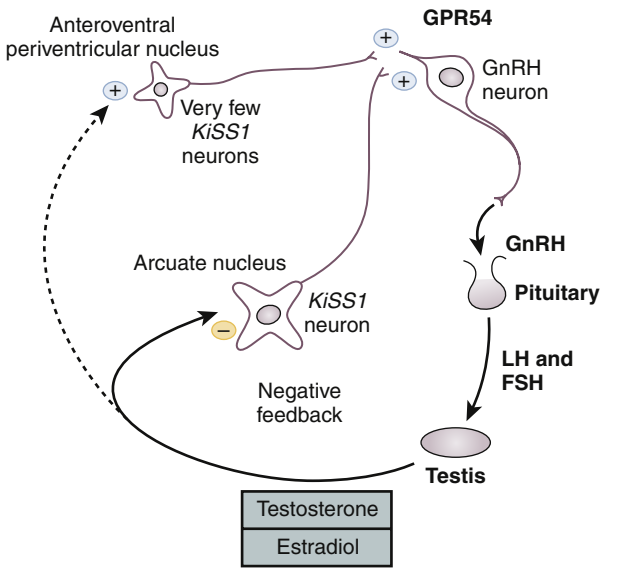

FIGURE 13.2 Model of kisspeptin-GPR54 signaling in the brain of male rodent. KiSS1 neurons in the arcuate nucleus (ARC) secrete kisspeptin, which acts as a stimulatory input to GnRH neurons. Kisspeptin signals via GPR54 expresses on GnRH neurons. KiSS1 neurons also express neurokinin B and dynorphin. The KiSS1 gene is negatively regulated by gonadal sex steroids, thereby providing a plausible mechanistic basis for inhibitory effects of Te and E_2 on hypothalamic GnRH, and secondarily on pituitary LH and FSH, secretion. Males possess very few, whereas females possess numerous, KiSS1 neurons in the anteroventral periventricular nucleus (AVPV). *(Adapted from Kauffman AS, Clifton DK, Steiner RA: Emerging ideas about kisspeptin-GPR54 signaling in the neuroendocrine regulation of reproduction.* Trends Neurosci *30:504–511, 2007, Fig. 1.)*

GnRH, kisspeptin stimulates LH release twofold more than FSH release in healthy men.[24] The putative bases for these distinctions include feedforward and feedback factors. With respect to feedforward, slower GnRH pulse frequencies prior to puberty favor gonadotrope biosynthesis of specific FSH-beta over LH-beta subunits.[2,25,26] In addition, the dimeric glycoprotein, activin A, may stimulate FSH secretion in the prepubertal rat and nonhuman primate.[27-29] At a second level of feedforward, blood-borne FSH acts on Sertoli cells in spermatogenic tubules to drive inhibin B and E_2 secretion, and LH acts on Leydig cells in the testis interstitium to cause Te production.[30] There is some indirect evidence that FSH can also increase Te production, possibly via Sertoli cell-secreted nonsteroidal factors,[31,32] but the effect is quantitatively small.[33] In relation to resultant feedback,[34-36] pubertal elevations in inhibin B and E_2 concentrations would tend to restrict FSH responses to GnRH.[37-39] Elevated Te concentrations would likewise tend to repress the rise in LH concentrations. The fact that the latter does not occur suggests muting of Te's feedback and/or strong central GnRH drive. Both mechanisms are inferable from mathematical feedback analyses performed in transpubertal cohorts of boys.[11]

Te's negative feedback on LH is mediated primarily[40] but not exclusively[41] via aromatization to E_2.[42] Significant feedback occurs at the pituitary level. Sex steroids repress GnRH secretion, but inhibition is not likely to be direct because GnRH neurons do not express the androgen receptor (AR) or estrogen receptor-α(ERα). Although ER-β is detectable and might enhance Ca^{2+}-dependent synchrony of GnRH neurons,[43] transgenic silencing of AR or ERα rather than ERβ is needed to elevate LH and Te concentrations in the adult animal.[44,45] These data favor a feedback role of KiSS1 neurons, which express both AR and ERα.[46] In addition, nongenomic actions of Te and E_2 transduced via membrane-dependent signaling may contribute to feedback in some species.[47]

GnRH and GnRH Receptors

More than 23 different GnRH peptides exist among species.[48] Human GnRH decapeptide exists in at least two forms designated GnRH I and GnRH II, cloned initially in mammals and chickens, respectively.[49] The genes encoding these peptides are located on chromosome 8p11-21 and 20p13, respectively.[50] Rapid and slow GnRH half-lives in men are about 2.6 and 5.2 min.[51] GnRH I is the predominant agonistic peptide regulating gonadotropin secretion in humans.[52] In animals, GnRH II seems to stimulate sexual arousal and courting behavior,[53] whereas GnRH III (lamprey) induces significant FSH release.[54] Truncational mutation of the GnRH-I gene occurs in the *hpg/hpg* mouse, but has not been described in man.[55]

At least 23 GnRH-receptor types have been cloned to date.[49] GnRH receptors are calcium-dependent G-protein coupled receptors (GPR's),[56,57] which control the activity of intracellular heterotrimeric G proteins by promoting guanine-nucleotide exchange and activation of adenylyl cyclase, transmembrane Ca^{2+} influx or intracellular Ca^{2+} mobilization.[56] GPR's contain seven transmembrane segments that form α-helices connected by three extracellular and three intracellular loops. Receptor activation causes a conformational change in the associated G protein α-subunit, promoting the release of GDP and binding of the activator nucleotide, GTP. The GTP-bound α-subunit dissociates from the receptor leaving a stable βγ-dimer. Dissociated subunits modulate cellular signaling as proximate messengers in the cyclic AMP-protein kinase A (α subunit) and phospholipase C-protein kinase C (βγ dimer) pathways. High intrahypothalamic concentrations of GnRH may mediate autoinhibition via a G_i subunit.[58]

Two distinct GnRH receptors have been identified in man. GnRH I receptor is the hypophyseal receptor coupled to LH and FSH synthesis, which is encoded by a gene located on chromosome 4. Two splice variants of the GnRH I receptor exist.[59] Both GnRH I (secreted) and GnRH II (brain) peptides can activate the GnRH I receptor. The GnRH II receptor gene is located on chromosome 1,[50] but is silenced in the human, chimpanzee, cow, and sheep.[53] GnRH regulates neurotransmission and sexual behavior in the rodent via the GnRH II receptor.[49] Truncational, nonsense, and missense mutations in the GnRH receptor I gene or homeobox genes (LHX3) can lead to nonexpression, inactivation, misfolding, and misrouting of nascent receptors, and thereby autosomal recessive hypogonadotropic hypogonadism without anosmia.[60,61] Activating mutations of the GnRH receptor could result in isosexual precocious puberty, but have not yet been identified.[62] Other non-GnRH signals (e.g., IGF-I, galanin, activin A, inhibin B, follistatin, cytokines, gonadotropin-inhibitory hormone) may

potentiate or inhibit GnRH action in the pituitary in animal models.[49,63-68]

Gonadotropins and Cognate Receptors

Gonadotropins comprise lutropins (LH and human chorionic gonadotropin, hCG) and follitropin (FSH). Gonadotropins and thyroid-stimulating hormone (TSH) are oligosaccharide-modified dimeric proteins with a molecular mass of 30-40 kDa. All four corresponding genes are expressed in the human pituitary gland, albeit minimally in the case of hCG.[69] Each contains a common α subunit and a hormone-specific β subunit. Subunits are associated by noncovalent interactions, but cysteine residues (10 in the α subunit and 12 in the β subunit) permit disulfide linkages within subunits. The α subunit is encoded by a single gene localized at 6q12.21.[70] Mutations of this gene have not been identified, possibly because simultaneous loss of all glycoprotein hormones may be lethal *in utero*. The α subunit gene is larger than the β subunit gene because of a noncoding exon 1 and a long first intron, but the translated proteins are comparable in size. Beta-subunit genes are located on chromosomes 19q13.32 (LH-hCG cluster) and 11p13 (FSH). The human LH-hCG cluster consists of one LHβ and 6 hCGβ genes and pseudogenes. Glycosylation and terminal sialylation or sulfation via critical N- and O-linked sites within α (two sites) and β (one site in LH, two in FSH and TSH) subunits influence *in vivo* bioactivity, receptor binding, and metabolical clearance.[71] In particular, four O-linked glycosylation linkages present in an extended C-terminal portion of hCGβ (but not LHβ) increase intact hCG half-life to 24 to 30 hours compared with 1 hour for LH, and augment biopotency by limiting hCG-receptor dissociation.[72]

Exonic polymorphisms and mutations have been described for each gonadotropin β subunit (hCG, LH and FSH) gene.[70] In mice, knockout of LHβ results in decreased production of Te and fewer elongated spermatids.[73] One polymorphism of LHβ, termed variant LHβ, occurs in as many as 30% of some Northern European and Australian aboriginal populations, and contains two amino-acid transversions (Ile15Thr and Trp8Arg) and a supernumerary consensus glycosylation site (Asn13-Ala-Thr) reminiscent of hCGβ. Variant LH is more biopotent, but has a shorter *in vivo* half-life than wild-type LH putatively due to resistance to peptidases or impaired sialylation and sulfation of terminal oligosaccharides.[74] In contrast, mutations of the FSHβ gene are rare in men. There are only three reported cases, each being associated with azoospermia[32,75,76] and one with hypoandrogenism.[76]

The LH-hCG receptor is a G-protein coupled receptor that is encoded by an 11-exon gene located on chromosome 2p21.[77] Unlike the FSH receptor, the lutropin receptor expressed is widely outside the gonad including in the brain, leading to speculative extragonadal actions of LH or hCG.[78,79] Men with inactivating LH-receptor mutations present with male pseudohermaphroditism and a phenotype ranging from micropenis and hypospadias to complete feminization, in each case without an extragonadal phenotype. Activating mutations of the LH-hCG receptor become manifest as gonadotropin-independent (familial) male sexual precocity or testotoxicosis.[80] LH-receptor polymorphisms have also been described (such as Asn291Ser and Asn312Ser) in association with undermasculinization[81] and Leydig cell hypoplasia.[82] A rare splice variant (deleted exon 9) is marked by inhibitory properties.[83] Thus, structural analyses of interactions among LH receptor, ligand, and relevant G proteins should lead to targeted ligand discovery.[84]

The FSH receptor is also a G-protein coupled receptor, but is encoded by a 10-exon gene located on chromosome 2p21.[85] The crystal structure has been determined, revealing a hand-clasp interaction between the receptor and FSH (follitropin) that orients the glycoprotein hormone perpendicular to the long axis of the ligand-binding domain.[86] The follitropin receptors appears to be expressed exclusively on Sertoli cells located within the blood-testis barrier formed by tight junctions.[87] For this reason, FSH is believed to regulate spermatogenesis primarily. A few controversial reports exist of FSH-receptor expression elsewhere, such as on spermatogonia[87] or skeletal osteoclasts.[88] Replication of these preliminary findings is required.[89]

Polymorphisms of the FSH receptor occur, but their influence on signal transduction and spermatogenesis remains unclear.[70] Inactivating mutations of the FSH receptor in five men were associated with subfertility (three cases) and fertility (two cases) with phenotypic variations ranging from oligozoospermia to euspermia.[90] Such data suggest that very low receptor activity is sufficient for spermatogenesis, or that other endocrine or intratesticular factors may compensate to varying degrees.[91] An activating mutation of the FSH receptor was reported,[92] but functional significance has not been corroborated.

In young men, FSH seems necessary for the formation of spermatogonia type B and pachytene spermatocytes, and LH/hCG for round spermatids.[93] In contrast, LH is the dominant agonist of steroidogenesis.[94]

Testicular Steroidogenesis

Testosterone (Te) is the most important local and systemic androgen produced by the testis. Te concentrations are similar by race and ethnicity, but decline with increased abdominal visceral fat and with age.[95-97] In contrast, African-American men have higher E_2 and sex-hormone binding globulin (SHBG) concentrations than their white counterparts. Androgens are crucial for male reproduction and general health. Testosterone triggers the development of male secondary sexual characteristics at puberty, maintains adult sexual behavior and function, and drives late stages of spermatogenesis independently of its metabolite 5α-dihydrotestosterone (DHT).[98] During fetal development, Te is essential for differentiation of the internal and DHT the external male urogenital system. Inactivation of 5α-reductase type I in mice is lethal to the embryo (putatively due to unopposed brain estrogen toxicity), whereas inactivation of 5α-reductase type II in mice and men leads to male pseudohermaphroditism (perineoscrotal pseudovaginal hypospadias, hypoplastic prostate tissue, and decreased male-pattern balding and beard growth).[99] Despite low or absent DHT in such XY individuals, Te is sufficient to ensure wolffian-duct differentiation (*viz.*, epididymides, vasa deferentia, seminal vesicles). Other androgens, such as the reduced metabolite, 5α-androstane-3α,17β-diol, are important for fetal sexual maturation in marsupials, but their roles in primates are unknown.[100,101]

Leydig cells are located in the interstitial compartment of the testis, which allows secretion of Te and E_2 into seminiferous tubules, gonadal lymphatics and venules. Fetal Leydig cells and maternal hCG are responsible for an intrauterine peak in Te secretion at 12 to 14 weeks of gestation. This peak is critical for male urogenital-tract organogenesis. Testosterone production declines during the remainder of *in utero* life as fetal Leydig cells begin to degenerate. Augmented pulsatile LH secretion and neonatal proliferation of Leydig cells result in a second peak of androgen production at 2 to 3 months of postnatal age.[9] The neonatal peak is putatively important for imprinting masculine behavior at least in animals. Fetal Leydig cells undergo apoptosis, but are slowly replaced as mesenchymal stem cells populate the interstitium, and differentiate into initially immature Leydig cells that secrete 3α- and 5α-reduced androgens rather than Te. Further division and differentiation occur in puberty, when mature (adult) Leydig cells secrete large amounts of Te (Fig. 13.3). Beginning in young adulthood and progressively thereafter, total Te concentrations fall gradually by 0.6% to 1.1% annually.[102,103] resulting in a net decrement of 35% to 50% from the young-adult maximum by the eighth decade in life.[96,104]

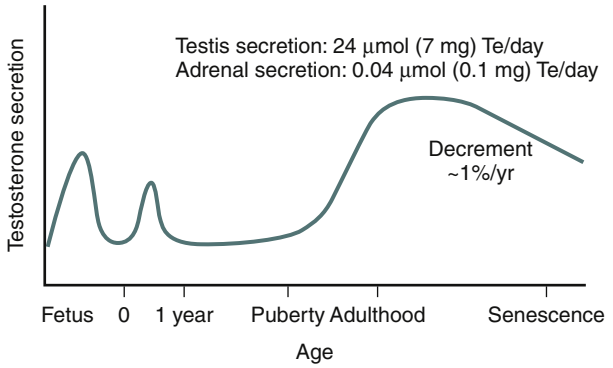

FIGURE 13.3 Schematic profile of testosterone (Te) secretion over the human male lifetime. There are three prominent intervals of amplified Te production.

Testosterone is synthesized from cholesterol through sequential reactions that are catalyzed by cytochrome P450-containing complexes. A defect in any step results in variably severe male pseudohermaphroditism (46XY infant with undermasculinization of the external genitalia). Five major steps are involved, namely cholesterol C20,22-desmolase (CYP11A cholesterol side-chain cleavage), 3 β-hydroxysteroid dehydrogenase/$\Delta^{4,5}$-isomerase, (3 β-OHSDH), C17,20-desmolase/17α-hydroxylase (CYP17A), and 17 β-hydroxysteroid dehydrogenase type III (Fig. 13.4). Cytochrome P450 refers to a 450-nm light-absorbing heme-binding peptide sequence that is critical for stoichiometry. The enzymatically rate-limiting step in steroidogenesis is encoded by CYP11A, which converts cholesterol to pregnenolone in the inner mitochondrial membrane. However, the kinetically rate-limiting step is delivery of LDL-, membrane, and cholesteryl ester-derived free cholesterol to the inner mitochondrial leaflet by steroidogenic acute regulatory (StAR) protein.[105,106] LH activates StAR rapidly via posttranslational modification and slowly via increased gene transcription. Combined responses ensure both immediate and sustained access of cholesterol to mitochondrial side-chain cleavage system.

Pregnenolone leaves mitochondria and enters endoplasmic reticulum, where subsequent enzymatic modifications occur. Pregnenolone (or its 3 β-reduced metabolite, progesterone) undergoes sequential cleavage and hydroxylation via CYP17A-encoded C17,20 lyase/17α-hydroxylase (a single enzyme with dual functions), which constitutes the androgen-committing step. The product is a weak ketosteroid, androstenedione,

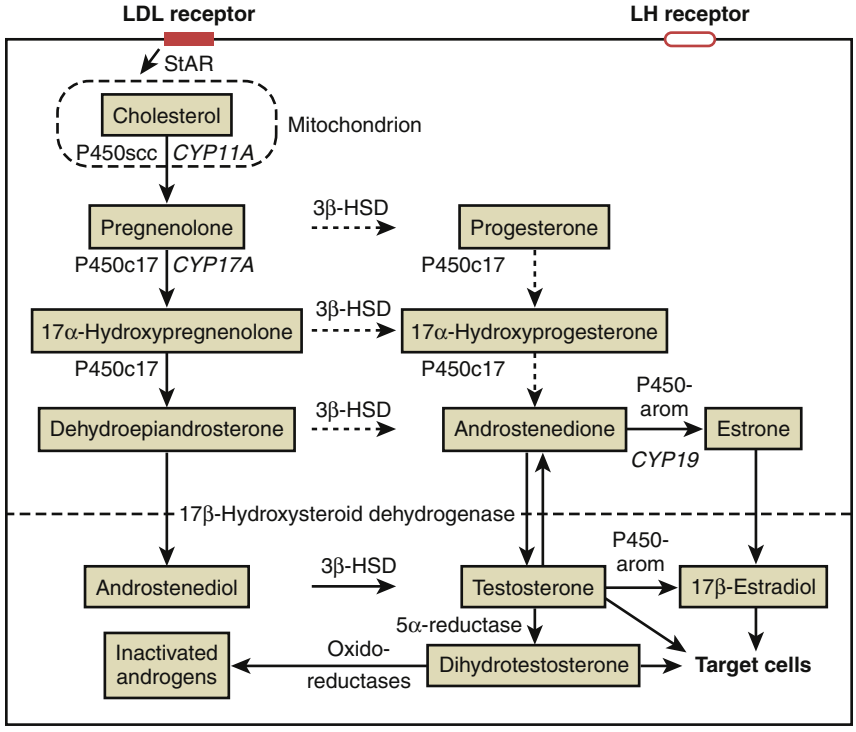

FIGURE 13.4 Testosterone (Te) biosynthesis in Leydig cells. The principal (Δ^5) pathway in humans is indicated by continuous arrows. The Δ^4 route *(dashed arrows)* is more important in other species. Some Te is taken up by Sertoli cells, which convert the androgen to E_2 and DHT. LDL, low-density lipoprotein; P450scc, cytochrome P450 cholesterol side-chain-cleavage enzyme (CYP11A); 3β-HSDH, 3β-hydroxysteroid dehydrogenase; P450c17, C17,20-lyase/17α-hydroxylase (CYP17A); P450arom, aromatase (CYP19); StAR, steroidogenic acute regulatory protein. DHT is inactivated to 3α- and 3β-diol metabolites.

which must be converted to the potent hydroxysteroid, Te, via 17β-hydroxysteroid dehydrogenase type 3.[107,108]

In men, gonadal steroidogenesis accounts for over 95% of Te production with the remainder produced by the adrenal gland and extraglandular conversion of the weak androgenic precursors, dehydroepiandrosterone and androstenedione, to Te.[109,110] Te production in young men averages 15 to 30 μmol (4 to 9 mg) per day. Estimates are consistent when determined by infusion of stable or radioactive isotopes and recent noninvasive analytical methods.[111-117] Testosterone secretion is determined genetically and environmentally. For example, men convert more Te to E_2 by peripheral aromatization and more androstenedione to Te via 17β-hydroxysteroid dehydrogenation than women.[118] In addition, Te concentrations differ between ethnic Chinese men living in an Asian compared with a Western environment.[113,119] Combined factors also may explain some populational differences in 5-α reduced metabolites and prostate volume.[120]

Intratesticular regulation of Leydig cells is complex, and not yet fully understood.[121] All three of spermatogonial, peritubular myoid, and Sertoli cells exert effects on Leydig-cell steroidogenesis.[94,122] Central nervous-system and spinal-cord pathways that innervate the testis further modulate testicular steroid production, particularly in the settings of inflammatory stress, alcohol intoxication and central adrenergic modulation.[123]

Aromatization, 5α-Reduction and Inactivation of Te

Untransformed Te exerts potent anabolical effects. Te also functions as a prohormone, which undergoes conversion to other steroids, such as E_2 and DHT.[1] Converted steroids can mute or amplify, and thus diversify, Te's actions through ligand-receptor and coactivator specificities (Fig. 13.5). In particular, DHT binds ERα negligibly,[124] whereas E_2 binds AR with an affinity one order of magnitude less than that of Te.[124] Testosterone directly stimulates AR, but with a potency two to thirtyfold less than that of DHT depending upon target tissue. Thus, by being reduced or aromatized, Te may oppose or potentiate the actions of E_2 on certain genes.

Estradiol acts via two primary (and multiple variant) ERs, whereas Te and DHT act via a single AR. Heterogeneity of tissue responses is presumably conferred via cellular differences in the expression of AR and important corepressors and coactivators. The existence of tissue-selective modulators of nuclear AR action confers a basis for designing pharmacologically selective AR modulators (SARM's) to target anabolism in osteoblasts, erythropoietic precursors, stellate cells in skeletal muscle and brain while exerting little or no effect on adipocytes or the prostate gland.[125-128] A subset of SARM's may be suitable for use in male contraception.[127,129] Compared with Te, DHT is more potent due to both higher affinity for and slower dissociation from AR.[130-132] DHT is considered a pure androgen in that it is nonaromatizable. Only 4% of blood Te is converted to DHT,[119,133,134] less than 1% is transformed to E_2,[114,135] and approximately 2% to androstenedione (Fig. 13.5).[119] Although systemic transformation is minimal, tissue-specific conversion of androstenedione to Te and of Te to DHT or E_2 may be critical in organs expressing AR or ER.[132] For example, systemic Te administration elevates intraprostatic DHT concentrations by providing substrate for local 5α-reductase type II, whereas exogenous DHT lowers prostatic DHT concentrations by suppressing LH and thereby Te secretion.[136] Other hormones such as vitamin D, glucocorticoids, and progesterone also modify 5α-reductase under pharmacological conditions.

The CYP19 gene, located on chromosome 15q21.1, encodes the enzyme aromatase, which converts Te to E_2 and androstenedione to estrone.[137,138] Aromatase is widely distributed in the testis (Leydig cells, Sertoli cells, spermatid lineage), bone, brain, pituitary, liver, intestine, skin fibroblasts, adipocytes, and breast stromal cells.[139] Systemic aromatization predominantly (>60%) proceeds in extraabdominal adipose tissue.[114,140] The coexistence of CYP19 and ER in the brain, pituitary, and testis suggests that locally produced E_2 is physiologically important in these key sites. Evidence favors a role for E_2 and ERα in stimulating libido and mating frequency especially in animals, inhibiting testis descent into the scrotum by repressing the INSL-3 gene, opposing germ-cell apoptosis in older animals, decreasing LH secretion, inhibiting Leydig-cell growth and differentiation, maintaining efferent spermatogenic ductule water reabsorption and endocytosis, and stimulating male breast anlagen (Table 13.2).[141-143] Moreover, transgenic silencing and rare human mutations of CYP19 and ERα have unmasked important roles for E_2 in bone-mineral density, fat-deposition patterns, appetitive behavior, and feedback on LH and FSH. Splice variants and polymorphisms of CYP19 exist,[144,145] which might modify the risks of prostatic cancer or osteoporosis.[145,146]

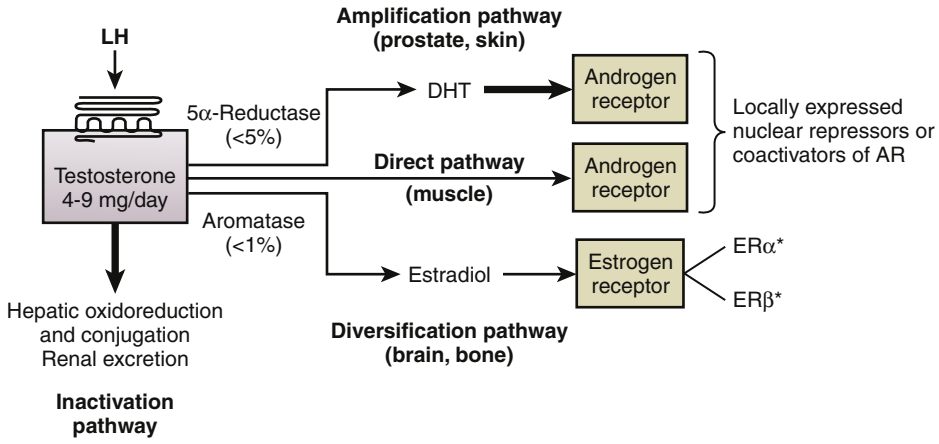

FIGURE 13.5 Amplification, diversification and inactivation of testosterone (Te) via its conversion to dihydrotestosterone (DHT) or E_2, and subsequent receptor-specific drive. *, Potentially activated by DHT metabolites. *(Adapted from Liu PY, Death AK, Handelsman DJ: Androgens and cardiovascular disease.* Endocr Rev *24:313–340, 2003.)*

Table 13.2 Estrogen Effects on Male Gonadal Axis

Action	Mechanism*
↓ GnRH gene transcription	GnRH neuronal ERβ and kisspeptin ERα[351]
↓ Gonadotropin concentrations	↓ LH and FSH pulse size
↓ GnRH-stimulated LH secretion	↓ GnRH efficacy at pituitary level
↓ Te biosynthesis	↓ CYP17A, StAR, and LH receptor[352]
↓ Testis descent	↓ Insulin-like factor 3 in Leydig cells via ERα
↓ Spermatogenesis	↓ FSH by feedback in adult
↓ Epididymal and seminiferous-tubule fluid absorption	Putatively via ERα, which maintains aquaporin-1 expression[355]
↓ Germ-cell apoptosis	Older male animal[356]
↓ Leydig cell proliferation	Fetal and puberal testis[357]
↑ Male sexual arousal and aggressive behavior	Neonatal brain ERα pathways[358]

*Male ERβ-knockout mice are fertile.[202]

Two isoforms (type I and type II) of 5α-reductase are present in the human, encoded by separate genes located on chromosomes 5p15 and 2p23.[131,147] Type I is found mainly in skin, liver, and brain, and type II primarily in male accessory sex glands, liver, and brain.[148] The isoenzymes share approximately 50% structural peptide homology. Polymorphisms of both isoenzymes have been reported, some of which (e.g., V89L) alter enzymatic activity[149] or correlate with sperm output (A49TT and V89LV).[150] Genetic variations in DHT synthesis or catabolism may thus contribute to interindividual variability in spermatogenic suppression by Te in male contraceptive regimens.[151] Prospective assessment of this postulate is needed.[152,153]

Testosterone and DHT are inactivated in the liver, kidney, and prostate by mixed-function oxidoreductases (e.g., 3α- and 3β-hydroxysteroid dehydrogenases) or glucuronidases (conjugation reactions).[154] Three-alpha reduction of DHT decreases its affinity for AR by a factor of 100,000-fold. The oxidoreduced and conjugated metabolites are lost into urine and bile, respectively. Certain metabolites of DHT, such as 5 alpha-androstane-3 beta, 17 beta-diol may mimic E_2 action via ERβ or modulate neurotransmission (Fig. 13.5).[101]

Progesterone

Although gonadotropes and KiSS1 neurons express nuclear progesterone receptors, there is no established role of progesterone in adult human male reproductive physiology. Exogenous progesterone and synthetic progestins can suppress gonadotropin output *in vivo* through the hypothalamic progesterone receptor,[155] and inhibit Te biosynthesis *in vitro* by down-regulating Leydig-cell LH receptors.[156] Reduced metabolites of pregnenolone and progesterone exert inhibitory effects on neurotransmission in experimental models, but the relevance of these actions in men is unknown.

Sex-Steroid Receptors

Sex-steroid hormones are lipophilic, thus allowing passive transmembrane diffusion into the cell before interaction with specific high-affinity nuclear receptors. Whether active transmembrane transport also occurs is possible but unproven. Ligand-receptor binding prompts dissociation of chaperone proteins (heat shock protein [Hsp] 90 and immunophilin Hsp 56), receptor dimerization, and interaction with distinct palindromic DNA sequences known as steroid-responsive elements.[157] Typical motifs consist of hexanucleotide sequences arranged as inverted repeats that are separated by three nonconserved base pairs (GGTACAnnnTGTTCT). The classical genomic mode of action is represented by this pathway, in which steroid-hormone receptors function as ligand-activated transcription factors.

Circumstantial evidence in many cell systems suggests that steroids may also act through nongenomic membrane-associated signaling mechanisms.[158-162] In general, nongenomic pathways are inferred when responses are: (1) too rapid to arise by nuclear effects; (2) evident in cells lacking sex-steroid receptors; (3) persistent in the presence of inhibitors of transcription and protein synthesis; or (4) elicited by steroids bound to substances that preclude entry into the cell.[158-162] When defined in this manner, membrane-associated pathways trigger calcium flux, cyclic AMP generation, and extracellular-regulated or mitogen-activated protein kinases. However, the precise molecular relationship between putative membrane and known nuclear receptors is not clear.

Androgen Receptor in Testes

The androgen receptor (AR) is encoded by a gene located on the X chromosome.[163] Splice variants of the AR exist,[163] but the full-length isoform is the predominant or only form expressed in many tissues including male reproductive organs.[164] In the testis, AR expression is prominent in early-stage Sertoli cells associated with stage III of the spermatogenic cycle,[165] and to a lesser extent Leydig and myoid but not germ cells.[165] Murine knockout models indicate that AR activity is essential in Sertoli and Leydig cells for fertility due to AR's role in spermatogenesis and steroidogenesis, respectively. In contrast, functional AR in peritubular myoid cells is not critical for reproduction.[166-169] Other tissues expressing AR include prostate, seminal vesicles, skin, fat, liver, all three of smooth, skeletal, and cardiac muscle, brain, pineal gland, bone, and cartilage.[139,170-175] Leydig-cell Te stimulates AR in spinal motoneurons, thereby activating gonadal descent into the scrotum via muscles in the outer layer of the gubernaculum (rudder) of the testis.[176] A Leydig cell-derived peptide, insulin-like factor (INSL3), albeit insufficient without Te, is necessary for development of gubernacular ligaments, and prevention of cryptorchidism.[177] INSL3 is a relaxinlike ligand, which signals by the LGR8-GREAT receptor.[178,179]

Inactivating mutations of AR result in the androgen-insensitivity (testicular-feminization) syndrome in the genetic male, and are the most common cause of male intersex.[163,180] Genotype and phenotype are strongly correlated, since mutations that increasingly impair receptor function result in more marked androgen insensitivity. A regularly updated electronic database of AR mutations is available at http://www.androgendb.mcgill.ca. (Accessed 19 July 2012.)

Polymorphisms that modify AR function have been described, such as polymorphic polyglycine (GGC) and polyglutamine (CAG) repeats. Increasing polyglutamine-repeat length is associated with decreasing AR transcriptional activity,[181] impaired spermatogenesis or subfertility,[182] and

genital abnormalities[183] in some but not all studies.[184,185] Polyglutamine-repeat length may contribute to nonuniform suppression of sperm output during male hormonal contraception.[185,186] Selected nuclear coregulators of AR could be targets of tissue-specific androgen-receptor modulators.[187-192]

Estrogen Receptors

The genes encoding ERα and ERβ have been mapped to chromosomes 6 and 14, respectively.[193,194] There are striking similarities in both the DNA-recognition and ligand-binding domains of the expressed receptor proteins. ERα is expressed in pituitary, brain, kisspeptin (but not GnRH) neurons, fat, skin, bone, seminal vesicles, Leydig cells, round spermatocytes, and spermatids,[139,195] whereas ERβ is detectable in gonadotropes; kisspeptin and GnRH neurons; prostatic epithelium; and Sertoli, Leydig, and spermatogonial cells in several mammals.[195-197] Male ERα-knockout mice exhibit elevated LH concentrations due to impaired negative feedback, enhanced Leydig-cell steroidogenesis, and oligo-azoospermia associated with efferent ductule occlusion.[198,199] In contrast, ERβ-disabled mice maintain normal LH and Te concentrations, have decreased germ-cell apoptosis in later adulthood, Leydig-cell hyperplasia, and normal fertility.[194,200-202] ERα and ERβ can act individually or as heterodimers, and can exert opposing or synergistic effects upon target genes, thus creating signaling diversity (Fig. 13.5). Splice variants and polymorphisms are described for both ER subtypes, some of which may be linked to reduced sperm output and infertility.[203,204] Environmental xenoestrogens and phytoestrogens could in principle influence spermatogenesis further in genotypically susceptible individuals.[205] Estradiol may also activate membrane-bound receptors, such as G-protein coupled receptor 30 (GRP30) linked to cyclic adenosine-5-monophosphate (cAMP), [206-207] and others coupled to extracellular-regulated kinases or Ca^{2+}.[208-210] Some but not all E_2 actions depend upon estrogen-response elements (ERE). For example, ERα and ERE are together necessary to maintain male sexual behavior, whereas either ERα or non-ERE-mediated pathways can suppress LH and Te secretion in mice.[211]

Progesterone Receptor

A single gene located on chromosome 11q22-3 encodes two progesterone receptor isoforms (termed A and B) through alternative transcriptional initiation sites.[212-214] The isoforms exert reciprocal effects via interactions with selected DNA motifs, defined as progesterone-responsive elements. Progesterone receptors are expressed widely including in KiSS1 neurons, gonadotropes, breast, brain, and adipose tissue.[213,215] Whether progesterone receptors are expressed in the testis is debated. Although physiological actions of progesterone remain to be elucidated in men, pharmacological amounts of progesterone and progestins suppress gonadotropin output, which has utility in the design of male hormonal contraception.[155]

Sex Hormone-Binding Globulin (SHBG): Steroid Transporter and Putative Ligand

SHBG in the male primate is expressed in the liver, adrenal cortex, prostatic alveoli, epididymides, and seminiferous tubules.[216] Infusion of SHBG acutely reduces the metabolical clearance of Te and E_2 in male monkeys.[217] Crystallographic studies show that SHBG is a homodimer structurally similar to the pentraxin family of proteins. Each monomeric subunit contains one hydrophobic steroid-binding pocket as well as tandem laminin G-like domains near the amino (N) terminus that are critical for dimerization.[218-220] Homodimerization is induced by the presence of steroid ligand, and stabilized by calcium ions. Both potential steroid-binding regions in the dimer are occupied by Te.[221] SHBG contains several glycosylation sites, which give rise to multiple posttranslational isoelectric isoforms,[222] and by common variants (polymorphisms) or mutations that alter glycosylation sites resulting in inefficient secretion or metabolical clearance of secreted SHBG.[223-225] Mutagenesis studies suggest that glycosylation sites in the C-terminus of SHBG may be important for cell-surface recognition.[218]

Te, E_2, and progesterone bind SHBG[218,226] and to a lesser degree corticosteroid-binding globulin.[227] About 45% of blood Te is bound to high-affinity SHBG, 4% to corticosteroid-binding globulin, and the remaining 50% to lower-affinity high-capacity binding proteins, such as albumin. Approximately 1% to 2% remains free-unbound.[228] DHT and anabolical steroids have greater affinity for SHBG than Te.[228] Although of higher affinity, the 1000-fold lower molarity of plasma E_2 than Te in men limits any substantial depression by E_2 of Te's binding to SHBG at physiological pH and temperature.[229,230] Low-affinity binding of Te (or E_2) to albumin may create a reservoir from which free Te (or E_2) arises rapidly due to an equilibrium dissociation half-time of about 0.2 second compared with 3.8 seconds for SHBG.[226,231] Significant one-pass dissociation is inferable in the liver, brain, and splanchnic circulation,[118] but whether capillary-bed dissociation kinetics are organ selective is unknown. In one study, experimentally controlled free, bioavailable, and total Te concentrations equally predicted feedback onto GnRH-LH outflow in healthy men.[232]

The traditional perspective is that protein binding mediates steroid-hormone retention and transportation in plasma, and restricts metabolism and inactivation.[233] This view has been challenged by recent experimental data,[234-236] since SHBG and albumin-bound steroids may also be biologically available for tissue-specific uptake.[226,231,237] Although only free (unbound) hormone is believed to enter the cell by diffusion, SHBG may associate with presumptive high-affinity membrane-binding receptors, such as megalin, which may facilitate SHBG-bound Te's entry into cells.[238] Mutagenetic studies suggest that certain glycosylation sites in the C-terminus of SHBG are important for cell-surface (albeit not necessarily megalin) receptor recognition.[218] Megalin-knockout mice exhibit apparent androgen resistance, inferable from impaired testicular descent into the scrotum.[235] Genetic studies also show that the risk of type 2 diabetes is influenced by certain polymorphisms of the SHBG gene,[239] which may not be related to SHBG-steroid binding. In addition, occupancy of membrane-bound SHBG by Te, DHT, or E_2 may activate intracellular Ca^{2+} or cAMP signaling purportedly via G-protein coupled and mitogen-kinase pathways.[240]

SHBG and testicular androgen-binding protein (ABP) are both encoded by a single gene located on the short arm of chromosome 17.[241] The proteins differ in their sites of production (SHBG by hepatocytes, brain, and placenta and ABP by Sertoli cells and possibly brain), as well as oligosaccharide composition.[218,242] SHBG secretion by hepatocytes is induced prominently by estrogens, thyroxine, and some anticonvulsant drugs and repressed by insulin, growth hormone-IGF-I, and nonaromatizable androgens. The presumptive intratesticular role of testicular ABP is to maintain high intratubular total Te concentrations required for spermatogenesis.[243-245] This notion is endorsed by the findings of increased germ-cell apoptosis and decreased fertility after transgenic overexpression of ABP in mouse testes.[243]

Physiology of Hypothalamo-Pituitary-Testicular Network

None of kisspeptin, GnRH, LH, or Te acts alone. Rather all four signals are interlinked in a network or ensemble (Fig. 13.6A). Pulsatile GnRH secretion drives pulsatile LH secretion, which stimulates pulsatile Te production.[246-248] Direct sampling of human spermatic-vein blood suggests that: (1) Te feeds back onto both LH and FSH secretion within 30 to 45 minutes (LH) or longer (FSH); (2) LH, but not FSH, feeds forward onto Te secretion after a delay of 40 to 90 minutes; and (3) secreted Te distributes rapidly among free (aqueous), albumin-bound and SHBG-bound compartments (Fig. 13.6B).[111,248-250] These concepts form the basis for constructing biomathematical models of time-delayed, nonlinear interactions among GnRH, LH, and Te with ultradian (pulsatile) and circadian (24-hour rhythmic) features.[111,232,251] Further model advances require inclusion of locally modulated Te actions via ER subtypes, AR, and membrane receptors.

Both GnRH outflow and LH secretion are subject to feedback inhibition by Te and E_2. Te feedback is substantially,[40,252] but not completely,[41,253] mediated by aromatization to E_2 systemically and/or within the hypothalamo-pituitary unit. Exogenous E_2 by acting on

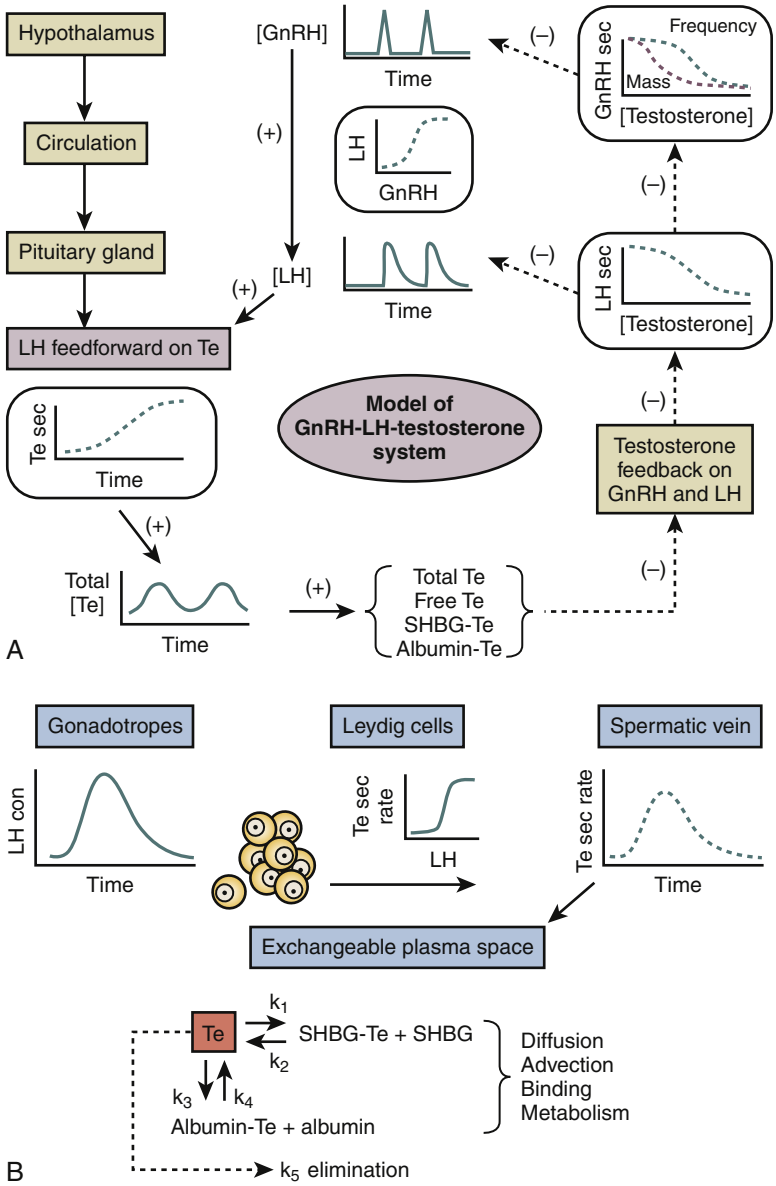

FIGURE 13.6 **A,** Ensemble construct of GnRH → LH and LH → Te feedforward and time-delayed Te → LH and Te → GnRH feedback. No single pathway or signal acts alone to maintain male reproductive function. **B,** Schema of regulated secretion, plasma distribution, protein binding, and elimination of secreted Te by LH pulses. GnRH, gonadotropin-releasing hormoe; LH, luteinizing hormone; sec, secretion; SHBG, sex hormone–binding globulin; Te, testosterone. *(From Keenan DM, Veldhuis JD: Divergent gonadotropin-gonadal dose-responsive coupling in healthy young and aging men. Am J Physiol 2004; 286:R381–R389. From Keenan DM, Veldhuis JD: Divergent gonadotropin-gonadal dose-responsive coupling in healthy young and aging men.* Am J Physiol *286:R381–R389, 2004.)*

the pituitary reduces LH pulse amplitude without altering pulse frequency,[254] whereas exogenous Te by acting on the hypothalamus and the pituitary gland decreases GnRH-LH pulse frequency and amplitude.[41] Conversely, depletion of endogenous E_2 concentrations with an aromatase inhibitor or blockade of E_2 action with an ERα antagonist augments LH pulse size and number,[40,255,256] therein mimicking the effects of nonsteroidal antiandrogens.[253,257] Inasmuch as E_2 depletion but not E_2 excess modulates GnRH-LH pulse frequency, endogenous estrogenic inhibition of the GnRH pulsing process (but not GnRH-driven LH pulse size) may be already maximal in normal men.

The characteristics of Te delivery may modulate inhibition of LH, since greater suppression is enforced by continuous than pulsatile Te infusions.[258] This outcome supports the male hormonal-contraceptive approach of sustained Te administration to suppress LH and thereby intragonadal Te concentrations. Endogenous DHT plays a lesser role in feedback onto GnRH and LH, given that patients with 5α-reductase type II deficiency exhibit minimally elevated LH concentrations.[259] Administration of a potent combined type I and II 5α-reductase inhibitor, dutasteride, in healthy young men, reduced systemic DHT concentrations by 95% and stimulated basal (constitutive) LH (and Te) secretion.[260] This mechanism could explain the rise in all three of mean, nadir, and peak LH concentrations in patients with 5α-reductase deficiency.

FSH concentrations are also regulated by negative feedback. Aromatization of Te to E_2 appears to be critical because: (1) combined deprivation of Te and E_2 and isolated depletion of E_2 elevate FSH concentrations to comparable degrees[36]; (2) physiological replacement of either Te or E_2 in hypogonadal men normalizes FSH concentrations; and (3) an aromatase inhibitor fully reverses suppression of FSH by Te.[40] Although nonaromatizable androgens can also suppress FSH and LH secretion, the study paradigms have been pharmacological rather than physiological.[41,261-263]

Nonsteroidal testicular products, such as inhibin B secreted by Sertoli cells, may be involved in feedback regulation in animals.[37] In humans, inhibin B concentrations exhibit a multimodal lifetime pattern. Values in umbilical cord blood are comparable to peripheral-venous levels in men, increase further in infancy, decline during subsequent childhood, rise in puberty, and fall by 25% by the eighth decade of life.[264] The changes are paradoxically concordant (birth through puberty) and reciprocal (adulthood) with FSH, LH, and Te secretion, indicating that other factors modulate both FSH and inhibin B. Albeit supported by corollary data, the role of inhibin B in restraining FSH production *in vivo* has been inferable only in the adult male rodent and monkey. To date, no clinical studies have infused or neutralized inhibin B in men, and no human mutations of inhibin B or its receptor have been described. The same qualifications apply to the roles of activin A, a homodimer that stimulates FSH-beta gene expression, and follistatin, a linear peptide that binds to and antagonizes feedforward by activin.[265,266] Inhibins and activins signal via transforming growth-factor (TGF) beta receptors and β-glycan coreceptors.[265] TGF receptors also strongly regulate cell proliferation, apoptosis, tumorigenesis, and hematopoiesis.[267] Contraceptive applications of safe and effective mimetics of inhibin B and antagonists of activin A remain to be exploited.

The Testis

The adult testes are paired ovoid structures suspended in the scrotum by the spermatic cord. Prepubertal testis volume is less than 7 mL, and postpubertal greater than 12 mL. Each is encapsulated by the fibrous tunica albuginea (white cloak), which is invaginated posteriorly to form the mediastinum testis perforated by neurovascular and lymphatic vessels and efferent ductules. Efferent ductules form from the rete (net-like) testis, which represents the convergence of all seminiferous tubules. Fibrous septa project from the tunica albuginea into the testis dividing it into 250 to 300 lobules. Each lobule contains 1 to 4 segments of seminiferous tubules. The latter develop at the time of puberty through canalization of the seminiferous cords. Peritubular-myoid and Sertoli-cell interactions mediate formation of seminiferous cords. Spermatogenic tubules are lined internally by Sertoli cells, which support the proliferation and differentiation of spermatogonial cells by secreting trophic and prosurvival factors, like stem-cell factor (*c-kit* ligand), which nourish and inhibit apoptosis of germ cells.[268] Sertoli cells protect spermatogonia by maintaining a unique tubular microenvironment through tight junctional complexes that constitute the blood-testis barrier. Conversely, spermatogonia and peritubular myoid cells both signal to Sertoli cells.[269,270] Sertoli cells abut a basement membrane, which is lined externally by peritubular myoid cells. Myoid cells are surrounded by an interstitium containing Leydig cells, lymphatics, venules, and nerve fibers. Peritubular myoid, Leydig, and Sertoli cells together regulate spermatogenesis.

Testes develop intraabdominally, and descend into the scrotum perinatally. Insulin-like 3 induction of gubernacular development is essential for transinguinal migration.[271] Male-sex determination and testicular morphogenesis are orchestrated by the SRY (sex-determining region of the Y chromosome), which is both necessary and sufficient for testis formation (Fig. 13.7). SRY in turn activates a family of homeobox-related genes, in particular Lim1 and SOX9, as well as steroidogenic-factor 1 (SF1). SF1 is a member of the NR5A subfamily of nuclear receptors required for testis, adrenal, and gonadotrope development. Mutations in SRY, SOX9, and SF-1 or its repressor, the dosage-sensitive X-linked sex-reveral (DAX1) gene, are responsible for the majority of known causes of aberrant sexual development.

Accessory Organs

Under the influence of Te, embryonic wolffian (mesonephric) ducts develop into the internal male reproductive tract, namely the epididymis (upper segment), vas deferens (middle) and ejaculatory duct, and seminal vesicles (lower). By the fourth week of embryonic life, the ejaculatory ducts arch anteriorly to join the ventral portion of the cloaca. The cloaca subsequently differentiates into the urogenital sinus. DHT is required for development of the prostate gland, urethra, scrotum, and penis from the urogenital sinus.

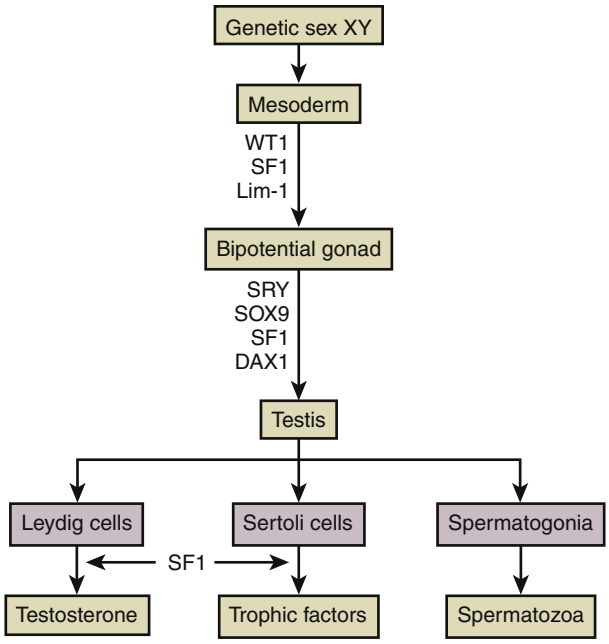

FIGURE 13.7 Critical embryogenetic determinants of testis formation given the genetic sex, 46 XY. The bipotential gonad of mesonephric origin must be directed definitively by SRY (sex-determining region of Y chromosome). SOX9 denotes SRY-related HMG-box 9, WT1 Wilms' tumor, DAX1 dosage-sensitive sex-reversal, SF1 steroidogenic factor 1, and DMRT sex-reversal gene on 9p. Further differentiation of the primitive male gonad entails development of Leydig, Sertoli, and germ cells. Testis formation and descent can be disrupted via estrogen.[353,354]

Vas Deferens

Vasa deferentia transport sperm by means of muscular layers that propel spermatozoa during ejaculation. In the absence of ejaculation, spermatozoa stored in each vas deferens dribble through the terminal dilated ampulla into the ejaculatory duct where they are washed away during micturition. The distal urethral meatus discharges urine or semen from the body.

Epididymis

The epididymis is formed from a single duct through which all spermatozoa pass, mature, gain fertilizing capability, and become motile before entering the vas deferens and ejaculatory duct. The human epididymis is 4 to 5 cm long and consists of the caput, corpus, and cauda. The cauda in man appears to differ from that in other species by way of more rapid transit of spermatozoa (2 to 4 days) and a less differentiated initial segment. Peptides and non-proteinaceous molecules are secreted into the epididymal lumen by principal cells. Although little is known in any species about precise regulation of luminal fluids that modulate sperm maturation and motility, microarray profiling of human epididymal tissue has demonstrated highly regionalized gene expression with maximal complexity in the caput and least in the corpus.[272] The maturation process is complete by the time spermatozoa enter the proximal (caudal) epididymis and are able to hyperactivate, bind the zona pellucida of the oocyte, and undergo the acrosome reaction.

The micromilieu of spermatozoa stored in the cauda epididymidis remains poorly understood. Ductal mucosa must play a critical role in controlling solute concentrations and degree of sperm hydration. Muscular cells exist only in the cauda epididymides and ductus deferens, and hence repeated ejaculation increases the rate of sperm transport from these regions only.

Epididymal growth, development, and function are dependent on androgens, estrogens, and other nonsteroidal luminal factors. Luminal androgen concentrations exceed those in peripheral blood, and for this reason systemic androgen exposure may not be critical for epididymal development and function. Amplification of luminal Te effects occurs by local synthesis of DHT via gonadal 5 α-reductase type II.

Seminal Vesicles

The seminal vesicles secrete the majority of fluid found in the ejaculate. Secretion includes fructose, prostaglandin, semenogelin I (responsible for coagulation of the seminal fluid), reactive-oxygen scavengers (superoxide dismutase, catalase), and immunoglobulin G receptor III. During embryogenesis, androgens transform simple saccular anlagen into active secretory epithelium by branching morphogenesis, yielding a highly folded internal structure with an expanded surface area. The precise molecular mechanisms are not yet defined.

Prostate Gland

The prostate is the largest accessory gland, but unlike the epididymis and seminal vesicles, it arises from the urogenital sinus rather than mesonephric ducts and requires DHT action (Fig. 13.8). Prostatic fluids, which comprise about one-third of the volume of the ejaculate, contain high concentrations of zinc, citric acid, choline, and proteins such as acid phosphatase, seminin, plasminogen activator, and prostate specific antigen (PSA). PSA is an important blood marker of prostate size and proliferation. PSA concentrations are elevated in benign prostate hypertrophy, inflammation, and prostatic cancer. The prostate gland develops from distinct sets of tubules that initially form discrete lobes, which become confluent by adulthood. Thus, the adult prostate gland is generally divided into peripheral, central, and transitional zones according to morphological and functional properties rather than lobular structure. The peripheral zone is subcapsular and surrounds the distal urethra, the central zone encircles the ejaculatory ducts, and the transition zone envelops the proximal urethra. The peripheral and central zones comprise respectively 70% and 25% of total prostate-gland volume in young men, accounting for equivalent proportions of prostate cancer in later life. In contrast, prostate cancer rarely arises from the transition zone (5% of volume), where benign prostate hypertrophy usually develops.

Spermatogenesis

Spermatogenesis is a dynamic, complex process contingent on systemic hormone support and local cellular, autocrine, and paracrine interactions directed *ab initio* via SRY and SOX9.[273,274] Sperm production proceeds in an orderly stage-specific fashion in all species (Fig. 13.9).

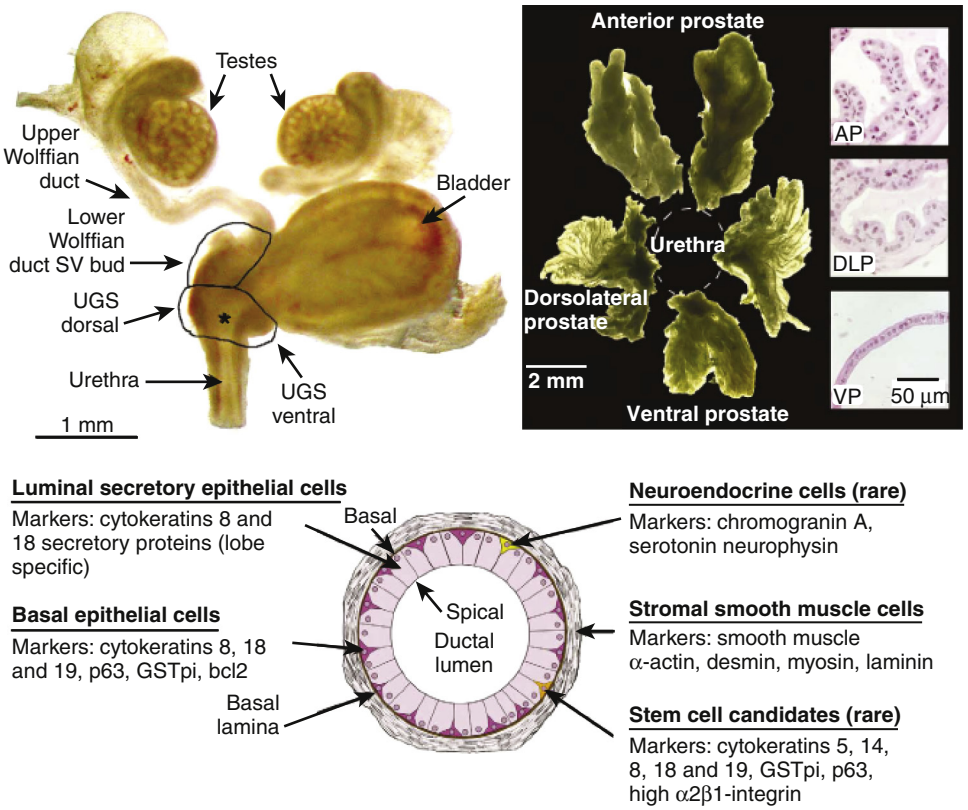

FIGURE 13.8 Micromorphometric features of the prostate gland. Portion of the urogenital tract from a male embryonic mouse day 16.5 *(top left)*. The prostate develops from the urogenital sinus (UGS), which is located at the base of the developing bladder. UGS epithelium is visible as a dilation of the urethra *(lighter area containing asterisk)* surrounded on the dorsal and ventral sides by condensed UGS mesenchyme *(darker areas)*. AP, anterior prostate; DLP, dorsolateral prostate; SV, superoventral; VP, ventral prostate. Lobes of the adult mouse prostate *(top right)* together with hematoxalin and eosin-stained sections of prostatic ducts from each lobe *(inset micrographs)*. Each lobe has a distinct shape and histological appearance. Diagram of a ductal cross-section *(bottom left)* with labels indicating cell types present in prostatic ducts, *viz*., luminal secretory epithelial cells, basal epithelial cells, neuroendocrine cells, stromal smooth-muscle cells, and stem-cell candidates. Below the label for each cell type is a list of differentiation markers commonly used to distinguish these cell types. Prostatic epithelial stem-cell candidate markers include cytokeratins 5, 14, 8, 18 and 19, GSTpi, p63, and α2β1-integrin. *(Adapted from Marker PC, Donjacour AA, Dahiya R, Cunha GR. Hormonal, cellular, and molecular control of prostatic development.* Dev Biol. *2003;253[2]:165–174, Fig. 1.)*

Seminiferous tubules exhibit a stratified and layered arrangement of germ cells wherein spermatogonia rest on the basement membrane and more mature germ cells fill the apical luminal regions. In humans and some other primates, stages follow an intertwined helical pattern so that a single tubular cross-section may contain up to six distinguishable stages.

Embryonic spermatogonia develop from primordial germ cells, which first appear in the yolk sac and then migrate to the hindgut and genital ridge during the fourth week of fetal life to form sex cords. The resultant seminiferous tubule permits spermatogenesis to proceed via four basic stages: development and repopulation of spermatogonia from stem cells accomplished via mitotic divisions that renew the stem cell-population and yield type A and B spermatogonia; meiosis requiring DNA synthesis and two meiotic divisions to produce haploid spermatids, specified as primary and secondary spermatocytes; spermiogenesis, defined by development and differentiation of the spermatid head and tail; and spermiation, denoting release of mature spermatozoa into the seminiferous tubule lumen.[275-279]

Type A spermatogonia are divided into A dark and A pale according to morphological criteria of chromatin staining. The A-dark spermatogonia exhibit uniform dark nuclei and are presumptive adult stem cells, but other theories claim that both A-pale and A-dark spermatogonia are capable of self-renewal.[275] Spermatogonial niches in the seminiferous tubules are thought to provide the necessary microenvironment to maintain self-renewal in the presence of relevant systemic and locally secreted Sertoli-cell factors. Endocrine, paracrine, and autocrine signals to spermatogonial mitosis include FSH, retinoic acid, stem-cell factor (*kit* ligand) and glial cell line-derived neurotropic factor. The last two peptides are produced by Sertoli cells. Inactivating mutations of the C-KIT gene (stem-cell factor receptor) cause azoospermia, bone-marrow failure, and absence of mast cells.[280,281]

Type B spermatogonia are characterized by granulated nuclear chromatin and a nucleolus, consistent with greater differentiation and commitment to meiosis. Meiosis requires 3.5 weeks in man, comprising a prophase (leptotene, zygotene, pachytene, and diplotene), metaphase and anaphase. Cells undergoing meiosis are primary spermatocytes, in which the preleptotene stage is characterized by DNA synthesis (occurring for the last time during spermatogenesis). Chromosome number remains diploid but DNA content doubles in association with finely granulated and uniformly

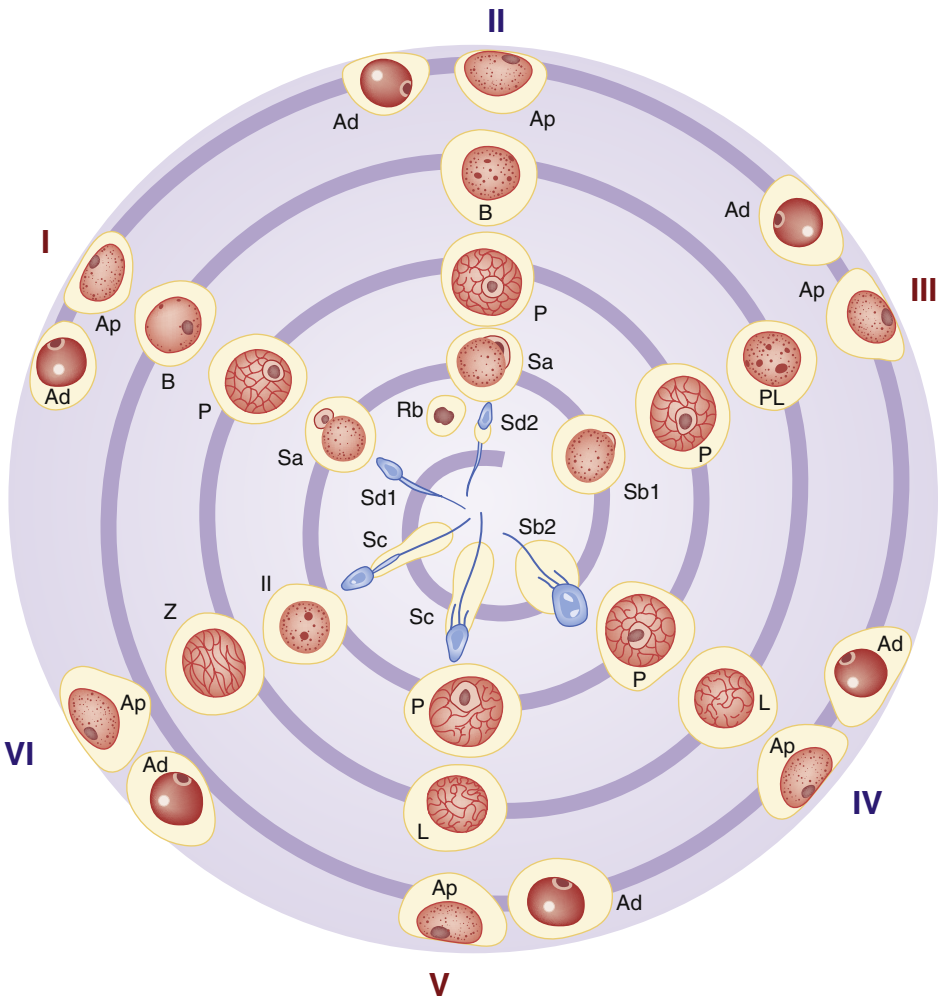

FIGURE 13.9 Spermatogenic cycle. Schematic representation of the six stages of the human spermatogenic cycle and with associated germ cells positioned to show sequence of development as a spiral pathway of ever-increasing radius. In actual tubules, some cell associations would be more superficial or deeper levels. Ad, Ap and B denote, respectively, dark and pale type A and B spermatogonia; PL, L, Z, P and II, preleptotene, leptotene, zygotene, pachytene and meiotic division I and II spermatocytes; Sa, Sb1, Sb2, Sc, Sd1 and Sd2, steps in spermiogenesis; Rb, excess residual body cytoplasm. *(From Kerr JB. Functional cytology of the human testis.* Baillieres Clin Endocrinol Metab *6[2]:235–250, 1992, Fig. 4.)*

distributed nuclear chromatin. Spermatocytes then lose contact with the basement membrane of the tubule (Fig. 13.9). Leptotene (thin and thread-like) spermatocytes begin in prophase, and then gradually enter the zygotene phase when homologous chromosomes pair and synapse. Cells continue to increase in volume until the pachytene (large size) stage of premeiotic chromosomal recombination that introduces genetic diversity. The subsequent first meiotic division produces secondary spermatocytes, in which chromosome number is halved thereby defining haploidy, and DNA content per cell is reduced from 4N to 2N. Secondary spermatocytes are rarely identified histologically, because the second meiotic division follows rapidly without an intervening S phase of DNA synthesis to form 1N spermatids.

Round and elongated spermatids undergo spermiogenesis, which can be divided into three interlinked phases referred to as Golgi, acrosomal, and maturational. Protein synthesis increases markedly during the Golgi stage, and the acrosome forms by coalescence of proacrosomic vesicles from the Golgi apparatus. Concomitantly, the nucleus of round spermatids condenses. Elongated spermatids emerge by further structural remodeling and differentiation. Although morphological features are used to stage spermatid development, spermiogenesis is a continuous, not a discrete, process. As acrosome formation proceeds at one nuclear pole to eventually form the head of the spermatozoon, centrioles gather at the opposite pole to form the flagellum (tail). The tail consists of the middle piece, principal piece, and end piece. Mitochondria migrate along the developing axoneme, the main cytoskeletal component of the sperm tail. Collapse of cytoplasmic volume results in a residual cytoplasmic body containing obsolete organelles and redundant nuclear membranes.

As the spermatid elongates, an ectoplasmic specialization orients the flagellum toward the seminiferous-tubule lumen. The ectoplasmic specialization is a unique cell to cell junction joining the plasma membranes of the spermatid acrosome and the Sertoli cell. Spermiation, or release of spermatids into the lumen of the seminiferous tubules, involves disassembly of these ectoplasmic specializations. During spermation, the residual cytoplasmic body is retained by Sertoli cells, and eventually phagocytosed.

Meiosis and spermiogenesis are hormonally regulated in rodents, whereas spermatogonial division and spermiation are so regulated in primates. Adequate FSH and LH secretion and action are required to initiate spermatogenesis in primates. The relative importance of FSH unlike Te in maintaining spermatogenesis remains controversial.[282,283] LH elevates intratesticular Te concentrations by sixtyfivefold more

than systemic Te concentrations, as is necessary to maintain spermatogenesis. Sertoli cells express an FSH-inducible aromatase system, thus permitting intratubular synthesis of E_2 as well. Te stimulates Sertoli cells expressing AR rather than germ cells, which probably do not express AR.[284]

Sertoli Cells

Adult Sertoli cells are nondividing asymmetric columnar cells with an elongated typically tripartite nucleus, a prominent nucleolus, abundant smooth endoplasmic reticulum, Golgi complexes, mitochondria, lysosomes, and cytoskeletal components. Immature Sertoli cells proliferate during fetal and neonatal life until the age of 12 to 18 months, and then again during the peripubertal period.[285] Secretion of müellerian-inhibiting substance by fetal Sertoli cells is critical for the regression of embryonic müellerian ducts, leaving the prostatic utricle as a remnant. Proliferation and maturation are subject to endocrine control. FSH stimulates proliferation whereas Te and thyroid hormones regulate maturation of Sertoli cells. With the neonatal surge of LH, FSH, and Te, the two Sertoli-cell products, inhibin B and MIS, both rise.[286] Sertoli cell number dictates maximal spermatogenic capacity in the adult, because each Sertoli cell can support only a fixed species-defined number of germ cells.

Estradiol and multiple proteins are secreted by Sertoli cells and serve as local paracrine signals, which further regulate spermatogenesis or Leydig-cell steroidogenesis.[91] For example, Sertoli cell-derived IGF-I induced by systemic delivery of FSH to the testis enhances LH-stimulated Te production synergistically, whereas Sertoli cell-secreted IGFBP-3 mutes IGF-I action.[121] Other systemic hormones that can act on the testis include interleukins, leptin, growth hormone, l-thyroxine, and cortisol.[287-289] In the human, a large amount of cortisol inhibits whereas growth hormone does not affect Te secretion.[290] Intratesticular mediators may further direct developmental and stress-related adaptations in gonadal function via local release of E_2, activin A, inhibin A, follistatin, atrial natriuretic hormone, catecholamines, ghrelin, growth-hormone releasing hormone, corticotrophin-releasing hormone, neuropeptide Y, serotonin, and arginine vasopressin.[291-295] In particular, E_2 is required for spermatogenesis, in contrast to its better known inhibitory effects on the hypothalamo-pituitary unit,[202] whereas activins influence apoptosis, proliferation, and differentiation.[267]

In humans, the spermatogenic cycle (transit time from spermatogonia to ejaculated spermatozoa) is 60 to 70 days according to kinetic studies using stable isotopes.[276,296] This cycle length is shorter than earlier estimates of 90 days.[297] Cross-species germ-cell transplantation experiments suggest that cycle length is dictated by the germ cell, rather than Sertoli cell.[298] Physiological principles of spermatogenesis confer a basis for understanding male-directed (hormonal and nonhormonal) contraceptive methods, since repression of spermatogonial proliferation only becomes evident 2 months later in ejaculated sperm.

Regulation of Male Fertility

Child rearing imposes major life demands, and consequently fertile couples practice family planning to obviate unintended pregnancies and to conform childbearing with personal desires and financial abilities. Accordingly, broadening contraceptive choices to allow men and women the option to share family-planning responsibilities satisfies important individual and societal needs. Surveys reveal that effective and safe male-directed contraceptive methods, if available and reversible, would be acceptable to many men and women.[299,300]

Hormonal methods that exploit exogenous feedback-based suppression of gonadotropin secretion, analogous to ovulation inhibition by combined estrogen-progestin contraceptives, are effective, reversible, and safe in the short term.[301-306] Androgen or androgen-progestin treatment combinations promote germ-cell apoptosis and inhibit spermatogenesis, resulting in azoospermia (no sperm in ejaculate) or near-azoospermia (≤1 million sperm/mL semen) with acceptable safety parameters.[307] Dual-hormone regimens are more effective and Caucasian populations more responsive than Asian cohorts.[308] Marked suppression of sperm output confers contraception with efficacy rates of 97% to 100%.[301-304] Subsequent restoration of spermatogenes to levels consistent with normal male fertility has been observed in all men.[305]

Additional approaches to male contraception are under active investigation. Long-acting GnRH-receptor antagonists with Te addback are candidate agents. Epididymal targets are plausible, because spermatozoal maturation is critical for fully motile sperm.[309,310] Other studies have explored contraceptive vaccines using GnRH or zona-pellucida (oocyte) proteins as antigenic targets.

Decremental Changes in GNRH-LH-TE Axis in Aging

A syndromic definition of late-onset hypogonadism requiring three sexual symptoms (decreased sexual interest and morning erections and erectile dysfunction) in conjunction with both total testosterone below 11 nmol/liter and free testosterone below 220 pmol/liter has been suggested.[311] However, the fundamental mechanisms that cause hypoandrogenemia in the aging male remain unknown. In fact, recent animal experiments and clinical investigations have disclosed multiple alterations in the aging gonadal axis, *viz.*: (1) lower amplitude LH pulses, suggesting reduced drive by GnRH or excessive sex-steroid inhibition; (2) more frequent LH pulses and less orderly patterns of LH release, pointing to diminished negative feedback; (3) preserved LH and heightened FSH responses to exogenous GnRH pulses, indicating intact gonadotrope function; (4) reduced pulsatile and thereby total daily Te secretion; and (5) impaired Te secretion in response to both elevated endogenous LH concentrations (stimulated by flutamide, tamoxifen, GnRH, or anastrozole) and infused pulses of recombinant human LH.[96,312,313] These alterations are summarized in Figure 13.10.

Collective clinical findings allow the hypothesis that relative androgen deficiency in older men reflects multisite failure of the GnRH-LH-Te axis. This postulate has not yet been tested in individual men. One noninvasive strategy is to exploit an integrative biomathematical model of reciprocal interactions among GnRH, LH, and Te via estimable feedback and feedforward interactions.[251] The analytical rationale is to reconstruct aging-related adaptations among all three interlinked signals, rather than any one

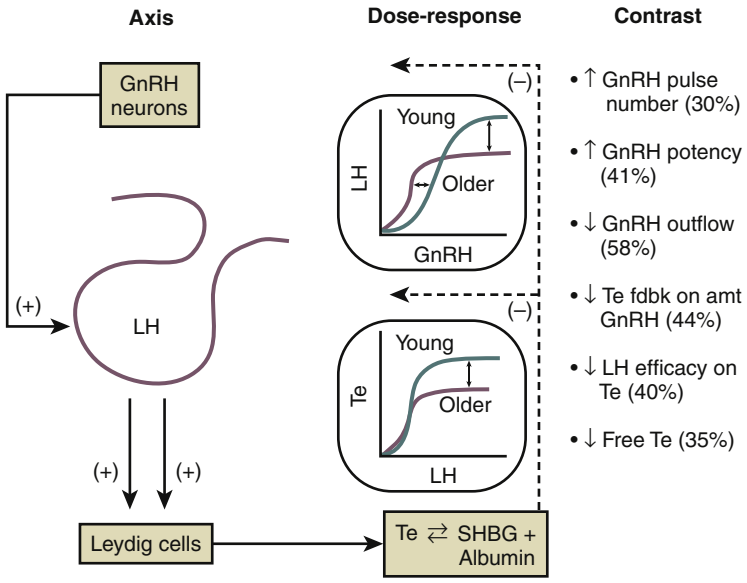

FIGURE 13.10 Schema of inferred anatomical sites *(left)* and adaptive mechanisms *(right)* that subserve relative testosterone deficiency in healthy older (age >60 years) compared with young (age <35) men. Arrows define stimulation (+) and inhibition (–). The two circled insets depict age-related contrasts in GnRH→LH drive *(top center)* and LH→Te feedforward *(bottom center)*. *(Adapted from Liu PY, Takahashi PY, Nehra AX, et al. Neuroendocrine aging: pituitary-gonadal axis in males. In Squire, LR. Encyclopedia of Neuroscience.* Oxford, Academic Press *6:317–326, 2009, Fig. 8.)*

signal in isolation.[232] According to such ensemble analyses, the most parsimonious explication of available clinical data is that aging (1) attenuates hypothalamic GnRH outflow, (2) impairs testicular responsiveness to LH pulses, and (3) decreases androgenic negative feedback.[111,232] Longitudinal studies will be required to establish the relative importance of inferred regulatory deficits in healthy aging men. In addition, the degree to which mechanisms associated with aging emerge in other clinical syndromes of hypogonadotropic hypogonadism, such as those associated with cardiovascular disease,[314] visceral adiposity, type II diabetes mellitus, uremia, hepatic failure genetic anomalies,[315] or chronic stress-anxiety states, has not been investigated.

CHAPTER 14

Immunology and Reproduction

William Hannah Kutteh
Dale W. Stovall
Danny J. Schust

The immune system may act as friend or foe. Fortunately, the human body has elaborate mechanisms to protect the individual from foreign pathogens. During development, the immune system is programmed and learns to distinguish self from non-self. The realization that a substantial number of potentially autoaggressive cells reside in healthy individuals has prompted the focus of attention on mechanisms of regulation that prevent autoimmune pathology. Despite the safeguards of the immune system, some self-reacting lymphocytes are not inactivated or killed and can cause one of several illnesses known as autoimmune diseases. Immunologists are well aware that if they understood all the mechanisms for tolerance induction, they might be able to prevent autoimmune diseases.

The immune system is capable of recognizing foreign proteins whose chemistry is only slightly different from its own molecules using three critical processes:

- Specific methods for recognition of foreign antigens involving antigen-specific receptors on B-lymphocytes and T-lymphocytes
- Exertion of control through the idiopathic network at both the T-cell and B-cell levels
- Processing and presentation of self-antigens, particularly as they relate to the induction of tolerance during ontogeny, are critical to the regulation of autoimmunity

A major focus of attention is on the three-party interaction of antigen plus the major histocompatibility complex plus T-cell receptor.

The failure of inherent mechanisms to prevent the recognition of "self" antigens by the immune system may result in an autoimmune response. Thus, *autoimmunity* refers to an immune reaction of the body against substances that are normally present in the body. To understand autoimmunity, it is important to first understand tolerance. *Tolerance* can best be defined as a state of antigen-induced immunological unresponsiveness. (Autoimmunity can be considered a failure of tolerance.) Tolerance is not synonymous with generalized immunosuppression; it is antigen-specific and causes no impairment of the immune response to antigens other than the ones used to induce tolerance.

Because tolerance is antigen-specific, it must involve the T lymphocyte, B lymphocyte, or both clone(s) specific to the antigen in question. At the clonal level, tolerance can only result from clonal deletion or clonal anergy. The clonal deletion theory states that T cell clones reactive to self-antigens are positively eliminated in the thymus during development. The clonal anergy theory states that self-reactive clones may exist but are in a long-term state of unresponsiveness. The suppressor T cell theory states that the peripheral auto reactive T cells are controlled by specially organized T cells.

Implantation is one of the most important aspects of pregnancy that immunological studies have targeted. Implantation represents a critical developmental process in that it requires the interaction of immunologically and genetically distinct tissues. The immune system may influence pregnancy success or failure during any of the critical steps of implantation. Blastocyst attachment occurs only during the "implantation window," the time period when the uterine epithelium is receptive. Failure of this synchronization precludes success, as demonstrated in human studies of implantation.

Implantation is the most important limiting factor in human reproduction. Only 25% of all fertilized ova will generate a live birth and 50% appear to fail at time of implantation. Studies of the karyotype on products of conception from early recurrent pregnancy loss have shown that chromosomal abnormalities alone do not account for this number of pregnancy losses, meaning that the majority of these losses are chromosomally normal human embryos, particularly in women under the age of 36 years.[1-3] Human preimplantation embryos express major histocompatibility antigens theoretically capable of inducing an immune response,[4] but the role of these antigens in pregnancy has not been delineated. It is possible that maternal immune responses play a role in the failure of implantation.[5]

Basic Immune Principles

Innate and Acquired Immune Defense Systems

The importance of effective defenses against foreign invaders has led to development of an *innate* (or natural) and an *acquired* (or specific) immune defense system. While these immune systems often cooperate in their defense against foreign invaders, their responses differ in intensity, timing, and specificity (Table 14.1).

Innate Immunity

The innate or natural defenses against pathogens consist of certain tissues, phagocytic and cytotoxic cells, and a

Table 14.1 Features of Innate and Acquired Immunity

Characteristic	Innate Immunity	Acquired Immunity
Specificity	Non-specific	Antigen-specific
Physicochemical barriers	Skin, mucous membranes	Peripheral and mucosal immune systems
Effector cells	NK cells, macrophages	B and T lymphocytes
Circulating molecules	Complement	Antibodies
Soluble mediators	Macrophage-derived cytokines (IFN-α, IFN-β, TNF-α)	Lymphocyte-derived cytokines (IFN-γ)
Response time	Rapid	Primary and secondary
Memory	None	Long-lived

variety of effector molecules. These defenses at the skin and mucous membranes may be perfectly adequate to clear potentially harmful environmental antigens. The initial entry of foreign organisms or cells is met by an initial inflammatory response which may be amplified by the activation of serum complement components resulting in the generation of enzymes and the deposition of their products on the surface of foreign antigens. The innate system can differentiate between a harmful invader, such as bacteria or viruses, by promoting an offensive environment. Other invaders, such as sperm or blastocyst, result in an inflammatory response that is accommodating to the guest. However, as a consequence of this first exposure to an antigen, and despite the intensity of the response, innate immune responses do not lead to any change in the type and magnitude of the response should the organism encounter this foreign antigen again. Thus, the innate response to unrelated or the same antigen seen more than once is exactly the same, there is no specificity to the defensive response and no adaptation to first exposure.

Acquired Immunity

The acquired immune response is characterized by an adaptation to the first exposure to the foreign antigen, known as the *primary response*. A subsequent exposure to the same antigen results in a *secondary response* that is quantitatively and qualitatively different than the primary response. The acquired immune response consists of antigen-specific cells and molecules that often interface with components of the innate immune defense systems. During *opsonization*, antibodies bind to bacterial surface antigens facilitating their *phagocytosis* by macrophages. In addition, macrophages may process and present protein antigens to specific T cells during a primary immune response.

Antigen-specific lymphocyte responses are characterized by their proliferation and further differentiation of function such as the production of soluble mediators including antibodies and cytokines and the development of antigen-specific memory. A typical primary response to antigen has a lag phase of about 5 days, has a slow rate of increase to a low plateau, with a low sensitivity to the antigen. The low affinity antibody produced is predominantly Immunoglobulin (Ig) M. In contrast, the secondary response (and all subsequent memory responses) to the same antigen are quantitatively and qualitatively different. The response occurs in 1 to 2 days, rises rapidly to a high plateau, and has a high degree of sensitivity to the antigen. The antibody affinity is high and may be predominated by IgG, IgA, or IgE depending on the location in which the immune response takes place.

The major features of the specific immune response are consistent with Burnett's *clonal selection theory*. This hypothesis states that (1) the antigen specificity of a single lymphocyte is established in the absence of antigen during its initial maturation, (2) each lymphocyte has a unique antigen specificity manifested by multiple copies of the same receptor, and (3) the proliferation and differentiation of the lymphocyte is induced by antigen binding to the specific receptors. The interaction of antigens and lymphocyte receptors is governed by the relative affinity of the receptor for the antigen. The clonal selection hypothesis explains that subsequent responses to the same antigen are more rapid, robust, and long lasting. The proliferation of specific lymphocytes in response to antigen results in the generation of antigen-responsive clones of cells.

As a consequence of antigen-induced proliferation, some of the proliferating lymphocytes may commit to long-term *memory cells* that persist for many years. Activated B cells may undergo *isotype switching* by changing from the production of IgM to IgG, IgE, or IgA thus allowing different physiological and biological properties. By these mechanisms, a maturing immune response maintains antigen specificity but establishes memory and functional diversity.

The development of adaptive immunity based on the clonal selection of lymphocytes bearing specific receptors is critical in allowing all pathogens, no matter how novel, to be recognized and in allowing the development of immunological memory.

Basic Effectors of Immune Responses

Cellular Effectors

Leukocytes are the cellular effectors of immunity and include the lymphocytes, monocytes, macrophages, dendritic cells, neutrophils, basophils, and eosinophils (Table 14.2). Lymphocytes can be further divided into subclasses based on function and upon cell surface markers, called "cluster of differentiation" or CD markers. Lymphocyte subclasses include T cells, B cells, and natural killer (NK) cells. Both B and T lymphocytes originate in the bone marrow and participate in antigen specific immune responses.

Thymus Derived (T) Cells

In humans, T cells circulate through the thymus, where they gain specific CD markers, antigen specificity and tolerance to self (discussed later in the chapter). T lymphocytes maturing in the thymus express both CD4 and CD8 cell surface receptors during early development, but those exiting the thymus express only one of these cell surface markers. CD4 positive T cells typically develop into helper T cells when they reach peripheral lymphoid tissues. Helper T cell effector functions include the secretion of soluble mediators of immune responses such as cytokines. These

Table 14.2 Characteristics of T, B, and NK Lymphocytes

Characteristic	T Cytotoxic T Suppressor	T Helper T Inducer	B Cells	NK Cells
Symbol	Tc/s	Th	B	NK
Surface antigen	CD8+	CD4+	CD19+	CD56+
MHC restricted	Class I	Class II	Class I and II	None
Target cells	Tumors, virally infected cells, allografts	B cells, Tc cells and precursors, macrophages		Tumor cells, virally infected autologous cells
Function	Kill foreign cells, down-regulate cells	Interleukin secretion	Immunoglobulin production	Immune surveillance, cytotoxic
Differentiation	Thymus	Thymus	Bone marrow	Bone marrow
Specificity	Antigen peptides	Antigen peptides	Native antigen epitopes	Unknown
Antigen receptor	T cell receptor	T cell receptor	Cell surface immunoglobulin	Fc portion of immunoglobulin

cytokines, in turn, modulate B cell, T cell, and macrophage responses. CD8 positive T cells leaving the thymus are destined to mature into either cytolytic T cells (CTLs), which function to lyse infected or otherwise altered target cells, or into suppressor T, currently called regulatory T (Treg) cells.[6,7] Less is understood about Treg cells than about T helper and cytolytic T cells.

Bone Marrow Derived (B) Cells

B cells appear to be educated in the bone marrow prior to exit into the peripheral immune system.[8] Like T lymphocytes, B lymphocytes are antigen specific. Unlike T lymphocytes, B cells function to secrete antibodies, which characterize humoral immune responses (discussed later in the chapter).

Natural Killer (NK) Cells

The third type of circulating lymphocyte is the natural killer cell. Natural killer cells have characteristic cell surface markers and receptors and their activities are typically not antigen specific, although this concept continues to evolve.[9] NK cells function in the recognition of cells lacking Major Histocompatibility Complex (MHC) Class I products (discussed later in the chapter) and in first–line defense against virally-infected or oncogenically-transformed target cells. NK cells also display cell surface receptors allowing recognition of antibody-coated target cells. Through these receptors, NK cells function as the major effector of antibody-dependant cellular cytotoxicity (ADCC).

Monocytes, Macrophage, and Dendritic Cells

Like other leukocytes, monocytes are derived from bone marrow stem cells. Monocytes circulate in the peripheral blood and populate nearly every tissue.[10] Within specific tissues, monocytes mature into macrophages. In some tissues, these macrophages have been given specific names (e.g., alveolar macrophages in the lung and Kupffer cells in the liver). Macrophages are phagocytic cells that participate in development of innate as well as antigen-specific immune responses. They can signal T and B cells via secretion of cytokines and via delivery of antigen in forms recognized by these cells (antigen presentation). They may also stimulate direct lysis of altered target cells. Dendritic cells are closely related to macrophages. Most derive from a similar cellular lineage in the bone marrow. Like macrophages, dendritic cells are phagocytic and they play an important role in antigen presentation.[11] Dendritic cells aid in the development of antigen-specific B cell responses.

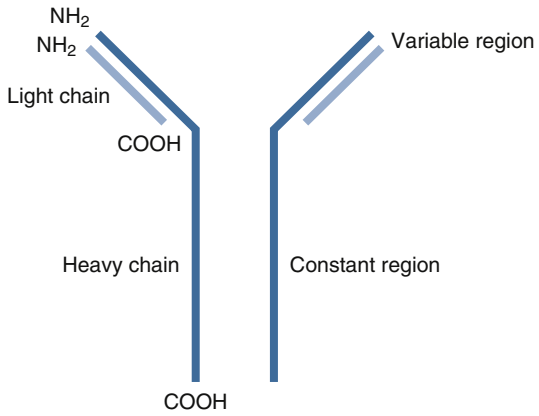

FIGURE 14.1 A typical immunoglobulin molecule. The constant region (carboxy [COOH] terminal) isotype of the heavy chain determines function. The combined variable regions (amino [NH_2] terminal) of the heavy and light chains determine antigen specificity. IgG, IgE, and IgD isotypes are typically monomers of this basic structure.

Other Effector Cells

Neutrophils, eosinophils, and basophils are effector cells with specific importance in innate defense against pathogens. Each has also been associated with specific immune-mediated disease states. Eosinophils, for instance, are classically associated with defense against parasites and have pathophysiological importance in asthma.

Soluble Components of Immune Responses

Immunoglobulins and Humoral Immunity

Immunoglobulin molecules are comprised of dimerized subunits of heavy and light chains (Fig. 14.1).[8] The N-terminal portions of each of the heavy and light chains are highly polymorphic and are termed their variable regions. The variable region of one heavy chain combines with the variable region of one light chain to give the immunoglobulin its antigen specificity. The C-terminal segments of the immunoglobulin heavy and light chains are called their constant segments and have minimal polymorphism. The constant portion of the immunoglobulin heavy chain interacts with other immune response components. Since these interaction

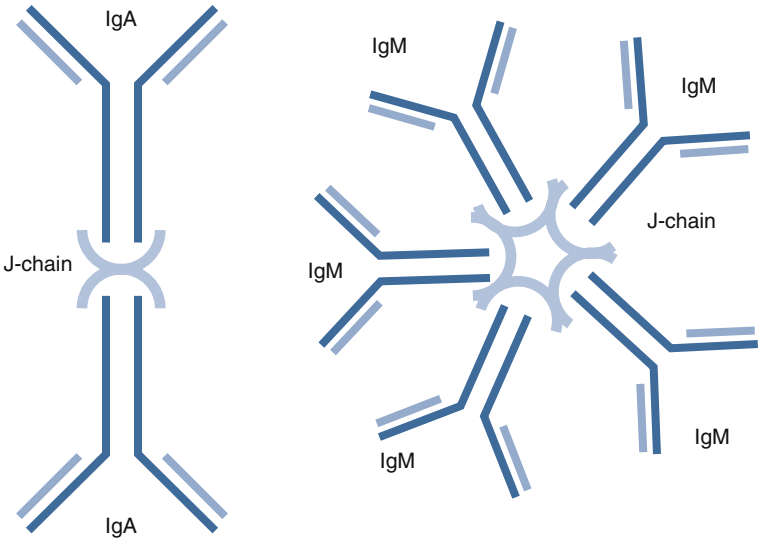

FIGURE 14.2 IgA dimers and IgM pentamers. Each structure is connected by a joining chain (j-chain).

are governed by the heavy chain constant region isotype, so too is immunoglobulin effector function. Ig molecule isotypes include IgA, IgD, IgE, IgG, and IgM. IgG, IgE, and IgD molecules are typically present as single Ig molecules (monomers). IgA molecules usually circulate as dimers and IgM molecules as pentamers (Fig. 14.2).

Each Ig isotype has distinctive functions. IgA dimers, connected by a joining or J chain, have been best described in the mucosa of the intestine and the female reproductive tract. Here, they are actively transported into the mucosal lumen via interaction of the J chain with a mucosally-derived secretory component. This allows exposure of IgA to antigens at the mucosal surface. IgE molecules interact with eosinophils in parasitic infections allowing eosinophil-mediated target lysis. IgE molecules are also implicated in delayed-type hypersensitivity via mast cell interactions. Membrane-bound IgD and IgM monomers are components of the antigen-recognizing B cell receptor on naïve B cells. Pentavalent IgM molecules activate the complement cascade. Secreted IgM multimers are also characteristic of the early antigen specific responses of naïve B cells.

Primary and Secondary Immune Responses

If the antigen recognized by the naïve B lymphocyte is not a peptide, T cell help will be absent. In turn, the initial response, albeit antigen-specific, will be of lowered affinity, will involve more IgM secretion than IgG, and will not generate immunological memory. In contrast, if the naïve B cell recognizes peptide antigen, the associated help from CD4+T cells will promote the generation of both primary and secondary humoral immune responses after repeated antigenic stimulus. As described earlier, the initial or primary immune response requires fairly significant antigenic stimulus and typically peaks approximately 5 to 10 days after antigen exposure. Primary responses usually involve more IgM secretion than IgG and the magnitude of the response is often lower than that after a second exposure to peptide antigen. Primary exposure to peptide antigen promotes the generation of memory B cells, which drive the characteristics of the secondary humoral immune response. Antigen exposure, in combination with T cell help, simultaneously activates B cells, leading to the antibody isotype switching that characterizes secondary responses. Upon re-exposure to the same peptide antigen, this secondary response ensues. Secondary responses require less antigenic exposure than primary responses, they peak more rapidly (2 to 5 days postexposure), and they are typically more robust than primary responses. As a result of isotype switching, IgG rather than IgM molecules represent the predominant immunoglobulin subtype in secondary immune responses.

These IgG molecules have multiple immune effector functions. They can cross the placenta, allowing immune transfer from mother to fetus. IgG can directly bind antigen via its variable region. This allows the free constant portion of the IgG heavy chain (Fc portion) to be recognized and internalized by phagocytic cells in a process termed opsonization. Similarly, IgG bound to cell-associated antigen can signal lytic attack by cytotoxic T cells, NK cells, or NKT cells promoting a process called antibody-dependant cellular cytotoxicity (ADCC). Finally, IgG molecules can activate the complement cascade.

Complement

The complement cascade is a vital part of innate immunity. It may be useful to compare the complement cascade to a more familiar clinical entity, the coagulation cascade. Both have components that circulate in inactive forms. Activation of each pathway can occur via two mechanisms. Reminiscent of the intrinsic and extrinsic coagulation pathways, the complement cascade can be activated via classical and alternative pathways (Fig. 14.3).[12] The classical pathway is activated when a complement component, C1, binds to antigen-antibody complexes (IgG or IgM). The alternative pathway is activated when complement component C3b binds to activating surfaces such as the cell wall of a bacterial pathogen. Each pathway sets off a series of activating enzymatic digestions of subsequent complement cascade components. Like the coagulation cascade, both of the activation pathways in the complement cascade intersect, joining as a final common effector pathway. Late components of the complement cascade can interact with specific complement receptors, resulting in pathogen phagocytosis, activation of the humoral immune system, or both. Alternatively, activation of the complement cascade can result in

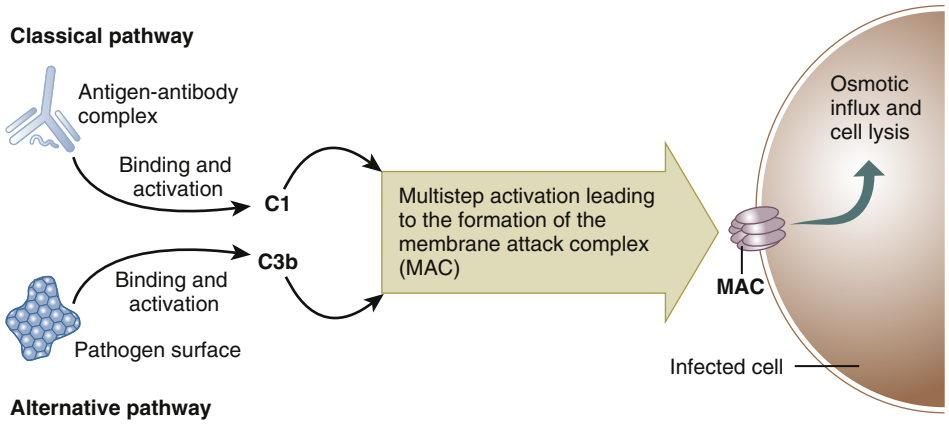

FIGURE 14.3 Activation pathways for complement-mediated cytolysis. The classical pathway of complement activation is initiated by the binding of antigen-antibody complexes to complement factor C1. The binding C3b to activating surfaces such as a bacterial cell wall activates the alternative pathway. Activation of either pathway results in a cascade of subsequent enzymatic activations. These pathways converge, forming the membrane attack complex (MAC). The MAC allows osmotic shifts that lyse the affected target cell. Complement-mediated activities can also include promotion of inflammatory responses, direct opsonization of pathogenic substances and clearance of unwanted immune complexes.

the formation of a membrane attack complex (MAC) that results in indirect osmotic lysis of a target cell via the formation of an ion permeable transmembrane pore in the target cell.

Cytokines

The rapidly enlarging and pleiomorphic family of cytokines joins the immunoglobulins and the components of the complement cascade to complete the list of important soluble mediators of immune responses. Cytokines are a family of secreted proteins, all of which are generated by immune cells. They include the interleukins, interferons, tumor necrosis factors, transforming growth factors, and the chemokines. The actions of cytokines may be autocrine, paracrine, or endocrine and effects are mediated by specific cytokine receptors. Most cytokines have short half-lives, so direct actions are typically of short duration. However, cytokines often stimulate additional immune cell activity with cascading cytokine secretion and effects. Members of this large family of soluble immune mediators often have complementary and/or redundant activities. In addition to myriad other roles in immunobiology, cytokines help to direct T helper cell differentiation. CD4+ T helper cells appear to circulate from the thymus to peripheral tissues in a functionally immature state (Th0[13]). The T helper cell phenotype/polarization model holds that Th0 cells differentiate into their mature phenotypes based largely upon the cytokine microenvironment in which they reside at the time when they first recognize antigen and on the cell surface coreceptors expressed on the Th0 cell (Fig. 14.4).[13] Certain cytokines appear to be of particular importance in the polarization of T helper cell responses. If antigen is recognized by Th0 cells in an environment dominated by the cytokines interleukin 12 (IL12), IL18, and interferon gamma (IFNγ), the resulting T helper effector phenotype is characterized by the secretion of inflammatory-type cytokines, including interferon gamma (IFNγ), interleukin 2 (IL2), and tumor necrosis factor alpha (TNFα). This type of response is called a T helper 1 (Th1) response. Alternatively, if Th0 cells recognize antigen in a microenvironment dominated

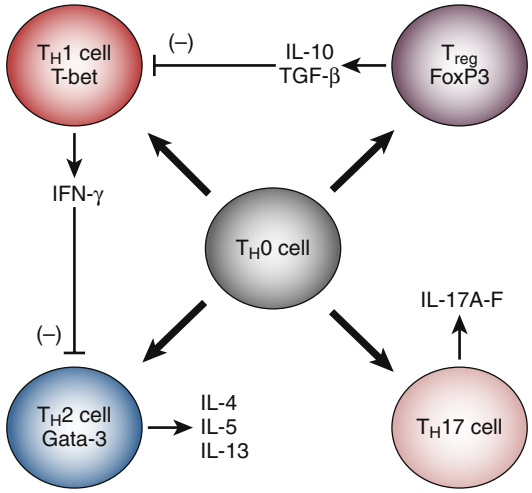

FIGURE 14.4 The TH1/TH2 polarization paradigm. The cytokine microenvironment in which antigen is presented by antigen-presenting cells to immature (TH0) T helper cells promotes development into TH1, TH2, TH17, and T_{reg} phenotypes. It appears that each T helper phenotype supports further development of itself while opposing developments of its counterparts.

by IL4, the predominant T helper response is of the Th2 type and is characterized by secretion of IL4, IL5, IL9, and IL13.[13,14] These Th2 cytokines, in turn, stimulate allergy-type responses, including mast cell and eosinophil activation and antibody production. Th1 responses enhance Th1 responses while inhibiting Th2 responses. Th2 responses initiate a positive feedback loop which promotes further Th2 activity while inhibiting Th1 effects. Several other T helper responses have also been distinguished. Th3 and Tr1 responses[14,15] are characterized by the secretion of transforming growth factor beta (TGFβ); T regulatory (Treg) responses are defined by the secretion of IL10; and Th17 responses by the secretion of IL-17.[16]

Altered T helper cell polarization may lead to immune-mediated diseases. Although the etiologies are often incompletely described, these disorders are characterized by a

dysregulation of cytokine secretion. For instance, patients with some forms of asthma appear to have inappropriate polarization of immune responses in their lungs towards the Th2 and Th17 phenotypes.[17,18] Those with Crohn disease polarize intestinal mucosal immune responses toward the Th1 phenotype. It has been hypothesized that some cases of spontaneous isolated or recurrent pregnancy loss may be the result of an insufficient Th2 polarization of maternal lymphocytes in the presence of placental antigens.

Basis of Immune Specificity and Immune Cell Education

While many of the salient attributes of the immune system can be addressed in a description of the cellular and soluble components of immune responses, there are two additional defining features of immune responses that require specific discussion: the specificity of immunological antigen recognition and T lymphocyte education.

Antigen Presentation

Most of the antigens recognized by the effector cells involved in acquired immune responses cannot be detected in isolation. Rather, antigens must be specifically presented to effector cells. This presentation process places antigens into a context in which the cell presenting the antigen can be recognized by the effector cell as "self-derived" and the antigen can be seen as foreign. This process is called antigen presentation and it is essential to antigen specific development of both cellular and humoral immune responses.[19]

The Major Histocompatibility Complex

The major histocompatibility complex region on the short arm of human chromosome 6 is a four million base pair deoxyribonucleic acid (DNA) segment that encodes many of the molecules involved in innate and acquired immune responses (Fig. 14.5**).** This highly polymorphic DNA region contains nearly 130 genes and approximately 100 pseudogenes. Not all of these genes are linked to immunity but two sets of genes within the region play central roles in antigen presentation. These genetic loci encode the MHC Class I and MHC Class II products (Fig. 14.6**)** and several other molecules involved in antigen presentation. MHC Class I molecules [e.g., human leukocyte antigen (HLA)-A, -B, and -C] are present on the surface of nearly every cell in the human body. They aid in defense against intracellular pathogens such as viruses by presenting virus-derived antigens at the surface of infected cells and in the detection of oncogenically-transformed cells by presenting abnormal intracellular cellular proteins that occur as a result of oncogenic transformation. Class I products also play a central role in transplant recognition and rejection. In each case, MHC Class I molecules act as important ligands for the T-cell receptor (TCR) on CD8+ cytotoxic-suppressor T cells. They may also act as important ligands for a variety of receptors on NK cells. MHC Class I-mediated intercellular interactions generally activate the cellular portion of the immune response and result in killing of the antigen-presenting (i.e., virally infected, cancerous, or transplanted) cell expressing the Class I molecule.

Unlike the globally-expressed MHC Class I molecules, MHC Class II molecules (human leukocyte antigen (HLA)-DR, HLA-DP, and HLA-DQ) are present on the surface of a limited number of "professional" antigen-presenting cells. These include dendritic cells, macrophages, monocytes, B cells, and tissue specific antigen presenters (e.g., Langerhan's cells in the skin). MHC Class II molecules are important in defense against extracellular pathogens, typically bacterial in origin. The T cell receptor on CD4+ T helper cells acts as the major ligand for MHC Class II products. Accordingly, MHC Class II-mediated interactions with these T helper cells typically modulate humoral immune responses.

The remarkable polymorphism of the classical MHC Class I and Class II genes allows for the recognition and presentation of an enormous diversity of peptides. In fact, the MHC genes are typically the most polymorphic of all loci in every species. Between the MHC Class I (intracellular pathogens-proteins) and Class II (extracellular pathogens-proteins) antigen presentation pathways, nearly every protein in the human body can be sampled. Those derived from foreign (non-self antigens) or altered self are recognized as such and trigger an immune response. In the absence of an autoimmune disorder, peptides derived from unaltered self do not trigger responses.

A large number of other immune related genes are located within the HLA locus. These include many of the complement component and cytokine genes (Fig. 14.5). Other MHC molecules are also encoded within the HLA region of chromosome 6. These include non-classical MHC Class I products (HLA-E, -F, and -G) and MHC Class I-like products such as MHC Class I polypeptide-related sequence A and B (MICA and MICB). These molecules tend to be less polymorphic than their classical counterparts and are thus predicted to have less important roles in antigen presentation. Non-classical and MHC Class I-related products have been implicated as central in immune responses at mucosal surfaces, including those within the reproductive tract (discussed later in the chapter).

Lymphocyte Education

It is essential that cells in the immune system be able to differentiate self from non-self. The education of B lymphocytes in this regard may involve only a single step process—one of negative selection. Those immature B cells that express receptors that recognize self antigen with high affinity do not survive to exit the bone marrow. This is negative selection against self-antigen and promotes B cell tolerance to recognition of self antigens. Self tolerance by B cells is independent of MHC molecules.

In contrast, T lymphocytes are educated in the thymus via a two step process.[20,21] Immature T cells entering the thymus express neither the T cell receptor (TCR) nor the CD4 or CD8 coreceptors. Upon entering the thymus, all three cell surface molecules come to be expressed. During a process called thymic education, CD4/CD8 double positive cells undergo both positive and negative selection events in which T cells "mature" from CD4/CD8 double positive cells to single positive (CD4+ or CD8+) cells. This two-step maturation positively selects for those T cells with T cell receptors that recognize self MHC products. Those recognizing self MHC Class I molecules are destined to become CD8 single positive T cytotoxic/suppressor cells. Those recognizing self MHC Class II molecules

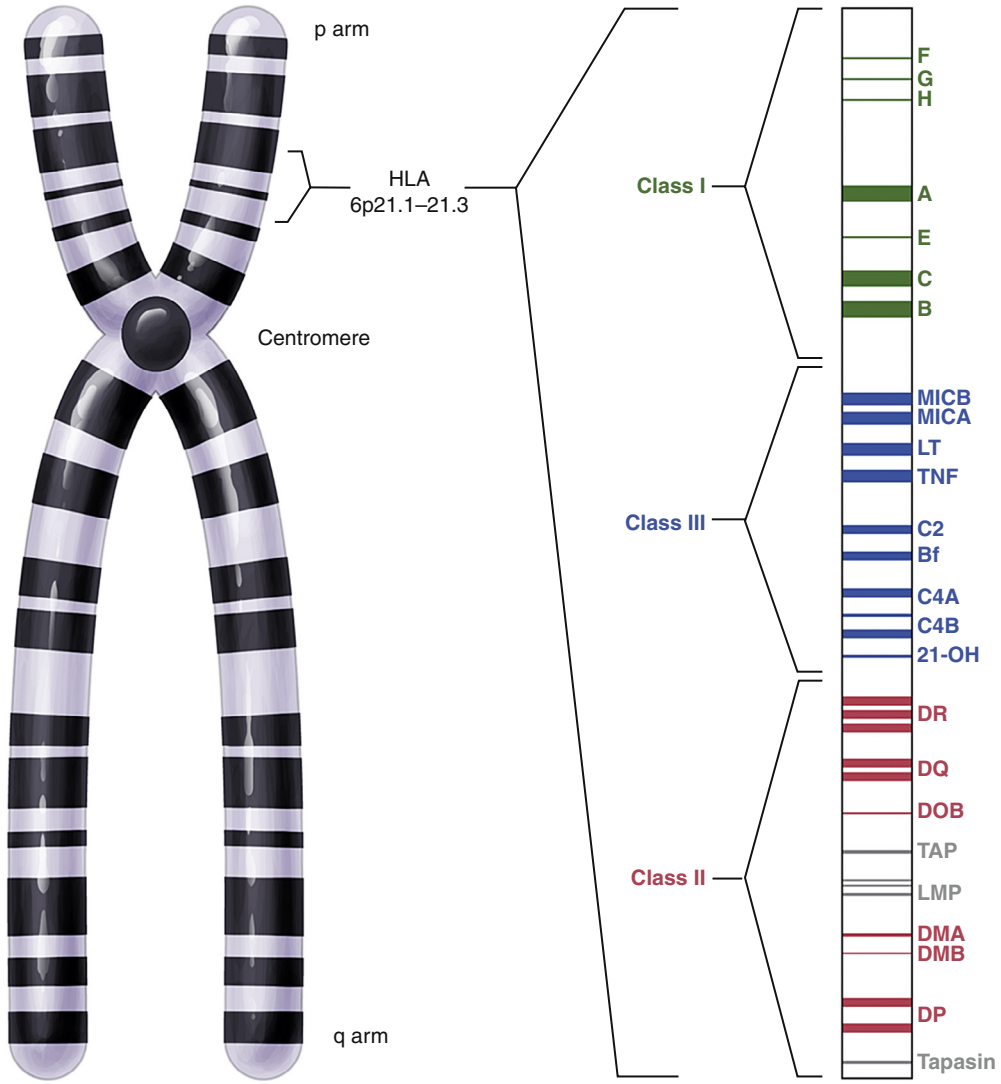

FIGURE 14.5 The Major Histocompatibility Complex. The major histocompatibility complex (MHC) is a region on the short arm (p arm) of human chromosome 6 that encodes the human leukocyte antigens and a variety of molecules related to antigen presentation and immune response. The MHC covers over four million base pairs (6p 21.1 to 21.3) and encodes well over 200 genes, many with an immense degree of polymorphism. The genes can be organized into MHC Class I, MHC Class II, and MHC Class III regions. The telomeric region encodes the MHC Class I molecule heavy chains, both those considered to be classical and highly polymorphic (HLA-A, -B and, with more limited polymorphism, HLA-C) and those which are considered non-classical (HLA-E, -F, -G, and -H). The centromeric region of the MHC encodes the MHC Class II heavy chains (HLA-DR, -DQ, and –DP) and several other molecules involved in antigen presentation. Among these are the transporter associated with antigen presentation (TAP) molecules (which move peptides from the cytoplasm into the endoplasmic reticulum to be loaded into the MHC Class I peptide-binding groove) and proteins involved in peptide loading of the MHC Class II molecule (DMA, DMB, DOB). Tapasin is a TAP-associated glycoprotein. The MHC Class III region is centrally located on the MHC and encodes for several components of the complement cascade (C2, factor B/Bf, C4A, and C4B), tumor necrosis factors alpha and beta (TNF-α and TNF-β), lymphotoxins (LT), and the MHC Class I like molecules, MICA and MICB.

are destined to mature into CD4 single positive T helper cells. The immature CD4/CD8 double positive thymocytes that do not recognize self MHC will die by apoptotic mechanisms. The second portion of the two-step intra-thymic T cell maturation process is one of negative selection. Negative selection of T cells within the thymus appears to depend on the strength of the recognition of MHC-peptide antigen complexes by the TCR of the developing T lymphocyte. If recognition is particularly strong, the cells undergo apoptosis. This functions to eliminate cells reactive against self-peptide antigens, which are likely to be fairly abundant within the antigen-binding clefts of the thymic antigen-presenting cells. T lymphocytes exiting the thymus should therefore recognize self MHC but ignore self antigen. Recent evidence indicates that NK cells are also educated,[22] possibly at the effector sites.

The Mucosal Immune System

The Common Mucosal Immune System

The large area of the body's mucosal surfaces is protected by innate humoral factors and cells and by specific antibodies that are selectively transported into external secretions. These antibodies are predominantly of the IgA isotype.

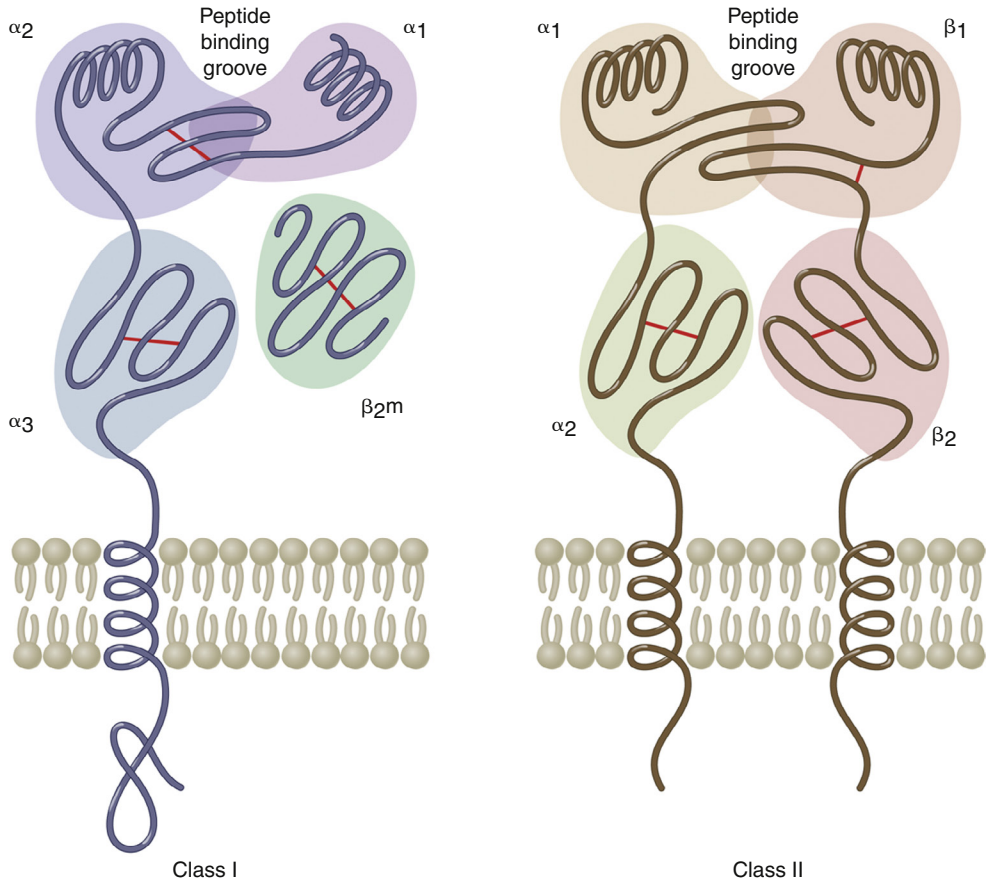

FIGURE 14.6 Molecular structure of the Class I and Class II molecules of the HLA system. To be stably expressed at the cell surface, the MHC Class I molecule must consist of a trimer of a heavy chain, a light chain (β_2 microglobulin; β_2 m) and an antigenic peptide bound within the peptide-binding groove. The MHC Class I heavy chain consists of three subunits. The α_1 subunit contains the heavy chain's amino terminus and, combined with the α_2 domain, creates the molecule's highly polymorphic peptide binding groove. These domains, along with the majority of the α_3 domain, lie in the extracellular space. The α_3 domain also contains the transmembrane segment and carboxy terminal portion of the Class I heavy chain. The carboxy terminal tail lies within the cytoplasm of the cell. Unlike most other MHC Class I molecules, the carboxy tail of HLA-G is truncated and contains only 6 amino acids. The MHC Class II molecule is a dimer of two heavy chains, α and β. The α_1 and β_1 domains of the heavy chains combine to create the Class II peptide-binding groove. The α_2 and β_2 domains contain the transmembrane segments and the intracellular carboxy-terminal tails.

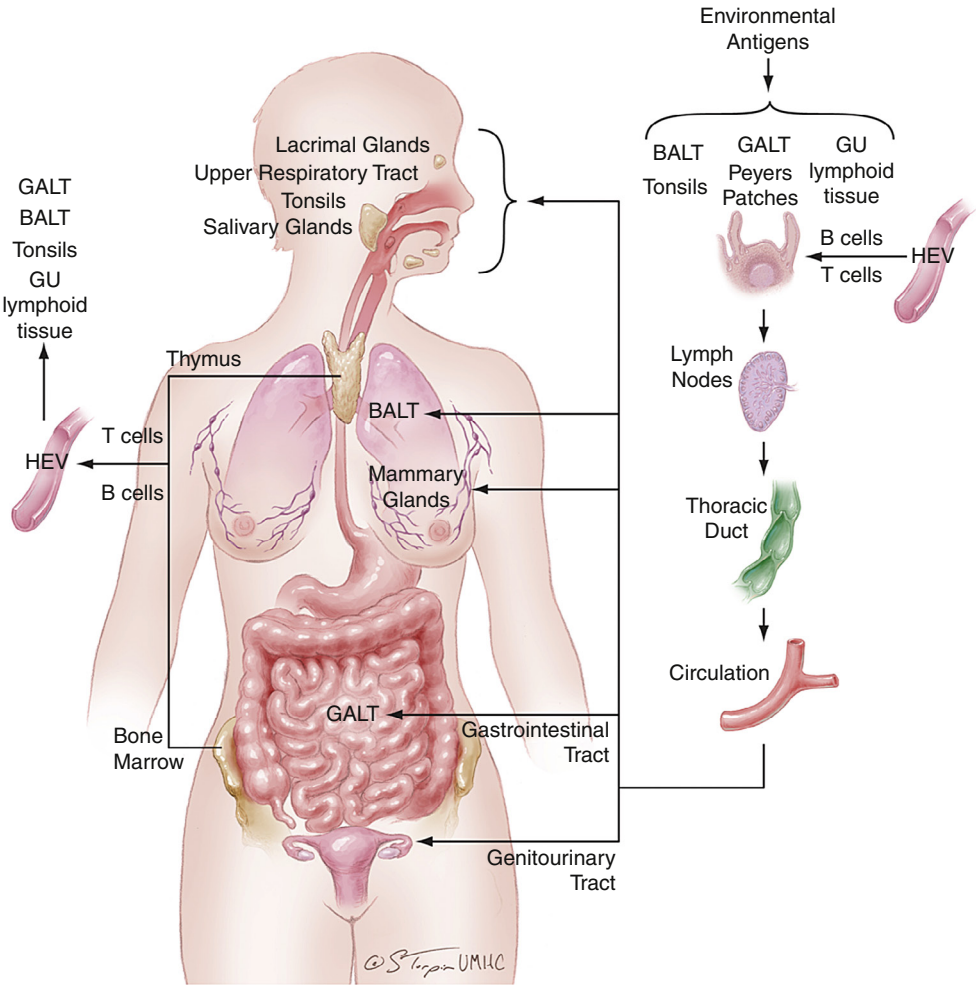
Environmental antigens from ingested food, inhaled particles in air, and resident microorganisms at mucosal surfaces represent the most important sources of exogenous stimulation of the entire immune system. The surface area of the mucosal membranes includes several hundred square meters versus only approximately 1.8 square meters for skin. Large numbers of cells that process antigens, produce antibodies, and produce innate humoral factors such as lysozyme, lactoferrin, peroxidase, and digestive enzymes are present in mucosal tissues and contribute to the protection of mucosal surfaces.[23] The existence of a common mucosal immune system and the determination of the origin of mucosal IgA plasma cells in humans are based on a number of indirect studies. External secretions of glands anatomically remote from the site of antigen stimulation contain secretory-IgA antibodies that are specific for microbial and food antigens. Ingestion of bacteria and viruses induces a parallel appearance of specific secretory-IgA in saliva, milk, and tears, but not in serum. The best known example is that of specific immunity passed on from mother to infant through secretory-IgA contained in breast milk. Specific antibody-forming cells can be transiently detected among peripheral blood mononuclear cells collected 7 to 12 days after oral immunization, and their presence precedes the appearance of specific secretory-IgA antibodies in saliva and tears. Analyses of the properties of IgA from stimulated human peripheral blood mononuclear cells revealed that such cells produce predominately polymeric IgA and display an IgA subclass distribution reminiscent of IgA cells in mucosal tissues.[24]

The common mucosal immune system can be summarized as follows (Fig. 14.7). Various environmental antigens are taken up by specialized epithelial cells (M cells) covering Peyer patches, and enter the Peyer patches which contain populations of antigen-processing and antigen-presenting cells. Immature surface IgM+ B cells, presumably of bone marrow origin, become surface IgA+ under the influence of special T cells, Peyer patch dendritic cells, or T-cell -derived cytokines. Such isotype-committed and antigen-committed cells exit the Peyer patches and, after maturation in mesenteric lymph nodes, enter the blood circulation through the thoracic duct and lodge in the mucosal tissues and glands



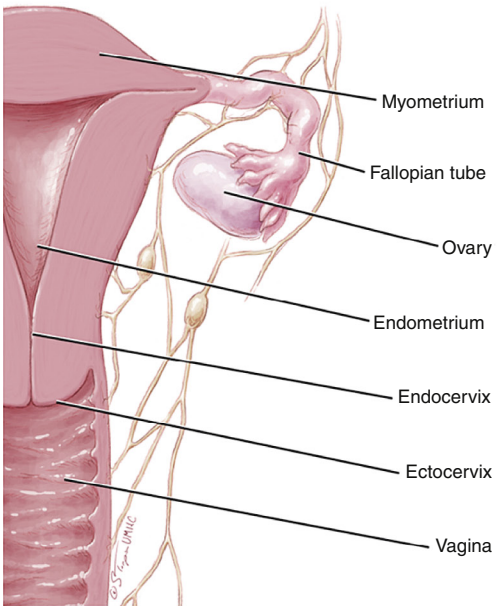


FIGURE 14.7 Model of the common mucosal immune system in humans. Human immune cells encounter environmental antigens largely across the immense area of mucosal surfaces that line the oral, gastrointestinal, respiratory, and urogenital tracts. Induction of antigenic responses at one of these sites often induces mucosal immune responses in the others. Although mucosal inductive sites are present at each of these mucosal surfaces, the best studied inductive site is in the gastrointestinal tract. Here, various environmental antigens are taken up by specialized epithelial cells covering an organized immune cell population called a Peyer patch. The classical immune cells populating the Peyer patch reach this site by traversing high endothelial venules (HEV) and include T cells, B cells, and dendritic cells. Antigen-processing and presentation at this site is robust and may also involve local mucosal epithelial cells. Isotype-committed and antigen-sensitized precursors of mucosal IgA plasma cells from mucosal inductive sites (largely gut-associated and bronchus-associated lymphoid tissues [GALT and BALT], but also tonsils and genitourinary mucosal tissues) pass through lymph nodes to enter the general circulation through the thoracic duct. The cells then home to and populate mucosal tissues and exocrine glands. B cells from the inductive sites will undergo terminal differentiation into IgA plasma cells. CD4+ and CD8+ T cells will also home to mucosal effector sites.

(primarily the intestine) where they terminally differentiate into IgA-producing plasma cells.

The Mucosal Immune System of the Female Reproductive Tract

Although the female reproductive tract is considered an integral component of the mucosal immune system, the genital immune system displays characteristic features that are distinct from those of other typical mucosal sites.[25] Most importantly, the mucosal immune system of the female reproductive tract is under a strong hormonal control that regulates the transport of immunoglobulins, the levels of cytokines, the distribution of various cell populations, and antigen presentation in the genital tissues during the reproductive cycle. In addition to protecting against potentially dangerous infectious agents, it must adapt to a spectrum of physiological events that include fertilization, implantation, pregnancy, and parturition. Throughout the menstrual cycle, an immunological balance is maintained to respond to the challenges of bacteria, yeast, and viruses without interfering with events that surround conception. During pregnancy, in addition to protecting against infection, the mucosal immune system undergoes further adaption to support a fetal-placental unit that is immunologically distinct. To meet these challenges, the reproductive tract has separate compartments consisting of the ovaries, fallopian tubes, uterus, cervix, and vagina that are precisely regulated by the endocrine system. Each of the sites displays aspects of the mucosal immune system that are designed to contribute to maternal and fetal survival. Unique to the genital tract and unlike other mucosal secretions in which secretory-IgA is the dominant isotype, IgG levels in the

	Humoral Immunity			Cellular Immunity

lower genital tract secretions equal or exceed the levels of secretory-IgA. Finally, local antigenic stimulation of the lower female genital tract appears to be less effective in the induction of immune responses because of the absence of classical mucosal lymphoepithelial inductive sites such as intestinal Peyer patches (Fig. 14.8).

Immunoglobulins in Genital Tract Secretions

Immunoglobulin concentrations in the genital tract are dependent on hormonal and local factors such as the presence of inflammation. Several studies concerning the origin of antigen-specific IgG in the female genital tract secretions suggest that locally produced, as well as plasma-derived IgG, contribute to the IgG pool in genital tract secretions. Regardless of the source, the route of passage of IgG into the lumen of the genital tract-passive, paracellular diffusion, or active, receptor-mediated transport has not been elucidated.

The IgA of cervical mucus is primarily secretory-IgA, with a small component of monomeric IgA. The IgA subclass distribution resembles that of the lower intestinal tract with IgA1 and IgA2 present in roughly equal proportions. The increased proportions of IgA2 may provide a functional advantage to certain specific antibodies because they are resistant to the IgA1 proteases of many pathogenic bacteria.[26]

Cytokines in Genital Tract Secretions

Unlike other mucosal tissues, the reproductive tract is characterized by progressive tissue growth and remodeling during each menstrual cycle. Cell proliferation, apoptosis, and cell migration are essential for reproductive tract renewal to occur. Growth in preparation for fertilization, implantation, and successful pregnancy is mediated by a changing pattern of cytokine and adhesion molecule expression that is regulated by the sex steroid hormones.[27] Multifunctional cytokines such as Il-1β, IL-6, and IL-10 that are produced throughout the reproductive tract have important roles in the maturation of B lymphocytes to immunoglobulin-producing plasma cells. Estrogen increases the expression of polymeric IgA receptor, thereby increasing the transport of IgA into the lumen when cultured human endometrial cells are incubated with Il-4 and IFN-γ. Regulatory cytokines, such as IL-10, IL-1β, and IL-6 are present in human cervical mucus and their levels correlate with the cyclic reproductive hormones estradiol and progesterone.[23] Cytokines and chemokines are differentially secreted from immortalized human endocervix-derived epithelial cell lines depending on the hormone milieu in which the cells are exposed.[28]

Cells of the Female Reproductive Tract

Estradiol and progesterone secreted during the menstrual cycle act both directly and indirectly on epithelial cells and other immune cells to modify immune function in a way that is unique to specific sites throughout the female reproductive tract.[29] The female reproductive tract contains a full spectrum of leukocytes with the potential to function in ways similar to those present in other mucosal tissues and in the peripheral blood. Macrophages, distributed primarily between the epithelial and muscle layers, are found both scattered throughout the fallopian tubes, cervix, vagina, and in small aggregates in the uterus. Uterine NK cells, which are CD56+/CD16− and therefore phenotypically distinct from peripheral blood CD56−/CD16+ NK cells, are present in the uterine endometrium and increase in number during the secretory phase of the menstrual cycle and during the first trimester of pregnancy.[30] Immune cells make up 6% to 20% of the total non-muscle cells in the fallopian tube, uterus, endocervix, ectocervix, and vagina and are not significantly influenced by the stage of the menstrual cycle.[31]

Table 14.3 Differences in the Properties of Human Serum and Secretory IgA Antibodies and in the Characteristics of IgA Cells in Non-Mucosal and Mucosal Compartments

Characteristic	Serum/Systemic	Secretory/Mucosal
Molecular form of IgA	Monomeric IgA	Polymeric IgA
Subclass of IgA	IgA1 > > IgA2	IgA1≥IgA2
Transport into secretions	No	Yes
Ontogeny	Matures late	Matures early
J-chain expression	Mostly negative	Mostly positive
Secretory component binding	Mostly negative	Mostly positive
Origin of precursors	Bone marrow	Peyer's patches

Approximately 50% of the leukocytes in the reproductive tract are CD3+T cells, with the remainder consisting of neutrophils (CD66b+), B cells (CD19+), and monocytes (CD14+). In particular, NK cells and CD3+ T lymphocytes, including the CD4+ T helper cells and CD8+ T cytotoxic-suppressor cells, are the two major leukocyte subsets present among endometrial leukocytes. Studies have demonstrated that cervical Class I MHC-restricted CD8+ and Class II MHC-restricted CD4+ cytotoxic T cells can lyse autologous target cells made to express HIV-1 and other viral proteins.

Discrete lymphoid aggregate (follicles) in the endometrium are composed primarily of a B cell core (CD19+) surrounded by T cells (CD3+, CD8+, CD4−) and an outer halo of macrophages (CD14+). Antigen presenting cells in the reproductive tract, which are responsible for initiating the immune response by presenting antigens to T lymphocytes, are derived proportionally from reproductive tract cells and peripheral blood mononuclear cells.

Independence of the Secretory and Systemic Immune Systems

Comparison of the molecular properties of IgA in serum and secretions and of the cells in the secretory tissues and bone marrow suggests that human serum and secretory IgA systems display a great degree of independence (Table 14.3). The molecular properties of IgA produced by the bone marrow (the primary source of serum IgA) and the secretory tissues and glands (the source of secretory IgA) are different in that serum IgA is predominantly monomeric, whereas secretory IgA consists of J-chain-containing polymers. Furthermore, the parallel distribution of IgA subclasses in serum and bone marrow cells, on the one hand, and external secretions and cells in the secretory tissues and glands, on the other, strongly suggest that the two systems are represented by populations of IgA molecules and cells with distinct properties. The ontogenies of the serum and secretory IgA systems display characteristically independent patterns of maturation. Adult levels of IgA are reached in external secretions as early as one month after birth but before 2 years of age, while adult levels of serum IgA are not achieved until adolescence.

Comparison of the levels and molecular properties of the immunoglobulins in blood and in the external secretions of the female genital tract indicate that in humans the systemic and mucosal compartment of the immune system display a considerable degree of independence.[23] In comparison to other components of the common mucosal immune system, the mucosal immune system of the female reproductive tract is characterized by a significant contribution of the systemic compartment with respect to the immunoglobulin isotype distribution, unique distribution and phenotypes of B and T cells, strong hormonal dependency, lack of typical lymphoepithelial inductive sites and relative weakness of immune responses to local infections or immunizations with certain antigens.

Alloimmunity and Reproduction

The Fetal Allograft

Maintenance of human pregnancy requires a tightly balanced and cooperative effort between the mother and fetus. Although the concept of the fetal allograft, first posited by Billingham and colleagues[32] nearly 6 decades ago, remains important, the immune interactions between mother and fetus are two-sided and even more complex than can be modeled by a simple allograft. The fetus, which carries maternal and paternal antigens, is more specifically called a semi-allograft but must still circumvent potentially catastrophic alloimmunity. It does this through alterations in antigen presentation and robust secretion of immunoregulatory pregnancy hormones. The mother, in turn, must balance tolerance to paternal alloantigens against a continued need for defense against pathogen invasion.[33] She does this via local alterations in decidual immune cell subpopulations combined with alterations in local and systemic immunoregulatory hormone and chemokine-cytokine secretion.

Cellular and Soluble Mediators of Immune Responses at the Maternal-Fetal Interface

Immune Cell Subtypes

As mentioned above, the immune cell repertoire of the human endometrium differs dramatically from that of the peripheral blood and is characterized by very few B lymphocytes but fairly abundant T cells, macrophages, NK-like cells, and a number of more specialized immune effector cell subtypes. The relative proportions of these resident cells demonstrate remarkable menstrual cyclicity. A few of these cellular populations deserve specific description, as their presence in both the female reproductive tract and in the peri-implantation decidua implicate a particularly important role for innate immune interactions during implantation and early pregnancy.

Peripheral immune cells have been described that have characteristics of both NK cells and T cells. These NKT cells and their ligands (e.g., CD1) have been detected in the endometrium and decidua of humans.[34] NKT cell interactions with the MHC-like antigen presenting molecule, CD1d, can result in proinflammatory or in tolerogenic effector functions,[35] suggesting that these interactions may be important in maintaining the delicate immune balance at the maternal-fetal interface. Other NK-like cells also populate the late luteal phase endometrium and decidua of women. These unusual cells have been variably called decidual granular lymphocytes, large granular lymphocytes (LGLs), and decidual natural killer cells (dNKs) and they exhibit phenotypic

differences in their cell surface CD expression from typical NK cells found in the periphery. Still, most investigators consider them to be NK cell variants. The proportion of NK cells in the decidua of early pregnancy rises to nearly 70% to 90% of the total endometrial lymphocyte population.[36] While NK cells can display activating and inhibitory receptors on their cell surfaces, the predominant interactions of those in the decidua involve killer inhibitory receptor (KIR) ligation with trophoblast MHC Class I products (discussed previously in the chapter)[36,37] and the outcome of these interactions is unlikely to be cytotoxic.[38] Rather, the cytokine and chemokine products of the decidual NK cell tend to be tolerogenic and to support trophoblast invasion and decidual spiral artery remodeling.[36,37] Very elegant investigations have shown that decidual NK cells are derived from a small population of endometrial NK cells that await pregnancy for robust expansion.[39] These cells do not appear to be recruited from the peripheral blood, as previously hypothesized. Thus, the measurement of *peripheral* NK cell number or activity as a predictor of pregnancy outcome is unlikely to reflect aberrancy in the function of *decidual* NK cells in pregnancy maintenance.

Animal and human data have also suggested roles for "suppressor" macrophages and TCR γδ+ T lymphocytes in the immunology of early pregnancy. Mimicking the subcategorization of T helper cells, macrophages have been classified based on their cytokine secretion patterns and the abundant macrophages of the uterine decidua typically exhibit an immunosuppressive phenotype or M2 polarization.[40] The M1 phenotype is proinflammatory. In contrast, M2 cells exert robust interleukin-10 (IL-10) secretion and indoleamine 2,3 dioxygenase activity. As mentioned above, TCRγδ+ T cells have presumed importance in innate immunity. Their presence within the human endometrium increases dramatically in early pregnancy, they preferentially secrete IL-10 and TGF-β and they support trophoblast invasion and inhibit trophoblast apoptosis.[41] All should promote pregnancy maintenance.

Soluble Immune Effectors

The human endometrium and decidua are replete with immune and inflammatory cells capable of cytokine and chemokine secretion, but the role of individual factors in pregnancy maintenance may be fairly minimal. Most cytokine genes have been individually deleted in animal models and few, if any, of these factors appear to be absolutely required in pregnancy maintenance. Still, two are frequently discussed as particularly integral. Leukemia inhibitory factor (LIF), and IL11, both IL6 family cytokines, have been demonstrated to be required for blastocyst implantation, but not for subsequent embryogenesis in mice,[42,43] indicating the defect induced by their deletion is in the maternal compartment. Further delineation of the mechanisms for these implantation abnormalities indicate that LIF functions at the blastocyst attachment/adhesion phase and IL-11 in the response to the implanted blastocyst.[44] The fact that essential roles for individual cytokines in pregnancy maintenance is so limited speaks to the likely redundancy in this system and spurs future studies addressing the integrated effects of multiple cytokines.

Application of the Th1/Th2 paradigm to pregnancy maintenance has led to the hypothesis that the intrauterine environment surrounding normal human pregnancies is Th2-dominant and *in vitro* data have shown that peripheral blood cells from women with normal pregnancy histories secrete Th2 type cytokines when exposed to placental antigens; some women with histories of recurrent pregnancy loss have Th1 responses in the same *in vitro* assay systems.[45,46] Inflammatory cytokines characteristic of Th1 responses (e.g., IFNγ) have been shown to be harmful to the implanting embryo.[47] While the Th1/Th2 paradigm has been useful as a stepping stone in our understanding of the immunology of pregnancy maintenance, rapid expansion in descriptions of cytokine/chemokine activities and in T helper cell subpopulations suggests that the Th1/Th2 paradigm must also be expanded to include Th17, Th3, T regulatory, and possibly even more cytokine-secreting immune cells at the maternal-fetal interface. Further, the antigen recognized at the site of implantation that might cause dysregulation of the local T helper response phenotype has yet to be identified *in vivo*. *In vitro* data have been based on the supposition that the antigen(s) is placental in origin, which is a reasonable but unverified hypothesis. Cytokine profiles in the microenvironment of an implanting fetus are also difficult to document and dysregulation in the presence of a failing pregnancy will always be obfuscated by the question of cause versus effect. The possibility that dysregulation of T helper response causes pregnancy loss remains intriguing but unproven.

Antigen Presentation in the Placenta

There is little controversy that the characteristics of antigen presentation in the placenta are unique. For many years, Medawar's paradox of the fetal allograft appeared consistent with the assumption that the placenta lacked MHC Class I and Class II transplantation antigens. This assumption, however, was only partially correct. It is true that MHC Class II molecules are not expressed on the surface of placental trophoblast cells, nor are the classical MHC Class I transplantation antigens HLA-A and -B. However, the classical MHC Class I product, HLA-C, and two non-classical products, HLA-G and HLA-E, are found on particular subpopulations of trophoblast cells.[48-50]

The human placenta, which is of the hemochorial type, is a complex structure that forms intimate association with maternal tissues primarily through two types of cells: (1) syncytiotrophoblast (SynT) cells, the fetally-derived trophoblast cell subset that coats the surface of the placenta villi, are directly bathed in maternal blood and (2) extravillous trophoblast (EvT), which invade deeply into the maternal decidua, interact directly with maternal decidual immune cells, and remodel the uterine spiral arteries.[51] Both of these trophoblast subsets are derived from an ill-defined, stem-cell like cytotrophoblast (cytoT) subpopulation (Fig. 14.9).[52,53] At the surface of placental villi, within the decidua and within decidual spiral arteries, fetally-derived trophoblast cells intimately contact maternal immune effector cells, thereby exposing the fetus to potential MHC-restricted recognition as non-self.

While the syncytiotrophoblast cells of the placental villi are devoid of MHC Class I and Class II molecules, those of the EvT and of the decidual endovascular trophoblast (EnT) are not. The unique MHC Class I expression pattern of the extravillous and endovascular cytotrophoblast

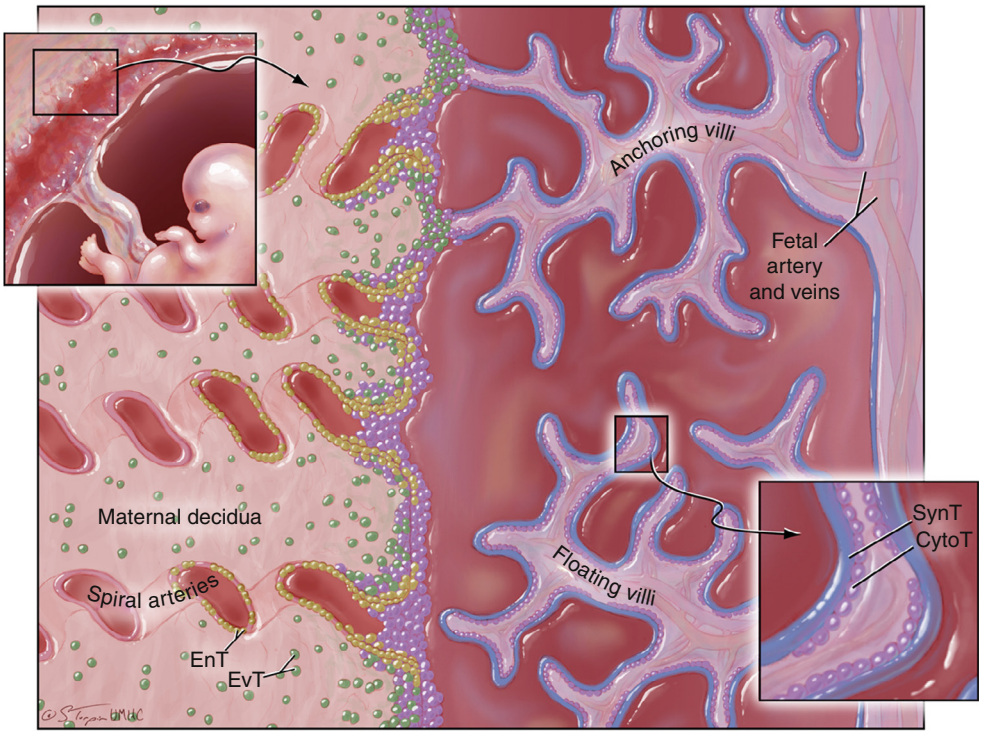

FIGURE 14.9 Trophoblast cells at the maternal-fetal interface. Only the trophoblast cells of the implanting blastocyst and developing fetus make direct contact with maternal tissues, including maternal immune cells. These cells include the syncytiotrophoblast (SynT) cells, the extravillous trophoblast (EvT) and the endovascular trophoblast (EnT) cells. SynT and EvT arise from stem cell-like cytotrophoblast cells. Over the entire surface of the floating and anchoring villi of the placenta, cytotrophoblast cells are covered by a multinucleated layer of SynT which comes into direct contact with maternal blood bathing the intervillous spaces. At the points of contact between the anchoring villi and the maternal decidua, a population of cytotrophoblast cells differentiates into extravillous trophoblast cells which have invasive properties. In humans (unlike mice) these cells can invade throughout the entire maternal decidua (where they contact decidual immune cells) and into the inner third of the myometrium. The endovascular trophoblast cells remodel and replace the typical cells in the walls of the maternal spiral arteries, making them relatively atonic conduits supplying maternal blood to the interstitial space. Here, the EnT are seen to be in direct contact with maternal blood. It is unclear whether EnV develop from EvT, directly from CytoT, or both. Here we depict a placenta with trophoblast plugging of the spiral arteries at their entry into the interstitial space. These plugs will be gone by about 12 to 13 weeks of gestation.

cell and its contact with the maternal immune system has spurred extensive hypotheses and investigations to explain why all placental cells down-regulate expression of the classical transplantation antigens (HLA-A and -B), while invasive extravillous and extravillous cytotrophoblast express HLA-C, -E, -G, and possibly -F[54,55] do not. These particular classical (HLA-C) and non-classical (HLA-E, -F, and -G) molecules are intriguing in that they seem to exhibit a fairly limited degree of polymorphism, making them less effective than their highly polymorphic classical MHC Class I molecule (HLA-A and -B) counterparts in antigen presentation. Most investigators now agree that trophoblast antigen-presenting molecules are central in innate immunity during pregnancy, particularly through interactions with the abundant, albeit somewhat enigmatic decidual NK cells (dNK; discussed later in the chapter). This novel approach, although radically shifting attention away from the Medawar allo-transplantation paradigm, does have attractive evolutionary support. For instance, since NK cells will recognize and kill cells that lack MHC Class I products, the expression of Class I products with limited polymorphism (HLA-G and -E) or limited surface expression half-life (HLA-C) may protect extravillous cytotrophoblast cells from NK-like dNK-mediated attack.[37,56] With deference to Medawar and colleagues,[32] down-regulation of more classical transplantation antigens (HLA-A and -B) on all trophoblast cells may protect from allogenic T cell attack. Trophoblast cells are, in fact, resistant to lysis by CD8+ T cells *in vitro* while fetal fibroblasts are not.[13] Alternatively, interactions of trophoblast-expressed HLA-C, -E, -F, or -G with surface receptors on maternal immune effector cells may modulate immune cell cytokine-chemokine expression profiles.[57,58] Interactions between trophoblast MHC molecules and activating and inhibitory receptors on decidual NK cells and macrophages have received particular attention.[37,58,59] These interactions are poor inducers of cytotoxicity,[38] but are important in promoting immune effector functions supporting pregnancy[58,60] as well as decidual and vascular trophoblast invasion, spiral artery remodeling and angiogenesis.[61-63] The effects of trophoblast MHC Class I products on maternal adaptation to implantation of the allogeneic pregnancy need not be direct. For instance, circulating soluble forms of MHC Class I products, such as HLA-B, have been shown to promote tolerance.[64] When secreted into the maternal circulation, similar soluble forms of trophoblast HLA-G appear to promote maternal tolerance to pregnancy-associated tissues.[57] Finally, isolated polymorphisms in trophoblast Class I molecules[54,65] and in its immune cell receptors[66] and alterations in the Class I/NK receptor repertoire[67,68] have been associated with adverse

pregnancy outcomes, particularly isolated and recurrent pregnancy loss. Interestingly, evidence in mice suggests that antigen presentation in pregnancy is severely restricted and only commences after the stage of endovascular invasion (after 9 to 12 weeks in humans).[69]

Immunomodulation and Pregnancy Maintenance

Most investigators now believe that during a normal pregnancy, the implanting fetus is usually recognized by the maternal immune system and immune responses, including proinflammatory-proangiogenic responses to fetal antigens, have been demonstrated.[62,70] These responses, however, occur in an environment characterized by dramatic systemic and local hormonal and metabolical alterations. Many of these alterations have potential immunomodulatory effects and any or all may be critical for pregnancy maintenance. While the pregnant state has long been considered a state of relative immunosuppression to protect the allogenic fetus, this appears to overly simplify the immunology of pregnancy. Pregnancy is not a state of total systemic immunosuppression but rather a state of dramatic immune modulation.

Some evidence does support the concept that a decrease in systemic maternal immune responses occurs in normal pregnancy and may be essential to pregnancy maintenance. For instance, failure to down-regulate maternal responses to recall antigens, such as tetanus toxoid and influenza, has been linked to poor pregnancy outcome among Recurrent Pregnancy Loss (RPL) patients.[71] T helper cell type 1 (Th1)-mediated autoimmune diseases, such as rheumatoid arthritis (RA) and multiple sclerosis (MS), often improve during pregnancy. T helper cell type 2 (Th2)-mediated disorders such as systemic lupus erythematosus (SLE), however, frequently worsen during pregnancy.[72] Further, some viral diseases and several parasitic diseases[73] are particularly aggressive when first encountered during pregnancy. Still, pregnant women are not more susceptible to the vast majority of infectious diseases, nor are they safeguarded from the effects of the majority of autoimmune disorders.

Whether pregnant or not, women are, in general, more susceptible to autoimmune diseases than men. This striking gender difference in immune resposivity[74] is thought to reflect effects of the reproductive hormones on peripheral cell mediated immunity. Reproductive steroid hormones (e.g., estrogen, progesterone, and testosterone) and protein hormones (e.g., prolactin) are all potent immune modulators.[75-77] The effects of reproductive hormones within the microenvironment of the maternal-fetal interface may be further enhanced by the fact that their concentrations are significantly higher than those in the maternal circulation.[78]

Circulating levels of maternal estrogens and progesterone are elevated early in pregnancy and this elevation continues throughout gestation (Fig. 14.10).[72] Many of the described immunomodulatory effects of these hormones can be considered to support pregnancy. Progesterone's immunosuppressive characteristics include an inhibition of mitogen-induced proliferation of CD8+ T cells and of cytokine secretion by these cells and a promotion of Th2-type responses with increased expression of LIF.[33,74,79] Both responses would be predicted to promote an immune environment favoring pregnancy maintenance. Interestingly, the effects of progesterone on immune cell function are not necessarily mediated by the classical cytoplasmic-nuclear receptor[80] but rather, can occur via direct cell membrane alterations[81] or via the membrane progesterone receptor. Estrogen-related immune alterations that would be predicted to promote pregnancy maintenance include the down regulation of delayed type hypersensitivity (DTH) reactions, the promotion of Th2-type immune responses and demonstrated protection against chronic allograft rejection.[79,82,83] Prolactin has stimulatory effects on both cell-mediated and humoral immune responsiveness.[77] The magnitude of these effects depends on posttranscriptional modifications of the prolactin molecule and may extend to innate immune effector cells such as γδ T cells.[84] Human chorionic gonadotropin has also been recently implicated in pregnancy immunomodulation through purported effects on recruitment of regulatory T cells to the site of implantation during early human pregnancy.[85]

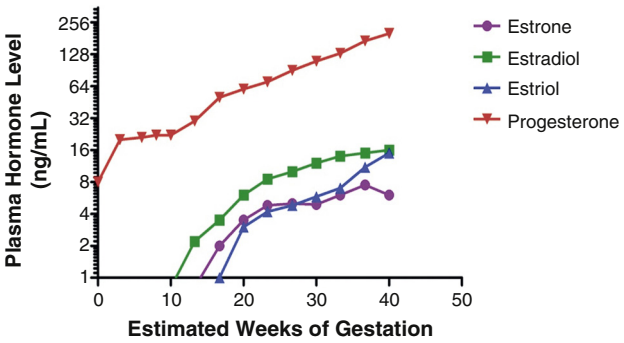

FIGURE 14.10 Plasma hormone levels during pregnancy. Levels of estrone, estradiol, estriol, and progesterone in ng/mL during human gestation to 40 weeks.

Metabolical alterations during pregnancy may also play a role in protective immunomodulation. Indoleamine 2,3 dioxygenase (IDO) is involved in the catabolism of the amino acid, tryptophan. Since T cells require tryptophan for activation and proliferation, local alterations in tryptophan supply and/or in IDO activity would be predicted to alter T cell mediated immune activity. IDO activity has recently been shown to support the suppressive function of T regulatory cells.[86] Alterations in tryptophan concentrations and in IDO activities have been linked to several adverse pregnancy outcomes, including pregnancy loss and preeclampsia.[52,87]

Alloimmunity and Recurrent Pregnancy Loss

Since the fetus is antigenically different from the mother, the mother's immune system might be predicted to identify the fetus as foreign and execute an immune response. The abundance of immune cells within the decidua and the production of numerous immunological cytokines at the maternal-fetal interface make the potential for an immune-associated pregnancy rejection plausible since, unless the appropriate mechanism(s) are in place to modify maternal immune processes, the semi-allogeneic fetus should be rejected. A variety of alloimmune factors have been postulated to cause recurrent pregnancy loss and innumerable investigations have been performed to address the potential role of alloimmune factors in RPL. Several approaches to the diagnosis of alloimmune RPL have been considered in almost painstaking detail, including antipaternal cytotoxic antibody testing, mixed lymphocyte culture reactivity

testing, embryotoxicity evaluations, immune cell phenotyping, peripheral cytokine phenotyping, and human leukocyte antigen (HLA) profiling. While none of this testing has proven to be clinically useful in its present forms, many of these diagnostic approaches are currently employed in clinical practice. They are outlined briefly here because they have historical and mechanistic interest and not as an endorsement of their clinical utility.

Embryotoxicity assays have been proposed as a means to detect abnormal peripheral cellular immune responses to human trophoblast-derived antigens.[88] The embryotoxic factor (ETF) assay measures the development of an inflammatory reaction to the presence of placental antigens by maternal peripheral immune cells that may predict similar *in vivo* responses during a subsequent pregnancy. While the theoretical basis for the use of the ETF assay may have some merit, the commercially available test has proven to be neither consistent nor predictive of pregnancy outcome.

Immune phenotyping using flow cytometric analysis of peripheral blood cells, especially CD56+ natural killer (NK) cells, has been extensively evaluated in recurrent pregnancy loss; a comprehensive review in 2011 reports over 780 publications, of which only 12 were deemed of sufficient quality for inclusion in an analysis.[89] The authors of this review found no consistent evidence that peripheral NK cell testing predicted subsequent pregnancy outcome in women with RPL. Flow cytometric analyses have recently confirmed in non-pregnant women with RPL that peripheral NK cell phenotypes are quite different from endometrial NK phenotypes,[65] further suggesting that peripheral phenotyping is unlikely to be useful in improving our understanding of immunology at the maternal-fetal interface. In summary, the current clinical literature supports neither testing for peripheral NK cell activity nor immunomodulatory treatments based on the results of these assays.[90]

Antipaternal cytotoxic antibody testing and antileukocyte antibody assays are likewise of little value in the assessment of couples with recurrent pregnancy wastage. These antibodies are usually not detected before 28 weeks gestation and are often not detectable in non-pregnant women. This makes them of little clinical utility as screening tools since they cannot prospectively and predictably direct interventions. Testing for the development of "blocking antibodies" using mixed lymphocyte culture (MLC) reactivity assays does not aid in the prediction of pregnancy outcome, but rather, reflects the number and duration of prior pregnancies.

Peripheral cytokine profiling studies are plagued by concerns about cytokine dysregulation being a cause rather than an effect of the pregnancy demise. Further, since the measurement of peripheral cytokine levels does not appear to reflect changes occurring locally at the maternal-fetal interface[91] and the specific cytokines or cytokine patterns of etiological importance in human pregnancy loss remain unclear, such testing among women with recurrent pregnancy loss remains experimental and should be offered only under an IRB-approved protocol and at no cost to the patient or third party insurer.

The use of HLA typing in the diagnostic work-up of recurrent pregnancy loss patients has also been specifically investigated. The best investigation of the hypothesis that maternal and paternal MHC haplotype similarities might result in pregnancy loss involved an isolated religious sect in South Dakota: the Hutterites. From this circumscribed, stable, and inbred population came initial data refuting a role for HLA matching in adverse pregnancy outcome.[92] However, a more recent and expanded investigation of the same population reported that maternal and paternal HLA matching can be associated with adverse pregnancy outcomes.[93] However, as discussed in this manuscript, exact HLA matching is virtually never seen in outbred populations and therefore HLA typing is not recommended in patients with recurrent pregnancy loss. Recent large studies have also shown no association between HLA-DQα homozygosity and RPL.

To summarize a long and voluminous literature, no testing for alloimmune-associated pregnancy wastage is currently indicated in the evaluation of RPL and no treatment interventions based on this testing should be instituted except as part of an IRB-approved research study. A multicentered, prospective, randomized, placebo-controlled trial comparing intravenous immunoglobulin to saline for the treatment of idiopathic secondary recurrent miscarriage concluded that there was no benefit in treatment of patients with potential alloimmune factors.[94]

Autoimmunity and Reproduction

Numerous studies have attempted to identify autoantibodies associated with pregnancy failure. The most commonly studied antibodies in women with pregnancy loss and infertility include antiphospholipid and antithyroid antibodies. Antiovarian antibodies have been associated with polyglandular autoimmune syndromes including ovarian insufficiency and ovarian failure. Other immunological factors of potential interest to reproductive endocrinologists include antigliadin antibodies, antinuclear antibodies, antisperm antibodies, and endometriosis-associated immune responses.

When autoantibodies are found in association with pregnancy failure there are several possible explanations:

- A direct stimulus generates autoantibodies which may impact the health of the pregnancy (e.g., autoimmune hemolytic immunity)
- A remote disease process leads to tissue damage that may result in antibody formation indirectly affecting the pregnancy (e.g., thyroiditis)
- A factor is present that simultaneously negatively impacts the pregnancy and induces autoantibodies (e.g., a virus)

Autoantibodies may be *organ-specific*, as in the case of Hashimoto's thyroiditis. In this disorder, there is a specific lesion in the thyroid involving infiltration by mononuclear cells and destruction of follicular cells; this is followed by the production of antibodies with absolute specificity to thyroglobulin or thyroid peroxidase. On the other hand, autoantibodies may be *non-organ specific*. For example, in patients with systemic lupus erythematosus, antibodies are formed but lesions and autoantibodies are not confined to any one organ. Although antibodies may be detected for many years after they are initially identified, their presence does not always indicate a disease process. There may be considerable overlap in the specificity of the autoantibodies; this is more common for non-organ specific antibodies.

An increased familial incidence of autoimmunity has been determined to be genetic based on studies of identical and non-identical twins. Familial autoimmunity more frequently is organ-specific. Strong associations have been established between the major histocompatibility complex and autoimmune disease.[95] Linkage of human leukocyte antigen (MHC Class II) haplotypes predispose individuals to Hashimoto's thyroiditis (DR4 and DR3), Celiac disease (DQ2 and DQ8), and Type 1 diabetes (DR3, DR4, and DQβ1).

Antiphospholipid Antibodies (aPL)

Antiphospholipid antibodies (aPL) are acquired antibodies (IgG, IgM, and/or IgA isotypes) directed against negatively charged phospholipids, a group of inner and outer cell membrane antigens found in mammals. Obstetrical antiphospholipid antibody syndrome (APS) is diagnosed in the presence of certain clinical features in conjunction with positive laboratory findings. Although obstetrical APS was originally reported in association with slow progressive thrombosis and infarction in the placenta, it is most often associated with poor obstetrical outcomes. In fact, obstetrical APS is one of the most commonly identified causes of recurrent pregnancy loss. Thus, obstetrical APS is distinguished from APS in other organ systems where the most common manifestation is thrombosis. Present in an estimated 2% to 5% of the general population, aPL are commonly associated with other autoimmune diseases (secondary APS) such as systemic lupus erythematosus, but can also present in isolation in the form of primary antiphospholipid syndrome.

Antiphospholipid syndrome was first described in 1983 in patients with systemic lupus erythematosus, the presence of anticardiolipin antibodies and thrombosis. Since this initial presentation the criteria for diagnosis have been revised.[96] In order for a patient to be diagnosed with antiphospholipid syndrome at least one of the clinical criteria and one of the laboratory criteria must be met (Box 14.1).

Box 14.1 Research Criteria for the Diagnosis of Antiphospholipid Antibody Syndrome

CLINICAL CRITERIA

1) Vascular Thrombosis: One or more episodes of arterial, venous, or small vessel thrombosis in any tissue or organ.
2) Morbidity in Pregnancy
   - One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation.
   - One or more premature births of a morphologically normal neonate prior to the 34th week of gestation secondary to eclampsia or severe preeclampsia or recognized features of placental insufficiency.
   - Three or more unexplained consecutive spontaneous miscarriages before the 10th week of gestation.

LABORATORY CRITERIA: (MUST BE PRESENT ON TWO OR MORE OCCASIONS AT LEAST 12 WEEKS APART):

- Lupus anticoagulant present.
- Anticardiolipin Antibody; medium or high titer (>40 micrograms of IgG or IgM phospholipids or >99th percentile) of IgG or IgM isotype.
- Anti-β2-glycoprotein; medium or high titer (>40 micrograms of IgG or IgM phospholipids or >99th percentile) of IgG or IgM isotype.

Recurrent Pregnancy Loss and Antiphospholipid Antibodies

Recurrent pregnancy loss affects up to 5% of reproductive aged women. Evaluation classically begins after three consecutive miscarriages of less than 10 weeks gestation but may be warranted earlier if a prior miscarriage was found to be euploid, or if there is concomitant infertility or advanced maternal age.[97] An identifiable cause of RPL will be detected in approximately 50% of couples after an investigation of possible genetic, anatomical, immunological, and endocrine causes (Table 14.4).[98]

Antiphospholipid antibodies (aPL) will be identified in a significant number of women with RPL after a careful evaluation. aPL interact with the maternal-fetal interface in multiple ways and are associated with RPL.[25] The involvement of aPL in adverse pregnancy outcomes is thought to be more as an autoimmune factor than a thrombophilic factor; histological studies of placentas obtained following spontaneous miscarriage have found defective endovascular trophoblastic invasion rather than intervillous blood clots.[99] Studies have linked aPL with decreased release of hCG from human

Table 14.4 Standard Evaluation and Management of Recurrent Pregnancy Loss

Etiology	Diagnostic Evaluation	Abnormal Result	Therapy
Structural genetic	Cytogenetic analysis of both partners	3%–5%	Genetic counseling, donor gametes, preimplantation genetic screening
Anatomical	Hysterosalpingogram, hysteroscopy, or sonohysterography	15%–20%	Hysteroscopic septum resection, myomectomy, lysis of adhesions
Endocrinological	Midluteal progesterone	8%–12%	Progesterone
	Thyrotropin		Levothyroxine
	Prolactin		Bromocriptine, cabergoline
	Hemoglobin A1c		Metformin
Immunological	Lupus anticoagulant Antiphospholipid antibodies β2 Glycoprotein 1	15%–20%	Heparin + aspirin
Lifestyle issues	Tobacco use	15%–20%	Eliminate consumption
	Excessive alcohol		Reduce consumption
	Exposure to toxins		Eliminate exposure
	Obesity		Lower body mass

placental explants, prevention of *in vitro* trophoblast migration and invasion, inhibition of trophoblast cell adhesion molecules and activation of complement on the trophoblast surface inducing an inflammatory response.[100] In women referred to reproductive endocrinologists with APS and histories of early loss, the prevalence of prior thromboembolic events is low. However, these patients are still at risk for thromboembolic events. Estrogen-containing oral contraceptive pills (OCPs) should be avoided in women with repeated positive aPL.

Antiphospholipid antibodies have been found in 15% of patients with recurrent first trimester loss. The original clinical trial on treatment of obstetrical APS that reported the superiority of unfractionated heparin and low-dose aspirin[101] has been reaffirmed by a recent systematic literature review and meta-analysis. Multiple independent investigators found that patients with aPL-associated recurrent pregnancy loss who were treated with unfractionated heparin and low-dose aspirin had improved live birth rates.[102] However, studies proposing anticoagulation for the treatment of unexplained RPL in women without aPL have not shown a benefit of treatment.[103,104]

Controversy still exists concerning testing for antibodies against other phospholipids, but an increasing number of studies suggest that antibodies to phosphatidyl serine are also associated with pregnancy loss. The College of American Pathologists added antibodies to phosphatidyl serine to its proficiency test profile in 2012. In women who have a diagnosis of APS by meeting both clinical and laboratory criteria, the chance for successful pregnancy is reduced. In these cases, treatment appears to be a clear option particularly in the case of those with prior thromboembolic events. Current clinical guidelines support the use of subcutaneous heparin and aspirin. This treatment should begin with a positive pregnancy test, continue throughout pregnancy, and extend postpartum.

Infertility and aPL

Antiphospholipid antibodies have been reported with increased frequency in women with unexplained infertility and in women with recurrent implantation failure after *in vitro* fertilization.[105] It is plausible that aPL contained in the serum could have a significant impact on ovulation, fertilization, or early embryonic development. As aPL have been shown to interact at the maternal-fetal interface resulting in a defective endovascular trophoblastic invasion, it is scientifically plausible that aPL may induce infertility via their negative effects on implantation.

One method of assessing the effects on aPL on fertility and implantation is to evaluate the effects of aPL on the success of IVF procedures in women who have not received aPL-related anticoagulation therapy. More specifically, one can compare the IVF outcomes among aPL positive subjects to those who are aPL negative. This analysis was performed by the American Society for Reproductive Medicine who concluded that although the frequency of aPL is increased in infertile patients undergoing IVF, the cumulative evidence does not demonstrate a clear negative impact of aPL on IVF success.[106] Therefore, since infertility outcomes, including IVF have not been demonstrated to be significantly impacted by the presence of aPL, these patients should not be routinely screened for aPL.

Antithyroid Antibodies (ATA)

Antithyroid antibodies (ATA) directed against thyroglobulin and thyroid peroxidase are commonly found in patients with Graves disease, postpartum thyroiditis, and Hashimoto's thyroiditis. However, ATA have been reported in healthy individuals and are observed more frequently in women during their reproductive years. The prevalence of ATA has been reported in 15% to 20% of normal pregnant women compared to 20% to 25% in women with recurrent miscarriage[107] and 46% of pregnant women with a diagnosis of hypothyroidism.[108]

Pregnancy Loss and ATA

Multiple investigations into the role of thyroid autoimmunity in RPL have been reported, but the interpretation of the evidence as a whole is difficult secondary to numerous variations in study design. Older studies have shown a significantly increased relative risk for thyroid autoimmunity in women with RPL who were euthyroid, but most of these studies used TSH values of 4.5 or 5.0 mIU/mL to define the upper limits of normal. The American Endocrine Society defines hypothyroidism as present when TSH values are greater than 2.5 mIU/mL and defines normal TSH levels between 1.0 and 2.5 mIU/mL during the first trimester of pregnancy. It is likely that many of the studies included women with ATA who had TSH levels greater than 2.5 mIU/mL but less than 5.0 mIU/mL and that clinical hypothyroidism, not the ATA, accounted for the increased prevalence of RPL.[109]

The most likely explanation is that hypothyroidism (TSH > 2.5 mIU/mL) resulting from ATA may be responsible for the increased incidence of RPL in this population. ATA have been reported in increased frequency among women with RPL and may indicate thyroid dysfunction. However, if the patient is euthyroid, the presence of antithyroid antibodies does not affect pregnancy outcome.[110,111] Women who have positive antithyroid antibodies and are euthyroid are at an increased risk for hypothyroidism during and after pregnancy. These women should have their thyrotropin levels tested during each trimester and postpartum for thyroiditis.

Studies on the treatment of subclinical hypothyroidism are variable and current guidelines on screening patients with RPL for thyroid dysfunction and autoimmunity are conflicted. Currently, it is advised to screen all women with RPL using an ultrasensitive assay for TSH. When TSH values are between 1.0 and 2.5 mIU/mL, no further action is indicated. If TSH values are above 2.5 mIU/mL, some clinicians will check for ATA and treat patients with levothyroxine to obtain TSH values between 1.0 and 2.5 mIU/mL. During pregnancy the requirement for replacement usually increases by about 25% so the clinician can increase replacement doses or monitor TSH levels closely during pregnancy. Because of the risk of postpartum thyroiditis, patients with thyroid dysfunction should be monitored and dosages of replacement adjusted as indicated.

Infertility and ATA

Clinical hypothyroidism that results from primary thyroid disease commonly leads to anovulation and infertility. The overall incidence of clinical hypothyroidism in anovulatory women is 4% to 7%.[108,112] The mechanism of anovulation in

these patients is an alteration of gonadotropin-releasing hormone (GnRH) pulsatility mediated through an increase in TRH and its effects on the production of prolactin. Therefore, any patient with both infertility and irregular menses should be screened with a serum TSH. The effects of subclinical hypothyroidism on fertility are unknown. However, individuals with subclinical hypothyroidism who conceive need to be re-evaluated during pregnancy as both their need for thyroid hormone will increase with pregnancy, and their "new normal" TSH levels will drop secondary to the stimulatory effects of hCG on thyroid hormone production.

Unlike the clear effects of hypothyroidism on anovulation and subsequent infertility, the effects of ATA on fertility are much less clear. Previous studies of infertile women undergoing IVF have not demonstrated either an increased rate of ATA in this population of patients nor a negative impact of ATA on IVF outcomes.[112] Despite the data against a relationship between the presence of ATA and adverse IVF outcomes, some investigators have evaluated the effects of immune-directed therapy in euthyroid women with elevated ATA levels on infertility treatment.[113] The relationship between ATA and fertility remains a subject that has not been extensively studied, and to date, there is clearly no indication for routinely testing infertile women for ATA.

Autoimmune Ovarian Insufficiency (AOI)

Increasingly ovarian autoimmunity is being implicated in the etiology of ovarian insufficiency, previously known as premature ovarian failure or premature menopause.[114] The diagnosis of autoimmune-mediated ovarian insufficiency is hampered because of the lack of specific and sensitive markers of disease. Antiovarian antibodies include antibodies against a heterogeneous group of antigens, including molecular targets in the zona pellucida, theca interna, granulosa cells, ooplasm and heat shock protein 90-β.[115] The best characterized cases of antiovarian antibodies has been in conjunction with polyglandular autoimmune syndromes.

When the dysfunction of two or more endocrine glands occurs in association with circulating organ-specific antibodies directed against the involved glands, the term polyglandular autoimmune syndrome (PAS) is applied.[116] The two major subtypes of PAS, types I and II, are distinguished according to age of presentation, characteristic patterns of endocrine deficiencies present, and inheritance pattern (Table 14.5). The principle endocrine components are adrenal insufficiency, thyroid hyperfunction or hypofunction, insulin-dependent diabetes mellitus, and premature gonadal failure. The basic underlying abnormality associated with polyglandular autoimmunity is a defect in the T-suppressor cell function and in PAS type I is caused by mutations in the autoimmune regulatory gene on chromosome 21.[117] There is increasing evidence that aberrant expression of HLA alleles B8 and DR3 located on chromosome 6 play important roles in the pathogenesis of PAS type II. Because of the key role of HLA-DR antigens in the processes of antigen presentation and T and B cell activation, it is thought that alleles of HLA DR3 and DR$ determine the targeting of specific tissues by autoreactive T cells, which leads to organ-specific autoimmunity as a result of a loss of tolerance.[118]

Table 14.5 Characteristics of Polyglandular Autoimmune Syndromes

Characteristic	PAS Type I (Blizzard Syndrome)	PAS Type II (Schmidt Syndrome)
Age of onset	Childhood	Adulthood
Incidence	<1:100,000	1:10,000
Genetics	Monogenic (*AIRE* gene)	Polygenic
Inheritance	Autosomal recessive	Autosomal dominant, linked to specific HLA haplotypes
Autoimmune Diseases		
Hypoparathyroidism	85%	100%
Adrenal insufficiency	65%	15%
Gonadal failure	45%	60%
Type I diabetes	10%	55%
Thyroid disease	10%	70%
Chronic mucocutaneous candidiasis	75%	None

Tissue damage and dysfunction occurring as a consequence of immune activation can develop through several mechanisms. Tissue damage may result from complement fixation and activation, from immune complex formation with complement activation, or via facilitation of natural killer cell binding. Polyglandular autoimmune syndromes include a spectrum of autoimmune endocrine disorders and can be divided into a rare juvenile type (PAS I) and a relatively common adult type with (PAS II) or without adrenal failure (PAS III).

Polyglandular Autoimmune Syndrome Type I

This syndrome is diagnosed in the presence of any two of the following three conditions: hypoparathyroidism, adrenal insufficiency, or chronic mucocutaneous candidiasis. More than 70% of individuals will have a combination of hypoparathyroidism and chronic mucocutaneous candidiasis, neither of which occurs in the other forms of polyglandular immunity. The onset of this disorder is during childhood with the first manifestations always developing before the age of 15 years. The average age of appearance of candidiasis, hypoparathyroidism, or both is 5 years of age and typically precedes the appearance of adrenal insufficiency, which generally occurs by age 13. Primary gonadal failure occurs in approximately half of these individuals.

The genetic mutation responsible for PAS I has been mapped to the autoimmune regulator gene on chromosome 21 (*AIRE* gene). Mutations in this gene result in the loss of central tolerance, the process by which developing T cells with potential reactivity for self-antigens are eliminated during early differentiation in the thymus. PAS type I has an autosomal recessive mode of inheritance. Females are affected about as frequently as males.

Circulating organ-specific antibodies are frequently present in patients with PAS type I. Patients with Addison's disease have circulating autoantibodies that have exclusive specificity to the adrenal cortex. Steroid cell antibodies cross-react with other steroidogenic tissues such as placental syncytiotrophoblast, Leydig cells of the testis, and the theca interna-granulosa layers of ovarian follicles.[119]

Early diagnosis and treatment of the hypoparathyroidism and adrenal insufficiency result in a favorable prognosis. Frequent clinical and laboratory surveillance of patients at risk of developing Addison's disease is important to enable diagnosis and initiation of replacement therapy before the development of acute adrenal crisis. Routine biochemical screening should be conducted at least annually but with increased frequency if clinical signs or symptoms suggestive of adrenal insufficiency develop. Early signals include complaints of weakness and easy fatigability with or without salt craving and, in children, a decrease in linear growth rate. In the past, biochemical monitoring of adrenal status was routinely accomplished with the ACTH stimulation test. More recently the adrenal-antibody test has been shown to have a comparable positive predictive value and a higher negative predictive value than the ACTH test, thus the adrenal-antibody test represents a more efficient tool in the clinical setting.[120]

Polyglandular Autoimmune Syndrome Type II (Schmidt Syndrome)

Polyglandular autoimmune syndrome type II (PAS II) is defined as the association of primary adrenal insufficiency with autoimmune thyroid disease or insulin-dependent diabetes. Individuals with PAS II present at a later age than PAS I with a peak incidence at ages 20 to 60 years, mostly in the third and fourth decades. There is often family clustering so it may be important to consider as affected those relatives of patients with a complete syndrome who themselves have one or more of the principle disease components but may still have normal adrenal function. In less than half of the cases, the initial manifestation is adrenal insufficiency with subsequent components of the disease appearing up to 20 years later. In approximately 30% of the cases, Addison's disease may follow the appearance of other endocrine disorders (Table 14.5). Primary hypogonadism is reported in approximately 10% of PAS II patients and may present as the only extra adrenal manifestation of this disorder.

The inheritance pattern of PAS II is complex. Autoimmune disease susceptibility appears to be inherited in an autosomal dominant fashion associated with specific HLA haplotypes. There is less than 100% concordance in monozygotic twins so environmental factors may be involved in disease pathogenesis contributing to a loss of self-tolerance. The alleles HLA B8 and HLA DR3 are found together more frequently than would be predicted from their frequency in the general population (linkage disequilibrium). The allele DR3 is most frequently associated with autoimmune endocrine disorders. Thus, PAS II is considered a polygenic disease with autosomal dominant inheritance and incomplete penetrance.

Immune Etiology of Ovarian Insufficiency

Premature ovarian failure has been defined as persistent amenorrhea between puberty and age 40 years associated with a hypergonadotropic state. The clinical manifestations are related to estrogen loss and include secondary amenorrhea, vasomotor instability, psychological symptoms, atrophy of the vagina and urethra, osteoporosis, and infertility. There are subcategories of women with regular menstrual cycles and elevated FSH who have incipient ovarian failure while other patients with transitional ovarian failure may present with oligomenorrhea and elevated FSH. Ultimately this heterogeneous condition of ovarian insufficiency develops through two major mechanisms, follicle dysfunction and follicle depletion.[121] Anti-müllerian hormone levels and antral follicle counts may be more accurate measures of follicular pool depletion in young women presenting with elevated FSH levels.[122]

Substantial evidence indicates that ovarian insufficiency can result from autoimmune processes directed against the steroidogenic cells of the ovarian follicle.[123] Ovarian histopathological studies in steroid cell antibody positive patients with premature ovarian failure consistently show lymphocyte oophoritis. CD4+ and CD8+ T lymphocytes and plasma cells make up most of the infiltrate.[124] This is reminiscent of other destructive autoimmune endocrinopathies such as Addison's disease. Microsomal enzymes catalyzing key steps of steroid hormone synthesis are the tissue antigen targets detected by immunofluorescent techniques. These enzyme targets include cytochrome P450 21-hydroxylase, an adrenal specific antigen, cytochrome P450 17-hydrolylase and cytochrome P450 side-chain cleavage enzyme, which are present in the adrenal cortex, the gonads, and the placenta. The presence of steroid cell antibodies may serve as a marker of ovarian insufficiency in women with Addison's disease; however, few women with premature ovarian failure will have ovarian antibodies in the absence of Addison's disease.[125]

Investigations into the causes of premature ovarian failure will infrequently provide answers for patients who are distressed with this diagnosis. The patient history will uncover cases of chemotherapy and/or pelvic radiotherapy while the karyotype will reveal Turner's syndrome and mosaic causes of ovarian failure. The family history should be explored for other similar cases as well as any history of autoimmune disorders. The initial hormonal evaluation of FSH, LH, estradiol, and TSH should include anti-müllerian hormone. Most clinicians include an initial test of serum levels of calcium and phosphorus with a complete blood count. Ultrasound evaluation of the ovaries for antral follicles has also been shown to be a useful prognosticator. Autoimmune testing for adrenal antibodies, cytochrome P450 microsomal antibodies, and thyroid antibodies are becoming increasingly more common. The value of periodic screening is unclear; however the suspicion of associated endocrinopathies should be high in physicians caring for patients with premature ovarian insufficiency. Spontaneous resumption of ovarian function has been reported in about 25% of young women with premature ovarian failure and with antral follicles documented by ultrasound, and subsequent live births have occurred in some cases.[126] Because intermittent ovarian activity is common in women diagnosed with premature ovarian failure, therapies utilizing corticosteroids for immunosuppression should be avoided. Periodic monitoring of ovarian reserve may be of benefit in assisting patients who may ultimately decide to use ovum donation as a means to having children.

Other Autoimmune Factors in Reproduction

Antisperm Antibodies (ASA)

Spermatozoa contain antigens that are foreign to both male and female immune systems. Sperm antibodies that are bound to spermatozoa are found in over half of men's

seminal fluid or serum after vasectomy as during this procedure, the blood-testis barrier is broken and sperm antigens are presented to the immune system. In this instance, the sperm-bound ASA can be found bound to the head, midpiece, or tail of the spermatozoa. ASA persist after vas reversal, and some of these individuals can subsequently father children, thus ASA generated in this fashion do not necessarily result in failure of fertilization in all cases.

The etiology of sperm-directed immunity in women is unknown; however, the possible mechanisms include cross-reactivity with microbial antigens, breach or sensitization at intestinal mucosal surfaces, and interferon gamma-mediated potentiating of the antisperm immune response in women whose male partners have sperm autoantibodies in their semen.[127] It has been suggested that ASA in women are a cause of unexplained infertility. Sperm immobilization, inhibition of cervical mucus penetration, and interference with events that lead to sperm-oocyte binding are some of the mechanisms by which antisperm antibodies impede fertilization. ASA have been postulated to interfere with successful pregnancy through inhibition of implantation of the early embryo. A few retrospective studies have suggested that sperm-bound antisperm antibodies decrease embryo quality and implantation rates. However, these data have not been replicated in large prospective studies.

Review of numerous retrospective and prospective analyses of pregnancy rates for couples with circulating ASA leads one to question the prognostic value of ASA screening for diagnosis of infertility. The inconclusive and inconsistent results of these studies may be attributed to the presence of heterogeneous populations of ASA, the varying antibody titers, the various populations studied, the source of the specimen (serum, cervical mucus, semen), and the method of testing.[128] Identification of several sperm antigens against which antibodies may be directed may help explain why ASA studies using samples from numerous infertile patients have not produced a clear explanation of a specific antibody's role in fertility impairment. It is now recognized that not all ASA interfere with fertilization or impair fertilization at the same level. A more practical approach to this question would be to first identify antibodies that bind to specific antigens that impair specific processes such as the acrosomal reaction. Until more specific testing can be developed, the routine testing of men and women for ASA cannot be recommended in infertile couples or in those with recurrent pregnancy loss. However, in men with asthenospermia suspected to be secondary to ASA, one should consider intracytoplasmic sperm injection (ICSI) in these patients as intrauterine insemination (IUI) does not preclude the effects of these antibodies in the uterus or fallopian tubes.

Antigliadin Antibodies (AGA)

Celiac disease is an immune-mediated enteropathy that develops in susceptible individuals upon ingestion of a gluten-containing diet.[129] The definition of celiac disease or gluten-sensitive enteropathy includes the following three features: (1) villous atrophy; (2) symptoms of malabsorption such as steatorrhea, weight loss, or other signs of nutrient or vitamin deficiency; and (3) resolution of the mucosal lesions and symptoms upon withdrawal of gluten-containing foods, usually within a few weeks to months. Patients with celiac disease possess antibodies against gliadin (AGA), tissue transglutaminase (IgA-tTG), or anti-endomysial antibodies (EMA-IgA).[130] In addition to the presence of one or more of these antibodies, the diagnosis of celiac disease includes the presence of intraepithelial lymphocytes within the enterocytes diagnosed from endoscopic-guided duodenal biopsies. Celiac disease is closely associated with other autoimmune endocrine disorders. In prospective studies, the prevalence of celiac disease has been reported to be between 1% to 19% in patients with type 1 diabetes, 2% to 5% in autoimmune thyroid disorders and 3% to 7% in primary biliary cirrhosis. The pathogenesis of the coexistent between celiac disease and other autoimmune diseases is not known.

Untreated celiac disease has been associated with pregnancy loss. The relationship between untreated celiac disease and pregnancy loss may be related to the immune system, since the lamina propria of the intestinal tract is the largest immune organ in the body. Patients with celiac disease have immune responses to gliadin fractions, primarily in the upper small intestine, characterized by inflammatory cells and villous atrophy in the lamina propria and epithelium. This association has been reported as resulting in an increased risk of miscarriage. Treatment of celiac disease with a gluten-free diet (reduction of wheat, barley, and rye from the diet) appears to prevent the problem of miscarriage. There is currently no clear linkage between celiac disease, associated autoantibodies, and infertility.

Although routine screening of women with either infertility or RPL for antigliadin, antitransaminase, or antiendomysial antibodies is not recommended, patients who present with symptoms of malabsorption such as steatorrhea, weight loss, or other signs of malnutrition should be screened for celiac disease. Women who have been diagnosed with celiac disease should delay pregnancy until they are stabilized on a gluten-free diet.

Antinuclear Antibodies (ANA)

Antinuclear antibodies (ANA) are a group of antibodies that target nuclear and cytoplasmic antigens. These antigens are essential to cell function through playing a role in transcription, translation, and cell cycle regulation. Low titer ANA (<1:80) are found in 20% to 30% of reproductive-aged women and are of no known consequence. However, higher positive ANA titers are associated with multiple autoimmune disorders such as systemic lupus erythematosus.[131]

In patients with SLE, these antibodies, particularly anti-Ro/SSA, can have a significant impact on their offspring. More specifically, the prevalence of congenital heart block, defined as an atrioventricular block diagnosed *in utero*, at birth, or within the neonatal period (0 to 27 days after birth) in the offspring of an anti-Ro/SSA-positive woman is 1% to 2%. Furthermore, 10% to 20% of these infants have a neonatal lupus rash.[132] However, in the absence of clinical disease, such as SLE, what impact a positive ANA has on either fertility or RPL is unknown. A prospective randomized trial evaluated the effect of prednisone and aspirin in women with ANA and RPL but concluded there was no benefit to therapy.[133] In the same study, women with RPL who were treated with prednisone during pregnancy had increased frequencies of gestational diabetes and hypertension and the babies were born earlier with lower weights.

Based on these data, screening asymptomatic women with RPL or who are infertile for ANA is not recommended. Patients who have a history of an autoimmune disease such as systemic lupus erythematosus, rheumatoid arthritis, or Reynaud's syndrome should be screened for ANA particularly for the effects that these antibodies may have on their neonates.

Endometriosis-Associated Immune Responses

Endometriosis is a benign gynecological disorder that affects 5% to 10% of reproductive-aged women. The disease is characterized by the presence of ectopic endometrial tissue that is commonly found adherent to the peritoneal surface of the posterior cul-de-sac and on the surface of the ovary. As endometriosis is a familial disease, it has the potential to carry a familial autoimmune pathogenic response. The disease is also associated with both a chronic inflammatory pelvic response and adhesion formation in many women. Endometriosis is clearly associated with both infertility and pelvic pain.

Despite decades of intensive investigations, little is known about the cellular pathogenesis of endometriosis. Although endometriosis is likely to be a multifactorial disease, the most prevalent theory of the pathogenesis of the disease is reflux menstruation. The pathogenic theory of reflux menstruation includes the proposition that women who are destined to develop endometriosis may have either a deficient immune system that cannot effectively clear endometrial tissue from their peritoneal surfaces or an immune system that develops a tolerance to the monthly flux of endometrium into the peritoneal cavity. Abnormal levels of immune cells such as macrophages, dendritic and natural killer cells have been found in the peritoneal cavity of women with endometriosis.[134] However these cells seem to be unable to detect and eliminate ectopic endometrial cells. In this regard, several studies have shown that peritoneal immune cells in women with endometriosis are dysfunctional and may contribute to the development of endometriosis. Still, the role of immune-surveillance in the pathogenesis of the disease is unclear.[135] Both IgG and IgA antibodies as well as lymphocytes have been found in increased levels within the normal endometrium of women with endometriosis. Whether an immunological abnormality predisposes an individual to the development of endometriosis, or whether the retrograde deposition of endometrium simply induces an inflammatory response is unknown. Although treatment with non-steroidal anti-inflammatory drugs (NSAIDs) can help reduce the pain associated with endometriosis, to date, no immune-directed therapy has been shown to improve either the infertility or the pelvic pain associated with this disease. Furthermore, no antibody or immune cell testing is recommended in women with endometriosis other than for the purposes of research.

Conclusions

For a pregnancy to succeed, two immunologically and genetically distinct tissues must coexist. During implantation, local and systemic immune factors, cytokines, and growth factors may interact with adhesion molecules and other matrix-associated proteins, glycoproteins, and peptides.[136] Several autoimmune factors have been investigated as possible influences on reproductive success and failure. Autoantibodies may persist for many years in the circulation as a marker of a prior autoimmune attack, but their presence alone does not necessarily indicate a current disease process. We are just beginning to understand the complex interactions between the endocrine and immune system that support the human fetal semi-allograft.

CHAPTER 15

Menopause and Aging

Rogerio A. Lobo

Epidemiology

Menopause is defined by the last menstrual period. Because cessation of menses is variable and many of the symptoms thought to be related to menopause may occur prior to cessation of menses, there is seldom a precise timing of this event. Other terms used are *perimenopause*, which refers to a variable time beginning a few years before and continuing after the event of menopause, and *climacteric*, which merely refers to the time after the cessation of reproductive function. While the terms *menopausal* and *postmenopausal* are used interchangeably, the former term is less correct because "menopausal" should only relate to the time around the cessation of menses.

As life expectancy increases beyond the eighth decade worldwide, particularly in developed countries, an increasing proportion of the female population is postmenopausal. With the average age of menopause being at 51 years old, more than a third of a woman's life is now spent after menopause. Here symptoms and signs of estrogen deficiency merge with issues encountered with natural aging. As the world population increases and a larger proportion of this population is made up of individuals over 50, medical care specifically directed at postmenopausal women becomes an important aspect of modern medicine. Between the years 2000 and 2005, the world population older than 60 years old is expected to double, from 590 million to 1 billion. In the United States, the number of women entering menopause will almost double in the 30 years between 1990 and 2020 (Table 15.1).[1]

Age of menopause, which is a genetically programmed event, is subject to some variability. The age of menopause in western countries (between 51 and 52 years old),[2,3] is thought to correlate with general health status.[4-6] Socioeconomic status is associated with an earlier age of menopause.[2] Higher parity, on the other hand, has been found to be associated with a later menopause.[7] Smoking has consistently been found to be associated with menopause onset taking place 1 to 2 years earlier.[3,8] While body mass has been thought to be related to age of menopause (greater mass with later menopause),[9] the data have not been consistent. Malnourishment and vegetarianism have both been found to be associated with earlier onset of menopause.[10,11] However, physical and athletic activity has not been found consistently to influence the age of menopause.

There also appear to be ethnic differences in the onset of menopause. In the United States, African American and Hispanic women have been found to have menopause approximately 2 years earlier than white women.[12,13] Although parity is generally greater around the world than in the United States, the age of menopause appears to be somewhat earlier. Malay women have menopause at approximately age 45, Thai women at age 49.5, and Filipina women between ages 47 and 48.[14-16] Countries at higher altitude (Himalayas or Andes) have been shown to have menopause 1 to 1.5 years earlier.[17,18] Because the average age of menopause in the United States is 51 to 53 years with an age distribution weighted toward white women, menopause prior to age 40 is considered premature. Conversely, by age 58, 97% of women will have gone through menopause.

The primary determinate of age of menopause is genetic. Based on family studies, heritability for age of menopause averaged 0.87—suggesting that genetics explain up to 87% of the variance in menopausal age.[19] Multiple genes have been identified which relate to the age of menopause.[19a] These genes have been implicated in DNA repair and immune function.[19a]

Premature Ovarian Failure

Premature ovarian failure (POF) is defined as hypergonadotropic ovarian failure occurring prior to age 40. Recently it has been suggested to refer to POF as premature ovarian insufficiency (POI) to more effectively reflect its heterogeneous nature.[19b] In practice, both these terms are used interchangeably. POF has occurred in 5% to 10% of women

Table 15.1 U.S. Population Entering the Postmenopausal Years, Ages 55 to 64

Year	Population
1990	10.8 million
2000	12.1 million
2010	17.1 million
2020	19.3 million

Adapted from U.S. Bureau of the Census. Current population reports: projections of the population of the United States 1977 to 2050. Washington, D.C., U.S. Government Printing Office, 1993.

who are evaluated for amenorrhea,[20,21] thus the incidence varies according to the prevalence of amenorrhea in various populations. Estimates of the overall prevalence of POF in the general population range between 0.3% to 0.9% of women.[22,23]

Throughout life, there is an ongoing rate of atresia of oocytes. Because this process is accelerated with various forms of gonadal dysgenesis due to defective X chromosomes, one possible etiology of POF is an increased rate of atresia that has yet to be explained. A decreased germ cell endowment or an increased rate of germ cell destruction can also explain POF.[20] Nevertheless, some 1000 (of the original 2 million) primarily follicles may remain.[24,25] While most of these oocytes are likely to be functionally deficient, occasionally spontaneous pregnancies occur in young women in the first few years after the diagnosis of POF.

There are several possible etiologies of POF (Table 15.2). Defects in the X chromosome may result in various types of gonadal dysgenesis with varied times of expression of ovarian failure. Even patients with classical gonadal dysgenesis (e.g., 45,XO) may undergo a normal puberty, and occasionally a pregnancy may ensue[26-29] as a result of genetic mosaicism. Very small defects in the X chromosome may be sufficient to cause POF.[30] Familial forms of POF may be related to either autosomal-dominant or sex-linked modes of inheritance.[31-33]

Mutations in the gene encoding the follicle-stimulating hormone (FSH)-receptor (e.g., mutation in exon 7 in the gene on chromosome 2p) have been described,[34] but these are extremely rare outside of the Finnish population in which these mutations were originally described. An expansion of a trinucleotide repeat sequence in the first exon on the *FMR1* gene (Xq 27.3) leads to fragile X syndrome, a major cause of developmental disabilities in males.[35] The permutation in fragile X syndrome has been shown to be associated with POF.[36-37] Type 1 blepharophi-mosis/ptosis/epicanthus inversus (BPES) syndrome, an autosomal-dominant disorder due to mutations in the forkhead transcription factor FOXL2, includes POF.[38] Triple X syndrome has been associated with POF and dystrophic myotonia has also been linked to POF, although the mechanism underlying this relationship is unclear.[39]

Under the category of enzymatic defects, galactosemia is a major cause of POF that is related to the toxic buildup of galactose in women who are unable to metabolize the sugar. Even in women with fairly well controlled galactose-free diets, POF tends to occur.[40,41] Another enzymatic defect linked to POF is 17α-hydroxylase deficiency. This rare condition manifests differently from the other causes discussed here because the defect in the production of sex steroids leads to sexual infantilism and hypertension.[42-44]

Because of the prevalence of autoimmune disorders in women, the degree to which autoimmunity may be responsible for POF is unclear. One study has suggested an association in 17.5% of cases.[45] Virtually all autoimmune disorders have been found to be associated with POF, including autoimmune polyendocrinopathies like autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy *(APECED)*, which is caused by mutations in the autoimmune *(AIRE)* gene on 21q22.3.[46] The presence of the thymus gland appears to be required for normal ovarian function as POF has been associated with hypoplasia of the thymus.[47] In patients who have undergone ovarian biopsy as part of their evaluation, lymphocytic infiltration surrounding follicles has been described, as well as resumption of menses after immunosuppression.[48-51]

Immunoassays utilizing antibodies directed at ovarian antigens have been developed and have demonstrated positive findings in some patients with POF,[52] although the relevance of these findings remains unsettled. Ovarian autoantibodies could also conceivably be a secondary phenomenon to a primary cell-mediated form of immunity. Specific enzymes such as 3β-HSD may also be the target of ovarian autoimmunity.[53] From a practical standpoint, screening for the common autoimmune disorders is appropriate in women found to have POF. Although relatively rare, as many as 2% to 4% of women with POF have anti-adrenal antibodies,[54] and may be at risk for adrenal failure. Commercial antibodies to 21-hydroxylase are available and agree with other assays for adrenal cortex antibodies.[55] It has been suggested that screening women using dehydroepiandrosterone sulfate [DHEA(S)] may also be useful to detect signs of adrenal insufficiency.

More from a theoretical standpoint, abnormalities in the structure of gonadotropins, in their receptors, or in receptor binding could be associated with POF. While abnormal urinary forms of gonadotropins have been reported in women with POF,[56] these data have not been replicated. Abnormalities of FSH-receptor binding, as mediated by a serum inhibitor, have been described.[57] A genetic defect that may lead to alterations in FSH receptor structure was mentioned previously.[34]

Table 15.2 Techniques for the Detection of Osteopenia

Technique	Anatomical Site of Interest	Precision *in Vivo* (%)	Examination and Analysis Time (min)	Estimated Effective Dose Equivalent (μSv)

Under the category of ovarian insults, POF may be induced by ionizing radiation, chemotherapy, or overly aggressive ovarian surgery. Although not well documented, viral infections have been suggested to play a role, particularly mumps.[58] A dose of 400 to 500 rads is known to cause ovarian failure 50% of the time,[59,60] and older women are more vulnerable to experiencing permanent failure. A dose of approximately 800 rads is associated with failure in all women.[60,61] Ovarian failure (transient or permanent) may be induced by chemotherapeutic agents, although younger women receiving this insult have a better prognosis.[61-63] Alkalyzing agents, particularly cyclophosphamide, appear to be most toxic.[64]

By exclusion, the majority of women are considered to have idiopathic POF because no demonstrable cause can be pinpointed. Among these women, small mutations in genes lying on the X chromosome or yet to be identified autosomal genes may be the cause.

Management of Primary Ovarian Failure/Insufficiency

Evaluation of women under age 30 who have POF should include screening for autoimmune disorders and a karyotype; detailed recommendations for screening of such women are available.[65] In addition, vaginal ultrasound may be useful for assessing the size of the ovaries and the degree of follicular development, which, if present, may signify an immunological defect.

Treatment usually consists of estrogen replacement. If fertility is a concern, the most efficacious treatment is oocyte donation. Various attempts at ovarian stimulation are usually unsuccessful, and the sporadic pregnancies that may occur are just as likely to occur spontaneously (−5%) as with any intervention.[66,67] These spontaneous pregnancies are frequently encountered while receiving estrogen replacement. Noting irregular or unscheduled bleeding (while receiving hormonal treatment) is important as a sign of endogenous sex steroid production. Serum Anti-Mullerian Hormone (AMH) has been used to characterize women with ovarian insufficiency to determine where they may be in the spectrum of ovarian failure.[67a] However, AMH levels cannot help predict the chance of a spontaneous pregnancy. It has been shown in a large cohort of women (n = 358) followed for POF, that spontaneous ovarian function may ensue in 24% of women, usually within a year of the diagnosis. In this longitudinal follow-up, 4.4% of women had spontaneous pregnancies.[67b]

It has been well established that POF as well as bilateral oophorectomy prior to the usual age of menopause is associated with an increased risk[68] of cardiovascular disease (CVD) as well as increased mortality (Fig. 15.1). CVD mortality specifically is increased twofold to fourfold, and observational studies have suggested that using hormonal treatment (HT) reduces this risk. Accordingly, unless there are contraindications, estrogen should be considered in all young women with POF, at least until the age of natural menopause.

The Menopausal Transition (Perimenopause)

A workshop was convened in 2001 to build a consensus on describing various stages of the menopausal transition.[69] Ten years later another workshop was convened to update the staging system with more updated data.[69a] The Stages of Reproductive Aging Workshop + 10 (STRAW + 10) simplified bleeding criteria for the early and late menopausal transition and modified criteria for the late reproductive stage (stage −3) and the early postmenopausal stage (stage +1) (Fig. 15.2). Then the late reproductive stages were expanded to include information on decreasing levels of AHM and inhibin B to reflect recent longitudinal data on fluctuating hormonal levels at the time of menopause, which will be described in more detail below.

The ovary changes markedly from birth to the onset of menopause (Fig. 15.3).[70] The greatest number of primordial follicles is present *in utero* at 20 weeks' gestation and undergoes a regular rate of atresia until around the age of 37. After this time, the decline in primordial follicles appears to

become more rapid between age 37 and menopause (Fig. 15.4) when no more than a thousand follicles remain.[71] These remaining follicles are primarily atresic in nature.

Types of Ovarian Changes

Although perimenopausal changes are generally thought to be endocrine in nature and result in menstrual changes, a marked diminution of reproductive capacity precedes this period by several years. This decline may be referred to as *gametogenic ovarian failure*. The concept of dissociation in ovarian function is appropriate. Gametogenic failure is signified by reduced early follicular phase inhibin secretion, rising serum FSH levels, and a marked reduction in fecundity. These changes may occur with normal menstrual function and no obvious endocrine deficiency, however, and they may occur in some women as early as age 35 (10 or more years before endocrine deficiency ensues).

Recent longitudinal data obtained from SWAN (study of women across the nation) have shown that estrogen levels begin to decline 2 years before the last menstrual period[71a] (Fig. 15.5). Older data had shown that this only occurred in the last 6 months.[72] The rise in FSH levels occurs several years before menopause but increases substantially in the last 2 years, and then stablilizes to steady state levels 2 years after menopause.[71a] These study levels then decrease in the late menopause (7th decade).[71a] There is also a very slow decline in androgen status (i.e., androstenedione and testosterone), which cannot be adequately detected at the time of the perimenopause.

Products of the granulosa cell are most important for the feedback control of FSH. As the functional capacity of the follicular units decrease, secretion of substances that suppress FSH also decrease. Most notably, inhibin B levels are lower in the early follicular phase in women in their late 30s (Fig. 15.6).[73-74] Indeed, FSH levels are higher throughout the cycle in older ovulatory women than in younger women (Fig. 15.7).[75]

The functional capacity of the ovary is also diminished as women enter into the perimenopause. With gonadotropin stimulation, while estradiol (E_2) levels are not very different between younger and older women, total inhibin production by granulosa cells is decreased in women over age 35.[76] From a clinical perspective, subtle increases in FSH on day 3 of the cycle, or increases in the clomiphene challenge test, correlate with decreased ovarian responses to stimulation and decreased fecundability.[77,78]

Although there is a general decline in oocyte number with age, an accelerated atresia occurs around age 37 or 38 (Fig. 15.4).[71] While the reason for this acceleration is not clear, one possible theory relates to activin secretion. Because granulosa cell–derived activin is important for stimulating FSH-receptor expression,[79] the rise in FSH levels could result in more activin production, which in turn enhances FSH action. A profile of elevated activin with lower inhibin B has been found in older women (Fig. 15.8).[80] This autocrine action of activin, involving enhanced FSH action, might be expected to lead to accelerated growth and differentiation of granulosa cells. Further, activin has been shown to increase the size of the pool of preantral follicles in the rat. At the same time, these follicles become more atretic.[81]

Clinical management of women in the perimenopause should address three general areas of concern:

1. Irregular bleeding
2. Symptoms of early menopause, such as hot flushes
3. The inability to conceive

Treatment of irregular bleeding is complicated by the fluctuating hormonal status. Estrogen levels may be higher than normal in the early follicular phase[72] and progesterone secretion may be normal, although not all cycles are ovulatory. For these reasons, short-term use of an oral contraceptive (usually 20 μg ethinyl estradiol) may be an option for otherwise healthy women who do not smoke to help them cope with irregular bleeding.

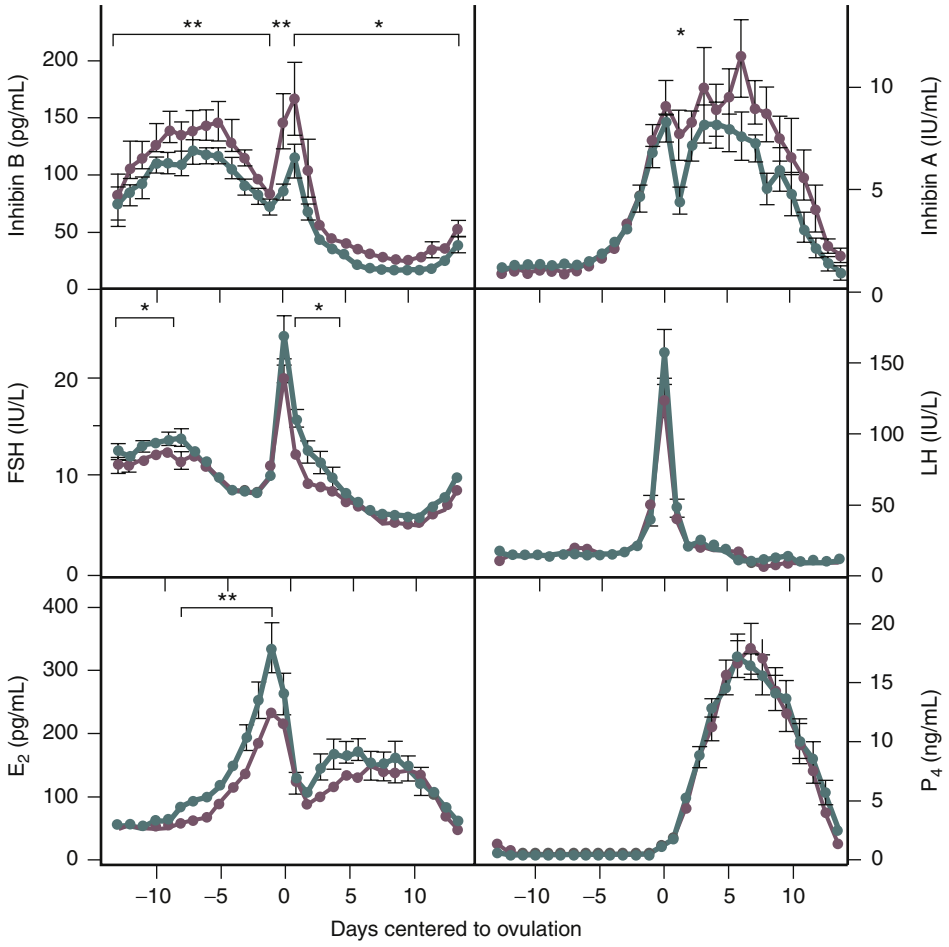

FIGURE 15.6 Mean inhibin B, follicle-stimulating hormone (FSH), estradiol (E_2), inhibin A, and progesterone (P4) levels in cycling women 20 to 34 years old *(purple)* and 35 to 46 years old *(green)*. Hormone levels are depicted as centered to the day of ovulation (*, $P < 0.04$;**, $P < 0.02$) when comparing the two age groups. *(Adapted from Welt CK, McNicholl DJ, Taylor AE, Hall JE. Female reproductive aging is marked by decreased secretion of dimeric inhibin.* J Clin Endocrinol Metab *84:105–111, 1999.)*

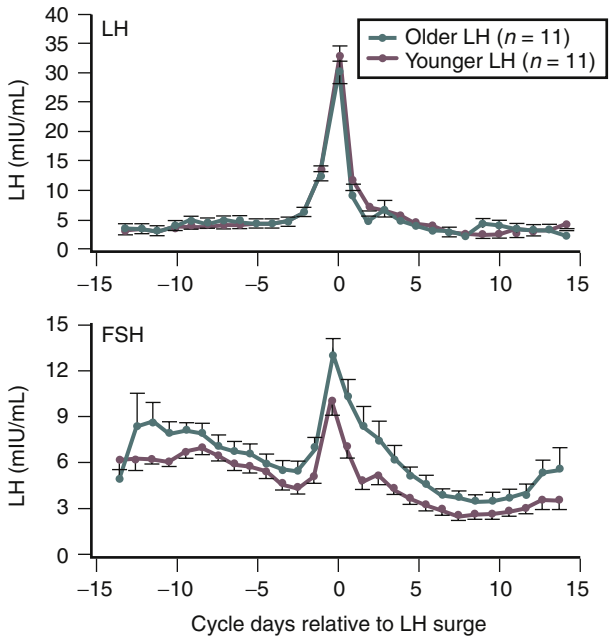

FIGURE 15.7 The daily serum follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels throughout the menstrual cycle of two groups (older and younger) of 11 women each (mean ± SE). The gonadotropin secretion pattern in normal women of advanced reproductive age is shown in relation to the monotropic FSH rise. *(Adapted from Klein NA, Battaglia DE, Clifton DK, et al. The gonadotropin secretion pattern in normal women of advanced reproductive age in relation to the monotropic FSH rise.* J Soc Cynecol Investig *3:27–32, 1996.)*

Early symptoms of menopause, particularly vasomotor changes, may occur as the result of fluctuating hormonal levels. In this setting, an oral contraceptive again may be an option if symptoms warrant therapy. Alternatively, lower doses of estrogen used alone may be another option.

Reproductive concerns often require more aggressive treatment because of decreased cycle fecundity. Once day 3 FSH levels increase and AMH levels are lower than established normative data (usually less than 0.4 ng/mL), the prognosis for pregnancy is markedly reduced. A more detailed discussion of AMH levels may be found in the next section.

Hormonal Changes with Established Menopause

Depicted in Figure 15.9 are the typical hormonal levels of postmenopausal women compared with those of ovulatory women in the early follicular phase.[82] The most significant findings are the marked reductions in E_2 and estrone (E_1). Serum E_2 is reduced to a greater extent than E_1. Serum E_1, on the other hand, is produced primarily by peripheral aromatization from androgens, which decline more slowly, principally as a function of age. Levels of E_2 average 15 pg/mL and range from 10 to 25 pg/mL, but are 10 pg/mL or less in women who have undergone oophorectomy. Serum E_1 values average 30 pg/mL but may be higher in obese women because aromatization increases as a function of the mass of adipose tissue.

Also shown is the percentage of women at each year of age who have transitioned to late perimenopausal status. *(Adapted from Lasley BL, Santoro N, Randolf JF, et al. The relationship of circulating dehydroepiandrosterone, testosterone, and estradiol to stages of the menopausal transition and ethnicity.* J Clin Endocrinol Metab *87:3760–3767, 2002.)*

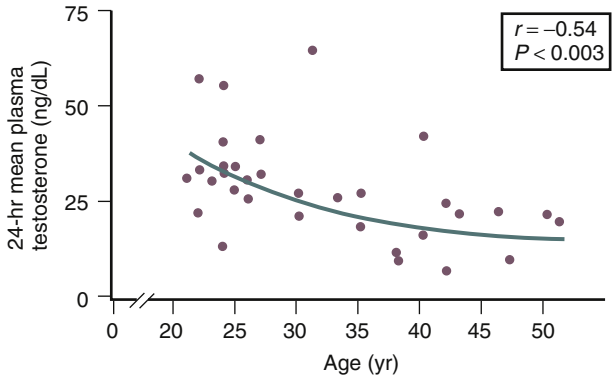

FIGURE 15.11 The 24-hour mean plasma total testosterone (T) level compared with age in normal women. The regression equation was T (nmol/L) = 37.8 × age (years)$^{-1.12}$ (r = –0.54; P < 0.003). *(Adapted from Zumoff B, Strain GW, Miller LK, et al. Twenty-four hour mean plasma testosterone concentration declines with age in normal premenopausal women.* J Clin Endocrinol Metab *80:1429–1430, 1995.)*

Estrone sulfate (E_1S) is an estrogen conjugate that serves as a stable circulating reservoir of estrogen, and levels of E_1S are the highest among estrogens in postmenopausal women. In premenopausal women, values are usually above 1000 pg/mL; in postmenopausal women, levels average 350 pg/mL.

Apart from elevations in FSH and luteinizing hormone (LH), other pituitary hormones are not affected. The rise in FSH, beginning in stage −3 as early as age 38 (Fig. 15.2), fluctuates considerably until approximately 4 years after menopause when values are consistently greater than 20 mIU/mL. Specifically, growth hormone, thyroid-stimulating hormone, and adrenocorticotropic hormone (ACTH) levels are normal. Serum prolactin levels may be very slightly decreased because prolactin levels are influenced by estrogen status.

Both the postmenopausal ovary and the adrenal gland continue to produce androgen. The ovary continues to produce androstenedione and testosterone but not E_2,[83,84] and this production has been shown to be at least partially dependent on LH. Androstenedione and testosterone levels are lower in women who have experienced bilateral oophorectomy, with values averaging 0.8 ng/mL and 0.1 ng/mL, respectively. The adrenal gland also continues to produce androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEAS); primarily as a function of aging, these values decrease somewhat (adrenopause), although cortisol secretion remains unaffected. Some data suggest that much "ovarian" testosterone production may actually arise from the adrenal.[85] Most likely, this production is by indirect mechanisms due to the adrenal supplying precursor substrate (DHEA and androstenedione).

Although DHEAS levels decrease with age (approximately 2% per year),[86] recent data have suggested that levels transiently rise in the perimenopause before the continuous decline thereafter (Fig. 15.10)[87] This interesting finding from the Study of Women Across the Nation (SWAN) also suggested that DHEAS levels are highest in Chinese women and lowest in African American women.[7]

Testosterone levels also decline as a function of age, which is best demonstrated by the reduction in 24-hour mean levels (Fig. 15.11).[88] Because of the role of the adrenal in determining levels of testosterone after menopause,[83] adrenalectomy or dexamethasone treatment results in undetectable levels of serum testosterone. Compared with total testosterone, the measurement of bioavailable or "free" testosterone is more useful in postmenopausal women. After menopause, sex hormone—binding globulin (SHBG) levels decrease, resulting in relatively higher levels of bioavailable testosterone or a higher free androgen index (Fig. 15.12).[89] In women receiving oral estrogen, bioavailable testosterone levels are extremely low because SHBG levels are increased. How this relates to the decision to begin androgen therapy in postmenopausal women will be discussed later in this chapter.

Elevated gonadotropin (FSH-LH) levels arise from reduced secretion of E_2 and inhibin as described earlier. Estrogen is important in controlling the production of GnRH mRNA in type 1 neurons.[90,91] In addition, the increase in gonadotropins observed at menopause appears to be enhanced by substance P[92] as well as by tachykinins produced in hypertrophied neurons,[93,94] which result from the decrease in E_2.

Unlike the rodent, where there is evidence for a hypothalamic factor involved in ovarian senescence,[95-97] no such clear evidence exists for women. The hypothesis proposed by Wise suggested that the effects of aging in the brain affect neurotransmitter systems that regulate GnRH, disrupting ovarian folliculogenesis and ultimately promoting senescence. Thus, the accelerated follicular loss that is apparent in the late 30s is postulated to be due to age-related desynchronization in the rhythmicity of GnRH secretion.[97]

Although some aging effects of the brain are likely to exist, there is abundant human evidence for an ovarian-induced menopause. While there is slowing of LH pulsatility with aging in rodents, LH pulse frequency and amplitude increase with age as menopause approaches in women (Fig. 15.13).[98] A sleep-entrained alteration in GnRH pulse dynamics has been observed in postmenopausal women, namely the inability to increase GnRH pulse amplitude at night.[99] There is some evidence that the high frequency and

Age effects on follicle-stimulating hormone and pulsatile LH secretion across the menstrual cycle of pre-menopausal women.* J Clin Endocrinol Metab *81:1512–1518, 1996.)*

amplitude pulses of LH observed in the first few years in postmenopausal women slows down in late menopause;[100] this latter effect is clearly related to aging per se.

Ovarian aging is a programmed event, and the return of atresia, accelerating at around age 37.5, until the natural age of menopause, has now been shown to occur in almost the exact way in the chimpanzee.[101] Ovarian aging from a hormonal standpoint is best characterized by small elevations in serum FSH occurring at the beginning of the menstrual cycle (days 2 to 3), reductions in inhibin B, as well as steep declines in serum müllerian inhibiting substance (MIS) or AMH was introduced previously[102] (Fig. 15-14). It has been confirmed that once a level of inhibin B or AMH becomes undetectable, menopause will ensue in 4 to 5 years (Fig. 15.14A). AMH is a very useful and practical determinant in that it tends to undergo less cycle to cycle variation compared to FSH or inhibin B, and can be measured during any phase of the cycle.[103]

Effects on Various Organ Systems

Central Nervous System

The brain is an active site for estrogen action as well as estrogen formation.[104] Estrogen activity in the brain is mediated via ERα and ERβ receptors. Whether or not a novel membrane receptor (non-ERα/ERβ) exists is still being debated.[105] However, both genomic and nongenomic mechanisms of estrogen action clearly exist in the brain. Figure 15.15 illustrates the predominance of ERβ in the cortex (frontal and parietal) and the cerebellum, based on work in the rat.[106,107]

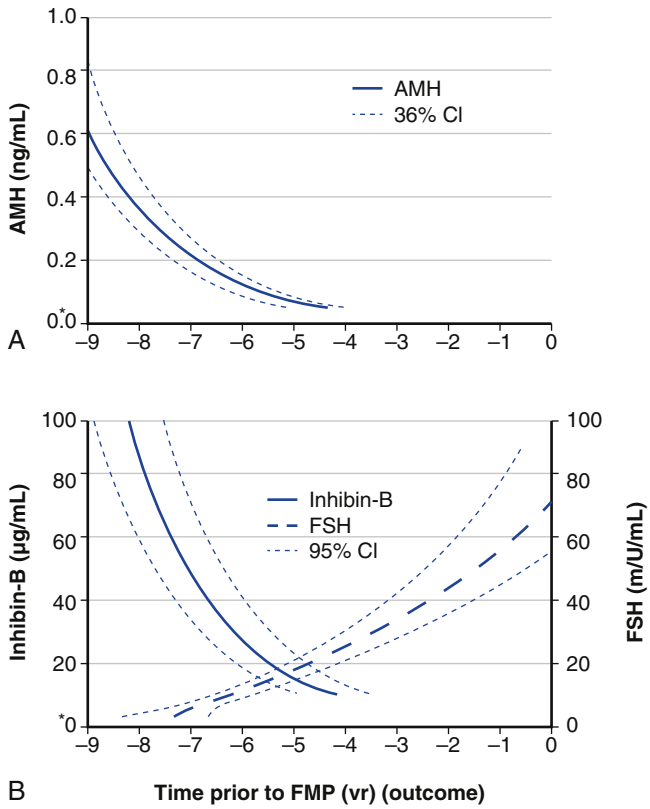

FIGURE 15.14 A, Anti-müllerian Hormone (AMH) decreases to undetectable levels (0.05 ng/mL) 5 years before the final menstrual period, and inhibin B (10 pg/mL) does so 4 years before the last menstrual period. **B,** Rapid decline in levels of AMH/MIS with aging. Levels are undetectable prior to menopause. *(Adapted From Sowers MR, Eyvazzadeth AD, McConnell D, et al. Clinical effects of sex steroids on the brain. In Lobo RA [ed].* The Treatment of Postmenopausal Woman: Basic and Clinical Aspects, *2nd ed. Philadelphia, Lippincott Williams & Wilkins, 1999, pp 247–262.)*

While 17β-E_2 is a specific ligand for both receptors, certain synthetic estrogens have a greater affinity for ERβ.

There are multiple actions of estrogen on the brain as reviewed by Henderson (Box 15.1)[108] thus there are important functions linked to estrogen that contribute to well-being in general and, more specifically, to cognition and mood. The hallmark feature of declining estrogen status in the brain is the hot flush, which is more generically referred to as a vasomotor episode.

The *hot flash* usually refers to the acute sensation of heat, while the *flush* or vasomotor episode includes changes in the early perception of this event and other skin changes (including diaphoresis). Hot flushes usually occur for 2 years after the onset of estrogen deficiency, but can persist for 10 or more years.[109,110] In 10% to 15% of women these symptoms are severe and disabling.[109,111] In the United States the incidence of these episodes varies in different ethnic groups. Symptoms are greatest in Hispanic and African American women, intermediate in white women, and lowest among Asian women (Fig. 15.16).[112]

The fall in estrogen levels precipitate the vasomotor symptoms. Although the proximate cause of the flush remains elusive, the episodes result from a hypothalamic response (probably mediated by catecholamines) to the change in estrogen status. The flush has been well characterized physiologically. It results in heat dissipation as witnessed by an increase in peripheral temperature (finger, toe); a decrease in skin resistance, associated with diaphoresis; and a reduction in core body temperature (Fig. 15.17).[113] There are hormonal correlates of flush activity, such as an increase in serum LH and in plasma levels of pro-opiomelanocortin peptides (ACTH, β-endorphin) at the time of the flush,[114] but these occurrences are thought to be epiphenomena that result as a consequence of the flush and are not related to its etiology. Data from Freedman has suggested that the major physiological finding in women with and without hot flushes

is a narrowing of the temperature threshold for sweating and shivering in symptomatic women (Fig. 15.18).[115]

One of the primary complaints of women with hot flushes is sleep disruption. They may awaken several times during the night, and require a change of bedding and clothes because of diaphoresis. Nocturnal sleep disruption in postmenopausal women with hot flushes has been well documented by electroencephalographic (EEG) recordings.[116] Sleep efficiency is lower, and the latency to rapid eye movement (REM) sleep is longer in women with hot flushes compared with asymptomatic women.[117,118] This disturbed sleep often leads to fatigue and irritability during the day. The frequency of awakenings and of hot flushes are reduced appreciably with estrogen treatment (Fig. 15.19).[116,119,120] Sleep may be disrupted even if the woman is not conscious of being awakened from sleep. In this setting, EEG monitoring has indicated sleep disruption in concert with physiological measures of vasomotor episodes.

In postmenopausal women, estrogen has been found to improve depressed mood regardless of whether or not this is a specific complaint[121-127] (critics of some of this work point out that mood is affected by the symptomatology and by sleep deprivation). Blinded studies carried out in asymptomatic women have also shown benefit.[126] In an estrogen-deficient state such as occurs after the menopause, a higher incidence of depression (clinical or subclinical) is often manifest. However, menopause per se does *not* cause depression, and while estrogen does generally improve depressive mood, it should *not* be used for psychiatric disorders. Nevertheless, very high pharmacological doses of estrogen have been used to treat certain types of psychiatric depression in the past.[128-130] Progestogens as a class generally attenuate the beneficial effects of estrogen on mood, although this effect is highly variable.[131,132]

Cognitive decline in postmenopausal women is related to aging as well as to estrogen deficiency. The literature is somewhat mixed in showing whether there are benefits of estrogen in terms of cognition. In more recent studies, verbal memory appears to be enhanced with estrogen[133-136] and has been found to correlate with acute changes in brain imaging signifying brain activation.[135-137]

Dementia increases as women age, and the most common form of dementia is Alzheimer disease (AD). Listed in Box 15.1 are several neurotrophic and neuroprotective factors that relate to how estrogen deficiency may be expected to result in the loss of protection against the development of AD. In addition, estrogen has a positive role in enhancing neurotransmitter function, which is deficient in women with AD. This function of estrogen has particular

Box 15.1 Effects of Estrogen on Brain Function

ORGANIZATIONAL ACTIONS
- Effects on neuronal number, morphology, and connections occurring during critical stage of development

NEUROTROPHIC ACTIONS
- Neuronal differentiation
- Neurite extension
- Synapse formation
- Interactions with neurotrophins

NEUROPROTECTIVE ACTIONS
- Protection against apoptosis
- Antioxidant properties
- Anti-inflammatory properties
- Augmentation of cerebral blood flow
- Enhancement of glucose transport into the brain
- Blunting of corticosteroid response to behavioral stress
- Interactions with neurotrophins

EFFECTS ON NEUROTRANSMITTERS
- Acetylcholine
- Noradrenaline
- Serotonin
- Dopamine
- Glutamate
- γ-Aminobutyric acid
- Neuropeptides

EFFECTS ON GLIAL CELLS

EFFECTS ON PROTEINS INVOLVED IN ALZHEIMER DISEASE
- Amyloid precursor protein
- Tau protein
- Apolipoprotein E

importance and relevance for the cholinergic system that is affected in AD.[138,139]

Estrogen use after menopause has been shown in observational studies to decrease the likelihood of developing or delays the onset of AD.[140-157] (Fig. 15.20). However, there are no randomized prospective studies as yet on this issue. It is clear, however, that if estrogen has a beneficial role, it is only in those women who receive estrogen at the onset of menopause; in older women it may be detrimental.[157a] Once a woman is affected by AD, estrogen is unlikely to provide any benefit.[158]

Collagen

Estrogen has a positive effect on *collagen*, which is an important component of bone and skin and serves as a major support tissue for the structures of the pelvis and urinary system. Both estrogen and androgen receptors have been identified in skin fibroblasts. Nearly 30% of skin collagen is lost within the first 5 years after menopause, and collagen decreases approximately 2% per year for the first 10 years after menopause.[159] This statistic, which is similar to that of bone loss after menopause, strongly suggests a link between skin thickness, bone loss, and the risk of osteoporosis.[160]

Although the literature is not entirely consistent, estrogen therapy generally improves collagen content after menopause and improves skin thickness substantially after about 2 years of treatment.[159,161-165] There is a possible biomodal effect with high doses of estrogen causing a reduction in skin thickness.[159-166] The supportive effect of estrogen on collagen has important implications for bone homeostasis and for the pelvis after menopause. Here, reductions in collagen support and atrophy of the vaginal and urethral mucosa have been implicated in a variety of symptoms, including prolapse and urinary incontinence.[167,168]

Symptoms of urinary incontinence and irritative bladder symptoms occur in 20% to 40% of perimenopausal and postmenopausal women.[169-171] Uterine prolapse and other gynecological symptoms related to poor collagen support, as well as urinary complaints, may improve with estrogen

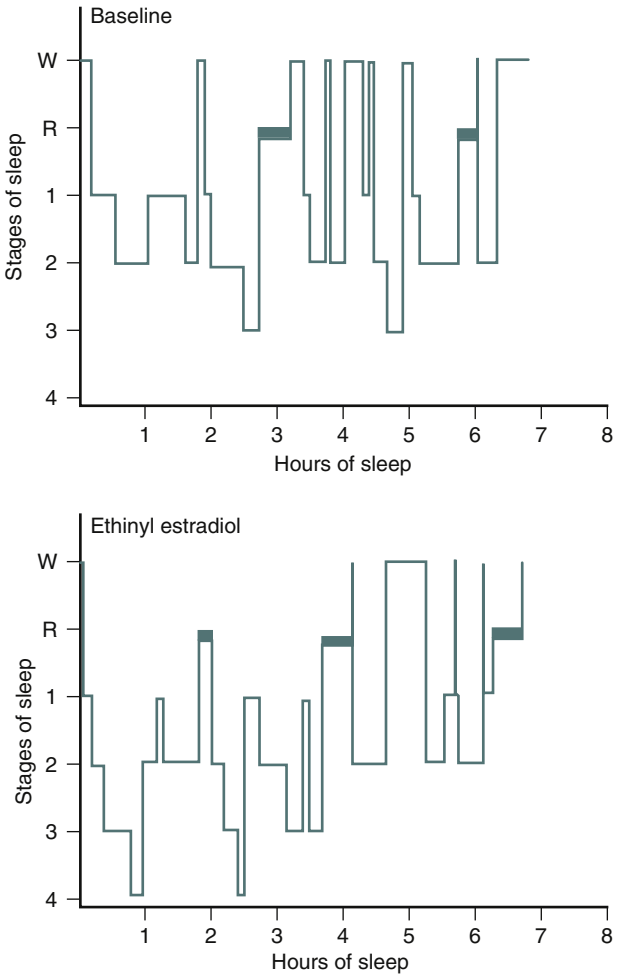

FIGURE 15.19 Sleepgrams measured in symptomatic patient before and after 30 days' administration of ethinyl estradiol, 50 μg four times daily. *(Adapted from Erlik Y, Tataryn IV, Meldrum DR, et al. Association of waking episodes with menopausal hot flushes.* JAMA *245:1741–1744, 1981.)*

therapy.[112,172-174] While estrogen generally improves symptoms, urodynamic changes have not been shown to be altered.[175,176] Estrogen has also been shown to decrease the incidence of recurrence of urinary tract infections.[177] These data relate to the use of vaginal estrogen, rather than the use of estrogen systemically. Somewhat paradoxically systemic estrogen may increase stress urinary incontinence, while local vaginal therapy may improve urge incontinence.[177a]

Restoration of bladder control in older women with estrogen has been shown to decrease the need for admission to nursing homes in Sweden.[178] Estrogen may also have an important role in normal wound healing. In this setting, estrogen enhances the effects of growth factors such as transforming growth factor-β (TGFββ).[179,180]

Genital Atrophy

Vulvovaginal complaints are often associated with estrogen deficiency. In the perimenopause, symptoms of dryness and atrophic changes occur in 21% and 15% of women, respectively. However, these findings increase with time, and by 4 years these incidences are 47% and 55%, respectively.[181,182] With this change, an increase in sexual complaints also occurs, with an incidence of dyspareunia of 41% in sexually active 60-year-old women.[183] Estrogen deficiency results in a thin and more pale vaginal mucosa. The moisture content is low, the pH increases (usually greater than 5), and the mucosa may exhibit inflammation and small petechiae.

With estrogen treatment, vaginal cytology changes have been documented, transforming from a cellular pattern of predominantly parabasal cells to one with an increased number of superficial cells. Along with this change, the vaginal pH decreases, vaginal blood flow increases, and the electropotential difference across the vaginal mucosa increases to that found in premenopausal women.[184] Recent studies have suggested that intravaginal DHEA (0.25% to 1%) is efficacious for altering vaginal cytology and symptoms of atrophy, presumably by allowing for local conversion to other androgens and estrogen.[184a] More studies, however, are needed.

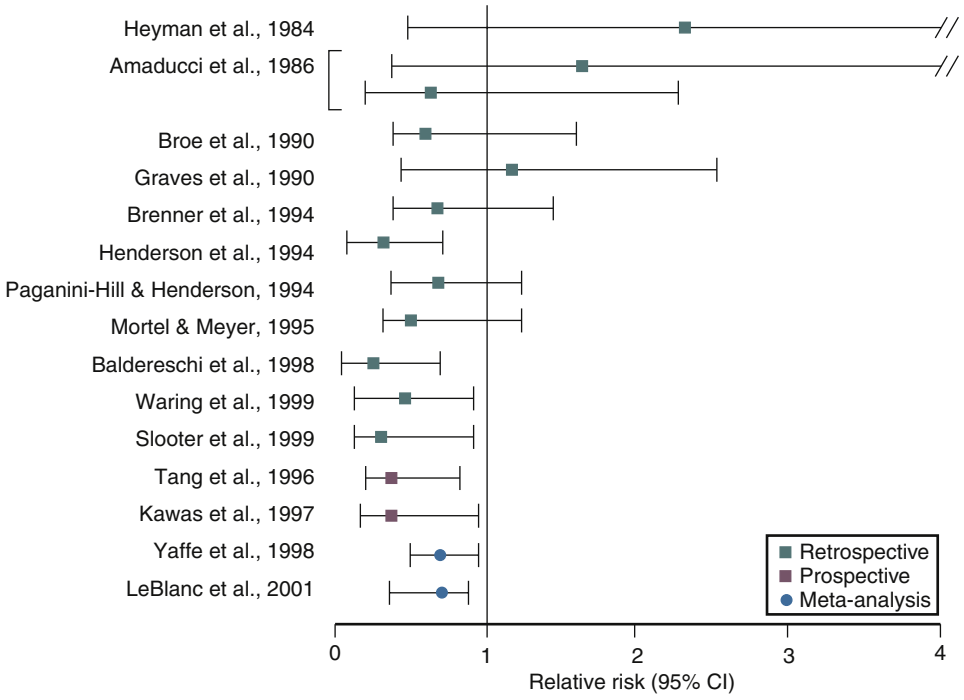

FIGURE 15.20 Estrogen and hormone replacement therapy use, and Alzheimer disease risk. *(Adapted from LeBlanc ES, Janoowsky J, Chan BK, Nelson HD. Hormone replacement therapy and cognition: systematic review and meta-analysis.* JAMA *285:1489–1499, 2001.)*

Bone Loss

Estrogen deficiency has been well established as a cause of bone loss. This loss can be noted for the first time when menstrual cycles become irregular in the perimenopause. From 1.5 years before the menopause to 1.5 years after menopause, spine bone mineral density has been shown to decrease by 2.5% per year, compared with a premenopausal loss rate of 0.13% per year.[185,186] Loss of trabecula bone (spine) is greater with estrogen deficiency than is loss of cortical bone.

Postmenopausal bone loss leading to osteoporosis is a substantial healthcare problem. In white women, 35% of all postmenopausal women have been estimated to have osteoporosis based on bone mineral density.[187] Further, the lifetime fracture risk for these women is 40%.[188] The morbidity and economic burden of osteoporosis is well documented.[189] Interestingly, there are data to suggest that up to 19% of caucasian men also have osteoporosis.

Bone mass is substantially affected by sex steroids through classic mechanisms to be described later in this chapter. Attainment of peak bone mass in the late second decade (Fig. 15.21)[190] is key to ensuring that the subsequent loss of bone mass with aging and estrogen deficiency does not lead to early osteoporosis. Estradiol, together with Growth Hormone (GH) and insulin-like growth factor-1, act to double bone mass at the time of puberty[191] beginning the process of attaining peak bone mass. Postpubertal estrogen deficiency (amenorrhea from various causes) substantially jeopardizes peak bone mass. Adequate nutrition and calcium intake are also key determinants. While estrogen is of predominant importance for bone mass in both women and men, testosterone is important in stimulating periosteal apposition; as a result, cortical bone in men is larger and thicker.[192,193]

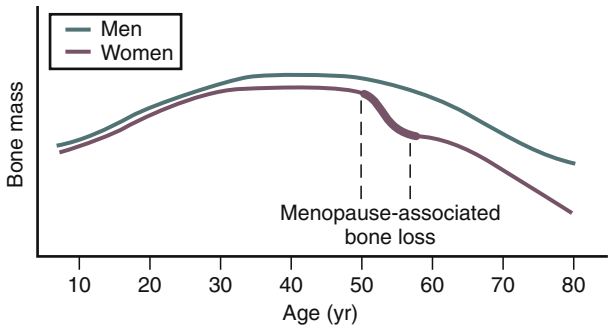

FIGURE 15.21 Bone mass by age and sex. *(Adapted from Finkelstein JS. In Cecil RL, Goldman L, Bennett JC [eds]. Cecil Textbook of Medicine, 21st ed. Philadelphia, Saunders, 1999, pp 1366-1373; and Riggs BL, Melton LJ III. Involutional osteoporosis.* N Engl J Med *314:1676–1686, 1986.)*

Estrogen receptors (ERs) are present in osteoblasts,[194,195] osteoclasts,[196,197] and osteocytes.[198,199] Both ERα and ERβ are present in cortical bone, while ERβ predominates in cancellous or trabecular bone.[200] However, the more important actions of estradiol are believed to be mediated via ERα.

Estrogens suppress bone turnover and maintain a certain rate of bone formation.[201] Bone is remodeled in functional units, called *bone multicenter units* (BMUs), where resorption and formation should be in balance.[202] Multiple sites of bone go through this turnover process over time. Estrogen decreases osteoclasts by increasing apoptosis and thus reduces their lifespan.[203] The effect on the osteoblast is less consistent, but E_2 antagonizes gluco-corticoid-induced osteoblast apoptosis.[201,204] Estrogen deficiency increases the activities of remodeling units, prolongs resorption, and shortens the phase of bone formation[201]; it also increases osteoclast recruitment in BMUs, thus resorption outstrips formation.

The molecular mechanisms of estrogen action on bone involve the inhibition of production of pro-inflammatory cytokines including interleukin-1, interleukin-6, and tumor necrosis factor, which inhibits bone resorption. Receptor-activation of NFKB ligand (RANKL) is responsible for osteoclast differentiation and action.[205,206] A scheme for how all these factors interact has been proposed by Riggs (Fig. 15.22).[207]

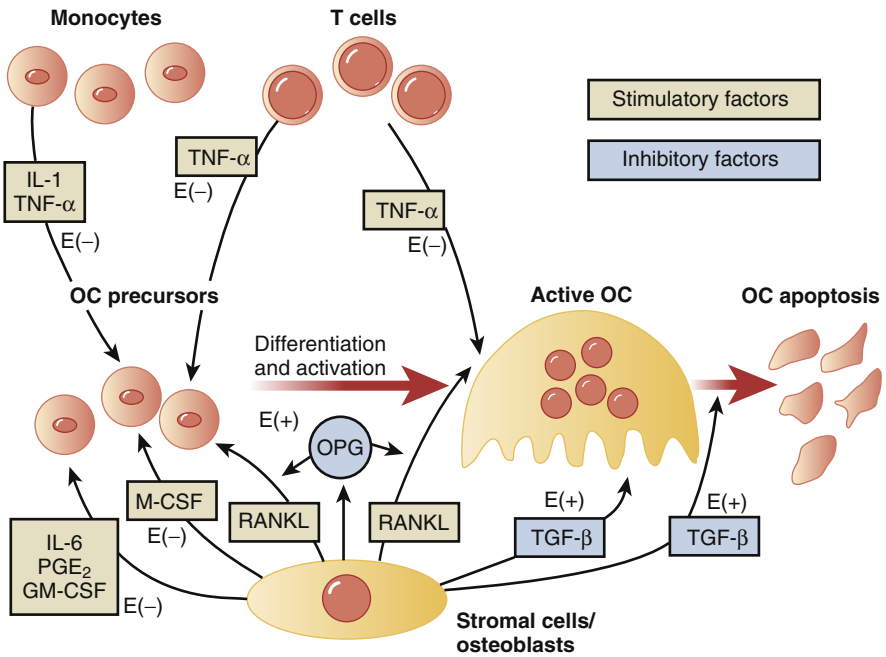

FIGURE 15.22 Model for mediation of effects of estrogen (E) on osteoclast formation and function by cytokines in bone marrow microenvironment. Stimulatory factors are shown in orange and inhibitory factors are shown in blue. Positive (+) and negative (–) effects of E on these regulatory factors are shown in red. The model assumes that regulation is accomplished by multiple cytokines working together in concert. *(Adapted from Riggs BL. The mechanisms of estrogen regulation of bone resorption.* J Clin Invest *106:1203–1204, 2000.)*

In women, Riggs has suggested that bone loss occurs in two phases. With estrogen levels declining at the onset of menopause—leading to an accelerated phase of bone loss—predominantly cancellous bone loss occurs. Here 20% to 30% of cancellous bone and 5% to 10% of cortical bone can be lost in a span of 4 to 8 years.[208] Thereafter a slower phase of loss (1% to 2% per year) ensues where more cortical bone is lost. This phase is thought to be induced primarily by secondary hyperparathyroidism.[209] The first phase is also accentuated by the decreased influence of stretching or mechanical factors, which generally promote bone homeostasis, as a result of estrogen deficiency.[210-212]

Genetic influences on bone mass are more important for attainment of peak bone mass (heritable component, 50% to 70%) than for bone loss. Polymorphisms of the vitamin D receptor gene, TGFβ gene, and the Spl-binding site in the collagen type 1 AI gene have all been implicated[213] as being important for bone mass.

While testosterone is important for bone formation and stimulation of bone mass, even in men estrogen action is of paramount importance.[214-216] Bone mass was shown to increase in an aromatase-deficient man upon estrogen administration.[217]

Bone mass can be detected by a variety of radiographic methods (Table 15.2).[218] *Dual energy x-ray absorptiometry (DEXA) scans* have become the standard of care for detection of osteopenia and osteoporosis. By convention, the *T score* is used to reflect the number of standard deviations of bone loss from the peak bone mass of a young adult. Osteopenia is defined by a T score of −1 to −2.5 standard deviations; osteoporosis is defined as greater than 2.5 standard deviations. Since bone mass does not completely reflect bone strength, which is really what matters in terms of fracture risk, several approaches have been made to assess bone strength. An assessment of biochemical bone turnover (discussed later in the chapter) in addition to bone mass is deemed important. One newer approach is to assess bone microarchitecture, a so-called virtual bone biopsy, by using a high resolution peripheral (p) QCT (Fig. 15.23).[219] This technique is only available as a research tool at present.

Various biochemical assays are also available to assess bone resorption and formation in both blood and urine (Table 15.3).[220] At present, serum markers appear to be most useful for assessing changes with antiresorptive therapy.

There are now many agents that can prevent osteoporosis. The use of estrogen will depend on whether or not there are other indications for estrogen treatment and whether there are contraindications. Estrogen has been shown to reduce the risk of osteoporosis as well as to reduce osteoporotic fractures. In the Women's Health Initiative study (WHI), hip fractures as well as all fractures were reduced with conjugated equine estrogens (CEE) and medroxyprogesterone acetate (MPA) and CEE alone, and this occurred in a non-osteoporotic population. Indeed, in a cohort of women who were followed after stopping hormones when the results of the WHI were published, there was increased risk of hip fracture and lower bone density compared to those women who continued therapy.[220a]

A dose equivalent to 0.625 mg of conjugated equine estrogens (CEE) was once thought to prevent osteoporosis, but we now know that lower doses (0.3 mg of CEE or its equivalent) in combination with progestogens are able to prevent bone loss[221,222] although there are no data on fractures. Whether or not the addition of progestogens, by stimulating bone formation, increases bone mass over that of estrogen alone is unclear. The androgenic activity of certain progestogens such as northindrone acetate also has been suggested to play a role.[223]

Effects of sex and age on bone microstructure at the ultradistal radius: a population-based noninvasive* in vivo *assessment.* J Bone Miner Res; *21:124–131, 2006.)*

Selective estrogen receptor modulators (SERMs) such as raloxifene, droloxifene, and tamoxifen have all been shown to decrease bone resorption. Raloxifene has been shown to decrease vertebral fractures in a large prospective trial.[224] Tibolone has also been shown to be an effective treatment for osteoporosis. Tibolone (not marketed in the United States) has SERM-like properties, but it is not specifically a SERM because it has mixed estrogenic, antiestrogenic, androgenic, and progestogenic properties due to its metabolites. The drug does not cause uterine or breast cell proliferation but is beneficial for vasomotor symptoms. It prevents osteoporosis and has been shown to be beneficial in treatment of osteoporosis as well.[225,226]

Bisphosphonates have been shown to have a significant effect on the prevention and treatment of osteoporosis. With this class of agents (etidronate, alendronate, residronate, ibandronate), and Zoledronic acid incorporation of the bisphosphonate with hydroxyapetite in bone increases bone mass. The skeletal half-life of bisphosphonates in bone can be as long as 10 years.[227] Most data have been derived with alendronate, which, at a dosage of 5 mg daily (35 mg weekly) prevents bone loss; at 10 mg daily (70 mg weekly), alendronate is an effective treatment for osteoporosis, with evidence available that this treatment reduces vertebral and hip fractures.[228] Ibandronate is available as a monthly pill and by injection. It has primary efficiency for vertebral fracture protection. Zoledronic acid, 5 mg, OK is available as an intravenous therapy. Calcitonin, 50 IU OK subcutaneous injections daily, or 200 IU intranasally has been shown to inhibit bone resorption. Vertebral fractures have been shown to decrease[229,230] with calcitonin therapy. Long-term effects, however have not been established.

Fluoride has been used for women with osteoporosis because it increases bone density.[231] Currently, a lower dose (50 μg daily) of slow-release sodium fluoride does not seem to cause adverse effects (gastritis) and has efficacy in preventing vertebral fractures.[232,233] Intermittent parathyroid hormone (PTH 1-34, Teriparatide) is an agent that increases bone mass in women with osteoporosis. In a randomized trial lasting 3 years, average bone density increased in the hip and spine with fewer fractures observed.[234] This therapy is now available in the United States, but is expensive and is reserved for women who are difficult to treat and have a history of fractures.[234a]

Adjunctive measures for prevention of osteoporosis are calcium, vitamin D, and exercise. Calcium with vitamin D treatment has been shown to increase bone in only older individuals.[235] These modalities alone are not thought to be effective for the treatment of osteoporosis. A woman's total intake of elemental calcium should be 1500 mg daily if no agents are being used to inhibit resorption, and 400 to 800 IU OK of vitamin D should also be ingested. Levels of serum 25 hyroxy (OH) vitamin D have been found to be abnormally low (<20 ng/mL) in a large population of women, particularly in geographic regions of less sunlight exposure. Exercise has been shown to be beneficial for building muscle and bone mass and for reducing falls.[236,237] Guidelines regarding management of osteoporosis were published by the National Osteoporosis Foundation in February 2008 (www.nof.org). An update analysis has suggested that 37% of women are candidates for treatment to prevent fractures.[237a] Also, World Health Organization (WHO) has produced guidelines for assessing an individual's risk of osteoporosis based on history, anthropometry, and bone mineral density (BMD). This new paradigm, called Fracture Risk Assessment Tool, may be obtained at www.shef.ac.uk/FRAX.

Table 15.3 Bone Turnover Markers

Marker	Specimen
Bone Resorption Markers	
Cross-linked N-telopeptide of type 1 collagen (NTX)	Urine, serum
Cross-linked C-telopeptide of type 1 collagen (CTX)	Urine (αα and ββ forms) Serum (ββ form)
MMP-generated telopeptide of type 1 collagen (ICTP or CTX-MMP)	Serum
Deoxypyridinoline, free and peptide bound (fDPD, DPD)	Urine, serum
Pyridinoline, free and peptide bound (fPYD, PYD)	Urine, serum
Hydroxyproline (OHP)	Urine
Glycosyl hydroxylysine (GylHyl)	Urine, serum
Helical peptide (HelP)	Urine
Tartrate-resistant acid phospharase 5b Isoform specific for osteoclasts (TRACP 5b)	Serum, plasma
Cathepsin K (Cath K)	Urine, serum
Osteocalcin fragments (uOC)	Urine
Bone Formation Markers	
Osteocalcin (OC)	Serum
Procollagen type 1 C-terminal propeptide (PICP)	Serum
Procollagen type 1 N-terminal propeptide (PINP)	Serum
Bone-specific alkaline phosphatase (bone ALP)	Serum

Eastell R, Hannon RA: Biochemical markers of bone turnover. In: Lobo RA, ed. Treatment of the Postmenopausal Woman Basic and Clinical Aspects, ed. 3, St. Louis: Elsevier Academic Press; 2007, p. 337-350.

Cardiovascular Effects

Clearly after menopause, the risk of cardiovascular disease in women is increased. Data from the Framingham study[238] have shown that the incidence is three times lower in women before menopause than in men (3.1 per 1000 per year in women aged 45 to 49). The incidence is approximately equal in men and women aged 75 to 79 (53 and 50.4 per 1000 per year, respectively). This trend also pertains to gender differences in mortality due to cardiovascular disease. Coronary artery disease is the leading cause of death in women, and the lifetime risk of death is 31% in postmenopausal women versus a 3% risk of dying of breast cancer.[239]

Although cardiovascular disease becomes more prevalent only in the later years following a natural menopause, premature cessation of ovarian function (before the average age of menopause) constitutes a significant risk. Premature menopause, occurring before age 35, has been shown to increase the risk of myocardial infarction twofold to threefold, and oophorectomy before age 35 increases the risk severalfold.[240]

An analysis of several studies on this issue has been conducted and reviewed[241] with the data depicted in Figure 15.24, on the effect of early menopause on the prevalence

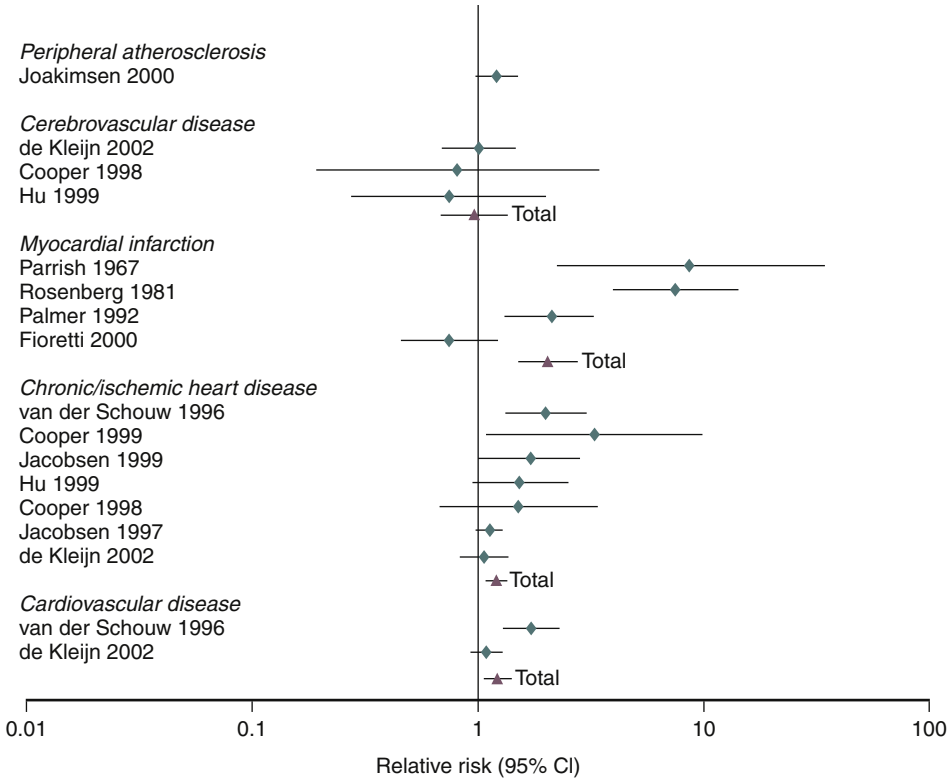

FIGURE 15.24 Effect of "early" menopause on types of cardiovascular disease. *(From Atsma F, Bartelink ML, Grobbee DE, et al. Postmenopausal status and early menopause as independent risk factors for cardiovascular disease: a meta-analysis.* Menopause *13[2]:265–279, 2006 [review]. See reference 68 for data sources.)*

and type of CVD. It has been suggested that total mortality is increased if bilateral oophorectomy occurs even after the natural menopause, until around age 60. This change in total mortality is due to an excess in coronary disease, suggesting a protective effect of the ovary even beyond the normal age of menopause.[242]

When the possible reasons for the increase in cardiovascular disease are examined, the most prevalent finding is that of the accelerated rise in total cholesterol in postmenopausal women. The changes of weight, blood pressure, and blood glucose with aging, while important, are not thought to be as important as the rate of rise in total cholesterol, which is substantially different in women versus men. This increase in total cholesterol is explained by increases in levels of low-density lipoprotein cholesterol (LDL-C). The oxidation of LDL-C is also enhanced, as are levels of very-low-density lipoproteins and Lp(a) lipoprotein. HDL-C levels trend downward with time, but these changes are small and inconsistent relative to the increases in LDL-C.[243]

Coagulation balance is not substantially altered as a counterbalancing change occurs. Some procoagulation factors increase (Factor VII, fibrinogen, and plasminogen activator inhibitor [PA1-1]), but so do counterbalancing factors like antithrombin III, plasminogen, protein C, and protein S.[244] Inflammation markers such as C-reactive protein and cytokines are increased; and blood flow in all vascular beds decreases after menopause. Prostacyclin production decreases, endothelin levels increase, and vasomotor responses to acetylcholine are constrictive, reflecting reduced nitric oxide synthetase activity. With estrogen, all these parameters (generally) improve and coronary arterial responses to acetylcholine are dilatory with a commensurate increase in blood flow.[245-252]

Circulating plasma nitrites and nitrates have also been shown to increase with estrogen, and angiotensin-converting enzyme levels tend to decrease. Estrogen and progesterone receptors have been found in vascular tissues, including coronary arteries (predominantly ERβ). In addition, there are membrane effects mediated by estrogen—which may or may not relate to either ERα or ERβ.[253,254]

Overall, the direct vascular effects of estrogen are viewed to be as important, or more important, than the changes in lipid and lipoproteins after menopause. While replacing estrogen has been thought to be beneficial for the mechanisms previously cited, these beneficial arterial effects may only be seen in younger (stage +1) postmenopausal women. Women with significant atherosclerosis or risk factors such as those studied in a secondary prevention trial do not respond in a beneficial manner[255-260] (Fig. 15.25). Some of this lack of effect may be accounted for by increased methylation of the promoter region of ERα, which occurs with atherosclerosis and aging.[261]

Another theory proposed to explain differences in the effects of estrogen when given early rather than later is the interfering effect of endogenous 27-hydroxy cholesterol. This endogenous metabolite of cholesterol increases with advancing levels of cholesterol and competes for binding with E_2 at the ER in the endothelium. Thus when cholesterol is elevated, high levels of 27-C may prevent estrogen action[262] (Fig. 15.26).

In normal, nonobese postmenopausal women, carbohydrate tolerance also decreases as a result of an increase in insulin resistance. This, too, may be partially reversed by estrogen.[263] Biophysical and neurohormonal responses to stress (stress reactivity) are exaggerated in postmenopausal women compared with premenopausal women, and this heightened reactivity is blunted by estrogen.[264] Whether or not these changes influence cardiovascular risk with

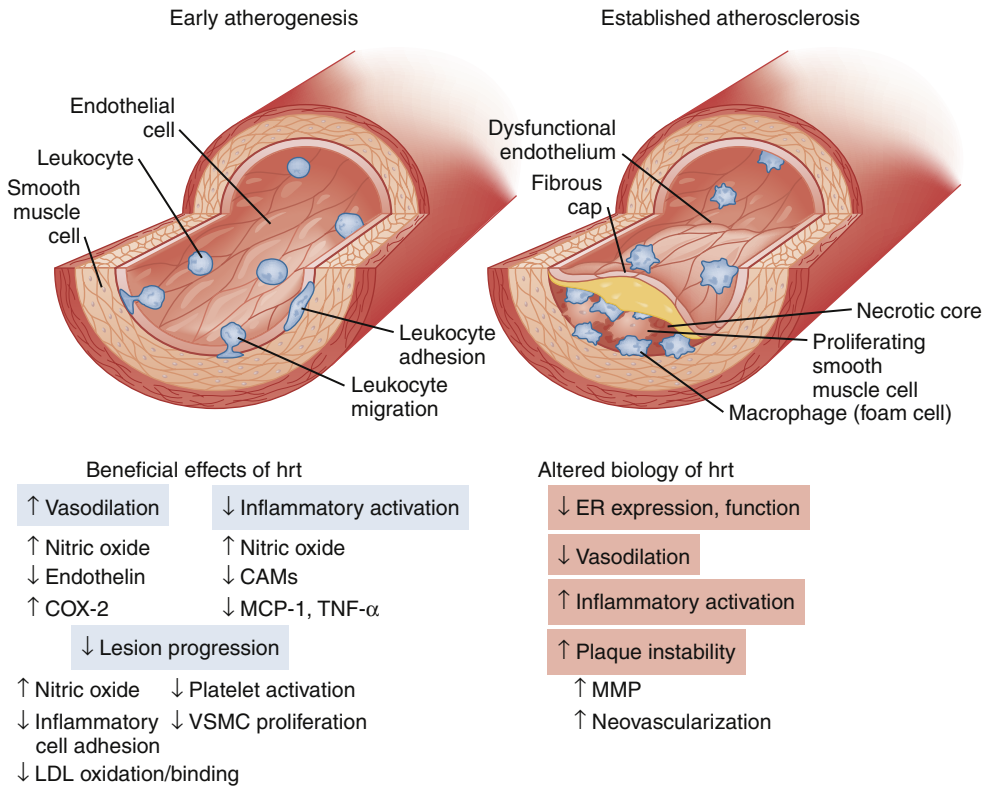

FIGURE 15.25 Early and esterified atherosclerosis with aging and the beneficial and negative effects of estrogen during these stages. ER, estrogen receptor; MMP, matrix metalloproteinase; TNF, tumor necrosis factor. *(From Mendelsohn ME, Karas RH. Molecular and cellular basis of cardiovascular gender differences. Science 308[5728]:1583–1587, 2005 [review].)*

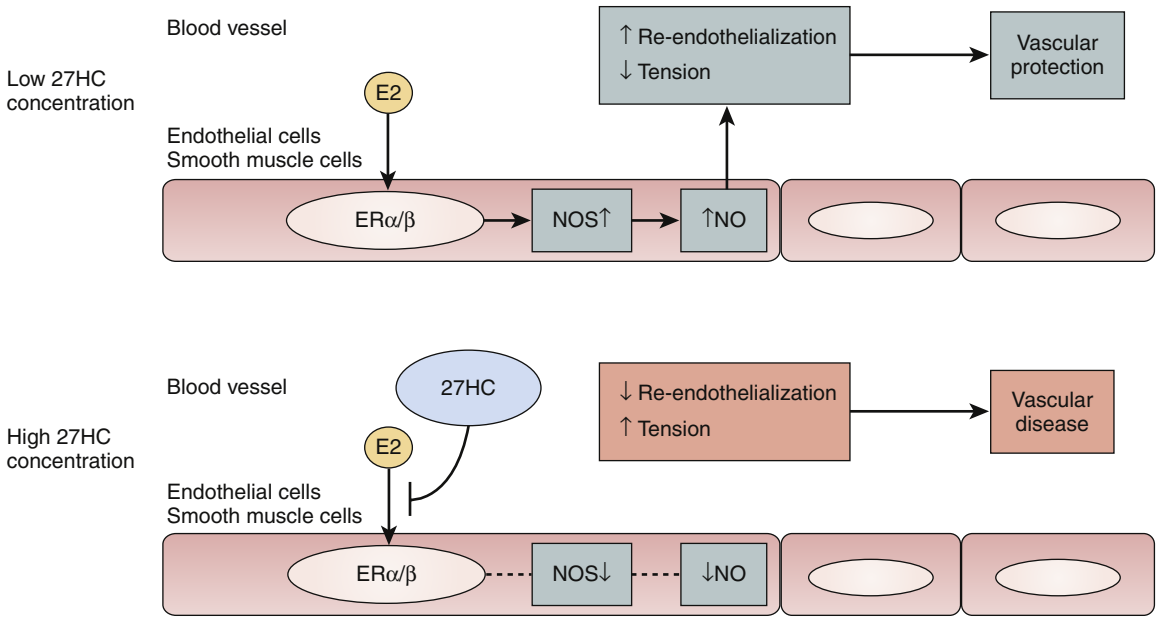

FIGURE 15.26 Hypothesis of how elevated cholesterol (27-hydroxycholesterol, 27HC) can influence the effect of estradiol (E_2). ER, estrogen receptor; NO, nitric oxide; NOS, nitric oxide synthase. *(From Umetani M, Domoto H, Gormley AK, et al. 27-Hydroxycholesterol as an endogenous SERM that inhibits the cardiovascular effects of estrogen.* Nat Med *13[10]:1185–1192, 2007.)*

estrogen deficiency is not known, but clearly estrogen treatment returns many parameters into the range of premenopausal women in early postmenopausal women.

These consistently strong basic science and clinical data for the protective effects of estrogen on the cardiovascular system, together with strong epidemiological evidence for a protective effect of estrogen (Fig. 15.27)[265] led to the belief that estrogen should be prescribed to prevent cardiovascular disease in women. However, randomized clinical trials (RCTs) have refuted this notion in women with established disease as noted previously. Results from several randomized trials in women,[255-257] have found there to be more coronary events in older women, given estrogen for the first time.[266]

This trend toward increased cardiovascular events in women who are older and/or who have documented diseased

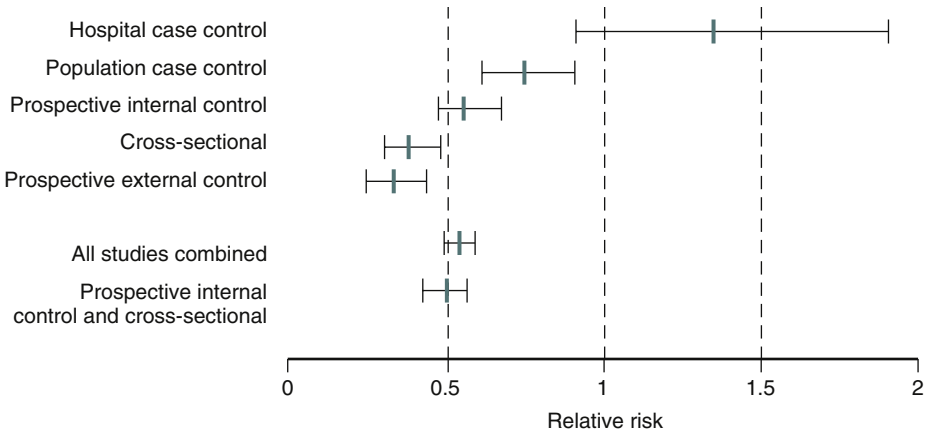

FIGURE 15.27 Estrogen replacement therapy and coronary heart disease. Relationship between relative risk and study type. *(Adapted from Stampfer MJ, Colditz GA. Estrogen replacement therapy and coronary heart disease: a quantitative assessment of the epidemiologic evidence.* Prev Med *20:47–63, 1991.)*

coronary arteries ("early harm")[267,268] occurs within the first 1 to 2 years. The Women's Health Initiative (WHI) trial, which compared CEE/medroxyprogesterone acetate (MPA) with placebo, came to similar conclusions.[269] This trial was considered to be a primary prevention trial that evaluated younger women without cardiovascular risk factors; the higher frequency of cardiovascular events were reported in an older cohort of women (mean age 63). These women did not have vasomotor symptoms and had more risk factors than the healthy women studied in observational cohorts.

The protective effect of estrogen demonstrated in the Nurse's Health Study (Fig. 15.27)[265] occurred predominantly in young healthy symptomatic women. Table 15.4 compares the demographics of the participants of WHI and the Nurse's study. Trials carried out in the monkey model have shown that there is a 50% to 70% protective effect against coronary atherosclerosis when estrogen is begun at the time of oophorectomy, with or without an atherogenic diet; delaying the initiation of hormonal therapy for even 2 years (in the monkey) prevents this protective effect (Fig. 15.28).[270-274]

No clear explanation exists for what the observed "early harm" may be due to, but these effects were not observed in those women receiving statins concurrently.[275] This finding suggests that hormone therapy (in the doses used) may lead to plaque destabilization and thrombosis in some women with coronary disease. The molecular mechanisms for this may be due to estrogen up-regulating matrix metalloproteinase-9 within the mural area of the plaque; the resultant disruption of the gelatinous covering then leads to thrombosis. This process is inhibited by statins. In women who had been receiving estrogen for a prolonged time, mortality was decreased in those who sustained a myocardial infarction.[276] No increase in cardiovascular events has been found in young healthy symptomatic women during the first two years of various hormonal regimens in clinical trials.[277]

It is now well established that the late treatment of postmenopausal women with standard doses of estrogen may be harmful and affords no coronary protection. This finding pertains to various trials with end points of coronary events, or angiographically-determined disease, as noted above, and does not appear to be modified by the hormonal regimen or route of administration. This is also true whether or not the woman has sustained a known coronary event. Since atherosclerosis is highly age dependent, even women who have not had a coronary event have diseased arteries. (Fig. 15.29) Also, as shown in Figure 15.28, well over 70% of the women studied in WHI would have been expected to have atherosclerotic vessels.

Table 15.4 Baseline Characteristics: Nurses' Health Study (NHS) Compared with Women's Health Initiative (WHI)

Characteristic	NHS	WHI
Mean age or age range at enrollment (years)	30-55	63
Smokers (past and current)	55%	49.9%
BMI (mean)	25.1 kg/m^2	28.5 kg/m^2*
Aspirin users	43.9%	19.1%
HT regimen	Unopposed or sequential	Continuous-combined
Menopausal symptoms (flushing)	Predominant	Uncommon

*34.1% had BMI ≥30 kg/m^2.
BMI, body mass index; HT, hormone therapy.

In concert with the view that estrogen given to early (and younger) postmenopausal women may have different effects, data have been analyzed in the 50- to 59-year-old age group in WHI, and in those less than 10 years from menopause. The definitions of menopause in WHI were not precise, and more women in the 50- to 59-year-old age group were older than 55 years old. The data are in strong contrast to the results of the entire group (two-thirds over 60 years old) In the estrogen only arm of WHI (hysterectomized women) receiving CEE 0.625 mg, the 50- to 59-year-old age group had reduced coronary event scores of borderline significance and a composite coronary score of statistical significance.[278] An analysis of 20 RCTs in younger women (which included WHI) showed a statistically significant benefit in a reduction of coronary events[279] and

mortality.[280] Younger women in WHI using estrogen only also had significantly reduced coronary calcium.[281] Ten-year follow up data of the estrogen alone arm published in 2011 confirmed that the 50- to 59-year-old group had a significant reduction in coronary heart disease (CHD) events and total mortality (Fig. 15.30).[281a]

While the data are not as strong for the use of combined HT (CEE/MPA) in WHI, it is difficult to conclude that MPA attenuates the benefit or may add harm in that the two trials in WHI were different, and studied different populations of women. The WHI conducted an observational trial in parallel with the RCTs. The results of the observational trials are more in keeping with the older observational data suggesting coronary protection and with no adverse effects on stroke.[282,283] These data could not be reconciled with the RCT data but reinforce the notion that early initiation of therapy and length of treatment influences these findings.[283]

The overall results of WHI for the 50- to 59-year-old age group in the two trials (CEE and CEE-MPA) were reanalyzed.[284] These data are more useful to assess in that this is the relevant population of symptomatic postmenopausal women who may be candidates for HT. For CHD, in the 50- to 59-year-old age group, the hazards ratio (HR) was 0.93 (0.65 to 1.33) for women receiving CEE & MPA; and was 0.63 (0.36 to 1.09) for CEE alone. For the entire group, total mortality was significantly decreased in this age group, 0.70 (0.51 to 0.96). These findings and point estimates are very much in line with the older observational data.

A Bayesian meta-analysis looking at randomized trials and observational data in younger women confirmed an approximate 30% reduction in mortality[284a] (Fig. 15.31), which is completely consistent with older data.

Although the "timing" hypothesis suggests that younger women receiving hormone therapy at the onset of menopause may have a reduction in cardiovascular disease, while older women may be subjected to harm, this has not been subjected to the rigors of randomized clinical trials until recently. Because cardiovascular events are rare in younger women, a very long trial would be required to demonstrate an effect. Therefore, in trials of approximately 4 to 5 years duration, only intermediate cardiovascular endpoints can be studied, such as carotid intima-media thickness and coronary calcium which may or may not relate to hard endpoints such as myocardia infarction and cardiovascular mortality. The Kronos Early Estrogen Prevention Study (KEEPS) and the Early versus Late Intervention Trial with Estradiol (ELITE) are two recently conducted trials on this point. In the 4-year KEEPS trial which compared CEE 0.45 mg to transdermal E_2, 50 μg and placebo, statistical benefit between the three arms in C-IMT was not seen although there were other beneficial effects of estrogen.[284b] There was a trend for a reduction in coronary calcium with estrogen (Fig. 15.32). It may be hypothesized that these younger healthy women at

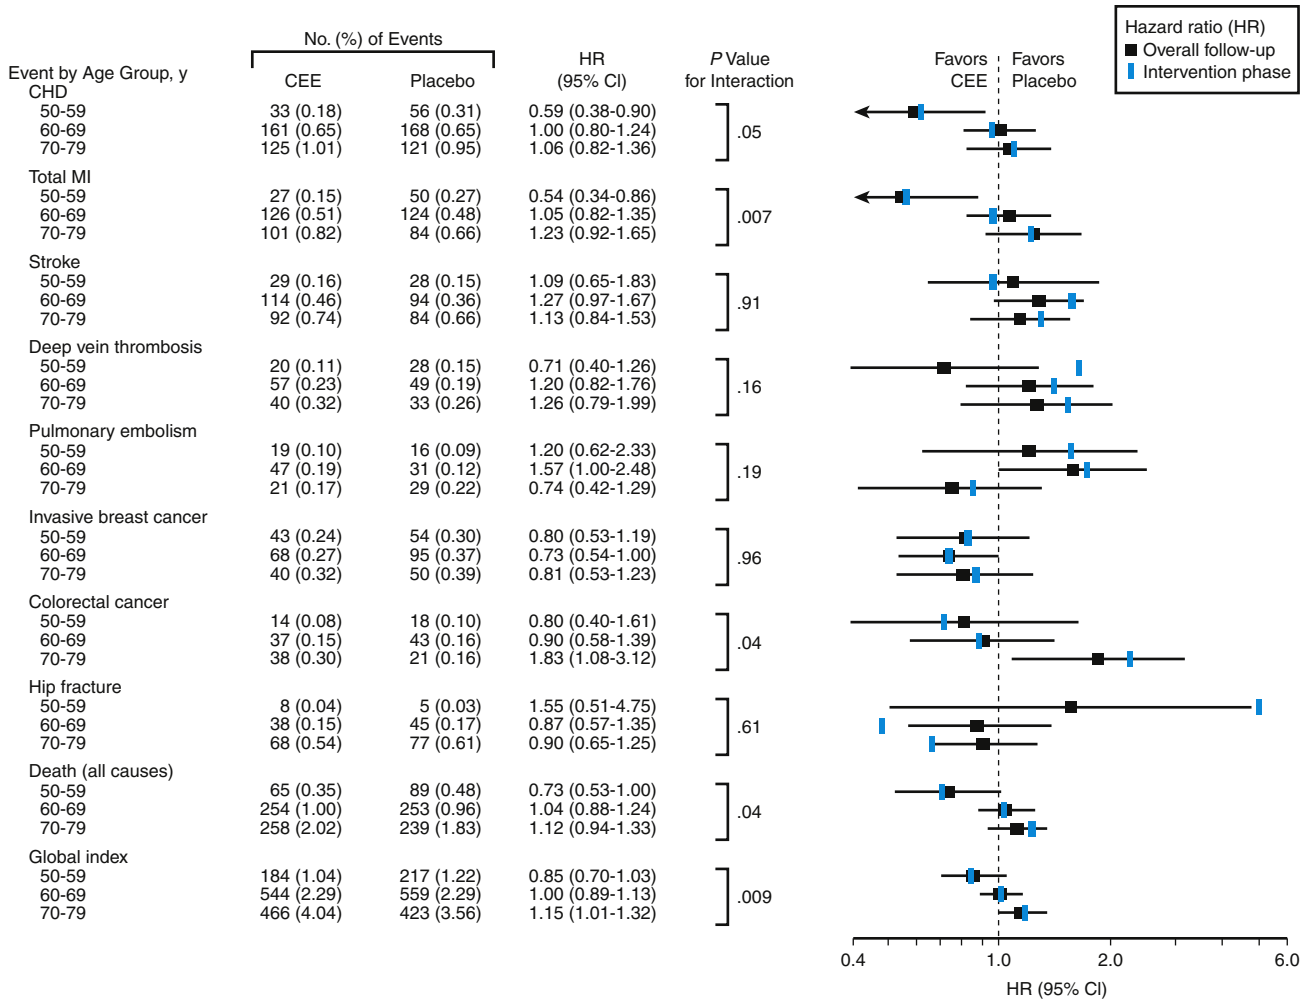

FIGURE 15.30 Ten-year follow-up of the estrogen alone arm in Women's Health Initiative (WHI) showing in the 50- to 59-year-old age group a significant reduction in CHD events and total mortality.

the onset of menopause did not have sufficient atherosclerosis progression over 4 years to differentiate placebo effect from estrogen. ELITE has not been analysed at the present time. However, a 10-year prospective trial in young Danish women treated at the onset of menopause and followed for 16 years recently showed a statistically significant reduction in cardiovascular events in users of oral estradiol, 2 mg, with and without norethindrone acetate[284c] (Fig. 15.33).

Stroke

Stroke is the third leading cause of death in women, and the interaction between hormones and stroke risk in women has been studied for some time.

In the original papers of WHI, overall stroke was significantly increased in women receiving CEE-MPA or CEE. However, the findings of increased stroke risk in younger women is more of a borderline nature and constitutes very few events. Age, obviously, and particularly hypertension, influences the risk of stroke in postmenopausal women; and this is significantly influenced by the dose and route of administration of estrogen.[285] It is ischemic stroke, and not hemorrhagic stroke which is influenced by the use of HT.

When large numbers of women are studied, both meta-analyses[285a] and observational studies[285b] have shown a small but significant increased risk of ischemic stroke with standard doses of hormone therapy. This is in the range of a 30% increase (relative risk ~1 to 3) because in younger postmenopausal women the risk of stroke is 6 to 8/10,000 women-years, the absolute risk is no more than 1 to 2 cases/10,000 women/year, a truly rare event. Our recent analysis suggests that those rare events in younger, postmenopausal women[285c] are related to thrombosis such as occurs rarely in women on oral contraceptives[285d] and is not due to atherosclerosis which occurs in older women. In concert with this, is the observation that less prothrombotic forms of hormone therapy (transdermal)[285a] and lower doses[285b] have not been found to increase the risk of ischemic stroke.

It has been acknowledged for some time that oral estrogen increases the risk of venous thrombosis and thromboembolism (VTE) in postmenopausal women. This risk tends to occur early (within the first 1 to 2 years of therapy) and is markedly increased if there is an underlying thrombophilia (about a fifteenfold increased risk).[286] However, in the absence of a family history or a prior thrombotic event, it is not standard practice to screen for factor V Leiden mutation or other abnormalities. Although the relative risk of thrombosis with oral estrogen is in the range of 2 to 3,

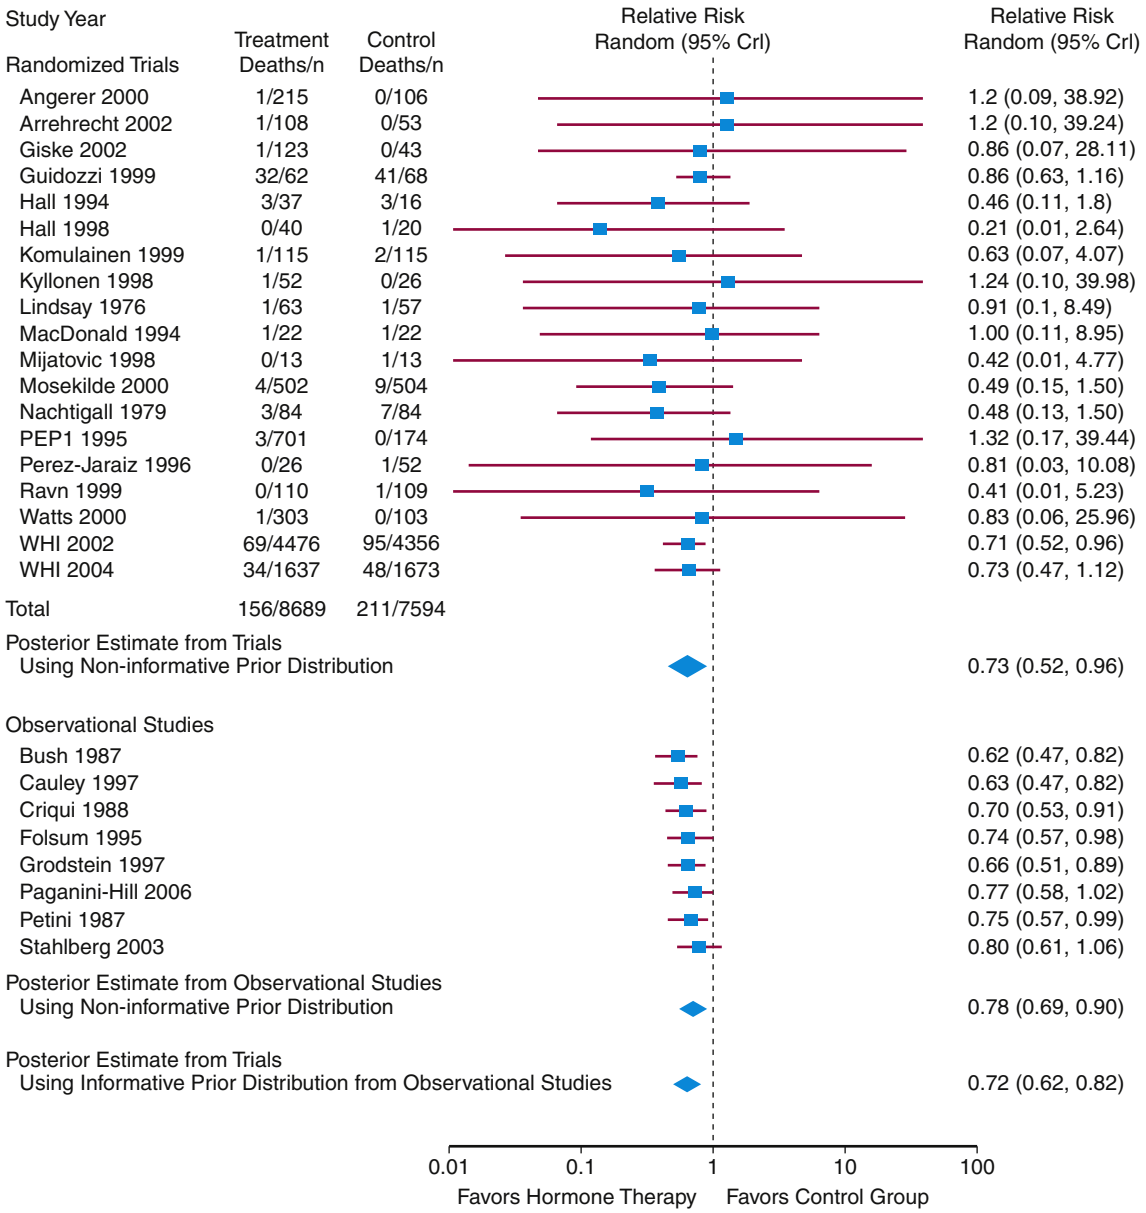

FIGURE 15.31 Bayesian meta-analysis of reduction in mortality with HT in younger women. *(Adapted from Salpeter SR. Bayesian meta-analysis of hormone therapy and mortality in younger postmenopausal women.* Am J Med *2009;122:1016–1022.)*

the prevalence of this is low, particularly in a younger population. For example, the risk of pulmonary embolism may increase from 20 to 40 cases per 100,000 women years with HT, but this is less than the general risk of VTE observed in pregnancy (60/100,000 women/year). The overall relative risk of VTE reported in WHI was in the range of 2 to 3 as noted above, but did not achieve statistical significance in the hysterectomized group using estrogen alone. Although this was a more obese group who could have been considered at higher risk, two other possibilities exist. The first is that approximately 50% of women had used estrogen in the past, and it is possible that this population of exposed women had received therapy beyond the first year or two when VTE usually occurs in susceptible women, and were not susceptible. Second, there is a possibility that the progestogen addition (MPA) with CEE increases the risk further. In a larger French observational study, the type of progestogen was considered to confer an additional risk of VTE with natural progesterone not enhancing the risk.[287] Further data from this cohort of women in the ESTHER study showed no increase in VTE risk with transdermal estrogen.[288] Several other recent studies have suggested the relative safety of transdermal over oral estrogen, even in high risk patients, unless higher doses (≥50 μg/day) are used[288a-c] (Fig. 15.34).

As noted earlier, blood pressure increases after menopause which increases CV risk. Apart from an idiosyncratic hypertensive response to oral estrogen in some women, the overall effect of estrogen on blood pressure is neutral, including women who are already hypertensive. There are studies showing some small increase, others showing no changes and others showing a decrease, even in hypertensive women.[289] Uncontrolled hypertension in postmenopausal women constitutes a major concern for stroke, and this may be aggravated in some women with the use of HT.

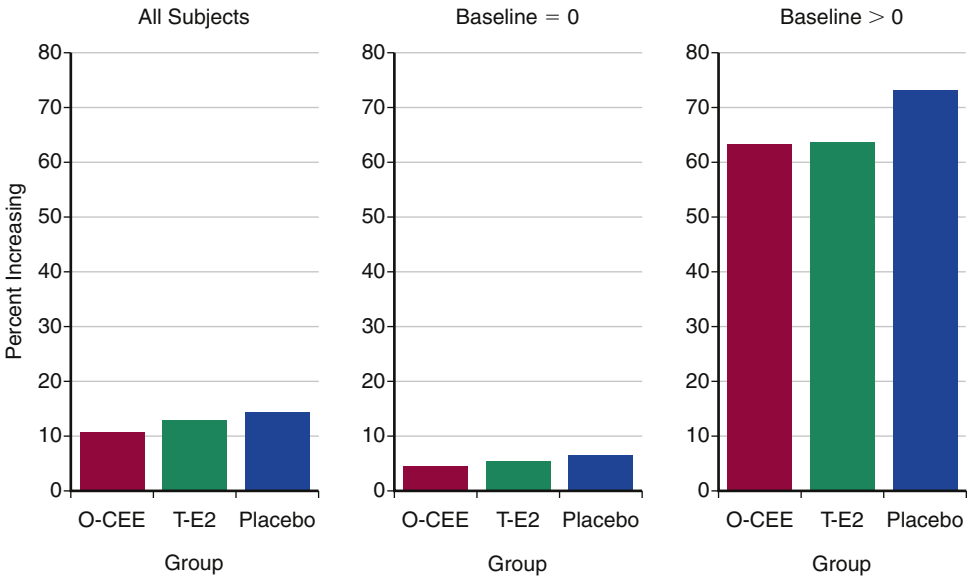

FIGURE 15.32 Data from the Kronos Early Estrogen Prevention Study (KEEPS) suggesting that there was less coronary calcium in women on HT (not statistically significant) and coronary calcium seen was very low. *(From Harman M: Primary findings of the KEEPS. 23rd annual meeting of the North American Menopause Society, Oct. 3, 2011, [submitted]).*

Breast Cancer

Because of the enormous importance of this topic, breast cancer and its relationship to HT use will be reviewed separately as well as in the context of the risk-benefit assessment discussed below.

Listed in Table 15.5 are the approximate rates of breast cancer by decade of life; clearly age is a major determinant of risk. More baseline risk information may be found in Chapter 11. However, postmenopausal breast cancer, fortunately, is not as lethal as lung cancer or CVD. In Figure 15.35 the age specific mortality rate is depicted, and shows that breast cancer mortality decreases after the initial age of menopause, while deaths from lung cancer are higher after menopause, and the rates of CVD mortality increase dramatically from this time onward. The effect of HT on breast cancer risk has been studied for at least 30 years, and only recently has there been a little more clarity on the issue.[290-293] Most of the data on breast cancer risk have been derived from case control and cohort observational studies. There have been several larger RCTs, such as data from WHI (at least for the use of two specific regimens)[291,292] and these will be presented separately as well.

In summary, RCTs show lower point estimates than observational data and little increased risk of estrogen alone.[292,293] With estrogen alone, the WHI showed reduced risk[292] and others, including the Million Women's Study that showed some increased risk.[294] This latter study, although large, has been widely criticized on methodological grounds. An update of the Nurses Health Study (NHS) showed no increasing risk for up to 20 years in hysterectomied women using CEE 0.625 mg.[293] As shown in Table 15.6, the overall risk going out 15 to 20 years is principally in lean women. Since obesity itself is associated with an increased risk of breast cancer, an additional risk with HT has not been demonstrated.

It has been known for some time, based on autopsy studies, that there is an "occult" or undiagnosed breast cancer rate of approximately 15.6%. These tumors have a doubling of time of 70 to 350 days leading to possible detection by mammography when they reach 0.88 to 1.66 cm in diameter. It has been estimated, based on iterative analysis and modeling that of the tumors that emerged in the E + P arm of WHI, 93.3% were occult lesions that grew and 6.7% arose *de novo*. Therefore the promotional effect of E + P shortened the doubling time from an average of 200 days to 150 days, allowing for early detection by mammography towards the end of the trial.[294a] With estrogen alone therapy in WHI the reverse was suggested with apoptosis occurring in some of the tumors, arresting the doubling time with estrogen causing a lower number of tumors to be detected compared to placebo.[294a]

In the CEE alone trial of WHI, there was a borderline significant reduction in breast cancer risk, which was statistically significant for adherent women and for ductal cancers.[292] These data are reassuring for a negligible effect of estrogen alone on breast cancer risk, but should

not be interpreted as estrogen being protective for breast cancer.

There seems to be consistent findings of increased risk with estrogen and progestogen regimens after 5 years of use. This risk estimate ranges from 1.2 to 1.7 and is related to dose, possibly the type of progestogen[295] and duration of use. However, there are no clear data showing a difference between continuous combined and sequential regimens of progestogen therapy. In a less well known publication from WHI, when adjustments were made for breast cancer risk factors, the overall risk for the 5 to 6 years of CEE and MPA use was not significant at 1.20 (0.94 to 1.53).[291] Of great importance was the finding that in women who had never received HT (70% of the WHI population), the relative risk (RR) was 1.02 (0.77 to 1.36)[291]; that is, the trend for an increased risk was accounted for by prior use and a longer cumulative exposure to estrogen and progestogen.[295] There also has been a suggestion that estrogen and progestogen

therapy increases the relative frequency of lobular cancers which are normally more rare, but generally more well differentiated and less aggressive. This, however, has not been proven.

In a follow-up of women in the WHI estrogen-only arm, over 10 years, the significant reduction in breast cancer incidence was confirmed.[295a] Moreover, in terms of breast cancer mortality, this was significantly lower among the users of estrogen as has been suggested before. This study also confirmed a statistically significant reduction in total mortality in estrogen users (Fig. 15.36).[295a]

If standard dose estrogen and progestogen therapy over 5 years increases the risk of breast cancer by 24%, (RR 1.24), what does this translate into in absolute terms? If the background risk between the ages of 50 to 60 is 2.8% (2.8 women out of 100 will be expected to get breast cancer over this 10 year time span), then the rate would increase to 3.4% (less than 1% increase). Clearly, there is probably no increased risk in women who have never had therapy for up to 5 years and, particularly if lower than the standard dose is used. Also, observational data from France have suggested that progesterone and dydrogesterone are not associated with an increased risk, as opposed to synthetic progestogens.[295] These data, however, remain to be confirmed.

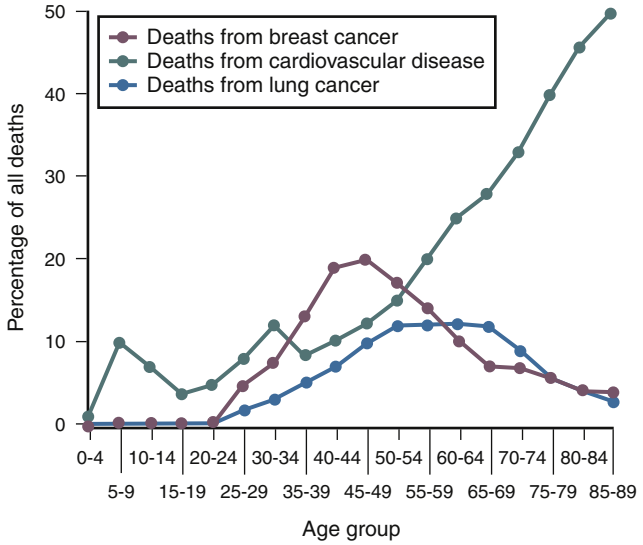

FIGURE 15.35 Risks of breast cancer and lung cancer versus cardiovascular disease in various age categories. *(Adapted from Phillips KA, Glendon G, Knight JA. Putting the risk of breast cancer in perspective.* N Engl J Med *340:141–144, 1999.)*

This RR of 1.2 to 1.6 for 5 years of estrogen and progestogen use as discussed above should also be compared to other experiences such as having a waist to hip ratio greater than 0.8: 3.3 (1.1 to 10.4) or being an airline flight attendant 1.87 (1.15 to 2.23). There are many more every day experiences such as these for breast cancer risk.[295b]

Compared to the small increase in breast cancer observed with standard dose E + P in WHI, other exposures are much higher[295c] (Fig. 15.37). The highest relative risk is seen in women with increased breast density, which also makes mammographic detection of small tumors challenging. While E + P treatment increases breast density, it is unclear if this imparts an additional risk for cancer; clearly these induced changes in breast density are reversible.

A report showing a downward trend in breast cancer rates in the U.S. suggested that this might be related to a reduction in hormone use after the WHI and other reports.[296] However, there are several other possible explanations as well, including a reduction in mammography use and other variables reviewed elsewhere. Of interest is that the reduction in breast cancer in the U.S. also occurred in older women in their seventh decade as well (not users of hormones) and has not been reported in many other countries[295c] where HT use has dropped as well. A 3-year follow-up of WHI showed that the breast cancer risk also persisted (nonsignificantly) over this follow-up period.[297]

The Decision to Use Estrogen

Whether or not hormonal therapy should be considered is a very individual decision. The woman must take into account symptoms, risk factors, and individual preferences and needs. The predominant indication for estrogen is for symptoms (vasomotor and vulvo-vaginal).

Alternatives should also be considered. If hormonal therapy is chosen, there should be flexibility in prescribing because there is no ideal regimen for every woman, and each woman has individual risks and needs.

Because hormone therapy is clearly the most efficacious treatment for symptoms, it should be considered a first line therapy. Since the results of WHI, which were misinterpreted and generalized to all women, caused most women and many providers to move away from hormone therapy, it was deemed important for several prominent medical societies to come together and make a definitive statement 10 years after WHI was first published. This statement of agreement amongst "experts" caring for women clearly states that estrogen is appropriate for younger, healthy women at the onset of menopause[297a]; in most cases the benefits far outweigh the risks. Since the original release of the findings of WHI, over 10 years later the following comment from a review seems most appropriate: "We have come full circle in some ways, with mounting evidence supporting the benefit of hormone replacement therapy started near menopause and with hard lessons learned about pathophysiology, publicity, and interpreting data."[297b]

Risk-Benefit Assessment

Several recent guidelines provide details regarding the use of HT for control of symptoms (International Menopause Society,[298] North American Menopause Society,[299] Medscape,[300] and American Association of Clinical Endocrinologists.[301] These guidelines stress the relative safety in symptomatic women, and that lower doses should be used with individualization regarding the length of treatment. Whether osteoporosis prevention alone is a sufficient indication for HT is controversial, but this should be considered as well.

At present there is no indication for using HT for the prevention of CVD or Alzheimer risk. Nevertheless, for both of these diseases there is the suggestion that early initiation of therapy (as was carried out in observational trials) may show protective effects.

Individualization of therapy is what is key in that there is no way to tally the risks and benefits of therapy in a global way. The "global index" used by WHI is an unvalidated instrument which gives equal weight to a number of parameters that are not expected to be equal in terms of risks for an individual woman. Further, data obtained to generate the global index for the trials (+ or – a certain number of events) included findings which were not statistically significant, making numbers of absolute risk inapplicable, although they were applied as such to create the composite score.

Changes in Mortality with Estrogen Use

In several cohort studies,[302-304] an overall 40% reduction in all-cause mortality has been observed with long-term estrogen use. Two studies have shown that the benefit in mortality is related to the duration of use; one study has suggested that the effect is decreased beyond 10 years of use because of an increase in breast cancer mortality (only reported in this cohort and not in the others).[304] Most studies have shown either no change in breast cancer mortality with estrogen use, or a decrease in mortality as was noted earlier from the updated data from WHI.[295a] In the re-analysis of data from WHI, in the 50- to 59-year-old age group, total mortality in the two trials was reduced significantly by 30% (HR 0.70 [0.51-0.96]) corroborating the findings of the earlier observational data. Figure 15.31 clearly points out the reduction in mortality in younger women combining randomized trials and observational data.[284a]

In these observational cohorts looking at all-cause mortality, the overall reduction was found to be attributable to a reduction in cardiovascular mortality, although there was a small effect in cancer mortality as well. It is important to note that the women in these observational (epidemiological) trials received estrogen therapy (ET) or estrogen/progestogen therapy (EPT) at the onset of menopause, and the women observed were healthier. In older women (10 or more years after menopause) who may have silent or established cardiovascular disease, there may not be a protective effect on mortality.

Several studies have also found hormone therapy to be a cost effective therapy for younger women; particularly looking at quality adjusted life years.[304]

Endometrial Disease Risk and Other Issues with HT

Among the risks that have been associated with estrogen are endometrial disease; breast cancer; side effects such as vaginal bleeding; somatic complaints; and idiosyncratic reactions, including hypertension. Cardiovascular events and thrombosis risk have been discussed earlier. All of the risks are, in part, dose-related, lending to the credence of using lower doses. Endometrial disease occurs with unopposed estrogen therapy in women who have a uterus. Although a woman's risk for endometrial cancer with unopposed estrogen use is twofold to eightfold higher than that for the general population, precursor lesions (primarily endometrial hyperplasia) signal the presence of an abnormality in most patients. Thus, the risk is far less for endometrial cancer than it is for varying degrees of hyperplasia.

One study showed that the risk of endometrial hyperplasia was 20% after 1 year of use of 0.625 mg of oral CEE.[305] In another study, the 3-year postmenopausal Estrogen/Progestin Interventions Trial,[306] the risk was approximately 40% at the end of 3 years. No cancers were reported in either of these two studies, and the addition of a progestin essentially eliminated the hyperplasia. Using a dose of 0.3 mg of CEE results in a risk in the range of 5% to 10% after 2 to 3 years. With the same dose of esterified estrogens (which is less potent), no hyperplasia was found after 2 years.[221]

The risk for endometrial cancer is the same for a woman taking estrogen and progestin EPT as for the general population. The addition of a progestin merely eliminates the excess risk attributed to estrogen. However, there are a few studies published suggesting a reduced risk with continuous

combined HT. Other endometrial cancers occurring in postmenopausal women are not thought to be hormonally related (see Chapter 29). Although the risk for endometrial cancer is increased substantially in estrogen users, the risk of death from this type of endometrial cancer does not increase proportionately.[307,308] Endometrial cancers associated with estrogen use are thought to be less aggressive than spontaneously occurring cancers, in part because tumors in women taking estrogen are more likely to be discovered and treated at an earlier stage—thus improving survival rates.

Several studies have also suggested an increased risk of ovarian cancer with long duration of use of ET and HT. However, the data are inconsistent and the purported risk is in the range of less than a twofold relative risk.[309,310] An analysis found no association, and there was no increase reported in the WHI studies.[311]

One of the concerns of women receiving estrogen is the return of menstrual bleeding. Somatic complaints such as breast tenderness and bloating may also occur with ET, but these can be alleviated by alterations in the dose and type of preparation. Such concerns should be addressed with a view of being flexible in prescribing, because there is no ideal product for any particular woman.

It has been estimated that the absolute increased risk for venous thromboembolic events is 15 per 100,000 women per year, which is categorized as an uncommon finding. Nevertheless, all patients must be informed of these findings. Women who have a family history of thrombosis or have had thrombotic events linked to oral contraceptives or any prior estrogen use should be counselled very carefully and monitored closely. A low-dose, nonoral form of estrogen would be a consideration for these patients; again, the need for choosing estrogen as a treatment should be clearly documented.

Approach to Therapy

In developed countries, much of what women know about healthcare is gleaned from the mass media.[312] In general, the more sensational an item is, the more noteworthy. For example, breast cancer risk is a real and serious concern for all women, but the fear of breast cancer seems to drive *all* decision-making, particularly regarding hormonal options.

American women believe that the leading cause of death in women is breast cancer and attribute only a small percentage of deaths to cardiovascular disease. In reality, the opposite is true. Statistics indicate that one in three women older than age 65 has some evidence of cardiovascular disease. Despite public perception, the overall incidence of breast cancer has remained constant in recent years. Nevertheless, what is not commonly appreciated by those healthcare professionals counselling patients is the age-associated relationship in the incidence of breast cancer.

The rationale for choosing estrogen at the onset of menopause for symptom control is expected to have a minimal effect on breast cancer incidence, particularly if the dose of estrogen is lowered and with a reduction in progestogen exposure in women with a uterus. Whether or not there is also some cardiovascular benefit in this setting cannot be determined with certainty at this time, but should not be used as an indication.

Table 15.7 Mean Serum Estradiol (E_2) and Estrone (E_1)

Estrogen Dose (mg)	Level (pg/mL) E_2	E_1
CEE (0.3)*	18	76
CEE (0.625)	39	153
CEE (1.25)	60	220
Micronized E_2 (1)	35	190
Micronized E_2 (2)	63	300
E_1 sulfate (0.625)	34	125
E_1 sulfate (1.25)	42	220

*Conjugated equine estrogen (CEE) contains biologically active estrogens other than E_2 and E_1.

Hormone Regimens

There are many hormonal preparations available for treatment, and the most comprehensive listing can be downloaded from the North American Menopause Society: www.menopause.org. Also medications for osteoporosis may be found, including the SERMS, bisphospohonatesdenosumab, tibolone, and human parathyroid hormone tariparatide.[1-34] For the clinician and patient, the decision to start estrogen therapy need not involve a long-term commitment. For short-term treatment of symptoms, estrogen should be used at the lowest dose that can control hot flushes or can be administered via the vaginal route for symptoms of dryness or dyspareunia.

Oral ET results in higher levels of E_1 than E_2; this is true for oral estradiol as well as estrone products. CEE is a mixture of at least 10 conjugated estrogens derived from equine pregnant urine. Estrone sulfate is the major component, but the biological activities of equilin, 17β-dihydroequilin, and several other B-ring unsaturated estrogens, including Δ dihydroestrone, have been documented. Table 15.7 compares the standard doses of the most frequently prescribed oral estrogens and the levels of E_1 and E_2 achieved.[313,314] Much of the clinical information contained below may be found in systematic reviews.[315]

Synthetic estrogens, given orally, are more potent than natural estradiol. Ethinyl estradiol is used in oral contraceptives, with a dose of 5 μg being equivalent to the standard ERT doses used (0.625 mg CEE or 1 mg micronized estradiol). Standard ERT doses are five or six times less than the amount of estrogen used in oral contraceptives.[316] For hepatic markers, CEE 0.625 mg is generally more potent than E_2 and is closer to 1.5 mg E_2.

Oral estrogens have a potent hepatic "first pass" effect that results in the loss of approximately 30% of their activity with a single passage after oral administration. However, this results in stimulation of hepatic proteins and enzymes. Some of these changes are not particularly beneficial (an increase in procoagulation factors), whereas other changes are beneficial (an increase in high density lipoprotein cholesterol [HDL-C] and a decrease in fibrinogen and plasminogen activator inhibitor-1).

E_2 can be administered in patches, gels, and subcutaneously. These routes of administration are not subject to major hepatic effects as with oral therapy. Standard doses in the United States of alcohol-based or matrix patches are 0.05 mg or 0.1 mg. Lower-dose patches of 0.025 mg are also

available for administration once or twice weekly. Matrix patches are preferable because there is less skin reaction and estrogen delivery is more reliable. Whereas levels of E_2 vary widely among women, levels with transdermal therapy are more constant in individual women than with oral ET. With the 0.05-mg patch, OK E_2 levels are in the 40 to 50-pg/mL range; with the 0.1-mg patch, levels are typically 70 to 100 pg/mL. Levels in excess of 200 pg/mL are not unusual for some women.[317] An ultralow dose patch, 0.014 mg has been approved for osteoporosis protection in older women.

In women with vulvovaginal or urinary complaints, vaginal therapy is most appropriate. Creams of estradiol or CEE are available, as well as tablets and an estrogen ring. With creams, systemic absorption occurs but with levels that are one fourth of that achieved after similar doses administered orally. Absorption decreases as the mucosa becomes more estrogenized. For CEE, only 0.5 g (0.3 mg) or less is necessary; for micronized E_2, doses as low as 0.25 mg are sufficient. Other products (tablets and rings) are available that have been designed to limit systemic absorption.[318,319] A silastic ring of E_2 is available that delivers E_2 to the vagina for 3 months with only minimal systemic absorption.[320]

Estrogen may be administered continuously (daily) or for 21 to 26 days each month. If the woman has a uterus, a progestogen should be added to the regimen.[321] For women who are totally intolerant of progestogens (regardless of the dose and route of administration) and take unopposed estrogen, annual endometrial sampling is necessary. Alternatively, different progestogens may be tried; micronized progesterone can be used vaginally, or an intrauterine system (IUS) can be used. The current IUS, releasing 20 μg levonorgestrel, is too large a dose for routine HRT and the 10 μg IUS, although well studied, will not be marketed as such.[322]

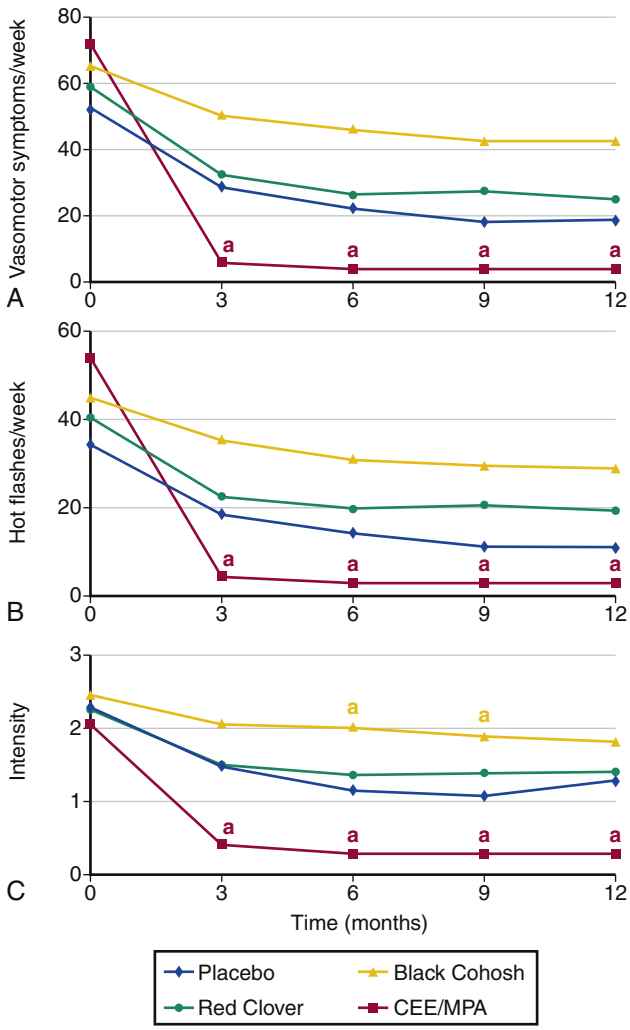
Colon Cancer and Other Changes

Observational studies have reported a reduced risk of colorectal cancer in menopausal women who are current and past users of EPT. This was confirmed in the WHI trial using EPT (HR 0.65). This protective effect is believed to increase with duration of use. With aging, there is a decline in macular function.[323] In observational studies, estrogen therapy has been reported to reduce macular degeneration and maintain visual acuity in menopausal women. There are also several studies showing that estrogen is associated with a reduction in tooth loss[324,325]

Androgen Therapy

In a very subtle way, some women are relatively androgen deficient.[326] Clinicians have proposed adding androgen to ET or EPT for complaints or problems relating to libido and energy, which are not relieved by adequate estrogen[327] though well-controlled trials using parenteral testosterone have shown benefit in younger oophorectomized women, there have been few data showing benefit using more physiological therapy, until recently. Recent data using a testosterone patch (with near physiological levels) have shown improvement in several scales of well-being and sexual function.[328-332] An oral preparation (esterified estrogens 0.625 mg with 1.25 mg of methyl testosterone) was shown to improve sexual motivation and enjoyment in women with hypoactive sexual desire who were unresponsive to estrogen alone.[333] The latter findings correlated with an increase in circulating unbound testosterone levels. As newer forms and doses of androgen become available, perhaps more women may benefit from this approach. At present, androgen therapy should be individualized and considered for those women who have symptoms that are not adequately relieved with traditional ET or EPT.[327] At lower doses, androgenizing side effects are very infrequent but should be discussed before prescribing testosterone. At present, small doses of methyltestosterone (1.25 and 2.5 mg) added to esterified estrogens are available in tablets, as are testosterone patches that are available for men (and therefore require dose reductions) and testosterone subcutaneous pellets. The testosterone patch (300 μg) has not been approved for use in women in the U.S. but is available in Europe. Administration of dehydroepiandrosterone at 25 to 50 mg/day may also be an option.[334]

Another SERM-like compound that is used worldwide but is not yet approved in the United States is tibolone. This progestin-like compound exhibits estrogenic, antiestrogenic, and androgenic effects by virtue of its structure and metabolites. At 2.5 mg, tibolone suppresses hot flushes, prevents osteoporosis, and has a positive effect on mood and sexual function.[335] There is also very limited (or no) uterine stimulation. However, there is a suppression of HDL-C, but at the same time a decrease in triglycerides. In the monkey, there was no deleterious effect of tibolone on coronary arteries.[336] In older women it may increase the risk of stroke.



Alternative Therapies for Menopause

Phytoestrogens

Phytoestrogens are a class of plant-derived estrogen-like compounds conjugated to glycoside moieties. Phytoestrogens are not biologically active in their native forms unless taken orally. After oral ingestion, colonic bacteria cleave the glycosides, producing active compounds that are subject to the enterohepatic circulation. These compounds can produce estrogen-agonistic effects in some tissues, whereas in other tissues they can produce antagonistic effects.

Few randomized trials have examined the efficacy of phytoestrogens. For large daily doses (60 mg isoflavone) there appears to be some limited efficacy in relieving hot flushes.[337] With doses of 30 to 40 mg, cholesterol levels are reduced, but it is no longer recommended as a strategy.[338] It should be noted that there is an important reduction in hot flushes with *any* placebo treatment. Phytoestrogens do not appear to have much of an effect on bone loss or on vaginal atrophy. A recent trial of longer duration has shown no benefit of red clover and soy (Fig. 15.38).[338a]

Estimates are that between 30% and 60% of women use so-called alternative interventions for the symptoms of menopause, including "natural" estrogens, plant estrogens, herbal medicines, and acupuncture. Botanicals, herbals, and many steroid products are sold over the counter, and some do in fact exert significant hormonal activity. The use of botanicals to alleviate the symptoms of menopause is extremely popular. This popularity is fostered by the notion that plant sterols might provide all the benefits of estrogen

CEE - Conjugated Equine Estrogens
MPA - Medroxyprogesterone Acetate
a - Statistically significant difference

FIGURE 15.38 Black Cohosh and Red Clover are not different from Placebo. *(Adapted from Geller SE. Safety and efficacy of black cohosh and red clover for the management of vasomotor symptoms: a randomized controlled trial.* Menopause *16:1156–1166, 2009.)*

replacement therapy without the risks. However, most plant products recommended for menopause have performed poorly in clinical trials. The Dietary Supplement Health and Education Act of 1994 classifies most botanical medicines as food supplements and removes them from regulatory oversight and scrutiny by the U.S. Food and Drug Administration (FDA). Adulteration, contamination, and poor quality control in their harvesting, manufacture, and formulation yield products of questionable efficacy and safety.

The FDA has determined that more than 25% of Chinese patent medicines are adulterated with hidden pharmaceutical drugs. These kinds of deficiencies make it difficult for consumers and practitioners to employ botanicals with confidence and security. Furthermore, clinical trial data obtained using one brand of herbal product cannot necessarily be extrapolated to other brands using the same plant. DHEA is marketed as a dietary supplement for a variety of purported benefits. There are no data in women to support its role in well-being or immune function. As an androgen, DHEA is converted to androstenedione and testosterone. Doses of 25 to 50 mg raised testosterone and has been mentioned as an option for androgen therapy.[334]

In recent years, more women have turned to "bioidentical" hormones. In essence, estradiol and progesterone, which are available as FDA-approved products, are "bioidentical"—that is, identical to the steroids produced by the body. However, an industry has arisen where compounding pharmacies add various combinations of steroids to be administered in cream form. These products are not FDA-approved and quality control cannot be guaranteed. There is no evidence that these preparations are safer than standard products. Use of saliva to quantify levels is extremely inaccurate. The major societies [e.g., North American Menopause Society (NAMS), Endocrine Society, American Society for Reproductive Medicine (ASRM), American Congress of Obstetricians and Gynecologists (ACOG)] do not endorse this use. A joint statement has recently been issued by ASRM and ACOG.[339]

Use of a Progestogen

There are many ways to administer progestogens. The most commonly used oral progestins are MPA in doses of 5 to 10 mg, norethindrone (NET) in doses of 0.3 to 1 mg, and micronized progesterone in doses of 100 to 300 mg. Equivalent doses to prevent hyperplasia when administered for at least 10 days in a woman receiving ET (equivalent to 0.625 mg GEE) are as follows: MPA, 5 mg; NET, 0.35 mg; and micronized progesterone, 200 mg.[340] Larger doses of estrogen may require larger doses and more prolonged regimens of progestins. In sequential administration of progestins, the number of days (length of exposure) is more important than the dose. Thus, if a woman is receiving oral ERT continuously, a regimen of at least 10 to 12 days of exposure is preferable to a seven-day regimen.

When progestogens are administered sequentially (10 to 14 days each month), withdrawal bleeding occurs in about 80% of women. Continuous administration of both estrogen and progestogen (continuous combined therapy) was developed to achieve amenorrhea. In the first 3 to 6 months, breakthrough bleeding and spotting is common. In some women on this regimen, amenorrhea is never completely achieved. The most common combinations in the United States are single tablets containing 0.625 mg CEE and 2.5 mg (or 5 mg) MPA, and the lower dose combination with 0.45 mg and 0.3 mg. (CEE) 5 μg of EE with 1 mg NET; 1 mg micronized E_2 with 0.5 mg NET, and 1 mg of E_2, with 0.5 mg of drosperinone. Patches with E_2 NET of levonorgesterone are also available. Currently, the only marketed sequential regimen is one that contains 0.625 mg CEE and 5 mg MPA, which is added for 14 days each cycle.

Equal efficacy to standard doses has been demonstrated for several low dose combinations in terms of reduction of hot flushes, maintenance of bone mass, metabolical profiles, and a reduction in the incidence of bleeding in the first year of treatment has been observed.

Progesterone administered vaginally (in low doses) avoids systemic effects and results in high concentrations of progesterone in the uterus. Intrauterine delivery of progestogens is ideal for targeting the uterus but is not approved in the United States.

Progestogens, particularly when taken orally, may lead to problems of continuance or compliance because of adverse effects, including mood alterations and bleeding. These have to be dealt with effectively, and they usually require more flexibility in prescribing habits. Most short-term clinical trials have demonstrated an attenuating effect of progestogens on cardiovascular end-points that are improved with estrogen; these effects include lipoprotein changes (an attenuation of the rise in HDL-C) and arterial and metabolical effects. A reduction in blood flow and some brain effects may also be found.

How progestogens influence cardiovascular risk is not clear at present. The observational studies, which showed a benefit for ET, did not find any diminution of this effect with EPT. Although there were differences in the effects of CEE with MPA and CEE alone in WHI, there were separate trials which are difficult to compare. The addition of progestogens probably is responsible for the observed increase in the risk of breast cancer in susceptible women. Progestogens should not be prescribed in women who have undergone hysterectomy.

Tissue Selective Estrogen Complex

The concept of a tissue selective estrogen complex (TSEC) is to pair estrogen (CEE) with a SERM (bazedoxifene) which has certain estrogen-antagonistic effects in certain organ systems (breast, uterus). Not all SERMS are successful in this pairing. The effects of bazedoxifene are less marked in the brain (affecting hot flush susceptibility) and is also agonistic in bone. Thus, a combination of CEE and bazedoxifene could be used to prevent hot flushes without the need for a progestogen while also having beneficial effects for bone and neutral effects on the breast. While not approved for use in the U.S. as yet, CEE 0.625 and 0.45 paired with bazedoxifene 40 mg have gone through successful phase 3 clinical trials demonstrating efficacy and safety.[340a,b]

Aging

It is extremely difficult to separate the effects of menopause from that of natural aging. Some of these problems have been reviewed in detail elsewhere, and the much needed research in this area has been outlined.[341] The key areas where it is important to dissect out aging effects from the effects of estrogen deficiency are in bone loss and osteoporosis, cardiovascular disease, cognitive decline, decline in sexual function, and depression. While premenopausal estrogen therapy may play a role in protecting against these entities, aging also has significant effects.

From a reproductive endocrine perspective, the hormonal systems that are most notably affected by aging are declines in the somatotropic axis, declines in adrenal steroids, and changes in cortisol secretion. Table 15.8 outlines the endocrine metabolical changes with aging.

The Somatotrophic Axis

In men and women, GH decreases with aging,[341] beginning around age 40[342,343]; this decrease may be responsible for some of the changes in body composition. A redifferentiated proportion of body fat increases by 100%. Concomitantly there is a 20% to 50% decrease in muscle mass and a 20% decrease in body fat. In women, declines in growth hormone-releasing hormone secretion and a loss of the priming effect of estrogen explain the decline in GH.[344-347]

The anabolical effects of replacing GH can result in stimulated muscle development and strength, a loss of fat, and an increase in bone mass.[348] Accordingly, GH releasing peptides have been studied for this purpose.[349,350]

Table 15.8 Endocrine-Metabolical Changes with Aging

Substance	Change
Luteinizing hormone	↑
Follicle-stimulating hormone	↑
Growth hormone	↓
Adrenocorticotropic hormone	→*
Prolactin	↓
Thyroid-stimulating hormone	→*
Estradiol	↓
Estrone	↓
Progesterone	↓
Triiodothyronine	→
Thyroxine	→*
Cortisol	↑
Dehydroepiandrosterone	↓
Dehydroepiandrosterone sulfate	↓
Testosterone	↓
Androstenedione	↓
Inhibin	↓
Melatonin	↓
Insulin-like growth factor-1	↓
Dopamine	↓
Norepinephrine	↑

*May be slightly increased or decreased in response to specific secretagogue (e.g., corticotropin-releasing hormone, thyrotropin-releasing hormone, somatostatin, growth hormone-releasing hormone, adrenocorticotropin) with age.

Metabolical Changes

With aging, weight gain and fat accumulation occurs, as stated above. These changes begin a few years before menopause and parallel increases in FSH[351] (Fig. 15.39). It has recently been confirmed in longitudinal studies that weight changes generally precede the hormonal changes, such as the decrease in SHBG.[351a] These changes are associated with increases in leptin. In early menopause, associated with normal BMI, adiponectin increases.[352] However, in late menopause, as with obesity, adiponectin is reduced increasing CV risk.[353] With aging, there is a reduction in pancreatic β cell secretion increasing the risk of DM. Adding to this risk, insulin resistance increases with age but is accelerated with weight gain and obesity.

The major concern with increasing adiposity and reduction in muscle mass (sarcopenic obesity) is the evolution of chronic diseases. Increasing immobility compounds the transition to metabolical syndrome and overt diabetes and cardiovascular disease. It has been shown in 18 randomized trials that the best way to combat sarcopenic obesity is by the combination of aerobic and strengthening exercise 2 to 3 days per week, combined with caloric restriction leading to a daily deficit of 750 Kcalories.[353a] Diet and exercise should be a mainstay for combating the aging process.[353a]

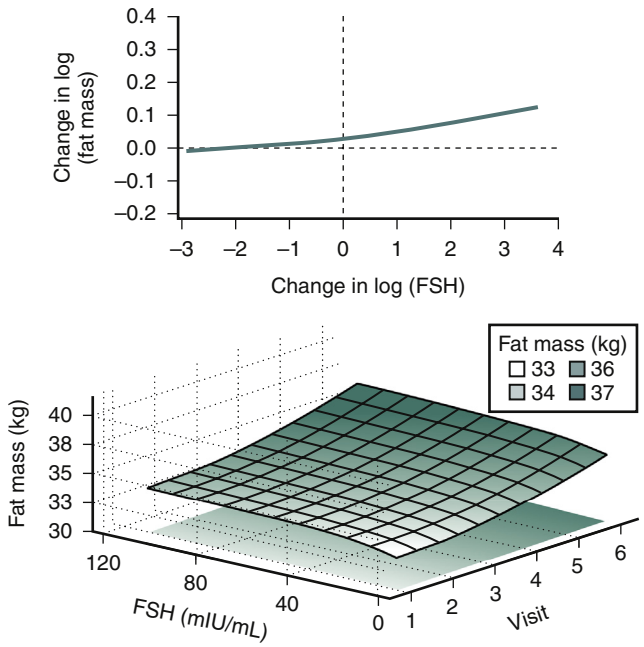


FIGURE 15.39 Changes in fat mass during the perimenopause and relationship to follicle-stimulating hormone (FSH). FMP, final menstrual period.

The increase in fat mass and decrease in lean muscle mass in postmenopausal women may be enhanced by estrogen deficiency. Indeed, hormone therapy does not increase fat mass and tends to decrease abdominal obesity.[353b,c] It appears that oral estrogen tends to slightly increase fat mass (not visceral fat mass) while transdermal estrogen does not affect fat mass.[353d] The effect of oral estrogen may be mediated by a decrease in IGF-1.[353e]

Adrenal Steroids

The age-related decline in adrenal androgens has been noted previously, as well as the possibility of administering DHEA for androgen support in postmenopausal women. While higher DHEAS levels in men are associated with a better cardiovascular survival, this correlation has not been found in women. Similarly, the data on enhancing insulin sensitivity and immune function, as well as quality of life assessments in postmenopausal women, are inconsistent,[354] requiring more study.

Because DHEA and DHEAS may be produced locally in the brain[355,356] and bind to the γ-aminobutyric (GABA) receptors,[357] there may be an important role for DHEA in remedying the mood and cognition declines that come with aging. Positive effects of DHEA on mood and cognition in the elderly have been reported.[358,359] Unfortunately, most clinical trials and DHEA in postmenopausal women have not shown benefit.

Cortisol levels are higher in older postmenopausal women.[360] This relates to a higher nocturnal rhythmicity which has been related to loss of resiliency and could explain sleep disturbances in the elderly.

CHAPTER 16

Male Reproductive Aging

Peter J. Snyder

As men age, reproductive function declines in several ways. Although the change is gradual, unlike the relatively abrupt decline that occurs in women at the time of menopause, it is progressive and probably has some adverse consequences. The decline is sometimes called *andropause*, *male menopause*, *late onset hypogonadism*, and other terms. This chapter reviews the changes in male reproductive function with aging and what is known about the consequences of attempting to prevent the changes by treatment with testosterone.

Changes in Male Reproductive Function with Age

Spermatogenesis and Semen Parameters

The little information available suggests that spermatogenesis does not decline severely with increasing age. Testicular volume, which reflects largely seminiferous tubular volume, averaged 20.6 mL, as determined by ultrasound, in 114 elderly men compared to 29.7 mL in 42 young men.[1] Sperm production was studied in an autopsy study of 89 men aged 21- to 50-years-old and 43 men aged 51- to 80-years-old who died suddenly. The older men had a daily sperm production rate per testis that was approximately 30% less than that in the younger men.[2] Ejaculated sperm were studied in 20 fathers aged 24- to 37-years-old and 22 grandfathers aged 60- to 88-years-old. Sperm density was somewhat higher in the older men, and percentage of sperm motility was somewhat lower in the older men, so that total number of motile sperm was similar in the two groups.[3] In 189 ambulatory men, the serum concentration of inhibin B, a reflection of Sertoli cell function, in men over 70-years-old was about 75% of that in men younger than 35-years-old ($P = 0.002$).[4] In the same study, the serum follicle-stimulating hormone (FSH) concentration was more than three times as high in the men over 70 years old than in the men under 35 years old ($P < 0.001$). From these data it appears that sperm production declines with age, but marginally.

Sex Steroid Hormone and Gonadotropin Concentrations

Serum Testosterone Concentration

The serum testosterone concentration has been found to decrease with age in both cross-sectional and longitudinal studies. The decrease appears to occur gradually beginning in the third decade of life. The magnitude of the decrease appears to be greater in longitudinal than cross-sectional studies, and greater in the free testosterone concentration than in the total. This decrease reflects a decrease in testicular secretion of testosterone, since in men testosterone is principally of testicular origin.

Several cross-sectional studies show a decrease in serum testosterone concentration with age. One cross-sectional study was performed on 302 healthy men in Belgium, in whom the serum testosterone concentrations decreased with increasing age.[5] The mean (± SD) total testosterone concentration in that study in the 70 men, 20- to 39-years-old, was 683 ± 289 ng/dL and that in 51 men, 70- to 79-years-old, was 428 ± 128 ng/dL. The calculated free testosterone concentration fell by a relatively greater amount; in 70- to 79-year-old men it was approximately half of that in 20- to 39-year-old men. In a study of 4263 men, 70- to over 85-years-old, total serum testosterone remained stable with age, but sex hormone binding globulin (SHBG) increased and free testosterone decreased.[6] In the European Male Aging Study of 3200 community dwelling, men ages 40- to 79-years-old, total serum testosterone was not associated with increasing age, but free testosterone was lower and luteinizing hormone (LH) higher (Fig. 16.1), suggesting that primary hypogonadism was the cause of the fall with age.[7] Comorbid conditions and obesity (Fig. 16.1) were also correlated with lower free testosterone concentrations but not higher LH, suggesting that these conditions cause secondary hypogonadism.

Longitudinal studies all show a decrease in testosterone with increasing age. In the Baltimore Longitudinal Study of Aging, the serum total testosterone concentration and a calculated free testosterone index fell from the third to the ninth decades in 890 men who were followed longitudinally.[8] By the eighth decade, approximately 30% of men were hypogonadal using the total testosterone concentration and 70% were hypogonadal by the free testosterone index. In the Massachusetts Male Aging Study, a population-based, random sample cohort of men aged 40 to 70 at baseline, 1156 men were followed for 7 to 10 years.[9] The serum concentration of total testosterone fell at a rate of 0.8% per year cross-sectionally, but 1.6% per year longitudinally.

The decrease in serum testosterone concentration with increasing age appears to be primarily the result of a decrease in the morning peak that younger men experience (Fig. 16.2).[10] When the serum testosterone concentration was measured once an hour for 24 hours in 17 men, aged 23- to 28-years-old, and in 12 men, aged 58- to 82-years-old, the

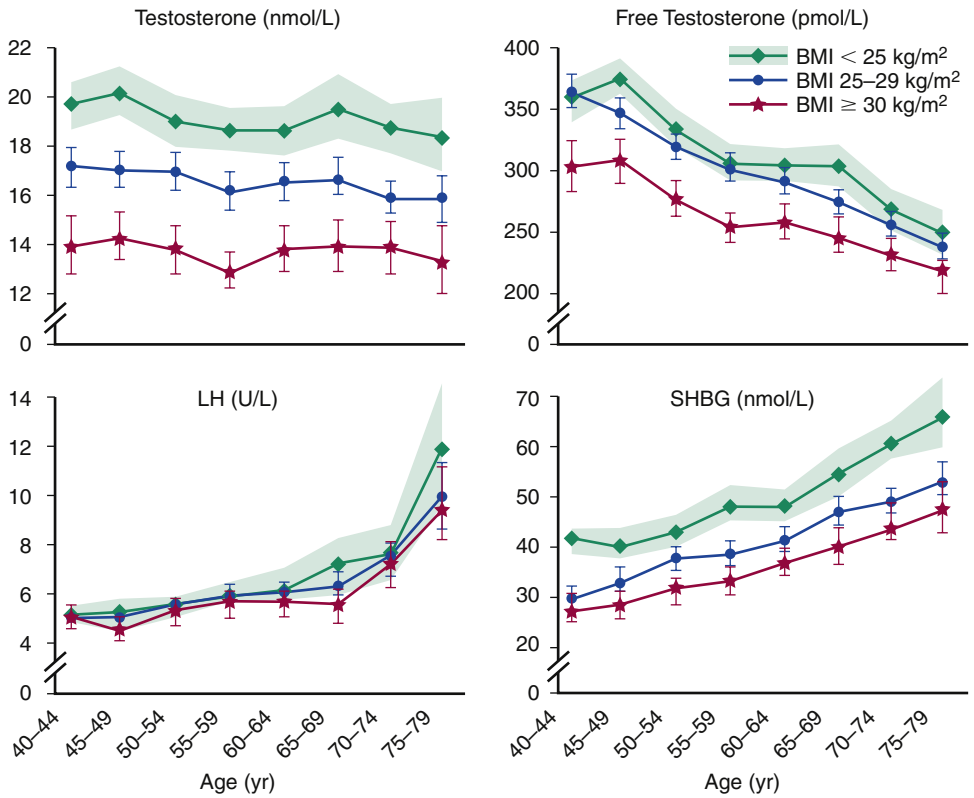

FIGURE 16.1 Serum testosterone, free testosterone, LH and SHBG concentrations as functions of aging in 3220 men in the European Male Aging Study. Free testosterone was significantly lower and LH and SHBG significantly higher in the older men. BMI ≥ 30 kg/m^2 was associated with significantly lower free testosterone and SHBG, but not higher LH. *(Adapted from Wu FCW, Tajar A, Pye SR, et al. Hypothalamic-pituitary-testicular axis disruptions in older men are differentially linked to age and modifiable risk factors: The European Male Aging Study.* J Clin Endocrinol Metab *93: 2737, 2008.)*

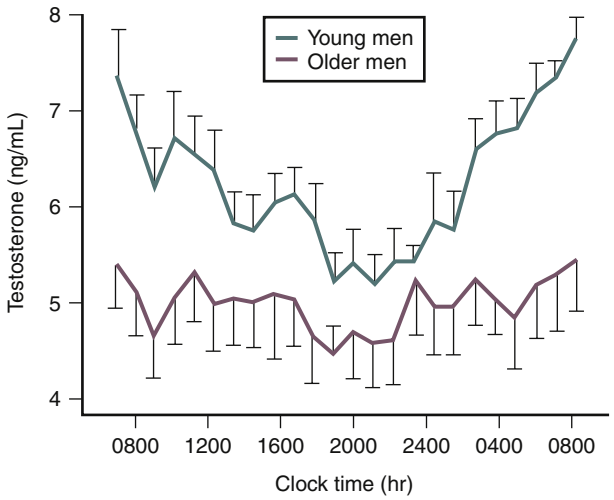

FIGURE 16.2 The pronounced diurnal variation in the serum testosterone concentration in young men but much less pronounced variation in elderly men. *(Adapted from Bremner WJ, Vitiello V, Prinz PN. Loss of circadian rhythmicity in blood testosterone levels with aging in normal men.* J Clin Endocrinol Metab *56:1278, 1983.)*

young men exhibited a clear diurnal variation: the peak at 8 AM and the nadir at 8 PM. The older men exhibited much less of a diurnal variation, so that the young men had a significantly higher serum testosterone concentration than the older men from 2 AM to 1 PM, but not from 2 PM to 1 AM. The decrease in serum testosterone concentration with increasing age also appears to be affected by other health factors. In the Massachusetts Male Aging Study, a decrease in body mass index of 4 to 5 kg/m^2 or a loss of a spouse resulted in a similar decrease in testosterone as 10 years of aging.[11]

Serum Estradiol Concentration

The serum total estradiol concentration does not appear to change with increasing age, but the serum bioavailable estradiol concentration, that not bound to SHBG, appears to decrease slightly. In a study of 810 men aged 24- to 90-years-old in Rancho Bernardo, California, the serum concentration of total estradiol decreased by only 0.3 pg/mL per year of age, but the concentration of bioavailable estradiol decreased by 0.12 pg/mL per year of age.[12] In Rochester, Minnesota, 130 men, aged 66- to 90-years-old, did not have a significantly different concentration of total estradiol than did 88 men, 22- to 39-years-old, but the older men had a significantly lower serum bioavailable estradiol concentration than did the younger men, 40 pmol/L compared to 59 pmol/L.[13] In a study of 206 men, 18- to 95-years-old in Parma, Italy, both the total and free serum concentrations of free estradiol fell with age.[14]

Serum Gonadotropin Concentration

Both cross-sectional and longitudinal studies show an increase in the serum concentrations of luteinizing hormone (LH) and FSH with increasing age. In 15 years of observation in the New Mexico Aging Process Study, the mean serum LH concentration increased from 9.4 mIU/mL to 13.7 mIU/mL and the FSH from 14.1 mIU/mL to 27.4 mIU/mL.[15] In the Massachusetts Male Aging Study, LH increased by 0.9% per year and FSH by 3.1% per year.[9] This increase in serum gonadotropins suggests that a degree of primary hypogonadism is responsible for the decline in testosterone, which is supported by the smaller testosterone response to human chorionic gonadotropin (hCG)[16] or recombinant human LH[17] stimulation of elderly men than young men. The increase in basal serum LH, however,

is not as great as one would expect for the magnitude of testosterone decline, suggesting secondary hypogonadism as well. In several aspects of LH secretion, the magnitude appears to be less in elderly men than in younger men. The LH response to a bolus dose of gonadotropin-releasing hormone (GnRH) is slightly less in older men than in younger men, and the peak response is somewhat delayed.[18] Spontaneous LH pulses are also different in elderly men compared to young men. LH secretory burst amplitude is less in elderly men than in young men.[19] The fall in testosterone with increasing age, therefore, appears to be the result of a combination of primary and secondary hypogonadism. As shown in the European Male Aging Study, age itself appears to result more in primary hypogonadism and comorbidity and obesity more in secondary hypogonadism.[7]

Consequences of Decreased Serum Testosterone Concentrations

The parallels between the consequences of frank hypogonadism due to known hypothalamic-pituitary or testicular disease and the consequences of normal aging in men suggest that the fall in testosterone with increasing age might contribute, at least in part, to the consequences of aging in men. These consequences include decreases in bone density and quality, muscle mass and strength, physical function, energy, and sexual function, and an increase in heart disease. Treatment of these deficiencies in frankly hypogonadal men often reverses those consequences.

Bone

The bone mineral density of men who are evaluated because of hypogonadism is lower than that of eugonadal men.[20,21] When men are made hypogonadal by GnRH agonist treatment for prostate cancer, their bone mineral density decreases. In a study of 152 men with prostate cancer—30 who had been kept hypogonadal for less than 6 months, 50 who had been kept hypogonadal for ≥6 months, and 72 who had prostate cancer but were eugonadal, as well as men who did not have prostate cancer—had areal bone mineral density (BMD) determinations on two occasions one year apart.[22] During this year, the men who had been kept hypogonadal for less than 6 months experienced a 4.0% decrease in BMD of the spine and 2.5% of the total hip, but the men who had been hypogonadal for ≥6 months and the eugonadal men did not experience a decrease. Men who are made hypogonadal to treat prostate cancer also are at greater risk for bone fracture, as shown in data from the Surveillance, Epidemiology, and End Results program and the Medicare database, in which the prevalence of fractures was determined in 50,613 men age >66 years with prostate cancer who had been made hypogonadal by a GnRH agonist or bilateral orchiectomy.[23] Men who had been made hypogonadal had a significantly higher prevalence of fracture (19.4%) than men not made hypogonadal (12.6%, $P < 0.001$). There was also significant relationship between the number of doses of GnRH agonists and the risk of fracture.

As men age, bone mineral density also decreases. In a study of normal men who had no history of hip fracture, bone mineral density of the spine and hip deceased linearly from age 20 to more than 80 years (Fig. 16.3); the decline

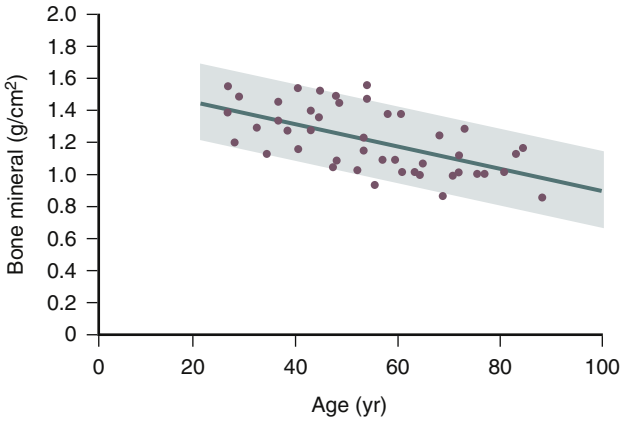

FIGURE 16.3 Decrease in bone mineral density of the intertrochanteric region of the proximal femur in 52 men with increasing age. *(From Riggs BL, Wahner HW, Seeman E, et al. Changes in bone mineral density of the proximal femur and spine with aging.* J Clin Invest *70:716, 1982.)*

was less than that in women,[24] similar to the findings of other cross-sectional studies.[25,26] However, a cross-sectional study in which bone density was measured by quantitated computed tomography (QCT) showed a greater rate of bone loss,[27] perhaps reflecting the greater sensitivity of QCT in detecting changes in trabecular bone than bone densitometry. A longitudinal study showed as rapid a loss of bone density in men as in women.[28] Within the 2908 men of an average age of 75.4 years in the Swedish Osteoporotic Fractures in Men (MrOS) study, serum free testosterone was a modest predictor of bone density and prevalent osteoporotic fractures.[29] In 728 men at two sites in the European Male Aging Study, increased age was associated decreased cortical BMD by peripheral QCT.[30] The association of the decrease in cortical bone with the serum concentrations of estradiol and testosterone was less clear.

Replacement of testosterone in unequivocally hypogonadal men greatly increases bone mineral density. Administration of 100 mg of testosterone enanthate for 18 months to 29 men with previously untreated hypogonadism resulted in a 5% increase in bone mineral density in the lumbar spine as determined by dual energy x-ray absorptiometry (DEXA).[21] Trabecular bone mineral density, as measured by quantitative computed tomography, increased by 14%. Administration of testosterone transdermally for 3 years to 18 hypogonadal men who had previously untreated hypogonadism resulted in increases in bone mineral density as determined by DEXA of 7.7% at the lumbar spine and 4.0% at the trochanter.[31]

Body Composition

When men become hypogonadal as the result of hypothalamic-pituitary or testicular disease, they experience a decrease in lean body mass and an increase in fat mass, and testosterone treatment of hypogonadal men usually reverses those changes. The same changes occur as men age. Whole-body lean mass in one study was about 15% less at age 70 than at age 20, and whole body fat mass was about 100% more.[32] In another study, appendicular skeletal muscle mass was 16% less in men over 75 years old than in men 18- to 34-years-old.[33] Percentage of body

fat was 26% in 36 hypogonadal men compared to 19% in 44 eugonadal men.[21] When six normal young men were made hypogonadal for 10 weeks by the administration of the GnRH agonist leuprolide, their fat-free mass decreased from 56.5 to 54.4 kg and their fat mass increased from 15.8 to 16.9 kg.[34]

Administration of testosterone reverses these changes in body composition. Administration of 100 mg of testosterone enanthate to previously untreated hypogonadal men resulted in a 14% decrease in total body fat and a 12% decrease in subcutaneous fat, as assessed by quantitated computed tomography.[21] Lean muscle mass, assessed by the same technique, increased 6.8%. When testosterone was administered transdermally to 18 previously untreated hypogonadal men, lean body mass increased 5.8%.[31]

Muscle Strength

Muscle strength has long been known to decrease with increasing age, but demonstration that hypogonadism leads to decreased muscle strength and that testosterone treatment improves strength have been much more difficult to demonstrate. In a study of 72 normal men in three age groups ages 20 to 86, strength of knee extension, both isometric and isokinetic, decreased with increasing age.[35] In another study in 114 men ages 11- to 70-years-old, quadriceps strength increased up to the third decade, was stable until age 50, then declined with increasing age.[36] The only clear demonstration that hypogonadal men have lower muscle strength than eugonadal men was provided by the study, described earlier in this chapter, in which six healthy young men were made severely hypogonadal for 10 weeks by administration of leuprolide. At the end of the 10 weeks, their strength of knee extension was 6% less than prior to treatment when measured isokinetically at 60 degrees angular velocity, but was not significantly different during treatment than before when measured isokinetically at 180 degrees angular velocity or isometrically at either angular velocity.[34]

Administration of testosterone transdermally to 18 previously untreated hypogonadal men did not increase their strength of knee extension or flexion or handgrip strength.[31] Administration of 100 mg testosterone enanthate once a week to men with wasting secondary to human immunedeficiency virus (HIV) infection resulted in a 16% increase in leg press strength compared to no significant change in those treated with placebo, whereas men who were treated with testosterone and resistance exercise did not exhibit a greater increase than those treated with placebo and exercise.[37] In short, it is clear that muscle strength decreases with increasing age, but it is not clear how much, if any, the decline in testosterone contributes to the decrease in muscle strength.

Physical Function

The relationship between testosterone and physical function in middle-aged to elderly men was evaluated in the Framingham Offspring Study, in which 1445 men, of average age 61 years, were evaluated twice, an average of 6.6 years apart. By logistical regression analysis, free testosterone, but not total, was associated with incident Short Performance Physical Battery score and usual walking speed but not with grip strength.[38] Free testosterone at the first visit was significantly associated with increased risk of self-reported mobility disability at the second visit.

Cardiovascular and Metabolical Risk

Because the prevalence of heart disease is greater in men than in women, the possible role of testosterone in the development of arteriosclerotic cardiovascular disease has long been discussed. An alternative explanation for the difference is higher estradiol concentrations in women before menopause. This possibility is suggested by the gradual decrease in the gap between the genders, the greater the length of time after menopause. A recent study, however, suggests that it may be low testosterone that is harmful. When 794 men of median age 73.6 years had a serum testosterone measurement and were followed for an average of 11.8 years, men whose serum testosterone concentrations were in the lowest quartile (<241 ng/dL) were 40% more likely to die of all causes and 38% more likely to die of cardiovascular causes[39] than men with higher values. This association was independent of age, adiposity, and lifestyle.

If low testosterone does cause increased mortality rate, one possible mechanism is via metabolical risk factors, because in epidemiological studies low testosterone precedes the development of central obesity, the metabolical syndrome, and diabetes.[40-42] However, in the study cited earlier in this chapter, the association between low testosterone and higher mortality rate persisted even after adjusting for metabolical syndrome and diabetes mellitus. Further, associations between testosterone and metabolical syndrome and diabetes are equivocal. In the Baltimore Longitudinal Study of Aging, the prevalence of the metabolical syndrome was associated with a lower total testosterone but a higher index of free testosterone.[43] Conversely, in an analysis of data from the Third National Health and Nutrition Survey (NHANES III), men in the lowest tertile of an index of free testosterone were four times as likely to have a diagnosis of diabetes mellitus than men in the highest tertile, but that relationship was not observed with total testosterone.[44] Perhaps the best evidence that testosterone influences glucose metabolism is a randomized, placebo-controlled crossover trial in which testosterone treatment of men for 3 months who had type II diabetes and low-normal to low serum testosterone concentrations improved their fasting glucose, hemoglobin A_1c, and homeostatic model assessment (HOMA) index, compared to placebo treatment.[45]

Other possible mechanisms by which testosterone could affect cardiovascular disease are via serum lipids, clotting factors, and markers of inflammation, but treatment of hypogonadal men with testosterone does not consistently change these parameters.[31,46-50]

Energy

Men's sense of energy decreases with increasing age, and when men who are hypogonadal due to known disease are treated with testosterone, their self-reported energy increases markedly. Administration of testosterone transdermally to 18 men with severe, untreated hypogonadism resulted in an increase in self-reported energy, reaching an apparent peak in about 3 months.[31]

Cognition

The association of low testosterone with declining cognitive function was evaluated in the Baltimore Longitudinal Study of Aging, in which 407 men ages 50- to 91-years-old at baseline assessment were followed for an average of 10 years. Men who were classified as hypogonadal, defined for this study as a free testosterone index (total testosterone/SHBG) below the 2.5 percentile, had significantly lower scores on measures of memory and visuospatial performance and a faster decline in verbal memory.[51]

Sexual Function

Low testosterone appears to be associated with decreased sexual function in middle aged and elderly men, as shown in data from the European Male Aging Study.[52] In a random population sample of 3369 men ages 40- to 79-years-old, the combination of three sexual symptoms (low sexual desire, poor morning erection, and erectile dysfunction) was significantly related to total and free testosterone concentrations; the relationship was stronger the lower testosterone. Hypogonadism also causes a decrease in libido. When men who were unequivocally hypogonadal were treated with a single dose of testosterone enanthate, sexual function increased much more within a few weeks after a dose of 100 mg than a dose of placebo, and even more after a dose of 400 mg than 100 mg.[53] When 18 severely hypogonadal men were treated with testosterone transdermally, sexual function increased markedly when first reassessed at 3 months but did not increase further when the observation was continued for a total of 3 years.[31]

Attempts to Reverse the Consequences of Aging by Testosterone Treatment

A few attempts have been made to administer testosterone to relatively small numbers of elderly men to raise their serum testosterone concentration to that of young men to determine if the changes of aging can be reversed. Improvements in some parameters occurred.

Testosterone Preparations Available for Treatment of Male Hypogonadism

Several preparations of testosterone are available for replacing testosterone in hypogonadal men (Table 16.1). Testosterone gels are the most commonly used preparations in countries where they are available, because they increase the serum testosterone concentration to within the normal range in most men, keep the concentration relatively steady within a 24-hour period and from day-to-day, and are easy to use.[54-57] A testosterone patch also keeps the serum testosterone relatively normal,[58] but about one-third of men cannot use it because of severe skin rash, and sometimes it falls off.

The enanthate[59] and cypionate esters of testosterone, when given by deep intramuscular injection every 1 to 2 weeks, are effective in treating hypogonadism, but produce wide fluctuations in the serum testosterone concentrations from supranormal the day after an injection, to low-normal to subnormal by the time of the next injection. Some patients notice these fluctuations in their energy, mood, and sexual interest. The undecanoate ester of testosterone, which is available in some countries, increases the serum testosterone concentration to normal when administered every 3 months.[60] This ester is also available in some countries for oral use, but that route requires ingestion with a fatty meal and results in serum concentrations that are variable and usually subnormal.[61] Several 17-α-alkylated androgens have been available for oral use for decades, but they may cause hepatotoxicity,[62,63] so they are not recommended. Testosterone pellets, which are available in some countries, must be implanted via trochar using a surgical incision and may extrude. The limited data suggest that the resulting serum testosterone concentrations peak at 4 weeks and decrease gradually to baseline at 24 weeks.[64]

Table 16.1 Testosterone Preparations Available for Treatment of Male Hypogonadism

Types of Preparations	Specific Preparations	Dosing	Comments
Transdermal	Testosterone gels	Daily	Normal, steady serum T levels usually achieved
	Testosterone patch	Daily	Normal serum T; high incidence of skin reactions
Esters for IM use	Testosterone enanthate	1-2 weeks	Peak serum T level supranormal; nadir subnormal
	Testosterone cypionate	1-2 weeks	Same as above
	Testosterone undecanoate	3 months	Steady serum T levels for 2-3 months
Oral	17-Alkylated androgens	Daily	Hepatic toxicity
	Testosterone undecanoate	3 times/day	Variable absorption, subnormal serum testosterone
Pellets implanted by incision	Testosterone pellets	3 months	May extrude; serum T data

Parameters of Improvement

Bone

In one study, 108 healthy elderly men over 65 years old with a serum testosterone concentration below 475 ng/dL were randomized to receive testosterone or placebo transdermally for 3 years. Bone mineral density of the lumbar spine increased somewhat more in the testosterone-treated group than in the placebo-treated group, but overall the difference was not statistically significant. When the data were analyzed by a linear regression model, there was an inverse correlation between the pretreatment serum testosterone concentration and the effect of testosterone on bone mineral density above that of placebo, called the testosterone treatment effect (Fig. 16.4). For example, for a pretreatment serum testosterone of 400 ng/dL, the testosterone treatment effect on the percentage of increase in bone mineral density above baseline was only 0.9%, but when the pretreatment serum testosterone concentration was 300 ng/dL, the testosterone treatment effect was 3.4%, and when the pretreatment serum testosterone was 200 ng/dL, the testosterone treatment

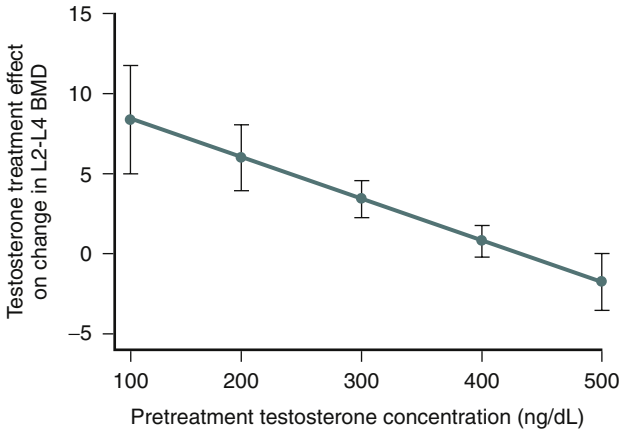

FIGURE 16.4 Effect of testosterone treatment for 3 years on spine bone mineral density (BMD) of elderly men. Shown is a linear regression model of the testosterone treatment effect (the effect of testosterone over placebo) as a function of the pretreatment serum testosterone concentration, showing that only men who have a lower than normal serum testosterone concentration would be expected to experience an increase in spine bone mineral density if treated with testosterone. *(Adapted from Snyder PJ, Peachey H, Hannoush P, et al. Effect of testosterone treatment on bone mineral density in men over 65 years of age.* J Clin Endocrinol Metab *84:1966, 1999.)*

effect was 5.9%.[65] No significant difference was observed in hip bone mineral density. In another study, 67 men over 65 years old who had subnormal bioavailable testosterone concentrations were randomized to receive testosterone transdermally for 1 year. In the 44 men who completed the trial, femoral neck bone mineral density increased 0.3% in the testosterone-treated group and decreased 1.6% in the placebo-treated group, a difference that was statistically significant, but there were no significant differences in bone mineral density at other sites in the hip or in the spine.[66] In a third study, in which elderly men were randomized to receive testosterone enanthate alone (24 men), testosterone enanthate plus finasteride (22 men), or placebo (24 men) for 3 years, the men treated with testosterone alone or with finasteride exhibited 10.2% and 9.3% increases in spine bone density, whereas the men treated with a placebo increased only 1.3%.[67] Increases in the total hip were less: 2.7% and 2.2% versus 0.2%, but still statistically significant.

Body Composition

Several studies show that testosterone treatment of elderly men increases lean body mass and decreases fat mass. In the 108 elderly men described earlier,[68] lean mass increased by 1.9 kg and fat mass decreased by 3.0 kg in the testosterone-treated men during the 3 years of treatment (Fig. 16.5). In the study of 67 men described earlier,[66] lean mass increased by 1.0 kg and fat mass decreased by 1.7% in the 1 year of treatment. In a study of elderly men treated with placebo or testosterone enanthate for 6 months,[69] 21 testosterone-treated men experienced a 1.4 kg increase in lean mass and a 1.2 kg decrease in fat mass, whereas 17 placebo-treated men experienced no change. In the study of 70 men treated with testosterone enanthate with or without finasteride or with placebo for 3 years, lean body mass increased by about 4 kg and fat mass decreased by about 5 kg in the two testosterone-treated groups.[70]

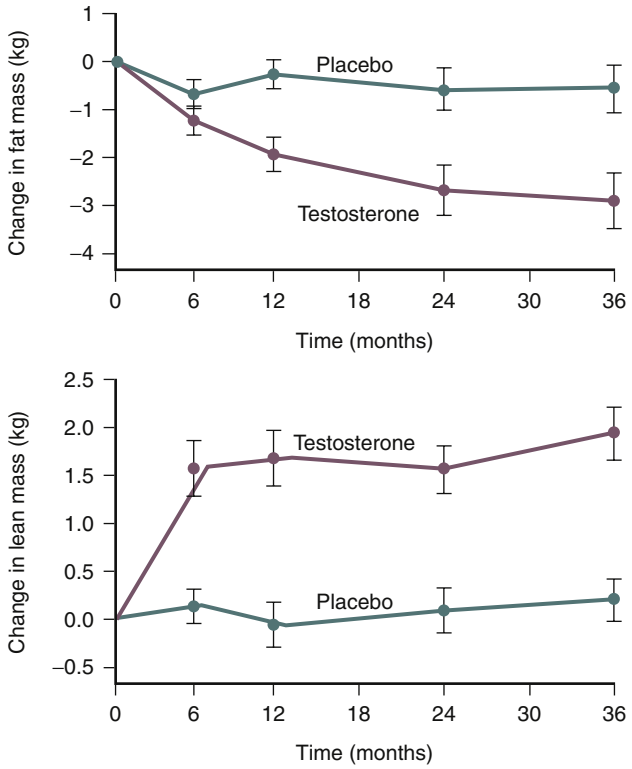

FIGURE 16.5 Effect on fat mass and lean mass when 108 men were treated with testosterone or placebo for 3 years. *(Adapted from Snyder PJ, Peachey H, Hannoush P, et al. Effect of testosterone treatment on body composition and muscle strength in men over 65 years of age.* J Clin Endocrinol Metab *84:2647, 1999.)*

Muscle Strength

Although an increase in muscle mass should result in an increase in muscle strength, controlled studies in which a physiological dose of testosterone has been administered to elderly men have generally not demonstrated an increase in muscle strength compared to placebo-treated men. In the study of 108 men described earlier in this chapter[68] who were randomized to receive either testosterone or placebo for 3 years, the testosterone-treated men did not differ from the placebo-treated men in change from baseline in strength of knee extension or flexion at 60 degrees or 180 degrees angular velocity at 3 years or earlier, nor in handgrip strength. In the study of 67 men described earlier[66] who were randomized to receive testosterone or placebo for 1 year, strength of knee extension by leg press was no different at the end of the year in the testosterone-treated group than in the placebo-treated group. In 40 men randomized to receive human chorionic gonadotropin (hCG) or placebo for 3 months,[71] shoulder and knee strength as measured by dynamometry did not differ in the two groups at the end of treatment. In the 70 men treated with testosterone enanthate with or without finasteride or treated with placebo, the testosterone-treated men exhibited a greater improvement than placebo-treated in right handgrip strength but not in left handgrip strength or in ankle or knee strength.[70] In 274 men ≥65-years-old chosen because of low-normal or low serum testosterone concentrations and a mild degree of frailty, and randomized to receive a testosterone gel or placebo for 6 months,

testosterone treatment was associated with greater isometric knee extension strength, but not with greater isokinetic knee strength, isokinetic or isometric knee flexion strength, or grip strength.[72]

Physical Function

Parameters of physical function also have not changed significantly following administration of testosterone to elderly men. In 108 men randomized to receive testosterone or placebo, walking time and stair climbing did not differ between the two groups at the end of 3 years of treatment.[68] The testosterone-treated men, however, had a more favorable perception of their physical function than the placebo-treated men had of theirs. In 67 men randomized to receive testosterone or placebo, physical function, as estimated activity by Physical Activity for the Elderly questionnaire, did not differ between the two groups.[66] In 40 men who were randomized to receive hCG or placebo; maximum reach, static and dynamic balance, gait, and chair rise did not differ between the two groups at the end of 3 months of treatment.[71] In the men treated with testosterone enanthate with or without finasteride or treated with placebo, the testosterone-treated men exhibited greater improvement than placebo-treated men after 3 years.[70] In men selected for a moderate degree of frailty, testosterone treatment was not associated with better performance in any of six tests of physical function.[72]

Energy

Testosterone treatment of elderly hypogonadal men has generally not affected their energy. In 108 elderly men randomized to receive either testosterone or placebo, self-reported energy and sense of well-being was no different in the two groups at the end of 3 years of treatment.[68] In 67 men randomized to receive testosterone or placebo, sense of well-being was no different between the two groups at the end of 1 year of treatment.[73] However, in the men selected for a moderate degree of frailty, those treated with testosterone indicated a better quality of life on the Aging Male Symptom scale than those treated with placebo.[72]

Cognition

The effects of testosterone treatment on cognition have been studied in elderly men who have low-normal serum testosterone concentrations, but the results have been variable. Some studies have shown in improvement in various aspects of cognitive function,[62] but others have not.[61]

Libido

Testosterone treatment of elderly men has not been shown to increase libido consistently. In 108 men randomized to receive testosterone or placebo for 3 years, the two groups did not differ in libido, as determined by questionnaire, either at the end of treatment or at any earlier time.[68] In 40 men randomized to receive either hCG or placebo for 1 year, libido also did not differ at the end of treatment.[71] In the men chosen because of moderate frailty, the testosterone-treated men exhibited a greater improvement in the sexual subscale of the Aging Male Symptom scale than those treated with placebo.[72]

Potential Deleterious Consequences of Testosterone Treatment of Elderly Men

Several diseases to which elderly men are prone are testosterone-dependent. These diseases include prostate cancer and benign prostatic hyperplasia, and possibly erythrocytosis and sleep apnea. Prostate cancer, for example, was the first cancer shown to be hormonally dependent,[74] and treatment of metastatic prostate cancer even now is based on blocking the secretion and action of testosterone.[75,76] An additional reason for concern that testosterone treatment of elderly men might increase the risk of prostate cancer is that approximately 50% of men who are 50- to 60- years-old harbor clinically silent prostate cancer.[77] If these men were treated with testosterone, would these clinically silent tumors become clinically significant? Benign prostatic hyperplasia has been known to be testosterone-dependent for over a century, and a current treatment for this condition is also based on blocking the action of testosterone in the prostate.[78,79] Testosterone stimulates erythropoiesis, which is why men have higher hemoglobin concentrations than do women, but it probably does not cause erythrocytosis unless the dose is excessive or there is a concomitant illness that treatment of hypogonadism unmasks. The evidence that testosterone exacerbates sleep apnea is based on studies of small numbers of patients.[80]

Prostate Events

Testosterone treatment of elderly men has generally not been associated with a significant increase in prostate disease, but the studies performed so far have been too small to draw any conclusions from these results. In a study of 108 men randomized to receive testosterone or placebo, the serum prostate specific antigen (PSA) concentration increased from 1.4 ng/mL to 2.1 ng/mL, which was statistically significant but still well within the normal range.[65] The testosterone-treated men experienced somewhat more prostate events, such as persistently elevated PSA, urinary retention, and urosepsis, than did the placebo-treated men. A meta-analysis of five testosterone studies reported that prostate cancer did not occur more often in men treated with testosterone than in men treated with placebo, but this analysis involved too few men upon which to do draw firm conclusions.[81]

Erythrocytosis

In 108 men randomized to receive either testosterone or placebo transdermally, hemoglobin and hematocrit increased significantly in the men treated with testosterone—although within the normal range—but not in men treated with placebo.[54] In men treated with 200 mg of testosterone enanthate every 2 weeks, 30% experienced an increase in hematocrit above the upper limit of normal (52%).[56]

Cardiovascular Risk

Administration of testosterone to elderly hypogonadal men has little effect on serum lipid or apolipoprotein concentrations, but other cardiovascular risk factors have not been well studied. In 108 elderly men randomized to receive either testosterone or placebo, there was no difference between the two groups in serum concentrations of total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, apolipoprotein

A_2, apolipoprotein B, triglycerides, or lipoprotein a at the end of 3 years of treatment.[82] In 67 men randomized to receive testosterone or placebo, total cholesterol and LDL cholesterol did not differ between the two groups after a year, but HDL cholesterol decreased in the men who received testosterone.[83] Endothelial brachial artery reactivity did not change in either group.

Cardiovascular adverse events have been reported in only a few studies. A study of elderly moderately frail men, of whom 106 were randomized to receive testosterone and 103 to receive placebo for 6 months, was stopped by its Data Safety Monitoring Board because 23 men who were receiving testosterone developed cardiovascular adverse events compared to 5 receiving placebo.[56] In a meta-analysis of seven prior testosterone trials, however, testosterone was not associated with an increased risk of myocardial infarction.[57]

Sleep Apnea

Although there are a few reports that men with frank hypogonadism who were treated with testosterone experienced an increase in apneic episodes during sleep, sleep apnea has not been shown to increase in elderly men treated with testosterone.[65,71]

Conclusions

Although the serum testosterone concentration falls as men age, the potential beneficial effects and potential risks of reversing that fall are still being discovered. Small, placebo-controlled trials of raising the serum testosterone of elderly men to that of normal young men suggest that this treatment increases lean muscle mass and decreases fat mass. They also suggest that testosterone treatment increases bone mineral density of the spine. Whether or not this treatment increases the risks of prostate cancer, benign prostatic hyperplasia, erythrocytosis, or sleep apnea, however, remains to be determined.

CHAPTER 17

Disorders of Sex Development

Valerie A. Arboleda
Eric Vilain

Introduction to Human Sex Development

From the moment of our conception, each of us has a sex. Our individual sex has a major role in determining the physical attributes of our bodies, the structure of our brains, our behavioral tendencies, and our self-concept. Understanding the development of sex differences has informed and been informed by the advances in the molecular dissection of genes responsible for disorders of sex development. New genes have been identified, allowing for rapid diagnosis, understanding of the pathophysiology, and prediction of future fertility.

In parallel to the progress in the biology of sexual development, the management of individuals with disorders of sexual development has started a gentle revolution. From a practice based on the opinions of a few leaders in the field, the clinical approach to disorders of sex development (DSD) is slowly entering the era of evidenced-based medicine, under the pressure of patient advocacy groups, who have been highly instrumental in establishing a dialogue between practitioners and their patients. As a result, physicians are beginning to understand the difficulties involved in defining normalcy, as well as the ethical dilemma of acting medically on children before they reach an age of consent.

For the first time in 2005, a consensus on the management of "intersex" disorders emerged, bringing together experts from a variety of fields (endocrinology, genetics, surgery, psychology, advocacy groups). The consensus statement provides guidelines in all aspects of management of "intersex," including genital surgery, the requirement of a multidisciplinary team and of mental health professionals, and the diagnostic approach. This chapter reflects the advances made in the field as well as the recommendations of the consensus statement.[1] One area that changed considerably was the nomenclature of intersexuality. The term *Disorders of Sex Development (DSD)* was proposed, as defined by "congenital conditions in which development of chromosomal, gonadal or anatomical sex is atypical." This broad definition replaces the word "intersex," which has social connotations and reflects a concept of sexual identity. It includes patients that do not necessarily have ambiguous external genitalia (such as complete androgen insensitivity, or Turner syndrome) and yet belong to the broad family of DSD.

The new nomenclature was guided by the following principles. First, although a modern categorization should integrate the important progress in molecular genetic aspects of sex determination and differentiation, it should not overemphasize one particular aspect of the biology of sex (for instance, gonadal sex) and should accommodate the spectrum of phenotypic variations. Second, terms should be as precise as possible and should reflect the genetic etiology when available. Finally, the new nomenclature should be understandable by patients and families and should be psychologically sensitive. In particular, gender labeling in the diagnosis should be avoided, and use of the words "hermaphrodite," "pseudohermaphrodite," and "intersex" should be abandoned, as they either are confusing or have a negative social connotation that may be perceived as harmful by some patients and parents.

The new nomenclature is summarized in Tables 17.1 and 17.2. This chapter will refer to the new nomenclature rather than the old nomenclature.

Normal Human Sex Development

Sex determination refers to the developmental decision that directs the orientation of the bipotential, undifferentiated embryo into a sexually dimorphic individual. In mammals, this decision occurs during the development of the gonads. In 1947, physiologist Alfred Jost, performed a series of elegant experiments showing that all mammalian embryos that are castrated early in development and reimplanted into the uterus develop into females, regardless of their genetic sex (Fig. 17.1).[2,3] This study established the

Table 17.1 Proposed Revised Nomenclature

Previous	Proposed
Intersex	DSD
Male pseudohermaphrodite, undervirilization of and XY male, and undermasculinization of an XY male	46,XY DSD
Female pseudohermaphrodite, overvirilization of and XX female, and masculinization of an XX female	46,XX DSD
True hermaphrodite	Ovotesticular DSD
XX male or XX sex reversal	46,XX Testicular DSD
XY sex reversal	46,XY complete Gonadal Dysgenesis

DSD, disorder of sex development.
From Lee PA, et al. Consensus statement on management of intersex disorders. International Consensus Conference on Intersex. *Pediatrics* **118**(2):e488–500, 2006.

Table 17.2 An Example of a DSD Classification

Sex Chromosome DSD	46,XY DSD	46,XX DSD
45,X (Turner syndrome and variants)	Disorders of gonadal (testicular) development: (1) complete gonadal dysgenesis (Swyer syndrome); (2) partial gonadal dysgenesis; (3) gonadal regression; and (4) ovotesticular DSD	Disorders of gonadal (ovarian) development: (1) ovotesticular DSD (e.g., SRY translocation, RSPO1 mutation); (2) testicular DSD (e.g., SRY+; dup-SOX9); (3) Gonadal Dysgenesis
47,XXY (Klinefelter syndrome and variants)	Disorders in androgen synthesis of actions; (1) androgen biosynthesis defect (e.g., 17-hydroxy dehydrogenase deficiency, 5αRD2 deficiency, StAR mutations); (2) defect in androgen action (CAIS, PAIS); (3) luteinizing hormone receptor defects (Leydig cell hypoplasia); and (4) disorders of anti-müllerian hormone and anti-müllerian hormone receptor	Androgen excess: (1) Fetal (e.g., 21-hydroxylase deficiency, 11-hydroxylase deficiency); (2) fetal-placental (aromatase deficiency, POR [P450 oxidoreductase] deficiency); and (3) maternal (luteoma)
45,X/46,XY (Mixed Gonadal Dysgenesis, ovotesticular DSD)		
46,XX/46,XY (Chimeric, ovotesticular DSD)		

Adapted from Lee PA, et al. Consensus statement on management of intersex disorders. International Consensus Conference on Intersex. *Pediatrics* **118**(2):e488–500, 2006.

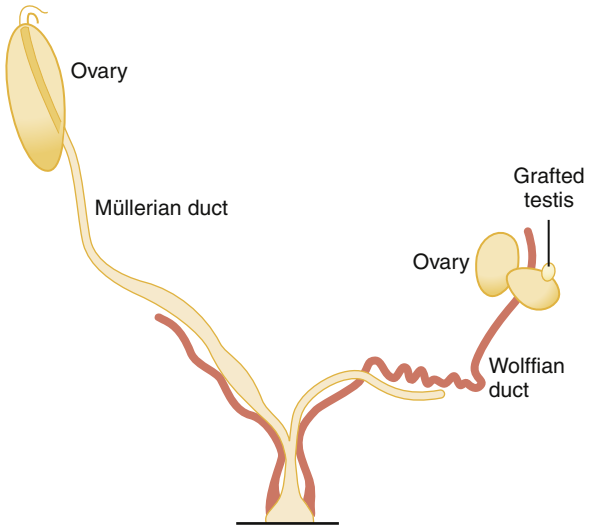

FIGURE 17.1 Alfred Jost's classic experiment defined the current paradigm of sex development by grafting testicular tissue to the right ovary of a rabbit fetus. The testis was able to stimulate the wolffian duct and inhibit müllerian development, but the effect was only ipsilateral to the grafted testes. *(From Austin C, Short RV.* Embryonic and fetal development [reproduction in mammals, book 2]. *New York: Cambridge University Press, 1972, p 58.)*

current paradigm of sex determination and differentiation in placental mammals: genetic sex determines gonad development, and gonadal sex in turn governs anatomical sex.

At conception, genetic sex is determined based on whether the X or Y chromosome was paternally inherited.[4,5] *Sex determination* is defined by the developmental choice of the bipotential and undifferentiated gonad to become either testis or ovary. Following this sex determination decision, the process of *sex differentiation* begins and the testes start producing the male hormones testosterone (T) and anti-müllerian hormone (AMH), which are responsible for male internal and external genitalia, while the lack of these hormones result in female internal and external genitalia (Fig. 17.2).

The molecular mechanisms of mammalian sex determination are still poorly understood. The vast majority (about 75%) of sex-reversed patients cannot be explained at the molecular level yet, suggesting the existence of a number of unknown sex determining genes.[6] The next section outlines the known molecular mechanisms affecting sex determination and sex differentiation.

Sex Determination: Testes or Ovary?

This paradigm for sex development established by Jost led to the search for a sex-determining gene that was a Testis Determining Factor (TDF). When the karyotypes of patients with Klinefelter syndrome who are male (47,XXY)[7] and Turner syndrome who are female (45,X)[8] were determined, it became clear that the Y chromosome was sex-determining and that TDF had to be located on the Y chromosome.

In the early 1990s, a series of elegant experiments found SRY to be the elusive mammalian testis determining gene. Positional cloning located a 35-kb fragment of the Y chromosome translocated to the X chromosome of 46,XX testicular and ovotesticular DSD patients.[9,10] Further sequence analysis defined a conserved sequence within this region. Sry gene expression analysis revealed a male-specific increase in transcript consistent with earliest known divergence of male and female gonadal development. Furthermore, XX mice transgenic for the 14kb fragment containing *Sry* developed testes and the full male phenotype. This was followed up with experiments showing that deletions and mutations in *SRY/Sry* result in XY sex reversal in both humans and mice.[11-13]

In humans, 8 weeks after conception the bipotential gonad progresses towards testis organogenesis in the presence of SRY and can be recognized on ultrasound by week 10. Factors expressed earlier than SRY prime the bipotential gonadal ridge to differentiate in the male pathway. Mutations in the MAP-kinase signaling pathway result in 46,XY sex reversal and is important in promoting SRY expression within the developing gonad.[14,15] Chromobox-2 *(CBX2)* has also been shown to be required for SRY expression in mouse sex determination and mutations result in 46,XY sex reversal.[16,17]

SRY expression in the Sertoli cell precursors initiates testis determination by activating downstream effectors

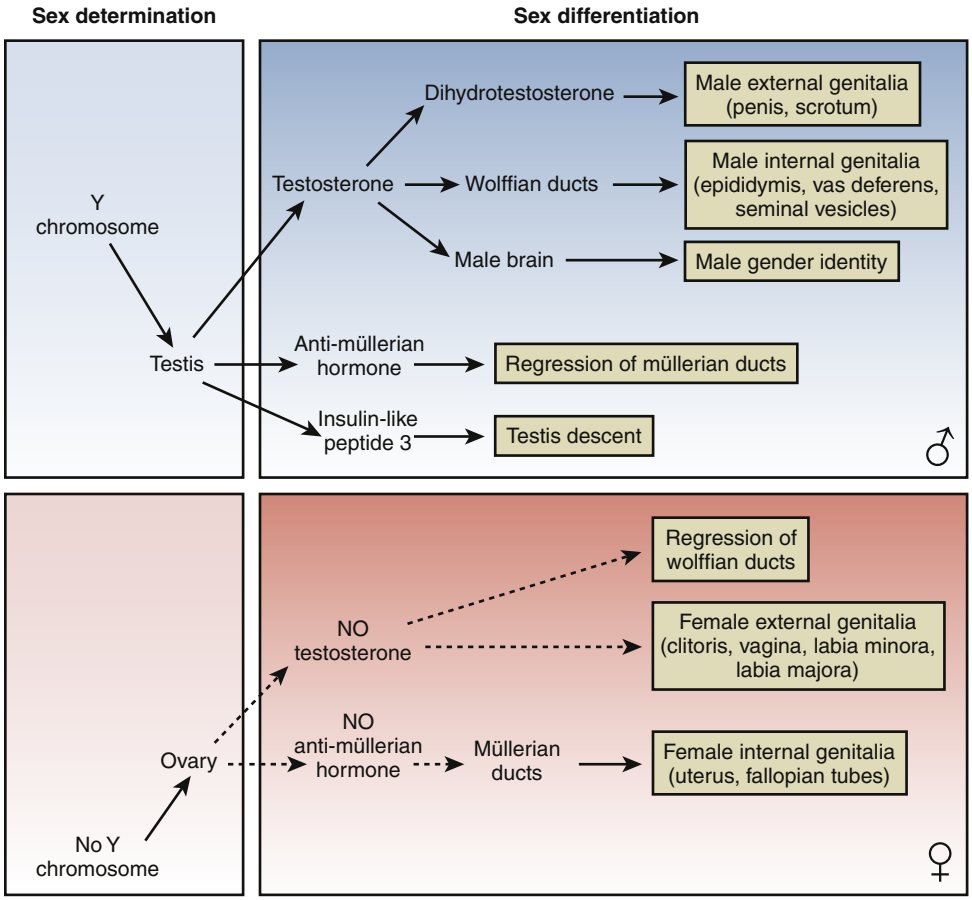

FIGURE 17.2 Sex determination is the process of genetic sex (presence of absence of the Y chromosome) to gonadal sex. Sex determination is the process of sex development after gonadal sex has been determined. In XY males, sex differentiation is an active process requiring testes derived hormones, testosterone, anti-müllerian hormone, and Insulin-3 (Insl3). In XX females, sex differentiation is a default pathway which occurs in the absence of testes-derived hormones.

such as *SOX9* (*SRY*-related HMG-box 9). Sertoli cell proliferation and organization into tubular cords is directed by *SOX9* (*SRY*-related HMG-box 9) and *SF1/NR5A1 (Steriodogenic Factor-1)*. At 9 weeks of gestation, after the organization of discrete tubules, Sertoli cells begin the secretion of AMH.[18,19] Other genes involved in sex determination are *DAX-1*, in which a single copy is required for testes development, however two copies in XY fetuses result in XY gonadal dysgenesis by repressing testis organogenesis.[20] Another gene involved in sex determination is Desert hedgehog *(DHH)*, which up-regulates SF1 and in turn regulates Leydig cell proliferation.[21,22]

The cellular fate of murine ovarian and testicular tissues is not sealed at the point of sex determination. In murine models of sex determination, cellular fates of the testis or ovary are actively maintained throughout adult life by *DMRT1* (Doublesex and mab-3 related transcription factor 1) and *FOXL2* (Forkhead box L2), respectively.[17,23] This lack of finality in the gonadal cell fate determination indicates that cell fate is carefully cultivated throughout adulthood, and if the factors important in maintaining cell fate are mutated, it may theoretically lead to decreased secondary sex characteristics and infertility.

Relative to testis organogenesis, there is much less information on the genes involved in ovary organogenesis. Studies suggesting that ovary development does not require a large number of genes are incomplete in that they look at timepoints that are important in testis determination but may not be critical in ovarian determination.[24,25] Despite this, researchers have uncovered several autosomal genes required for proper ovarian development, including *WNT-4* (wingless-related MMTV integration site 4), *RSPO-1* (R-spondin-1), and *FST* (Follistatin).[26]

Sex Differentiation

The type of internal and external genitalia is decided by the presence of a viable testis. Therefore, the testis actively governs *sexual differentiation*. Conversely, the growth of female genitalia is the default process in sexual differentiation. The bipotential ductal system consists of the müllerian and wolffian ducts which give rise to female and male internal genitalia, respectively (Fig. 17.3).

Hormones secreted from testes are essential to the development of male internal and external genitalia. Normally developed testes have both Sertoli cells and testicular cords. Sertoli cells secrete AMH causing müllerian duct regression. At the same time, Leydig cells, the steroidogenic cells of the testes, secrete testosterone and INSL3 (insulin-like 3) to promote development of wolffian structures (epididymis, vas deferens, and seminal vesicles) and mediate transabdominal descent of the testes to the internal inguinal ring, respectively.[27] To mediate the development of the male external genitalia, testosterone is converted into 5α-dihydrotestosterone (DHT), a more potent androgen, by the enzyme 5α-reductase (Fig. 17.4). Except for phallic growth and inguinoscrotal descent in the third trimester, male sexual differentiation is essentially complete by week 14 of gestation. Defects in labioscrotal fusion and urogenital sinus growth cannot be modified by high doses of androgens after week 14.

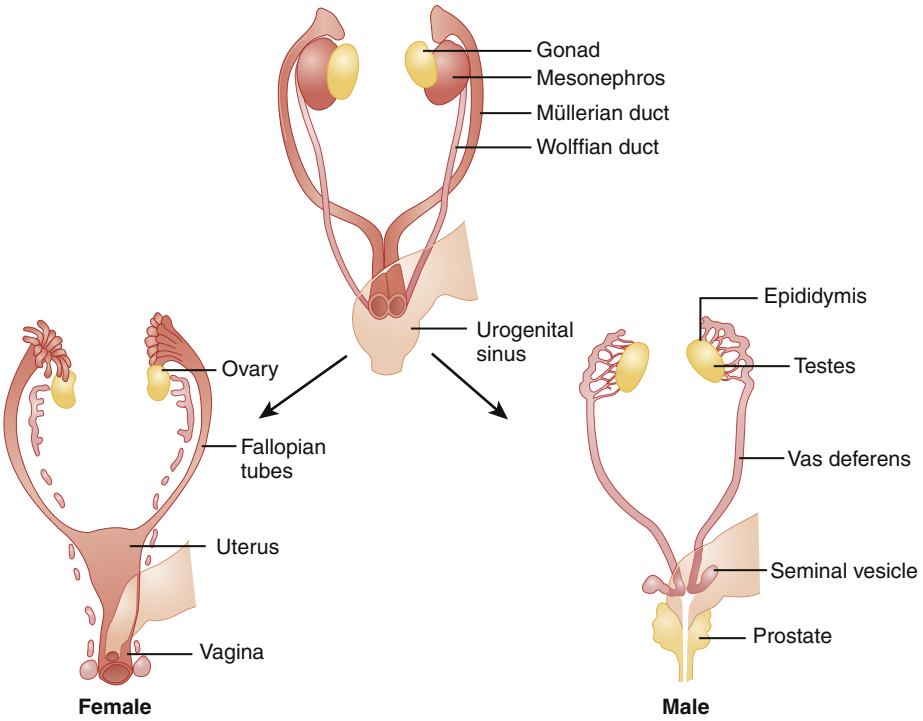

FIGURE 17.3 Internal genital development of male and female ductal system. *(Courtesy of Dr. J. Wilson, University of Texas, Southwestern Medical School, Dallas, TX.)*

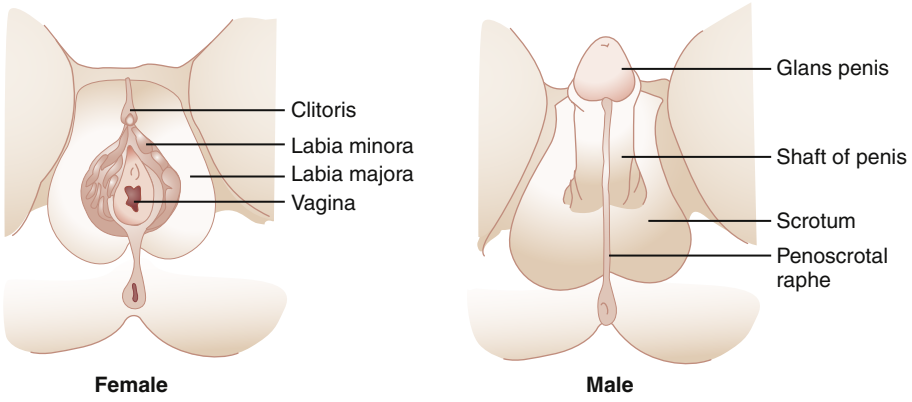

FIGURE 17.4 External genital development, demonstrating homologies and common anlagen in male and female. *(Courtesy of Dr. J. Wilson, University of Texas, Southwestern Medical School, Dallas, TX.)*

In females, the absence of a testicular tissue and its' associated hormones, such as AMH or testosterone, result in müllerian structure development (fallopian tubes, uterus, upper vagina) and wolffian duct regression, around 12 weeks of gestation. Finally, absence of DHT results in no virilization of external genitalia.

Disorders that can cause ambiguous genitalia but are not associated with dysgenic gonads (e.g., complete and partial androgen insensitivity syndrome [CAIS, PAIS] and congenital adrenal hyperplasia [CAH]) are considered disorders of sexual differentiation, not disorders of sex determination. Overview of the diagnostic differences in disorders of sex development, including both disorders of sex determination and sex differentiation, are presented in Table 17.3.

Sex Chromosome Disorders of Sexual Development (DSD)

Sex Chromosome DSDs are defined by aneuploidy of the sex chromosomes, X and Y. In disorders of aneuploidy (i.e., Trisomy 21, 18, etc), maternal errors in meiotic non-disjunction during meiosis-I account for the majority of cases. With few exceptions, such as in Klinefelter Syndrome, maternal and paternal errors are equally likely (47,XXY).[28]

Turner Syndrome

In 1938, a group of females with short stature, primary amenorrhea, and a lack of secondary sex characteristics was described by Turner in 1938. Turner syndrome is classified as a sex chromosome DSD, with the majority having a 45,X karyotype, and the remaining having a 46,XX karyotype with a deletion in part of one X chromosome or having various mosaics involving 45,X and 46,XX, and 46,XY cells or more complex combinations. In 100% of patients with 45,X and 80% of mosaic patients, the universal feature in patients is short stature (Fig. 17.5), with average height less than 58 inches. The genetic locus for short stature in both Turner syndrome and idiopathic short stature lies in the pseudoautosomal region (PAR1) of the X chromosome. This region is

Table 17.3 Syndromes Associated with DSD

	Syndromes Associated with Ambiguous Genitalia	Phenotype	Gene	Locus	OMIM #
Syndromes associated with gonadal dysgenesis	Denys-Drash	Early diffuse mesangial sclerosis of kidneys, Wilms' tumor, XY gonadal dysgenesis	WT-1	11p13	194080
	Frasier	Early adolescent development of focal segmental glomerulosclerosis, gonadoblastoma, XY gonadal dysgenesis	WT-1	11p13	136680
	Campomelic dysplasia	Congenital bowing of long bones, hypoplastic scapulae and thoracic vertebrae pedicles, ambiguous genitalia	SOX9	17q24.3-q25.1	114290
	GD with neuropathy	XY gonadal dysgenesis with associated minifascicular neuropathy (one of 4 cases)	DHH	12q12-13.1	607080
	X-linked alpha-thalassemia/mental retardation	Hemoglobin H disease, mental retardation, dysmorphic facies, genital abnormalities	XH2	Xq13.3	301040
	Palmoplantar hyperkeratosis with squamous cell carcinoma and XY sex reversal	Variable degrees of XY gonadal dysgenesis, ranging from full sex reversal to ovotesticular DSD	RSPO1	1p34.3	610644
	Blepharophimosis-ptosis-epicanthus inversus syndrome Type I	Blepharophimosis, ptosis, and epicanthus inversus syndrome, either with premature ovarian failure	FOXL2	3q23	110100
Syndromes associated with small penis and/or cryptorchidism	VACTERL/VATER	Vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial dysplasia. Limb anomalies	Unknown	Unknown	192350
	Goldenhar syndrome (Hemifacial Microsomia)	Unilateral deformity of the external ear and small ipsilateral half of the face with epibulbar dermoid and vertebral anomalies	Unknown	Unknown	164210
	SmithLemli Opitz syndrome (SLOS)	Multiple congenital malformation and mental retardation syndrome	DHCR7	11q12-q13	270400
	Pallister Hall syndrome (PHS)	Hypothalamic hamartoblastoma, postaxial polydactyly, and imperforate anus	GLI3	7p13	146510
	Robinow syndrome	Mesomelic limb shortening associated with facial and genital abnormalities	ROR2	9q22	180700
	Prader Willi syndrome	Obesity, muscular hypotonia, mental retardation, short stature, hypogonadotropic hypogonadism	SNRPN	15q12, 15q11-q13	17620
	Kallmann syndrome	Hypogonadotropic hypogonadism and anosmia	FGFR-1	8p11.2-p11.1	147950
	Holoprosencephaly	Craniofacial dysmorphology	Many	21q22.3, 2q37.1-q37.3	236100
	Malpeuch facial clefting syndrome	Short stature, hypertelorism, eye anomalies, facial clefting, hearing loss, urogenital abnormalities, mental retardation	Unknown	Unknown	248340
	Najjar syndrome	Genital anomaly, mental retardation, and cardiomyopathy	Unknown	Unknown	212120
	Varadi-Papp syndrome	Big toes, hexadactyly, cleft lip/palate or lingual nodule, and somatic and psychomotor retardation. Some showed absent olfactory bulbs and tracts, cryptorchidism	Unknown	Unknown	277170
	Juberg-Marsidi syndrome	Cleft lip/palate with abnormal thumbs and microcephaly	Unknown	Unknown	216100
	Johanson-Blizzard syndrome	Aplasia or hypoplasia of the nasal alae, congenital deafness, hypothyroidism, postnatal growth retardation, malabsorption, mental retardation, midline ectodermal scalp defects, and absent permanent teeth	Unknown	15q15-q21.1	243800
	Borjeson-Forssman-Lehmann syndrome	Severe mental defect, epilepsy, hypogonadism, hypometabolism, marked obesity	Unknown	Xq26.3	301900
	Torticollis, keloids, cryptorchidism, renal dysplasia	Torticollis, keloids, cryptorchidism, renal dysplasia	Unknown	Xq28	314300
	Hypertelorism with esophageal abnormality and hypospadias	Laryngotracheoesophageal cleft; clefts of lip, palate, and uvula; swallowing difficulty and hoarse cry; genitourinary defects, mental retardation; congenital heart defects	Unknown	22q11.2	145410

Table 17.3 Syndromes Associated with DSD—cont'd

	Syndromes Associated with Ambiguous Genitalia	Phenotype	Gene	Locus	OMIM #
Syndromes associated with small penis and/or cryptorchidism—cont'd	Faciogenitopopliteal syndrome	Cleft palate and webbing intercrural pterygium	Unknown	1q32-q41	119500
	Dubowitz syndrome	Short stature, microcephaly, mild mental retardation with behavior problems, eczema, and distinctive facies	Unknown	Unknown	223370
	Noonan syndrome	Hypertelorism, a downward eye slant, and low-set posteriorly rotated ears, short stature, webbed neck, cardiac anomalies	PTPN11	12q24.1	163950
	Aarskog syndrome (Faciogenital Dysplasia)	Embryonic ocular hypertelorism, anteverted nostrils, broad upper lip, and peculiar penoscrotal relation	FGD1	Xp11.21	305400
	Cornelia de Lange syndrome	Low anterior hairline, anteverted nares, maxillary prognathism, long philtrum, 'carp' mouth in association with prenatal and postnatal growth retardation, mental retardation	NIPBL	5p13.1	122470
	Rubinstein-Taybi syndrome	Mental retardation, broad thumbs and toes, and facial abnormalities	CREBBP	16p13.3, 22q13	180849
	Seckel syndrome	Growth retardation, microcephaly with mental retardation, and a characteristic 'bird-headed' facial appearance	SCKL1	3q22-q24	210600
	Miller Dieker syndrome	Microcephaly and a thickened cortex with 4/6 layers	LIS1	17p13.3	247200
	Lenz-Majewski hyperostosis syndrome	High palate; short, yellow, carious teeth; progeroid appearance; short, increased venous pattern of the forehead and thorax	Unknown	Unknown	151050
	Lowe syndrome	Ophthalmia, cataract, mental retardation, vitamin D-resistant rickets, amino aciduria	OCRL1	Xq26.1	309000
Syndromes associated with müllerian malformations	MURCs	Müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia	Unknown	Unknown	601076
	Mayer-Rokitansky-Kuster-Hauser syndrome (MRKH)	Müllerian duct aplasia	WNT4 in subset with hyperandrogenism	Unknown; 1p35	277000
	McKusick Kaufman syndrome (MKKS)	Hydrometrocolpos, congenital heart malformations, post-axial polydactyly	Unknown	20p12	236700

deleted in individuals with short stature caused by the lack of one copy of the short stature homeobox gene, *SHOX*.

The classic Turner 45,X karyotype is thought to be one of the most common human chromosomal abnormalities and is estimated to occur in 0.8% of all zygotes. However, less than 3% of these zygotes survive to term, and this karyotype is commonly found in spontaneous abortions.[29] The incidence of 45,X karyotypes is approximately 1 in 2500 live newborn phenotypic females.[30,31]

The gonads of Turner syndrome females do not develop normally, having reduced growth and follicle formation *in utero*.[31] A normal number of eggs develop in girls with Turner syndrome, but, for unknown reasons, they disappear prematurely.[32] The gonads appear as streaks of white tissue next to the fallopian tubes—called "streak gonads" which on histology have primitive connective tissue stroma without primary follicles. Patients with Turner syndrome have fewer follicles and therefore less estrogen secretion from granulosa cells than normal females, resulting in delayed puberty.

Presentation and Diagnosis

In the prenatal period, fetuses with 45,X DSD and its variants frequently have intrauterine growth restriction. Suspicion for Turner syndrome should be raised if the presence of large septate cystic hygromas, nuchal thickening, short femur, total body lymphangiectasia, or cardiac defects is detected by ultrasound. At birth, Turner syndrome babies often have low birth weights; 30% of babies will present with lymphedema of the upper and lower extremities (Fig. 17.6), an extension of the lymphangiectasias *in utero*, which disappears in the first few months of life. Additionally, the presence of a webbed neck (pterygium colli) (Fig. 17.5) and dysmorphic features including: high-arched palate, low set prominent ears, low posterior hairline, epicanthal folds, micrognatia, hypoplastic nail beds, or hypoplastic fourth and fifth metacarpals at birth should raise the suspicion for 45,X DSD.[33] Turner syndrome patients may have increased carrying angle of the arms (cubitus valgus), shield-like chest with wide set nipples, hearing loss, and a higher frequency of cardiovascular disease such as coarctation of the aorta.

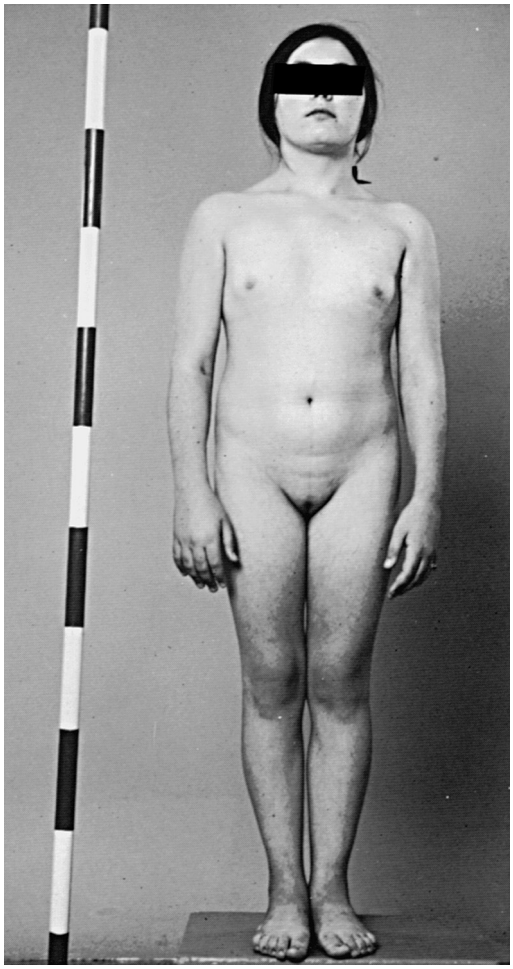

FIGURE 17.5 Patient with Turner syndrome. Note the short stature, webbed neck, and lack of secondary sex development.

Furthermore, the incidence of renal anomalies is between 30% to 50%, with the most common being a horseshoe kidney followed by abnormal vasculature.

During adolescence, the most common presentation is short stature, amenorrhea, and lack of secondary sex characteristics. Patients may also have any of the other characteristics mentioned above. 45,X DSD patients have normal intelligence. Depending on the degree of gonadal dysgenesis, up to 30% of Turner patients undergo some degree of spontaneous puberty.[34]

Diagnosis is made by karyotype, which will show in a 45,X or mosaic variant of cells. If the karyotype appears normal, but the presentation is suggestive of Turner syndrome, a fluorescent *in situ* hybridization (FISH) or comparative genomic hybridization (CGH) study should be done, as there may be a cryptic deletion in the pseudoautosomal region in one of the X chromosomes. Typically patients with 45,X or 46,XX with a chromosomal abnormality in one X chromosome have more prominent phenotypic features than those who are a mosaic.

Management

For most patients with 45,X DSD, the greatest concern is for short stature and secondary sexual development. The treatment of both of these should be carefully titrated. For cases diagnosed in childhood, the use of low dose anabolical steroid coupled with growth hormone has been shown to increase final adult height with increased beneficial effects compared to those who started therapy late.[35-37] At the onset of the age of puberty, high dose estrogen and progesterone should be given to promote the development of secondary sex characteristics. Estrogens and progesterone should be taken throughout life to prevent complications, such as osteoporosis.[38]

FIGURE 17.6 Lymphedema in the lower extremities of an infant with Turner syndrome.

In young patients diagnosed with Turner syndrome, spontaneous puberty is a good indicator of the presence of functional ovarian tissue. Overall, it is estimated that 2% to 5% of patients with Turner syndrome have the potential for spontaneous pregnancy.[39]

Klinefelter Syndrome

In utero, the XXY fetal testis has the normal complement of primordial germ cells in the XXY testes. However, these germ cells degenerate during childhood, most likely due to a defect in Sertoli cells and germ cell communication during testes maturation.[40] In theory, the etiology of the nondisjunction in Klinefelter can be from maternal meiosis I or II or paternal meiosis II, and thus each situation should contribute to 33% of cases. However, nearly 50% of Klinefelter patients show a paternal origin[41] with some studies showing increased frequency of XY sperm with advanced paternal age.[42]

Presentation and Diagnosis

Klinefelter syndrome is largely undiagnosed in the general population.[43] In early life, Klinefelter may be diagnosed in boys with behavioral disorders, abnormally small testes, and long legs (Fig. 17.7). The presence of only long lower extremities distinguishes Klinefelter syndrome from the other forms of eunuchoidism that results in equally long upper and lower extremities. In patients with Klinefelter syndrome, IQ typically falls in the normal range, however it tends to be below that of other siblings.[42,44] Most patients present in adolescence with small firm testes and hypogonadism with varying degrees of androgen deficiency.[42] In later life, many males present at infertility centers with azoospermia.

Diagnosis of Klinefelter syndrome is performed by lymphocyte karyotype. Some mosaic cases will only be detected by karyotype of skin fibroblasts and occasionally of testicular biopsy specimens.

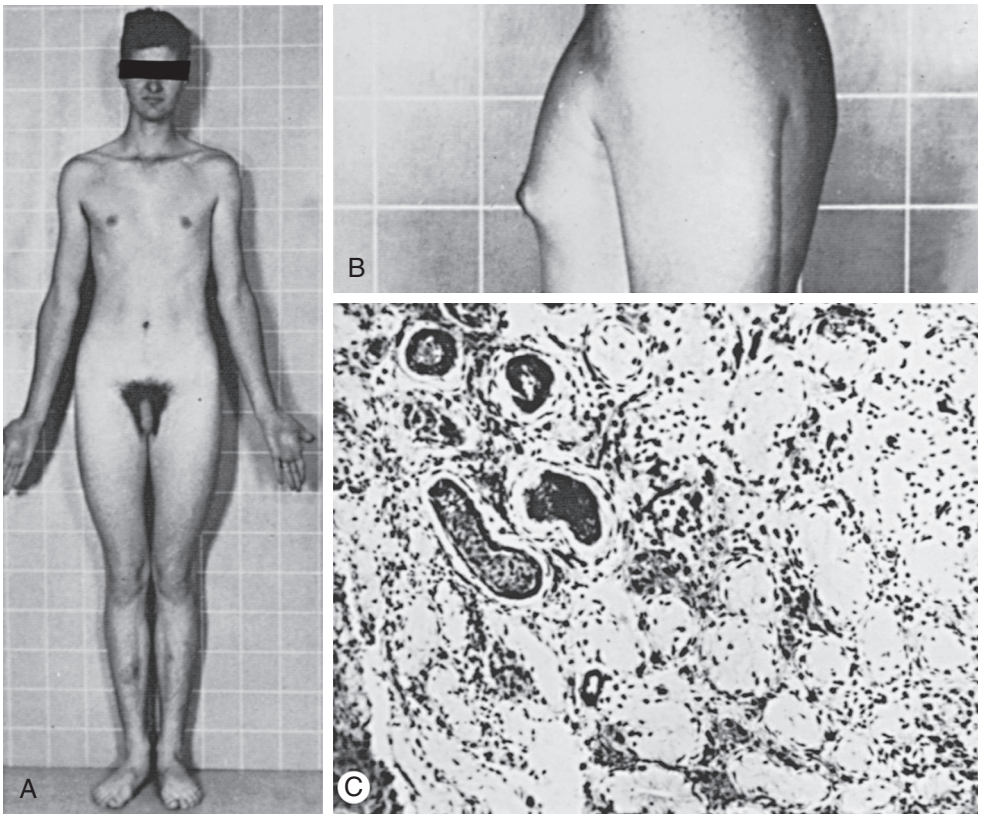

FIGURE 17.7 Klinefelter syndrome. **A**, Phenotypic male with XXY. Note the long lower extremities as compared with upper extremities **B**, Well virilized patient with gynecomastia. **C**, Testicular biopsy of patient in **B**. Note marked hyalinization of seminiferous tubules and Leydig cell hyperplasia. *(From Gumbach, MM, Conte FA. Disorders of Sex Differentiation. In Wilson JS, Foster DW, Kronenberg HM, Larsen PR [eds],* Williams textbook of endocrinology. *Philadelphia: WB Saunders, 1998, p 1368.)*

Management

Early detection of Klinefelter allows for early intervention for cognitive and behavioral disorders. Current studies are underway exploring the role of androgen replacement therapy in childhood, to help with cognitive and behavioral disabilities. Replacement of androgens also allows for development of masculine secondary sex characteristics, improved self-esteem, and increased libido, strength, and bone mineral density.[45] With regards to fertility, testicular mosaicism is an important factor to determining spermatogenesis and the potential for fertility. The vast majority of 47,XXY patients are azoospermic, but since the advent of Intra Cytoplasmic Sperm Injection (ICSI) technology have the potential to be fertile. It should be noted that there is a higher rate of sex chromosomal hyperploidy and autosomal aneupoloidy[46] in the sperm of Klinefelter patients. However, the risk of passing sex chromosome aneuploidy to the offspring remains unclear. Regardless, preimplanation genetic diagnosis (PGD) or fetal karyotype should be implemented to prevent chromosomal abnormalities in the progeny. Using testicular sperm extraction (TSE) technology, sperm can be successfully extracted from the testes[47] and injected into a donor oocyte.

46,XY Disorders of Sex Development

46,XY Disorders of Gonadal Determination

46,XY Gonadal Dysgenesis

Etiology and Pathophysiology of Pure-Complete Gonadal Dysgenesis

XY gonadal dysgenesis (GD) is a result of abnormal testis development *in utero*. There are three types of GD, pure (or complete), partial, or mixed, all of which can be differentiated by the extent of normal testicular tissue within the gonad and karyotype of the individual. In pure-complete GD, individuals have intra-abdominal, bilateral, fibrous streaks which do not secrete AMH or testosterone. Phenotypically, pure XY GD individuals are unambiguously phenotypic females (previously known as Swyer syndrome) but usually internally possess hypoplastic müllerian structures.

Given the primary importance of *SRY* in human testes determination, it is surprising that mutations in SRY only account for approximately 15% of all pure XY *GD*.[15,48-50] This suggests the existence of many other genes involved in primary human sex determination. SRY is a transcription factor, but its mechanism of action remains poorly understood. For instance, it is still unclear whether it acts as an activator or repressor[51] and its only identified and confirmed target is SOX9, another transcription factor from the Sox (Sry-box) family of genes. To date, there are over 50 verified mutations within the *SRY* gene. Mutations which result in streak gonads primarily occur within the high mobility group (HMG) box, and cause reduced DNA binding,[48,50] alterations in DNA bending,[52] or prevents nuclear import of the *SRY* protein.[53] There are over 50 known mutations of the *SRY* open reading frame. Larger cytogenetic deletions of Yp which include *SRY* have also been implicated in XY GD.[48,49,54]

Steroidogenic factor 1 (SF1, also known as NR5A1) is an orphan nuclear receptor necessary for adrenal and testicular development. Interactions between SF1 and the transcription factors GATA binding protein 4 (GATA4) and friend of GATA 2 (FOG2) appear to be necessary for *SRY* expression in developing testes.[55,56] Recent studies have underlined the importance of SF1 in testicular development, as nearly 15% of isolated XY GD can be attributed to *SF1* haploinsufficiency.[57]

However, three cases have reported *SF1* mutations with XY GD and adrenal hypoplasia congenita, which reflect the role of SF1 in adrenal development. Together, mutations or deletions of *SRY* and *SF1* account for 30% of XY gonadal dysgeneses, indicating that other genes critical to the testes determination cascade still remain to be discovered.

Mutations in genes involved in testis sex determination *(XH2, SOX9, WT-1, DHH)* and duplications of putative "anti-testis" genes *(WNT-4, DAX1)* are responsible for a minority of all XY GD,[58-60] but are usually associated with other syndromic features, which are outlined in Table 17.3.

Etiology and Pathophysiology of Partial or Mixed Gonadal Dysgenesis

Like many developmental disorders, there is a wide range in phenotypic variability in patient presentation. When testes dysgenesis does not involve the entirety of both gonads and the phenotype is ambiguous rather than female, the condition is called "partial" gonadal dysgenesis. The internal genitalia display varying degrees of wolffian and müllerian development, which correspond with the percent of the gonads, which are dysgenic, or "streak." The medical literature is often confusing in regards to the difference between "partial" and "mixed" GD, which are often used interchangeably. Partial XY GD refers to intermediate stages of dysgenic testes, between streak gonads and normal testes, and usually has a 46,XY, nonmosaic karyotype. However, mixed 46,XY GD typically refers to a situation in which one gonad is a streak gonad while the opposite gonad is partially dysgenic or a normal testis. Mosaicism for 45,X/46,XY is the most frequent cause of mixed GD, although a minority have a 46,Xi (Yq) karyotype.[61] The evidence of the variable phenotypic spectrum of individuals with 45,X/46,XY mosaicism was reported in a series of 10 45,X/46,XY patients in which 4 individuals were undervirilized males with bilateral testis, 3 were diagnosed with mixed GD and genital ambiguity, and 3 were diagnosed with Turner syndrome.[62] While not proven, there is preliminary evidence that percent of normal testicular tissue and phenotypic maleness is correlated with an increase in the proportion of gonadal Y chromosome.[63,64]

Familial cases of pure and partial 46,XY, GD[13,14,50,65] have been reported. In some of these cases, *SRY* mutations present with phenotypic variability in which the father and male relatives are phenotypically normal and fertile, while their XY offspring have gonadal dysgenesis.[50,65,66] From these cases, it is clear that autosomal genetic modifiers influence the sex determination cascade and ultimate phenotypic appearance of the individual. There are also cases of fathers who are mosaic for mutant and normal *SRY* transmitting the mutation to their XY female daughter.[67,68] Presumably, the normal father's mosaicism reflects a postzygotic mutation event. These unique cases provide more hints about the molecular basis of sex determination. This is particularly relevant since the genetic cause of 70% of 46,XY GD remains unknown.

Presentation and Diagnosis of Gonadal Dysgenesis

Pure XY GD presents as a phenotypic female with normal or tall stature, bilateral streak gonads, delayed puberty, amenorrhea, small or normal müllerian structures, and without signs of Turner syndrome. If patients are not diagnosed at birth (e.g., when *in utero,* karyotype does not match the phenotypic sex at birth) most patients will be diagnosed during adolescence due to pubertal delay and primary amenorrhea. Patients can rarely present with an abdominal or pelvic mass, which often is a gonadoblastoma. Occasionally, XY GD can be part of a constellation of other symptoms, which are outlined in Table 17.3.

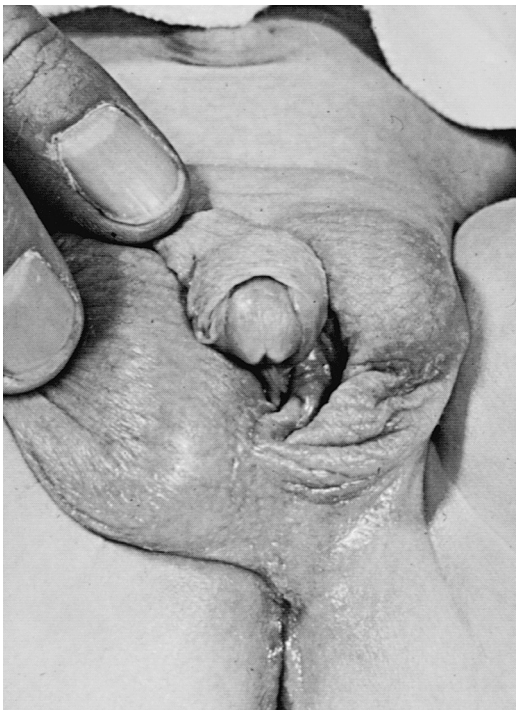

FIGURE 17.8 External genitalia of infant with XO/XY mosaicism. Note enlarged phallus, labioscrotal fusion, and gonadal bulges (histologically, testes) in labioscrotum.

Individuals with partial or mixed 46,XY GD typically present at birth with varying degrees of masculinization of external and internal genitalia. Depending on the percent of testicular tissue, dysgenetic testes can be found anywhere along the line of testes descent, from the abdomen, and in cases of normal testes, in the scrotum. However, the streak gonad in mixed 46,XY GD is always abdominally located. Patients with partial 46,XY GD usually have female external genitalia with some degree of virilization, such as clitoromegaly or a bifid scrotum (Fig. 17.8). Uterus and fallopian tubes are usually well-formed, but occasionally may be hypoplastic. In mixed GD, the development of wolffian and müllerian structures as well as the virilization of external genitalia correlates with the degree of development of the ipsilateral testis resulting in asymmetric virilization of the external or internal genitalia and unilateral cryptorchidism. Pelvic ultrasound often can detect presence of absence of male or female internal genitalia and in the case of mixed XY GD, asymmetry in development of the müllerian and wolffian structures. There are rare reported cases of patients presenting with premature adrenarche in an otherwise unambiguous female, due to a testosterone-producing gonadal tumor.[69]

Isolated 46,XY pure GD is considered in an adolescent with primary amenorrhea and sexual immaturity with a full female external phenotype, while partial or mixed GD should be considered more likely in the differential diagnosis of a 46,XY patient with ambiguous genitalia. The biochemical changes in complete, partial, and mixed GD are outlined in Table 17.4.

Table 17.4 Diagnostic Criteria for Disorders of Sex Development

	DSD	Biochemical Changes	Differentiating Features	Major Genetic Diagnostic Criteria
46,XY Disorders of Gonadal Development	46,XY pure/partial/mixed gonadal dysgenesis	Pure/partial/mixed ↑FSH, LH Nml to ↓ AMH No ↑ with hCG NmL adrenal hormones and precursors Pure ⇓; T, DHT, E2 ⇓ AMH Partial/mixed ↓ T, DHT, E2 ↓ T, DHT, E2	Presence of partial testicular function (T, AMH) points towards partial or mixed GD. However, histological examination of testes after prophylactic gonadectomy can differentiate between pure, partial, and mixed GD. There is little genotype-phenotype correlation, however the presence of mosaicism 45,X/46,XY is often associated with mixed GD.	Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Genetic mutations in SF1, SRY, MAP3K1 provide a definitive genetic diagnosis. If partial/mixed GD suspected, patient should be tested for mosaicism. CGH should be performed to look for copy number[71] variants as a source for XY, GD.
	Testicular regression	↑ FSH, LH ⇓ T, DHT, E2 ⇓ AMH No ↑ with hCG	Complete absence of gonad or fibrosis of gonad (as opposed to streak of dysgenic testes in GD patients). Completely virilized male phenotype.	Fibrous nodules on laporoscopic exam, (not streak of dysgenic testes)
Disorders of Sex Differentiation: Disorders in Androgen Synthesis and Action	StAR deficiency; P450scc deficiency	↑ Renin ↓ Aldo ↑ K ↓ Na ↓ All adrenal hormones ↓17-OHP	Presence of lipid vacuoles in adrenals on histology. P450scc deficiency does present with enlarged adrenals. No HTN and hyperkalemia differentiates from CYP 17 deficiency	Presence of lipid filled vacuoles on histology; clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Identification of mutations in the StaR or P450scc genes gives a definitive diagnosis.
	3βHSD type II	↑ Renin ↓ Aldo, F ↑ K ↓ Na ↑ Ratio Δ^5-17-pregnenolone: cortisol ↓ Δ4A, T	Baseline and ACTH-stimulated ratios of Δ^5-17-pregnenolone:cortisol consistently distinguished between patients affected and non-affected patients.	Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Mutations, deletions, and insertions in the 3βHSD type II gene provide a definitive genetic diagnosis.
	17α-hydroxylase/17,20-lyase	↓ Renin ↓ Aldo, F ↓17-OH Progesterone ↑ LH, FSH ↑ Progesterone, DOC, B ↑ Na ↓ K ↓ DHEA-S, Δ4A, T; no response to hCG stim	Hypertension and hypokalemic alkalosis in the presence of low 17-OH Progesterone. Isolated 17,20-lyase deficiency would have decreased levels of sex steroids with normal mineralocorticoids and normal glucocorticoids.	Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Identification of mutations of CYP17 or CYPB5 gene provide a definitive diagnosis.
	P450 oxidoreductase	↑ 17OH-progesterone ↑ Progesterone ↓ F, DHEA-S ↓ Δ4A, T	Hypertension, in the presence of elevated 17-OH progesterone (differentiates from CYP17 deficiency); sometimes presence of Antley-Bixler skeletal malformations.	Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Mutations in CYP450 oxidoreductase provide a definitive diagnosis.
	17βHSD Type 3	Nml to ↑ Δ4A ↑ ratio Δ4A/T (>15) ↓ T, DHT	Differentiated from 5α-reductase Type 2 by levels and ratios of serum hormones.	Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Sequencing of the 17βHSD gene for deletions, insertions, and point mutations.
	Leydig Cell Hypoplasia	↑ LH Nml FSH ↑ AMH ↓ T, DHT, E_2 ↓hCG response Nml Δ4A/T ratio	To differentiate LCH from GD, AMH is used as a marker of testicular function.	Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Deletions, insertions, and point mutations in the *LHR* gene provide a definitive diagnosis.

Table 17.4 Diagnostic Criteria for Disorders of Sex Development—cont'd

	DSD	Biochemical Changes	Differentiating Features	Major Genetic Diagnostic Criteria
	5α-Reductase Type 2 Mutations in the backdoor pathway to androgen activity.	Nml FSH, LH Nml T, E_2 ↓ DHT ↑ ratio T/DHT (>30) Nml ratio T/DHT (>30) Nml AMH Nml cortisol ↓ DHEA-S after hCG ↑ 17OH-pregnenolone	Development of male secondary sex characteristics in puberty with fine and sparse facial hair. These can be differentiated clinically from 17βHSD and AIS by the lack of gynecomastia during puberty. Similar in phenotype to 17βHSD and 5-alpha reductase deficiency but can be differentiated by serum hormone levels.	Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Point mutations, deletions, insertions, and parental isodisomy in *SRD5A2* gene provides a definitive genetic diagnosis. Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Mutations in *AKR1C2* and *AKR1C4* gene that result in a reduction of their enzymatic activity provides a definitive genetic diagnosis.
	Androgen receptor	Nml FSH, LH (PAIS) ↓ FSH, LH (CAIS) Nml to ↑ AMH Nml Δ4A, T, DHT; nml ratios ↑↑ hCG response	Female phenotype with breast development at puberty, with sparse pubic and axilla hair	Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Sequencing of AR gene looking for single amino acid substitutions, which account for 90% of reported cases.
	AMH/AMHR	Nml hormonal profile	Presence of both müllerian and wolffian derivatives, usually discovered incidentally.	
46,XX Disorders of Sex Determination	XX Testicular/ovo-testicular DSD	↑ FSH, LH ↓T, DHT Nml AMH No ↑ with hCG	Only way to differentiate between 46,XX testicular and ovotesticular DSD is by complete gonadal histological examination looking for the presence of ovarian tissue.	Testicular DSD: FISH for presence of SRY or SOX9 or if clinical phenotype appropriate, sequence RSPO1 gene. If no molecular diagnostic is successful, CGH should be performed. Ovotesticular DSD: Search for XX/XY mosaicism should be done (30%-33% ovotesticular DSD) and sequencing for SRY should be done (7%-10% of ovotesticular DSD).
	XX Gonadal dysgenesis	↑ FSH, LH No ↑ with hCG No AMH	Full female phenotype with amenorrhea and lack of secondary sex development	For cases of isolated 46,XX GD, sequencing for FSH mutations can be performed If clinical presentation matches, sequence FOXL2 mutation. CGH can also be done to identify delirious duplications or mutations.
Disorders of Androgen Excess	21α-hydroxylase	↑ Renin ↓Aldo, DOC, F ↑ K ↓ Na ↑ 17OH-progesterone ↑ DHEA-S, Δ4A, T	17-OH Progesterone elevated in the absence of hypertension, which is typical in 11βHSD1 deficiency.	Sequencing of CYP21 gene gives definitive diagnosis. Knowledge of the mutation can inform parents about genetic counseling and fetal diagnosis to prevent adverse effects of hyperandrogenism *in utero.*
	11βHSD1	↓ Aldo, F, Renin ↑ DOC ↑ K ↓ Na ↑ 17OH-progesterone ↑ DHEA-S, Δ4A, T	Differentiate from CYP21 deficiency by presences of hypertension and hypokalemic alkalosis.	Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Mutations in 11βHSD1 gives a definitive diagnosis.
	P450 aromatase	↑ 16OH-Δ4A (maternal) ↑ FSH, LH, Δ4A, T ↓Estrone, E_2	The presence of maternal virilization during pregnancy and XX virilization which stops after delivery.	The presence of maternal virlization during pregnancy and XX virilization which stops after delivery. Clinical whole exome sequencing or Sanger sequencing can be performed to assess for mutations in known DSD genes. Mutations in p450 aromatase gives definitive diagnosis.

The major criteria for the diagnosis of pure, partial, or mixed gonadal dysgenesis are the appearance and histology of both gonads. Therefore, the ultimate diagnosis of any of the forms of gonadal dysgenesis, particularly the distinction between mixed and partial GD, requires biopsy of both gonads. Since the risk of gonadoblastoma in these patients is so high, precise diagnosis of the type of gonadal dysgenesis is usually determined after prophylactic or therapeutic gonadectomy. In pure 46,XY GD both gonads are streak gonads. Partial GD is defined by bilateral dysgenetic gonads, while mixed GD typically has one streak gonad. Karyotype of peripheral leukocytes shows 46,XY in pure and partial GD, and mosaic 45,X/46,XY is frequent in mixed GD. However, if there is a streak gonad on one side and a normal testis contralaterally, but the peripheral karyotype is 46,XY, cryptic mosaicism can often be revealed within the gonad.

Once a presumptive diagnosis is made in 46,XY patients, FISH for *SRY* or for Yp can be performed. Only a minority of cases of XY GD can be explained by complete or partial *SRY* deletion or mutation, or *SF1* mutation. The majority of patients are 46,XY and positive for *SRY* and *SF1*. Sequencing of the *SRY* or *SF1* open reading frames for mutations is only positive in up to 30% of 46,XY pure GD.[49,50,57,67] Certain isolated and syndromic forms of XY gonadal dysgenesis can be diagnosed molecularly with cytogenetics, comparative genomic hybridization, or sequencing of known genes (Table 17.4). 46,XY DSD in conjunction with congenital heart disease may increase the suspicion for a *GATA4* mutation.[68] Whole-genome CGH array studies have identified many rare copy number variants associated with patients with 46,XY gonadal dysgenesis and 46,XX testicular and ovotesticular DSD,[70,71] including deletions and duplications in and around *SOX3*,[72] *GATA4*,[70] *WWOX*,[73] and *DMRT1*.[71] Deletions or duplications in the up-stream promoter region of *SOX9* are associated with isolated and familial cases of 46,XY gonadal dysgenesis and 46,XX testicular DSD.[74,75]

If a mutation or translocation involving *SRY* is found, the father should be tested for a possible familial mutation since *SRY* mutations can result in a full spectrum of phenotypes, from 46,XY fertile males to ambiguous individuals to females with partial and pure GD. Due to potential autosomal modifiers, it is very difficult to predict the risk of recurrence of a GD phenotype in XY offspring.

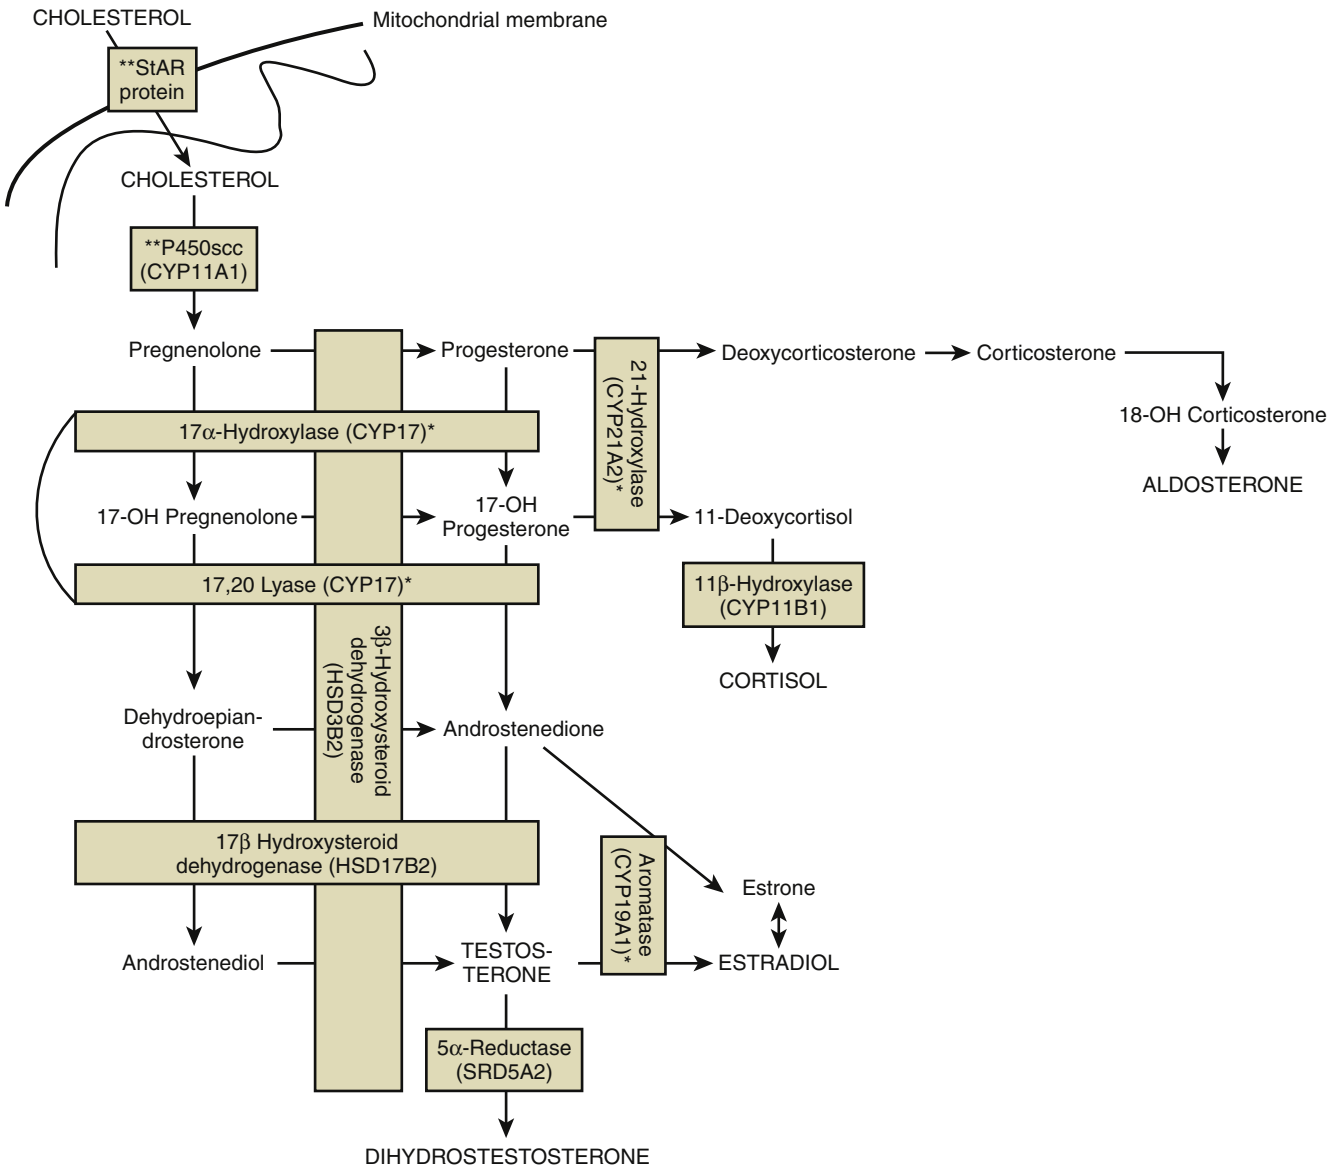
Management of XY Gonadal Dysgenesis

The major concern in the treatment of patients with XY GD is the risk of gonadoblastoma, a mixed germ-cell, sex-cord tumor. The risk of gonadoblastoma formation in XY GD patients increases with age and has been estimated to be as high as 30% by 30 years of age.[54,76,77] Due to the high risk of gonadoblastoma formation, patients should undergo prophylactic or therapeutic gonadectomy preferably in the first decade of life. Patients are followed with regular ultrasounds every 6 months starting at age 2 until gonadectomy can be performed. With the advent of laparoscopic techniques, the invasiveness of these surgeries is decreasing and the results are improving.[77]

In patients with XY pure GD, genitals and gender identity are unambiguously female. There are no reported cases of gender dysphoria. In patients with partial or mixed GD, the degree of genital masculinization can be used for initial gender assignment. However, issues of gender identity do arise in partial and mixed GD and are outlined further in the management section.[78]

In order to complete secondary sex development, sex steroid replacement should be initiated at puberty. Sex steroid replacement is essential for not only development of secondary sex characteristics but also growth spurt, and normal accrual of bone mineral density. Height, weight, and bone density should be monitored regularly. Furthermore, a dual-energy x-ray absorptiometry (DEXA) scan for bone density should be performed prior to induction of puberty with exogenous hormone replacement, and yearly thereafter for the first 2 years. As long as the first three DEXA scans are reported as normal, they can be done every 2 to 3 years.

Since a normal uterus is often present, hysterectomies are not common in order to preserve child-bearing potential with *in vitro* fertilization methods. Despite this, most patients do not carry successful pregnancies for unknown reasons.[7] Mixed XY GD individuals with more masculinization of the external genitalia are often raised as males and consequently require lifetime testosterone therapy, through intramuscular injections or transdermal patches or gel.



Testicular Regression Syndrome

In some cases, initial testicular development occurs normally, but there is an insult to the developing testes during sex differentiation, resulting in variable degrees of masculinization of the internal and external genitalia. Testicular regression syndrome (TRS), also known as bilateral anorchia, is distinct in that the insult typically occurs after initial testes determination.[79-81] Internal and external genitalia are variably developed, which presumably depends on when the loss of fetal testes occurred *in utero*.[80-83] Rarely, patients can present in adulthood as females with primary amenorrhea.[82,83] Typically, however, TRS is characterized by primitive epididymis and spermatic cord in the presence of a fibrous nodule rather than streak, or dysgenetic gonads.[79,80,84] The presence of spermatic cord structures, the absence of müllerian derivatives, and normal male external phenotype suggest viable testes existed early in development, and imply a late fetal or early neonatal regression. Diagnostic criteria are outlined in Table 17.4. In the literature, this variant is often called "vanishing testes."[79]

The incidence of TRS has been estimated at 5% of males presenting with cryptorchidism,[79] and as high as 12% of cryptorchid patients older than 1 year.[79,85] Correct diagnosis of TRS versus XY, GD is essential because of significant malignant potential of abdominal or dysgenic testes. Mutational analysis of *SF1* as a cause of TRS did not find any association between mutations in *SF1* and TRS.[86]

Disorders in Sex Differentiation: 46,XY Disorders of Androgen Biosynthesis and Action

46,XY DSD, with phenotypes ranging from full sex reversal to undervirilized XY males, can be a result of defects in steroidogenic enzymes (Fig. 17.9) or their receptor action. The biosynthesis of testosterone is essential for development of secondary sex characteristics in XY individuals, including differentiation of wolffian structures, inguinoscrotal

*P450 oxidoreductase deficiency results in partial activity of this enzyme.
**Both of these proteins result in congenital lipoid adrenal hyperplasia.

FIGURE 17.9 Adrenal steroidogenesis pathways. Many disorders of sex differentiation are due to defects in steroidogenesis, with the majority of them occurring in the adrenal gland.

testes descent, and masculinization of external genitalia after conversion to DHT. Additionally, mutations in Sertoli cell products, such as anti-müllerian hormone or its respective receptor can result in incomplete regression of female internal genitalia. Mutations in the synthesis and action of testosterone, or up-stream regulators of testosterone production, can all cause incomplete virilization or müllerian regression in the XY male. However, in these individuals, the testes are of normal size.

Congenital Lipoid Adrenal Hyperplasia

Mutations in genes encoding proteins involved in the initial enzymatic regions of steroidogenesis, such as steroidogenic acute regulatory protein (STAR) and cytochrome P450 side chain cleavage (P450scc, also known as *CYP11A1)*,[87,88] result in global silencing of adrenal and gonadal steroidogenesis. The accumulation of cholesterol in the adrenals and gonads, ultimately results in primary adrenal and gonadal failure.[89] StAR protein transports cholesterol across the inner and outer mitochondrial membranes of steroidogenic cells. P450scc catalyzes the initial reaction in all steroidogenic tissues, the conversion of cholesterol to pregnenolone (Fig. 17.9).[90,91] On adrenal histology, patients with mutations in StAR protein or P450scc have lipid vacuoles. However, patients with *STAR* mutations have adrenal hyperplasia, while the six patients with *P450SCC* mutations did not exhibit adrenal enlargement.

Presentation and Diagnosis

Newborns with congenital lipoid adrenal hyperplasia usually present with a salt wasting adrenal crisis at birth which

is usually fatal if not immediately diagnosed and treated, however there are reports of delayed presentation. All XY patients present with a female phenotype or, in cases of partial defect, some degree of genital ambiguity. XX patients only exhibit the features of adrenal insufficiency at birth.

46,XY patients have testes, no müllerian structures due to the presence of AMH, partial or absent wolffian derivates due to a lack of testosterone biosynthesis, and a blind vaginal pouch. The spectrum of external genital phenotype ranges from female external genitalia to ambiguous genitals. Testes can be in the abdomen, inguinal canal, or labia. Additionally, intrauterine glucocorticoid deficiency results in elevated adrenal corticotropic hormone ACTH levels, which manifests clinically as generalized hyperpigmentation at birth.

Partial deficiency of StAR protein may result in 46,XX patients who can experience spontaneous puberty, menarche, and anovulatory menses because their ovaries are able to produce estrogen through StAR-independent pathways.[89,92,93] However, at puberty, XX females develop multiple cysts in their ovaries, possibly from anovulation. Since the ovaries do not produce steroids until puberty, they are spared from the cholesterol-induced damage, which occurs in the adrenals from birth.[93]

Definitive diagnosis of congenital lipoid adrenal hyperplasia is done by sequencing of *StAR* or *CYP11A1*. Characteristic biochemical abnormalities are outlined in Table 17.4.

Management

Patients should be given physiological replacement doses of glucocorticoid and mineralocorticoids. At the onset of puberty patients should be given sex hormones in concordance with phenotypic sex.

3β-Hydroxysteroid Dehydrogenase Deficiency

This rare variant of congenital adrenal hyperplasia can have a wide range of phenotypes, and ranging from classical presentation (salt wasting, with a range of female external genitalia to ambiguous genitalia in genetic XY individuals) to non-classical (no salt wasting and later presentation). Rare defects in adrenal and gonadal 3β-hydroxysteroid dehydrogenase *(HSD3B2)* affect the synthesis of three major adrenal steroid hormones: cortisol, aldosterone, and testosterone synthesis. The resulting phenotype is adrenal insufficiency in XX and XY patients but genital ambiguity only in XY patients.

17α-Hydroxylase/17,20-Lyase Deficiency

Biosynthesis of adrenal and sex hormones require cytochrome P450 17α-hydroxylase/17,20-lyase (P450C17). Here, a single gene, *P450C17* catalyzes two steps in the steroidogenic pathway, which are essential for sex steroid and glucocorticoid synthesis. Mutations in this gene, ultimately result in decreased cortisol synthesis with shunting of steroidogenesis towards a mineralocorticoid precursor that has mineralcorticoid activity (Fig. 17.9). Isolated cases of 17,20-lyase deficiency are caused by mutations in Cytochrome b5 *(CYB5A)*, a gene that promotes the specific allosteric interaction between CYP17A1 and POR.[94,95]

Presentation and Diagnosis

Most patients present at puberty with primary amenorrhea, low-renin hypertension and hypokalemia (due to elevated mineralocorticoids). This autosomal recessive disorder results in ambiguous genitalia only in 46,XY patients. 46,XY affected individuals have phenotypes ranging from female external genitalia with no wolffian duct development to ambiguous genitalia with partial development of the male ductal system, depending on the severity of the enzymatic defect. All patients show müllerian structure regression, due to presence of functional Sertoli cells. In contrast to individuals with 3βHSD deficiency or Lipoid CAH, patients do not develop adrenal crisis due to the presence of glucocorticoid precursors that maintain some activity.[96] Serum diagnostic criteria are outlined in Table 17.4. Rare C*YP17A1* mutations which cause isolated 17,20-lyase deficiency[97] only affects sex steroid biosynthesis and results in variably feminized 46,XY individuals with normal levels of cortisol.

Management

Patients should be treated with physiological levels of glucocorticoids and appropriate sex steroid replacements to develop secondary sex characteristics.

P450 Oxidoreductase Deficiency

Cytochrome P450 oxidoreductase (POR) deficiency is a recently characterized cause of congenital adrenal hyperplasia, which affects the enzymatic activity of all microsomal P450 enzymes, including the steroidogenic enzymes P450c17, P450c21, and P450aro.[98-100] POR is a flavoprotein that is required for the action of all microsomal p450 enzymes. Unlike other genetic defects, which only affect one enzyme in the steroidogenesis pathway (Fig. 17.9), POR causes partial enzymatic activity in multiple enzymes. Therefore, POR deficiency presents with a wide range of phenotypes and is particularly difficult to diagnose using serum hormone levels. Partial enzymatic deficiencies in 21α-hydroxylase account for the CAH phenotype and virilization in XX females, while partial 17α-hydroxylase deficiency accounts for undervirlization of XY individuals. Aromatase deficiency secondary to POR deficiency is the likely cause of virilization of mothers carrying fetuses with POR deficiency.

In addition to the genital phenotype, some POR deficiency patients present with a complex skeletal phenotype known as Antley Bixler syndrome (ABS). These skeletal malformations, include but are not limited to craniosynostosis, radiohumeral synostosis, midface hypoplasia, and choanal stenosis.

Presentation and Diagnosis

The unique pathophysiology of POR deficiency results in a wide phenotypic spectrum, in which XX and XY patients present in the prenatal period, as newborns with ambiguous genitalia, or as XX adolescents with amenorrhea and poly cystic ovarian syndrome (PCOS). During prenatal screening, this diagnosis should be considered in the differential of a pregnant woman with low estriol levels but with a normal ultrasound exam and virilization. Endocrine changes are shown in Table 17.4. The majority of patients have compound heterozygous mutations in *POR*. The most common mutation is Ala287Pro in Caucasians,[101] and Arg457His in

Japanese patients.[102] More severe genital and skeletal malformations are associated with loss of function alleles, while missense mutations result in mild to moderate genital and skeletal malformations.[101]

17β-Hydroxysteroid Dehydrogenase Deficiency

The17β-HSD3 enzyme is a member of the 17β-HSD family, which catalyzes the conversion of Δ4A to testosterone in the testes (Fig. 17.9). However, isoenzymes 17β-HSD2 and 17β-HSD4 are widely expressed in peripheral tissues postnatally. This is a rare cause of 46,XY DSD, with less than 30 reported cases in the literature.

Presentation and Diagnosis

In XY individuals with female external genitalia, HSD17B3 deficiency may be difficult to recognize in infancy since they manifest no other significant clinical problems and near normal lab values. However, depending on the degree of residual enzyme activity, *HSD17B3* deficiency can cause a range of undervirilization of XY individuals at birth, from an empty bifid scrotum with perineoscrotal hypospadias to clitoromegaly and posterior labioscrotal fusion. Testes can be undescended or labial. Müllerian ducts are absent but interestingly, wolffian duct derivatives are present, despite the decreased testosterone production. During puberty, 46,XY patients may experience progressive adrenarche, including virilization, clitoral-phallic enlargement, muscle and breast development, testicular descent, and plasma T levels within the normal range of pubertal males.[103,104] To date, no affected 46,XX females have been reported. Biochemical changes in patients with *HSD17B3* mutations are outlined in Table 17.4.

Management

XY patients can be raised as females[96,98] or males. However, in one study, up to 40% of affected XY individuals who were raised as female successfully switched gender roles at puberty.[98] General management is covered below.

Defects in 5α-ReductaseType 2

Steroid 5α-reductase deficiency (SRD5A2) results from a defect in the enzyme converting testosterone to dihydrotestosterone (DHT). DHT is responsible for the differentiation of male external genitalia (Fig. 17.2). Peripheral conversion of testosterone to DHT is an irreversible reaction catalyzed by the two isoenzymes of 5α-reductase, SRD5A1 and SRD5A2. During puberty, the SRD5A1 isozyme is active in skin fibroblasts. During fetal development, SRD5A2 isozyme is expressed in the genital skin tissue and male accessory sex organs. Mutations in *SRD5A2* result in undermasculinized external genitalia (e.g., micropenis, perineal hypospadias). Examination of internal genitalia demonstrates normally differentiated wolffian ducts, with no müllerian structures, in addition to a blind vaginal pouch.[105,106] Adrenal and gonadal biosynthesis remains normal.

Presentation and Diagnosis

In 46,XY infants with mutations in *SRD5A2*, the degree of ambiguity ranges from isolated hypospadias to severe undermasculinization, complete with perineal hypospadias, micropenis, bifid scrotum, and hypoplastic prostate.[107] At puberty, 46,XY patients experience a surge of testosterone, which can cause development of male secondary sex characteristics, such as male body habitus, deepening of the voice, and penile enlargement. However, these individuals have unusually fine upper lip hair. Due to the underdevelopment of the prostate and seminal vesicles, their semen is highly viscous and their ejaculate volume is extremely low (<1 mL). Despite the low ejaculate volume, sperm counts are normal. Patients who are unambiguously female at birth often present in puberty with complaints of amenorrhea, a deepening voice, clitoromegaly, and increased musculature. In contrast to patients with 17β-HSD3 deficiency and androgen insensitivity syndrome, mutations in SRD5A2 do not develop gynecomastia during puberty. 46,XX females with SRD5A2 deficiency have normal sexual differentiation and fertility, but delayed puberty and sparse pubic hair.

Diagnosis of SRD5A2 deficiency during early infancy and puberty can be made based on an elevated ratio of testosterone to DHT (normal <30:1), either with or without human chorionic gonadotropin (hCG) stimulation.[105,108] DHT is low in infants but can reach near-normal levels during adolescence without treatment, presumably by peripheral SRD5A1 activity. If the diagnosis is suspected during pre-pubertal childhood or during adolescence, hCG stimulation is necessary to elicit the diagnostic hormone levels since the hypothalamo–pituitary–gonadal axis is inactive. Affected females are phenotypically normal, but have the same biochemical abnormalities (outlined in Table 17.4) as affected males.

Mutational analysis of the *SRD5A2* gene can be performed, and mutations have been reported in all five exons. 5-alpha reductase deficiency results from either homozygous or compound heterozygous mutations. To date, over 50 mutations in *SRD5A2* have been found, ranging from point mutations resulting in missense or nonsense mutations, deletions, and uniparental isodisomy.[109]

Management

This autosomal recessive disorder has been described in a number of consanguineous families in Turkey, New Guinea, Saudi Arabia, and the Dominican Republic. Many XY patients with this disorder are raised as female during childhood, but upon the onset of puberty identify with the male gender.[104,110,111] It is not clear why there is such a high prevalence of change in gender identity in this disorder, but it does not appear to be related to the degree of external genitalia masculinization at birth.[112] Topical DHT cream application in the pubic area promotes phallic growth prior to puberty and local application results in increased facial and body hair. These patients are not spontaneously fertile despite their normal sperm counts due to their highly viscous ejaculate. However, fertility is possible with surgical correction of the male ductal system or through assisted reproductive technology.

"Backdoor" Pathway to Fetal Testicular Androgen Production

An alternative pathway towards androgen synthesis has been described in familial and isolated human patients with 46,XY DSD. The severity of the disorder is dependent on the number of mutations in two genes that facilitate the conversion of 17-OH progesterone to DHT. The number of allelic mutations in both *AKR1C2* and *AKR1C4* determine the severity of the genital phenotype.[113]

Isolated 46,XY DSD with Apparently Normal Testosterone Levels

Mastermind-like domain containing 1 *(MAMLD1)* is expressed during fetal Leydig cell development and important in modulation of fetal testosterone synthesis. Nonsense mutations in *MAMLD1* have been identified in several patients with isolated 46,XY DSD with severe hypospadias and microphallus.[114,115] Mutations in *MAMLD1* result in a decrease in MAMLD1's transactivating properties[116] and a reduced testosterone and CYP17A1 expression *in vitro*.[117] Specific polymorphisms in *MAMLD1* have been associated with hypospadias.[118]

Defect in Androgen Activity

Complete and Partial Androgen Insensitivity Syndrome

In the presence of normal gonads and steroid biosynthesis, mutations in the steroid hormone receptors can also mute the effects of circulating steroid on specific tissues. Mutations in the androgen receptor (AR), which is located on the X-chromosome, result in androgen insensitivity syndrome (AIS). Both testosterone and DHT can bind to AR, and transcriptionally activate downstream genes. AR plays important roles in the differentiation of male internal and external genitalia and in the maintenance of spermatogenesis. Currently, there is an estimated incidence of 1:20,400 liveborn XY individuals, in whom more than 300 mutations have been identified.

AIS is characterized by a range of phenotypes in 46,XY individuals, from unambiguous XY female, termed complete AIS (CAIS) phenotypic XY males. In CAIS, the major reproductive manifestation is amenorrhea, typically presenting at puberty, and the associated infertility.[119,120] At the other extreme is minimal AIS (MAIS) in which phenotypically male patients often present with infertility, gynecomastia, or hypospadias. Patients who exhibit various degrees of XY ambiguity are referred to as partial AIS (PAIS). CAIS is generally associated with a complete absence of androgen binding and AR activation. Beyond this, there is almost no correlation between the percentage of residual AR activity and phenotype.[121] This suggests that there exist other genetic modifiers that modulate the phenotype. Even within families, the phenotype resulting from the same mutation can vary between PAIS and CAIS.[122,123]

The majority of mutations resulting in AIS are caused by single amino acid substitutions, which account for approximately 90% of the cases. Mutations are found throughout the gene, with the majority of mutations located within the ligand-binding domain. Exon 1 rarely possesses a causative mutation.[124] The majority of cases are inherited, but 30% of all AIS cases are *de novo* mutations which is consistent with other X-linked traits.[125]

In familial PAIS, and in both familial and sporadic CAIS, mutations in *AR* exonic sequences are found in 85% to 90% of cases.[122,124] In contrast, detectable mutations in *AR* account for only 10% to 15% of sporadic cases with hormonal profile and clinical presentation suggestive of *de novo* PAIS,[122] and the molecular defect in these cases is unknown. While the genotypes causing CAIS are consistent in phenotypic presentation, in PAIS there is phenotypic variability among affected individuals carrying the same mutation.

Presentation and Diagnosis

The phenotype of patients with PAIS is extremely heterogeneous. Patients present in infancy or childhood with variable degrees of virilization such as micropenis, cryptorchidism, and perineoscrotal hypospadias. Infants and children may present with unilateral or bilateral inguinal hernias. Testes are present and functional, producing high levels of testosterone and AMH resulting in variable wolffian derivative development and regression of müllerian structures in most patients.[126] In patients presenting at puberty, breast development and sparse pubic hair are suggestive of PAIS, and help differentiate it from a SRD5A2 deficiency.

CAIS usually presents at puberty with primary amenorrhea. Physical exam reveals a short, blind vagina, absent uterus, and sometimes palpable inguinal or labial testes. Testosterone dependent wolffian derivatives and prostate are absent or vestigial. Height, bone maturation, and breast development are normal but pubic and axillary hair, an androgen-mediated feature, is absent or sparse. Patients' identity and behavior are feminine without gender dysphoria.[127] Less commonly, CAIS may present in infancy with phenotypic female genitalia and inguinal or labial masses representing testes.

Diagnostic criteria for serum hormone levels are outlined in Table 17.4. In prepubertal children, basal luteinizing hormone (LH) and testosterone may be normal, but hCG stimulation elicits an exaggerated androgen response (a tripling instead of a doubling of testosterone and DHT). Exam and pelvic ultrasound reveals abdominal testes and the absence of müllerian structures.

Molecular genetic testing of the *AR* gene detects mutations in more than 95% of probands with CAIS. Molecular testing has been shown to be more consistent than biochemical functional assays of AR function which has been discredited based on high degree of variation due to biopsy site and testing laboratory.[128] PCR-based sequencing of *AR* exons 2 to 10 can be routinely performed,[129] as well as sequencing of the much longer exon 1, and some intronic and promoter regions. Prenatal testing by mutation analysis is available for families in which the AIS-causing allele has been identified in an affected family member.[122]

Luteinizing Hormone Receptor Defects

Leydig Cell Hypoplasia-Agenesis

Leyding Cell Hypoplasia (LCH) is a disorder caused by inactivating mutations of hCG/LH receptor (LHR) and characterized by impaired Leydig cell differentiation and testosterone production. HCG and LH activate a shared G protein-coupled hCG/LH receptor. *In utero*, placental hCG stimulates Leydig cells to produce testosterone, resulting in male internal and external genitalia. LH takes over during the third trimester of gestation and neonatal life to complete Leydig development and continue testosterone production.

Over 20 inactivating mutations of *LHR* have been identified scattered throughout the gene,[130,131] which cause variable degrees of loss of receptor activity. More severe mutations resulting in truncation, decreased surface expression, or decreased coupling efficiency are usually associated with unambiguous female phenotype. Partial inactivating mutations often result in an undervirilized phenotype such

as micropenis or hypospadias.[132] One specific mutation highlights the differential binding sites of hCG and LH to the same receptor. A splice variant resulting in the absence of exon 10 was described in an 18-year-old male who presented with normal male phenotype, pubertal delay, small testicles, and delayed bone age.[133] The receptor's response to hCG was normal, inferred from normal fetal sex development. However, LHR was not activated by LH resulting in delayed puberty and bone age.

Presentation and Diagnosis

Patients with severe inactivating mutations in *LHR* are often missed at birth and present in puberty with amenorrhea. Partially inactivating mutations present at birth, with undervirilization of the external genitals (e.g., micropenis, hypospadias, and cryptorchidism). In XX females, *LHR* mutations result in hypergonadotropic hypogonadism with primary amenorrhea or oligoamenorrhea, cystic ovaries, and infertility.[134-137] However, XX females will undergo spontaneous breast and pubic hair development during puberty.

Pelvic ultrasound demonstrates absence of uterus and fallopian tubes. To distinguish LCH from patients with XY gonadal dysgenesis, AMH is used as a marker of testicular Sertoli cell function and is normal-to-high in LCH patients and low-to-undetectable in XY GD patients.[138] Histological analysis of the testis shows normal Sertoli cells, hyalinized seminiferous tubules, without mature Leydig cells or spermatogenesis. Patients with partially inactivating mutations may show some early spermatogenesis, with arrest prior to spermiation. Therefore, patients have potential for fertility using assisted reproductive technology.

Biochemical changes are outlined in Table 17.4. Definitive diagnosis requires sequencing of the *LHR* gene for deletions, insertions, and point mutations.

Disorders of Anti-Müllerian Hormone or Anti-Müllerian Hormone Receptor

Persistent Müllerian Duct Syndrome

Unlike many of the conditions mentioned previously, there is no underdevelopment of the male internal genitalia, but rather the incomplete destruction of female precursors. Mutant *AMH* or AMH receptor type II (AMHR2) in XY individuals fail to cause müllerian duct regression, causing mixed (male and female) internal genitalia called persistent müllerian duct syndrome (PMDS). During the critical time in sex differentiation, between weeks 10 and 12 of gestation, testicular AMH causes the regression of the müllerian derivatives. However, inactivating mutations can prevent this regression, resulting in both male and female internal genitalia, but normal male external genitalia.

Presentation and Diagnosis

The diagnosis of PMDS is commonly made incidentally during abdominal imaging studies or surgical exploration of the abdomen.[139] XY patients with PMDS are phenotypically male. Aside from having a uterus and fallopian tubes in addition to the male external genitalia, they often have no clinical abnormalities. Therefore the true prevalence of PMDS is difficult to ascertain. The vast majority of cases of PMDS have mutations in the *AMH* or *AMHR2* in approximately equal proportions.[140,141] Inheritance is autosomal recessive for both loci.

Boys can also present with cryptorchidism (20%) or with an inguinal hernia[142] containing müllerian structures, but normal virilization.[141,143] The increased likelihood of abdominal testes in PMDS causes an increased incidence of gonadoblastoma.[144]

46,XX Disorders of Sex Development

46,XX Disorders of Gonadal Development

46,XX Testicular DSD

The spectrum of individuals who are XX and have a disorder of sex determination have a range of phenotypes, from phenotypic males to all degrees of genital ambiguity. Gonad histology ranges from immature testis to combinations of both testicular and ovarian tissue within an individual. Compared to XY DSD, the incidence of XX testicular DSD and XX ovotesticular DSD is estimated to be much less common, at 1:20,000. Eighty-five percent of all patients with XX testicular DSD are unambiguously male[145] and possess an Xp:Yp translocation including *SRY*. One-third of all recombination occurs at the *PRKX* locus hotspot on Xp22.3 and the Y-homologue *PRKY*.[146] In these cases, there is often skewed X-inactivation in favor of the X chromosome without Y-chromosome translocation,[145,147,148] cryptic mosaicism,[145,149] or duplications of the region of chromosome 17 with *SOX9*.[70,74,75,150] The rare families where XX DSD is inherited are typically *SRY*-negative, whose members can present with either 46,XX partial or complete testicular DSD, or ovotesticular DSD.[151]

Presentation and Diagnosis

In the classic medical literature, individuals with 46,XX DSD presenting with fully masculinized genitals have been referred to as *de la Chapelle syndrome*. While some characteristics of XX testicular DSD, such as small testes, azoospermia, and gynecomastia, and lack of secondary sex development are similar between 47,XXY (Klinefelter) and XX Testicular DSD,[148] these patients are neither short nor do they exhibit the same learning and behavioral issues. In XX Testicular DSD, phallus size is small to normal and patients exhibit normal sexual function.

The majority of cases are discovered during adolescence, because the majority of patients are unambiguously male. Occasionally, patients will present earlier with undervirilized genitalia. Typically, the presence of SRY is correlated with completely masculinized genitalia. The diagnosis of most XX testicular DSD patients is outlined below in 46,XX Testicular and Ovotesticular DSD.

46,XX Ovotesticular Disorder Sexual Development (DSD)

Ovotesticular DSD (previously known as *true hermaphrodites*) is defined by the presence of both testicular and ovarian gonadal tissue within a single individual. Testicular tissue is characterized by the presence of seminiferous tubules and ovarian tissue by the presence of follicles. The presence of both tissue types can be within the same gonad, which is known as an ovotestis. Within 46,XX Ovotesticular DSD, bilateral ovotestis occurs 20% of the time, an

ovotestis with a contralateral ovary or testis occurs in 50%, and an ovary and testis opposite each other occurs in 30% of the time.[152]

The predominant tissue within the individual gonad typically determines where in the abdominal or pelvic region the gonad can be found. Gonads with high percentage of testis material are typically found in the scrotal sac, while gonads with more ovarian tissue can be found in the abdomen.[152] Both side and the amount of testicular tissue determine the virilization of the internal and external genitalia. The degree of internal genitalia development correlates with the ipsilateral gonad and, like in cases of XY DSD, can be asymmetrical. The development of a uterus and fallopian tubes can occur in the presence of an ovary or ovotestis. However, the male wolffian structures require a well-formed testis to fully develop. External genitalia development is governed by the testis hormone production.

Patients with XX ovotesticular DSD lie on the spectrum with XX testicular DSD. Both of these can be caused by skewed X-inactivation of the *SRY* carrying X-chromosome,[147,153] or by cryptic mosaicism.[145,149,154] However, 90% of all XX ovotesticular DSD patients are not *SRY*-positive.

A fraction of ovotesticular DSD are found in patients with a 46,XY karyotype and in these, there have been two reports of mutations found in *SRY*.[49,152,154] Approximately one-third of ovotesticular DSD cases are mosaics, with one of the cell lines containing Yp material.[152,154] Some of these mosaics are 46,XX/46,XY and may actually represent chimeras.[155-159]

A form of syndromic ovotesticular DSD has been shown to be due to a single gene mutation in *RSPO1*[160] and associated with hyperkeratosis and squamous cell carcinoma.

Presentation

The majority of patients with ovotesticular DSD present in infancy due to underdeveloped genitalia. The phenotype of the internal and external genitalia is controlled by the gonad's hormonal status and often reflects the asymmetric mixture of ovarian and testicular tissue within the gonads. In all patients, müllerian duct regression is incomplete, yet the uterus remains immature, and a unicornate uterus is a common finding. However, more phenotypically female patients, the adnexa and vagina are generally better developed and approximately half of phenotypic females menstruate.[140,142]

Patients with a high degree of masculinization and male phenotype may have some uterine remnants, such as a prostatic utricle (prostatic vagina). Phenotypic males also tend to have bilateral palpable gonads, or at least one descended gonad. The undescended gonad may be an intra-abdominal ovary or an ovotestis and located at any point of the pathway of testicular descent.

In some rare cases, patients with unambiguous genitalia present with atypical secondary sex characteristic, opposite of their assigned gender. For example, at puberty, phenotypic female patients may experience clitoromegaly and deepening voice while phenotypic males may experience gynecomastia. In these cases, ultrasound may not fully demonstrate the testicular or gonadal nature of either gonad, but gonadal biopsy can definitively demonstrate the presence of both ovarian and testicular tissue.

Diagnosis of 46,XX Testicular and 46,XX Ovotesticular DSD

In males without genital ambiguity, a diagnosis is often made during an investigation of infertility or delayed puberty. Patients with XX Testicular DSD have hypergonadotropic hypogonadism with elevated follicle stimulating hormone (FSH) and LH, decreased T, DHT, and a less than twofold increase in response to the hCG-stimulation test. Unlike individuals with GD or XX Testicular DSD, the gonads of patients with ovotesticular DSD have some degree of function and therefore normal levels of FSH, LH, estradiol (E_2), T, and DHT. In children with 46,XX karyotype and genital ambiguity, the biochemical diagnostic criteria are the same as 46,XX testicular DSD. However, *SRY* is positive in only 10% of 46,XX ovotesticular DSD. Serum AMH levels are a good biochemical indicator of functioning testicular tissue, suggestive of XX testicular DSD or ovotesticular DSD.[138] Pelvic ultrasound shows absence of a uterus and semen analysis demonstrates normal semen volume with azoospermia. A combination of both male and female internal and external genitalia is suggestive of 46,XX ovotesticular DSD.

Genetic tests that should be performed are FISH for *SRY,* which is positive in 90% of phenotypically males with XX testicular DSD. The 10% of patients with XX testicular DSD who are negative for *SRY* should undergo further cytogenetic testing to explore the presence of *SOX9* promoter microduplication or microdeletion,[70,74,75] *SOX3* or *SOX3* promoter microduplication or microdeletion,[72] or cryptic mosaicism for Yp.

It is important to note that the only way to obtain definitive diagnosis of either ovotesticular or testicular DSD is by gonadal tissue confirmation in which both gonads are extensively examined for the presence of ovarian tissue. Complete absence of ovarian tissue can allow for definitive diagnosis of 46,XX Testicular DSD, while the slightest presence of ovarian tissue gives rise to 46,XX Ovotesticular DSD. If gonadal biopsy material is available, it should be tested for karyotype, cryptic mosaicism, and *SRY* mutations, as SRY expression in the gonads has been seen despite the lack of Yp in the karyotype.[145,149,161] Patients who are mosaic for 46,XX and 46,XY should be tested for potential chimerism particularly for those conceived with *in vitro* fertilization.

Management of 46,XX Testicular and Ovotesticular DSD

Of primary concern in patients with testicular or ovotesticular DSD are the surgical repair of issues, such as inguinal hernias, fistulas, and malignancies. Continuing management is determined by the gender assignment of these patients, which is discussed later in the chapter.

There is a 5% incidence of gonadal tumors in ovotesticular DSD,[162,163] which likely represents an increased risk from abdominal gonads possessing testicular tissue, as well as the increased risk of gonadoblastoma in dysgenic gonads with Yp material. Phenotypic male patients with XX testicular DSD, who are *SRY*-positive, are not at increased risk for gonadoblastoma, since they lack a complete Y chromosome. Some reports also indicate that the risk of breast cancer may be increased in 46,XX Testicular and Ovotesticular patients.[164,165]

Patients with 46,XX ovotesticular DSD with partially developed müllerian structures can also have ovarian follicles, with the potential to carry a biological pregnancy to

term.[152] There are eight reported pregnancies in patients with ovotesticular DSD. In all these patients, the karyotype was 46,XX, which contributes to the belief that patients with the Y chromosome cannot get pregnant. However, one case report describes a 20% 46,XX/80% 46,XY patient with ovotesticular DSD who carried a successful pregnancy to term.[163] Ovotesticular DSD males are generally azoospermic, but there have been infrequent cases of males with mature sperm,[152,166] and even more rare cases of ovotesticular DSD who have fathered children.[152]

Since the majority of individuals with XX testicular DSD carry the Xp:Yp translocation, paternal karyotype and FISH for *SRY* should also be performed to determine whether or not the father carries a balanced translocation, or if the translocation occurred in the germline, or *de novo*. Fathers who carry the balanced translocation can only produce offspring that are 46,XX *SRY*-positive testicular DSD or 46,XY *SRY*-negative complete gonadal dysgenesis offspring.

46,XX Gonadal Dysgenesis

The majority of cases of ovarian dysgenesis involve abnormal complements of X chromosomes in phenotypic females.[167,168] The most common of these is Turner syndrome, discussed earlier as a Sex Chromosome DSD. Impaired ovary development can occur with a normal female sex chromosome complement, referred to as 46,XX GD, which can occur as either an isolated entity or as part of a syndrome. Females possess normal female genitalia at birth, but remain sexually infantile and do not experience normal puberty. Ovarian failure with hypergonadotropic hypogonadism at puberty is highly suggestive of ovarian dysgenesis. Müllerian structures are normal, and gonadal histology reveals bilateral streaks. Patients often present with amenorrhea in adolescence of infertility in adulthood.

Several studies in familial ovarian dysgenesis have noted the frequent reports of consanguinity, suggesting that isolated 46,XX GD is inherited as an autosomal recessive condition.[167,169-171] Mutations in the gene for FSH receptor *(FSHR)* have been implicated in some cases,[170,172,173] but does not explain the phenotype in all populations studied.[174,175] Translocations involving the critical region Xq13.3-q26 have also been described.[176] The molecular basis for 46,XX GD remains unknown for the majority of patients.

46,XX Disorders of Sex Differentiation: Androgen Excess

High levels of intrauterine androgens or androgenic precursors result in masculinization of the 46,XX fetuses' internal and external genitalia. In these patients, development of the wolffian ducts and virilization of the external genitalia occur to varying degrees. Patients often present with clitoromegaly, "scrotalization" of the labia, urogenital sinus, and phallic urethra along with fully developed müllerian derivatives.

In XX infants with normally developed gonads and müllerian structures, the most common cause of genital ambiguity in newborns are the virilizing forms of CAH.[177] Inactivating mutations of any of the enzymes steroidogenic pathway, shown in Figure 17.9, are the most common cause of virilization in XX infants and are discussed later in the chapter. Rare mutations in *CYP11A1*, *STAR*, *HSD3B2*, and *HSD17B3* can result in CAH that can result in both 46,XY DSD or 46,XX DSD are described above in 46,XY DSD: Disorders in Androgen Biosynthesis.

There are three major sources of excess androgens *in utero:* fetal steroidogenesis, fetal-placental steroidogenesis, and maternal causes of excess androgens (i.e., iatrogenic, androgenic tumors).

Fetal Sources of Androgen Excess

Congenital Adrenal Hyperplasia

Congenital Adrenal Hyperplasia (CAH), depending on the enzyme implicated, can cause either 46,XY DSD or 46,XX DSD. 21-hydroxylase *(CYP21A2)* deficiency accounts for over 90% of CAH, and represents the most common etiology of ambiguous genitalia in the newborn.[177-179] CYP21A2 deficiency results in blockage of both aldosterone and cortisol biosynthetic pathways. The build-up of 17α-hydroxyprogesterone is shunted towards androgen biosynthesis, resulting in virilization of XX fetuses. The disease frequency in the general population is 1:15,000 people, but is much higher in certain ethnic groups, including Hispanics and Ashkenazi Jews.[180]

Mutations in 11β-hydroxylase *(CYP11B1)* account for another 5% of virilizing CAH.[177,181] Like in 21-hydroxylase deficiency, XX neonates are virilized, but XY neonates have normal genitalia. Blockage of CYP11B1 results in elevated levels of aldosterone and androgens, by shunting of cortisol precursors to biosynthesis of other hormones. Other adrenal causes of excess androgen, such as 3βHSD2 and P450 oxidoreductase defects, were discussed earlier in the chapter.

Presentation and Diagnosis

XX fetuses typically present at birth with ambiguous genitalia. XY fetuses do not exhibit any degree of undervirilization. However, there is a wide range of phenotypes, from the classical salt-wasting to simple virilizing to non-classical forms which present with hyperandrogenism and precocious puberty. There is a strong correlation between degree of enzymatic activity and the severity of clinical phenotype.[182] Figure 17.10 shows the wide-range of genital phenotypes in CAH.

XY individuals with 21-hydroxylase deficiencies are often not detected in the newborn period, unless accompanied by a salt-wasting crisis. XY patients often present with premature masculinization and accelerated physical development. If left untreated, there is premature fusion of epiphyses resulting in short stature.

Diagnosis of 21-hydroxylase deficiency can be initially ascertained by elevated 17-OH Progesterone. Biochemical changes are outlined in Table 17.4. Clinically 11-β-hydroxylase deficiency can be differentiated from 21-hydroxylase deficiency by the presence of hypertension with hypokalemic alkalosis. Molecular diagnosis can be ascertained by sequencing of the gene.

Management

Treatment for 21-hydroxylase defiency can begin *in utero* in order to prevent over virilization of XX fetuses. Due to the timing of genital development, oral treatment with dexamethasone begins at 4 weeks gestation, even before determination of sex and presence of disease genes in the fetus.

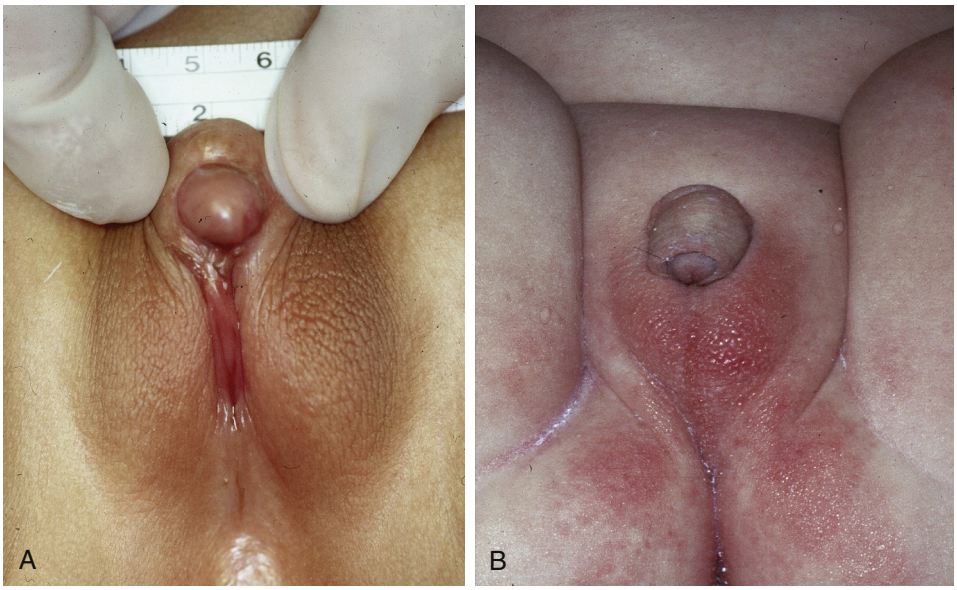


FIGURE 17.10 External genitalia of two CAH patients with CYP21A2 mutations with varying degree of virilization. **A**, The labia appear partially fused posteriorly, and show some rugae. The clitoris is moderately hypertrophic. **B**, The labia are completely fused and have a scrotal appearance. No gonads are palpated. The clitoris is very hypertrophic, and has a penis-like appearance.

Maternal dexamethasone can be continued until chorionic villous sampling or amniocentesis demonstrates XY karyotype or lack of homozygousity of the 21-hydroxylase mutation. If the fetus is XX and affected, treatment with oral dexamethasone continues until delivery.[183] This treatment remains controversial, because of a high likelihood of unnecessary treatment of unaffected fetuses, with little knowledge of long-term effects.

Newborns diagnosed with 21-hydroxylase deficiency should be monitored carefully for salt-wasting crises in early life. For newborns with either CYP21A2 or CYP11B1 deficiency, glucocorticoid replacement is essential to preventing adrenal crises and normalizing serum levels of steroidogenic precursors.

Fetal-Placental Causes of Androgen Excess

P450 Aromatase Deficiency

Aromatase *(CYP19A1)* catalyzes the conversion of androgens to estrogen. Mutations that affect aromatase activity have effects on both male and females. Estrogen is required for spermatogenesis in males and for the development of secondary sex characteristics in females.

Presentation and Diagnosis

The initial manifestation of aromatase deficiency is placental, with maternal virilization.[184-186] These mothers have elevated levels of androgenic precursors in their liver, causing their own virilization and that of their XX fetuses. Biochemical findings are outlined in Table 17.4. CAH is the major differential diagnosis considered and can be ruled out with ACTH-stimulation test showing increase in adrenal hormones and not androgens.

XX patients fail to undergo spontaneous puberty, and often have polycystic ovaries, increased virilization, and amenorrhea, without breast development.[184,187,188] XY males experience normal puberty but are infertile due to the lack of estrogen, which is essential to spermatogenesis.[186,189,190]

With regards to growth, both XX and XY patients do not experience a growth spurt during puberty and rather, experience linear growth. Patients end up tall but skeletal maturity is delayed and osteoporosis develops early.[186,191] Patients often complain of bone pain.[186] Refer to general management section later in the chapter for sex hormone replacement therapy at puberty.

P450 Oxidoreductase Deficiency

POR is a rare cause of ambiguous genitalia and 46,XX and 46,XY infants. Pathophysiology and presentation is described in detail in the 46,XY DSD section.

Maternal Etiologies of Androgen Excess

Maternal ingestion of androgens is a potential cause of virilization of XX newborns. However, present-day progestin containing oral contraceptives are not highly androgenic and this cause of XX virilization is rare.[192-194] Hormonally active tumors, such as luteomas are another uncommon causes of maternal virilization and ambiguous genitalia in an XX baby.[195] Rare cases of *hyperreactio luteinalis*, a cystic ovarian condition associated with virilization of the mother and fetus is associated with XX-virilization in 15% of cases.[195] While CAH causes the majority of cases of XX virilization, one should always consider oncological and iatrogenic causes of maternal and fetal virilization.

General Management for Patients with DSD

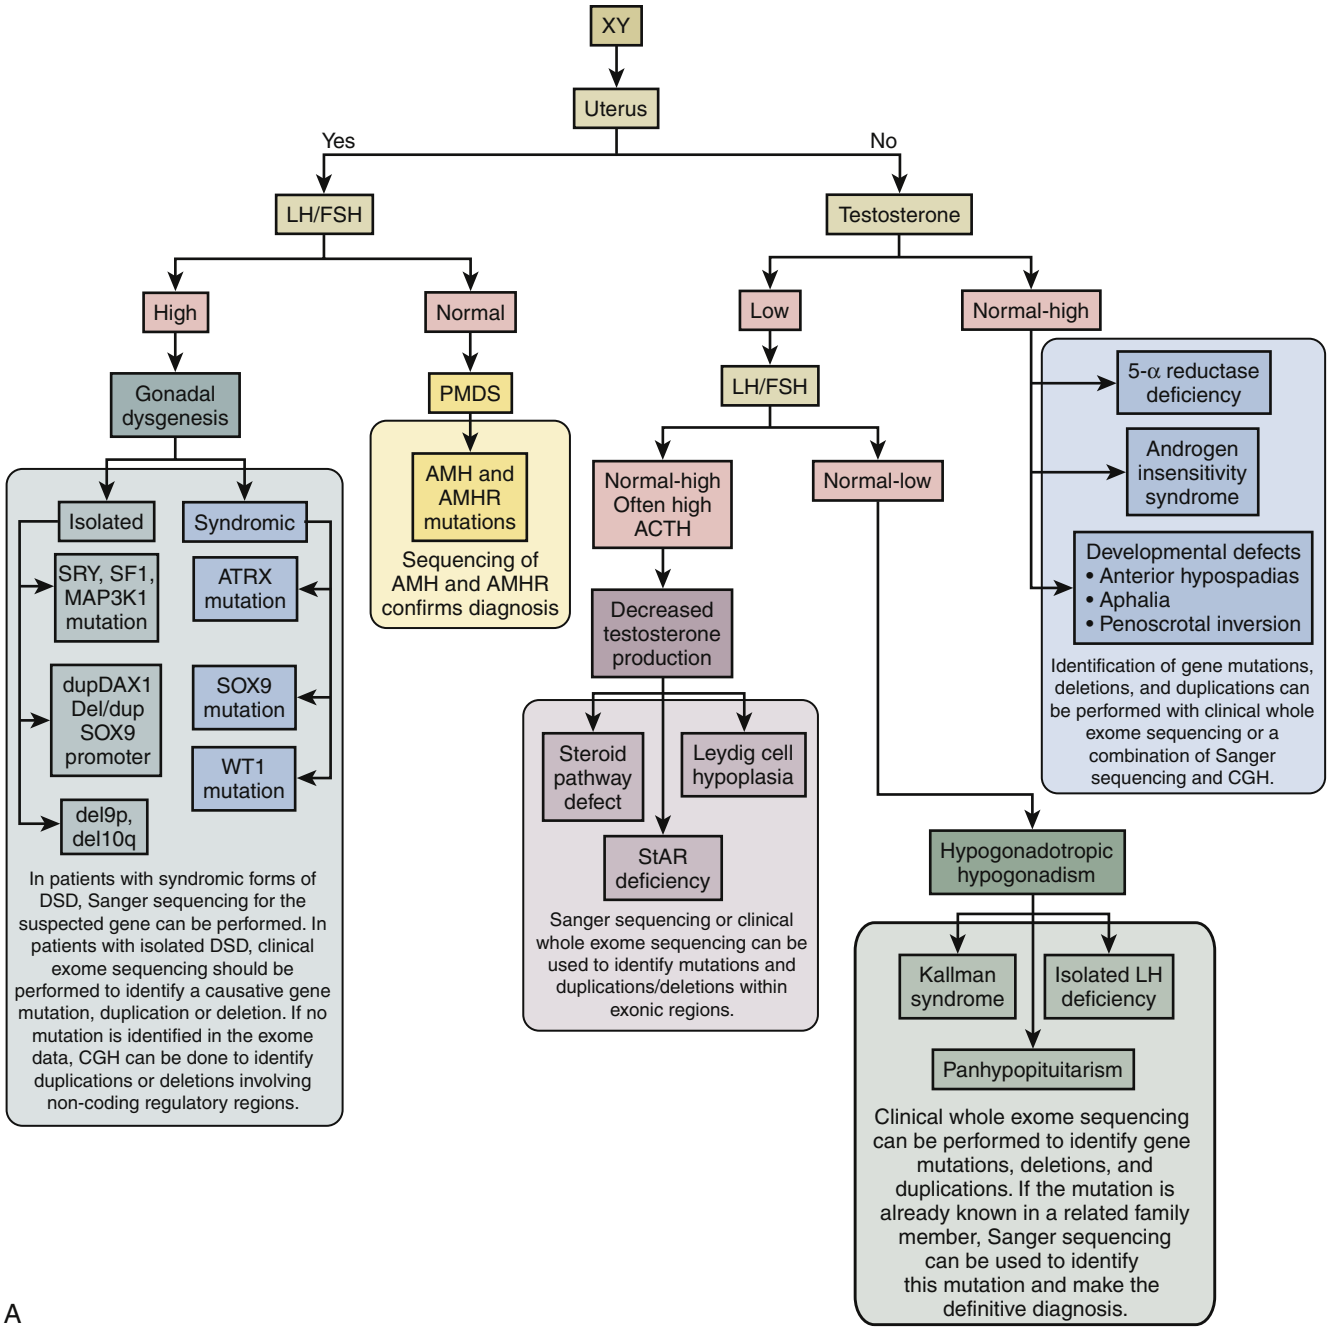
Patients with DSDs have grown up. What was viewed as a rare and unusual phenomenon, only seen in a few highly specialized academic centers, has become global. First, the issues generated by the management of DSDs have had wide exposure in the media, feeding societal debates on gender assignment and on patients' rights to be involved in medical decisions. The clinical issues that were limited to genital surgery have expanded to the management of low fertility, cancer, and psychosexual dysfunction in adulthood, thus informing knowledge of many other, more frequent conditions.

Multidisciplinary Approach

An essential aspect of care for children with DSDs is an experienced multidisciplinary team that typically includes an endocrinologist, a pediatric surgeon or urologist, a psychologist or psychiatrist, a gynecologist, a geneticist, a pediatrician or neonatologist, and, if available, a social worker, a nurse, and a medical ethicist.[196] Open communication between the team and the family, as well as participation in decision-making is essential. Support groups may have an important role in the delivery of care. Transition to adult care is also a key element of care. Fundamental concepts to initially establish with the family include the following: a child with a DSD has the potential to become a fully functional member of society; that DSD is not shameful; and that the situation is often complex and the best plan may not be obvious initially.

Diagnosis

Extraordinary progress has been made in the molecular and endocrine evaluation of patients with DSDs. After a thorough interview for family and prenatal history, the initial testing includes sex genotyping, which can be performed rapidly by FISH with X and Y probes, or by regular karyotype. It is followed by pelvic imaging (with ultrasound) increasingly being replaced by pelvic magnetic resonance imaging (MRI), and measurement of levels of 17-hydroxyprogesterone, testosterone, LH, FSH, AMH and electrolytes. Algorithms, such as the ones proposed in Figure 17.11, guide subsequent and more specialized investigation.



The clinical availability of next generation sequencing allows for the rapid sequencing of all known genes important in disorders of sex development. These large-scale approaches can be performed in a targeted manner, only sequencing the genes known to cause DSD.[197] Such approaches can be used to look for gene mutations, copy number variations, and sex chromosome copy number. Effectively, this high-throughput sequencing approach can combine the three major genetic tests performed in DSD patients: the sex chromosome karyotype, comparative genomic hybridization (CGH), and single gene sequencing. For practical purposes, karyotype and CGH are still performed as separate tests, but as turn around time and costs of whole exome and whole genome sequencing decrease, it is anticipated that high-throughput sequencing will be the primary test for diagnosis of DSD. In addition, high-throughput sequencing provides a more comprehensive and rapid diagnosis than single gene sequencing approaches. In the same vein, whole exome sequencing, which sequences nearly all the known exons within the human genome, can be performed and can identify mutations in known genes as well as novel mutations. In whole exome sequencing approaches, bioinformatics filtering can initially allow for the focus to remain on known genes that cause DSD. However, if no mutations are identified in known DSD genes, one can examine the entire genome in search of rare mutations in novel genes involved in DSD. The cost of whole exome approaches is comparable to the cost of sequencing a single gene. Genetic mutations underlying a clinically defined disorder, such as 46,XY gonadal dysgenesis (which can result from mutations in *SRY*, *SF1/NR5A1*, *MAP3K1*, or copy number variations in 9p and 10q) would require multiple tests, which is costly, time consuming, and inefficient. High throughput sequencing diagnostic approaches provide an accelerated time to diagnosis and decreases the risk of diagnostic uncertainty that often accompanies a clinical diagnosis of DSD.

Gender Assignment

Until the mid-1950s, the medical management of individuals with DSD was based on the assumption that the "true sex" was equivalent to the sex of the gonads. Human sexual anatomy was indeed classified in 5 categories in the 19th century: (1) male and (2) female (with typical feminine or masculine external genitalia, respectively; (3) male and (4) female pseudohermaphrodites (with ambiguous genitalia and presence of testes or ovaries, respectively); and (5) true hermaphrodites (with both testicular and ovarian tissue).[198] It was assumed that a person's identification as male or female would naturally conform to ''true sex.''

In the late 1950s, however, under the influence of psychologist John Money and pediatric endocrinologist Lawson Wilkins, gender assignment began to be influenced by the "optimal gender" principle. It became standard practice in the 1970s, and was only challenged recently, starting in the mid-1990s.

The "optimal gender" approach considered multiple aspects of outcome, giving greatest consideration to the potential for complete sexual functioning. It is based on the two assumptions that gender identity is not firmly established at birth, but rather is influenced by socialization and sex of rearing, and that stabilization of gender identity and favorable psychological outcome depends on the congruence between genital appearance and the assigned gender. The clinical consequences of the "optimal gender policy" are that gender should be assigned as early as possible, during a window of gender flexibility that ends at 18 to 24 months of age; reconstructive genital surgery should be performed equally early to match the chosen gender; the assignment should be to the gender that carries the best prognosis for reproductive and sexual function; and uncertainty for parents and health care providers about the gender of rearing should be minimized. Recent challenges of this paradigm view the determinant of gender identity and gender role as biological (with prenatal androgens as the best candidate),[199] and the appearance of genitals as a reflection of brain masculinization, and not the reverse. What was seen as an absolute requirement for gender assignment (a typical penis and scrotum for males, a typical clitoris and labia for females) was questioned by outcome studies of XY patients born with cloacal exstrophy, a complex abdominal malformation resulting in a *de facto* absence of functional penis, but normal testicular function. Only 5 out of 14 patients assigned female at birth had a clear female gender identity at follow-up in their teen years.[200] On balance, cases of ablatio penis in early childhood caused by botched circumcision have had diverse outcomes. Although the most famous example of the literature (the "John-Joan" case) which prompted the recent challenges to the optimal gender policy ended in a disastrous outcome (gender dysphoria, and ultimately suicide),[201] another case resulted in a clear, stable female gender identity in an otherwise bisexual woman with a history

A

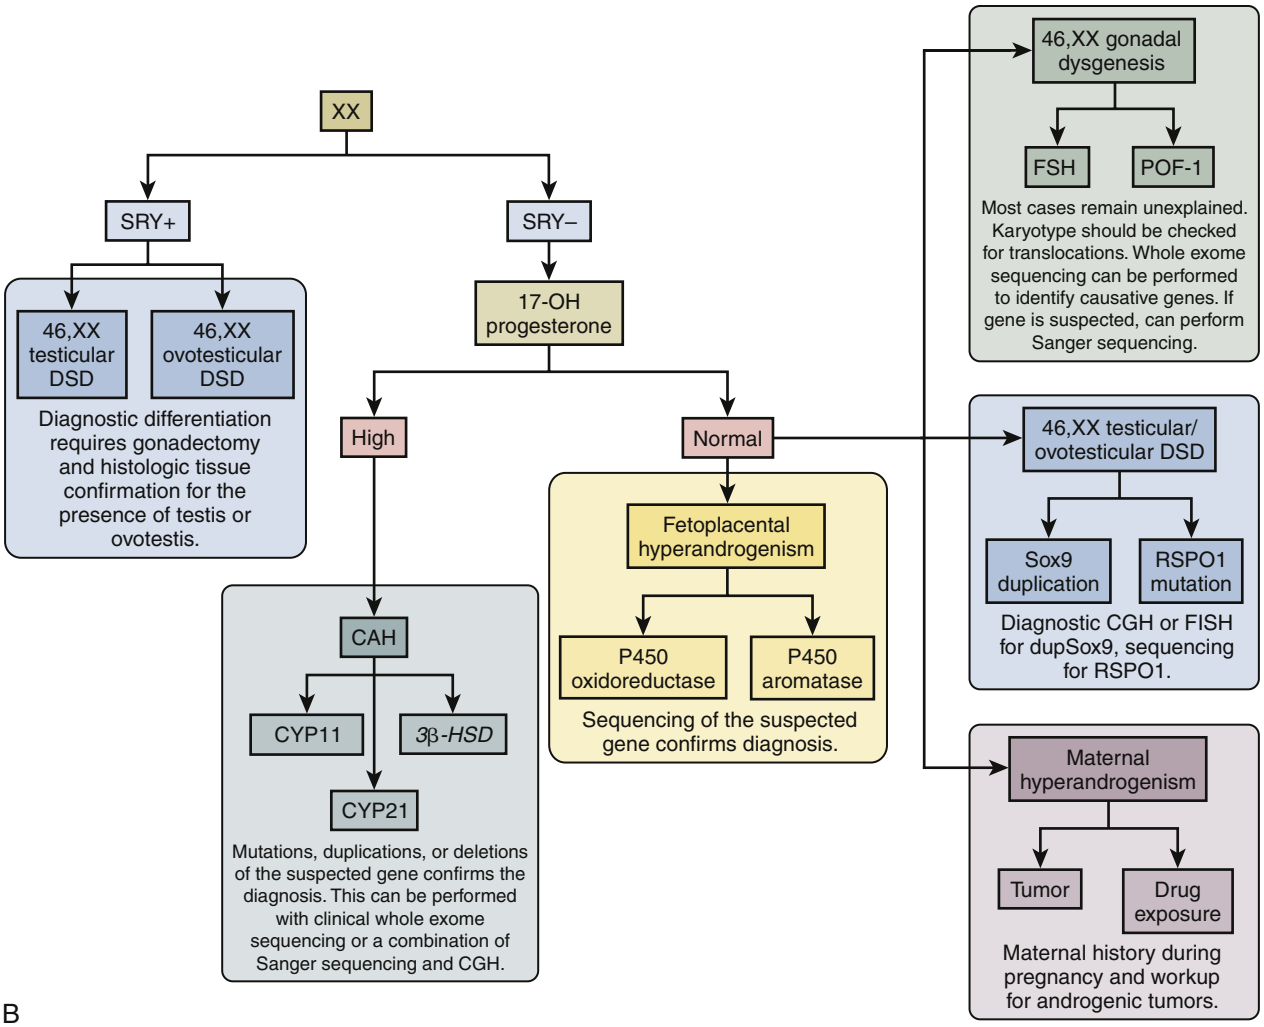


FIGURE 17.11 A, Diagnostic flowchart of the major disorders of sexual development in undervirilized XY individuals.

of "tomboyism" during childhood, who requested on two occasions (at ages 16 and 26) a vaginoplasty. This shows that female gender identity can develop in a genetic male.

So, what is the best way to assign gender in this post-"optimal gender" era? Just like before, based on the medical literature and outcome studies for specific diagnoses. Considerations of chromosomal constitution, hormonal levels, potential fertility, and sexual function, are, as always, quite important. The main difference is that early genital surgery is not necessarily directly linked to the gender assignment decision. One clear recommendation is that all individuals should receive a gender assignment early on.

Genital Surgery

As seen above, the traditional perspective, at least since the 1950s, has been to provide an anatomy that matches the sex of rearing. The goal has been to influence gender identity, provide a positive psychological adjustment and allow sexual intercourse. In this model, the decision-makers are the physician and the family, since the genital surgery has to happen during the early period of gender flexibility. This traditional paradigm has been challenged in the 1990s, initially by patients' advocacy groups, then by physicians,[202] arguing that the rationale for early genital surgery was the comfort of others, not necessarily the patient, and that there are negative consequences if the assigned gender does

B

FIGURE 17.11—cont'd **B**, Diagnostic flowchart of the major disorders of sexual development in XX individuals. *(Adapted from Fleming A, Vilain E. The Endless Quest for Sex Determination Genes.* Clin Genet *67:15–25, 2004.)*

not correspond to the ultimate gender identity, and if sexual function is impaired as a consequence of the surgery. In the challenging model, the decision-maker is the patient, when old enough. The 2005 consensus statement on DSD provides guidelines to a more cautious approach to surgery. The statement requires that the surgeons outline the consequences of surgery from infancy to adulthood, and that only surgeons with specific training in the care of DSD perform genital surgeries. It is also argued that clitoral surgery should only be considered in severe cases (Prader III to V), that no vaginoplasty in patients with short or absent vaginas be performed in infancy, and that no vaginal dilatation be performed before puberty.

Hormonal Therapy

Hormonal therapy may be used for several purposes. In the case of classic CAH, glucocorticoids and mineralocorticoids are used as a life-saving replacement therapy. In the cases of DSDs raised as males, testosterone may be used as a way to increase penile tissue growth, as well as to induce puberty. In the cases of DSD raised as females, estrogens are used for induction of puberty and bone protection.

Glucocorticoid Replacement Therapy

In CAH, it is in the form of hydrocortisone (10-20 mg/m^2 per 24 hours) given orally in two or three doses per day. The treatment needs to provide sufficient hormone to replace the adrenal steroids and suppress the adrenal androgens, and not too much to avoid iatrogenic Cushing's syndrome and its effect on growth rate and bone maturation. Daily doses are increased by two to three times in periods of stress (fever or surgery for instance).

More potent glucocorticoids (e.g., prednisone) can be used in adulthood, after growth is complete.

Mineralocorticoid Replacement Therapy

In the salt-wasting form of CAH, treatment with 9-fludrohydrocortisone (Florinef®) (0.05 to 0.3 mg/day PO) and sodium chloride (1-3 g/day in supplement) is often required in early infancy with maintenance doses slightly less. This is given in addition to the glucocorticoid therapy.

Testosterone Replacement Therapy

Management of individuals with testosterone deficiency (e.g., 46,XX testicular DSD or Klinefelter syndrome)

includes the initiation of low-dose testosterone therapy after age 14. Testosterone enanthate is given intramuscular (IM) every 3 to 4 weeks, starting at 100 mg and increasing by 50 mg every 6 months to 200 to 400 mg. Initial high doses of testosterone should be avoided to prevent priapism. The treatment should plateau, in adulthood, at the best possible dosage, typically between 50 and 400 mg every 2 to 4 weeks.

If an individual has short stature and is eligible for growth hormone therapy, testosterone therapy should be either

Table 17.5 Fertility in Patients with Disorders of Sexual Development

Disorder		Level of Fertility	Potential use of Assisted Reproductive Technology
Sex Chromosomes Disorder of Sex Development	Turner syndrome	Only 2%-5% of Turner patients are spontaneously fertile[205] There have been ~170 reported spontaneous pregnancies in patients with mosaic variants of Turner.[206] Recently 2 cases of spontaneous pregnancy in non-mosaic variants were reported.[207,208] 30%-60% pregnancy rates after oocyte donation; high risk of pregnancy complications (i.e., hypertension, pre-eclapmsia)[209]	Cryopreservation of follicles in youth Single embryo transfer from donor oocytes
	Klinefelter syndrome	3 case reports of spontaneous pregnancy with 47,XXY patients[210-212] 43 reports of pregnancy after ICSI leading to liveborn children[213]	Cryopreservation of sperm Testicular sperm extraction (TSE) ICSI
46,XY DSD: Testes Development	46,XY Gonadal Dysgenesis (pure, partial, mixed)	7 case reports of successful pregnancy after oocyte donation in patients with complete 46,XY GD[214-220] No reports in 46,XY partial or mixed GD. Patients with mixed GD are usually infertile.	Single embryo transfer from donor oocytes
	Testicular Regression syndrome	Infertile	None
46,XY DSD: Adrenal Synthesis and Action	Disorders of Androgen Biosynthesis	In XY patients with forms of CAH, infertility is often caused by testicular adrenal rest tumours.[221] 3B-HSD: XY: Lower levels of spermatogenesis; 2 case reports of severely affected male fathering 2 children. Fertility in XX females unknown[222,223]	Glucocorticoid therapy to optimize fertility; ICSI and *in vitro* fertilization
	Leydig Cell Hypoplasia	Untreated patients are azoospermic and infertile.[224]	Unknown
	5-α Reductase Deficiency	Fertility is possible with surgical reconstruction of the male ductal system.[225]	ICSI
	Complete/Partial Androgen Insensitivity syndrome	Male infertility; no uterus and therefore cannot carry pregnancy	
	Persistant Müllerian Duct syndrome	In patients with cryptorchidism, fertility is better preserved in adulthood if orchiopexy is done prior to age 2.[226]	ICSI
46,XX DSD: Ovarian Determination	XX Testicular DSD XX Ovotesticular DSD	Case report of patients with 46, ovotesticular DSD with 1 ovary and 1 ovotestis who became spontaneously pregnant after removal of ovotestis.[227,228] Fertility and pregnancy has been reported after removal of testicular portion of ovotestis removed.[228,229]	Potential for biological children using *in vitro* fertilization techniques or selective removal of only testicular tissue to stimulate spontaneous ovulation
46,XX DSD: Adrenal Excess	Congenital Adrenal hyperplasia 21-Hydroxylase 11-β Hydroxylase	In XX patients, excess adrenal steroids, ovarian hyperandrogenism, PCOS, ovarian adrenal rest tumors, neuroendocrine factors, genital surgery, and psychological factors contribute to decrease in fertility. Normalization of hormonal factors can increase chance for spontaneous pregnancy in these women.[221,231]	Long acting glucocorticoids can be used to regulate menstrual cycles and maximize fertility.[221] ICSI and *in vitro* for patients who cannot conceive spontaneously. Single embryo transfer in patients with stenotic vaginas due to genital surgery.
	P450 Aromatase P450 Oxidoreductase	XX patients have polycystic ovaries and do not undergo spontaneous puberty.[232] XY individuals undergo normal puberty but are sterile, due to the lack of estrogen. No reports of spontaneous pregnancy to date, however long-term studies of these patients have not been completed.	In theory, single embryo transfers (from biological or donor oocytes) for XX, DSD patients.
	Maternal Sources of DSD	No known effect on adult fertility. Fertility in XX individuals is affected by management of ambiguous genitalia, such as genital surgery, and psychological factors.

delayed or given at lower doses initially in order to maximize the growth potential. Alternative delivery systems to injections that result in a more stable dosing include transdermal patches (scrotal and nonscrotal) and transdermal gels. Testosterone-containing gels have an increased risk of interpersonal transfer which can be reduced by the use of new hydroalcoholic gels.[203]

Estrogen Therapy

In order to develop and maintain secondary sexual characteristics in women who are hypogonadic (or in postgonadectomy CAIS patients) and to prevent osteoporosis, estrogens are started at the lowest available dose and progressively increased (starting, for instance, at 0.3 mg PO per day of conjugated estrogens and increasing to 0.625 mg/day). Other delivery systems include transdermal patches.

Disclosure

The traditional paradigm of the "optimal gender" policy calls to limit disclosure, based on the rationale that it prevents gender identity confusion, within the reasoning that nurture influences gender identity. The challenging view is full disclosure, in order to support patient autonomy, and with the rationale to prevent secrecy and shame. Studies of chronic medical disorders and of adoptees shows that disclosure is associated with enhanced psychosocial adaptation.[1] Although there is no rule about what age to fully disclose a condition, it is recommended to proceed gradually and recurrently with children, and adapt disclosure and cognitive and psychological development.[204]

Mental Health

Psychological care should be integral to the medical management of patients with DSD. Multidisciplinary teams caring for children with DSD should include a mental health professional, who should inform the decisions of gender assignment and re-assignment, and timing of surgery. Although atypical gender-role behavior is more common in children with DSD, it should not be taken as an indicator for gender re-assignment. The mental health professional should help parents cope with their child's condition, should help the process of full disclosure and, most importantly, should provide long-term behavioral support to the patient. This includes support for quality of life items such as falling in love, dating, intimacy, sexual functioning, ability to build relationships and raise children.

Fertility

Not long ago, infertility was seen as an immutable feature of DSD. Advances in assisted reproductive technologies (ART) have changed this view. Some patients with DSDs, who were previously infertile or subfertile have the opportunity to have biological children. If germ cells are present, sperm or oocytes can be biopsied from the gonads and used in intracytoplasmic sperm injection (ICSI) and *in vitro* fertilization. In Table 17.5, we have outlined the fertility levels and ART options for patients with various DSDs.

The ability to produce biological offspring in females is solely dependent on the presence of oocytes. Adolescent patients who undergo premature ovarian failure (i.e., Turner syndrome) can cryopreserve their oocytes for future use. Furthermore, phenotypic female patients with a uterus can undergo donor embryo transfer with a 30% rate of pregnancy. For phenotypic female patients, carrying a pregnancy to term is associated with higher risk of maternal complications and therefore should be followed closely by an obstetrician specializing in high-risk patients.

Cancer

DSD conditions are accompanied by variable risks of germ cell tumor, which should be taken into consideration in the long-term management of these patients. Higher risks of gonadal tumors have been shown in gonadal dysgenesis positive for the presence of TSPY (testis-specific protein Y encoded) on the Y chromosome, and for partial androgen insensitivity syndromes with intraabdominal gonads. Lower risks are observed in ovotesticular DSD and complete androgen insensitivity syndrome. A review of the risk of germ cell tumor according to the diagnosis is provided in Table 17.6.

Table 17.6 Gonadoblastoma Risk

Risk Group	Disorder	Malignancy Risk, %	Recommended Action	Patients, n	Studies, n
High	GD* (+Y)† intraabdominal	15-35	Gonadectomy	12	>350
	PAIS nonscrotal	50	Gonadectomy	2	24
	Fraisier	60	Gonadectomy	1	15
	Denys-Drash (+Y)	40	Gonadectomy	1	5
Intermediate	Turner (+Y)	12	Gonadectomy	11	43
	17β-hydroxysteroid	28	Watchful waiting	2	7
Low	CAIS	2	Biopsy and possible	2	55
	Ovotesticular DSD	3	gonadectomy	3	426
	Turner (-Y)	11	Testicular tissue removal	11	557
			None		
No (?)	5α RD2	1	Unresolved	1	3
	Leydig Cell Hypoplasia	1	Unresolved	1	2

Adapted from Lee PA, et al. Consensus statement on management of intersex disorders. International Consensus Conference on Intersex. *Pediatrics* **118**(2):e488–500, 2006.

*Gonadal dysgenesis (including not further specified 46,XY, 45,X/46,XY, mixed, partial, complete).

†GBY region positive, including the TSPY (testis-specific protein Y encoded) gene.

Patient-Centered Care

DSD conditions should be managed in a patient-centered model of care. In this model, open communication with patients and family should be promoted, especially at times of decision-making. Gender change should be supported by the multi-disciplinary team, as needed, in accord with patient's wishes. The consensus statement also calls for a limit on genital exams and on medical photography.

CHAPTER 18

Puberty: Gonadarche and Adrenarche

Selma Feldman Witchel
Tony M. Plant

Puberty in humans is defined as the period of first becoming capable of reproducing, and is marked by maturation of the genital organs, development of secondary sex characteristics, acceleration in linear growth velocity, changes in affect and, in the female, the occurrence of menarche.[1] In humans, the transition into puberty is driven by two physiological processes: gonadarche and adrenarche. *Gonadarche* comprises growth and maturation of the gonads and is associated with increased secretion of sex steroids and with the initiation of folliculogenesis and ovulation in the female and spermatogenesis in the male. Gonadarche leads to thelarche and menarche in girls and testicular enlargement in boys.

Adrenarche, which typically precedes gonadarche,[2] comprises maturation of the adrenal cortex associated with increased secretion of adrenal androgens—namely, dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), and androstenedione—and leads to the appearance of sexual hair (pubarche). Adrenarche occurring late in prepubertal development appears to be peculiar to our own species and to the great apes[3] and, in humans, the absence of adrenarche does not prevent gonadarche or the attainment of fertility.[4,5]

The age at onset of puberty and the tempo at which puberty progresses is dependent on many factors. In girls, increased ovarian and adrenal sex steroid secretion leads to the physical manifestations of puberty, thelarche, and pubarche. In general, these changes occur between 8 and 13 years of age. The mean age at menarche among multiple ethnic groups is between 12 and 13 years old.[6] In boys, the earliest physical manifestation of puberty is an increase in testicular volume, and this usually occurs between 9 and 14 years of age.

Traditionally, the diagnosis of precocious puberty is considered when signs of puberty develop prior to 8 years of age in girls and 9.5 years in boys, but these criteria should be used as guidelines to complement the evaluation of individual patients.[7] For girls, the absence of thelarche or menarche by age 13 and 16 years, respectively, is considered to be delayed puberty.[8] For boys, delayed puberty is defined as absence of testicular enlargement by age 14 years.

While the mechanism underlying the onset of adrenarche remains to be elucidated, it is now established that gonadarche results from the resurgence of activity in the hypothalamic-pituitary axis, which has been relatively quiescent since early childhood. The neuroendocrine regulation of gonadarche in man is similar to that observed in other higher primates,[5,9] and nonhuman primates (in particular the rhesus monkey) have been extensively employed as paradigms for the study of human puberty. Subsequently, our discussion of the control of the onset of gonadarche will be based on both the human and nonhuman primate literature.

Stages of Pubertal Development, Secular Trends, and Racial and Ethnic Differences

Pubertal Staging

For both sexes, the genital and pubic hair changes that unfold at puberty are classified into five stages: stage 1 is prepubertal and stage 5 is adult (Fig. 18.1; Table 18.1). These physical changes may either be the result of gonadarche (as in the case of breast or testicular enlargement) or adrenarche (as in the case of pubic hair development). Although the physical sequelae of gonadarche and adrenarche generally occur concomitantly a discordance of the two processes may also occur in normal development.

Increased estrogen secretion promotes breast development in girls. The development of breast buds with increased areolar diameter is considered to be stage 2; greater enlargement of the breasts occurs in stage 3, accompanied by increased pigmentation of the areolae and nipples. During stage 4, the areolae are mounded above the breast tissue. Recession of the areola to the general breast contour represents breast stage 5. Palpation of the breast is necessary to better differentiate between breast tissue and lipomastia. Additional effects of estrogen at this stage of development include cornification of the vaginal mucosa, uterine growth, and morphogenesis of an adult female body habitus.

Menarche follows an anovulatory cycle and generally occurs 2 to 3 years after the onset of breast development. Menstrual cycles during the first year after menarche are typically irregular and anovulatory, with most ranging in duration from 21 to 45 days. Within 5 years of menarche, most cycles are regular and range from 21 to 35 days. Although primordial and pre-antral follicles predominate during the prepubertal years, one should note that small antral follicles develop during this phase of maturation. During the early postmenarcheal period, ovarian morphology on ultrasound differs from that observed in older women. Specifically, multicystic ovaries and

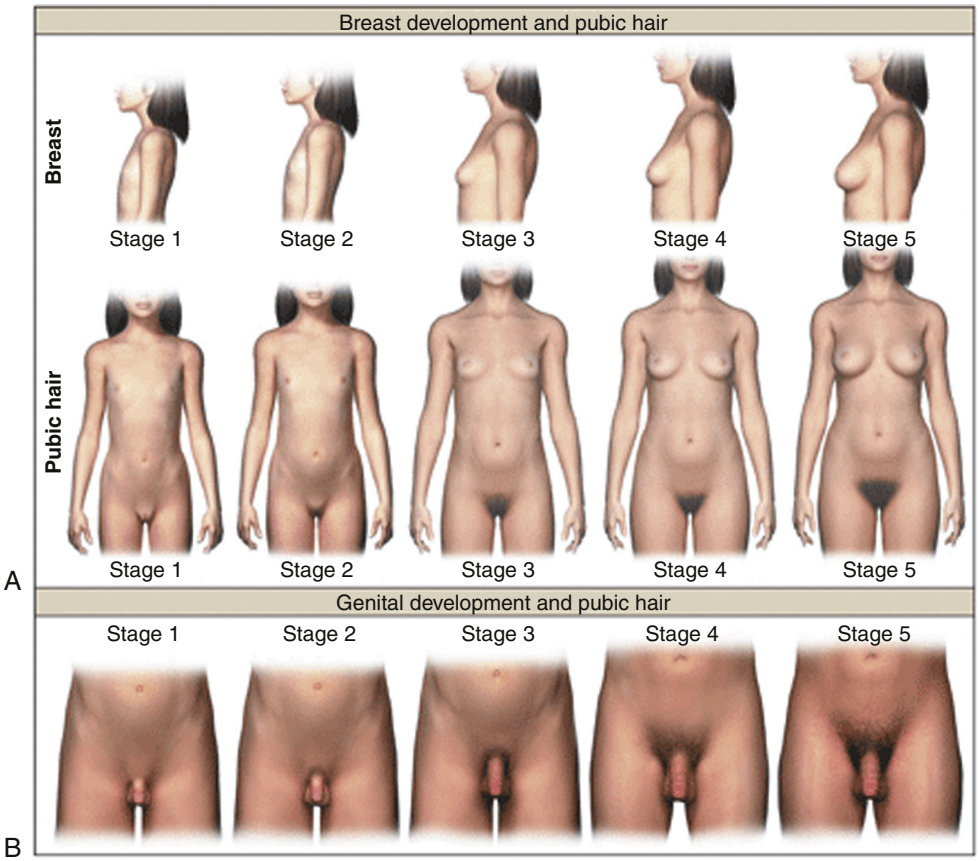

FIGURE 18.1 Pubertal Rating According to Tanner Stages. **A**, Breast development in girls is rated from 1 (prepubertal) to 5 (adult). Stage 2 breast development (appearance of breast bud) marks the onset of gonadarche. For girls, pubic hair stages are rated from 1 (prepubertal) to 5 (adult). Stage 2 marks the onset of adrenarche. **B**, Genital development in boys is rated from 1 (prepubertal) to 5 (adult). Stage 2 genital development, characterized by enlargement of the testes and scrotum accompanied by a change in the texture of the scrotal skin, marks the onset of gonadarche. Pubic hair development in boys is rated from stage 1 (prepubertal) to stage 5 (adult). Stage 2 represents the onset of pubarche, which can reflect adrenarche or gonadarche. Although pubic hair and genital or breast development are represented as synchronous in the figure, they do not necessarily take place simultaneously and should be scored separately. In normal boys, stage 2 pubic hair generally develops 1 to 1.5 years after stage 2 genital development. *(From Carel JC, Léger J. Clinical practice. Precocious puberty.* N Engl J Med. *358:2366;2008. Reproduced with permission of the New England Journal of Medicine.)*

Table 18.1 Stages of Pubertal Development (Tanner)

Girls

Stage	*Breast*	*Pubic Hair*
1	Prepubertal	No pigmented hair
2	Budding with larger areolae	Small amount of coarse, pigmented hair mostly along labia majora
3	Enlargement of breast and areolae	Spread of coarse, pigmented hair over mons pubis
4	Secondary mound of areolae	Almost adult pattern
5	Mature contour	Adult pattern

Boys

Stage	*Genitalia*	*Pubic Hair*	**Testicular Volume**
1	Prepubertal	No pigmented hair	<3 mL
2	Thinning and darkening of scrotum, increased size of penis	Small amount of coarse, pigmented hair at base of penis	3-8 mL
3	Increased diameter of penis	Coarse, pigmented hair extends above penis	10-15 mL
4	Increased diameter and length of penis	Almost adult pattern	15-20 mL
5	Adult size and shape	Adult pattern	>25 mL

increased ovarian volume have been observed using transabdominal ultrasound.[10,11]

In girls, increased adrenal androgen secretion is considered to be responsible for the development of darker hairs along the labia, which is classified as pubic hair stage 2. The hair becomes darker and coarser during pubic hair stage 3, spreading over the pubic symphysis with gradual progression to a full female escutcheon. Apocrine odor may precede or accompany the development of pubic hair. Associated findings include axillary hair, acne, and oiliness of skin and hair.

For boys, an increase in testicular volume and enlargement of the scrotum is considered genital stage 2. At stage 2, the testes are approximately 4 to 8 mL in volume with the longest axis being approximately 2.5 cm. The volume of the mature human testis is approximately 20 to 30 mL and represents increased growth of the seminiferous tubule due to Sertoli cell proliferation and differentiation, and initiation of spermatogenesis. At genital stage 3, further growth of the testes has occurred, and the length and diameter of the penis has increased. At genital stage 4, penile size has increased and the scrotal skin has become darkened. Palpation and use of orchidometer is preferable to inspection. Male pubic hair stage 2 consists of downy hair at the base of the penis. For pubic hair stage 3, the hair is longer, darker, and extends over the junction of the pubic bones. For pubic hair stage 4, the extent of hair has increased, but has not yet achieved the adult male escutcheon. Other secondary sexual characteristics in boys include axillary hair, increased size of the larynx, deepening of the voice, increased bone mass, and increased muscle strength. Approximately 3 years after the appearance of pubic hair, terminal hair appears in androgen-dependent regions on the face and trunk where it may develop for years thereafter. There is considerable variation in the distribution and density of beard, chest, abdominal, and back hair, presumably reflecting genetic differences. The appearance of spermatozoa in early morning urine specimens (spermaturia) occurs during genital stage 3. Gynecomastia is observed in 50% of boys.[12] Typically, this is most prominent in midpuberty when the ratio of circulating concentrations of estradiol to testosterone is relatively high. In most instances, gynecomastia resolves spontaneously by 16 years of age.

The pubertal growth spurt in girls occurs concurrently with the onset of breast development. Usually only 4 to 6 cm of growth occur after menarche. The pubertal growth spurt in boys, with an average height velocity of 9.5 cm per year, occurs around genital stages 3 and 4. In general, the age at peak height velocity shows an inverse relationship with the magnitude of the growth spurt.[13,14] Linear growth is approximately 99% complete for girls at a bone age of 15 years and for boys at a bone age of 17 years.[15]

Breast development in girls and testicular enlargement for boys generally precede pubic hair development. Yet, the tempo for pubic hair development is faster such that synchrony between genital and pubic hair development occurs during the later stages of puberty.[16] Schemata for the temporal development of the secondary sexual characteristic and their relationship to growth velocity is shown for girls and boys in Figures 18.2 and 18.3, respectively.

Secular Trends and Racial and Ethnic Differences in the Onset and Tempo of Puberty

Reports of secular changes in the onset of puberty have focused on girls. Available historical data indicate that there was a decline in the age of menarche in Europe and North America from the early nineteenth century (16 to 17 years of age) to the latter half of the twentieth century (13 years of age). This trend has been attributed to the improving socioeconomic conditions during this epoch.[4] Although the most recent data from North America, several European countries, and other regions of the industrialized world indicate that the trend to earlier menarche has been reduced or halted,[6,17-21] breast and pubic hair development are apparently occurring earlier than 50 years ago in both North America and Europe.[6,22] The biology underlying this

continued positive secular trend in sexual development in girls, which in some populations is loosely associated with a similar trend in growth, is unclear and may or may not involve an earlier onset of gonadarche or adrenarche. This earlier onset of breast development is not associated with increased gonadotropin or estradiol concentrations, suggesting that this represents a gonadotropin-independent event.[22] Analogous studies of boys are limited, but no striking sex differences in secular trends in puberty and growth are apparent. Using both genital staging and the orchidometer, the Copenhagen Puberty Study reported pubertal onset occurring 3 months earlier in Danish boys and that obesity advanced the onset of testicular enlargement.[23] However, other studies suggest that obesity delays onset of puberty in boys.[24]

It is important to also recognize that the age at onset of puberty varies between ethnic groups. Among American girls, mean ages for breast development, pubic hair development, and menarche were 9.5, 9.5, and 12.1 for African-American girls; 9.8, 10.3, and 12.2 for Mexican-American girls; and 10.3, 10.5, and 12.7 years for white girls.[25] Data obtained through the Third National Health and Nutrition Examination Survey (NHANES III) between 1988 and 1994 showed that black girls enter puberty first, followed by Mexican-American and white girls.[25,26] For boys in NHANES III, median estimated ages for genital and pubic hair stage 2 were 9.3 and 11.1 for African-American boys; 10.4 and 12.3 for Mexican-American boys; and 10.1 and 12.0 for white youths. For genital and pubic hair stage 5, median ages were 14.9 and 15.2 for African-American boys; 15.8 and 15.7 for Mexican-Americans; and 16.0 and 15.6 for white boys.[27]

Physiology of Puberty

Steroidogenesis

The biosynthetic pathways for gonadal and adrenal steroids are considered together because of their similarities and importance in understanding the physiology and pathophysiology of puberty (Fig. 18.4; also see Chapter 4). Synthesis of steroids from cholesterol requires expression of specific enzymes and other proteins in the adrenal cortex and the gonads. The adrenal cortex consists of three zones, the zona glomerulosa, zona fasciculata, and zona reticularis. The zona glomerulosa synthesizes aldosterone, a mineralocorticoid, and is primarily regulated by potassium concentrations and renin-angiotensin. The zona fasciculata synthesizes cortisol. Steroidogenesis in the zona fasciculata is primarily governed by adrenocorticotropin (ACTH). The zona reticularis synthesizes the so-called adrenal androgens, which are weak androgen-like hormones that do not bind to the androgen receptor (AR).

ACTH is a peptide derived following proteolytic cleavages of pro-opiomelanocortin (POMC) and has both acute and chronic effects on the adrenal cortex. Acutely, it promotes uptake of plasma low-density lipoproteins, stimulates cholesterol esterase activity, enhances synthesis and phosphorylation of steroidogenic acute regulatory protein (StAR), and promotes cortisol secretion. The chronic effects of ACTH involve stimulation of transcription and translation of steroidogenic enzyme genes. Luteinizing hormone (LH) and follicle stimulating hormone (FSH) influence gonadal steroid biosynthesis. LH promotes ovarian theca cell and testicular Leydig cell steroidogenesis. FSH promotes ovarian granulosa cell estrogen biosynthesis. ACTH, LH, and FSH bind to cognate G-protein-coupled seven-transmembrane domain receptors that signal via cyclic adenosine monophosphate (cAMP) and protein kinase A.

Most enzymes involved in steroidogenesis are cytochrome P450s (CYPs) or hydroxysteroid dehydrogenases. The rate-limiting step of steroidogenesis is transport of cholesterol into mitochondria mediated by StAR. Within the mitochondria, cholesterol desmolase (also known as side-chain cleavage or P450scc) converts cholesterol into pregnenolone. One enzyme, 17 α-hydroxylase/17,20-lyase (P450c17), encoded by the *CYP17A1* gene, is the qualitative regulator of adrenal and gonadal steroidogenesis. This enzyme mediates 17α-hydroxylation to convert pregnenolone into 17α-hydroxypregnenolone. In the adrenal zona reticularis, ovarian theca, and Leydig cells, this same enzyme catalyzes scission of the C17–20 bond to produce DHEA. Although this one protein is capable of two distinct enzymatic reactions, these enzyme activities are differentially regulated. The three factors known to modulate 17,20-lyase activity include: (1) amount of P450 oxidoreductase; (2) expression of cytochrome b_5; and (3) phosphorylation of serine/threonine residues on P450c17.[28] P450 oxidoreductase (POR) is a protein that transfers electrons from nicotinamide adenine dinucleotide phosphate to microsomal cytochrome P450 enzymes such as P450c17, P450c21, and aromatase (P450aro). Cytochrome b_5 modulates adrenal androgen secretion by increasing the 17,20-lyase activity of (P450c17).[29-31]

The Δ^5-steroids are converted to the Δ^4-steroids by 3β-hydroxysteroid dehydrogenase type 2, the adrenal and

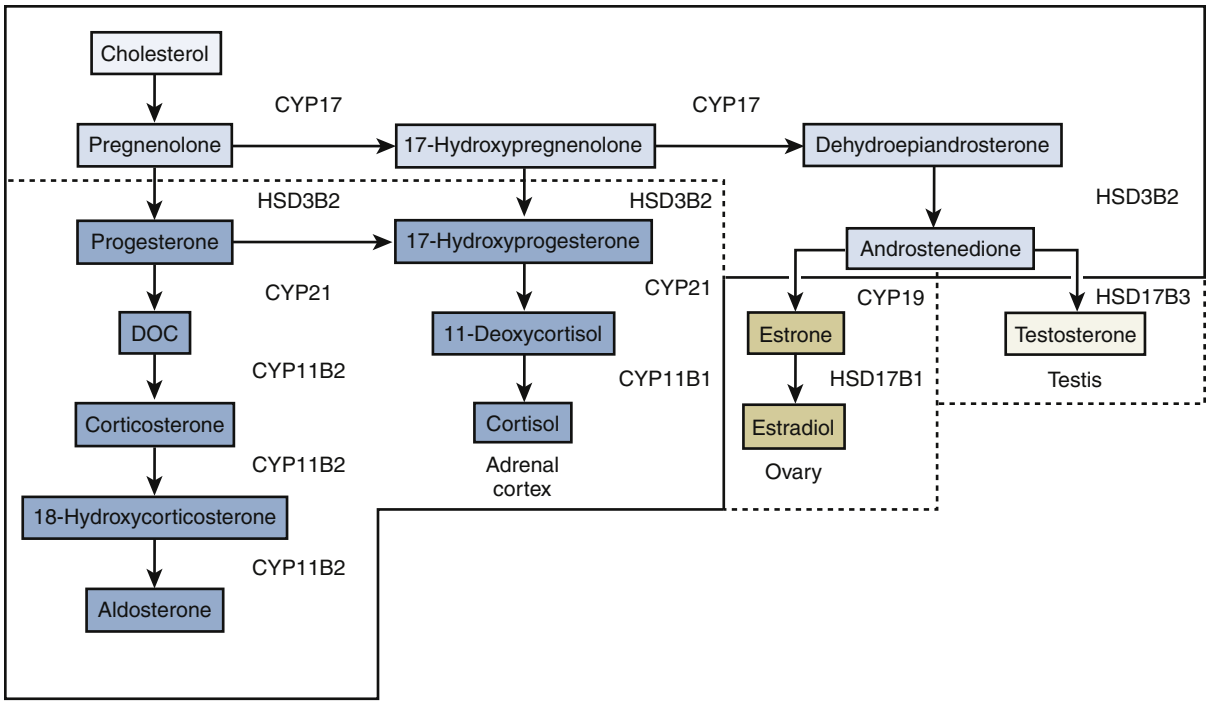

FIGURE 18.4 Steroidogenesis. This figure shows pathways of adrenal, ovarian, and testicular steroidogenesis. *Dark solid lines* indicate predominant pathways for adrenal steroidogenesis. *Dashed lines* indicate predominant pathways for gonadal steroidogenesis. Genes responsible for specific enzymatic steps are indicated. Enzymatic steps for which P450 oxidoreductase serves as a cofactor (encoded by POR) are indicated. *Arrow* indicates "backdoor pathway" of steroidogenesis. DOC, deoxycorticosterone. *(Adapted from Witchel SF, Lee PA. Ambiguous genitalia. In Sperling MA [ed].* Pediatric Endocrinology, *2nd ed. Philadelphia: WB Sounders, 2002, p 119.)*

gonadal isoform, resulting in conversion of DHEA to androstenedione. In the zona fasciculata, 17-hydroxypregnenolone is converted to 17-hydroxyprogesterone (17-OHP) by 3β-hydroxysteroid dehydrogenase. Subsequently, 17-OHP is converted to 11-deoxycortisol by 21-hydroxylase (P450c21) and to cortisol by 11β-hydroxylase (P450c11β).

The adrenals, ovaries, and testes synthesize sex steroids. In the zona reticularis of the adrenal cortex, DHEA sulfotransferase (SULT2A1) converts DHEA to DHEAS; this enzyme is also expressed in the liver. Sulfation of steroids by SULT2A1 requires a sulfate donor, 3′-phosphoadenosine 5′-phosphosulfate (PAPS), and the enzyme PAPS synthase.[32] In the ovary, androstenedione is synthesized in the theca cell and diffuses into the granulosa cell, where it is aromatized by aromatase (P450aro) to estrone and converted to estradiol by 17β-hydroxysteroid dehydrogenase type 1. In Leydig cells, androstenedione is converted to testosterone by 17β-hydroxysteroid dehydrogenase type 3. In many androgen target cells, such as those in the external genitalia and prostate, testosterone is converted to DHT by 5α-reductase type 2. In other androgen sensitive tissues, such as bone and adipose, testosterone is converted to estradiol by aromatase.

The 17β-hydroxysteroid dehydrogenase enzymes comprise a large family of enzymes involved in steroid biosynthesis and metabolism. At least 17 different enzymes have been described.[33] Differences in tissue distribution, substrate preferences, subcellular localization, and mechanisms of regulation lead to micro-environment adjustment of sex steroids.[34] The type 1 isozyme, 17βHSD1, is expressed in ovaries, placenta, endometrium, and liver where it favors conversion of estrone to estradiol. The type 3 isozyme, 17βHSD3, is expressed in the testis where it preferentially converts androstenedione to testosterone.[35] The type 5 enzyme, 17βHSD5, is an aldo-keto-reductase (AKR) enzyme (AKR1C3) which is expressed in steroidogenic and peripheral tissues; it can convert androstendione to testosterone.[36]

Through investigations of the tammar wallaby and patients with disordered steroidogenesis, the presence of another pathway leading to dihydrotestosterone (DHT) synthesis was uncovered.[37] In this "backdoor pathway," 17-OHP undergoes 3α- and 5α-reduction followed by 17,20-lyase, 17β-hydroxysteroid dehydrogenase, and 3α-oxidation steps to generate DHT in the absence of the intermediates, DHEA, androstenedione, and testosterone, requisite to the classical pathway. In human, since 17-OHP is not a favorable substrate for the 17,20-lyase reaction, this pathway acquires functional importance in disorders of steroidogenesis associated with increased 17-OHP concentrations such as congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency and oxidoreductase deficiency.

Once secreted, sex steroids circulate bound to sex hormone-binding globulin (SHBG) and to albumin.[38] The unbound or free hormone is considered to be the bioavailable form that diffuses passively into target cells and interacts with nuclear steroid receptors. These are ligand dependent transcription factors, comprising three functional domains: the N-terminal domain serves to modulate function; the DNA-binding domain mediates binding of the receptor to DNA; and the ligand-binding domain binds to steroids.[39] Steroid receptor activity is modulated by various tissue-specific cofactors, both coactivators and corepressors.

It should also be noted that nongenomic actions of steroids have been reported.[40] For example, testosterone can

activate phospholipase C leading to calcium influx into Sertoli cells and can activate the mitogen-activated protein kinase as well as other intracellular mediators.[41] Sex steroids can be metabolized to inactive forms by a variety of enzymes. Glucuronidation decreases the biological activity of steroid hormones and increases solubility to facilitate renal excretion. This process, catalyzed by UDP-glucuronyltransferase (UGT) enzymes, involves the transfer of glucuronic acid from uridine diphosphoglucuronic acid to steroid hormones. In humans, the UGT2B isoforms show greater specificity for C19 androgens.[42] A second mechanism is sulfoconjugation, in which DHEA sulfotransferase catalyzes conversion of DHEA to DHEAS and estrogen sulfotransferase converts estrogens to estrone sulfate. The inactive sulfated steroids can be hydrolyzed to active forms by steroid sulfatase.

Activation of Gonadarche

Increased gonadal steroidogenesis and the completion of gametogenesis during gonadarche are stimulated by enhanced secretion of the gonadotropins, LH and FSH. LH and FSH are heterodimeric proteins comprised of a common α-subunit and a unique β-subunit; all are glycosylated peptides (also see Chapter 2). The temporal increments in circulating LH and FSH concentrations at the time of puberty, and their relationships to those of the gonadal steroids, testosterone and estradiol, respectively, at this stage of development, have been well documented in both boys and girls.[4,5,43] The actions of LH and FSH are mediated by their cognate seven-transmembrane domain G-protein—coupled receptors: the LH receptor (LHR) and FSH receptor (FSHR), respectively (also see Chapter 2). In the female, LH stimulates androgen production by the thecal cells of the ovarian follicles and progesterone secretion from luteinized granulosa cells of the corpus luteum. FSH is critical for the process of follicular recruitment and selection.[44] In granulosa cells of the developing follicle, FSH induces expression of aromatase, which is responsible for aromatization of androgens secreted by the theca cells. FSH also induces LHR in granulosa cells of the dominant follicle, which selectively amplifies the effect of declining FSH concentrations on the dominant follicle.[33] In the male, LH regulates the secretion of testosterone from Leydig cells.

Recently, studies of mice have provided evidence that osteocalcin, an osteoblast-specific secreted hormone from bone, is a facilitator of testicular testosterone secretion.[45,46] In its undercarboxylated form, osteocalcin is biologically active signalling at its receptor, GPRC6A, which is expressed by Leydig cells.[45] Posttranslationally, osteocalcin is carboxylated on three glutamic acid residues, and the carboxyated form of the molecule is considered to be biologically inactive. Interestingly, increased osteocalcin concentrations are associated with the puberal rise in testosterone concentrations in boys.[47] Osteocalcin appears to have sexually dimorphic actions since it seems to modulate Leydig cell testosterone production, but not ovarian estrogen production.

FSH, together with testosterone, is responsible for initiating and maintaining spermatogenesis.[48] The action of FSH in this regard is indirect and exerted on the somatic Sertoli cell of the seminiferous tubule. While the actions of testosterone are also indirect, several somatic cell types in the testis (Sertoli, Leydig and peritubuar) express AR and are considered to be involved in the control of spermatogenesis.[49]

Activation of the ovary and testis during gonadarche also results in the increased secretion of the gonadal proteins, known as *inhibins*, which are members of the TGF-β superfamily. Mature inhibins are dimers composed of a common α-subunit covalently linked with one of two β-subunits (β_A and β_B). The α/β_A and α/β_B dimers are known as inhibin A and inhibin B, respectively.[50] The gonadal inhibins, like the gonadal steroids, play both an endocrine role in the regulation of gonadotropin secretion and a paracrine role within the gonads. Inhibin B, which is synthesized in part by the Sertoli cell, is the principal inhibin secreted by the testis.[51] In prepubertal boys, mean concentrations of circulating inhibin B are approximately 60 pg/mL, which compare with adult values that vary considerably about an average of 200 pg/mL.[52,53] The pubertal increase in inhibin B may be attributed to Sertoli cell proliferation and to the initiation of spermatogenesis, both of which reflect the increased gonadotropin drive to the testis at the time of gonadarche.[48]

In girls, circulating levels of inhibin A and B are low or undetectable prior to puberty.[54] Inhibin B begins to rise with the onset of puberty, as does inhibin A in breast stages 3 and 4. Adult levels are attained at approximately 14 to 15 years of age.[55] During the menstrual cycle, inhibin A levels are elevated in the luteal phase, while inhibin B predominates in the circulation of the follicular phase.[56]

Anti-müllerian hormone (AMH) or müllerian-inhibiting hormone (MIH) is also a member of the TGF-β superfamily. While AMH plays a critical role in testicular development and in the regression of the müllerian ducts during male fetal development, it continues to be secreted postnatally by the Sertoli cells of the testis and the granulosa cells of the ovary. In boys, AMH concentrations decline at puberty.[57] Although FSH stimulates AMH production, testosterone inhibits Sertoli cell AMH secretion. The decline in AMH concentrations appears to be closely coupled to rising inhibin B concentrations at the onset of puberty in boys,[58] the latter presumably reflecting androgen induced differentiation of the Sertoli cell. Both AMH and inhibin B concentrations are low in boys with bilateral anorchia or complete hypogonadotropic hypogonadism (complete HH).[59] Immunohistochemical studies of human ovaries showed no AMH staining in primordial follicles, highest expression in growing preantral and small antral follicles, and disappearance in larger follicles (greater than 8 mm).[60]

Insulin like factor-3 (INSL3), a peptide hormone secreted by Leydig cells, plays a major role in directing testicular descent during gestation. INSL3 concentrations are low during infancy, rise during puberty, and reflect Leydig cell function during adulthood.[61]

The pubertal drive to the pituitary-gonadal axis is generated by a diffusely distributed network of hypothalamic neurons expressing gonadotropin releasing hormone-1 (GnRH-I)[62] known as the "hypothalamic GnRH pulse generator" (discussed later in the chapter and also Chapters 1 and 8). As the name implies, the hypothalamic GnRH pulse generator produces an intermittent discharge of GnRH into the hypophysial portal circulation that is obligatory for gonadotropin synthesis and secretion by the pituitary gonadotrophs.[44] LH and FSH secretion is stimulated by GnRH acting through its receptor, GnRH-R1, located

on gonadotropin secreting cells (gonadotrophs) in the pituitary gland.[63,64] A unique feature of the human GnRHR, a 7-transmembrane domain G-protein coupled receptor, is its lack of a C-terminal cytoplasmic domain.[65]

A second GnRH gene *(GnRH-II)* is also expressed by neurons in the primate brain and a GnRH-II receptor has been cloned from the pituitary, but in the human the gene encoding for this receptor does not generate a functional protein.[66] The significance, if any, of this second GnRH system in the control of the human pituitary-gonadal axis has not been delineated. Similarly, a hypothalamic RFamide-related peptide (RFRP3) that is inhibitory to gonadotropin secretion in several species and considered to be the homolog of gonadotropin-inhibitory hormone (GnIH) in birds has been identified in mammalian species,[67] but its neuroendocrine role in man is unclear.

In conditions under which pulsatile GnRH release is compromised, such as occurs in anorexia nervosa and during periods of strenuous physical training especially in young women, gonadotropin secretion is attenuated and pubertal development is arrested. Thus, the pituitary-gonadal axis in both males and females may be viewed as being a slave to the hypothalamic GnRH pulse generator, and this analogy should be held in mind when considering the mechanisms triggering the onset of gonadarche.

In the pubertal and postpubertal individual, the ovaries and testes are governed by feedback control systems.[68] GnRH and the gonadotropins comprise the feed-forward components from hypothalamus to pituitary and from pituitary to gonad, respectively. Steroid and protein hormones from the gonads, in turn, provide the feedback signals that regulate the secretion of LH and FSH. The feedback actions of these gonadal hormones, which involve both negative and stimulatory (positive) actions, may be exerted directly at the level of the pituitary gonadotrophs to modulate expression of the genes encoding LHβ and FSHβ (*LHB* and *FSHB*, respectively).[63] Feedback may also be exerted indirectly at the level of the hypothalamus to regulate the release of GnRH (see Chapter 1).

In the male, a negative feedback action of testosterone and inhibin B are the major regulators of LH and FSH secretion, respectively.[48,68,69] The action of testosterone is predominantly exerted at the hypothalamic level, while that of inhibin appears to occur directly at the pituitary. The role of aromatization of testosterone to estradiol in mediating the negative feedback action of this androgen on LH secretion continues to be an area of active investigation.[70-72] The feedback control of LH and FSH throughout the menstrual cycle is complicated and involves both negative and positive feedback actions of ovarian steroids at both the hypothalamic and pituitary levels[44] (see also Chapter 8). The maintenance of normal ratios of circulating LH and FSH concentrations is important for gonadal function, particularly for folliculogenesis and ovulation. The role of ovarian inhibins in regulating gonadotropin secretion in the pubertal and premenopausal women remains to be fully elucidated.

The Hypothalamic GnRH Pulse Generator

In the human hypothalamus there are some 1000 to 2000 diffusely distributed GnRH neurons, many of which send their projections to the median eminence where they synchronously and intermittently discharge their peptide into the primary plexus of the hypophysial portal circulation thereby providing the pituitary gonadotrophs with the pulsatile stimulation that is essential for maintaining gonadotropin secretion.[44,62] While the neurobiological mechanisms that underlie GnRH pulse generation remain controversial, compelling evidence indicates the fundamental role of KNDy neurons in the arcuate nucleus (aka infundibular nucleus).[73-76] These hypothalamic neurons, named because they co-express kisspeptin, neurokinin B (NKB), and dynorphin,[77] project their axons to the median eminence where they mingle intimately with GnRH fibers en route to the portal vessels.[78] It is proposed that GnRH pulse generation is achieved by reciprocating stimulatory (NKB) and inhibitory (dynorphin) connections within the arcuate nucleus, while the output of the pulse generator is relayed to GnRH fibers projecting to the median eminence by an intermittent kisspeptin signal. Thus, these neurons may represent the anatomic site of the GnRH pulse generator. Loss of function mutations in the genes encoding for kisspeptin *(KISS1)* or the kisspeptin receptor, also called GPR54, *(KISS1R)* and for NKB *(TAC3)* or the NKB receptor *(TACR3)* in humans lead to a profound hypogonadotropic state that is typically manifest at puberty.[79-82] The importance of these neurons has also been demonstrated by the finding that selective ablation of KNDy neurons in the postpubertal rat results in a loss in hypothalamic drive to LH secretion.[83] A contemporary model for the GnRH pulse generator is shown in Figure 1.15.

Neurobiology of Gonadarche

Fetal Development of the GnRH Pulse Generator

The 1000 to 2000 GnRH neurons in the postnatal hypothalamus are born in the olfactory placode and migrate during early fetal development from the nose through the forebrain to the hypothalamus.[84] The fetal ontogeny of the GnRH neurons can be categorized into several stages each with distinct regulatory mechanisms; (1) differentiation of GnRH neurons; (2) migration along with axons of the vomeronasal nerve and guidance into the forebrain; (3) localization in the hypothalamus and development of processes to the median eminence; and (4) attainment of final location and functionality.[84] Specific mutations in families with disorders of puberty and studies of transgenic mice have established some of the factors involved in GnRH neuron migration. Precise spatiotemporal expression of these factors, which include cell matrix or adhesion proteins, neurotransmitters, growth factors, hormone receptors, and transcription factors is essential to normal GnRH pulse generator activity and therefore pituitary-gonadal function.

GnRH neurons are derived from a heterogenous stem cell population in the embryonic olfactory placode. Factors involved in the differentiation of GnRH neurons include fibroblast growth factor receptor-1 (FGFR1), fibroblast growth factor-8 (FGF8), heparan sulfate 6-O-sulfotransferase 1 (HS6ST1); chromodomain helicase DNA-binding protein 7 (CHD7), and nasal embryonic LH-releasing hormone (NELF). The FGFR1 is a tyrosine kinase receptor composed of three extracellular immunoglobulin domains, a transmembrane domain, and a cytoplasmic tyrosine kinase domain. The extracellular domain interacts with heparan

sulphate proteoaminoglycan, its coreceptor. Heparan sulfates are cell membrane and matrix-associated proteoglycans involved in neural development. These polysaccharides undergo nonrandom modifications of the sugar moieties to facilitate cell to cell communication. HS6ST1 introduces a sulfate at the 6-O position within heparan sulfate. This action appears to be necessary for FGFR1 function. CHD7 is a large protein that participates in chromatin remodeling and transcription.

Identification of a missense mutation in the FGF8 gene in families with HH confirmed that FGF8 is the cognate ligand for FGFR1.[85] Upon ligand binding, FGFR1 and its co-receptor dimerize leading to autophosphorylation, and protein kinase activity.[86] Expression studies in human fetuses demonstrated FGF8 is detected in the telencephalon and ventral diencephalon, but not in Rathke's pouch. FGF8 plays a role in the development of the neuroendocrine system; loss of function *FGF8* mutations have been associated with holoprosencephaly indicating its role in the development of the hypothalamus and pituitary.[87]

Around the 6th week of human gestation, GnRH neurons begin their migration along vomeronasal nerves to the cribiform plate and eventually find their way to the hypothalamus. Several adhesion and guidance molecules have been implicated in this process, including anosmin-1, ephrins, fibroblast growth factor 1, and prokineticin 2 (PROK2).[84]

The gene encoding anosmin-1, *KAL1*, is located at Xp22.3 in the pseudoautosomal region of the X chromosome and encodes anosmin-1.[88-90] Anosmin-1 is an extracellular matrix glycoprotein that contains motifs found in other molecules involved in neuronal guidance activity, including fibronectin III repeats and a whey-acidic protein domain. The precise function of anosmin-1 is unclear. However, putative functions include a guidance platform for migrating GnRH neurons, chemoattractant for olfactory axon pathfinding, and/or interactions with FGFR1.[84]

NELF is hypothesized to play a role in neuronal migration.[91] Semaphorins comprise a large and diverse family of secreted and membrane-associated proteins that influence navigation of growing axons. Semaphorin-3A (SEMA3A) is a secreted protein with repulsive effects on primary olfactory axons expressing the coreceptor neuropilin-1 (Nrp1), which may influence the migration of GnRH neurons. PROK2 and its receptor (PROKR2), a G-protein-coupled receptor, appear to modulate GnRH neuron migration.

Upon arrival in the hypothalamus, the GnRH neurons then extend projections to the median eminence to form a network, which can secrete GnRH into the primary plexus of the hypophysial portal circulation. LH and FSH reach detectable levels by the 10th week of gestation in the human pituitary, peak in midgestation, and are higher in female fetuses than male fetuses.[4,5] Although the hypothalamic control of the fetal pituitary gonadal axis has not been extensively studied in higher primates, the GnRH pulse generator is clearly driving the gonadotrophs of the fetal pituitary around the 15th week of gestation.[5,62] Functional activity of this hypothalamic-pituitary system is essential for fetal testicular testosterone synthesis by the Leydig cell and normal male sex development. In contrast to the fetal testis, the ovary at this stage of development is relatively quiescent, and the absence of gonadal feedback signals likely account for the higher gonadotropin levels in the female fetus. As gestation progresses, the secretion of estradiol and other steroids by the fetoplacental unit increases dramatically, and suppresses gonadotropin secretion from the fetal pituitary by exerting an inhibitory action either directly at the pituitary or indirectly on the hypothalamus to restrain GnRH release.

Postnatal Development of GnRH Pulsatility

Following birth, GnRH pulse generator activity is robustly expressed presumably due to the the loss of placental steroids, and the pituitary gonadotrophs of the infant respond with LH and FSH secretion.[5] At the hypothalamic level, kisspeptin and NKB are found in the arcuate nucleus at this stage of development,[92,93] and a loss of function mutation in *KISS1* has been associated with HH during infancy.[94] Moreover, in the case of the infant boy, the Leydig cells of the testis are stimulated such that circulating testosterone levels are similar to those observed in adult men.[95] Peak testosterone concentrations occur at approximately 2 to 3 months of age and typically decline by 6 months of age. Among preterm male infants, LH and testosterone concentrations are higher than among full term infants; phallic growth was positively correlated with urinary testosterone levels and testicular growth was positively correlated with urinary FSH levels.[96] Despite the "adult-like" endocrine milieu of increased gonadotropin secretion and elevated testosterone concentrations during the first few months of life, sexual hair does not develop and gametogenesis is not initiated presumably due to limited androgen receptor signalling in skin and the immature Sertoli cell.[97,98] The hypothalamic-pituitary-ovarian axis is active in term and preterm girls and is associated with a transient increase in antral follicles.[99]

Full hormonal responsivity of the gonad is acquired during childhood but by this stage of development the GnRH pulse generator has been brought into check resulting in the hypogonadotropic state that guarantees continued gonadal quiescence until the prepubertal phase of development is terminated by a resurgence of GnRH pulse generator activity.[100,101] During childhood and juvenile development neither the GnRH neurons, pituitary gonadotrophs, nor the cells of the gonads are limiting to the onset of gonadarche.[5] Accordingly, during these stages of development when the primate hypothalamus or pituitary is provided with pulsatile neurochemical (N-methyl-D-aspartate [NMDA], a glutamate receptor agonist)[102,103] or GnRH stimulation, respectively, or when the ovary and testis are stimulated directly with LH and FSH, gonadarche may be readily elicited. This phenomenon is graphically illustrated in children with GnRH-dependent precocious puberty, a disorder discussed later in this chapter. That the GnRH neuronal network in the juvenile monkey hypothalamus is able upon NMDA stimulation to immediately elicit an adult hypophysiotropic GnRH drive is consistent with the finding that hypothalamic GnRH gene expression and peptide content are maintained throughout this phase of prepubertal development.[102] Thus, transcriptional regulation of the gene encoding GnRH from birth to puberty appears to be minimal, and the locus of the developmental control of GnRH release must lie upstream to the GnRH neuronal network.

Because GnRH is secreted in only picogram quantities into the hypophysial portal circulation, changes in the concentration of this neuropeptide in the peripheral circulation

do not reflect hypothalamic activity. Therefore studies of the dynamics of the pubertal resurgence of GnRH pulse generator activity in man and other higher primates have generally utilized the high-fidelity relationship that exists between the frequencies of pulsatile GnRH release and episodic LH secretion.[104] The latter may be tracked with relative ease by measuring moment-to-moment changes in LH concentrations in the peripheral circulation.[68] Although the pubertal increase in hypothalamic GnRH drive to the gonadotroph probably involves both frequency and amplitude modulation of the GnRH pulse generator, the relationship between GnRH and LH pulse amplitude is more complex than the relationship between frequency; amplitude modulation of LH release may not reflect changes in GnRH pulse amplitude. During initiation of gonadarche in boys and girls, an acceleration in LH pulse frequency and an increased LH pulse amplitude is observed in association with an amplification of a pre-existing sleep-related diurnal pattern in release.[5,105-109] This change in neuroendocrine activity may occur before the physical changes of gonadarche are manifest. In boys in particular, LH pulse frequency appears to decline later in pubertal development, probably due to a negative feedback action of rising testosterone concentrations.[110] A longitudinal study of the agonadal monkey[111] suggests that, as in humans, the pubertal acceleration of pulsatile GnRH release is an early neurobiological event in the initiation of gonadarche, and that it is a rapidly completed process. Thus, the slow tempo of the overall progression of puberty probably results from mechanisms downstream from the hypothalamus, and particularly at the level of the pituitary. A model illustrating the ontogeny of GnRH pulse generator activity from fetal to pubertal development in the male and female is shown in Figure 18.5.

The control system that dictates the up-down-up pattern of GnRH pulse generator activity from birth until puberty may be viewed as a neurobiological "brake" (or central restraint, as it has been previously described in the pediatric literature[4]) that holds GnRH neuronal activity in check during the greater part of prepubertal development.[102] Here it is important to recognize that the notion of a brake is conceptual, i.e., the pubertal resurgence in robust GnRH pulsatility could be occasioned either from the removal of an inhibitory input or by the application of a stimulatory signal to the GnRH pulse generator, or a combination of the two. A similar argument may be applied to the earlier transition between infancy and childhood when GnRH pulsatility is markedly diminished. The neurobiological brake on pulsatile GnRH release throughout childhood and juvenile development is imposed in the absence of the ovary or testis. Consequently, the characteristic pattern of gonadotropin secretion observed during postnatal development in humans—with robust gonadotropin secretion during infancy and puberty, separated by a prolonged hiatus in LH and FSH secretion—is maintained in the agonadal situation (Fig. 18.6).[112,113] Similarly, in male infants with partial androgen insensitivity, LH concentrations are generally elevated and this is associated with higher testosterone levels. Yet, infants with complete androgen insensitivity often fail to demonstrate a postnatal rise in LH and testosterone secretion.[114] The later finding is counterintuitive, and an understanding of the molecular basis of this phenomenon may well reveal fundamental insights into the ontogeny of GnRH pulse generation. In agonadal children, the degree of the prepubertal suppression of gonadotropin release is less than that observed in eugonadal individuals.[4] Interestingly, in agonadal children circulating gonadotropin levels are higher in girls than boys indicating that the intensity of the neurobiological brake imposed on the GnRH pulse generator during prepubertal development is less in the female than in the male. As a result, the gonadotropin drive to the prepubertal ovary stimulates a low level of estradiol secretion,[43] which, through negative feedback action on LH and FSH release, amplifies the relatively weaker neurobiological brake restraining gonadotropin secretion in the prepubertal girl. This sex difference in the strength of the neurobiological brake on prepubertal GnRH release is associated

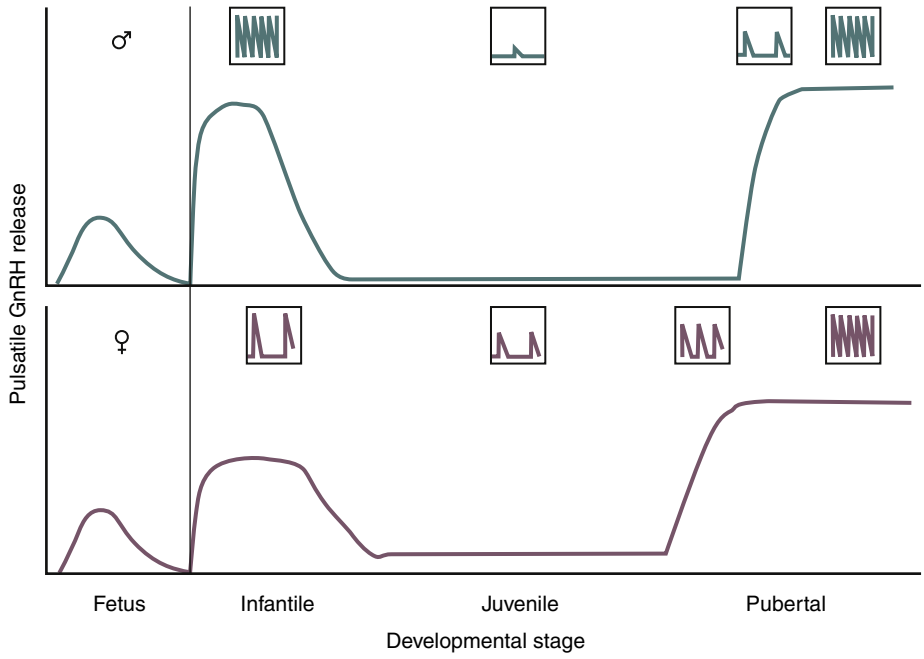

FIGURE 18.5 A schematic of the pattern of pulsatile gonadotropin-releasing hormone (GnRH) release during juvenile development (including childhood) in boys *(above)* and girls *(below)*. FIGURE 18.6 The neurobiological restraint that holds the gonadotropin-releasing hormone (GnRH) pulse generator in check during childhood is imposed in the absence of the gonads, as reflected by the time courses of circulating concentrations of luteinizing hormone (LH; *top*) and follicle-stimulating hormone (FSH; *bottom*) in 58 patients with gonadal dysgenesis. *Closed triangles*, 45,X karyotype; *circles*, X chromosome mosaicism or structural abnormalities; cross-hatching, mean plasma gonadotropin concentrations in normal girls. *Bold curves* represent polynomial regressions of gonadotropin concentration with age. *(From Conte FA, Crumbach MM, Kaplan SL. A diphasic pattern of gonadotropin secretion in patients with the syndrome of gonadal dysgenesis.* J Clin Endocrinol Metab *40:670, 1975.)*

with a shorter duration of the brake in girls, which probably accounts for the relatively earlier age of gonadarche in the female. These and other sex differences in the developmental control of the GnRH pulse generator are presumed to result from greater exposure of the fetal male hypothalamus to testosterone.[5]

The Nature of the Neurobiological Brake

The discovery in 2003 that loss of function mutations in *KISS1R* in humans were associated with HH and delayed or absent puberty,[79,80] demonstrated the critical role of kisspeptin in regulating GnRH secretion. A multitude of subsequent studies in several different experimental models supported this finding.[76,81,115-118] These data led to the proposal in the previous edition of this book that a major component of the neurobiological brake imposed upon pulsatile GnRH release during the greater part of prepubertal development is comprised by a hiatus in a stimulatory kisspeptin input to the GnRH neuronal network. This proposal was based on findings in the monkey, that hypothalamic expression of *KISS1* and release of kisspeptin in the region of the median eminence increase at the time of the pubertal resurgence in GnRH pulsatility.[119,120] Additionally, intermittent administration of kisspeptin at hourly intervals during juvenile development elicits a precocious and sustained adult-like pulsatile pattern of GnRH,[121] and the pubertal increase in GnRH release may be suppressed by administration of a KISS1R receptor antagonist directly to the median eminence.[122]

The recent finding in humans, however, that loss of function mutations in the NKB signalling pathway are associated with a phenotype similar to that reported earlier for inactivating mutations in *KISS1R*,[82] together with the fascinating observation that these two neuropeptides are expressed in the same neurons (KNDy neurons) in the arcuate nucleus,[77] have led to the emergence of the idea that these neurons are responsible for the generation of GnRH pulsatility (described earlier in this chapter). Thus, the current data justify revision of the earlier model. While kisspeptin signalling remains obligatory for puberty in the revised model, this is simply because the kisspeptin expressing KNDy neurons in the arcuate nucleus comprise a critical component of the GnRH pulse generator.[76] In the absence of an intact kisspeptin signalling pathway, the output of the GnRH pulse generator will be abrogated and pulsatile GnRH release would be compromised resulting in a delay or absence of puberty. According to this model, KNDy neurons in the arcuate nucleus play no "regulatory" role in controlling the timing of puberty: rather, as a component of the GnRH pulse generator they are subservient to upstream regulatory mechanisms that govern the developmental pattern of pulsatile GnRH release and the onset of puberty (Fig. 18.7).

The nature of the upstream pathways that comprise the neurobiological brake on the GnRH pulse generator during childhood and juvenile development remain poorly understood. Studies of the female rhesus monkey provide evidence that γ-aminobutyric acid (GABA), the major

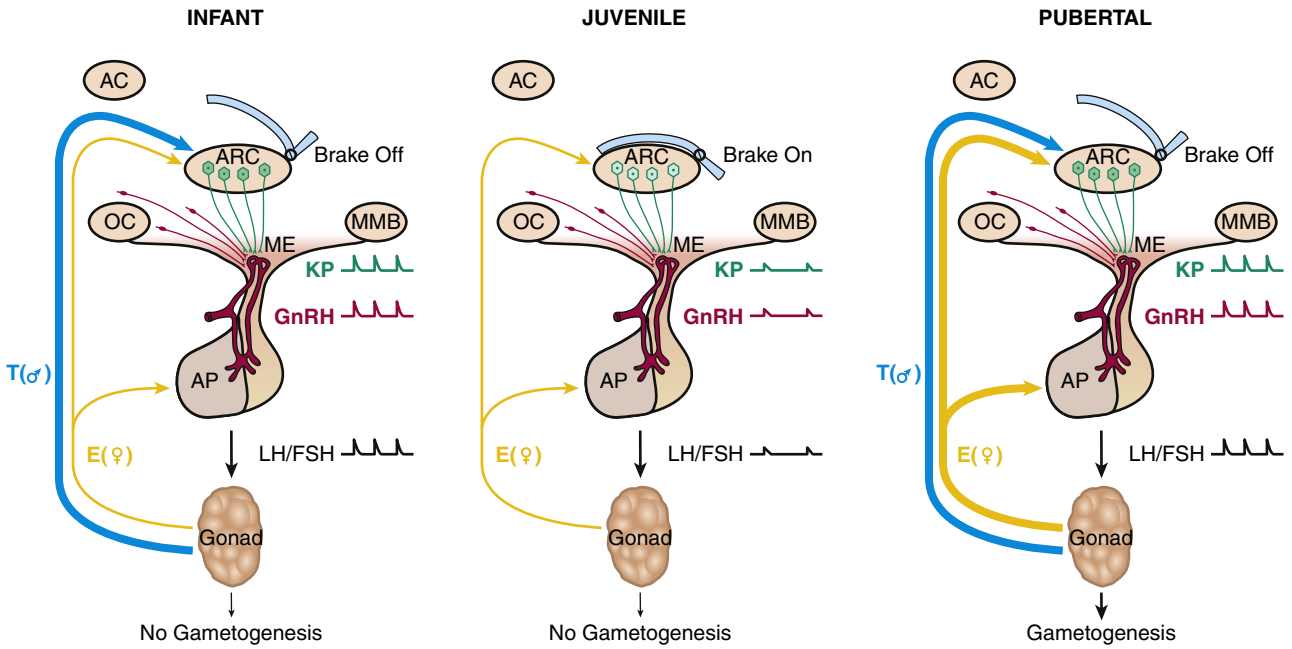

FIGURE 18.7 A model for the control of the timing of puberty. The role of kisspeptin signaling is posited to be a critical component of the neural machinery that generates pulsatile gonadotropin-releasing hormone (GnRH) release from the hypothalamus (the hypothalamic GnRH pulse generator). In this model, the hypothalamic GnRH pulse generator resides in the arcuate nucleus (ARC) and the output of the pulse generator is relayed to GnRH terminals *(red)* in the median eminence (ME) by kisspeptin projections arising from KNDy neurons in the ARC *(green)*. During infancy *(left panel)*, GnRH pulse generator activity is robust leading to intermittent release of kisspeptin in the ME, resulting in a corresponding pattern of GnRH release into the portal circulation. This, in turn, drives pulsatile gonadotropin secretion. In the transition from infancy to the juvenile phase of development *(middle panel)*, a neurobiological brake (central inhibition) restrains the GnRH pulse generator and pulsatile release of kisspeptin in the ME is markedly suppressed. This leads to reduced GnRH release and to a hypogonadotropic state in the juvenile period. Puberty is triggered when the neural brake is released and GnRH pulse generator activity with robust intermittent release of kisspeptin in the ME is reactivated *(right panel)*. According to this model, the mystery of primate puberty lies in the nature of the neurobiological brake and in the mechanism that times its application during infancy and its release at the end of the juvenile phase of development. It should be noted that the ability of the postnatal gonad to respond fully to gonadotropin stimulation is not acquired until the juvenile stage of development, by which time luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion is low as a result of the GnRH pulse generator being brought into check. The thickness of the *blue* (T, testosterone) and *gold* (E, estradiol) *arrows* indicating negative feedback by the testis and ovary, respectively, reflect the degree of gonadal steroid inhibition exerted on LH secretion at these three stages of development. Kisspeptin and puberty in mammals. In Kauffman AS, Smith JT, (eds).* Kisspeptin Signaling in Reproductive Biology, *Springer, New York, p 253, 2013.)*

inhibitory neurotransmitter in the brain, is upregulated during juvenile development and inhibition of GABA tone in the hypothalamus of the prepubertal monkey leads to precocious menarche and ovulation.[9,123] Interestingly, infusion of the GABA antagonist, bicuculline, into the median eminence of prepubertal female monkeys stimulates release of kisspeptin-54 into this region of the hypothalamus in association with that of GnRH, and the bicuculline-induced GnRH release is blocked by simultaneous infusion of a kisspeptin antagonist.[124] It is unclear, however, what reduces GABA inhibition prior to puberty and how GABA signalling interacts with the GnRH pulse generator.

Other transynaptic signals implicated in the regulation of the pubertal resurgence of GnRH pulse generator activity include glutamate and neuropeptide Y (NPY). Glutamate is the major excitatory neurotransmitter in the brain and, in contrast to GABA, hypothalamic release of this amino acid is increased at the time of puberty in the female monkey,[123] and as discussed earlier in the chapter, repetitive activation of glutamate receptors in the juvenile monkey leads rapidly to the onset of precocious gonadarche.[103] Neuropeptide Y (NPY) neurons are found in the arcuate nucleus and, in the male rhesus monkey, NPY gene expression in the hypothalamus is inversely related to the up-down-up pattern of GnRH pulse generator activity from birth to puberty.[125] NPY receptors are inhibitory G-protein receptors, and their activation leads to hyperpolarization and inhibition of neural activity.[126,127]

While neuroglia have classically been regarded as subserving only a "supporting role" in the central nervous system (CNS), contemporary views hold that these non-neuronal cells play important functional roles within the brain.[128] Moreover, in the context of the hypothalamus, secretion of transforming growth factor-α (TGFα) by astroglia has been postulated to provide the GnRH neuronal network with a stimulatory input at the time of puberty.[129,130]

As discussed earlier in this chapter, attempts to elucidate the neural mechanism dictating the postnatal pattern of GnRH pulse generation have traditionally led investigators to focus in relative isolation on a "favorite" signalling pathway. Recently, however, systems biology has been applied to the problem. With this contemporary approach, global gene discovery is combined with computational *(in silico)* biology to identify functional linked networks of hypothalamic

genes that are found to be associated with changes in GnRH pulse generator activity.[131,132] To date this has been conducted without regard to the phenotype of the cells in which the respective genes are expressed and gene networks are operating. Accordingly, it has been proposed that developmental changes in a network of genes encoding for a cohort of transcriptional factors lie, in a molecular sense, upstream of the *KISS1* gene and therefore presumable in a functional sense upstream to GnRH pulse generation. It is argued that such a network of genes serve as a governing hierarchy to orchestrate the resurgence of pubertal GnRH release and therefore the timing of puberty. Since such networks of genes are further proposed to function in the absence of signals derived from the periphery, conceptually they may be viewed at a systems level as comprising a pubertal clock (discussed later in the chapter). Until information is forthcoming on whether the "governing" gene network is expressed in KNDy neurons or by other cells in the hypothalamus or both it will be difficult to integrate the contemporary ideas with those that have evolved from more classical approaches.

Nevertheless, it is interesting to note that one of these transcriptional regulators, enhanced at puberty 1 (EAP1), has been studied in the classical manner, and shown to be expressed in kisspeptin neurons in the arcuate nucleus of the monkey.[133] Moreover, its expression in the hypothalamus increases at the time of puberty in the female monkey, and knock down of *EAP1* using a lentivirus approach interrupts menstrual cyclicity in the adult female.[134] Additionally a single nucleotide polymorphism (SNP) upstream of the *EAP1* gene has been associated with irregular menses in the monkey.[135]

Regardless of the components of the neurobiological brake, which dictate the up-down-up pattern of pulsatile GnRH release from birth until puberty, it is to be anticipated that application and withdrawal of the brake will be associated with a corresponding structural remodelling in those hypothalamic neuronal and glial circuits involved.[136,137] In this regard, the hypothalamus of the postnatal brain retains its capacity for plasticity, as reflected by the expression of polysialic acid-NCAM.[138]

Putative Physiological Control Systems Governing the Timing of Gonadarche

The physiological control systems that dictate the timing of puberty have intrigued investigators for decades, but the governance of this fundamental developmental event in humans remains largely a mystery. Two basic schemata, however, may be proposed.[139] In the first, a cue to reawaken the GnRH pulse generator is provided by the attainment of a particular state of somatic maturation. According to this hypothesis, the brain receives this information by way of a signal in the circulation that is tracked by a somatometer resident within the CNS. In the second schema, a pubertal clock (presumably resident in the CNS) generates the signal.

In the case of the somatometer hypothesis, the attainment of a particular proportion of body fat has long been argued to be necessary for the onset of gonadarche.[140] Interest in this hypothesis was rekindled with the discovery of leptin and its receptor. Leptin, encoded by the leptin *(LEP)* gene, is primarily secreted by adipocytes and regulates feeding behavior and body weight by providing the hypothalamus with information on fat mass and energy status.[141-143] Leptin action is mediated by leptin receptors, which are single transmembrane domain receptors. Six isoforms of the leptin receptor have been described; all represent alternatively spliced products derived from a single gene *(LEPR)* located at chromosome 1p31.3.[144]

In girls, it is generally recognized that plasma leptin levels increase progressively through breast stages 1 to 5.[145-147] In boys, plasma leptin levels also increase during early puberty to reach peak levels between 10 and 12 years of age, but subsequently decline as blood levels of testosterone rise into the adult range.[145,148,149] The finding that circulating concentrations of the soluble form of the leptin receptor progressively decrease during childhood until approximately 11 years of age suggests that the increase in bioavailable leptin during early puberty may be greater than that reflected in total leptin concentrations.[149,150]

Individuals with mutations in leptin signalling, resulting from loss of function mutations in either *LEP* or *LEPR*, have failed to progress through puberty.[151-153] The phenotype of *LEPR* mutations included morbid obesity, abnormal eating behaviors, and lack of spontaneous pubertal development.[153] Over the last 15 years, leptin replacement has been administered to several patients with leptin deficiency due to *LEP* mutations. When administered at an age appropriate for puberty, leptin promoted pubertal development. Importantly, there has been no evidence of premature puberty in younger children following replacement treatment.[152,154,155] Moreover, among children with GnRH-dependent precocious puberty, leptin concentrations correlated with body mass index and not pubertal status.[156] These findings provide compelling evidence that the action of leptin, albeit obligatory for the onset of puberty, is nevertheless permissive.[157-160] This action of leptin may require only low circulating levels of the adipocyte hormone because pubertal development in both male and female subjects with various lipodystrophies has been reported to be normal despite low leptin concentrations.[160-162]

The neuronal targets for leptin's action in the hypothalamus to permit puberty to unfold is an area of considerable contemporary interest. While it is generally recognized that GnRH neurons do not express *LEPR*, data obtained in rodents and sheep for the KNDy neurons are inconsistent and the site of action of leptin may be upstream to the GnRH pulse generator.[163]

Before leaving the subject of leptin and obesity it should be noted that although overweight girls tend to "mature" earlier,[164,165] sleep related increments in LH secretion, and therefore presumable GnRH pulse generator activity, have recently been reported to be blunted in healthy obese premenarcheal girls.[166]

Other somatic factors have been proposed to serve as signals to the somatometer. The hypothesis that such a factor is skeletal in origin[139] is based on the finding that, in children with an accelerated or retarded maturational tempo, menarche and testicular enlargement correlate better with skeletal age than with chronological age.[167,168] Skeletal age, also known as "bone age," is a surrogate marker of biological maturation and may be determined by comparing a radiograph of the left hand to gender-specific standards

obtained at various chronological ages. Several caveats are relevant when assessing skeletal maturity. The degree of skeletal maturation at various sites, such as hands, elbows, and knees, may differ. Skeletal maturation of the carpal bones, distal radius, and distal ulna often lag behind the metacarpals and phalanges.[169] Nevertheless, the association between bone age and the onset of gonadarche is maintained in disorders of growth. In children with constitutional delay of growth and with true isolated growth hormone (GH) deficiency, gonadarche occurs at a late chronological age but at a normal skeletal age.[170,171] On the other hand, when skeletal maturation is advanced, as may occur in association with congenital adrenal hyperplasia (CAH) or familial testotoxicosis, secondary GnRH-dependent precocious puberty may develop.[171] Although proteins synthesized in bone enter the vascular compartment,[172,173] the ability of osteocalcin and other bone proteins to modulate the activity of the GnRH pulse generator has not been addressed.

GH secretion during childhood is relatively stable, but GH release is amplified up to threefold in boys and girls with the initiation of gonadarche and the rise in circulating levels of sex steroids.[174] The pubertal increase in GH, in combination with the increased circulating concentrations of insulin-like growth factor-1 (IGF-I),[175] estrogens, and androgens, contribute to the adolescent growth spurt. The increased secretion of GH at the time of gonadarche is not sustained; by late puberty, GH levels begin to decline.[174] Because the increases in GH and IGF-I appear to be in response to the initiation of gonadarche and particularly to increased gonadal steroid secretion at this time,[174] neither GH nor IGF-I represent compelling candidates for the signal responsible for the resurgence of GnRH release.[5]

At the time of gonadarche, insulin resistance increases. This insulin resistance is greatest among children in Tanner stages 2 and 3 when compared with prepubertal children and adults.[176] Manifestations of insulin resistance appear to be limited to effects on carbohydrate metabolism and are associated with compensatory hyperinsulinemia. Using euglycemic-hyperinsulinemic clamp studies in conjunction with investigation of substrate utilization, one longitudinal study found that puberty was associated with decreased insulin sensitivity, increased insulin secretion, increased total body lipolysis, decreased glucose oxidation, and increased IGF-1 concentrations.[177] In a longitudinal prospective cohort study involving healthy children, insulin sensitivity decreased before the onset of physical features of puberty.[178] The ability of insulin to suppress hepatic glucose production was noted to be preserved during puberty[179] indicating that decreased insulin sensitivity is limited to peripheral glucose uptake. Although cross-sectional studies suggest that the magnitude of insulin resistance is influenced by body mass index (BMI; body weight/height^2 [kg/m^2]), gender, and ethnic background, these associations have not been consistently noted in longitudinal studies. IGF-1 concentrations during puberty have been reported to mirror those in insulin sensitivity.[180] Mean 24-hour serum GH and IGF-I concentrations positively correlate with the degree of insulin resistance during puberty, and the pubertal changes in insulin sensitivity may be partially mediated by increased GH and IGF-I concentrations.[177] Yet, while it is generally recognized that increased gonadal steroid levels are responsible for activation of the GH/IGF1 axis at puberty (discussed earlier in the chapter), a causal relationship between testosterone or estradiol and insulin resistance has not been demonstrated.[181]

Treatment of nonobese Catalunyan girls with premature adrenarche and advanced skeletal maturation with the insulin sensitzer, metformin, was associated with later onset of breast development and menarche.[182] Moreover, in this relatively homogenous ethnic population, metformin treatment for 3 years slowed pubertal tempo among low birth weight girls who are at risk for early puberty and shorter adult stature.[183,184] Taken together, the foregoing considerations raise the possibility that decreased insulin sensitivity may represent a component of the cue that times the onset of gonadarche.

Ghrelin is a small peptide, secreted predominantly by the stomach, which circulates in two forms. The active form is acetylated and promotes GH secretion.[185] Circulating ghrelin concentrations are higher during fasting and decrease after food intake, suggesting that ghrelin signals energy deficient states and modulates appetite and carbohydrate metabolism. Ghrelin concentrations peak during the first 2 years of life and decrease during puberty.[186] The ghrelin receptor, GH secretagogue receptor-1a (GHSR-1a) is expressed in human hypothalamus, pituitary, testis, and ovaries.[187]

Ghrelin and leptin appear to act as reciprocal regulators of energy homeostasis exerting opposing influences on the hypothalamic-pituitary-gonadal axis.[181,188] Resistin and adiponectin are two recently described hormones secreted by adipocytes, which appear to provide metabolical and nutritional status information.[189,190] The respective roles, if any, of these hormones on gonadarche or adrenarche remain to be determined.

Activation and Timing of Adrenarche

Adrenarche is characterized by development of the zona reticularis in the adrenal cortex and increased DHEA, DHEAS, and androsenedione secretion. DHEA and DHEAS are not bioactive androgens; these hormones serve as precursors for more potent sex steroids. Prior to birth, the fetal zone of the adrenal cortex produces large amounts of DHEAS, which serves as the precursor for placental estrogen synthesis. Following involution of the fetal zone after birth, DHEAS concentrations remain low until 6 to 7 years of age at which time they begin to increase. This elevation in DHEAS secretion is the earliest hormonal manifestation of adrenarche; it is not associated with changes in pituitary ACTH secretion or changes in cortisol secretion.

The onset of adrenarche is associated with increased 17,20-lyase activity and decreased 3β-hydroxysteroid dehydrogenase activity.[191] Available data suggest that, at the time of adrenarche, changes in expression of cytochrome b_5 (CYB5A), DHEA sulfotransferase (SULT2A1), and 3β-hydroxysteroid dehydrogenase (HSD3B2) play essential roles in DHEA and DHEAS production.[192] Histologically, increased thickness of the zona reticularis occurs concurrently with the increase in DHEAS concentration. Using more sensitive methodology such as urinary GCMS, studies indicate that concentrations of DHEA and its metabolites show a continuous rise beginning at 3 to 4 years old. These data contradict conventional concepts and imply that

adrenarche is a gradual process beginning earlier than previously considered.[193] DHEAS concentrations continue to rise and peak between 20 and 25 years of age, followed by progressive decline. Although the findings have been inconsistent, clinical studies suggest that insulin, IGF-I, and GH concentrations influence the timing, onset, and progression of adrenarche.[194] Comparison of IGF-I concentrations among prepubertal children have shown higher concentrations in African-American children.[195] Whether these ethnic differences contribute to the earlier onset of adrenarche or increased incidence of premature pubarche in African-American girls is unknown. Clinical observations regarding associations between adrenarche and body size and fatness have been inconsistent; one longitudinal study showed that DHEAS concentrations increased commensurate with the largest increase in BMI, whereas another longitudinal study found no association between DHEAS and weight, BMI, or body surface area.[196,197]

Despite numerous hypotheses, the primary signal for adrenarche remains to be elucidated.[198] Hypothalamic releasing factors, such as corticotropin-releasing hormone (CRH) and vasopressin (ADH), play important roles in governing hypothalamic-pituitary-adrenal axis function. In contrast to the role of hypothalamic GnRH in gonadarche, however, CRH and ADH do not appear to trigger the onset of adrenarche. No specific adrenal androgen-stimulating factors have been isolated from the pituitary.[199]

Moreover, adrenarche occurs independently of developmental changes in the hypothalamic-pituitary-gonadal axis. For example, children with gonadal dysgenesis experience normal adrenarche and pubarche, whereas children with primary adrenal insufficiency may have normal gonadarche.[200] Nevertheless, despite the long-established notion that gonadarche and adrenarche are independent events, recent data hint that adrenal androgens may influence pubertal timing. Specifically, using methodology with lower limits of detection, these data show that higher pre-pubertal urinary androgen excretion correlated with an earlier onset of breast development and penile growth respectively and with a shorter duration of pubertal growth spurt.[201]

Genetics and Puberty Genes

The observations that (1) the temporal correlation in somatic maturation and attainment of pubertal stages in monozygotic twins is more robust than that in dizygotic twins, (2) the age of menarche in mothers and daughters is correlated, (3) parents of children with constitutional delay of puberty (discussed later in the chapter) recall a later age of menarche and the adolescent growth spurt than those of a control group of children,[202-204] (4) precocious gonadarche in girls may be familial and transmitted in an autosomal dominant mode,[205] and (5) the age of menarche varies with racial group, underline the major influence of genetic factors for timing the onset of puberty. However, it remains unclear whether the genetic factors directly dictate the timing of the pubertal resurgence of GnRH release (perhaps a network of clock genes in analogy to circadian time keeping)[206] or simply control permissive factors that are required for expression of pubertal mechanisms.

We suggest that the term "puberty" gene should therefore be restricted to those genes that are specifically involved in the timing of either adrenarche or gonadarche.[5] For gonadarche, such genes would determine the age of the pubertal resurgence of pulsatile GnRH release by regulating the timing of the application or withdrawal of the neurobiological brake to the GnRH pulse generator of the juvenile hypothalamus. Puberty genes could time the resurgence of pulsatile GnRH release not only by triggering a hypothalamic signal at puberty but also potentially by determining the duration of the prepubertal brake on pulsatile GnRH release or by timing the "turn off" of the GnRH pulse generator during infancy. In the case of adrenarche, the developmental increase in adrenal androgen secretion would presumably be timed by genes that are responsible for the changes in adrenal steroidogenesis manifested by increased zona reticularis activity.

Despite the accelerating pace of elucidation into the genetic causes of disorders of pubertal development,[207] the identity of specific puberty genes that dictate the timing of the resumption of pulsatile GnRH release (and therefore determine the age of gonadarche) and those that regulate the developmental increase in adrenal androgen secretion that determine the age of pubarche have not been identified. Association studies have shown no significant associations between common variants in several genes (*GNRH1*, *GNRHR*, *KISS1R*, *LEP*, *LEPR*, *FGFR1*, *KAL1*, *PROK2*, and *PROKR2*) and age at menarche.[208] Thus, rather than being the master genes responsible for triggering the pubertal resumption of pulsatile GnRH secretion, these genes are critical for GnRH release at all stages of development, and therefore do not meet the criteria of a puberty gene. The whole genome can be interrogated by linkage and genome wide association (GWA) analyses without a priori hypotheses regarding specific candidate genes. However, these approaches have largely been unsuccessful.[209] Two loci located at chromosome 9q31.2 or chromosome 6q21were significantly associated with age at menarche in normal women.[210,211] In addition to *LIN28B* at chromosome 6q21, meta-analyses have identified additional loci associated with age at menarche.[212]

Genetic information is also transmitted by DNA (CpG) methylation, chromatin packaging, and small RNA or microRNA effects on transcription. Whereas most autosomal genes are expressed from the alleles of both parents, a number of growth regulatory genes show parent-of-origin effects due to genomic imprinting.[213] Environmental factors such as nutrition, hormone and chemical exposures, and physical factors can alter gene expression through these epigenetic modifications.[214,215] Maternal nutritional status can influence fetal gene expression through epigenetic mechanisms; animal studies suggest that this effect may be transmitted to subsequent generations.[216] Developmental disorders such as Prader-Willi syndrome, in which the timing and tempo of puberty is altered (discussed later in the chapter), are associated with abnormal expression of imprinted genes.[213] These disorders may represent the "tip of the iceberg" for epigenetic influences on the genes that dictate or modulate the timing of puberty.

Factors Modulating the Timing of Puberty

In general, the majority of studies that have examined the influence of various parameters on the onset and tempo of

puberty have focused on the process of gonadarche. Considerably less attention has been paid to the timing and progression of adrenarche. Additionally, many factors that influence the onset and tempo of puberty (for example, nutritional status) also modulate hypothalamic GnRH pulse generator activity in the majority of adults. Therefore, a modulator of puberty is not necessarily a component of the mechanism that initiates this developmental event. Rather, it is more likely that such factors play permissive, albeit in some cases obligatory, roles to allow the process of puberty to unfold once the signal responsible for the resurgence in pulsatile GnRH secretion has been activated.

Nutrition and Diet

Adequate energy stores are essential for the accelerated linear growth and achievement of reproductive competence at puberty. Nutritional state modulates the onset of gonadarche in girls,[217] as reflected by the findings that menarche is delayed in malnourished girls,[218] and menarche tends to occur at a particular or "critical" body weight rather than at a set age.[219] Obesity is associated with early breast development and menarche.[220] In addition, the timing of adrenarche may also be influenced by nutritional status. In the female rhesus monkey, high calorie diets were associated with a precocious increase in nipple volume, sex-skin swelling, and menarche in association with increased concentrations of leptin and IGF-1 concentrations, and an increased BMI.[221] While the impact of undernutrition on gonadarche in boys has received less attention, there is no reason to suspect that the male axis is unaffected in this regard.

Leptin and osteocalcin appear to communicate energy status to several tissues including adipose tissue, bone, CNS, and gonads.[222] In its undercarboxylated (active) form, osteocalcin promotes insulin secretion, improves insulin sensitivity, induces β-cell proliferation, increases adiponectin secretion, and decreases lipolysis.[223] In osteoblasts, insulin signalling increases bone formation, bone resorption, and secretion of active osteocalcin production. Whereas insulin acts to promote bone formation and secretion of active osteocalcin, leptin acts indirectly through the hypothalamus to decrease bone formation.[224] Rapid weight gain during the first year of life is associated with obesity and early menarche in a prospective UK cohort study.[225]

Differences unrelated to racial or ethnic background in the timing and tempo of gonadarche have been reported even among well-nourished girls. Researchers have suggested that diet may account for such variations.[226-228] Attention has been drawn to subtle relationships between diets high in animal protein and early menarche, and between diets high in vegetable grains and delayed onset or tempo of gonadarche. Moderate to vigorous exercise in the absence of weight restriction appears to have a negligible impact on the timing and tempo of puberty in either sex. However, breast development, menarche, and skeletal maturation can be delayed in girls involved in strenuous physical training.[229] The association between extreme energy expenditure and delayed gonadarche in the female is particularly marked in ballerinas, long-distance runners, and figure skaters, who must maintain their body weight within strict limits. Such girls have amenorrhea secondary to hypothalamic hypogonadism (HH). The factors responsible for compromising pulsatile GnRH release in pubertal children who exercise vigorously are probably similar to those resulting from undernutrition. The life of the young female dancer or athlete is stressful and, therefore, stress may also represent a contributing factor underlying exercise-induced delayed gonadarche. Because certain physical and psychological characteristics are necessary for outstanding athletic performances, there may be a significant contribution of self-selection involved in the decision of girls to participate at such an exceptional level. In a study of young female gymnasts and their parents, menarche in the mothers was found to be delayed relative to that of mothers of sedentary girls.[229] Therefore, the possibility of a genetic contribution to this phenomenon cannot be totally excluded. The effect of physical training on the timing of pubarche in girls has been less studied and the available data are contradictory.[230,231]

Although the relationship between strenuous physical training and male puberty has received less attention, this developmental process is apparently less susceptible in boys than it is in girls.[232] This may be related, in part, to sex differences in the age at which training is initiated, and to the intensity of the exercise. Nevertheless, in sports like wrestling that require weight control achieved with a combination of strenuous exercise and dietary restriction, impaired testosterone secretion may occur.[232]

Environmental Disruptors

Increased attention has been focused on endocrine disrupting chemicals (EDCs) as modulators of pubertal timing.[233] Most EDCs have estrogenic or anti-androgenic activities. Most occur as mixtures rather than single agents. Sexually dimorphic actions can occur. Dioxins, polychlorinated biphenyl (PCB), polybrominated biphenyl (PBB), bisphenol A (BPA), plasticizers (phthalates), pesticides, fungicides (vinclozolin), and pharmaceutical agents (diethylstilbestrol) are considered to be EDCs. Phytoestrogens, which can function as selective estrogen receptor modulators (SERMS), are found in soybeans, flaxseed, peanuts, and some vegetables. Most are diphenolic compounds with structural features common to estrogenic steroid agonists and antagonists. EDCs can affect peripheral reproductive systems such as inducing breast development. These chemicals may also exert neuroendocrine effects to influence hypothalamic and pituitary function. EDCs can act through hormone receptors and by affecting enzymatic processes.[234] Further investigation into EDCs, defining mechanisms of action and consequences, is necessary.[235]

Prenatal Influences

The role of prenatal influences and environment on postnatal development including puberty are increasingly recognized.[236,237] Children with intrauterine growth retardation (IUGR) or born small for gestational age (SGA) have increased risks to develop insulin resistance, hypertension, diabetes mellitus, metabolical syndrome, and coronary artery disease in adulthood.[238] Increased weight gain during the first few years of life exaggerates these risks. Increased adrenal androgen levels and in some cases precocious or exaggerated adrenarche has been reported in both boys and girls born SGA.[239-241] Some, but not all, girls with premature adrenarche have an increased risk to develop polycystic ovary syndrome (PCOS) during adolescence.[239,240,242] Despite inconsistent reports, the majority of studies indicate that

the timing of menarche in girls born SGA does not appear to be markedly different from girls born at an appropriate size for gestational age.[243-246] The timing of puberty in boys born SGA appears to be normal,[245] although sub-fertility has been reported after they reached adulthood.[247]

Adoption or Migration From Developing to Developed Countries

Several European countries have reported precocious gonadarche in a relatively dramatic proportion of children—particularly girls—adopted from developing world regions like Asia and South America.[248,249] This precocity is preceded by increased endocrine activity in the pituitary-ovarian axis prior to the onset of physical manifestations of puberty, indicating a central origin to the condition.[250] While it was initially argued that improved nutritional and social conditions were in some way responsible for this phenomenon, the cause of the precocity appears to be complex. Precocious gonadarche is also seen in immigrant girls arriving with their parents and without evidence of earlier compromised growth and nutrition.[251] Moreover, ethnic background does not appear to be involved. A study of immigrant girls in Belgium with premature gonadarche found an association with previous exposure to organochlorine pesticides.[251] A study in Spain found an increased relative risk for precocious gonadarche in adopted girls (both national and international), but not in immigrant girls.[252]

Disorders of Puberty

The terminology used to describe disorders of puberty has evolved as the pathophysiology and molecular etiologies of these disorders have been clarified (Box18.1; Table 18.2). The term "central precocious puberty" or GnRH-dependent precocious puberty refers to premature resurgence of GnRH pulse generator activity, which we have labeled as *GnRH-dependent precocious gonadarche*. The terms "partial," "incomplete," "peripheral," "pseudo," and "GnRH-independent precocious puberty" have been used to describe other etiologies of premature sexual development. We refer to these disorders as *GnRH-independent precocious puberty*. *Isosexual* refers to the development of sexual characteristics typical for the patient's gender. *Heterosexual* refers to the development of sexual characteristics typical of the other gender (e.g., feminizing tumors in males). Delayed puberty has been categorized as being either *hypogonadotropic* (low gonadotropin concentrations) or *hypergonadotropic* (elevated gonadotropin concentrations). With expanding knowledge of the functional genomics of the pubertal process and the molecular genetics underlying its pathophysiology, the classification of the etiologies of disorders of puberty will continue to evolve.

Disorders of Early Puberty

GnRH-Dependent Precocious Pubertal Development

Progressive Precocious Gonadarche or Central Precocious Puberty

Although this disorder is labeled GnRH-dependent precocious puberty or central precocious puberty (CPP), it represents precocious gonadarche due to either premature

Box 18.1 Etiologies of Precocious Puberty

GnRH-DEPENDENT GONADARCHE
- Idiopathic: Progressive, nonprogressive
- Congenital CNS lesions: Hypothalamic hamartoma, septo-optic dysplasia, arachnoid cysts, suprasellar cysts, *KISS1R* activating mutation
- Acquired CNS disorders: Postinflammatory, postradiation therapy, abscess, hydrocephalus, trauma, tumors
- Chronic exposure to androgens: Congenital adrenal hyperplasia, familial male limited precocious puberty
- Other conditions: Williams-Beuren syndrome, maternal uniparental disomy of chromosome 14, histiocytosis X

GnRH-INDEPENDENT GONADARCHE
- McCune-Albright syndrome
- Feminizing disorders, estrogen secreting tumors: Ovarian (granulosa cell, Peutz-Jeghers syndrome, gonadoblastoma/dysgerminoma, carcinoma, cystadenoma, theca cell, lipoid) and adrenal
- Feminizing disorders, estrogen secretion unrelated to tumors: Aromatase mutation
- Isolated premature menarche: Estrogen-secreting cyst, tumor, McCune-Albright syndrome, primary hypothyroidism
- Premature thelarche: Variant of normal development, Rubinstein-Taybi syndrome, Kabuki make-up syndrome
- Primary hypothyroidism
- Exposure to exogenous sex steroids or endocrine disruptors

VIRILIZING DISORDERS
- Premature adrenarche
- Congenital adrenal hyperplasias (21-hydroxylase deficiency, 3β-hydroxysteroid dehydrogenase deficiency, 11 β-hydroxylase deficiency)
- Other disorders affecting steroidogenesis (oxidoreductase deficiency, apparent cortisone reductase deficiency, apparent DHEA sulfotransferase deficiency)
- Inherited glucocorticoid resistance
- Familial male-limited precocious puberty (testotoxicosis)
- Androgen-secreting tumors (adrenal sex steroid-secreting tumors like adenoma and carcinoma; ovarian tumors like arrhenoblastoma; testicular Leydig cell), hCG-secreting tumors (hepatoblastoma/hepatoma, dysgerminoma, teratoma, choriocarcinoma)
- Cushing syndrome (Cushing disease associated with increased ACTH secretion, adrenal disease, ectopic secretion of CRH or ACTH)

Table 18.2 Monogenic Disorders Associated with Precocious Puberty

Gene	*Locus*	*Phenotype*
GNAS1	20ql3.2	McCune-Albright syndrome
STK11/LKB1	19pl3.3	Peutz-Jeghers syndrome
CYP21A2	6p21	CAH due to 21-hydroxylase deficiency
HSD3B2	Ipl3.1	CAH due to 3β-hydroxysteroid dehydrogenase deficiency
CYP11B1	8q21	CAH due to llβ-hydroxylase deficiency
LHR	2p21	Familial male-limited precocious puberty
CYP19A1	15q21.1	Precocious puberty/gynecomastia
GRL	5q31	Inherited glucocorticoid resistance
KISS1R	19p13.3	Precocious puberty associated with activating mutations

CAH, congenital adrenal hyperplasia.

resurgence or incomplete suppression of the hypothalamic GnRH pulse generator. It occurs more often in girls than in boys. This sex difference is probably related to the lesser prepubertal suppression of the GnRH pulse generator in girls than boys. The sequence of pubertal development is typical of a normal puberty including adrenarche in some cases, but it begins at an earlier-than-normal age.

Useful laboratory studies include x-ray assessment of skeletal maturation (bone age), and gonadotropin, IGF-1, and sex steroid concentrations. A GnRH (Factrel or a GnRH-R agonist [GnRH-Ra] such as leuprolide) stimulation test is important to demonstrate a pubertal pattern of gonadotropin responses. Generally, a stimulated LH predominant response is noted which confirms the increased GnRH pulse generator activity. In girls, when gonadotropins are measured using third-generation monoclonal fluorometric assays, basal and GnRH-stimulated LH concentrations greater than 0.6 and 6.9 U/L, respectively, are 70% and 92% sensitive for the diagnosis of GnRH-dependent precocious gonadarche.[253] Comparison of two third generation LH assays, Architect and Delfia, to assess for precocious puberty in girls indicated that basal LH values may be adequate to diagnose CPP in most instances.[254] Girls with CPP had higher IGF-1, fasting insulin, and oral glucose-stimulated insulin concentrations compared to healthy girls; these differences persisted after adjustment for chronological age, skeletal age, and pubertal stage.[255] The IGF-1 concentrations do not decrease to pre-pubertal values despite adequate treatment.

Since affected children appear older than their chronological age, parents and teachers may have inappropriate expectations regarding psychosocial development and abilities. Cognitive and emotional development, however, are normal for chronological age. Thus, the guilelessness and naiveté of such children exposes them to an increased risk of sexual abuse, with affected girls at risk of becoming pregnant.

Although GnRH-dependent precocious puberty is considered to be idiopathic in girls, the recognition of genes involved in GnRH and gonadotropin secretion has allowed for identification of specific gene mutations in patients with CPP. A heterozygous missense mutation, Arg386Pro, in the *KISS1R* gene was associated with precocious puberty in a girl.[256] The mechanism of action of this mutation may be related to delayed degradation of the receptor yielding prolonged duration of action.[257]

Magnetic resonance imaging (MRI) and computerized tomograpghy (CT) imaging are helpful to identify anatomical lesions such as hypothalamic hamartomas.[258] Hypothalamic hamartomas, congenital malformations composed of a heterotropic gray matter, neurons, and glial cells usually located on the floor of the third ventricle or attached to the tuber cinereum, are a common etiology of precocious gonadarche. The tumors can be classified as *parahypothalamic*, attached or suspended from the floor of the third ventricle, or as *intrahypothalamic*, in which the mass is enveloped by the hypothalamus and distorts the third ventricle. The lesions do not grow over time and do not metastasize. Extreme precocity or the absence of circulating tumor markers such as β-human chorionic gonadotropin-(β-hCG) and α-fetoprotein[259,260] suggests a hamartoma. Although gelastic or laughing seizures can be associated with precocious puberty due to hypothalamic hamartomas, the majority of patients with hypothalamic hamartomas do not exhibit neurological symptoms.[261]

Hypothalamic hamartomas are generally sporadic, but may occur as a feature of Pallister-Hall Syndrome. Pallister-Hall Syndrome is an autosomal dominant disorder associated with mutations in the *GLI3* gene located at chromosome 7p13. Additional features can include pituitary anomalies, hypopituitarism, imperforate anus, and polydactyly.[262]

On CT or MRI, hamartomas appear as an isodense, abnormal fullness. Imaging with MRI is superior to CT, but the lesions do not enhance with contrast material. Histological examination of hypothalamic hamartoma tissue has shown immunoreactivity for GnRH and for astroglial-derived factors such as TGFα.[263] Two potential mechanisms have been hypothesized, with one being increased GnRH secretion from tissue emancipated from suppression by the prepubertal brake. The other possibility is that factors such as TGFα provide an ectopic drive to GnRH neurons with a normal distribution in the hypothalamus. In one series, hypothalamic hamartomas associated with precocious puberty tended to be larger and were more likely to contact the infundibulum or tuber cinereum than those without precocious puberty.[264] Gene expression profiling of hypothalamic harmartomas associated with precocity may provide clues regarding genes, proteins, and regulatory pathways associated with the timing of puberty.[265]

In addition to hypothalamic hamartomas, optic gliomas, suprasellar cysts, arachnoid cysts, previous head trauma, static cerebral encephalopathy, CNS infections, CNS radiation, hydrocephalus, meningomyelocele, and neurodevelopmental disabilities may also be associated with progressive precocious gonadarche.[266-268] For hypothalamic-pituitary disorders, the endocrine symptoms of precocious puberty may precede neurological symptoms.[269] Three predictors associated with CNS lesions in girls are: (1) age younger than 6 years; (2) absence of pubic hair; and (3) estradiol concentrations greater than 110 pmol/L.[270] The type of CNS lesion influences the presentation of GnRH-dependent precocious puberty presumably due to differences in the mechanisms inducing puberty and to the hypothalamic-pituitary deficiencies associated with the initial lesion or its treatment.[271] Optic gliomas are associated with neurofibromatosis type 1 (NF1), an autosomal dominant disorder that is diagnosed based on clinical features that include size and number of cafe-au-lait spots, macrocephaly, and family history of the disorder. The mechanism of action has been presumed to be a mass effect.[272] Pineal tumors can be associated with precocious puberty due to tumor-induced hydrocephalus or germ cell tumors.[273] CNS radiation used to treat intracranial tumors or used prophylactically for malignancies can induce precocious gonadarche, perhaps as a result of an astroglial response with increased TGFα production.[274] The Childhood Cancer Study Group noted that higher radiation doses and younger age, less than 4 years old, conferred a greater risk for premature menarche.[275] In this situation, it is important to note that simultaneous GH deficiency may be masked by an accelerated growth velocity due to precocious gonadarche.

Precocious gonadarche, which appears to be GnRH-dependent, has been reported in the Williams-Beuren syndrome, histiocytosis X,[276,277] and maternal uniparental disomy for chromosome 14.[278] An imprinted domain located

at chromosome 14q32 appears to be the critical region for the phenotype associated with maternal uniparental disomy. In addition to precocious puberty, clinical features include prenatal and postnatal growth retardation, developmental delay, hypotonia, and joint laxity. Deletion of the paternal allele and imprinting defects involving this region can result in a similar phenotype.[279] Other situations associated with progressive precocious gonadarche include children with virilizing disorders (such as CAH) and familial male-limited precocious puberty (testotoxicosis) in whom skeletal maturation is usually markedly advanced. In these situations, the precocious gonadarche is considered to be secondary to the virilizing disorder, but the mechanism through which the GnRH pulse generator is prematurely activated is unclear.

The treatment of choice for children with progressive precocious gonadarche is a GnRH receptor agonist (GnRH-Ra). In situations of coexisting GH deficiency, combined treatment with recombinant human GH may be helpful to preserve height potential. GnRH-Ras are modifications of the native GnRH decapeptide, have greater resistance to degradation, and possess increased affinity for the GnRH-R. They are, therefore, perceived by the pituitary as a continuous GnRH stimulation, which induces down-regulation of GnRH-R function and leads to decreased gonadotropin secretion. GnRH-Ras are available as daily injections or depot forms that are currently administered every 28 days. The depot formulation of leuprolide acetate is commonly used in the United States; the recommended dose is 0.3 mg/kg administered every 28 days. Another GnRH-Ra, histrelin, has been formulated as a hydrogel subdermal implant that is surgically inserted into the inner aspect of the upper arm.[280] Over the course of 1 year, histrelin diffuses from the 50 mg implant. Studies indicate excellent gonadotropin suppression.[281,282] When the progressive nature of the disorder is equivocal, serial evaluations are necessary to detect a sustained acceleration in tempo of pubertal development, including skeletal maturation (and therefore loss of height potential), before initiating therapy. This strategy is necessary because children with nonprogressive precocious puberty do not benefit from treatment. The major goals of treatment are to prevent further pubertal progression until appropriate for chronological age and to achieve improved adult height.

Clinically, the cessation of pubertal progression is apparent within 3 months of initiating treatment. Signs related to adrenarche neither regress nor are prevented, and may progress. In girls, breast size typically decreases, but may not completely regress. Vaginal bleeding secondary to estrogen withdrawal, and acne may occur during the first month of treatment. Subsequently, there should be no further vaginal bleeding even if menarche occurred prior to initiation of therapy. The ovaries and uterus decrease in size. In boys, testicular volume decreases. Linear growth velocity and the rate of bone mineral accretion decrease. Longitudinal evaluation of a cohort of children with precocious gonadarche showed increased lumbar bone mineral density and BMI standard deviation (SD) scores at initiation of therapy. Two years after cessation of therapy in these children, bone mass, bone turnover, and percent body fat were normal, suggesting that peak bone mass will be appropriate.[283]

Adequacy of treatment is judged by prepubertal estradiol/testosterone concentrations and prepubertal gonadotropin response to GnRH stimulation. Monitoring to confirm efficacy of therapy includes interim history, physical examination to ascertain height, weight, and stage of pubertal development, and bone age x-rays. In addition, GnRH stimulation tests should be repeated at regular intervals (3 to 12 months) to document gonadotropin suppression. This monitoring is necessary because bone maturation may progress despite regression of the clinical features associated with gonadarche. Urinary gonadotropin determinations do not provide adequate sensitivity to judge efficacy of therapy.[284]

The duration of GnRH-Ra therapy should be individualized with the decision to discontinue therapy based on chronological age, skeletal maturation, projected adult height, and psychosocial readiness for resumption of puberty. For girls, menstruation usually occurs 9 to 15 months after discontinuation of GnRH-Ra therapy, with earlier onset in those who had experienced menarche prior to treatment. Studies indicate that final height is improved over initial predicted height at diagnosis but is still less than that based on midparental height. Rapidly progressive pubertal development, advanced skeletal maturation, predicted compromise of adult height, and psychosocial considerations justify treatment.[285,286]

Among the adverse effects of treatment, parents may note increased emotional lability and moodiness just prior to the GnRH-Ra injection. Local or systemic allergic reactions or sterile abscesses may occur, but are uncommon. Some children show increased weight gain disproportionate to their linear growth. Intermittent therapy, often due to poor compliance, may have the deleterious effect of increasing gonadotropin and gonadal steroid secretion, leading to progressive skeletal maturation and further compromise of adult height.

Long-term experience (more than 20 years) has now accrued for GnRH-Ras. Pregnancies with normal offspring have been observed.[287] Although no major adverse effects on reproductive function have been noted, some girls appear to have an increased risk to develop PCOS.[288-290]

Nonprogressive Precocious Gonadarche

Some children experience a nonprogressive (or slowly progressing) form of precocious gonadarche attributed to a premature but intermittent or transient activation of the hypothalamic GnRH pulse generator.[291] Among this latter group of children, basal gonadotropin concentrations and gonadotropin responses to GnRH stimulation may be normal for chronological age but can overlap values observed among children with progressive precocious gonadarche. Because the physical signs of pubertal development do not always correlate with GnRH-stimulated gonadotropin responses, physical findings alone cannot differentiate between progressive and non-progressive precocious gonadarche.[292] In general, children with this nonprogressive form of precocious gonadarche show no evidence of pubertal responsiveness to GnRH stimulation, no loss of height potential, and do not usually benefit from GnRH-Ra therapy.[293]

GnRH-Independent Precocious Pubertal Development

Precocious pubertal development may occur independently of pulsatile GnRH secretion. In these situations of

peripheral precocious puberty, inappropriate gonadal or adrenal steroid secretion or exposure to exogenous steroids induces the physical signs of puberty. In most instances, the pubertal development is incomplete and fertility is not attained.

McCune-Albright Syndrome

The classical clinical triad of McCune-Albright syndrome (MAS) is precocious pubertal development, cafe-au-lait spots, and bony fibrous dysplasia. The café-au-lait lesions are generally large, do not cross the midline, and have irregular "coast of Maine" margins, but exceptions to the classic features can occur. Precocious pubertal development is not observed in all cases and appears to be more common among girls than boys. This disorder is due to constitutive activation of the $G_{s\alpha}$ protein that is coupled to membrane-bound glycoprotein hormone receptors and is associated with autonomous function of endocrine glands. The syndrome is due to postzygotic somatic cell mutations in the *GNAS1* gene; missense mutations Arg201His and Arg-201Cys are among the most common.[294] Partial or atypical forms are increasingly recognized; among 113 children with 1 to 3 features typical of MAS, a PCR-based mutation analysis protocol identified a missense mutation at codon 201 in 90% when an affected tissue, e.g., ovarian, bone, adrenal tissue, etc was analyzed.[295] These gain-of-function mutations in the $G_{s\alpha}$ gene lead to constitutive activation of gonadotropin receptors, and subsequent increased autonomous ovarian estrogen and testicular testosterone secretion in affected girls and boys, respectively.[296]

Vaginal bleeding, with or without breast development, is the typical presentation in prepubertal girls. The vaginal bleeding represents estrogen withdrawal following resolution of an estrogen secreting cyst. Estrogen concentrations may be elevated and pelvic ultrasound may confirm a unilateral ovarian cyst. The frequency of recurrent episodes of ovarian cysts and vaginal bleeding is variable. Because the precocious pubertal development is GnRH-independent, GnRH-Ra treatments are ineffective. Treatment with aromatase inhibitors, estrogen receptor modulators, and medroxyprogesterone acetate have been tried.[297,298] Although safe, treatment with anastrozole for 1 year did not halt vaginal bleeding or attenuate rates of skeletal maturation and linear growth in girls with MAS suggesting that aromatase inhibitors may not be useful in the treatment of this form of precosity.[299] Letrozole, another aromatase inhibitor, has some efficacy, but was associated with ovarian torsion in one girl.[300] A partial estrogen antagonist, tamoxifen, has been helpful. Preliminary results using Fulvestrant, a pure estrogen blocker, are promising to decrease vaginal bleeding and slow bone maturation.[301] One outcome study showed variable gonadal function in affected adult women, with some having regular menses and fertility while others had persistent autonomous gonadal function associated with irregular menses and infertility.[302]

Among boys with MAS, precocious puberty is less common. In a cohort of 54 males, 11 (21%) presented with precocious puberty. Gonadal involvement occurred in approximately 80% and one patient had a testicular embryonal carcinoma.[303] Macroorchidism may be noted on examination. Ultrasound features can include macroorchidism, hyperechoic lesions, hypoechoic lesions, and testicular microlithiasis. Leydig cell hyperplasia can occur in postpubertal men, but is rare in boys. AR blockers, aromatase inhibitors, and blockers of sex steroid synthesis have been used to treat the precocious puberty. A conservative approach to MAS-associated testicular lesions has been endorsed with emphasis on serial imaging and testicular preservation.[303]

The typical bone lesion is polyostotic fibrous dysplasia. Lesions tend to be asymmetric and can affect any bone, including the skull. Skeletal disease is generally apparent by 10 years of age. The cystic bone lesions can lead to pathological fractures and deformities. Pseudoarthrosis can occur. With involvement of the skull, hyperproliferation of the pre-osteoblastic cells results in impingement into cranial foramina leading to compression of cranial nerves. Blindness, deafness, facial asymmetry, or ptosis can result. Rather than being associated with a single abnormality of bone, the specific histopathology varies depending on anatomical location: axial or appendicular skeleton, cranial bones, or gnathic bones.[304] Bone lesions may be apparent on bone scans before they are visible on x-rays. Hypermetabolical bone disease is indicated by increased serum osteocalcin and alkaline phosphatase concentrations, as well as increased urinary hydroxyproline concentrations. Short-term studies suggest that bisphosphonate therapy may benefit the bone disease. In one small series, bone pain decreased without apparent change in the bone lesions by radiography or scintigraphy.[305] However, other patients showed increased bone mineral density and radiographic evidence of bone healing with pamidronate treatment.[306]

Hypophosphatemic rickets can occur secondary to increased fibroblast growth factor 23 (FGF23) production by the bone lesions. There is a positive relationship between disease activity and FGF23 concentrations. Treatment of the hypophosphatemia includes phosphate and vitamin D. Other endocrine manifestations include nodular thyroid hyperplasia with hyperthyroidism, multiple pituitary adenomas associated with gigantism, acromegaly or hyperprolactinemia, and parathyroid adenoma or hyperplasia with hyperparathyroidism. Cushing syndrome is extremely rare and almost always occurs during infancy.[307]

Feminizing Disorders

Estrogen-Secreting Tumors

Estrogen-secreting tumors are a rare cause of premature or abnormal pubertal development. Types of tumors include granulosa cell, gonadal stromal cell, ovarian sex cord stromal, and theca cell tumors.[308,309] The majority of juvenile granulosa cell tumors can be palpated on bimanual examination. Estrogen concentrations may be very elevated, and circulating tumor markers such as α-fetoprotein or hCG may be detected. Rarely, gonadoblastomas in streak gonads, lipoid tumors, cystadenomas, and ovarian carcinomas can secrete estrogens, androgens, or both. Elevated serum inhibin and AMH concentrations, and the finding of AMH immunoreactivity in the tumor, indicate that the tumor cells are of granulosa or Sertoli cell origin.[310-312] Expression of *FOXL2*, *SOX9*, and other specific genes can be helpful to discriminate between gonadoblastomas and intratubular germ cell neoplasias; *FOXL2* expression suggests that a gonadoblastoma has a granulosa cell component.[313,314] If originally positive, these markers may be useful to recognize recurrence.

Sex cord tumors with annular tubules are common in patients with Peutz-Jeghers syndrome (PJS), an autosomal-dominant disorder characterized by mucocutaneous pigmentation and gastrointestinal polyposis. These tumors, which are multifocal and bilateral, may differentiate into granulosa cell or large cell calcifying Sertoli tumors with the potential to secrete estrogen. Thus, affected males may present with gynecomastia.[315] Although usually benign, granulosa or Sertoli cell tumors can undergo malignant changes.[316] Affected individuals have an increased risk for colon, stomach, small intestinal, breast, and pancreatic cancers. The Sertoli cell tumors have been found in association with both PJS and the Carney Complex (CNC).[317] PJS is associated with mutations in the *STK11/LKB1* gene, which encodes a serine-threonine kinase.[318] CNC is often associated with mutations in the protein kinase, c-AMP dependent, regulatory, type 1, alpha *(PRKAR1A)* gene which encodes the regulatory subunit type 1 of protein kinase A. Among boys, adrenal, testicular, or hepatocellular tumors can express aromatase, leading to secretion of estradiol and estrone.[319-321] In instances where gynecomastia is excessive, prolonged, and apparent at a time other than midpuberty (around stage 3), further evaluation may be warranted.[322] The evaluation should include testosterone, estradiol, hCG, LH, FSH, thyroid stimulating hormone (TSH), and DHEAS measurements. In addition to tumors, the differential diagnosis of gynecomastia includes Klinefelter syndrome, impaired testosterone biosynthesis, androgen insensitivity, and hyperprolactinemia.

Estrogen Secretion Unrelated to Tumors

In one family, autosomal-dominant familial gynecomastia was due to aberrant transcription of the aromatase gene; the affected girl developed GnRH-independent precocious pubertal development.[323] Autosomal dominant aromatase excess syndrome is characterized by high systemic estrogen levels, short stature, prepubertal gynecomastia and testicular failure in males, and premature breast development, macromastia, and uterine pathology in females. Small chromosomal arrangements in the promoter region of the aromatase gene appear to be associated with increased promoter activity resulting in increased aromatase activity.[324] Novel cryptic deletions and duplications were identified; phenotypic severity in this gain of function disorder is primarily determined by the tissue expression pattern of *CYP19A1*.[325]

Isolated Premature Menarche

Isolated premature menarche refers to vaginal bleeding at an inappropriately early age in the absence of other signs of puberty. The duration of bleeding is usually limited to a few days. The most common endocrine etiology is spontaneous resolution of an estrogen-secreting ovarian cyst. Often, the ultrasound shows no abnormality because the cyst has resolved by the time the study is obtained. Most instances are self-limited, remit spontaneously, and are associated with normal pubertal development. Typically, isolated menarche due to an estrogen-secreting cyst is a sporadic event that usually occurs once. However, such cysts and episodes of vaginal bleeding may recur. The bloody vaginal discharge noted in female infants during the first week of life is a physiological event secondary to estrogen withdrawal.

Tumors or trauma usually do not cause cyclic bleeding. The other major differential diagnoses of isolated vaginal bleeding include sexual abuse, vaginal foreign bodies, vaginal infection, MAS, and primary hypothyroidism. Neoplasms such as rhabdomyosarcoma and scleroing stromal tumors can present with isolated vaginal bleeding.[326]

Premature Thelarche

Premature thelarche is defined as isolated breast development without other signs of pubertal maturation. Typically, the parents or pediatrician note breast development, either unilateral or bilateral, between 9 and 18 months of age. No significant nipple development or pigmentation occurs, and the vaginal mucosa remains pink and shiny.

Breast ultrasound can help distinguish breast tissue from cysts, fibroadenomas, neurofibromas, or other less common lesions, but is usually not needed.[327] Pelvic ultrasound may show a bilateral increase in the number of ovarian follicular cysts. Using a recombinant cell bioassay with increased sensitivity, estradiol concentrations are higher among girls with premature thelarche than healthy controls. However, estradiol concentrations in such patients are still low and remain below assay detection limit for most radioimmunoassays.[328] FSH concentrations may be increased for chronological age, but LH concentrations and LH responses to GnRH stimulation are prepubertal. No acceleration in linear growth velocity or skeletal maturation occurs, and the breast development usually regresses spontaneously over time.[329] Although premature thelarche prior to 2 years of age is often transient, closer observation is indicated if growth velocity is accelerated or if the basal LH concentration is greater than 0.3 IU/L.[330] In most instances, onset of puberty, adult height, and adult reproductive function are normal.[331] Premature thelarche can usually be considered as a normal variant. Nevertheless, longitudinal evaluation is helpful to ensure the nonprogressive nature of this disorder.[332]

Premature thelarche has been described in Rubinstein-Taybi syndrome (RTS), an autosomal-dominant disorder characterized by short stature, psychosocial retardation, a characteristic fades, broad thumbs and halluces, and increased risk for neoplasia. Premature breast development is also observed in approximately 23% of female infants with the Kabuki make-up syndrome, which is characterized by a peculiar facies with eyes reminiscent of Kabuki actors, mental retardation, and decreased growth velocity.[333]

Hypothyroidism

Girls with primary hypothyroidism can, on rare occasions, present with breast development or isolated vaginal bleeding.[334] This constellation of clinical features was first described by Van Wyk and Grumbach in 1960.[335] On ultrasound, enlarged multi-cystic ovaries may be noted.[336,337] Additional features may include delayed bone age, ascites, and pleural and pericardial effusions.[338] This is the only etiology for precocious puberty associated with delayed bone age. Thyroid hormone replacement therapy is associated with regression and resolution of the cysts; surgical treatment is not indicated.[339] The mechanism underlying the ovarian stimulation is unclear. One possibility is that the excessively elevated TSH concentrations cross-react with the FSHR to promote estrogen secretion.[340] Another

explanation is that increased FSH secretion observed in the hypothyroid state is responsible.

Hypothyroid boys may show increased testicular volume (macroorchidism) for age. Interestingly, after thyroxine replacement to a cohort of such boys and the subsequent attainment of stage 5, testicular volume was found to be considerably greater than that in controls.[341] The macroorchidism associated with prepubertal hypothyroidism is probably the result of an expanded population of undifferentiated Sertoli cells resulting from increased FSH signaling in response to elevated concentrations of either FSH or TSH.[341-344]

It should be noted that at the hypothalamic-pituitary level, hypothyroidism leads to a delay in the pubertal resurgence of LH secretion,[345] which presumably accounts for the delayed puberty that is generally associated with chronic hypothyroidism (discussed later in the chapter).

Exogenous Hormone Exposures

Exposure to exogenous estrogenic steroids or estrogen receptor agonists can induce pubertal development.[21,346] Potential sources of estrogenic steroids include oral contraceptives, creams, shampoos, and various lotions.[347] In addition, phytoestrogens found in a variety of foods, and phthalate esters present in plastics are environmental endocrine disruptors with estrogen agonist activity.

Epidemics of premature breast development reported in Puerto Rico and Italy have been attributed to increased exposure to estrogenic steroids, phthalates, phytoestrogens, or estrogenic mycotoxins.[348] Mycotoxins are naturally occurring substances that can be found as environmental contaminants in cereals, corn, and nuts.[349] In the Puerto Rico epidemic, 69% of samples from girls with premature thelarche contained phthalates compared with 3% of control children.[346] It has been suggested that prenatal exposure to endocrine disruptors may influence fetal programming of the endocrine system and, therefore, may influence the timing and tempo of puberty. Certain drugs such as marijuana, isoniazid, spironolactone, ketoconazole, and cimetidine can induce gynecomastia by a variety of mechanisms. The use of lavender and tea tree oils has been associated with gynecomastia.[350]

Testosterone gels are used to treat male hypogonadism. Several case reports have been published reporting precocious puberty and virilization in children accidentally exposed to these gels.[351]

Virilizing Disorders

Premature pubarche is defined as the development of pubic hair, axillary hair, and apocrine body odor prior to age 8 years in girls and age 9.5 years in boys. The differential diagnosis includes premature adrenarche, CAH, and androgen-secreting tumors.

Premature Adrenarche

While the age of adrenarche varies considerably among ethnic groups, it is generally considered premature when it occurs prior to age 8 years in girls and age 9.5 years in boys. As in normal adrenarche, pubic hair, axillary hair, adult type apocrine odor, and acne may develop, whereas skeletal maturation may be appropriate for chronological age or slightly advanced. Clitoromegaly and marked phallic enlargement are unusual findings in patients with premature adrenarche. Usually, gonadarche occurs at an appropriate chronological age and subsequent pubertal development proceeds normally. More girls tend to be referred for evaluation than boys. Despite BMI comparable with controls, one recent study reported that girls with premature pubarche appear to have increased total and central fat mass.[352] In one study of Spanish and Italian girls, mean age at menarche for girls with documented premature pubarche was 6 months earlier than healthy controls.[353]

Typically, androgen concentrations are elevated for chronological age but within normal limits for the stage of pubic hair development. However, a subset of girls with premature adrenarche show persistent hyperandrogenism upon gonadarche.[354,355] Insulin resistance, hyperinsulinemia, and dyslipidemia have been described in these girls. These girls may develop chronic anovulation, hirsutism, insulin resistance, hyperinsulinemia, severe acne, and an increased LH:FSH ratio. These features are suggestive of incipient PCOS. Subsequently, adolescent girls with PCOS have an increased risk to develop impaired glucose tolerance and type 2 diabetes mellitus.[356] In some populations, the frequency of heterozygosity for mutations in the 21-hydroxylase *(CYP21A2)* gene is higher among children with premature pubarche and adolescent girls with incipient PCOS.[357]

Premature pubarche due to premature adrenarche is a diagnosis of exclusion. The majority of children with premature adrenarche require no pharmacological intervention. However, at this time, the ability to predict outcome and risk for PCOS is imperfect. Because lifestyle interventions involving food choices and exercise programs decrease the progression from impaired glucose tolerance to diabetes mellitus among adults,[358,359] it seems prudent to counsel children with premature pubarche to adopt healthy lifestyles. The interested reader is referred to recent reviews regarding premature adrenarche and polycystic ovary syndrome.[360,361]

Disorders of Steroidogenesis

Virilizing Congenital Adrenal Hyperplasias

The virilizing CAHs are a group of autosomal-recessive disorders in which cortisol synthesis is impaired due to decreased 21-hydroxylase, 3β-hydroxysteroid dehydrogenase, or llβ-hydroxylase activity (see also Chapters 4 and 17). The specific pattern of circulating steroid hormone concentrations reflects which steroid enzyme is involved. Approximately 90% to 95% of cases are due to 21-hydroxylase deficiency, which is due to mutations in the *CYP21A2* gene.[362-364] Mutations in 3β-hydroxysteroid dehydrogenase type 2 *(HSD3B2)* and 11β-hydroxylase *(CYP11B1)* genes account for the remaining 5% to 10% of patients with virilizing CAH.[365]

In all cases, decreased cortisol concentrations lead to loss of negative feedback inhibition, increased ACTH secretion, and increased adrenal androgen biosynthesis. The clinical spectrum for these disorders ranges from complete loss of function mutations, which typically present during infancy with genital ambiguity, to partial loss of function mutation, which may present in childhood, adolescence, or adulthood. Here, discussion is limited to the milder, so-called

non-classical or late-onset forms of CAH where the major symptoms are secondary to hyperandrogenism, rather than to adrenal cortical insufficiency, as in the classical forms of this disease.[366]

During childhood, boys or girls with milder forms of CAH can present with premature pubic hair, adult type apocrine odor, increased growth velocity, and tall stature. In contrast to premature adrenarche, clitoromegaly or phallic enlargement and advanced skeletal maturation are more common. In female patients, the symptoms of late-onset CAH are similar to those of PCOS. Chronic hyperandrogenism associated with mutations involving any of the three steroidogenic enzymes can be associated with increased LH: FSH ratios and polycystic ovaries on ultrasound, but such patients typically lack the magnitude of insulin resistance associated with PCOS. The late onset of hyperandrogenic signs and symptoms of the milder forms of CAH (e.g., hirsutism and amenorrhea) result in an ascertainment bias such that affected males are generally not recognized unless sisters with CAH have been detected.

21-Hydroxylase Deficiency. The milder form (non-classical or late onset) of this disorder is reported to affect 1 in 1000 patients, whereas the reported incidence of the more severe forms is approximately 1 in 14,000. In 21-hydroxylase deficiency, decreased 21-hydroxylase activity leads to increased concentrations of 17-OHP, 17-OH-hydroxypregnenolone, DHEA, androstenedione, and testosterone. The gene coding for 21-hydroxylase, *CYP21A2*, maps to chromosome 6p21. A highly homologous nonfunctional pseudogene, *CYP21A1P*, is located in close proximity to the functional gene. The *CYP21A2* and *CYP21A1P* genes show greater than 95% homology within coding regions.[367] The majority of mutations associated with 21-hydroxylase deficiency represent gene conversion events in which the functional gene has acquired deleterious nucleotide sequences from the pseudogene. To date, over 100 mutations have been reported, but approximately 10 mutations account for the majority of affected alleles.[368] Functional analysis of mutations associated with non-classical CAH generally indicates a 50% to 80% loss of enzymatic (21-hydroxylase) function. Most affected individuals are compound heterozygotes and carry different *CYP21A2* mutations on each allele (Fig. 18.8). For individuals with non-classical CAH, the missense mutation, V281L, accounts for at least one of the *CYP21A2* alleles for most patients with non-classical CAH. Phenotype—genotype correlations are fairly consistent, with the phenotype usually representing the least severe mutation.[369-372] However, phenotypic heterogeneity does occur and is most commonly identified with either the intron 2 splicing mutation or I172N.[373-375] A single *CYP21A2* allele can carry multiple mutations; two mutations on the same allele can act synergistically to impair enzyme activity to a greater extent than would be anticipated for each mutation individually.[376,377]

Although random 17-OHP concentrations can be diagnostic (especially in the more severe forms), ACTH-stimulation tests may be necessary to confirm the diagnosis of milder forms. Despite the availability of *CYP21A2* genotype analyses, the complexity of this locus precludes routine use of molecular diagnostics; therefore, ACTH-stimulation tests may be necessary to confirm CAH. Techniques that

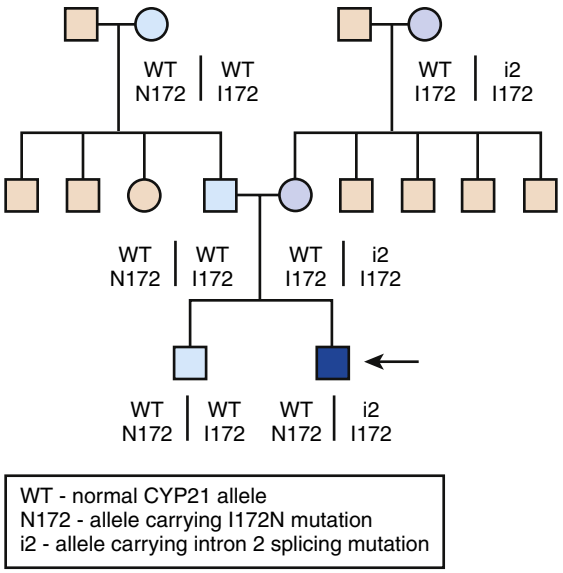

FIGURE 18.8 Molecular genetics of congenital adrenal hyperplasia. The proband *(arrow)* presented with premature pubarche at age 5 years, 9 months. His height and weight were greater than the 95th percentile. He had Tanner 3 pubic hair, phallic enlargement, prepubertal testes, and a small amount of axillary hair. His bone age was 13 years. Laboratory findings showed elevated 17-OHP (10,735 ng/dL), androstenedione (1372 ng/dL), and testosterone (220 ng/dL). Molecular genotype analysis showed that he was a compound heterozygote with I172N on his paternal allele and the intron 2 splicing mutation on his maternal allele. This paradigm is applicable for other autosomal recessive disorders.

genotype each allele or inclusion of parental DNA samples to segregate the alleles are helpful.

3β-Hydroxysteroid Dehydrogenase Deficiency. In this form of virilizing CAH, decreased activity of the adrenal and gonadal specific form of 3β-hydroxysteroid dehydrogenase leads to increased concentrations of 17α-hydroxypregnenolone and DHEA.[378] This disorder is due to mutations in the gene coding for 3β-hydroxysteroid dehydrogenase type 2, *HSD3B2*. Patients with classical 3β-hydroxysteroid dehydrogenase deficiency have been found to have mutations in the *HSD3B2* gene.[379-381] However, non-classical CAH due to *HSD3B2* mutations is extremely rare.[382-384] Thus, molecular genetics have shown that non-classical 3β-hydroxysteroid dehydrogenase deficiency is not a common allelic variant. Consequently, correlation of molecular genotype data with hormonal responses has led to adoption of more stringent criteria for the diagnosis of 3β-HSD deficiency. In general, ACTH-stimulated 17-OH-hydroxypregnenolone and DHEA responses are elevated.

11β-Hydroxylase Deficiency. The clinical features associated with 11β-hydroxylase deficiency are similar to 21-hydroxylase deficiency. Patients with this type of virilizing adrenal hyperplasia may develop hypertension attributed to increased deoxycorticosterone secretion. This disorder is due to mutations in the *CYP11B1* gene located on chromosome 8. Non-classical CAH due to *CYP11B1* mutations is extremely rare. The incidence of 11β-hydroxylase deficiency has been estimated to be 1:100,000 among Caucasians,

but the incidence among Israeli Jews of Moroccan origin is reported to be as high as 1:7000.[385,386] Elevated basal and ACTH-stimulated 11-deoxycortisol concentrations are typically found in this form of CAH. Serum 17-OHP, androstenedione, and testosterone concentrations may be mildly elevated. Plasma renin activity concentrations are low or suppressed.

Other Disorders Affecting Steroidogenesis

Oxidoreductase Deficiency

This autosomal recessive disorder of steroidogenesis is characterized by a steroid profile suggesting combined 17α-hydroxylase and 21-hydroxylase deficiencies.[387,388] The more severe phenotype is characterized by ambiguous genitalia, adrenal insufficiency, and skeletal anomalies and is known as the Antley-Bixler syndrome. The skeletal abnormalities can include craniosynostosis, midface hypoplasia, choanal atresia, low set ears, pear-shaped nose, arachnodactyly, clinodactyly, and radiohumeral synostosis. This disorder is due to mutations in the P450 oxidoreductase *(POR)* gene located at chromosome 7q11.2.[389] The protein encoded by the *POR* gene functions as an electron donor to cytochrome P450 enzymes. *POR* loss of function mutations influence the activities of 21-hydroxylase, 17α-hydroxylase, and aromatase enzymes.

Prenatal virilization of female fetuses occurs, but there is minimal postnatal virilization. Maternal virilization during pregnancy may occur and has been attributed to the aromatase deficiency. Curiously, some patients, both male and female, present with delayed puberty; ovarian cysts can occur in adolescent females.[390] One woman was found to be a compound heterozygote with loss of function mutations on both alleles; she presented with breast development, primary amenorrhea, and cystic ovaries.[391] Basal and ACTH-stimulated steroid profiles are variable because oxidoreductase deficiency affects multiple steroidogenic enzymes; serum 17-OHP concentrations tend to be elevated. Urinary analysis of steroid excretion using gas chromatography and mass spectroscopy can provide hormonal confirmation of the diagnosis. Cortisol deficiency may occur; affected individuals may benefit from glucocorticoid replacement therapy.[388] Mutations in the *FGFR2* gene are associated with similar skeletal anomalies, but have normal steroidogenesis and normal external genitalia.[392]

Apparent Cortisone Reductase Deficiency (ACRD)

Cortisol is the active glucocorticoid secreted by the adrenal zona fasciculata. Concentrations of cortisol and its inactive metabolite, cortisone, are modulated by the enzymes, 11β-hydroxysteroid dehydrogenase type 1 (HSD11B1) and 11β-hydroxysteroid dehydrogenase type 2.[393] ACRD is due to hexose-6-phosphate dehydrogenase deficiency and has been associated with premature adrenarche. This disorder is due to loss of function mutations in the hexose-6-phosphate dehydrogenase *(H6PD)* gene which interferes with HSD11B1 oxo-reductase activity and prevents local conversion of cortisone to cortisol.[394] The net result is accelerated peripheral clearance of cortisol resulting in decreased negative feedback inhibition of the HPA axis, increased ACTH secretion, and increased ACTH-mediated adrenal androgen secretion. DHEAS, androstenedione, and testosterone concentrations are increased. Urinary steroid metabolite profiling by combined gas chromatography and mass spectrometry (GC/MS) may be helpful in the differential diagnosis of ACRD.[395]

Apparent DHEA Sulphotransferase Deficiency (PAPSS2). In the adrenal cortex, DHEA can be converted to DHEAS by the enzyme DHEA sulphotransferase (SULT2A1). The catalytic activity of SULT2A1 depends on availability of sulphate donor 3′-phosphoadenosine-5′-phosphosulphate (PAPS). The isoform predominantly expressed in the adrenals and liver is *PAPSS2*. Sequencing of the *PAPSS2* gene in a girl with premature adrenarche who subsequently developed a PCOS-like phenotype revealed compound heterozygous mutations.[396]

Diagnosis and Treatment of CAH and Other Disorders of Steroidogenesis. Steroid hormone responses to ACTH stimulation help to differentiate between premature adrenarche and CAH. To perform an ACTH-stimulation test, a pharmacological dose of synthetic ACTH (0.25 mg cosyntropin) is administered after a basal blood sample has been obtained. A second sample is collected 30 to 60 minutes later. Basal and stimulated steroid hormone concentrations and hormone ratios provide important information. Stimulated 17-OHP responses of less than 500 ng/dL at 30 minutes are within normal limits. Responses greater than 1500 ng/dL are consistent with 21-hydroxylase deficiency.[397] Intermediate responses, 500 to 1500 ng/dL, are consistent with heterozygosity for 21-hydroxylase deficiency. Children with premature pubarche due to *HSD3B2* mutations have had ACTH-stimulated 17-OH-hydroxypregnenolone values greater than 9000 ng/dL.[398] Genetic testing is necessary to confirm the molecular diagnosis.[399]

Treatment of the virilizing CAHs involves hormone replacement therapy with glucocorticoids.[400] The goal of treatment is suppression of excessive ACTH and adrenal androgen secretion without hypercortisolism. Hydrocortisone or a synthetic glucocorticoid, such as prednisone or dexamethasone, can be used. During childhood, hydrocortisone is generally the preferred glucocorticoid because linear growth in the growing child is extremely sensitive to glucocorticoid levels. Longer-acting glucocorticoids such as prednisone and dexamethasone may interfere with linear growth velocity. Typically, hydrocortisone dosages range from 7 to 15 mg/m^2/day and must be administered three times daily because of the hormone's short duration of action. This relatively short duration of action is the major disadvantage of hydrocortisone because patients may have significant variation in serum hormone concentrations between doses.

Some suggest the use of a reverse diurnal dosing such that the highest dose is administered at night whereas other suggest that the highest dose should be administered in the morning.[401] Older adolescents and young adults may like the convenience of fewer daily doses and use prednisone (5.0 to 7.5 mg divided into two daily doses) or dexamethasone (0.25-0.5 mg daily). The growth suppressive potencies of prednisone and dexamethasone are greater than their anti-inflammatory potencies.[402] It is also important to remember that the mineralocorticoid activity of these glucocorticoids varies with prednisolone having less mineralocorticoid

activity than hydrocortisone and dexamethasone having no mineralocorticoid activity.

Long-term management involves interim medical history, physical examination with assessment of growth velocity, and hormone measurements to assess for adequate adrenal suppression.[402,403] Glucocorticoid therapy alone is generally sufficient for children with milder forms of CAH. For patients with oxidoreductase deficiency, ACRD, and PAPSS2, the decision to initiate glucocorticoid replacement therapy needs to be individualized and based on clinical features, ACTH-stimulated cortisol response, and skeletal maturation.

Stress doses are indicated for fever, persistent vomiting, serious injuries, and surgery. Families should have injectable hydrocortisone readily available for situations in which oral medications are not tolerated. General guidelines for oral stress doses are 3 to 4 times the maintainance doses or approximately 50 mg/m^2/day. Parenteral stress dosing varies by age.[364] All affected individuals should wear a MedicAlert identification badge to alert emergency health care providers to their disorder.

Children with CAH who develop a secondary GnRH-dependent precocious gonadarche may benefit from GnRH-Ra treatment. Children with overt salt loss, as well as those with simple virilizing forms, benefit from receiving mineralocorticoid replacement therapy.

Now that increased numbers of children with CAH or other disorders of sexual differentiation survive into adulthood, the medical and psychosocial aspects of their health care are undergoing re-evaluation. Thus, interest in the determinants of gender identity, approach to genital reconstructive surgery, and outcome has increased.[404] Hence, issues related to gender identity, surgery, sexuality, and outcome should be discussed when evaluating patients with these disorders.

Because CAH is one of the most common disorders associated with aberrant external genital differentiation, most of the literature in this area relates to outcome in women with classical CAH. One study reported that adult women with CAH tended to be unmarried, have fewer children than healthy controls, and have negative self-images. In this study, the frequency of homosexuality was not increased.[405] Girls with CAH tend to have female gender identity with preferences for male-type play and male career choices.[406] Gender identity in adolescent girls with CAH was not associated with the extent of prenatal androgen exposure, magnitude of virilization of the external genitalia, or age at reconstructive surgery.[407] Preliminary data from a limited number of outcome studies indicates that honesty, extensive education, and counseling benefit these patients with disorders of sexual differentiation and their families.[408,409]

Testicular adrenal rest tumors (TARTS) may develop in the testes of boys with CAH.[410] These testicular tumors are more common in those boys who are undertreated or poorly compliant. The tumors tend to be benign, bilateral, and are believed to arise from aberrant ACTH-responsive adrenal cells. Due to their location in the mediastinum testis, obstruction of the seminiferous tubules leading to gonadal dysfunction and infertility can occur.

Inherited Glucocorticoid Resistance

Familial glucocorticoid resistance is an autosomal-dominant disorder due to loss of function mutations in the glucocorticoid receptor (*GRL* or *NR3C1*) gene. Consequently, in the face of normal or elevated cortisol concentrations, there is loss of negative feedback inhibition leading to increased ACTH secretion and adrenal androgen biosynthesis, similar to that seen in CAH patients. The predominant symptoms of this disorder are due to excessive androgen and mineralocorticoid secretion rather than glucocorticoid deficiency. Affected children may present with premature pubarche, hypertension, fatigue, or hypokalemia.[411] Laboratory investigation shows elevated plasma concentrations of cortisol, adrenal androgens, aldosterone, and ACTH; these levels recede after administration of a high dose of dexamethasone. Treatment involves high-dose therapy with a potent glucocorticoid (i.e., dexamethasone), leading to suppression of ACTH release and decreased adrenal androgen secretion.

Familial Male-Limited Precocious Puberty

This autosomal-dominant disorder is due to constitutive activating mutations of the *LHCGR* gene[412,413] that alter the tertiary confirmation of the receptor protein, leading to increased cAMP signaling in the absence of ligand.[414] Clinical manifestations are limited to male patients and include phallic enlargement, increased testicular volume, pubic hair, body odor, accelerated growth velocity, and advanced skeletal maturation. These characteristics may present within the first few years of life. Testosterone concentrations are high, while gonadotropin concentrations are low. Short-term treatment with steroid synthesis inhibitors like testolactone, spironolactone, or ketoconazole can be used. If a secondary GnRH-dependent gonadarche develops, GnRH-Ra treatment can improve height prediction.[415] Long-term treatment with cyproterone acetate or ketoconazole revealed similar outcomes without major side effects in 10 boys with testotoxicosis; effects on final height outcome were variable.[416,417] The lack of a female phenotype[418] is a mystery; perhaps the most attractive possibility is that expression of *LHCGR* by the prepubertal ovary is low.

Androgen-Secreting Tumors

Leydig cell tumors secrete testosterone, leading to precocious pubertal development in boys. Testicular volume may be asymmetric because the tumors are often unilateral. Because some tumors are too small to be palpated, ultrasonography may be helpful to localize the tumor. The majority of Leydig cell tumors are benign. Malignant tumors tend to be larger, show greater cell atypia, and tend to infiltrate beyond the testis. In rare instances, the tumor can secrete large quantities of other steroids like 17-OHP, which may confound the diagnosis.[419] A novel somatic cell-activating mutation of the *LHCGR* gene has been found in some adenomas.[420] The D578H mutation associated with familial male-limited precocious puberty has been found in association with Leydig cell adenomas and nodular hyperplasia of Leydig cells in prepubertal boys.[421] Alterations in other factors, such as AMH, inhibin, and other growth factors, may also contribute to the development of such tumors. Hence, the etiologies of tumors at the molecular level are heterogeneous.[422] If possible, the tumor should be excised without removing the testis. Ovarian androgen-secreting tumors are a rare cause of virilization in girls. Such tumors can occur at

an anatomical location distinct from the ovary such as the round ligament.[423]

hCG-Secreting Tumors

In boys, hCG-secreting tumors induce testicular testosterone secretion, leading to precocious pubertal development. These tumors are frequently hepatic in origin. In girls, hCG-secreting tumors in the absence of pubertal levels of FSH are not usually associated with precocious pubertal development. Although exceptions have been described.[424] this finding is consistent with the idea that *LHCGR* expression in the prepubertal ovary is low.

Cushing Syndrome

Cushing syndrome is characterized by excessive glucocorticoid concentrations, whether endogenous or exogenous in origin. Although the predominant features of glucocorticoid excess in children and adolescents are arrested pubertal development and growth failure, precocious virilization may occur when the hypercortisolism is accompanied by hyperandrogenism. This occurs in Cushing disease, in cases of ectopic secretion of ACTH or CRH, and in rare cases of adrenal tumors. Individuals with chronic conditions like rheumatoid arthritis, steroid dependent nephropathies, and asthma requiring high-dose steroid treatment may develop signs and symptoms due to glucocorticoid excess. Intranasal steroids can cause iatrogenic Cushing syndrome and adrenal suppression.[425]

Among children younger than 8 years of age, adrenal tumors are the most common cause of Cushing syndrome. Such tumors are often malignant. The combination of rapid pubertal development and hypercortisolism suggests an adrenal tumor. Such tumors, which are rare, can secrete a mixture of steroid hormones. Nevertheless, virilization is a common presentation for childhood adrenocortical tumors. There is a female predominance. Complete surgical excision is the treatment of choice; complete resection is required for cure. Residual or metastatic disease is associated with a poorer prognosis.[426] Histological examination may not be able to accurately differentiate benign adenomas from carcinomas. Cushing disease due to excessive pituitary ACTH secretion is extremely rare in young children, but can occur in adolescents.

Primary pigmented adrenocortical nodular disease (PPNAD) is often associated with the periodic or episodic hypercortisolism. The adrenal glands are characterized by multiple pigmented autonomously functioning nodules. PPNAD is associated with inactivating mutations of the *PRKAR1A* gene. The majority of benign lesions of the adrenal cortex appear to be associated with abnormalities of the cAMP signaling pathway, whereas adrenocortical carcinomas are linked to aberrant expression of insulin-like growth factor II, tumor protein p53 and related molecules.[427,428] Syndromes associated with adrenocortical tumors include CNC, Li-Fraumeni syndrome, and Beckwith-Wiedemann syndrome.

Confirmation of excessive glucocorticoid secretion is essential prior to imaging studies. Loss of diurnal variation in cortisol secretion, excessive 24-hour urinary free cortisol excretion, and inadequate dexamethasone-induced suppression are valid diagnostic studies. In some instances, due to periodic hypercortisolism, these studies need to be repeated. Treatment is directed by the underlying disorder.[429]

Approach to the Child with Precocious Pubertal Development

Identification of the etiology of sexual precocity begins with a thorough medical history, with questions focusing on the physical manifestations of puberty and the age and sequence of their appearance (Figs. 18.9 and 18.10). Does the patient have neurological symptoms or gelastic seizures? Has the patient received radiation therapy? Was the patient exposed to exogenous hormones? Obtaining a complete family history is important because some disorders, such as familial male-limited precocious puberty, glucocorticoid resistance, and NF1, show autosomal-dominant inheritance.

Next, a complete physical examination, including auxological measures, should be performed; particular attention should be paid to development of secondary sexual characteristics. For girls, are breast and/or pubic hair development present? For boys, is testicular volume increased? Because increased growth velocity occurs concomitantly with breast development among girls, observation of accelerated growth velocity helps to differentiate GnRH-dependent precocious gonadarche from non-progressive gonadarche or premature thelarche. The physical examination should be directed to detect physical signs indicating onset of gonadarche or adrenarche, as well as features suggestive of specific disorders such as café-au-lait spots in McCune-Albright syndrome or NF1. Does the patient have manifestations of hypothyroidism?

Laboratory studies are used to confirm or exclude specific disorders based on the possible differential diagnoses. Bone age is usually, but not always, advanced among patients with GnRH-dependent precocious gonadarche and the CAHs. Typically, bone maturation is not significantly advanced among subjects with premature thelarche or premature adrenarche. In healthy individuals, the bone age interpretation should lie within two standard deviations of the normative data.

Because gonadotropin secretion is pulsatile, random concentrations usually provide only limited information. GnRH-stimulation tests help to differentiate GnRH-dependent precocious gonadarche from premature thelarche, because an LH predominant response is typical of GnRH-dependent precocious gonadarche whereas an FSH predominant response is typical of premature thelarche.[430] The limited availability of GnRH (Factrel) has led to development of stimulation tests utilizing Lupron as the provocative agent.[431] Comparison of immunochemiluminometric (ICMA) and immunofluorometric (IFMA) assays indicated that for prepubertal children, the upper limit of normal for LH after GnRH stimulation test by ICMA was 4.1 IU/L for boys and 3.3I IU/liter for girls, and that measured by IFMA was 3.3 IU/liter for boys and 4.2 IU/liter for girls.[432] It is important to be aware of the normal values for the specific methodology used. Most current assays for gonadotropins are sandwich assays specific to the β-subunit. Using the newer third generation gonadotropin assays (e.g., Architect and Delfia) random LH concentrations greater than 1.0 U/L in girls with features consistent with precocious puberty may be sufficient to diagnosis central precocious puberty.[433] MRI of the pituitary and brain is helpful for patients with GnRH-dependent precocious gonadarche. Boys with elevated hCG concentrations may require imaging of the head, chest, and abdomen to detect an extra-testicular hCG-secreting tumor. Among girls, pelvic ultrasound can

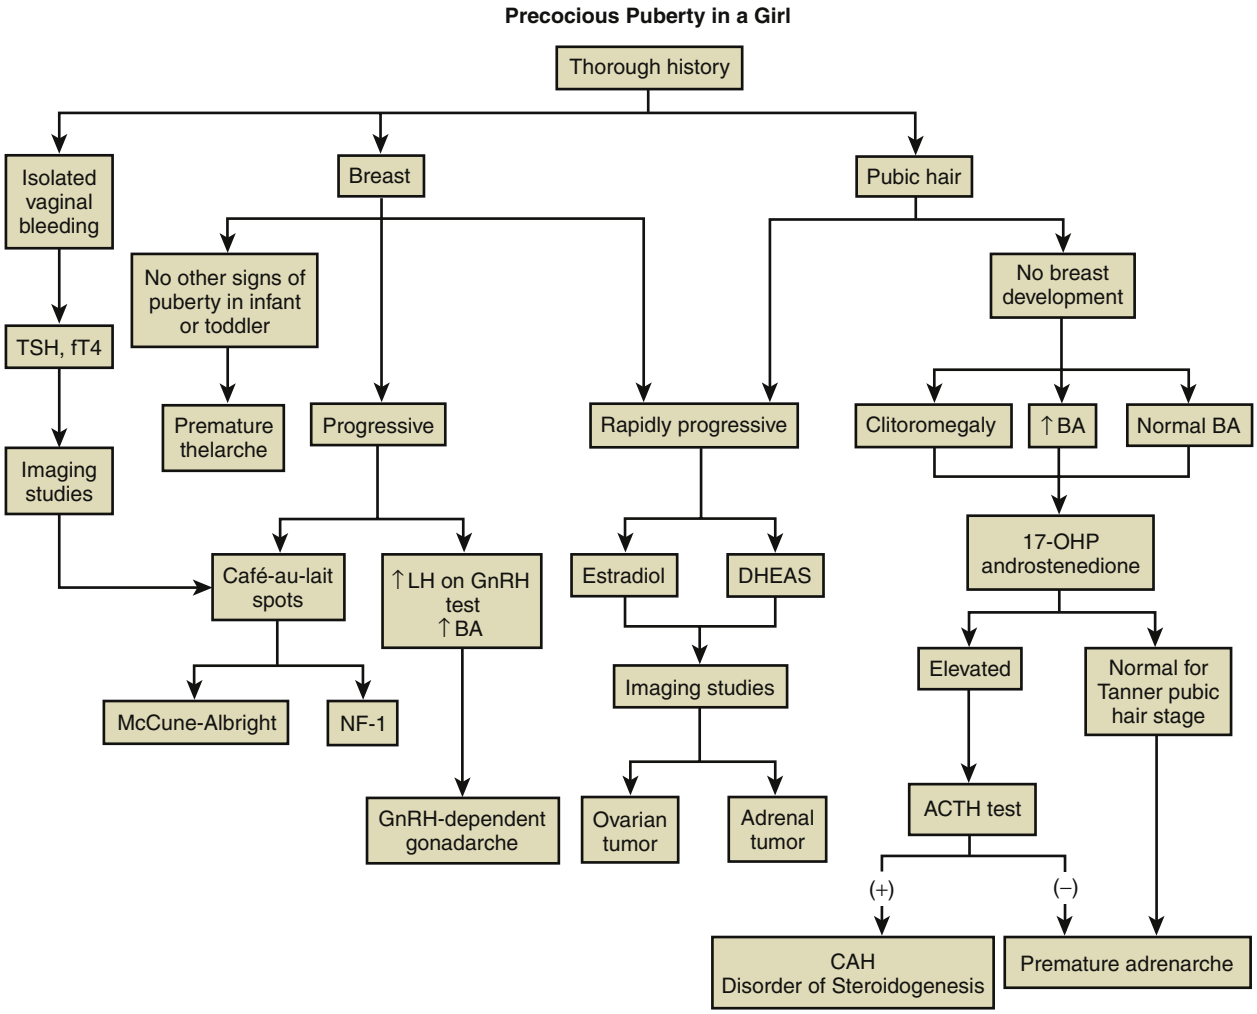

FIGURE 18.9 Algorithm for initial approach to precocious puberty in a girl. Beginning with a thorough medical history, this flowchart provides guidelines to the differential diagnosis of the most common causes of precocious puberty in girls. 17-OHP, 17-hydroxyprogesterone; ACTH, adrenocorticotropin; BA, bone age; CAH, congenital adrenal hyperplasia; DHEAS, dehydroepiandrosterone sulfate; fT4, free thyroxine; LH, luteinizing hormone; NF1, neurofibromatosis type 1; TSH, thyroid stimulating hormone.

assess for pubertal development of the ovaries and uterus; it can also detect tumors and ovarian cysts.[434]

Pelvic ultrasound is helpful for the evaluation of girls with precocious puberty because the size and morphology of the uterus and ovaries reflect function and hormone exposure. The prepubertal uterus is tubular in configuration; the cervix is similar or slightly larger than the fundus in size. Estrogen exposure causes a disproportionate enlargement of the fundus such that the uterus acquires a pear-like shape. The mean ovarian volume in prepubertal girls between 2 to 7 years of age is 1 cm^3. Small follicles (less than 9 mm) may be present.[435]

For patients with suspected disorders of steroidogenesis, liquid-chromatography—tandem mass spectrometry (LC-MS/MS) is rapidly becoming the method of choice for clinical steroid analysis because of the higher sensitivity, better reproducibility, greater specificity, and low sample volume compared to immunoassay techniques. This technique offers the ability to analyze multiple steroids simultaneously. Prior to clinical utilization, reliable reference ranges need to be established for specific analytes according to gender and pubertal stage.[436] Testicular ultrasound to assess for Leydig cell tumors or microlithiasis may be indicated especially when the testicular volumes are discordant. Adrenal ultrasound to assess for adrenal tumors or adrenal hyperplasia is appropriate for children with premature pubarche and extremely elevated DHEAS concentrations.

Disorders of Delayed Puberty

In most instances, delayed puberty is the result of delayed gonadarche and is defined as secondary sexual characteristic development at an age greater than two standard deviations more than for the normal population. Thus, for girls, lack of breast development by age 13 years or menarche by 16 years may be viewed as delayed. For boys, prepubertal testicular volume at age 14 years is considered to be delayed. Pubertal delay can be broadly sub-classified as constitutional, hypogonadotropic, or hypergonadotropic. Patients with hypogonadotropic pubertal delay can be further classified as GnRH-dependent, pituitary dependent, and hypothalamic-pituitary dependent. HH can be due to gonadal failure, defects of steroidogenesis, or defects of steroid action.

Atypical pubertal development during the adolescent years may also reveal disorders of sexual differentiation that escape diagnosis during infancy. Failure to complete puberty within 5 years also warrants evaluation.[437] In general,

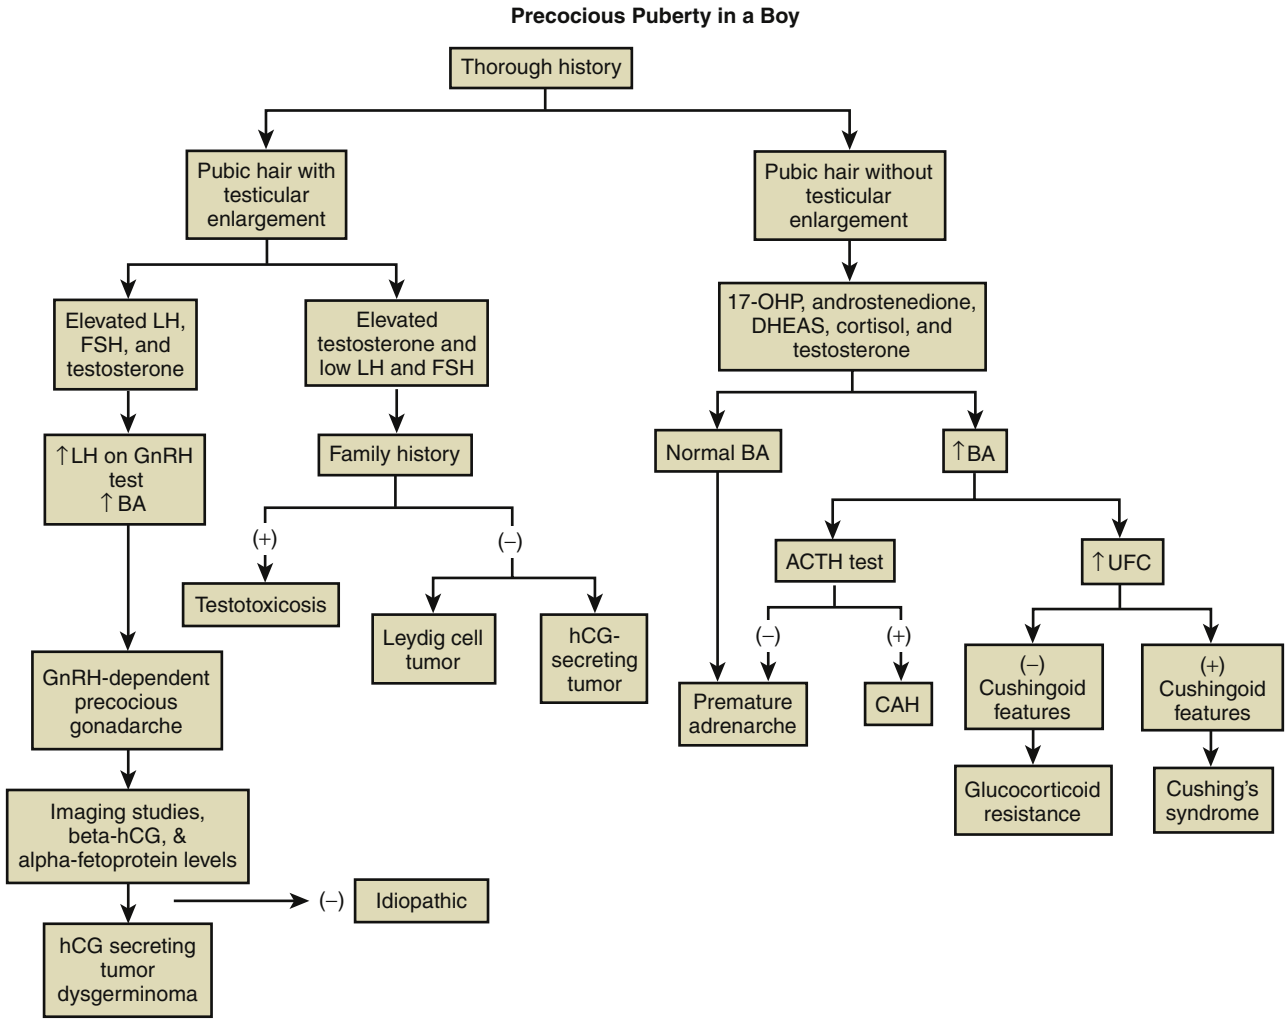

FIGURE 18.10 Algorithm for initial approach to precocious puberty in a boy. Beginning with a thorough medical history, this flowchart provides guidelines to the differential diagnosis of the most common causes of precocious puberty in boys. 17-OHP, 17-hydroxyprogesterone; ACTH, adrenocorticotropin; BA, bone age; CAH, congenital adrenal hyperplasia; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; UFC, urinary free cortisol.

treatment of delayed puberty involves steroid hormone replacement, which is discussed in detail at the end of the section (Box18.2; Table 18.3).

Constitutional

Rather than being a truly pathological condition, constitutional delay of puberty is considered an extreme of the normal variation of pubertal timing. Typically, both gonadarche and adrenarche are delayed. There is no definitive diagnostic test and, therefore, constitutional delay of puberty is a diagnosis of exclusion. Often, linear growth velocity during the first few years of life is decreased. Subsequently, growth velocity normalizes and tracks close to the fifth percentile during childhood. Growth velocity again decreases during the early adolescent years, associated with an apparent transient decrease in GH secretion. Typically, the family history is positive for delayed puberty. Skeletal maturation is retarded, and the predicted height is often in the lower range of genetic height potential, based on midparental height calculations.[438]

A recent report of SNPs predicted to generate missense mutations in the ghrelin receptor gene in two females with constitutional delay hints at a possible association.[439] A novel missense mutation in the leptin gene speculated to have increased bioactivity was associated with delayed puberty, poor appetite, and low BMI in a mother and son.[440] However, variants in genes associated with idiopathic HH (IHH) appear to be rare.[441,442]

GnRH-Deficiency (Hypothalamic Hypogonadism)

This category of delayed puberty is the consequence of absent or impaired GnRH secretion that may result from either a primary developmental anomaly of the hypothalamus or secondary pathophysiological conditions. GnRH deficiency or HH, reported to affect one in 7500 male patients and one in 70,000 female patients, and comprises a diverse group of reproductive disorders.[443] The term "IHH" has been used in the past for this group of disorders. However, with greater knowledge regarding the molecular causes of GnRH deficiency, the term HH is preferable.

Sporadic cases are more common than inherited forms. Inheritance patterns include X-linked, autosomal dominant,

Box 18.2 Etiologies of Delayed Puberty

CONSTITUTIONAL DELAY

GnRH-DEPENDENT (HYPOTHALAMIC-HYPOGONADOTROPIC HYPOGONADISM)
- *KAL1* mutation
- *PROK2* and *PROKR2* mutations
- *FGFR1* and *FGF8* mutations
- *HS6ST1* mutation
- *NELF* mutation
- CHARGE syndrome (*CHD7* mutation)
- *WDR11* mutation
- *SEMA3A* mutation
- *GNRH1* mutation
- *KISS1* and *KISS1R* mutations
- *TAC3* and *TACR3* mutations
- Anorexia nervosa
- Undernutrition/chronic disease/intensive exercise
- Leptin-dependent

PITUITARY-DEPENDENT (PITUITARY HYPOGONADOTROPIC HYPOGONADISM)
- *GNRHR* gene mutation
- *FSHB* gene mutation
- *LHB* gene mutation
- Developmental anomalies: *SOX2* mutation, *HESX1* gene mutation (septo-optic dysplasia), *PITX2* gene mutation (Rieger syndrome), *LHX3* mutation, *PROP-1* gene mutation, maternal cocaine abuse, valproate toxicity, intrauterine CMS vascular events

HYPOTHALAMIC AND PITUITARY-DEPENDENT HYPOGONADOTROPIC HYPOGONADISM
- Adrenal hypoplasia congenital (*DAX1/NROB1* mutation)
- Intracranial tumors
- Histiocytosis X
- Hyperprolactinemia
- Steroidogenic factor-1 (*NR5A1* mutation)
- Prader-Willi syndrome
- Bardet-Biedl syndrome
- Bloom syndrome
- Hereditary hemochromatosis

GONAD-DEPENDENT
- Primary gonadal failure:
- Gonadal dysgenesis (Turner syndrome, mixed 45,X/46,XY, pure 46,XY gonadal dysgenesis like SRY gene mutations, pure 46,XX gonadal dysgenesis, Denys-Drash syndrome, Frasier syndrome, 46,XX male, *SOX9* gene mutation),
- Klinefelter syndrome
- Testicular regression syndrome (vanishing testis)
- Auto-immune ovarian failure
- Nonautoimmune premature ovarian failure
- Galactosemia
- Noonan syndrome
- Down syndrome
- Other: trauma, torsion, post-infectious (e.g., mumps)
- Defects in steroidogenesis: *LHCGR* gene mutation, *FSHR* gene mutation, congenital lipoid adrenal hyperplasia, 17α-hydroxylase/17–20-lyase deficiency, AKR1C2/AKR1C4 gene mutations, aromatase deficiency, 17β-hydroxysteroid dehydrogenase deficiency, 5α-reductase deficiency
- Steroid hormone receptor-dependent: androgen insensitivity, estrogen receptor mutation
- Anatomical abnormalities: Mayer-Rokitansky-Kuster-Hauser syndrome
- Chemotherapy
- Radiation therapy

GnRH, gonadotropin-releasing hormone.

Table 18.3 Monogenic Disorders Associated with Hypogonadotropic Hypogonadism

Gene	***Locus***	***Associated Phenotypes***
KAL-1	Xp22.3	Anosmia, bimanual synkinesis, renal anomalies
FGFR1	8p11.2-p11.l	Anosmia, cleft lip/palate, dental anomalies
FGF8	10q24	Anosmia, cleft lip/palate, dental anomalies
HS6ST1	2q14.2	None
NELF	9q34.3	Anosmia
PROK2	3p21.1	None
PROKR2	20p13	None
CHD7	8q12.1	CHARGE syndrome
SEMA3	7q21.11	Anosmia or normosmia
KISS1R	19p13.3	None
KISS1	1q32	Normosmic
WDR11	10q26.12	Anosmia
TAC3	12q13-q21	Microphallus, cryptorchidism
TACR3	4q25	Microphallus
GNRH1	8p21-p11.2	None
GnRHR	4q21.2	None
FSHB	11p13	Hypogonadism
LHB	19q13.32	Hypogonadism
HESX1	3p21.2-p21.1	Hypopituitarism (septo-optic dysplasia)
PITX2	4q25-q26	Hypopituitarism (Rieger syndrome)
PROP-1	5q	Hypopituitarism
LHX3	9q34.4	Hypopituitarism
SOX2	3q26.33	Optic nerve hypoplasia, microphthalmia
LEP	7q31.3	Obesity
LEPR	1p31	Obesity
DAX-1	Xp21.3-p21.2	Adrenal hypoplasia congenita
NR5A1 (SF-1)	9q33	Adrenal insufficiency, hypogonadism
PTPN11	12q24.1	Noonan syndrome

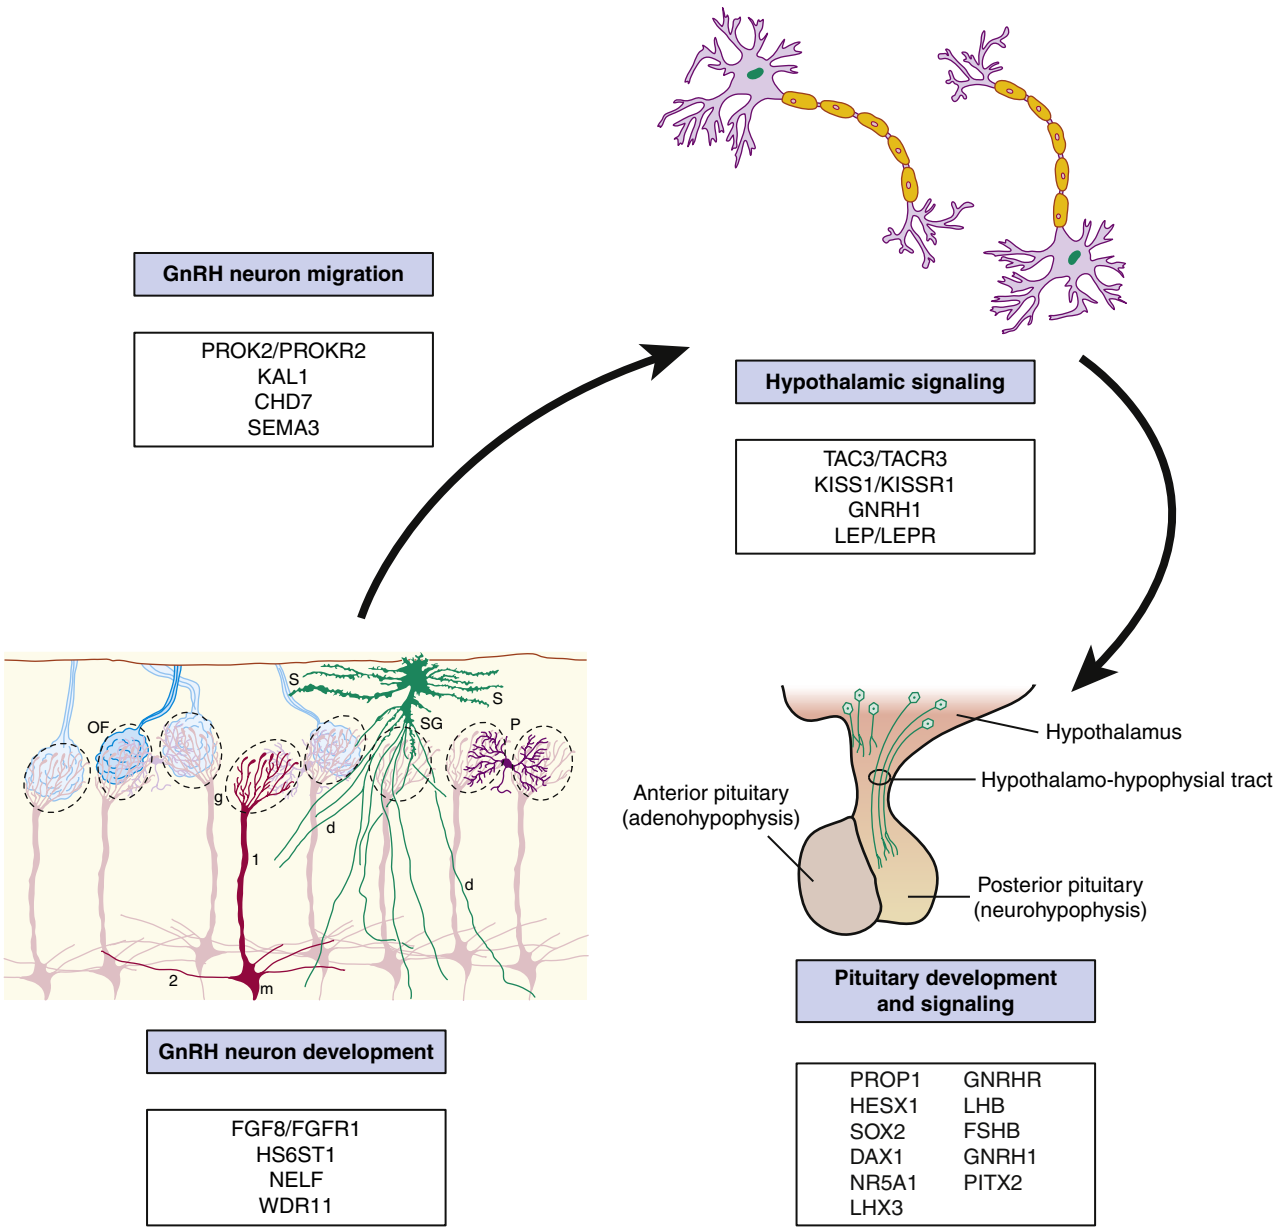

FIGURE 18.11 Genes implicated in gonadotropin-releasing hormone (GnRH) neuron development, GnRH neuron migration, and GnRH neuron activity and signaling. It also shows genes implicated in pituitary development and signaling. Genes have been classified by presumed function in these processes.

and autosomal recessive. However, it has become apparent that GnRH deficiency can be due to mutations in several genes (an oligogenic disorder).[444] In addition, there can be a spectrum of reproductive, olfactory, and nonreproductive clinical features.[445]

Traditionally, these heterogeneous disorders have been sub-classified into three major categories: (1) Kallmann syndrome with anosmia; (2) HH without anosmia; and (3) acquired HH. Correlation of olfactory function by formal smell test with genetic analysis among patients with HH revealed a spectrum ranging from normosmia to hyposmia to anosmia. Mutations associated with the hyposmia or anosmia phenotype include genes discussed above that influence GnRH neuron development and migration.[445] Mutations associated with normosmic HH include genes that influence function (Fig. 18.11).

Mutations in Genes Influencing GnRH Neuron Development and Migration

KAL1

The classic form of Kallmann syndrome is characterized by isolated gonadotropin deficiency, anosmia, X-linked inheritance, and the failure of GnRH neurons to migrate from the olfactory bulb into the hypothalamus during embryonic development.[446] The defective olfactory bulb development can be confirmed by MRI. Investigation of patients with classic Kallman syndrome led to identification of the first gene associated with anosmic HH.

Patients with *KAL1* mutations show complete loss of LH pulsatility, suggesting greater deficits in the GnRH system than patients with autosomal forms in whom low amplitude LH pulses can often be detected.[447] Men with X-linked

Kallmann syndrome have been found to have a higher incidence of cryptorchidism and microphallus, lower inhibin B concentrations, higher AMH concentrations, and increased frequency of immature testicular morphology. Nonreproductive features associated with the X-linked form include unilateral renal agenesis, synkinesia, sensorineural hearing loss, cleft palate, and cerebellar ataxia. Phenotypic heterogeneity, even with the same mutation, suggests that modifier loci or epigenetic factors modulate the clinical manifestations.[448] Rare *KAL1* missense sequence variants have been identified in women with GnRH deficiency.[449] Nevertheless, the majority of cases of Kallmann syndrome or IHH are not associated with *KAL1* mutations.

PROK2 *and* PROKR2

Mutations in *PROK2* and *PROKR2* genes have been identified in patients with IHH.[450,451] The phenotype of individuals with *PROK2* and *PROKR2* mutations includes normosmic HH as well as anosmia in the absence of a reproductive phenotype.[452] Nonreproductive features include fibrous dysplasia, obesity, synkinesia, and epilepsy.[453] Most carry heterozygous mutations, but *PROK2* mutations were detected in siblings with autosomal recessive HH; two siblings had anosmia and an affected female sibling was normosmic.[450] Patients with HH and *PROKR2* mutations are often found to carry mutations in other genes associated with HH such as *KAL1*, *PROK2*, and *FGFR1*. Heterozygous *PROKR2* gene mutations have been identified in patients with congenital hypopituitarism and pituitary stalk interruption.[454] A specific incompletely penetrant *PROKR2* mutation, Leu173Arg, has been identified in individuals with HH from diverse ethnic and geographic origins suggesting that this mutation demonstrates an ancient founder effect.[455]

FGFR1 *and* FGF8

FGFs and their receptors induce proliferation and differentiation of GnRH neurons. Investigation of families with autosomal dominant IHH led to identification of loss of function mutations in the *FGFR1* and the *FGF8* genes. Numerous point mutations and deletions in *FGFR1* have been identified in affected individuals and families. Additional clinical features include impaired development of the olfactory bulbs, skeletal anomalies, and bimanual synkinesis.[456] Cerebellar ataxia (Gordon-Holmes syndrome) is an associated clinical feature in some families in which autosomal-recessive inheritance occurs.[457] Phenotypic heterogeneity occurs associated with a broad spectrum of reproductive abnormalities. Both anosmia and normosmia have been described.[458] Mutations in *FGFR1* have been described in women with hypothalamic amenorrhea.[459] Variability in the extent of the GnRH deficiency and the olfactory phenotype has been reported for *FGF8* mutations.[460] Clinical features associated with *FGF8* mutations also includes holoprosencephaly, septo-optic dysplasia, and Moebius syndrome.[461]

HS6ST1

Loss of function mutations in the gene encoding HS6ST1 are associated with HH. Phenotypic heterogeneity occurs for both reproductive manifestations and anosmia. Among families with *HS6ST1* mutations, HH segregates as a complex trait and mutations in other genes associated with HH have been identified in some families. It remains to be determined if *HS6ST1* mutations can be solely responsible for GnRH deficiency or whether other genetic or epigenetic variations are necessary for development of clinical symptoms.[462]

NELF

Mutations in the *NELF* gene have been reported in a few patients in HH in association with anosmia.[463] In most instances, digenic inheritance is present with mutations detected in additional genes such as *KAL1* and *TACR3*.[464]

CHD7

Mutations in the C*HD7* gene are associated with the coloboma, heart anomaly, choanal atresia, mental retardation, genital and ear anomaly (CHARGE) syndrome. This syndrome is characterized by eye coloboma, heart malformations, atresia of the choanae, retardation of growth or development, genital anomalies, and ear abnormalities. Although usually sporadic, autosomal dominant cases have been described. Nonreproductive features include hearing loss, balance disturbances, and dysmorphisms affecting the ear.[465] The evaluation of patients with HH should include evaluation for features of CHARGE syndrome.[466]

WDR11

Finding a balanced translocation at chromosome 10q in a patient with HH led to investigation of the *WDR11* gene. Heterozygous mutations in this gene were identified in additional patients with HH. The protein contains multiple WD domains likely to mediate interaction with protein-binding partners; one potential binding partner is EMX1.[467] EMX1, a homeodomain transcription factor, is related to the Drosophila developmental genes empty spiracles and involved in the development of the olfactory system: no human mutations in the *EMX1* gene have yet been identified.

SEMA3A

Heterozygous mutations in the *SEMA3A* gene were identified in patients with anosmic HH.[468] However, available data suggest that *SEMA3A* mutations are unlikely to be the sole molecular basis of HH in affected individuals.[469]

Mutations in Genes Influencing GnRH Function

GNRH1

Interestingly, loss of function mutations in the *GnRH1* gene itself were not identified until 3 to 4 years ago.[470,471] Individuals with homozygous loss of function mutations of this gene have hypogonadism; affected males may have microphallus. Heterozygous missense mutations have also been described. Aberrant processing of the GnRH prohormone due to mutations in the prohormone convertase 1/3 *(PCSK1)* gene are also associated with HH.[472]

KISS1 *and* KISS1R

As noted above, investigation of familial autosomal recessive HH led to identification of mutations in the *KISS1R* gene[79,80] and to the subsequent elucidation of the *KISS1-KISS1R* (kisspeptin-GPR54) system. To date, several loss of function mutations have been reported in the *KISS1R* gene. Cryptorchidism and a small phallus have been reported in some affected males.[473] As would be anticipated from our understanding of the role of kisspeptin in GnRH pulse generation (discussed earlier in the chapter), LH and FSH concentrations are low in patients with *KISS1R* mutations.[79]

A homozygous missense *KISS1* mutation affecting a conserved amino acid was reported in a consanguineous family.[81] Autosomal recessive inheritance patterns have been described for both *KISS1* and *KISSR1* mutations.

TAC3 *and* TACR3

As described previously, loss of function mutations in the NKB gene *(TAC3)* and its cognate receptor gene *(TACR3)* were found to be associated with profound normosmic HH in consanguineous families.[82,474] Affected individuals have been found to carry mutations on both alleles, homozygous or compound heterozygous. Heterozygous mutations have also been described. Microphallus, but not cryptorchidism, is a common feature of *TAC3* mutations indicating the importance of NKB in GnRH pulse generation during fetal development.[475] Patients with *TAC3* or *TACR3* mutations tend to have low LH with relatively normal FSH concentrations consistent with diminished GnRH pulse frequency.[476]

Reversibility

Curiously, a few individuals with HH who carry loss of function mutations have demonstrated reversible HH.[477,478] Genes associated with reversal of HH in patients include *FGFR1*, *CHD7*, *TAC3*, and *TACR3*.[479,480] Regarding the NKB pathway, although reversibility has been documented in biallelic (homozygous) loss of function mutations in both the ligand *(TAC3)* and receptor *(TACR3)*[479] (Topaloglu personnal communication) there is controversy surrounding the view that frequency of reversal is typically high in these subjects.[479,481] Resolution of this issue is relevant and important not only from a clinical perspective but also because NKB signalling is a pivotal component in the contemporary model of GnRH pulse generation (discussed earlier in the chapter).

Coexistence of IHH and constitutional delay in the same pedigree raises the question as to whether, in some instances, constitutional delay and IHH reflect a phenotypic spectrum characterized by delayed reactivation of the GnRH pulse generator.[482] Nevertheless, the biological mechanism responsible for recovery of endogenous gonadotropin secretion and duration of this recovery remain to be elucidated.[483] Androgen exposure is one proposed influence.

Other Factors

Investigation of GnRH neuron development and migration in animals has identified additional factors involved in these processes,[484-486] but their role in HH has not yet been established.

Anorexia Nervosa

Anorexia nervosa is a chronic psychiatric disorder characterized by decreased caloric intake, weight loss, distorted body image, and excessive physical activity (also see Chapter 21). Approximately 90% of individuals with this disorder are females. Delayed puberty and associated oligomenorrhea or amenorrhea are secondary to deficient GnRH secretion. Primary or secondary amenorrhea can precede weight loss and can persist despite weight gain. This condition would suggest that factors other than metabolical and nutritional determinants are involved in the suppression of the GnRH pulse generator. Other hormone findings include elevated cortisol and GH concentrations and decreased IGF-I concentrations. The "low T_3 (triiodothyronine) syndrome" is also common, in which T_3 is decreased, T_4 is normal or subnormal, and TSH is normal.[487] Bulimia nervosa, characterized by binging and purging induced by vomiting or laxative abuse, is a variant of anorexia nervosa. Osteopenia and osteoporosis are serious and persistent consequences of anorexia nervosa in both sexes. The current therapies, for decreased bone mineral density include transdermal estradiol, vitamin D, and recombinant IGF1. Although these treatments are helpful, they do not fully restore bone accrual.[488]

Undernutrition, Chronic Disease, and Intensive Exercise

Undernutrition and chronic diseases, such as inflammatory bowel disease, cystic fibrosis, hypothyroidism, and poorly controlled type 1 diabetes mellitus, are associated with delayed or arrested puberty (see also Chapter 21). Primary or secondary functional amenorrhea can occur. In many chronic illnesses, inadequate nutrition leads to impaired GnRH secretion resulting in hypothalamic hypogonadism. Effective treatment of the underlying disorder is associated with pubertal progression and reversibility of the functional hypothalamic amenorrhea. For example, after successful renal transplantation, children with chronic renal disease manifest resumption of gonadotropin secretion and progressive pubertal development. Anemias, such as sickle cell anemia and thalassemia, are also associated with compromised GnRH release. It should be noted that treatment of these anemias with frequent transfusions may lead to iron overload, iron deposition in the pituitary, and exacerbation of the hypogonadotropism. Curiously, heterozygosity for mutations in genes associated with HH may increase susceptibility for hypothalamic amenorrhea.[488a]

Intensive exercise and other athletic training schedules including caloric restriction to maintain a weight class, may delay or interrupt pubertal development due to decreased GnRH secretion. Long-distance runners, gymnasts, ballerinas, and wrestlers are among the most commonly affected athletes. During the competitive season, male wrestlers lose body weight, fat mass, and lean body mass, such that disruption of the neuroendocrine axes governing testicular function and growth may ensue. These changes, however, reverse within months after conclusion of the wrestling season.[489] Administration of leptin to eight women with hypothalamic amenorrhea was associated with improvement in reproductive, GH, and thyroid function providing additional evidence for leptin's important role as a signal indicating energy status.[490]

Leptin-Dependent Obesity

Retarded pubertal development has been associated with early onset morbid obesity due to autosomal homozygous mutations of *LEP* or *LEPR* genes.[151,491,492] The consequences of leptin replacement administered to patients with mutations of *LEP* have been described in detail above.

Pituitary-Dependent (Pituitary Hypogonadotropism)

Pituitary hypogonadotropism in subjects with delayed puberty may be due to a mutation in the gene for the GnRH-R, a mutation in a gene coding for one of the gonadotropin subunits, or a more generalized developmental anomalies of the pituitary (Fig. 18.11).

GnRH-R Gene Mutations

The inheritance pattern of HH secondary to mutations in the *GNRHR* gene is autosomal-recessive, but sporadic cases are

observed.[493] Reported phenotypes range from microphallus and undescended testes at birth to presentation with delayed puberty in adolescence.[494] In general, the clinical phenotype correlates with biochemical LH pulsatility profiles and responses to exogenous GnRH. Complete HH is usually associated with low levels of apulsatile LH, whereas some spontaneous LH pulses, albeit reduced in amplitude, may be seen in patients with partial forms. The clinical phenotype correlates with the magnitude of the functional consequence of the mutation upon receptor function. Nevertheless, phenotypic heterogeneity for the same mutation has been observed.[495,496] Thus, the phenotype of individuals with *GNRHR* mutations ranges from partial to complete hypogonadism. The mutations in *GNRHR* reported to date appear to impair receptor folding and ligand binding, and decrease activation of the inositol phosphate or phospholipase C signaling pathways.[497-499]

FSH-β Gene Mutations

Women found to have mutations in the *FSHB g*ene have presented with absent breast development and primary amenorrhea.[500] Circulating FSH and estrogen concentrations were low, while LH secretion was elevated.[501,502] Three affected males have been reported with phenotypes ranging from absent to normal secondary sexual development. All three had azoospermia,[503-505] and, as in females, FSH concentrations were low whereas LH tended to be elevated.[506]

LHβ Gene Mutations

One male homozygous for a missense mutation, Gln55Arg, in the *LHB* gene had delayed puberty, elevated immunoreactive LH concentrations, few Leydig cells, and arrested spermatogenesis; treatment with hCG stimulated testosterone synthesis and spermatogenesis (also see Chapter 2).[507] Another variant, Gly102Ser, has been associated with male and female infertility.[508] Functional characterization of the Gly102Ser variant at high LH concentrations showed impaired receptor binding and decreased ability to stimulate progesterone biosynthesis compared with wild-type LH.[509] Homozygosity for a splicing mutation in the *LHB* gene was associated with hypogonadism in the affected male siblings and spontaneous pubertal development with secondary amenorrhea and infertility in the female sibling.[510]

One *LHB* variant appears to be relatively common; the frequency varies widely between ethnic groups ranging from near 0% in Kotas of Southern India up to 50% in Australian aborigines.[511] This variant has two single nucleotide polymorphisms (SNPs) in the coding region, which are predicted to generate the missense mutations, Tyr8Arg and Ile15Thr, and eight SNPs in the promoter region. Differences in transcriptional activity between the variant and wild-type have been attributed to the SNPs in the promoter of the variant.[512] Comparisons of the recombinant variant peptide subunit with the native subunit revealed differences in carbohydrate side chains and in intracellular trafficking.[513] More specifically, the Arg8/Thr15 variant contains an additional sialic acid residue per molecule and a longer half life.[514] Among healthy boys, heterozygosity for the Arg8/Thr15 variant was associated with smaller testicular volumes, slower growth rates, and lower IGFBP3 concentrations, suggesting that this variant affects the tempo of puberty.[513] Existing data suggest that, in girls, this variant may be associated with subfertility, lower frequency of PCOS, and delayed appearance of breast cancer.

Developmental Anomalies of the Pituitary

The pituitary consists of the anterior and posterior portions. The anterior portion is derived from an invagination of the oral ectoderm. The posterior pituitary originates from the neural ectoderm. Transcriptional activators, repressors, and other signalling molecules direct the development of the pituitary. Genetic variants in these factors have led to identification of genes associated with human disease. These developmental anomalies of the CNS, such as midline defects or septo-optic dysplasia, may be associated with gonadotropin and other pituitary hormone deficiencies, and, therefore, with delayed pubertal development. Septo-optic dysplasia, also known as de Morsier syndrome, is characterized by abnormalities of the septum pellucidum, thinning of the corpus callosum, and hypoplasia of the optic nerve. With optic nerve hypoplasia, physical examination reveals pendular nystagmus and pale hypoplastic optic discs.

The homeobox gene expressed in ES cells *(HESX1)* gene is an early marker of pituitary differentiation with limited spatiotemporal expression early in gestation. The protein functions as a transcriptional repressor and is important for midline development. Mutations in *HESX1* have been reported in familial cases of septo-optic dysplasia.

Mutations in the sex-determining region Y (SRY) box 2 *(SOX2)* gene are associated with hypopituitarism, eye anomalies, and HH.[515,516] Nonreproductive features include hypoplasia of the corpus callosum, sensorineural hearing loss, and esophageal atresia. SOX2 plays a role in regulation of cell proliferation in the anterior pituitary during early development. *SOX2* mutations appear to decrease the number of anterior pituitary progenitor cells.[517] SOX2 interacts with CHD7 to regulate common target genes.[518]

Mutations in other genes involved in pituitary differentiation have been identified among patients with multiple anterior pituitary hormone deficiencies. Rieger syndrome is an autosomal-dominant disorder characterized by eye anomalies, dental hypoplasia, and anterior pituitary hormone deficiencies associated with mutations in the paired-like homeodomain transcription factor 2 *(PITX2)* gene, which encodes a transcription factor involved in pituitary cell differentiation and maintenance.

Delayed puberty associated with impaired gonadotropin secretion has been reported in patients with mutations in the *LHX3* gene, which codes for a homeo-domain-containing transcription factor expressed early in the differentiation of the anterior pituitary.[519] Mutations in the *PROP-1* (paired like homeodomain factor 1, Prophet of PIT1) gene are associated with combined pituitary hormone deficiencies. The *PROP-1* gene codes for a transcription factor involved in development of somatotrophs, thyrotrophs, and lactotrophs.[520] Most patients with *PROP-1* gene mutations reported to date have presented in childhood with TSH and GH deficiencies. LH and FSH deficiencies develop later with a variable age of onset, such that the clinical presentation ranges from delayed puberty to secondary amenorrhea. Corticotroph dysfunction associated with ACTH deficiency and acquired adrenal insufficiency can also develop over time.[521,522] Thus, phenotypic heterogeneity occurs in regard to age at presentation and the spectrum of anterior pituitary hormone deficiencies.[523]

Nongenetic factors may also lead to CNS developmental abnormalities with hypogonadotropism and should therefore be considered in the etiology of pituitary-dependent delayed

puberty. Three such entities, maternal cocaine abuse, valproate toxicity, and intrauterine vascular disruptive events, have been implicated as possible etiologies of septo-optic dysplasia.[524-526]

Hypothalamic and Pituitary-Dependent Hypogonadism

This section discusses disorders that involve both the hypothalamus and pituitary. Some disorders, such as adrenal hypoplasia congenita (AHC), also affect the development of the adrenal cortex. For some disorders, inconsistency of investigative reports precludes precise definition of the anatomical localization.

Adrenal Hypoplasia Congenita

Adrenal hypoplasia congenital (AHC), which is characterized by primary adrenal insufficiency and HH, is an X-linked recessive disorder due to mutations in the *DAX-1* (dosage-sensitive sex reversal, AHC-critical region of the X chromosome, gene 1 which is also known as *NROB1*) gene located on the short arm of the X chromosome.[527] In AHC, the development of the fetal zone of the adrenal cortex during fetal development and its regression during the first year of postnatal life occur normally. The adult zone of the adrenal cortex, on the other hand, fails to develop. Thus, symptoms of adrenal insufficiency in AHC generally do not manifest until after 6 to 8 weeks of age, and affected males can present in infancy or childhood with primary adrenal insufficiency. Delayed adrenarche may occur. In addition, complete or partial HH can occur. The HH reflects a combination of inconsistent hypothalamic GnRH secretion and/or abnormal pituitary responsiveness to GnRH.[527]Isolated HH due to *NROB1* mutations may occur rarely in the absence of adrenal insufficiency or a family history of hypogonadism.[528] Heterozygotic females may have delayed puberty but show normal fertility.[529]

The *NROB1* gene codes for a receptor protein expressed in the hypothalamus, pituitary, adrenal, and gonads. Because no ligand has been identified for the receptor as of yet, it is classified as an orphan nuclear receptor. Through its C-terminus transcriptional repression domain, the protein silences transcription of many genes involved in steroid hormone metabolism. The majority of mutations detected in patients with AHC cluster in the region encoding the C terminal of the protein.[530] Structure—function analysis suggests the mechanism through which *NROB1* mutations cause AHC involves abnormal folding of the receptor leading to impaired nuclear translocation and transcriptional silencing.[531] Mutations in this region of the X chromosome may be part of a contiguous gene deletion syndrome, which includes glycerol kinase deficiency and Duchenne muscular dystrophy. Phenotypic heterogeneity can occur even within a family.[532]

Intracranial Tumors

Depending on their precise location and size, intracranial tumors can suppress gonadotropin secretion either directly or indirectly, via interruption of GnRH release. Those that present before or during puberty, therefore, lead to delayed or arrested gonadarche. Deficiencies of other pituitary hormones may be present or develop at a later time. Thus, concurrent GH, TSH, ACTH, and ADH deficiencies may be present. Acquired pituitary hormone deficiencies, especially if accompanied by diabetes insipidus, suggest the presence of a CNS tumor.

The most common neoplasm is a craniopharyngioma, which is believed to arise from remnants of Rathke's pouch, the embryonic anlagen of the anterior pituitary. These tumors account for approximately 10% of childhood CNS tumors with the peak chronological age at presentation occurring between 5 and 20 years.[533] In addition to delayed pubertal development, signs and symptoms suggestive of a craniopharyngioma include decreasing growth velocity, headache, polyuria, and visual disturbance (bilateral temporal field deficits, optic atrophy, or papilledema). Suprasellar or intrasellar calcifications may be seen on skull radiographs. MRI and CT scans confirm the presence of the tumor and reveal whether it is cystic or solid. Treatment usually involves surgical resection, with outcome dependent on the size and precise location of the tumor. Radiation therapy may be used as adjunctive therapy. Recurrences are common.[534]

Other types of tumors include germ cell tumors, epidermoid and dermoid cysts, chromophobe adenomas, prolactinomas, and optic gliomas. Germ cell tumors include germinomas, dysgerminomas, embryonal cell carcinomas, and teratomas. Such tumors account for approximately 6.5% of intracranial neoplasms in children. Diabetes insipidus is a common manifestation, however, other anterior pituitary hormone deficiencies may occur. Germ cell tumors often originate in the suprasellar hypothalamus or pineal, and they may show subependymal spread along the lining of the third ventricle such that seeding of the cerebrospinal fluid leads to involvement of the lower spinal cord and cauda equina. Elevated β-hCG or α-fetoprotein concentrations may be detected secondary to secretion by the tumor cells. Usually, the response to radiation therapy is good which averts the need for surgery unless a tissue diagnosis is necessary.

Epidermoid and dermoid cysts are epithelial-lined intracranial cysts that are often located in the suprasellar region or at the cerebellopontine angle. Chromophobe adenomas are rare in children but may occur in older adolescents, leading to delayed puberty, secondary amenorrhea, or acquired testosterone deficiency. Optic nerve and chiasmatic gliomas (astrocytomas) account for approximately 5% of pediatric brain tumors and tend to present during the first 2 decades of life.[535] Although optic nerve gliomas are often associated with NF1 and precocious puberty, delayed puberty due to hypogonadotropism (with other anterior pituitary hormone deficiencies) may also occur.

Histiocytosis X

Histiocytosis X, also known as Langerhans cell histiocytosis or Hand-Schuller-Christian disease, is characterized by infiltration of lipid-laden histiocytes into skin, bone, or visceral organs. These specific dendritic cells can infiltrate almost any organ. The clinical course can be unpredictable such that spontaneous resolution or progression to a disseminated form may occur. Infiltration of the orbit can cause exophthalmos. The typical radiographic findings include cyst-like areas involving flat bones of the skull, ribs, pelvis, scapula, lower spine, and long bones of the limbs. Pituitary MRI reveals loss of the posterior pituitary bright spot and thickening of the infundibulum. Although not malignant, the histiocytes can invade adjacent tissues.

Diabetes insipidus is the most common endocrine manifestation occurring in approximately 25% of affected children, but other pituitary hormone deficiencies can occur.[536] Once established, anterior pituitary hormone deficiencies

are generally permanent. Gonadotropin deficiency may develop several years following the initial diagnosis. Thus, delayed puberty may be seen. Hypothalamic infiltration can manifest as neuropsychiatric and behavioral disorders as well as autonomic dysregulation.[537]

Hyperprolactinemia

Hyperprolactinemia can lead to hypogonadotropism as a result of the action of prolactin to directly suppress pulsatile GnRH secretion (see also Chapter 3).[538] Thus, if hyperprolactinemia occurs prior to puberty, delayed or interrupted gonadarche with galactorrhea may be observed.[539] Even if galactorrhea is not readily apparent, nipple manipulation may induce fluid release. Because prolactin release may be stimulated by nipple manipulation, evaluation of serum prolactin levels should be conducted on blood samples collected in the morning from fasting subjects prior to breast examination. Hyperprolactinemia can be due to microadenomas (adenomas measuring less than 10 mm) and macroadenomas (larger than 10 mm).[540] Although CT scans can be used to identify pituitary adenomas, MRI provides more anatomical detail. Individuals taking antipsychotic medications and patients with primary hypothyroidism may also have hyperprolactinemia.[540,541] Prolactin secretion is tonically inhibited by hypothalamic dopamine release, and dopamine receptor agonists (bromocriptine or cabergoline) are effective to decrease tumor size and prolactin concentrations.[542,543]

Steroidogenic Factor-1/NR5A1 Mutations

This gene encodes Steroidogenic factor-1 *(NR5A1/SF1)*, which plays a major role in male sexual differentiation, steroidogenesis, and development of the hypothalamus, pituitary, adrenal glands, and testes. Because inactivating mutations impair testicular differentiation and testosterone secretion, affected 46,XY individuals would be predicted to have undervirilization of the external genitalia. The phenotype reported for one 46,XY patient who was heterozygous for an inactivating mutation included undervirilization of the external genitalia (46,XY male to female sex-reversal), adrenal insufficiency in the neonatal period, and delayed puberty.[544] A 46,XX patient presented with adrenal insufficiency and apparently normal ovarian differentiation, but it is unclear whether or not she will undergo spontaneous pubertal development.[545] Haploinsufficiency of *NR5A1* can also manifest as a predominantly gonadal phenotype characterized by hypergonadotropic hypogonadism. Heterozygous mutations in *NR5A1* have been reported among patients with 46,XY partial gonadal dysgenesis and underandrogenization but normal adrenal function.[546,547] Müllerian structures are generally absent. Penoscrotal hypospadias, bilateral anorchia, and testicular regression syndrome have been described. Haploinsufficiency of *NR5A1* can also manifest associated with delayed puberty or premature ovarian failure in 46,XX individuals. More recently, the phenotypic spectrum associated with *NR5A1* mutations has greatly expanded. The phenotypic spectrum extends to include 46,XY girls who present with delayed puberty, primary amenorrhea, and low testosterone concentrations in the absence of adrenal insufficiency.[548]

Other Syndromes Associated with Delayed Puberty

Delayed puberty due to HH is observed in several unrelated syndromes such as Prader-Willi, Bardet-Biedel, Alström, and Bloom syndromes. While both premature pubarche and GnRH-dependent premature gonadarche have been reported to occur in Prader-Willi syndrome, the majority of affected boys have cryptorchidism. When spontaneous pubertal development occurs, it generally progresses slowly and is often incomplete.[549] Hormone replacement therapy may not be necessary for all patients with Prader-Willi syndrome. Prader-Willi syndrome is also characterized by short stature, hypotonia, hyperphagia, obesity, mental retardation, and decreased fetal movements. It is a contiguous gene deletion syndrome involving loss of the paternal allele or uniparental disomy of the maternal allele for several genes, including the necdin and small nuclear ribonucleoprotein polypeptide N *(SNRPN)* genes located in the region of chromosome 15q11-13.[550]

The Bardet-Biedl syndrome is a rare autosomal recessive ciliopathy. Typical clinical features include include retinal dystrophy, dystrophic extremities (polydactyly, syndactyly, brachdactyly), mental retardation, learning difficulties, hypogonadism, and obesity.[551] Affected females may have structural abnormalities involving the internal genitalia, and they may experience hydrometrocolpos.[552] Inheritance is autosomal recessive with linkage to least 14 distinct loci.[553]

Alström syndrome is a progressive autosomal-recessive disorder characterized by cone–rod retinal dystrophy, cardiomyopathy, hypertriglyceridemia, and type 2 diabetes mellitus. Hypogonadism is an inconsistent feature. Weight gain leading to obesity begins during early childhood. Affected males often have small external genitalia and testicular atrophy with obliterating fibrosis of seminiferous tubules.[554] The reproductive phenotype in females ranges from polycystic ovary-like features presumably related to the insulin resistance to abnormal breast development, precocious puberty, endometriosis, irregular menses, or amenorrhea. The syndrome is due to mutations in the *ALMS1* gene mapped to chromosome 2p13. The gene is widely expressed; the protein appears to be involved in ciliary function, cell cycle control, and intracellular transport.[555]

Bloom syndrome is an autosomal-recessive disorder characterized by impaired prenatal and postnatal growth, predisposition to neoplasia, chromosomal instability, and hypogonadism due to inactivating mutations in the gene coding for DNA helicase RecQ protein-like-3 *(RECQL3)* which is located at chromosome 15q26.1. Men have azoospermia and are infertile and women are subfertile due to premature ovarian failure.

Hereditary hemochromatosis is associated with iron overload and iron deposition in endocrine organs. The typical endocrine manifestations include HH, impaired glucose tolerance, and diabetes mellitus. Mutations in several different genes are associated with the iron overload phenotype.[556] Iron accumulation in endocrine disorders is responsible for the clinical endocrine manifestations which include hypogonadism, diabetes, and hypothyroidism.

Gonadal Causes of Delayed Puberty (Primary Gonadal Failure)

Primary gonadal failure is associated with hypergonadotropic hypogonadism (see also Chapter 17). Etiologies include sex chromosome abnormalities leading to aberrant differentiation of the gonads (gonadal dysgenesis), absence of the

Table 18.4 Monogenic Disorders Associated with Hypergonadotropic Hypogonadism

Gene	*Locus*	*Associated Phenotypes*
WT1	11p13	Deny-Drash and Fraser syndromes
SRY	Yp11.3	Gonadal dysgenesis
SOX9	17q24.3	Campomelic dysplasia (loss of function)
SOX9	17q24.3	Sex reversal (duplication)
SOX10	22q13	Sex reversal
SOX3	Xq27.1	Sex reversal (over-expression)
RSPO1	1p34	Sex reversal
AIRE	21p22.3	Auto-immune polyendocrinopathy candidiasis ectodermal dystrophy
FOXL2	3q23	Blepharophimosis ptosis epicanthus inversus syndrome
NOBOX	7q35	Premature ovarian failure
FIGLA	2p13.3	Premature ovarian failure
BMP15	Xp11.22	Premature ovarian failure
FMR1	Xq27.3	Premature ovarian failure
LHCGR	2p16.3	Leydig cell hypoplasia
FSHR	2p16.3	Premature ovarian failure, oligospermia
StAR	8p11.23	Congenital lipoid adrenal hyperplasia
CYP17A1	10q24-q25	Hypertension, glucocorticoid deficiency, delayed puberty
AKR1C2/AKR1C4	10p15.1	Under-virilized males
CYP19A1	15q21.2	Estrogen deficiency
HSD17B3	9q22.32	46,XY Sex reversal with virilization at puberty
SRD5A2	2p23.1	46,XY Sex reversal with virilization at puberty
AR/NR3C4	Xq11-12	Androgen insensitivity

gonads, and injury to the gonads (Table 18.4). The hypergonadotropism associated with primary gonadal failure and with disorders of steroidogenesis or steroid hormone action is a result of loss of negative feedback inhibition by gonadal steroids at both the hypothalamic and pituitary level.

Gonadal Dysgenesis

Gonadal dysgenesis is used to describe disorders in which gonadal differentiation is aberrant (see also Chapter 17). Gonadal dysgenesis can be due to haploinsufficiency for the X chromosome (e.g., Turner syndrome). Other forms may result from mutations in genes involved in the process of sexual differentiation.

Turner Syndrome

Turner syndrome (TS) is due to deletions or structural rearrangements of the X chromosome. The reported incidence of liveborn females with this form of gonadal dysgenesis is 1:2000 to 1:5000.[557] Initially, the process of ovarian differentiation proceeds normally in fetuses with TS. During the 4th week of gestation, the primitive germ cells begin to migrate from their extra-gonadal site of origin to the genital ridge. Premature degeneration of ovarian follicles begins by 18 weeks of gestation. Ovarian follicles are replaced by abundant connective tissue (streak gonad). This accelerated prenatal and postnatal follicular atresia is generally associated with ovarian failure; the majority of girls with TS do not spontaneously enter puberty. Nevertheless, 25% to 30% of girls with TS show partial pubertal development at the appropriate time, and 2% to 5% may have spontaneous menses. As anticipated with primary ovarian failure, LH and FSH concentrations show a biphasic pattern (Fig. 18.6) with elevated concentrations during the first year of life and again at the expected age of puberty. For this reason, gonadotropin concentrations obtained between ages 5 to 9 years old cannot be reliably used to assess ovarian function.

Spontaneous pubertal development is more common among girls with mosaic karyotypes. AMH concentrations have been correlated with ovarian function. In general, AMH values less than 8 pmol/L have a high sensitivity for predicting ovarian failure. AMH concentrations appear to be a marker of ovarian function in girls, adolescents, and adult women with TS.[558] Low inhibin B concentrations may be another indication of ovarian failure.[559]

Short stature is a characteristic feature of TS.[560] Approximately 95% of individuals with TS have short stature. Common skeletal features include cubitus valgus, shortened fourth metacarpals, short neck, high arched palate, and Madelung deformity. Scoliosis may develop during the adolescent years.[561] Haploinsufficiency for the short stature homeobox-containing *(SHOX)* gene, located in the pseudoautosomal region of the X chromosome, contributes to the short stature and skeletal abnormalities associated with TS.[562] Because the majority of patients with TS present with short stature, exclusion of this form of gonadal dysgenesis is essential in the evaluation of all girls with short stature.[563] Bone mineral density is decreased with bone markers, indicating both increased resorption and normal to decreased bone formation.[564]

Aberrant development of the lymphatic system, especially in the nuchal region, is associated with a short webbed neck, peripheral lymphedema, and low posterior hairline. Additional features include bilateral otitis media, sensorineural hearing loss, cardiac malformations (especially of the left side of the heart), renal abnormalities, hypoplastic and hyperconvex nails, and multiple pigmented nevi. Phenotypic heterogeneity is common among girls with TS. Only about 25% of affected girls are diagnosed with TS as infants or toddlers.

Mosaicism with coexistence of multiple cell lines is not uncommon, although detection may require evaluation of multiple tissues. It has been speculated that mosaicism in critical cell lines is essential for fetal viability.[565,566] If the clinical suspicion for TS is high despite a normal peripheral blood karyotype, it may be worthwhile to examine a second tissue, such as skin. When a cell line containing a Y chromosome is present, the external genital phenotype may vary from female to ambiguous to male and the gonadal structure can range from a streak to a functional testis. In some instances, Y chromosome-specific sequences can be detected using sensitive molecular techniques.[567] The requirement to assess for the SRY gene or other Y chromosomal material remains controversial for girls with TS without any signs of virilization.[568] Girls with TS and evidence of virilization or presence of a marker chromosome should be thoroughly evaluated for presence of Y chromosomal material. If Y chromosomal sequences are present, the risk for development of gonadoblastoma is estimated to be 7% to 10%.[569] Such gonadoblastomas may secrete testosterone or estrogens and become calcified, but rarely become malignant.

Girls with Turner syndrome tend to have normal verbal abilities. As a group, however, they demonstrate specific deficits in visuospatial processing, visuoperceptual skills, motor function, and nonverbal memory compared with normal girls. These deficits may be associated with one or more deletions of a critical region in the pseudoautosomal region of the X chromosome.[570] For example, some girls with Turner syndrome may experience difficulty with interpretation of body language and facial expressions, trouble in maintaining relationships with peers, reading maps, and geometry. Although most deficits persist into adulthood, some cognitive deficiencies improve either due to a maturational or developmental lag, or due to effects of estrogen therapy. Nevertheless, the neurocognitive deficits, psychosocial issues, and school difficulties can lead to frustration and poor self-esteem.[571] Mental retardation is typical for girls with ring X chromosomes lacking the *XIST* gene (the gene responsible for X inactivation) because one copy of certain genes is not activated.[572]

Prior to the use of GH treatment, girls with TS who did not receive GH therapy achieved an average adult stature approximately 20 cm shorter than normal. The growth deficit of girls with Turner syndrome can be partially ameliorated by GH treatment. Earlier treatment and use of GH doses of 0.36 mg/kg per week are associated with improved final height outcome.[573] One study showed a modest growth benefit and improved final height outcome with the combination of ultra-low-dose childhood estrogen replacement and growth hormone.[574] Estrogen replacement therapy is generally necessary to induce pubertal development.[575] Yet, despite adequate estrogen replacement therapy, uterine maturation may be incomplete and may contribute to a high rate of miscarriage in both spontaneous and assisted pregnancies among women with TS.[576]

Girls with TS have an increased risk of chronic lymphocytic thyroiditis; thyroid function studies should be obtained regularly. Screening for renal structural abnormalities, skeletal malformations (congenital dislocated hips, Madelung deformity, scoliosis), hypertension, diabetes mellitus, and celiac disease is also necessary.[577] At diagnosis, a thorough cardiac evaluation is essential to ascertain for specific cardiovascular abnormalities such as coarctation of the aorta, bicuspid aortic valve, or mitral valve prolapse. Prophylactic antibiotic therapy is generally indicated if bicuspid aortic valve or mitral valve prolapse are detected. Repeat echocardiograms for adolescent and young adult women are necessary to evaluate for changes (dilatation) of the aortic root because of the increased risk of aortic dissection.[578] Although echocardiology may be sufficient for some, MRI with gadolinium provides better visualization of the entire aortic arch.[561]

Available data have led to reconsideration of oocyte donation and pregnancy in women with TS. In the past, adolescent girls were informed that reproductive options included adoption and oocyte donation. At the present time, counseling mandates frank and brutally honest discussions of the risk for aortic dissection during, or years after, pregnancy. As noted by the Practice Committee of ASRM, "Turner syndrome is a relative contraindication for pregnancy, and patients should be encouraged to consider alternatives, such as gestational surrogacy or adoption."[579] With the vast diversity of clinical features, a multidisciplinary approach is essential for the long-term clinical management of girls with TS.[580]

46,XY Gonadal Dysgenesis

Aberrant testicular differentiation in 46,XY fetuses is one cause of gonadal dysgenesis (see also Chapter 17). Because the degree of gonadal dysgenesis and testosterone deficiency vary, the external genital development can range from normal female external genitalia to undervirilization of male external genitalia. In "complete" or "pure" 46,XY gonadal dysgenesis, affected individuals appear to be normal females at birth. This disorder of gonadal differentiation is also known as Swyer syndrome or 46,XY sex reversal disorder of sexual differentiation. Affected individuals usually present with delayed puberty and primary amenorrhea; they are usually found to have streak gonads. The internal genital structures are usually female due to prenatal testosterone and AMH deficiencies. "Partial" or "incomplete" 46,XY gonadal dysgenesis is characterized by defective testicular differentiation, ambiguous external genitalia, and a combination of wolffian and müllerian duct structures. Compared to healthy controls, women with complete gonadal dysgenesis were taller and had smaller uterine sizes.[581]

Patients with 46,XY sex reversal have an increased risk of gonadoblastoma because the dysgenetic gonad carrying a Y chromosome has an increased risk for neoplastic changes. Although gonadal tumors typically do not develop until the second decade of life, they can occur earlier. Indeed, some patients present with the gonadal tumors.[582] In one series of 22 patients, 32% were found to have dysgerminoma and 14% had gonadoblastoma.[581] Spontaneous breast development in patients with gonadal dysgenesis may be secondary to estrogen secretion by these gonadal tumors.[583,584] Early diagnosis is beneficial to detect gonadal neoplasia and to initiate hormone replacement therapy.

Laboratory evaluation shows elevated gonadotropin concentrations, low testosterone concentrations, and 46,XY karyotype. Approximately 15% of patients with 46,XY gonadal dysgenesis have mutations in the testis-determining *SRY* gene. Most *SRY* mutations are *de novo* events. Curiously, some mutations are familial and present in unaffected fathers.[585,586] Because the majority of patients with 46,XY sex reversal do not have mutations in the *SRY* gene, it is presumed that they carry mutations involving other genes either upstream or downstream of *SRY* in the process of sexual differentiation.

Other Forms of Gonadal Dysgenesis

Denys-Drash and Frasier syndrome are associated with gonadal dysgenesis. Both disorders are due to heterozygous mutations in the Wilms' tumor-1 *(WT1)* gene.[587,588] Denys-Drash syndrome is characterized by 46,XY male to female sex reversal, Wilms' tumor, and chronic renal failure due to diffuse mesangial sclerosis. In addition to 46,XY male-to-female sex reversal and renal disease, patients with Frasier syndrome have a higher incidence of gonadoblastomas than patients with Denys-Drash syndrome. Patients with either of these syndromes and 46,XX karyotypes tend to have normal female external genitalia.

Ovotesticular disorder of sexual differentiation (previously known as true hermaphroditism) is characterized by

the concurrent presence of testicular tissue with seminiferous tubules and ovarian tissue with follicles. Although an ovotestis is the most commonly identified gonad, an ovary may be present on one side with a testis on the other side. The development of müllerian and wolffian duct derivatives is variable and depends on the amount of functional testicular tissue. Patients with true hermaphroditism are usually recognized in infancy due to genital ambiguity. The most frequent karyotypes are 46,XX (60%), mosaic 46,XX/46,XY (33%), and 46,XY (7%).[589]

Heterozygous inactivating mutations in the *SOX9* gene are associated with campomelic dwarfism and 46,XY male-to-female sex reversal.[590] Because some of the related skeletal abnormalities (such as small thoracic cage, undermineralized ribs, and tracheobronchomalacia) can cause respiratory distress, affected individuals often die early. However, milder forms can present with delayed puberty due to primary gonadal failure.[591] Another form of gonadal dysgenesis is 46,XX gonadal dysgenesis, which is characterized by female internal and external genital structures, delayed puberty, and streak gonads.

46,XX Males

The frequency of the XX male syndrome is approximately 1 in 25,000 males. Since 46,XX males often have normal male external genital development, they typically seek medical attention for delayed puberty, infertility, or gynecomastia. On physical examination, the testes are usually small. Some present in the newborn period with genital ambiguity or hypospadias.

This form of a disorder of sex development (DSD) can be subclassified into *SRY*-positive and *SRY*-negative groups.[592] In approximately 80% of 46,XX males, the *SRY* gene is detected by molecular genotype analysis. When the *SRY* gene is present, it is usually located on an X chromosome due to recombination between the X and Y chromosomes. However, translocation to an autosome can occur. The *SRY*-positive 46,XX males generally have normal male external genitalia, small azoospermic testes, hypergonadotropic hypogonadism, and often present with infertility.

Molecular etiologies are more diverse for the *SRY*-negative 46,XX patient. Overexpression of the *SOX10* gene at 22q13 was found in one patient with 46,XX sex reversal in association with multiple congenital anomalies.[593] Duplication of *SOX9* was described in one family; all affected family members had normal male secondary sexual characteristics and azoospermia.[594] Overexpression of the *SOX3* gene has also been associated with XX male sex reversal.[595] The R-spondin 1 *(RSPO1)* gene codes for a secreted furin-like domain protein that stabilizes β-catenin in the wingless-type mouse mammary tumor virus integration site-4 (WNT4) signaling pathway. Mutations in this gene are associated with 46, XX sex reversal.[596]

Klinefelter Syndome (KS)

KS is a chromosomal abnormality characterized by 47,XXY karyotype and primary testicular failure that may manifest before or after puberty (see also Chapter 17). Parental origin of the supernumerary X is approximately equal regarding maternal and paternal origin.[597] Gonadarche may be variable ranging from normal to absent. In one study, the incidence of KS was 1 in 667 males when diagnosed by prenatal cytogenetic analysis, whereas the incidence was much lower when patients were detected by clinical features alone. Thus, incomplete clinical ascertainment of patients with KS likely occurs.[598] Clinical features include gynecomastia, small firm testes, clinodactyly, and tall stature with disproportionate increase in limb lengths. Affected boys may have reduced penile length and small testes in childhood. The phenotype in boys with KS does not differ according to presenting clinical features or parental origin of the extra X chromosome.[599] It has been suggested that the extra copy of the short stature homeobox-containing *(SHOX)* gene located in the pseudoautosomal region on the short arm of the X chromosome contributes to the increased height in boys with KS.[600]

The initial development of the testis during gestation appears to be comparable to normal boys. Although the incidence of cryptorchidism and micropenis are slightly increased, anomalies of external genital development are uncommon.[601] KS affects both androgen secretion (Leydig cells) and spermatogenesis (Sertoli cells and germ cells). As would be anticipated, gonadotropin concentrations are elevated and testosterone concentrations tend to be low. Inhibin B concentrations tend to be normal during the prepubertal years but decline during puberty consistent with progressive testicular failure at the time of gonadarche.[602] AMH concentrations follow a similar pattern, but show a slower decline during puberty.

Affected boys may experience academic difficulties. The cognitive phenotype is characterized by deficits in language and executive function. Although IQ scores are generally in the normal range, boys with KS tend to have learning disabilities in arithmetic, reading, and spelling, which become more apparent and limiting over time.[603] Indeed, the learning disabilities may be the presenting clinical feature for some boys. Additional nonreproductive features include an increased incidence of mediastinal germ cell tumors, breast cancer, and vascular disease.[603] Patients with KS tend to have altered body composition with increased total body and truncal fat and risks to develop type 2 diabetes mellitus appear to be increased.[604,605]

The magnitude of primary testicular failure varies between patients. Goals of treatment include preservation of linear growth velocity, development of secondary sexual characteristics, increased muscle mass, and optimal bone mineral density. Hence, dosage and age at initiation of hormone replacement therapy need to be individualized.

Fertility preservation is an important topic to discuss with patients and their families. Paternity has been achieved for some using testicular sperm extraction combined with intracytoplasmic sperm injection (TESE-ICSI).[606] One reason for the success of this procedure is that foci of spermatogonia seem to exist within the testes. It has been speculated that these foci arise from clones of spermatogonia that have lost one of the X chromosomes.[607] Among men with KS undergoing TESE, testicular volume, testosterone concentrations, and hCG-stimulated testosterone responses correlated with sperm production.[608] It has been suggested that spermatogenesis decreases with age in men with KS. This hypothesis has been used to justify collection of testicular tissue from younger boys with hopes for *in vitro* sperm maturation. However, this approach is currently considered to be experimental and may prove to be

deleterious by removing the few functional spermatogonia resident in the testis.[609]

Testicular Regression Syndrome

This disorder, also known as "vanishing testis syndrome," affects at least 5% of boys who present with cryptorchidism. Typically, the external genitalia are male, but one or both testes cannot be identified. Rather, a nubbin of discrete vascularized fibrosis usually located in close proximity to a blind-ending spermatic cord structure is found at the time of orchidopexy. Histological examination often reveals calcification or hemosiderin deposits.[610] Often attributed to testicular torsion, the precise etiology of this condition responsible for primary testicular failure remains to be established. A novel heterozygous missense mutation (Val-355Met) in the steroidogenic factor-1 *(NR5A1)* gene was identified in a single boy with a micropenis and testicular regression syndrome.[611]

Auto-Immune Ovarian Failure

Autosomal-recessive type I autoimmune polyglandular syndrome (APS-1), also known as auto-immune polyendocrinopathy candidiasis ectodermal dystrophy (APECED), is characterized by mucocutaneous candidiasis, hyperparathyroidism, and adrenal insufficiency.[612] APS-1 is due to mutations in the *AIRE* gene.[613] Ovarian failure is common in APS-1 and may be associated with autoantibodies to the P450 steroidogenic enzymes expressed in the gonads and adrenal glands such as 3β-hydroxysteroid dehydrogenase.[614] Auto-immune testicular failure may also occur. Women with autoimmune Addison disease, particularly in association with APS-1, manifest an increased risk for premature ovarian failure.[615] The incidence of auto-immune primary gonadal failure is low in APS-2, which is characterized by immune-mediated type 1 diabetes mellitus, chronic lymphocytic thyroiditis, vitiligo, and pernicious anemia.[613] Some researchers have suggested that, in unexplained infertility, ovarian antibodies are an independent marker of ovarian failure that may precede changes in FSH and inhibin B concentrations.[616]

Nonimmune Premature Ovarian Failure

With increasing awareness that *in utero* ovarian development is an active process, disorders due to mutations in genes involved in this process may manifest as delayed puberty, primary amenorrhea, or premature ovarian failure (POF).[617] Genes associated with a POF phenotype include Forkhead box L2 *(FOXL2)*, Newborn Ovary Homeobox *(NOBOX)*, Factor in germline alpha *(FIGLA)*, and bone morphogenetic protein 15 *(BMP15)*.[618] The autosomal dominant blepharophimosis ptosis epicanthus inversus syndromes (BPES) is associated with mutations in *FOXL2*,[619] BPES is characterized by eyelid dysplasia consisting of small palpebral fissures (blepharophimosis), ptosis, epicanthus inversus, and a broad nasal bridge. Two BPES phenotypes have been described. The type 1 consists of eye findings and POF. Patients with BPES type 2 manifest only the eye features. Patients heterozygous for *FOXL2* mutations generally experience spontaneous pubertal development culminating in menarche, but undergo premature follicle depletion leading to POF. An increased number of CGG trinucleotide repeats ranging from 55 to 200 repeats in the fragile X gene *(FMR1)* is associated with POF.

Noonan Syndrome

Clinical features of Noonan syndrome include short stature, hypertelorism, short webbed neck, mental retardation, bleeding disorders, and right-sided cardiac anomalies. The estimated incidence ranges from 1:1000 to 1:2500 live births. Though inherited in an autosomal-dominant manner, 60% of cases are sporadic.[620] Cryptorchidism is common in affected males. Noonan syndrome is not a homogenous entity; patients with Noonan syndrome are found to carry mutations in genes within the RAS/MAPK pathway. At least 50% of cases have missense mutations in the *PTPN11* gene, which encodes the nonreceptor protein tyrosine phosphatase SHP2.[621] Other genes in the RAS-MAP kinase pathway found to be associated with Noonan syndrome include *KRAS*, *SOS1*, NRAS, *MEK1*, *BRAF*, *SHOC2*, and *NF1*.[622] Reproductive function tends to be normal in women. Postpubertal men tend to have elevated LH and FSH concentrations and declining AMH and inhibin B concentrations suggesting that Sertoli and/or germ cell function progressively deteriorates, resulting in impaired spermatogenesis and subfertility.[623]

Galactosemia

Galactosemia is an autosomal-recessive metabolical disorder characterized by abnormal galactose metabolism. Three different genes encode proteins involved in galactose metabolism: galactokinase *(GALK)*, galactose-1-phosphate uridyl transferase *(GALT)*, and UDP-galactose 4′epimerase *(GALE)*. Mutations in any of these genes can result in human disease. Affected women have elevated FSH concentrations and ovarian failure.[624] AMH concentrations may be useful to assess ovarian reserve in women with galactosemia.[625] Affected males appear to have normal testicular function.[626]

Down Syndrome

The occasional child with Down syndrome presents with abnormal pubertal development. Normal uterine size and the presence of follicles in ovaries have been documented.[627] However, for both sexes, gonadal failure with elevated gonadotropins may develop in adulthood.[628] For counseling purposes, women with Down syndrome can conceive, but affected men tend to be infertile. Children with Down syndrome have an increased risk for other chronic disorders, which may affect onset and progression of puberty. These disorders include hypothyroidism, celiac disease, and diabetes mellitus.[629]

Defects in Steroidogenesis or Steroid Hormone Action

LH-R Gene Mutations

In males, inactivating *LHCGR* mutations impair testosterone biosynthesis; such patients may present with delayed puberty (see Chapter 2). Inherited as an autosomal-recessive disorder, the most severe form is characterized by Leydig cell hypoplasia, testosterone deficiency, and 46,XY male-to-female sex reversal. Müllerian duct derivatives are absent. Milder forms may present with hypogonadism in 46,XY

individuals. The typical presentation for 46,XX individuals who carry severe inactivating mutations of this gene is the absence of puberty with primary amenorrhea, which may be associated with LH hypersecretion, cystic ovaries, and infertility.[630,631] A 46,XY patient who presented with delayed puberty was found to have a homozygous deletion of exon 10. Functional analysis to determine the consequences of the mutation showed that despite being able to bind LH, the mutant receptor was less effective at stimulating increased cAMP production than the normal receptor.[632]

FSH-R Gene Mutations

Although inactivating mutations of the *FSHR* gene are associated with primary ovarian failure and infertility, the development of secondary sex characteristics is variable in this autosomal-recessive disorder (also see Chapter 2).[633-635] While pubarche appears normal, breast development varies from absent to normal. Menarche is typically absent, although early secondary amenorrhea is occasionally observed. The variation in phenotype would suggest that the FSHR is not completely inactivated and that low levels of estradiol may be secreted. The phenotype is less severe in males, and pubertal development has occurred in those cases reported to date.[636] Testicular volume and sperm count, however, were decreased.

Congenital Lipoid Adrenal Hyperplasia

Mutations in the *StAR* gene are the molecular basis of congenital lipoid adrenal hyperplasia (see also Chapter 4). Consequently, sustained trophic hormone stimulation of the adrenal and the testis or ovary leads to the accumulation of cholesterol esters and cholesterol auto-oxidation in the cytoplasm of steroidogenically active cells. Cell destruction ensues because the accumulated lipid droplets lead to both physical engorgement and chemical damage from the cholesterol auto-oxidation products. Thus, the phenotype of congenital lipoid adrenal hyperplasia reflects the consequences of two separate events—the inactivating mutation and subsequent cellular damage.[637] These two hits interfere with fetal testicular testosterone biosynthesis, leading to androgen deficiency and undervirilization of affected 46,XY fetuses. Yet, despite the genetic mutation in the *StAR* gene, StAR-independent steroidogenesis allows for normal placental steroidogenesis and low, but measurable, adrenal steroid concentrations in the immediate newborn period. Subsequent cellular damage, however, leads to complete loss of adrenal steroidogenesis. Because the fetal, neonatal, and prepubertal ovary are relatively quiescent, ovarian lipid accumulation is minimal at these stages of development, and gonadarche may be initiated in affected 46,XX individuals.[638] Milder non-classical forms of congenital lipoid adrenal hyperplasia have been reported.[639]

17α-Hydroxylase or 17,20-Lyase Deficiency

The clinical features of decreased 17α-hydroxylase or 17,20-lyase activity, resulting from mutations in the *CYP17A1* gene can include glucocorticoid and sex steroid hormone deficiencies (see also Chapters 4 and 17). Because mineralocorticoid biosynthesis is unaffected, patients may have hypertension and/or hypokalemia due to increased aldosterone production. Affected males may present with complete or partial male-to-female sex reversal due to impaired testosterone secretion. Affected females have normal female internal and external genitalia; they typically present with delayed puberty secondary to inadequate estrogen production.[640]

In some patients, the lyase activity of the enzyme is more impaired than its hydroxylase activity. The molecular basis for this differential effect appears to be related to the consequences of mutations in specific domains of the mature protein such that mutations in the steroid-binding domain are associated with deleterious effects on both activities. The 17,20 lyase activity is particularly sensitive to interactions with the accessory proteins P450 oxidoreductase and cytochrome b_5.[641] Documented isolated 17,20-lyase deficiency is extremely rare.[642]

AKR1C2 and AKR1C4 Deficiencies

Genetic investigation of the original Swiss families purported to have isolated 17,20-lyase deficiency uncovered the importance of the alternative "backdoor pathway" for normal male sexual development. Through this pathway, DHT can be synthesized without testosterone as an intermediary hormone. Dihydrodiol dehydrogenase type 2 (AKR1C2) and dihydrodiol dehydrogenase type 4 (AKR1C4) are members of the aldo-oxo reductase (AKR) superfamily. Loss of function mutations in these genes were identified in these Swiss families.[643] Adrenal insufficiency and virilisation at puberty do not occur.

Aromatase Deficiency

Aromatase deficiency is an autosomal recessive disorder due to inactivating mutations in the aromatase *(CYP19A1)* gene (see Chapter 4).[644] The major consequence of decreased aromatase activity is impaired conversion of androgens to estrogens. Affected female infants may present with genital ambiguity due to excessive androgen exposure *in utero*. Subsequently, affected females show absence of breast development, primary amenorrhea, estrogen deficiency, progressive virilization, and hypergonadotropic hypogonadism.[645] From the small number of male patients who have been reported with this mutation, gonadarche appears to be initiated and male secondary sexual characteristics are normal.[646] When semen analysis has been performed, oligozoospermia or azoospermia has been noted. The cardinal feature of the mutation in the male is delayed bone maturation and decreased bone mineralization. Interestingly, women pregnant with affected fetuses can virilize due to impaired placental aromatase activity leading to hyperandrogenism.

17β-Hydroxysteroid Dehydrogenase Deficiency

In this autosomal-recessive disorder, testicular conversion of androstenedione to testosterone is impaired secondary to mutations in the *HSD17B3* gene (also see Chapters 4 and 17). Affected 46,XY individuals show varying degrees of external genital ambiguity at birth ranging from microphallus to perineoscrotal hypospadias with bilateral labial gonads. Affected 46,XY individuals have hypoplastic Wolffian duct development. Progressive virilization occurs at puberty, which is presumed to be due to increased peripheral conversion of sex steroids to testosterone. Affected individuals, raised as females, may convert to male gender

roles as puberty progresses. Appropriate gender assignment can be made when the diagnosis is made in the neonatal period. Phenotypic heterogeneity even within a single family has been reported.[647] Although increased basal androstenedione: testosterone ratios are anticipated, hCG stimulation and molecular genetic analysis may be necessary to confirm the diagnosis.

5α-Reductase Deficiency

In specific androgen target cells, such as the developing external genitalia and prostate, testosterone is converted to DHT by 5α-reductase type 2 (also see Chapters 4 and 17). In this autosomal-recessive disorder, the conversion of testosterone to DHT is impaired due to mutations in the 5α-reductase type 2 *(SRD5A2)* gene. This disorder is prevalent in the Dominican Republic; southern Lebanon; eastern highlands of Papua, New Guinea; and southern Turkey.[648] Affected 46,XY individuals show phenotypic heterogeneity with varying degrees of male-to-female sex reversal at birth.[649] Typically, at birth, they have perineoscrotal hypospadias, bilateral labial gonads, and absence of müllerian structures. At puberty, affected individuals virilize with phallic enlargement and development of pubic hair. When initially raised as girls, some affected individuals change to a male gender when virilization occurs. Spermatogenesis is usually impaired. Females homozygous for *SRD5A2* mutations generally have no reproductive symptoms.

Although random testosterone to DHT ratios may be elevated, hCG-stimulation testing may be necessary to confirm the diagnosis. Urinary steroid profiles with measurement of specific metabolites (androsterone/aetiocholanolone, 5α-tetrahydrocortisol/tetrahydrocortisol, and 5β-tetrahydrocorticosterone/tetrahydrocorticosterone) may be helpful to screen for 5α-reductase deficiency for females who present with primary amenorrhea, 46,XY karyotype, mild virilisation, and absent uterus.[650]

Androgen Receptor (AR) Gene Mutations

The phenotype of 46,XY individuals with mutations in the *AR* gene varies from male-to-female sex reversal to male infertility (also see Chapter 17). Inheritance is X-linked recessive; the *AR* gene is located on the X chromosome. This gene is also known as *NR3C4*. Similar to other members of the steroid and thyroid nuclear hormone receptor family, AR consists of a modular structure with ligand binding, DNA binding, N-terminal regulatory, and hinge region domains. Over 500 mutations have been reported in the *NR3C4* gene.[651] Mutations in the ligand-binding domain interfere with androgen binding. Although ligand binding is normal if the mutation is located in the DNA binding domain, the AR activity is impaired.

Individuals with complete androgen insensitivity have female external genitalia with labial masses or undescended testes. Müllerian-derived structures are absent because testicular AMH secretion *in utero* is normal. They are often considered to be females at birth and can present with either inguinal hernias in childhood or delayed menarche with sparse sexual hair development in adolescence. Typically, in the adolescent girl presenting with primary amenorrhea, LH and testosterone concentrations are elevated. FSH and inhibin B concentrations are usually normal. As noted previously, infants with CAIS often lack the neonatal testosterone surge. Recommendations for interventions upon the unanticipated finding of a gonad during a hernia repair in a female child include biopsy of the gonad, leaving the gonad *in situ*, obtaining a karyotype and other appropriate hormone measurements, and detailed discussion with the parents.

If the diagnosis of CAIS is confirmed, therapeutic options in the child include gonadectomy or leaving the gonad intact to allow for spontaneous breast development. The risk for neoplastic degeneration of the gonad is low in childhood.[652] Females with CAIS have a blind vaginal pouch and, generally, vaginal dilation is the only therapy needed to create a functional vagina.[653]

Full disclosure and psychosocial support are fundamental to the management of females with CAIS. From the first discussion regarding inheritance, it is important to realize that mothers of girls with CAIS may feel guilty for transmitting this X-linked disorder. Topics for the dialogue with the patient and her parents include implications of an XY karyotype, status of the testes, infertility, and sexual function. Although this information has been discussed at diagnosis with the parents, repeated age-appropriate discussions benefit the child. The complexity of the information disclosed increases as the child matures. A reasonable goal is to complete education about AIS by midadolescence.[654]

In partial androgen insensitivity, the phenotype is often that of an undervirilized male. For partial androgen insensitivity, presenting complaints can include gynecomastia, decreased sexual hair, hypospadias, cryptorchidism, small penis, and infertility. Androgen treatment may be beneficial in the adolescent male.[655]

Even within a family, phenotypic heterogeneity can occur.[656] In some instances, phenotypic heterogeneity appears to be secondary to somatic cell mosaicism.[657] No mutation in the coding region of *NR3C4* has been identified for some patients with prototypic features of AIS. Some researchers have speculated that these cases of apparent androgen insensitivity may be due to abnormalities of receptor cofactors or due to mutations in distant regulatory regions of *NR3C4* gene.[658]

Mayer-Rokitansky-Kuster-Hauser Syndrome

This congenital disorder is characterized by anatomical abnormalities of müllerian duct derivatives with prevalence reported between 1 in 4000 to 1 in 10,000 female patients. The disorder is due to abnormal development of the müllerian duct derivatives during the first trimester. Despite much investigation, the molecular etiologies have not been elucidated apart from a few women found to have *WNT4* mutations or duplications of the *SHOX* gene.[659,660] Affected patients usually have normal ovarian function such that breast development occurs normal. These patients typically present with primary amenorrhea or cyclic abdominal pain. Müllerian duct remnants may be palpable on bimanual recto-abdominal examination as a midline band of tissue. While ultrasound and MRI are helpful, laparoscopy may be needed to confirm the diagnosis.[661-663] Renal abnormalities especially ectopic kidneys or unilateral renal agenesis and skeletal abnormalities may be present. Vaginal development is variable, and often, vaginal dilation is helpful to enlarge the vagina for intercourse. Successful outcome of vaginal dilation depends on the patient's motivation and compliance.

Gynecomastia

Gynecomastia is the presence of palpable breast tissue in males. Approximately 50% of boys experience gynecomastia during midpuberty. Pathological causes of gynecomastia in boys include alterations in steroidogenesis such as Klinefelter syndrome, disorders of androgen biosynthesis, and androgen insensitivity. Other etiologies include hormone exposures, drug exposures, hyperprolactinemia, and other chronic disorders. Increased endogenous estrogen exposure can be due to hormone secreting tumors or the familial aromatase excess syndrome. Chronic medical conditions associated with gynecomastia include hepatic cirrhosis, renal failure, and hyperthyroidism. Drugs associated with gynecomastia include marijuana, cimetidine, spironolactone, and digitoxin.[664]

Chemotherapy and Radiation Therapy

As over 75% of young cancer patients are long-term survivors, quality of life concerns have become increasingly important considerations for adolescents and young adults especially regarding fertility. Chemotherapy and radiation therapy for childhood cancers can affect multiple components of the hypothalamic-pituitary-gonadal axis. The specific consequences depend on the specific drugs and fields of irradiation. The germ cells of the gonads are particularly vulnerable to radiation. For example, spermatogenesis is more sensitive to the effects of low-dose irradiation (greater than 1 or 2 Gy) than Leydig cell steroidogenesis (approximately 12 Gy).[665,666] Chemotherapeutic agents can be classified by gonadotoxicity into high, medium, and low-risk categories. High-risk drugs include alkylating agents such as cyclophosphamide which can injure germ cells.[667] Alkylating agents can generate bonds between DNA strands disrupting cell division. The net result is destruction of oocytes and follicular depletion in females and oligo or azospermia in males.[668]

CNS irradiation may lead to gonadotropin deficiency and other pituitary hormone deficiencies. Boys with brain tumors who received cranial irradiation and adjuvant chemotherapy have an increased risk for HH. In such patients, low inhibin B concentrations suggest damage to the seminiferous tubules and impaired spermatogenesis.[669] Pituitary hormone deficiencies may develop many years after CNS irradiation necessitating long-term follow-up of childhood cancer survivors.

Because the indications for bone marrow transplant are expanding to include malignant and nonmalignant hematologic disorders, solid tumors, and inherited metabolical disorders, more children are undergoing this procedure. After total body irradiation and bone marrow transplant, boys tend to have normal pubertal development whereas girls tend to have delayed puberty. However, low serum testosterone and elevated FSH concentrations among boys suggest that the prognosis for fertility is poor.[670] Other anterior pituitary hormones, in addition to the gonadotropins, can be affected by cancer treatment in childhood.[671]

Discussions regarding fertility preservation are essential for pediatric patients with cancer and their parents. Detailed discussion of this important topic is beyond the scope of this chapter.[672,673]

Approach to the Child with Delayed Puberty

As with sexual precocity, a thorough medical history and physical examination are crucial to the identification of the etiology of delayed puberty (Figs. 18.12 and 18.13). Is the patient undergoing treatment for any other disorder? What,

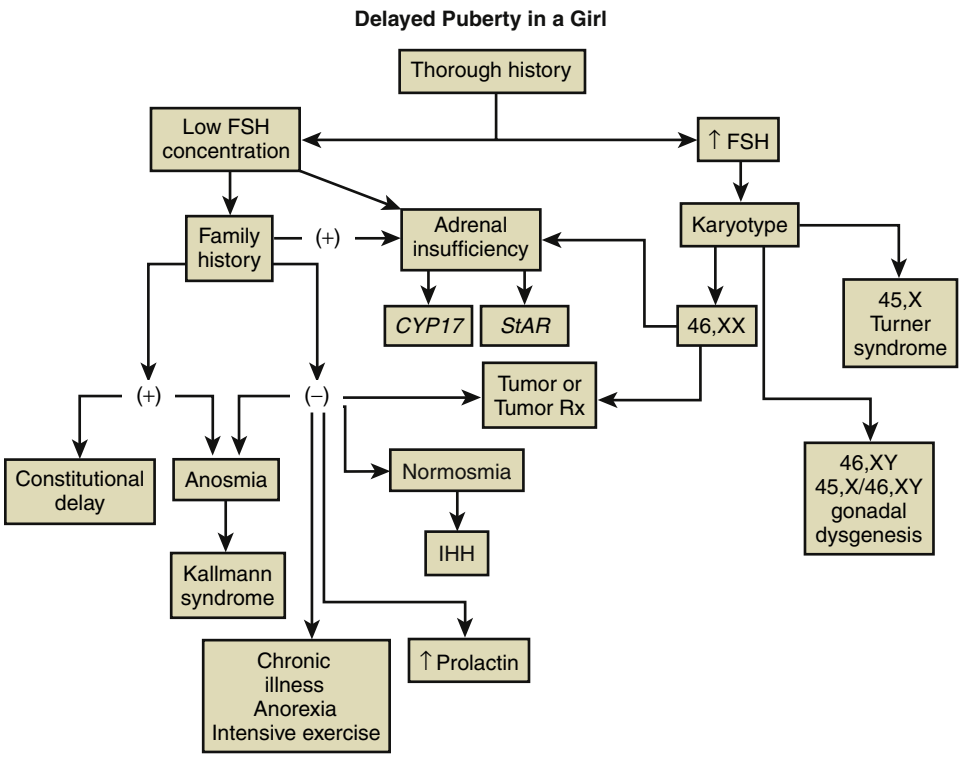

FIGURE 18.12 Algorithm for initial approach to delayed puberty in a girl. Beginning with a thorough medical history, this flowchart provides guidelines to the differential diagnosis of the most common causes of delayed puberty in girls. FSH, follicle stimulating hormone; CYP17, 17-alpha hydroxylase/17,20-lyase; StAR, steroidogenic acute regulatory protein.

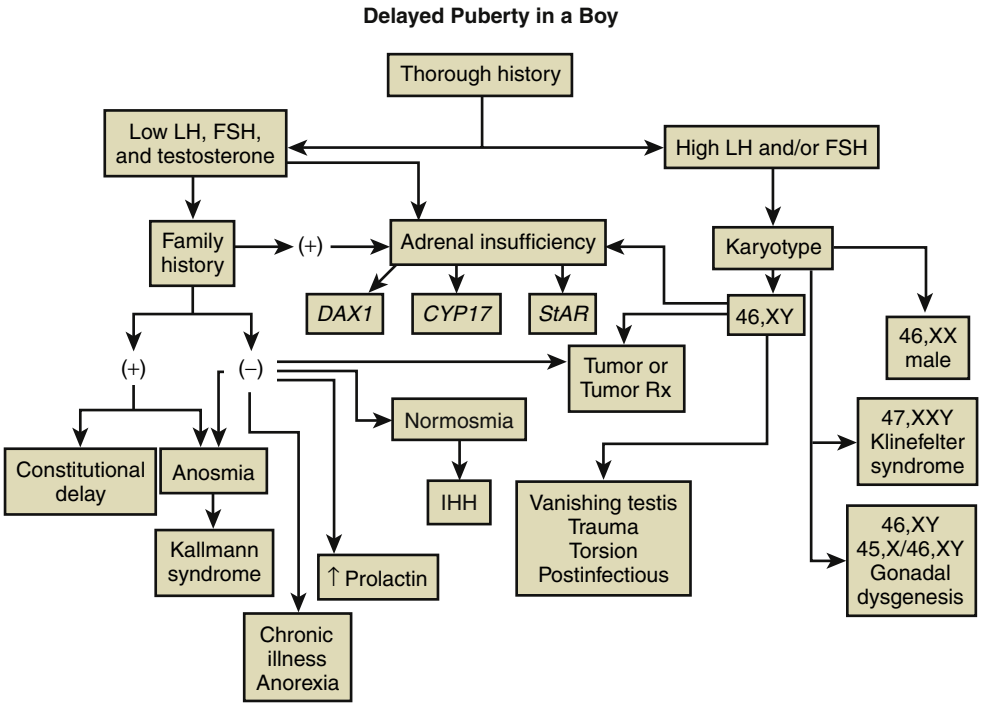

FIGURE 18.13 Algorithm for initial approach to delayed puberty in a boy. Beginning with a thorough medical history, this flowchart provides guidelines to the differential diagnosis of the most common causes of delayed puberty in boys. LH, luteinizing hormone; FSH, follicle stimulating hormone; DAX1, dosage sensitive sex reversal, AHC-critical region of the X chromosome, gene 1; CYP17, 17 alpha-hydroxylase/17,20-lyase; StAR, steroidogenic acute regulatory protein.

if any, pubertal development has occurred? Is there a family history of delayed puberty? What was the age of onset and sequence of any pubertal development? If the patient is a boy, was he treated for a micropenis or cryptorchidism? If the patient is a girl, is she experiencing hair growth in androgen-dependent regions? What is the family history regarding age at onset of puberty? Is there any history of infertility in the family? Does the patient or any family members have anosmia or neurological abnormalities? What does the child eat? Are there any concerns or clues suggesting an eating disorder? Is the child a competitive athlete or dancer?

Growth records to assess for stature, changes in growth velocity, weight loss, body mass index (BMI), and decreased weight for height should be examined. A thorough physical examination focusing on the physical features associated with estrogen and androgen actions should be performed. In boys, testicular length greater than 2.5 cm along the longitudinal axis or testicular volume greater than 4 mL suggests the onset of gonadarche. Breast development and pubic hair development should be assessed in girls. Are labial masses or clitoromegaly present in girls?

Features suggestive of specific disorders should be sought on physical examination (e.g., Turner syndrome, midline defects, and Prader-Willi syndrome). Short stature in a girl is suggestive of Turner syndrome and warrants measurement of gonadotropin concentrations and a karyotype, even in the absence of other stigmata of the condition. Small, firm testes, especially when gynecomastia is present, suggests Klinefelter syndrome. Height, upper-to-lower segment ratios, and arm span help define eunuchoid habitus. Tall stature, especially with long limbs, suggests hypogonadism, such as Kallmann syndrome or 46,XY gonadal dysgenesis. Patients should be carefully examined for features associated with *CHD7* mutations.

Useful laboratory studies include LH, FSH, DHEAS, sex steroid, inhibin B, AMH, and prolactin concentrations. Hypothyroidism should be excluded by measurement of free T_4 and TSH concentrations. Bone age determinations are used to assess the degree of delay, monitor subsequent development, and estimate final adult height. The bone age and height prediction should be assessed and related to the mid-parental height. Urinalysis, erythrocyte sedimentation rate, and renal function studies help exclude chronic disorders. Assessment for celiac disease, chronic inflammatory bowel disease, hemoglobinopathies, or hematochromatosis may be indicated based on clinical features. Even if the patient declares that he or she has a normal sense of smell, formal olfactometry may be necessary.

Imaging studies may be warranted depending upon the differential diagnosis formulated from the history and physical examination. Brain MRI studies may identify hypoplastic or absent olfactory bulbs. Renal anomalies can be associated with *KAL1* mutations. Dental or skull malformations can be associated with *FGFR1* mutations and may be identified by imaging.

Elevated basal gonadotropin concentrations confirm primary gonadal failure, but this assessment is less reliable when skeletal maturation is less than 11 years in girls and 12.5 years in boys. In most instances when the gonadotropin concentrations are elevated, cytogenetic analysis is indicated to assess for Turner syndrome in girls, Klinefelter syndrome in boys, disorders associated with gonadal dysgenesis, or defects in sex steroid synthesis or action. The current recommendation for first tier cytogenetic evaluation for patients with congenital anomalies or developmental disorders includes chromosomal microarray analyses because these analyses more readily detect subtelomeric copy number variations than G-banded karyotype studies.[674] Custom genome microarrays may also be helpful to detect genetic variations associated with hypogonadism.[675] For patients diagnosed to have HH, sequencing of specific genes can be performed through both commercial and

research laboratories. The sequence of genes to be tested should be based on the patient's clinical presentation, physical examination, laboratory data, and family history.[676]

After ensuring that pregnancy is not the cause of primary amenorrhea, progesterone withdrawal can be performed to assess estrogenization of the uterus and patency of the vaginal outflow tract. Withdrawal bleeding generally occurs within 24 to 72 hours of completing a course of progesterone (5 to 10 mg daily for 10 days). If no bleeding occurs, imaging studies to assess for a uterus should be performed. Another explanation for lack of withdrawal bleeding is estrogen deficiency.

In males, if random gonadotropin concentrations are not elevated, testing with hCG may be indicated when the testes are not palpable or if defects in testosterone biosynthesis are suspected. Multiple regimens have been described for hCG-stimulation tests, ranging from daily injections for 5 days to biweekly injections over several weeks. At least 5000 units should be administered over the treatment period, with total dosage not exceeding 3000 units per injection or 15,000 units over the treatment period. A blood sample to measure testosterone, DHT, DHEA, and androstenedione should be obtained within 24 hours of the last injection. When *CYP17A1* mutations are being considered, serum pregnenolone and 17-OHP levels should also be determined.

Discrimination of hypothalamic and pituitary gonadotropin disorders from constitutional delay may be difficult. In both situations, basal gonadotropin concentrations and GnRH-stimulated (100 μg GnRH) gonadotropin responses are low and show considerable overlap. Bone age x-rays generally show delayed skeletal maturation. A family history of delayed puberty is more common in constitutional delay. The presence of coincidental disorders, such as other anterior pituitary hormone deficiencies, decreases the chances of the delay being constitutional. In addition, constitutional delay of puberty is usually associated with delayed adrenarche; however, adrenarche may also be delayed among subjects with ACTH deficiency.

Comparison of various diagnostic studies suggests that low inhibin B concentrations may best distinguish HH from constitutional delay.[677] Two studies suggest that boys with constitutional delay tend to have inhibin B concentrations greater than 35 pg/mL.[678,679] Nevertheless, constitutional delay remains a diagnosis of exclusion. No single blood test, stimulation study, or imaging study accurately distinguishes constitutional delay from HH. Despite the importance of genetic factors underlying these disorders, detection of specific genetic variants associated with either disorder is uncommon. Thus, serial observation remains the best way to distinguish constitutional delay from HH.

Girls with 46,XY karyotypes associated with gonadal dysgenesis will likely require gonadectomy due to the risk for malignancy in dysgenetic gonads. Surgery may be deferred until later adolescence in girls with CAIS to allow for breast development.[680]

Estrogen Replacement

The goal of estrogen replacement therapy is to mimic the normal pattern of ovarian estradiol secretion to induce development of secondary sexual characteristics. Considerations such as chronological age, actual height, and predicted height are factored into the decision-making process as to when to initiate therapy. Estrogens promote both linear growth acceleration as well as stimulating bone maturation culminating in epiphyseal fusion.

It is important for girls with hypogonadism to experience menarche at the same time as their peers; for this reason estrogen therapy is generally initiated around age 12 years. Estrogen replacement therapy can be administered by oral or transdermal routes. Since oral estrogens undergo first-pass metabolism in the liver, oral estrogens can trigger an imbalance between antithrombotic mechanisms and procoagulant factors and are associated with higher estrone concentrations.[681] Currently, oral ethinyl estradiol is no longer commercially available as a single agent in the United States. Conjugated equine estrogens are available, but this formulation contains multiple estrogenic substances with varying biological potencies and is, thus, not appropriate for this population. Thus, transdermal estrogen is often preferred for the initial stages of pubertal development. Beginning doses can be as low as 6 to 7 mcg estradiol daily; transdermal estradiol patches can be cut into halves and quarters. The dose can be gradually increased over several years. The use of transdermal matrix patches only at night can mimic the spontaneous estrogen concentrations, as well as diurnal variation observed in early gonadarche.[682] Initially, estradiol is administered for 1 to 2 years to induce breast development. Two types of transdermal patches are available: reservoir and matrix. One advantage of matrix patches is the ability to cut the patches into pieces to administer lower doses.

Once breakthrough bleeding occurs, or after 1 to 2 years of unopposed estrogen, a progestin should be added. The girl can then be switched to an oral contraceptive or a combination of patches and pills can be used for cyclic estrogen-progesterone therapy. The estrogen dosage can be titrated according to the tempo and adequacy of pubertal development. Medroxyprogesterone (5 to 10 mg) or prometrium can be added to achieve cyclic estrogen and progestagen treatment. Upon completion of pubertal development, the estrogen dose should be the minimum necessary to prevent breakthrough bleeding, support regular menstrual cycles, and promote calcium deposition.

Hormone replacement therapy for women with TS and HH begins in adolescence and ends 40 to 50 years later. Women receiving estrogen-containing hormone therapy may have an increased risk to develop venous thromboembolism. In addition, certain progestagens influence thrombotic risk. Inherited forms of thrombophilia include point mutations in Factor V (Factor V Leiden) and Factor II (prothrombin G20210A). Protein C, protein S, and antithrombin deficiencies are rare inherited causes of thrombophilia. Although VTEs can occur at any time, the risk is highest in the first year of oral contraceptive use. Hence, understanding and identifying potential risk factors for thromboembolic events is essential.

For females with complete androgen insensitivity, congenital adrenal hyperplasia, or Mayer-Rokitansky-Kuster-Hauser syndrome, nonsurgical self-vaginal dilation supervised by a multi-disciplinary team is an effective alternative to vaginal surgery and often improves vaginal length.[683]

Androgen Replacement

Testosterone replacement therapy will induce and maintain secondary sexual characteristics in boys. Other goals include enhancement of libido and increased bone mineralization. Testosterone can be administered by intramuscular injection or transcutaneous absorption. To induce pubertal genital changes, intramuscular depot testosterone esters (such as testosterone enanthate or testosterone cypionate) are administered monthly, initially at low doses such as 50 mg per month with subsequent increases in dose. Medication impregnated patches or testosterone gel can be used. Some individuals complain of itchiness or inadequate adherence of the patches.

Studies in adult men showed achievement of steady-state testosterone concentration within 72 hours of therapy with the gel.[684] However, optimal dosing regimens have not been established for induction of puberty with these newer forms of testosterone. Adult testosterone replacement therapy consists of weekly depot injections of 100 mg given at one-, two-, or three-week intervals. When the interval between injections is increased beyond 3 weeks, testosterone concentrations may be supraphysiological immediately after the injection and decline to sub-therapeutic concentrations prior to the next injection. Transdermal testosterone impregnated patches and testosterone gel provide less variable serum concentrations. Testosterone gels must be allowed to dry completely to avoid transfer of the gel to clothing or bedding with the potential for accidental exposure to female family members and younger siblings.

Boys with anorchia can be offered the choice of having saline-filled testicular prostheses surgically placed into the scrotum. The scrotum should be able to accommodate adult-sized prostheses so that only a single operation is necessary to minimize the risk for infection and scarring.

Psychosocial Considerations for Precocious and Delayed Puberty

Early puberty, especially among girls, negatively influences self-esteem and is associated with increased risks for psychosocial stress.[685,686] Thus, older girls with residual behavioral issues as a consequence of precocious puberty may benefit from counseling.[687] Although premature adrenarche is usually benign, some girls meet diagnostic criteria for psychological disorders.[688] Boys with precocious puberty may demonstrate increased activity, increased aggressive behavior, and may masturbate. Parents report decreased self-esteem and self-confidence in some late maturing boys. Because early or late puberty can create stress for a child and his or her family, discussion to ascertain how the deviation from the normal timing of puberty impacts the patient is crucial. Importantly, maturation of cognitive function appears to correlate better with chronological age than biological maturation.[689]

Among children with delayed puberty, in the absence of major psychosocial issues, longitudinal re-evaluations to ensure pubertal development and progression may be sufficient. For those children suffering significant consequences, short courses of sex-appropriate steroids in small doses may be beneficial. For prepubertal boys, intramuscular depot testosterone (50 to 75 mg) can be administered monthly for three injections. After a medication-free period of at least 2 months, testosterone concentrations should be measured to assess for gonadarche. If the testosterone concentration remains low, a second course of therapy may be indicated. When used in small doses, testosterone increases growth velocity (by direct steroid action on bone and indirectly by stimulating GH secretion) and does not compromise adult height.[437] If testosterone, LH, and FSH concentrations remain low after a second course of testosterone therapy, the boy may have HH and require long-term testosterone replacement therapy.

The ability to reproduce is presumed, and is closely linked to self-esteem, gender identity, and body image. Thus, when infertility is likely to occur based on the underlying disorder, it is important to be honest and discuss the possibility of infertility. Patients and their families may need to mourn this loss of fertility, and thus involuntary childlessness, without the availability of established religious and social rituals that are extant in the case of death.[690] Subsequent discussion should include alternative ways to achieve a family such as adoption or marriage to someone with children from a prior relationship. Advancements in assisted reproductive technologies offer the opportunity for parenthood. For example, girls with premature ovarian failure can carry pregnancies. Short-term hCG treatment successfully stimulated spermatogenesis in a man with HH.[691]

Conclusion

Puberty, which normally unfolds toward the end of the first, or the beginning of the second, decade of life, results from initiation of two independent developmental processes: gonadarche and adrenarche. Gonadarche describes the pubertal activation of the gonad that results in gametogenesis and the production of adult patterns in gonadal steroid synthesis. Gonadarche results from increased gonadotropin secretion, which, in turn, is triggered by a resurgence in the activity of the hypothalamic GnRH pulse generator that has been held in check by a neurobiological brake (viewed to be conceptual in nature) from the time of late infancy.

Current models posit that the GnRH pulse generator is comprised of KNDy neurons in the arcuate nucleus of the hypothalamus, and that the output of the pulse generator is relayed to the GnRH neuronal network by the intermittent release of kisspeptin. The components of the neurobiological brake that dictates the postnatal pattern of GnRH pulse generator activity remain a mystery. The lifting of the brake at the end of juvenile development, and therefore the timing of the pubertal resurgence of pulsatile GnRH release probably involves somatic cues—although the identity of these signals remains unclear.

Adrenarche describes the pubertal increase in adrenal androgen production that is responsible for pubarche. The timing of adrenarche, in contrast to that of gonadarche, does not appear to require a signal from the brain. The timing and tempo of puberty may be modulated by genetic and environmental factors. Understanding the genomics of puberty and the interaction of environmental determinants to time the onset of human fertility is critical to improved therapeutic approaches for disorders of pubertal development.

With an appreciation and understanding of the physiology underlying gonadarche and adrenarche, a differential

diagnosis can be derived for patients presenting with disorders of pubertal development. With the tools of molecular genetics, the molecular etiology and risk for recurrence can often be determined. Evaluation and treatment include consideration of the psychosocial complications of "off-time" pubertal development or possible infertility.

CHAPTER 19

Nutrition and Reproduction

Nanette Santoro
Alex J. Polotsky
Jessica Rieder
Laxmi A. Kondapalli

In males, pulsatile gonadotropin releasing hormone (GnRH) and gonadotropin secretion occurs at a mean interval of every 2 hours,[1] a frequency sufficient to maintain testosterone secretion, normal virilization, and spermatogenesis. In females, a more complex series of gonadal tasks must be accomplished, which include maturation of a single follicle, follicular rupture and ovulation, and corpus luteum formation. The mature female hypothalamic-pituitary-ovarian (HPO) axis must respond dynamically with negative, then positive (bimodal) feedback to rising estradiol, which is secreted by the developing follicle.[2] The positive feedback response, in the form of a luteinizing hormone (LH) surge, must be sufficient to initiate the molecular events of follicle rupture and subsequent luteinization. Optimal functioning of the female reproductive system requires more versatility of the HPO axis and this system is therefore more vulnerable to disruption than is the male.[3]

Pulsatile secretion of hypothalamic GnRH and pituitary LH occurs prior to birth, and continues throughout the prepubertal period.[4] Pulsatile LH secretion has been detected in children and occurs at a normal, adult frequency in boys and girls[5]; however, the amplitude of the signal is miniscule and requires highly sensitive measurement methods to detect. Suppression of pulsatile GnRH-LH secretory amplitude in prepuberty has been attributed to a combination of enhanced sensitivity of the childhood reproductive axis to estradiol, as well as a predominance of inhibitory neural and neuroendocrine signals that ultimately dampen the amplitude of the central GnRH pulse generator.[6] This working model hypothesizes that prepubertally, the HP axis is inhibited, and during puberty the axis is released from this inhibition.

Almost 40 years ago, Frisch and Revelle noted a direct relationship between body weight and age at onset of puberty[7,8] and concluded that a critical amount of body fat was needed for the onset of puberty.[9] These investigators predicted correctly that adipose tissue somehow provided a permissive signal to the reproductive system. The discovery of the endocrine nature of adipose tissue has since led to the identification of a number of adipokines as well as inflammatory factors, and the elucidation of their role in reproduction is emerging rapidly. The best characterized molecule to date is leptin. It has been shown in both animal models[10] and in humans that inadequate leptin is associated with lack of GnRH secretion, and that leptin replacement can restore normal cycles in women who have hypothalamic amenorrhea and hypoleptinemia.[11] However, leptin alone is insufficient to initiate pubertal maturation of the HPG axis and a specific leptin concentration or threshold, above which maturation occurs, has not been identified.[12]

One of the final common pathways that appears to activate GnRH-LH secretion during puberty involves kisspeptin and its cognate receptor, G-protein coupled receptor-54 (GPR54).[13] Kisspeptin appears to act directly on GnRH neurons and amplifies GnRH and consequently LH and follicle stimulating hormone (FSH) secretion. Both kisspeptin and its receptor, GPR54, increase coincident with the onset of puberty. In addition to kisspeptin, there are many other upstream regulators of GnRH that appear to provide redundancy to prevent reproductive failure.

Puberty is also a time during which acquisition of functional networks of neurons and glial cells provide necessary communication pathways through which reproductive signaling can occur. The acquisition of these networks may involve anatomical changes in cell populations or recruitment as well as increases in neuronal connectivity. For example, glial cells long believed to be inert but helpful in providing scaffolding, may play a more direct role in GnRH secretion. Microglia, macrophages that differentiate into glial cells, are necessary for optimal GnRH secretion. CSF-1 knockout mice, who lack adequate macrophage function, do not have adequate microglial development and are deficient in hypothalamic GnRH secretion.[14] The interaction of immunomodulatory molecules with the reproductive neural networking is not yet well characterized.

Much research to date on abnormalities of pubertal maturation has focused on inadequate nutritional states. However, in the U.S. as in most developed nations, these conditions are becoming increasingly rare and are being replaced by reproductive dysfunction due to overweight and obesity. Obesity has been linked to altered pubertal progression and adult reproductive dysfunction. Polycystic ovary syndrome (PCOS) has been well studied in its interactions between obesity and anovulation; however, a far greater proportion of the population is affected by simple obesity. Pubertal onset is earlier in obese girls and boys, but the tempo of puberty is slowed in simple obesity.[15,16] A relative state of hypogonadotropic hypogonadism has been

described in obese women without PCOS.[17] Decreased fecundity, increased reproductive wastage, and a less favorable response to fertility treatments have all been described in association with adult female obesity.[18-21] In men, reduced fertility and a marked increase in bioavailable estrogen have been described.[22,23]

This chapter will discuss the role of overnutrition and undernutrition in relation to reproduction.

Nutrition and Puberty

The known and conjectured mechanisms initiating puberty are reviewed elsewhere in this volume. We will focus on the relevant epidemiology of normal puberty in boys and girls.

Puberty appears to be imminent when hypothalamic-pituitary sensitivity to negative feedback inhibition by estradiol is reduced,[24] and attendant inhibitory neural networks diminish in activity. These processes lead to increased GnRH secretion[25] as well as increased gonadotropin pulsatility, initially at night time, which then extends throughout 24 hours.[26] The result is folliculogenesis in girls, spermatogenesis and testosterone production in boys, and the attainment of fertility milestones. In females, the ultimate maturation of the HPO axis is the manifestation of positive hypothalamic-pituitary feedback to increasing estradiol, which initiates an LH surge and ovulation of the pre-ovulatory dominant follicle.[2]

Sexual maturation is a progressive process, but it is not linear. Girls who have their first menstrual period do not always continue to ovulate monthly thereafter. It is also not certain if menarche routinely reflects an antecedent ovulatory cycle, or if it is merely indicative of a rise and fall in estradiol. Prior epidemiological studies have observed that the attainment of regular menstruation takes from as little as 2[27] to as much as 7 years after menarche.[28-30] However, many such studies were conducted in populations of girls who differ from our modern day U.S. population. There were few young women of color, yet African-American girls are known to attain menarche and to undergo pubertal maturation earlier than Caucasian girls. This has been related in part to increased body mass index (BMI) but may also be due to other factors.[31] It is possible that prior populations studied have been enriched in girls who were nutritionally marginal, certainly so by today's standards. However, weight or BMI data are not available from these earlier studies.[29,32,33] Given the high rates of obesity among adolescents in the current U.S. population, and the increase in body fat in adolescent women in the United States over the past century,[34] it is likely that any restraint that low body weight might place upon the HPO axis is minimally operative in our current society.[35] The virtual elimination of under-nutrition might be expected to reduce the overall age at menarche in population studies. However, this is not uniformly the case. In one 50-year cohort and family study of a population sample in Ohio, higher BMI was not shown to be independently related to an earlier age at menarche.[36] However, this population reflects minimal minority representation, and had a mean age at menarche of 12.7 prior to 1954 and 12.6 after 1954, a minimal decrease. It is possible that overall body composition or BMI in this sample was optimal prior to 1954 (i.e., few girls who were critically underweight were present in this sample).

One study of 112 Caucasian girls, followed every 6 months perimenarcheally, observed elevated urinary progesterone levels consistent with regular ovulation within 1 year of menarche in the majority.[37] However, sampling was only done every 6 months, a frequency inadequate for the detection of monthly ovulatory events. Zhang and colleagues have recently completed a study of perimenarcheal girls using daily urinary sampling, and the findings reinforce the notion that regular ovulation occurs relatively rapidly, within months instead of years after menarche.[38] Metcalf and colleagues[28] and Borsos and colleagues,[39] who did weekly hormonal assessments in perimenarcheal girls, concluded that a mature pattern of ovulatory cycles was established in a majority of girls after the 20th menstrual period. However, even weekly urine sampling may be inadequate for the detection of brief excursions of progesterone, or its urinary metabolite, pregnanediol glucuronide (Pdg). Luteal phases may also be shorter than the adult norm of 14 days when adolescents are observed. Recent data from our group indicates that the capacity to produce an ovulatory LH surge in response to estrogen is present even before the onset of the first menses.[38] These findings indicate that, at least in some girls, a biphasic feedback response to estradiol is not the rate limiting step in attaining regular, ovulatory menses. Irregular menstruation has been associated with low gynecological age, low BMI, chronic nonspecific lung disease or allergic disease, weight loss, and stress.[40]

Rosenfield[41] has hypothesized that low-amplitude hormonal cycles occur in early puberty, with nighttime levels greater than daytime. Indeed, it may be that all the hormonal components of the HPO axis are functioning at an adult frequency, but the hormonal signals are dampened and slowly increase to detectable levels.

The notion that body weight or body fat is a permissive maturational signal to the hypothalamic-pituitary axis in girls is also supported by clinical data demonstrating an increase in leptin associated with puberty. Within developing countries, pubertal timing variations exist between girls in well-off versus underprivileged conditions, with earlier ages at menarche in well-off girls.[42] Whether these differences relate to nutritional status, physical activity or energy expenditure, or perceived environmental stressors is not known. Environmental exposures are also hypothesized to contribute to the trend of earlier puberty in Western societies. Endocrine disruptors contained in plastics are ubiquitous in industrialized societies and most individuals demonstrate appreciable levels of exposure. In general, these compounds bind weakly to sex steroid receptors and their signaling is likely to be overridden by endogenous sex steroids in gonadally intact, reproductive aged males and females. However, at the extremes of reproductive life in women and prepubertally in men, these mixed sex steroid agonists may play a role in providing nonphysiological input to the reproductive axis.

How Does Fat Signal the HPO Axis?

Leptin and Its Effects on the Reproductive Axis

Leptin is a 16kD protein secreted primarily by adipocytes. Initially described as a satiety factor,[43] it conveys an afferent signal to the CNS about body fat stores. Mice deficient in leptin protein (ob/ob) or leptin receptor (db/db)

exhibit hyperphagia, profound obesity, and central hypogonadotropic hypogonadism. It has been proposed that leptin exerts dual regulation of energy balance, based upon the organism's state of energy regulation. When energy input is equal to output, leptin concentrations reflect total body fat mass. Alternatively, in conditions of energy disequilibrium, leptin functions as a sensor of energy imbalance, with low concentrations in states of net weight loss and elevated in positive energy balance states (reviewed in[44]). Leptin has been shown to modulate GnRH pulse frequency *in vitro*.[45] It does not act directly on GnRH neurons, but rather via indirect mechanisms through interneurons secreting hypothalamic neuropeptides, such as neuropeptide Y, galanin-like protein, melanocyte stimulating hormone (MSH), and endogenous opioids.[46]

Leptin's role as a peripheral adipose signal to the central reproductive axis gave rise to speculation that it was the missing link in the Frisch hypothesis[47] and, thus, served as a major trigger of pubertal development. Leptin's role, while necessary, is insufficient to bring about pubertal maturation on its own. Leptin reverses pubertal arrest in leptin-deficient mice.[48] When given to normal prepubertal animals, leptin hastens sexual development as manifested by the advancement of vaginal opening.[49] However, when Cheung and colleagues assessed the temporal sequence of pubertal events in rodents,[50,51] serum leptin was not detectably elevated prior to pubertal development. Moreover, expression of leptin receptor messenger ribonucleic acid (mRNA) in the hypothalami of female mice did not increase with pubertal development. Finally, administration of leptin to starved animals advanced estrus to the same degree as food-restricted untreated controls but first estrus occurred at the same time as mice fed ad libitum. Taken together, these results imply that leptin provides a necessary input of adequacy of energy stores to the brain, thus authorizing but not initiating puberty.

In humans, leptin levels are markedly elevated in obesity[52] and pregnancy,[53] and are overall higher in women than in men.[54] Similar to rodents, deficiencies of leptin or leptin receptor, though rare, are characterized by early-onset obesity and variable degrees of hypogonadotropic hypogonadism.[55,56] Dramatic reversal of pubertal delay with leptin administration in a leptin deficient girl has been described.[57]

In the absence of a deficiency, serum leptin increases during childhood, with the highest concentrations in children who gain the most weight; higher serum leptin concentrations are associated with an earlier menarche.[58] In boys with constitutional delay of puberty, a leptin rise was not required for pubertal progression.[59] Furthermore, two women with lipoatrophic diabetes and chronic hypoleptinemia were reported to have normal menarche and childbearing, suggesting that normal pubertal maturation is possible even with very low serum levels.[60] Thus, while leptin does not act as a "trigger," it somehow conveys an essential metabolical permission for the body to prepare for procreation. Women with amenorrhea of hypothalamic origin, with or without weight loss as a precipitating factor, demonstrate improvement of their menstrual cycles and restoration of regular, pulsatile GnRH-LH secretion in response to leptin.[61,62] Leptin remains the most compelling molecule among currently known adipokines for having a major role in reproduction.

Leptin has numerous affects on peripheral components of the reproductive system in a variety of animals and model systems. On the gonadal level, leptin has been found in ovarian follicular fluid and a leptin receptor has been localized to the human granulosa, theca, and Leydig cells. In a bovine model, leptin decreased gonadotropin-mediated sex steroid production from granulosa and theca cells.[63] In humans, leptin may interrupt normal oocyte maturation[64] and has been correlated with poor implantation potential.[65,66] The predominant effect of leptin's action on the HPG axis has been hypothesized to be dependent upon its concentration, whereby low leptin exerts a negative influence centrally and elevated leptin yields a negative effect peripherally at the gonadal or embryo level.

Other Potential Molecules that Communicate Metabolical Signals to the HPO Axis

Adiponectin, another major adipokine, is the most abundant adipose gene transcript and is the natural peroxisome proliferator-activated receptor gamma (PPAR-gamma) ligand.[67] It plays an overall protective role in the development of insulin resistance and, most notably, is profoundly decreased in obesity and type II diabetes.[68] Adiponectin plasma concentrations reveal a sexual dimorphism, with adult females having significantly higher levels than males[68]; prepubertal children demonstrate no gender difference. Adiponectin levels significantly decrease after puberty,[69] however it remains to be seen if this represents a consequence of the increasing body mass or is a distinct phenomenon.

Ghrelin, a 28 amino acid stomach-secreted peptide, is a ligand for the growth hormone secretagogue receptor.[70] Ghrelin is a central appetite stimulator that regulates hunger and stimulates meal initiation[71] and is another putative link between metabolical and reproductive axes. In cross-sectional studies, ghrelin concentrations decrease from childhood to adolescence,[72] but children with central precocious puberty do not exhibit an increase in serum ghrelin after GnRH agonist treatment.[73] In children evaluated for short stature, administration of exogenous sex steroids decreased serum ghrelin in boys but not girls.[74] While one group related the fall in ghrelin levels to insulin-like growth factor (IGF-I) and IGF binding proteins as a putative mechanism for pubertal growth acceleration,[75] larger longitudinal studies are needed to evaluate ghrelin's role in pubertal development and reproduction.

Inflammatory cytokines, most notably tumor necrosis factor (TNF)-α and interleukin (IL)-6 among others, are produced by adipose tissue, and are elevated in obesity. In monkeys, leptin has been shown to modulate this inflammatory response.[76] Weight loss results in a decrease in macrophage infiltration of adipose tissue and improvement of the cytokine profile.[77] In obese adolescents, C reactive protein is significantly elevated, providing the first indication that low-grade inflammation starts at a young age.[78] It is not currently known whether mediation of this inflammatory response could mitigate some of the reproductive consequences of obesity. On the other hand, the hormonal status of the individual may be linked to the inflammatory cytokine profile. Recent studies have demonstrated an association between vasomotor symptoms and IL-8, implying that low estrogen levels somehow modulate expression of this cytokine.[79,80]

Neuropeptide Y (NPY), a member of the pancreatic polypeptide family, is a 36 amino acid neurotransmitter predominantly found in sympathetic neurons.[81] NPY is one of the most potent orexigenic peptides known and was recently shown to stimulate fat angiogenesis, proliferation and differentiation when administered peripherally.[82] Leptin decreases NPY gene transcription in the arcuate nucleus,[83] thereby sending a signal to decrease food intake. In the male rhesus monkey, antagonism of an NPY receptor led to precocious GnRH release, suggesting a role for NPY in maintenance of the prepubertal brake on the GnRH pulse generator.[84]

Sex Steroid Modulation of Feeding Behavior and Fat Accrual

The arcuate nucleus of the medial basal hypothalamus is a central relay station for body fat signaling and is a site of GnRH release. It functions to converge influences of orexigenic stimuli, such as NPY and agouti-related protein (AGRP), and anorexic stimuli, such as alpha-melanocyte-stimulating protein, corticotropin releasing hormone (CRH), and opioids. In rats, exogenous leptin administration results in down-regulation of NPY and AGRP.[85] Expression of leptin receptors in the arcuate and ventro-medial hypothalamic nuclei suggests this is a site of modulation of leptin effects on the reproductive axis.[64,86] Recent evidence suggests that ER-alpha expressing hypothalamic neurons regulate both feeding behavior and activity. Targeted deletion of ER-alpha in proopiomelanocortin (POMC) neurons leads to hyperphagia alone, but when steroidogenic factor-1 (SF-1) neurons undergo targeted deletion of ER-alpha, hypometabolism and hyperphagia can be created; deletion of ER-alpha in both of these neurons causes hyperphagia, hypometabolism, and abdominal adiposity.[87] Moreover, ER-alpha deletion in these hypothalamic areas causes reproductive dysfunction. These data imply a critical and possibly developmental role for hypothalamic estrogen sensitivity and metabolism.

How Does Body Weight Modify Puberty and Adult Reproduction?

Childhood Nutrition and Modification of Puberty

Reproductive maturation is delayed in a nutritionally deprived environment. The effect of obesity on pubertal timing has more recently been addressed in obese youth with premature pubarche in children with low birth weight and rapid postnatal catch-up in weight, and in boys and girls with simple obesity. These conditions will be addressed in turn, as all inform the pathophysiology of nutritionally associated reproductive disorders in adults.

The Effects of a Nutritionally Deprived Environment

Pugliese and colleagues evaluated 14 boys and girls. Nine boys and 5 girls, ages 9 to 17 years, with growth failure and delay in puberty (7 of the 14) due to malnutrition resulting from self-imposed caloric restriction.[88] In these children, who restricted caloric intake for fear of becoming obese, increased linear growth and pubertal progression resumed with the resumption of age-appropriate caloric intake. Matejek and colleagues studied the relationship between leptin levels, fat stores, and reproductive hormone levels in 13 female juvenile elite gymnasts and 9 adolescent girls with anorexia nervosa.[89] Leptin levels were subnormal and were related to body fat mass in girls with anorexia nervosa, but were lowest in the elite gymnasts. In both groups, estradiol levels were low and menarche was delayed. Catch-up height and weight in immigrant and adopted children, who move from developing to developed countries, is associated with precocious menarche.[90] Taken together, these studies support the notion that a critical body fat mass is necessary for normal pubertal progression.

The Effects of Low Birth Weight and Prematurity

Low birth weight, small for gestational age (SGA) status, and prematurity are all associated with precocious pubarche (appearance of pubic hair earlier than 8 years of age) and early and exaggerated adrenarche in girls.[91-94] Prenatal stress associated with prematurity may have an independent or additive effect on the programming resulting from growth restriction. Low birth weight (LBW) children have higher dehydroepiandrosterone levels compared to children of normal weight, indicating amplified adrenarche,[93,95] and LBW has also been associated with an increased likelihood of developing Polycystic Ovary Syndrome (PCOS). Although a majority of studies indicate that SGA is associated with premature pubarche (PP) and earlier onset of menarche,[96] van Weissenbruch and colleagues observed no differences in the timing and progression of puberty, including age at menarche, between SGA and appropriate for gestational age (AGA) girls[95]; another study found SGA to be associated with pubertal delay.[97] Studies associating birth weight with age at menarche have been similarly variable in outcomes, with findings ranging from no association to lower birth weight being linked to earlier pubertal onset.[98-100] More recent work by Ibanez and colleagues provides further insight into the progression of puberty in girls with precocious pubarche attributed to amplified adrenarche.[101] Followed from birth through adult stature, 187 Northern Spanish girls differed in the timing of the onset of puberty and menarche dependent on the degree of prenatal growth restraint. Girls with precocious puberty and LBW had menarche 8 to 10 months earlier and obtained an adult stature that was as much as 6.5 cm lower than non-LBW girls. While the LBW-PP girls demonstrated an accelerated onset of puberty and progression to adult stature, most of the height loss was observed prior to the onset of puberty and even before the development of PP. Low circulating levels of sex hormone binding globulin (SHBG) (a marker for hyperinsulinemic insulin resistance in nondiabetic girls)[93] and hyperleptinemia may contribute to the accelerated onset and progression of puberty in these LBW-PP girls. The DONALD (Dortmund Nutritional and Anthropometric Longitudinally Designed) Study evaluated 215 children for the effects of early life exposures on the initiation of puberty. The authors found that children weighing between 2500 and 3000 g at birth initiated their growth spurt (defined as the age at minimal height velocity at the onset of the pubertal growth spurt) approximately 7 months earlier than children weighing more than 3000 g at birth.

Children with low birth weight and rapid weight gain in the first 2 years of life displayed initiation of the growth spurt 4 months earlier than those with normal weight gain, indicating earlier pubertal onset. These children also had an earlier age at peak height velocity and earlier menarche in girls, indicating more advanced pubertal maturation. The associations were independent of prepubertal BMI, suggesting that other early life factors may influence the timing of puberty independent of the influences of body fat mass.[102] The findings relating to the relationship between birth weight and puberty initiation are variable and imply that there is not a simple, direct relationship. The variability may in part be explained by the different methods used for documenting pubertal initiation and progression; the use of Tanner staging, initiation of breast development, adrenarche, growth velocity and initiation of growth spurt or menarche, as well as variability in the measures of assessing fat mass or body composition.

The Effects of Simple Obesity in Girls

Longitudinal and cross-sectional data from studies conducted since the 1970s have demonstrated an overall close association between obesity and early pubarche in girls. The majority of members of an expert panel, recently convened to review studies conducted between 1940 to 1994 evaluating the secular trends of pubertal timing, concluded that thelarche and menarche are occurring earlier in U.S. girls.[103] These trends coincide with the rise in obesity prevalence, leading to the hypothesis that increasing adiposity is associated with earlier pubertal development. Several authors have examined the relationship between obesity and early puberty in girls. In comparison with nonobese girls, obese girls have been found to have earlier menarche in Japan (9 months earlier)[104] and Thailand (0.9 year earlier).[105] Early menarche has also been associated with an increased risk of adult obesity, indicating that early menarche may precede the development of obesity.[106,107] Yet other studies have shown that obesity precedes early menarche. Cooper and colleagues found that age at menarche was inversely associated with weight at 7 years[108] and He and Karlberg noted that incremental increases in BMI between the ages of 2 and 8 years were associated with early onset of the pubertal growth spurt in both boys and girls.[109] The Fels longitudinal study examined the relationship between the mean age of menarche and the simultaneous change in BMI from age 3 to 35 years in successive birth cohorts (born from 1929-1990).[110] While the age at menarche in the 1980s cohort was significantly lower than the age in girls born previously, and these findings match the findings of several recent reports which suggest a decline in the mean age at menarche of U.S. girls over the past 20 years, the decline in age at menarche was not associated with a significant concurrent increase in BMI in childhood or adolescence. In a longitudinal study evaluating the relationship between BMI and puberty onset in 354 girls, Lee and colleagues found that an increased BMI as early as age 3 as well as an increased BMI between the ages of 3 and 6 years was associated with an earlier onset of puberty.[111] While these findings do not prove a causal effect, they suggest that increased adiposity precedes early puberty.

Precocious puberty has been linked with childhood obesity[92] and girls with precocious pubarche tend to be hyperinsulinemeic,[93] and insulin resistant,[112-115] especially if there is a history of low birth weight. Yet pubertal progression appears to be alternatively regulated in girls with simple obesity (i.e., obesity that is not complicated by premature adrenarche or PCOS). It is not clear whether early thelarche in overweight girls is related to central activation of the GnRH–gonadotropin axis or whether estrogens from other sources are responsible for the production of breast tissue. Increased estrogen production results from the peripheral conversion of androstenedione by aromatase contained in adipose tissue.[116] Further, the hyperinsulinemia that results in low levels of sex hormone binding globulin and higher levels of free circulating estrogen and androgens has been associated with excess total and central adiposity.[91,113,117] Pharmacological insulin sensitization appears to improve body composition and dyslipdemia, and delays or prevents the progression to PCOS.[114,118] These data favor an association between obesity and subsequent development of PCOS.

The Effects of Simple Obesity in Boys

Data on the association of obesity with pubertal onset timing in boys lacks concurrence. Utilizing Third National Health and Nutrition Examination Survey (NHANES III) survey data, Wang demonstrated that boys with a higher body mass index were more likely to have a later, rather than earlier, sexual maturation.[119] The accuracy of the ascertainment of genital stage in boys in the NHANES III has been called into question based on the observation by Herman-Giddens and colleagues that 25% of 8-year-old boys were at genital stage 2,[120] whereas there had been no concurrent increase in the rate of boys being evaluated for precocious puberty (defined as the onset of testicular enlargement at <9 years). The early staging of puberty (without assessment of testicular volume) is subjective, and inadequate criteria for genital assessment may have resulted in an over-classification of prepubertal boys as having initiated puberty. Evaluation of pubertal onset utilizing testicular size to define pubertal onset has yielded variable results. Increased testicular size was noted in obese prepubertal Chinese boys relative to nonobese age-matched boys (1.18 mL vs. 0.82 mL).[121] Further, morning inhibin B, dehydroepiandrosterone (DHEA), and DHEA-S and bone age were also higher in obese versus non-obese controls. In contrast, Laron demonstrated that while obese Israeli boys were taller and their bone age was more advanced, at all ages, relative to age-matched controls, there was no difference between the two groups in terms of the onset and development of pubarche, voice change, testicular volume, and penile size.[122]

Longitudinal studies have been conducted to further understand the association between obesity and pubertal onset and progression. Recently, in a 10-year longitudinal population-based study on 401 boys enrolled in the National Institute of Child Health and Human Development Study of Early Child Care and Youth Development, Lee and colleagues found that a higher BMI Z-score trajectory during early to middle childhood was associated with a later onset of puberty.[123] A higher proportion (14%) of boys in the highest BMI trajectory were prepubertal (defined as a Tanner stage 1 determined by visual inspection) at 11.5 years old than those in the lowest BMI

trajectory (7.7%), indicating a delay rather than advancement of puberty in obese boys. Vizmanos and colleagues, following 323 boys annually to assess pubertal onset at ages 11, 12, 13, or 14 years old, noted a positive relationship between BMI and age of pubertal onset (defined by testicular volume and genital development according to Tanner stage), yet significant differences in percentage body fat between the different ages at onset of puberty were not noted. These findings suggest that, like girls, boys require a critical fat mass to initiate pubertal maturation.[124] Sorenson and colleagues conducted a cross-sectional study from 1991 to 1993 and a combined cross-sectional and longitudinal study from 2006 to 2008.[125] Measuring pubertal onset based on testicular volume assessments and genital staging in healthy Danish boys, the authors found that age at pubertal onset declined by 3 months from 1991 to 2006 and that age at entry into genital and pubic hair stages 4 and 5 was reached significantly earlier in 2006 than 1991. In addition, BMI increased significantly during that time period. Importantly, earlier age at onset of pubertal testicular growth in 2006 compared with 1991 was no longer significant after adjustment for BMI—indicating that BMI at least partly explained these findings. Juul and colleagues studied pubertal onset in 826 boys and found that while taller compared to youth in 1964, the timing of pubertal onset between 1964 study and the 1991 to 1993 study had not changed.[126] In another 10-year longitudinal study, Juul and colleagues utilized voice change as a marker for later pubertal development in 463 boys and found a downward trend in the age at voice break between 1994 and 2003. Further, boys in the heaviest BMI quartile at 8 years of age had a 1.74-fold risk of early voice break relative to boys in the thinnest quartile.[127] Tracking skeletal maturity and linear growth acceleration throughout infancy, childhood, and adolescence from birth through 18 years old in 521 subjects from the Fels Longitudinal study, Johnson and colleagues found that overweight or obese adults were more skeletally advanced throughout childhood. While BMI-related differences in peak height velocity were observed for both boys and girls, these differences decreased as puberty progressed so that by 18 years old, overweight or obese adults were not significantly taller than their normal weight peers.[128] Overall, the relationship between obesity and timing of puberty appears to differ by the manner in which markers of puberty are defined and documented. There also appear to be differences among different populations.

Recent research on the physiology of puberty in obese girls and boys may shed light on these apparent discrepancies. Bordini and colleagues examined nighttime LH pulsatility in 40 pubertal girls and observed blunted LH secretion in girls with a body weight greater than the 85th percentile.[129] These investigators hypothesize that there is a bimodal female HPO axis response to androgens.[16] As described above, adrenal androgen excess is linked to premature adrenarche and early onset of puberty. This process seems to occur in girls whether or not they are destined to develop PCOS. However, once puberty is initiated in non-PCOS related obesity, the relative hypogonadotropic hypogonadism of obesity retards the process, leading to a normal onset of menarche. The research focus on menarche, as an easily measurable physiological end point of reproductive maturation, may be obscuring the pathophysiological alterations in the stepwise process of puberty in girls.

Adult Obesity and Reproduction

Genetic Predisposition to Simple Obesity: Reproductive Correlates

The latest NHANES study indicates that over 35 percent of all U.S. adults are obese, defined as BMI of greater than 30 kg/m^2.[130] By 2015, 75% of all U.S. adults are projected to be overweight or obese with BMI of at least 25 kg/m^2.[131] Perhaps even more concerning are the recent data on U.S. women born in the 1980s who were found to exhibit up to 21% higher propensity to large body mass when compared to women born in the 1960s.[132] Thus, further escalation of the current obesity rates is likely as the 1980s generation ages and reaches the peak obesity prevalence. Easy availability of high calorie nutrition and low physical activity have been implicated as potential causes for these trends,[133] yet there are few definite answers as to why the obesity epidemic is continuing unabated.

Individuals respond differently to the environmental obesogenic challenges. In twin studies, up to 60% to 70% of total variation in percentage of body fat has been attributed to genetic contribution.[134] In 2007, one genome-wide association study has identified multiple single nucleotide polymorphisms (SNPs) in a gene designated *Fat mass and obesity-related transcript* (FTO) as mediators of the relationship between large body mass and type II diabetes mellitus.[135] This breakthrough in understanding of genetic contribution in patients with simple or nonsyndromic obesity has been replicated by other groups with an underlying theme that specific FTO variants correlate with human obesity. Up to 16% of adults who are homozygous carriers for the risk of FTO allele were reported to weigh 3 kilograms more and have up to 70% increased risk of obesity when compared with noncarriers.[135] The FTO gene was first reported in 1999 in a fused toe (Ft) mouse model.[136] Some of the deleted genes in this model had no known function at the time and one of these genes was serendipitously termed "Fatso (FTO)" because of the large size of the gene.[137] Subsequent studies have shown that FTO primarily functions as a single stranded RNA demethylase[138,139] and is upregulated in rodent hypothalamus after food deprivation.[140] While genes that predispose to adiposity may mediate impaired energy expenditure, FTO genes appear to be important in regulating food intake. In human studies, subjects with some FTO risk alleles were found to have diminished satiety awareness and loss of eating control.[141,142]

Polycystic ovary syndrome (see Chapter 22), is the most common endocrinopathy affecting up to 10% of all reproductive age women. It is frequently accompanied by obesity with some studies reporting up to 50% prevalence in PCOS women.[143] Obesity appears to modulate the risk of PCOS. Studies from Asian populations with lower adiposity as compared to non-Asians, typically report fewer affected subjects, as exemplified by 2.2% PCOS prevalence in a cohort of 915 Chinese women presenting for an annual physical.[144] Similarly, one Spanish study reported 28.3% prevalence of PCOS among consecutively studied obese or overweight women which was markedly higher than

the 5.5% prevalence reported among lean women by the same investigators.[145] A recent study of Polish women suggested that FTO risk alleles may portend a greater impact in women with PCOS as compared to general population.[146] In this study of 136 young women with PCOS, a 10 kg difference in weight was found between the carriers and noncarriers of the FTO risk allele, a difference that is two-to-three times greater than what was reported for the population at large. A recent meta-analysis from 7 studies and 2548 PCOS women has confirmed this trend.[147] This novel relationship between FTO inheritance and PCOS may reflect either an interaction between FTO physiology and environment or multifactorial and polygenic nature of PCOS. The take home message here is that FTO may affect obesity in PCOS or PCOS may, in turn, amplify the effects of FTO on adiposity. While a more complete picture of all genes linked with adiposity and reproductive competence is still emerging, it is imperative to emphasize that the recognition that these exist is important for understanding why some women are particularly vulnerable to obesity and its reproductive consequences.

Women

Adult obesity in women is associated with two reproductive phenotypes. In the presence of marked hyperandrogenism, women who are genetically vulnerable, including those with the newly identified FTO risk alleles, can develop PCOS in association with weight gain. This notion is implied by abundant data on the salutary effects of weight loss on fertility in anovulatory women with PCOS. However, PCOS is only present in 5% to 7% of the adult population, and the current population prevalence of obesity in reproductive aged women is much higher. Therefore, a second pathway must be hypothesized to explain the reproductive phenotype in simple obesity that is unrelated to PCOS. As PCOS will be covered in great detail elsewhere in this volume, this discussion will center on the model for reproductive dysfunction in women with simple obesity.

Increased body size is associated with reduced fecundity in both women and men.[18,148,149] Women who are overweight and obese in their late teens are almost four times more likely never to conceive compared to normal weight women.[20] If they do conceive, obese women experience increased reproductive wastage and worse outcomes with assisted reproductive technologies than do normal weight women.[150] In 162 patients undergoing *in vitro* fertilization (IVF) at one center,[151] obese women required more gonadotropin, yet had lower numbers of oocytes retrieved, and 45% lower fertilization rates compared to women of normal weight. Fedorcsak and colleagues[152] reported similar findings in a sample of over 5000 IVF cycles in 2660 couples. Cumulative live births were 10% lower (41.4% versus 50.3%) in women with a BMI over 30 kg/m^2, compared to women with BMIs between 18.5 and 24.9 kg/m^2, along with increased gonadotropin requirements and reduced oocytes retrieved. Others have reported similar detrimental outcomes for obese women undergoing ART.[153] Among 1293 women who underwent *in vitro* fertilization at one U.S. center, women with a BMI > 40 kg/m^2 had more than double the cancellation rate of normal weight women (and more than triple the cancellation rate when polycystic ovary syndrome was ***not*** present),[154] and a linear trend towards higher risks of preeclampsia and cesarean delivery.

Obesity and Preeclampsia

Preeclampsia complicates 5% to 7% of pregnancies and maternal obesity is a consistent risk factor for preeclampsia, however, the mechanisms involved are not understood.[155,156] The dose-dependent relationship between increasing body mass index (BMI) and the risk of developing pre-eclampsia is well established.[157-160] For instance, an elevated BMI results in an odds ratio of 7.2 for developing preeclampsia as opposed to normal BMI women.[161] Obesity and preeclampsia are both associated with oxidative stress[162-164] as well as circulating markers of inflammation. Plasma levels of C-reactive protein and inflammatory cytokines, tumor necrosis factor-alpha, interleukin-6, and interleukin-8 are elevated in obese individuals and preeclamptic women.[165-168] In addition, obese and preeclamptic women often have comorbidities of dyslipidemia, insulin resistance and impaired endothelial function.[169-171] These shared features suggest that preexisting inflammation may be the link between obesity and preeclampsia.[172,173]

The relative hypogonadotropic hypogonadism of obesity partially explains the fertility impairments. Sherman and Korenman reported longer cycle length, longer follicular phase length, and reduced daily LH, FSH, and progesterone secretion in association with hirsutism in five ovulatory midreproductive aged women who were overweight or obese compared to a larger sample of normal weight women.[174] Grenman and colleagues compared 25 women of very high BMI (mean weight = 120 kg) to 25 normal weight controls and observed decreased estradiol (E2), sex hormone binding globulin (SHBG), androstenedione, and LH in the obese.[175] These changes were partially reversed by acute, modest weight loss (mean loss of 13.2 kg). A number of investigators have reported decreased inhibin B in association with increased weight,[176-178] along with reduced follicular phase gonadotropins and E2.[179,180] The reduced follicular phase gonadotropin and luteal phase progesterone secretion[17] observed in women of large body size can be attributed to relatively insufficient FSH stimulation of folliculogenesis, a model that has been well described in nonhuman primates.[181]

Studies to date in animals and humans[17,174,182] consistently point to a defect in LH pulse amplitude in association with obesity. In obese, leptin resistant Zucker rats—a model similar to human obesity—there is profound suppression of pulsatile LH amplitude but not frequency.[183] It seems likely that some consequence of excess nutrient sensing plays a role in the reproductive dysfunction associated with obesity. Jain and colleagues have observed a dramatically reduced amplitude of endogenous LH pulses in women with a BMI greater than 35 kg/m^2, implying a central defect in reproductive function that may in turn impair ovarian and endometrial function. Women awaiting bariatric surgery who underwent frequent blood sampling had mean LH pulse amplitude of 0.87+/− 0.1 compared to 1.59 +/− 0.15 IU/L in normal weight controls.[17] Post-surgery, after at least 25% of initial body weight had been lost and weight had stabilized, there was a partial return of LH pulsatility and menstrual cycle parameters to those of normal weight controls.[184]

There is also evidence that physiological restraint of FSH secretion is reduced in obese women. Both inhibin B and Müllerian Inhibiting Substance (MIS) or anti-müllerian hormone (AMH) are reduced in obese women,[177,178] despite the lower overall sex steroid secretion throughout the menstrual cycle. These data indicate that FSH is inappropriately low for the given inhibin B levels in obese women. The fact that inhibin B is suppressed in obesity is interesting because inhibin B is widely regarded as a marker of ovarian reserve.[185] However, obese women do not have an earlier menopause.[186] The dual suppression of both MIS and inhibin B in obesity indicates that factors other than low ovarian reserve are operative, perhaps at the level of the ovary.

It is tempting to speculate a role for leptin in this process, because it is a molecule that sends nutritional signals to the CNS component of the reproductive axis. Obesity, because of its associated extreme leptin resistance, might also be construed as a leptin-deficient state.[187] Leptin receptors are not present on hypothalamic GnRH secreting neurons, and leptin is believed to exert effects on GnRH secretion via intermediary molecules,[188] such as neuropeptide Y (NPY) and agouti-related peptide (AGRP). These molecules also affect primarily LH pulse frequency when given intracerebroventricularly.[189,190] An adipokine or nutrient signaling pathway interaction with the hypothalamus that would reduce the amount of GnRH secreted per bolus (which would be reflected in a reduced LH pulse amplitude) would certainly provide a candidate pathophysiological mechanism for these findings.

Mice that experience dietary induced obesity (DIO) have hypogonadotropic hypogonadism,[191,192] and animals who are resistant to DIO-related reproductive dysfunction have reduced central inflammation.[193] Recent studies demonstrating the ability of melanocortin to block pro-inflammatory cytokine or peptide-mediated LH suppression suggest a potential mechanism by which pituitary output of LH and FSH are inhibited in obesity.[192-194] Thus, the emerging relationship between inflammation, nutrient sensing, and reproduction may provide further clues to explain the reproductive phenotype of obese women.

Men

In contrast to the substantial body of literature on the impact of female obesity on reproduction, the corresponding effect of male body mass on the ability to reproduce is only recently coming to the forefront of investigative attention. Obese women with an overweight or obese male partner have up to twofold further loss in fertility as compared to their obese counterparts with normal weight male partners.[195] A dual loss of fertility is more likely, however, because overweight and obese women tend to marry or cohabit with men of similar weight.[196,197] At the population level, several large observational studies have recently demonstrated an inverse relationship between male obesity and fecundity. Data from U.S. farmers indicated that each 3-unit rise of male BMI was associated with a 12% increase in prevalent infertility in affected couples.[198] Similarly, Danish National Birth Cohort records indicated a dose-response relationship between male adiposity and involuntarily delayed pregnancy.[195] Further, data from over 26,000 Norwegian pregnancies revealed that the detrimental influence of male obesity on fertility was demonstrated even when coital frequency data was included in the analysis, suggesting that this effect was not mediated by sexual dysfunction.[199] More recently, adiposity of the male partner has been associated with decreased chance for clinical pregnancy after ART.[200,201]

Male obesity may affect spermatogenesis and has been linked with reduced semen parameters. A study of over 500 infertile couples from Utah has shown that large body mass tripled the relative risk of oligospermia and reduced total motile count in men with BMI over 30 kg/m^2.[202] Similar associations were reported in healthy young Danish men reporting for a pre-army physical[203] and Egyptian infertility patients.[204] In further support of these observations, increased DNA fragmentation has been demonstrated in sperm from obese men.[205-207] Recently, a meta-analysis based on data from over 9700 men from 14 studies worldwide demonstrated that, as compared to men of normal BMI, both overweight and obese men were more likely to have oligospermia and azoospermia.[208] Remarkably, men with BMI over 30 kg/m^2 had approximately 40% higher chance of presenting with oligospermia and up to 80% higher chance of presenting with azoospermia. While the precise mechanisms underlying these associations remain uncertain, adiposity leads to reproductive hormonal changes that may alter spermatogenesis.

Similar to obese women, decreased LH pulse amplitude but unaffected LH pulse frequency have been reported in obese men.[209] The endocrine profile of hypogonadotropic hypogonadism in obese men leads to significantly depressed testosterone and is often, but not always, associated with erectile dysfunction.[210] A dose-response relationship between hypoandrogenism and the degree of obesity has also been reported and is thought to occur in concert with a corresponding increase in circulating estrogens.[211] On the pathophysiological level, obstructive sleep apnea (OSA), commonly diagnosed in obese men, has been linked with reproductive hormone alterations. In 1989, Grunstein and colleagues demonstrated reduced overnight secretion of testosterone in obese men with OSA.[212] Treatment of OSA has been demonstrated to result in the increase of serum testosterone with either surgical (uvulopalatal resection) or medical (nasal continuous positive airway pressure, nCPAP) management.[212,213] In obese men with OSA, pituitary gonadotropins have been demonstrated to be significantly reduced as compared with normal weight controls and partially reversed by correction of hypoxia.[214,215] Taken together, the potentially reversible hypogonadism associated with OSA and the decreased fertility and semen parameters associated with male obesity make a strong case to explore the mechanistic implications of symptomatic sleep disruption on sperm production. This is especially relevant given the recently shown significant improvement of male fertility with antioxidants[216] and findings in the murine diet-induced obesity model of *de novo* induced oxidative stress, sperm DNA damage, and decreased fertilizing ability.[217]

Impact of Weight Loss and Bariatric Surgery on Reproductive Function

In normal weight women, weight loss of as little as 10% to -15% induces reversible deficits in reproductive function that

include altered LH pulsatility.[218] In overweight and obese women, small improvements of fertility have been reported with diet-achieved moderate weight loss.[219] Increased regularity of menstrual cycles and improved fertility has been reported in women who maintain weight loss.[220] However, conservative weight reduction is difficult to achieve and is notoriously reversible when dieting is not aggressively maintained. Bariatric surgery produces dramatic and long lasting weight loss with the reductions up to 60% of presurgical body weight.[221] Most bariatric patients experience an initial, dramatic weight reduction of 3 to 4 pounds per week for the first 6 months, followed by a plateau phase within a year. The chief mechanism for weight loss is thought to be consumption of smaller meals due to the decreased volume of the stomach. In women who have undergone bariatric surgery, improvement in menstrual irregularities and higher fertility rates have been reported.[222] Most of the literature support a favorable risk-benefit ratio in support of bariatric surgery in patients with a BMI greater than 40 kg/m^2. In men, with the exception of one case report of unexplained spermatogenic arrest after bariatric surgery-induced weight loss,[223] there is a paucity of studies assessing the impact of weight loss on male reproductive success, assisted or unassisted. In small case series, obese men showed an overall improved reproductive hormone profile following weight loss, with an increase in SHBG and testosterone and decrease in estrogen after bariatric surgery.[224,225] Given the increasing utilization of bariatric surgery for morbid obesity as well as recently advocated indication for type II diabetes mellitus,[226] comprehensive studies on the impact of surgical loss on male and female reproductive potential are urgently needed.

Nutrition in the Young Oncology Patient

The American Cancer Society estimates there will be over 12,000 newly diagnosed pediatric cancer patients in 2012.[227] However, improvements in chemotherapy, radiation and surgery, and supportive care have dramatically increased survival and cure rates. Pediatric and young adult cancer patients represent a special population in which nutrition and metabolical status may be intimately associated with disease status.

Nutritional Status at Cancer Diagnosis

Although weight loss may be a presenting sign of malignancy in adults, pediatric patients appear to have good baseline nutritional status. In fact, Carter and colleagues[228] found a low incidence of malnutrition in 277 children with newly diagnosed tumors. When malnutrition was detected, it was primarily due to inadequate caloric intake, not protein deficiency. Pediatric cancer patients with advanced disease or those undergoing intensive chemotherapeutic protocols are at high risk of losing weight and becoming malnourished.[229] In addition, certain treatments such as abdominal radiation, surgery, frequent chemotherapy, severe infection, or pain may predispose patients to nutritional depletion.[230] Brain tumors are the most common solid tumors in children.[227] While some tumors are surgically managed, many brain tumors require a combination of surgery, radiation, and chemotherapy—resulting in nutritional compromise. Additionally, long-term steroid use is common and may lead to nutrition complications such as obesity, with associated depleted protein reserves and metabolical abnormalities including hyperglycemia, myopathy, and osteoporosis.[231,232]

Malnutrition has been associated with a number of adverse clinical outcomes, including reduced quality of life, decreased response to treatment, increased risk of chemotherapy-induced toxicity and reduction in overall survival.[233-236] Specific sequelae include inability to tolerate aggressive chemotherapy or radiation, frequent delays in therapy due to myelosuppression, increased risk of infection, and decreased overall survival. In fact, malnutrition and weight loss are associated with overall decreased median survival and decreased performance status in adult patients.[237,238] In pediatric oncology, children who are underweight or overweight at diagnosis have poorer outcomes compared to children who are well nourished at diagnosis.[239-242] Furthermore, a direct relationship between nutritional status and disease-free interval has been observed in children with solid tumors.[238]

Nutritional Concerns of Childhood Cancer Survivors

While many nutritional issues during childhood cancer treatment are associated with weight loss or poor growth, more recently, the risk of obesity, excess body fat, and metabolic syndrome is an emerging issue for survivors. Cranial radiation and hematopoietic stem cell transplant (HSCT) are two primary risk factors that have been associated with the development of these late effects. For example, obesity is a common finding in survivors of acute lymphoblastic leukemia (ALL) treated with cranial radiation, which correlates with significant reduction in physical activity and energy expenditure.[44,243-246] The Childhood Cancer Survivor Study, a multicenter, retrospective cohort study of pediatric cancer survivors, reported a higher prevalence of overweight and obesity in cancer survivors who received high-dose cranial radiation (≥20 Gy) compared to healthy sibling controls, particularly in female patients.[247] Hypothalamic-pituitary-adrenal and gonadal axis impairment can lead to a variety of hormone deficiencies and downstream effects. The association between cranial radiation and obesity is due, in part, to radiation-induced growth hormone insufficiency and leptin insensitivity.[248-250] In addition, a significant association between hypogonadism and metabolical syndrome has been noted.[251,252] However, even survivors treated without radiation (which represent the majority of children with ALL treated in the current era) may be at risk for obesity as a consequence of their cancer therapy.

Features of metabolical syndrome, including insulin resistance and dyslipidemia, have been found in ALL survivors, however, prevalence appears to be most common in patients who received HSCT.[253,254] Oudin and colleagues examined the prevalence and risk factors associated with metabolical syndrome in 184 young adult survivors of childhood leukemia and found an overall prevalence of 9.2%.[251] In addition, HSCT with total body irradiation (TBI) was associated with elevated triglycerides (OR = 4.5, P = .004), low high-density lipoprotein cholesterol (OR = 2.5, P = .02), and elevated fasting glucose (OR = 6.1, P = .04). Beyond serum abnormalities, cancer survivors are at risk of vascular

disease. For example, the Childhood Cancer Survivor Study demonstrated that cancer long-term survivors were 8.2 times more likely to die of cardiac-related events and were more likely to develop coronary artery disease and cerebrovascular events than healthy siblings (RR = 10.4 and 9.3, respectively).[255-257]

Summary

From the time of diagnosis through the survivorship period, nutrition should be integrated in the care and recovery of the pediatric cancer patient. Children must maintain growth and development during extended treatment courses as well as post-treatment. Malnutrition should not be accepted as an inevitable consequence of malignancy or its treatment. Likewise, effort should be made to prevent obesity and metabolical chronic diseases in long-term cancer survivors. Complications of oncological treatment, including obesity, metabolical dysfunction, and hypogonadism, need further evaluation and management.

Conclusions

Amplification of the pulsatile GnRH signal appears to be the obligatory final pathway for pubertal maturation; however, the many inputs into the hypothalamus imply that there are numerous concurrent factors that act as permissive signals. Moreover, it is likely that these signaling pathways are redundant, as it is in the best interests of the survival of the human species to assure that reproductive maturation will take place. It is now clear that environmental modifiers of the pubertal transition also contribute to the process. Psychological stressors, xenoestrogens, and body fat are but three such factors. It appears that none of these factors bears a simple relationship to the pubertal process, in that both accelerations and delays are associated with various stressors and increasing body fat.

CHAPTER 20

Environmental Factors and Reproduction

Jessica Trowbridge
Patrice Sutton
Tracey J. Woodruff
Linda C. Giudice

Documented adverse trends in reproductive health in the U.S. include a decline in the age of onset of puberty[1]; declines in fertility and fecundity[2,3]; increased rates of poor birth outcomes such as babies born prematurely,[4,5] small for gestational age,[6] and with certain birth defects[7]; increased rates of childhood diseases such as autism,[8] certain types of cancer,[9] and obesity[10]; and declines in life expectancy, with some communities having life expectancies already well behind those of the best-performing nations.[11] Due to the time course of these changes they cannot be explained by changes in genetic makeup alone.[12] A possible explanation is exposure to environmental chemicals, which has increased over sixteenfold over the past 70 years.[13] There are currently over 80,000 chemicals in commerce including over 3000 high production volume chemicals—those imported or manufactured in excess of 1 million pounds each per year.[14,15] The vast majority of chemicals in commerce have not been fully tested for reproductive and/or developmental health effects.[16]

In recognition of the scientific evidence linking ubiquitous exposure to environmental chemicals to adverse health impacts, leading scientists, clinicians, and their professional societies have called for timely action to prevent harm.[17-20]

Of particular importance to endocrinologists is a statement published in 2009 by the Endocrine Society based on a review of the scientific evidence.[21,22] The Endocrine Society review concluded that environmental chemicals that disrupt the endocrine system (i.e., "endocrine disrupting chemicals" [EDCs]) have been found to have an effect on male and female reproduction, breast development and cancer, prostate cancer, neuroendocrinology, thyroid, metabolism and obesity, and cardiovascular endocrinology. The Statement concluded that, "The Endocrine Society is concerned that the public may be placed at risk because critical information about potential health effects of endocrine disrupting chemicals to which Americans are exposed is being overlooked in the development of federal guidelines and regulations," and "Until such time as conclusive scientific evidence exists to either prove or disprove harmful effects of substances, a precautionary approach should be taken in the formulation of EDC policy.[21]" A recent position statement by The Endocrine Society emphasizes the importance of the developmental stage when considering EDCs and that there is no "safe" dose[23] and a 2012 review of EDCs also concluded that these chemicals can act at low doses and in a non-linear fashion, and echoed the Endocrine Society's call for improved methods of chemical testing and prevention of exposure to EDCs.[24]

This chapter summarizes key themes related to the reproductive and developmental health impacts of exposure to environmental chemicals and the role of clinicians in prevention.

What Is Reproductive Environmental Health

Reproductive environmental health addresses the exposure to environmental contaminants, such as synthetic chemicals and metals, and the effect to reproductive health and development. Exposure to environmental chemicals can have an impact during all periods of human reproduction including fertility, conception, pregnancy, child and adolescent development, and adult health.[18]

Classic Examples of Thalidomide and Diethylstilbestrol

Two key principles of reproductive environmental health are supported by evidence from human exposure to the drugs Thalidomide and Diethylstilbestrol (DES).

The Fetus Can Be Uniquely Sensitive to Chemical Exposures: Thalidomide

In the 1960s, the drug Thalidomide was given to pregnant women to prevent morning sickness. Women who took the drug experienced no ill health effects; their children however, experienced a high rate of congenital limb and gastrointestinal malformations, particularly when the drug was taken during the 28th through 42nd day postconception.[25-27] In the 46 countries where the drug was approved, more than 10,000 children in 46 countries were born with deformities as a consequence of their mothers using the drug during pregnancy.[28]

Intergenerational Harm Can Result from *In-Utero* Chemical Exposures: Diethylstilbestrol

Diethylstilbestrol (DES) was prescribed in up to 10 million pregnancies from 1938 to 1971 to prevent miscarriage. DES

was subsequently found to be a "transplacental carcinogen." When the sons and daughters of DES-exposed mothers reached puberty they began presenting with both benign and malignant reproductive tract abnormalities. These abnormalities, which, in contrast to Thalidomide only appeared decades after exposure, were found to be causally linked to the mothers exposure to DES during pregnancy.[29] The established health impacts of DES in females exposed *in utero* include: vaginal clear cell adenocarcinoma, vaginal epithelial changes, reproductive tract abnormalities (e.g., gross anatomical changes of the cervix, T-shaped and hypoplastic uteri), ectopic pregnancies, miscarriages, premature births, and infertility.[30] Likewise, males exposed *in utero* also had delayed adverse health effects including reproductive tract abnormalities such as epididymal cysts, hypoplastic testis, and cryptorchidism.[30]

Although DES has not been prescribed for over 40 years, evidence of the delayed health consequences of exposure continues to emerge. Women exposed *in utero* to DES have a higher risk of breast cancer at age 40 than women who were not exposed.[31] A 2011 study found that women exposed to DES *in utero* have a higher lifetime risk of multiple adverse health outcomes compared to women who were not exposed, including infertility, spontaneous abortion, preterm delivery, early menopause, and breast cancer.[32] Studies have also shown that the delayed health impacts of DES also extend to the mothers who took the drug, as they too have an increased risk for breast cancer.[30] Animal studies support the evidence of the health effects of DES that have been documented in humans and predict that inter-generational impacts will extend to the next generation among the granddaughters of DES-exposed women.[33]

Key Scientific Concepts

Environmental Chemicals

Environmental chemicals include synthetic chemicals and metals found in our homes, workplaces, and communities. Common pathways of exposure to environmental chemicals include air, water, soil, dust, consumer products, and food. Paradoxically, the industrialized food system contributes a large proportion of environmental contaminants from food production, packaging, and transport including Bisphenol-A (BPA), perfluorooctanate (PFOA), phthalates, and certain organophosphate pesticides.[34]

Table 20.1 presents examples of reproductive and/or developmental health impacts of prenatal exposure to environmental contaminants.

Extent of Exposures

Exposure to environmental chemicals is widespread among the U.S. population. "Biomonitoring" is the study of human samples, usually blood, urine, or breast milk, to measure the amount of chemicals and their metabolites in people's bodies. It can also be used to evaluate the rate of placental transfer of chemicals by correlating levels across various biological matrices such as maternal blood, cord blood, amniotic fluid, meconium, placenta, and fetal tissue.

Biomonitoring data have documented ubiquitous exposure to environmental chemicals among the U.S. population.[64,65] Studies have also found multiple chemicals measured in human tissues in Europe and in populations in the Arctic indicating the wide range of global of exposure.[66]

Examples of environmental chemicals for which exposure is widespread include persistent organic pollutants (POPs), pseudo-persistent compounds, and metals. POPs are chemicals that do not break down in the environment; for example, the pesticide dichloro-diphenyl-trichloroethane (DDT) and its metabolite dichloro-diphenyl-dichloroethylene (DDE), and polychlorinated biphenyls (PCBs). These chemicals have been banned in the U.S. for over 30 years yet they are still found in virtually all of the population; other POPs such as some of the perfluorinated compounds have been phased out more recently but are still found in over 98% of the U.S. population; and polybrominated diphenyl ethers (PBDEs) are found in over 95% of the U.S. population.[67,68]

Pseudo-persistent compounds are those that can be metabolized and removed from the body, but because exposure is so consistent that they are almost always found in human samples. Examples of pseudo-persistent compounds include certain phthalates, polyaromatic hydrocarbons (PAHs), and phenols such as BPA and perchlorate.[68]

Metals are also common environmental contaminants and include mercury, lead, and arsenic. Due to public policy initiatives that removed lead from gasoline, paint, food cans, and other products, the levels of lead have dropped precipitously in the U.S. However, there remain populations both within and outside the U.S. with high blood lead levels, often from exposure to lead contaminated paint.[9] A recent CDC report summarizes new findings suggesting that the adverse health effects of blood lead levels less than 10 μg/dL in children extend beyond cognitive function to include cardiovascular, immunological, and endocrine effects.[39] The effects do not appear to be confined to lower socioeconomic status, and the report concludes that there is no identified blood lead level without deleterious effects, underscoring the critical importance of primary prevention.[39]

Pregnancy Exposures

A study examining chemical exposures among pregnant women sampled as part of 2003-2004 National Health Examination and Nutrition Survey (NHANES) found that virtually all pregnant women in the U.S. were exposed to at least 43 different chemicals.[69]

Among pregnant women, several classes of chemicals were particularly well represented. For example, 13 different phthalates were measured in the population and 9 were measured simultaneously in the average individual. In addition, specific PCBs, organochlorine pesticides, perfluorochemicals (PFCs), phenols, PBDEs, phthalates, PAHs, and perchlorate were detected in 99%–100% of pregnant women. Many chemicals were measured at levels similar to the levels found in epidemiological studies that were found to have adverse reproductive and developmental outcomes. Furthermore, virtually all women were exposed to multiple chemicals. Exposure to multiple chemicals that affect the same health endpoint can result in a greater risk than by exposure to a single chemical—the U.S. National Academy of Sciences recommends that health risk assessments account for such simultaneous exposures to multiple chemicals.[70]

Table 20.1 Examples of Reproductive and Developmental Health Impacts of Prenatal Exposure to Environmental Contaminants

Chemical	Exposure Sources and Pathways	Reproductive/Developmental Health Impact
Bisphenol A (BPA)	Chemical intermediate for polycarbonate plastic and resins. Found in consumer products and packaging. Exposure through inhalation, ingestion, and dermal absorption.	Recurrent miscarriage[36] Aggression and hyperactivity in female children[37]
Lead	Occupational exposure occurs in battery manufacturing/recycling, smelting, car repair, welding, soldering, firearm cleaning/shooting, stained glass ornament/jewelry making; non-occupational exposure occurs in older homes where lead-based paints were used, in or on some toys/children's jewelry, water pipes, imported ceramics/pottery, herbal remedies, traditional cosmetics, hair dyes, contaminated soil, toys, costume jewelry.	Alterations in genomic methylation[38] Intellectual impairment[39] Increased likelihood of allergies[40]
Mercury	Mercury from coal fired power plants is largest source in the U.S. Primary human exposure by consumption of contaminated seafood.	Reduced cognitive performance[41,42] Impaired neurodevelopment[43,44]
Polybrominated diphenyl-ethers (PBDEs)	Flame retardants that persist and bioaccumulate in the environment. Found in furniture, textiles, carpeting, electronics, and plastics which are mixed into, but not bound to foam or plastic.	Impaired neurodevelopment[45] Premature delivery, low birth weight and stillbirth[46]
Polychlorinated Biphenyls (PCBs)	Used as industrial insulators and lubricants. Banned in the 1970s, but persistent in the aquatic and terrestrial food chains resulting in exposure by ingestion.	Development of ADHD associated behavior[47] Increased BMI[48] Reduced IQ[49]
Perfluorochemicals (PFCs)	Widely used man-made organofluorine compounds with many diverse industrial and consumer product applications. Examples are perfluorooctane sulfonate (PFOS) and perfluorooctanate (PFOA), which are used in the manufacture of non-stick Teflon® and other trademark cookware products and in food-contact packaging to provide grease, oil, and water resistance to plates, food containers, bags, and wraps that come into contact with food. They persist in the environment. Occupational exposure to workers and general population exposure by inhalation, ingestion, and dermal contact	Reduced birth weight[50]
Perchlorate	Used to produce rocket fuel, fireworks, flares, and explosives and can also be present in bleach and in some fertilizers. Primary pathway for exposure is through drinking water due to contaminated runoff.	Altered thyroid function[51]
Pesticides	Applied in large quantities in agricultural, community, and household settings. In 2001, over 1.2 billion pounds of pesticide active ingredients were used in the U.S. Pesticides can be ingested, inhaled, and absorbed by the skin. The pathways of pesticide exposure include food, water, air, dust, and soil.	Impaired cognitive development Impaired neurodevelopment[52,53] Impaired fetal growth[54] Increased susceptibility to testicular cancer[55] Childhood cancers[56]
Phthalates	Synthetically derived, phthalates are used in a variety of consumer goods such medical devices, cleaning and building materials, personal care products, cosmetics, pharmaceuticals, food processing, and toys. Exposure occurs through ingestion, inhalation, and dermal absorption.	Reduced masculine play in boys[57] Reduced anogenital distance[58] Shortened gestational age[59] Impaired neurodevelopment in girls[60]
Toluene	Exposure occurs from breathing contaminated workplace air, in automobile exhaust, some consumer products, paints, paint thinners, fingernail polish, lacquers, and adhesives.	Decreased fetal and birth weight[61] Congenital malformations[62,63]

From Sutton P, et al: Toxic environmental chemicals: the role of reproductive health professionals in preventing harmful exposures. *American Journal of Obstetrics and Gynecology,* 207(3):164-173, 2012.

Fetal Exposures

Maternal body burden of chemicals during pregnancy can lead to the potential for fetal exposure. Chemicals that have been found in the fetal environment include pharmaceuticals, illicit drugs, alcohol, tobacco, metals, pesticides, PCBs, PBDEs, and phytoestrogens among other chemicals.[71]

The placental transfer of chemicals is well established and varies depending on the chemical structure and composition; for example some chemicals may have a higher or lower affinity for crossing the placenta. Several studies highlight the ability and correlation of maternal-fetal doses from exposure to common environmental contaminants.

In a birth cohort study from the Faroe Islands, where the population is exposed to high levels of environmental chemicals through their marine-based diet, the authors measured the concentration of 87 environmental pollutants in mother-child samples and found that virtually all substances that were found in the mothers were also present in fetal tissues and cord blood, however, the degree of transplacental passage and correlation with

maternal serum varied depending on structure and size of the chemical.[72] For example, amongst the five perfluorinated chemicals measured, shorter chain PFCs and PFCs with sulfonic acid as the active group transferred more readily than long chain PFCs or PFCs with carboxylic acid as the active group. Similarly PBDEs that are more highly brominated were detected at lower concentrations than those with fewer bromines, supporting the evidence that brominated substances are less efficiently transferred into cord blood.[72]

A 2011 study by Gützkow and colleagues measured perfluorinated alkyl acids (PFAAs) in 123 paired samples of maternal and fetal plasma from a subcohort of the Norwegian Mother and Child Cohort Study. Strong and highly significant correlations were found between maternal and cord blood concentrations on fresh weight basis for PFOA, PFOS, and three other PFAAs.[73] Compared to the maternal samples, cord plasma had a 1.4 to fourfold lower median concentration of all the PFAAs measured. Placental transfer was found to be selective with a higher proportion of shorter chained PFAAs in cord blood together with a higher amount of branched isomers of PFOS indicating specific fetal exposures.

Balakrishnan and colleagues (2010) investigated the placental transfer of the pseudo-persistent chemical BPA at environmentally relevant concentrations. Within 3 hours of exposing the placenta to BPA, about 27% of BPA was detected in the fetal compartment, demonstrating that BPA at low concentrations can cross the human placenta mainly in the unconjugated or active form.[74]

In addition to crossing the placental barrier, some environmental chemicals are capable of bioaccumulating in the fetus resulting in greater exposure during this sensitive period of development. For example, fetal methyl mercury levels have been shown to be about 1.7 times greater than maternal levels.[75] Higher blood pressure and maternal alcohol use have been shown to be associated with relatively greater fetal blood lead concentration compared to maternal concentrations while other factors appear to reduce the degree of bioaccumulation.[76]

Mechanisms of Action

There are many environmental contaminants that can affect reproductive health,[18] and they can do so through diverse biological mechanisms. Traditionally the concern with exposures to chemicals has focused on genotoxic or mutagenic effects—i.e., those that can damage or interfere with the integrity of genetic material. However, exposure to chemicals can act in other dangerous and subtle ways, for example, by epigenetic and/or by affecting the production and transport of hormones.

Mutagenic Mechanisms

Mutagenic mechanisms are caused by exposures that induce DNA damage and can adversely affect reproduction and development. A well-documented example is radiation-induced cancer due to exposure to ionizing radiation, which is the rationale for the growing concern about the sharp rise in the use of computed tomography scans in medicine due to the non-negligible radiation exposures involved, particularly for pediatric patients.[77] It is generally believed that complex forms of DNA double-strand breaks are the most biologically important type of lesions induced by ionizing radiation, and these complex forms are likely responsible for subsequent molecular and cellular effects.[78]

Epigenetic Mechanisms

Epigenetic, in contrast to mutagenic, mechanisms act by altering the gene activity without changing the DNA sequence. This is often accomplished through methylation of the DNA and chromatin modification that can lead to changes in chromatin folding and gene expression.[79] Recent animal studies have demonstrated that a single exposure to the commonly used fungicide vinclozolin affected the physiology, behavior, and metabolical activity in offspring three generations removed through the inheritance of epigenetic changes.[80]

Endocrine Disrupting Mechanisms

Endocrine disrupting compounds (EDCs) are chemicals that act by perturbing the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body that are responsible for the maintenance of homeostasis, reproduction, development, and/or behavior.[81] Mechanisms of EDCs (e.g., estrogenic, anti-estrogenic, anti-androgenic) involve binding to receptors and having effects on enzymes or transport proteins (Table 20.2A, 20.2B). EDCs can bind to hormone receptors producing agonist effects, those that mimic endogenous hormones[21] (for example, experiments have demonstrated that BPA can act additively on ovarian estrogens[23]), or antagonist effects (i.e., those that inhibit receptor activity such as vinclozolin that interferes with the androgen receptor).[21,82] EDCs can also act at the level of steroid biosynthesis or metabolizing enzyme[83]—for example, PCBs can interfere with thyroid hormone action and it has been known to cause a decrease in circulating total and free T_4 levels.[23] Hormone action can also be prevented by enzymatic conversion of the hormone from the active to the inactive form.[23] Furthermore, EDCs can disrupt neural and immune signaling pathways[84-86]; and alter the regulation of gene expression by way of DNA methylation, RNA stability, protein degradation (reviewed in Edwards and Myers[87]).

Common EDCs include BPA, phthalates, and certain pesticides. Often the molecular structure of EDCs contains a central ring that mimics the structure of steroid hormones. Thus, these compounds generally affect estrogen, androgen, and thyroid signaling, which are essential for normal embryonic development and reproductive activity in all vertebrates studied to date.[89-91]

EDCs are clinically relevant because they are associated with a wide range of effects on male and female reproduction including breast development and cancer, prostate cancer, neuroendocrinology, thyroid, metabolism and obesity, and cardiovascular endocrinology.[21] EDCs can have multiple hormonal effects, for example, DDT is an estrogen disruptor, while its metabolite, dichlorodiphenyl dichloroethylene (DDE), is an androgen antagonist[21]; and BPA perturbs both estrogen and thyroid hormones.[92] EDCs may exert dose-response curves that are not linear,[21] and as described in the next section, low dose exposure during critical and sensitive periods of development may be more potent than higher dose exposures.[24]

Table 20.2 Mechanisms of Action of Endocrine Disrupting Chemicals

A. Binding to Receptors

Substances	Mechanism	Major Effect	Biological Effects
Agonists			
Bisphenol-A Phthalates Polyphenols including isoflavones and genistein Some UV-screens (benzophenone 2; cinnamate; camphor derivatives)	Activation via ERE	Estrogenic	Adverse effects on reproduction; uterus, mammary gland
Antagonists			
Pesticides, fungicides, herbicides (linurone, procymidone, vinclocolin) dioxin	Various mechanism often inhibition of ARE mediation	Antiandrogenic	Adverse effects on reproduction

B. Effects on Enzymes or Transport Proteins

Substances	Mechanism	Affected Hormone(s) Biological Effect
Fungicides (azoles)	Synthesis inhibitors: Inhibition affected step of synthesis (sterol dementhylase and chromatase)	All steroids; inhibition of adrenal steroids is particularly important; life-threatening reduction of adrenal corticoids
Isoflavones	Inhibition of thyroid peroxidase	Thyroxin synthesis (hypothyroidism)
Polyphenols (isoflavones, genistein)	Sulfatase increased Decreased sulfo-transferase Effects on proteins transport	Free estrogen increased
Isoflavones, polychlorinated diphenols	Transthyretin (the transport protein of thyroid hormones)	Altered amounts of free thyroid hormones

EDs, Endocrine disruptors; ERE, Estrogen Response Elements; ARE, Androgen Response Elements.
From Wuttke W, Jarry H, and Seidlova-Wuttke D, *Definition, classification and mechanism of action of endocrine disrupting chemicals.* Hormones (Athens). **9**(1):9-15, 2010.

Critical and Sensitive Windows of Susceptibility

Exposure to chemicals during pregnancy and development are of particular import since these are times of DNA demethylation-methylation during gametogenesis and embryogenesis, rapid growth, and differentiation.[93] The nature and extent of the health consequences of exposure to environmental chemicals are influenced by the timing of exposure, i.e., the "window of susceptibility." A critical window of susceptibility is when exposures to environmental contaminants can disrupt or interfere with the physiology of a cell, tissue, or organ[19]; exposures that occur during this time can lead to permanent and lifelong health effects and can often be passed down to future generations. Sensitive windows of susceptibility can still cause disease but with less intensity and severity as compared to those occurring in the critical window.[94] Critical and sensitive windows occur during times of rapid development and cellular differentiation such as periconception, pregnancy, infancy, childhood, puberty, and lactation.

Exemplary of the concept of windows of vulnerability, studies have found that ethylene oxide can induce skeletal effects when administered to mice at the zygote stage of development—at a time that is long before skeletogenesis begins.[95,96] The skeletal effects that are observed after exposure at the zygote stage are different than those observed after exposure during organogenesis. Another example of how timing of exposure matters is the neurotoxic impacts of the pesticide chlorpyrifos. The conventional view of the mechanism for neurotoxicity from chlorpyrifos exposure involves the irreversible inhibition of acetylcholinesterase. However, animal studies demonstrated that the effects of chlorpyrifos on the developing brain are subtle, widespread, and can occur below the threshold for any signs of exposure and even without any detectable cholinesterase inhibition.[97,98] Moreover, these studies have shown that chlorpyrifos disrupts rat brain development through a variety of cellular and molecular mechanisms, with both the mechanism and the outcome changing with the progression of cell differentiation.

Of note are recent data regarding differences in DNA methylation in placentae and cord blood from children conceived by IVF vs. naturally conceived children. DNA methylation was investigated at 1536 CpG sites (700 genes) in placenta and cord blood. IVF was associated with lower mean methylation at CpG sites in placenta and higher mean methylation at CpG sites in cord blood. Differences were observed in imprinted and nonimprinted genes, and several of these expressed genes have been implicated in chronic metabolical disorders (e.g., obesity, type II diabetes). The reasons for this are unclear, but environmental influences in culture conditions or on parental loci have been postulated.[99]

Developmental Basis of Disease and Dysfunction

The Developmental Basis of Adult Disease and Dysfunction describes the interaction between the *in utero* environment, the external environment, an individual's genes, and the propensity to develop disease or dysfunction later in life.[21] The central nervous system, the cardiovascular system, the endocrine system, and the immune system appear to be particularly vulnerable to adverse effects during development, and specific diseases, such as particular forms of cancer, may well be initiated before birth or during early postnatal life.[19]

Box 20.1 Features of "Developmental Origins of Disease and Dysfunction" Paradigm Common to Both Nutritional and Environmental Exposure Studies

TIME SPECIFIC (VULNERABLE WINDOW) AND TISSUE-SPECIFIC EFFECTS MAY OCCUR WITH BOTH NUTRITIONAL AND ENVIRONMENTAL CHEMICAL EXPOSURES
The initiating *in utero* environmental insult (nutritional or environmental chemical) may act alone or in concert with other environmental stressors. That is, there could be an *in utero* exposure that would lead by itself to pathophysiology later in life or there could be *in utero* exposure combined with a neonatal exposure (same or different environmental stressor[s]) or adult exposure that would trigger or exacerbate the pathophysiology.

THE PATHOPHYSIOLOGY MAY MANIFEST AS: THE OCCURRENCE OF A DISEASE THAT OTHERWISE WOULD NOT HAVE HAPPENED; AN INCREASE IN RISK FOR A DISEASE THAT WOULD NORMALLY BE OF LOWER PREVALENCE; OR EITHER AN EARLIER ONSET OF A DISEASE THAT WOULD NORMALLY HAVE OCCURRED; OR AN EXACERBATION OF THE DISEASE
The pathophysiology may have a variable latent period from onset in the neonatal period, to early childhood, to puberty, to early adulthood, to late adulthood depending on the environmental stressor, time of exposure, and tissue/organ affected.

EITHER ALTERED NUTRITION AND/OR EXPOSURE TO ENVIRONMENTAL CHEMICALS CAN LEAD TO ABERRANT DEVELOPMENTAL PROGRAMMING THAT PERMANENTLY ALTERS GLAND, ORGAN, OR SYSTEM POTENTIAL. THESE STATES OF ALTERED POTENTIAL OR COMPROMISED FUNCTION (REGARDLESS OF THE STRESSOR—NUTRITIONAL OR CHEMICAL EXPOSURE) ARE LIKELY TO RESULT FROM EPIGENETIC CHANGES (E.G., ALTERED GENE EXPRESSION DUE TO EFFECTS ON IMPRINTING, AND THE UNDERLYING METHYLATION-RELATED PROTEIN-DNA RELATIONSHIPS ASSOCIATED WITH CHROMATIN REMODELING). THE END RESULT IS AN INDIVIDUAL THAT IS SENSITIZED SUCH THAT IT WILL BE MORE SUSCEPTIBLE TO CERTAIN DISEASES LATER IN LIFE
The effect of either developmental nutrition or environmental chemical exposures can be transgenerational, affecting future generations.

WHILE THE FOCUS OF NUTRITIONAL CHANGES DURING DEVELOPMENT HAS BEEN ON LOW BIRTH WEIGHT, EFFECTS OF *IN UTERO* EXPOSURE TO TOXIC ENVIRONMENTAL CHEMICALS OR NUTRITIONAL CHANGES MAY BOTH OCCUR IN THE ABSENCE OF REDUCED BIRTH WEIGHT. THE LACK OF A SPECIFIC EASILY MEASURABLE BIOMARKER FOR THESE EFFECTS THAT IS SIMILAR TO BIRTH WEIGHT MAKES IT MORE DIFFICULT TO ASSESS DEVELOPMENTAL EFFECTS. THUS, FOR BOTH EXPOSURES, NEW, MORE SENSITIVE BIOMARKERS OF EXPOSURE ARE NEEDED
Extrapolation of risk from both nutritional studies and environmental exposures may be difficult because effects may not follow a monotonic dose–response relationship. Nutritional effects which result in low birth weight are different from those that result in high birth weight. Similarly, low dose effects of environmental chemicals may not be the same as the effects that occur at higher doses. Also, the environmental chemical and/or nutritional effects may have an entirely different effect on the embryo, fetus, or perinatal organism, compared to the adult.

EXPOSURE OF ONE INDIVIDUAL TO AN ENVIRONMENTAL STRESSOR (ENVIRONMENTAL CHEMICAL OR NUTRITIONAL OR COMBINATIONS) MAY HAVE LITTLE EFFECT, WHEREAS ANOTHER INDIVIDUAL WILL DEVELOP OVERT DISEASE OR DYSFUNCTIONS DUE TO DIFFERENCES IN GENETIC BACKGROUND INCLUDING GENETIC POLYMORPHISMS

From Environmental Impacts on Reproductive Health and Fertility, edited by Tracey J. Woodruff, Sarah J. Janssen, Louis J. Guillette, Jr, and Linda C. Giudice. Copyright (c) 2010 Cambridge University Press. Reprinted with permission.

The influence of perinatal exposures and their effect on adult disease was first described in the field of nutrition when it was seen that "low birth weight" resulting from poor maternal nutrition is a cause of disease and illness later in life such as obesity, coronary heart disease, type II diabetes, and metabolical dysfunction among others.[100] This concept was later independently developed in the field of developmental toxicology (Box 20.1).[33] Animal studies have demonstrated that the *in utero* and neonatal development periods are a "critical window" for nutrition as well as for exposure to environmental chemicals and can have an impact on developing regulatory systems.[101] For example, there is some evidence that environmental endocrine disrupting chemicals can act as "obsesogens" and can permanently alter the developing regulatory systems required for body weight homeostasis.[101,102]

Identification of Chemicals with Reproductive and Developmental Toxicity

The information available to clinicians in the field of environmental health science differs from that available for decision-making in the clinical health sciences. Clinicians are accustomed to pharmaceuticals going through comprehensive *in vitro* and *in vivo* testing as mandated by regulatory agencies. However, in regards to environmental exposures, clinicians cannot assume that the safety of products has been established and must recognize that most patient exposure occurs in the absence of information on reproductive, developmental, and other toxicities.

Randomized control trials (RTCs) are considered the "gold standard" for establishing the risk-benefit of clinical decision-making. However, ethical considerations preclude RCTs in the assessment of the health impacts of exposure to environmental chemicals. In the clinical arena, RTCs are conducted to assess whether the benefits of exposure to an exogenous chemical outweigh the risks. With environmental chemicals the benefits are often unrelated to patient's health and exposures are often unavoidable and highly variable.

Therefore, clinicians must rely on the available animal and epidemiological data to shape patient recommendations and prevention strategies related to environmental chemicals. Animal studies of reproductive and developmental toxicity are recognized as reliable predictors of human health effects.[103-106] Since 1984, a technical report by the National Center for Toxicological Research, as well as other studies, have established the concordance of developmental and reproductive effects between animal and human studies

and concluded that the humans are as sensitive as or more sensitive than even the most sensitive animal species.[95,105]

Epidemiological studies provide the most direct link between an environmental exposure and increased risk of an adverse human health outcome. However, these studies require waiting a long time after exposures have occurred to assess harm, as it can take decades for the health impacts of exposure to be manifest. Thus, sole reliance on epidemiological studies squanders the option of preventing exposures before such harm has occurred.

The Role of Clinicians in Prevention

Clinicians can serve as a science-based source of guidance for their patients on recognizing, avoiding, and preventing harmful exposures to environmental chemicals.[107,108] For example, clinicians can provide information on the science and areas of uncertainty about environmental chemicals so that patients can make informed choices based on their values and preferences. Science-based, patient-centered educational materials to support patient counseling activities can be found at: http://www.prhe.ucsf.edu/prhe/toxicmatters.html. Patients who are pregnant or who are planning on becoming pregnant are often highly motivated and interested in finding out about chemical exposures or unaware about the risks caused by exposure.

When counseling patients it is important that clinicians have the capacity to:

- Understand the patient risk from exposure to environmental chemicals. Patient risk is a function of the toxicity and dose of the exposure. Routes of exposure include dermal, inhalation and ingestion and exposure is determined by the concentration, frequency and duration, and patient vulnerability, including any underlying health conditions.[109]
- Advise all patients on how to prevent exposures at home, work, and in the community. Women often do not know they are pregnant until after organogenesis has already begun so intervening in the periconception period to identify and address patient exposure is a way to maximize the potential to prevent harm.
- Understand socioeconomic and racial disparities can exacerbate the amount of environmental exposures experienced by an individual and understanding the environment of the patient population can help target high risk exposures.[110]
- Identify patients with hazardous exposures by taking an exposure history. Workplace exposures can be a significant source of exposure to toxic chemicals for pregnant women and legal workplace limits are not created to protect pregnant women.[111] Women of reproductive age with occupational exposures to substances with reproductive and developmental toxicity are at high risk and susceptible to adverse reproductive outcomes.[112]

While taking an exposure history is a key first step, many environmental exposures are not actionable by individuals, for example, air and water pollution. There are also many legal, economic, and social justice issues interwoven into the distribution of environmental chemicals throughout our society that cannot be addressed by individual action alone. Thus society-wide actions to prevent exposures are essential to patient and population health. Harnessing the voice of health professionals to policies to prevent exposure to environmental chemicals can be a powerful contributor to improved patient health.[20,34,111,113]

Summary and Conclusion

Adverse trends in indicators of reproductive and developmental health have occurred over roughly the same time frame as vast increases in population exposure to environmental chemicals. Currently, exposure to toxic environmental chemicals is ubiquitous and linked to a myriad of adverse reproductive and developmental health impacts that can occur across the lifespan of individuals. Exposures that occur during critical and sensitive windows of development (i.e., preconception, prenatal, infant, child, and adolescence) are of particular concern because the health impacts of these exposures can occur at environmentally-relevant levels of exposure and be permanent. Health professionals can play a critical role in patient health by intervening in clinical and policy arenas to prevent developmental exposure to environmental chemicals.

CHAPTER 21

Physiological and Pathophysiological Alterations of the Neuroendocrine Components of the Reproductive Axis

Ralf Nass*
Kristin D. Helm†
William S. Evans*

Reproductive dysfunction of central etiology can result from any process that disturbs the tightly regulated hypothalamic–pituitary system. The reproductive axis itself relies on pulsatile release of gonadotropin-releasing hormone (GnRH) from a collection of neurons that are distributed diffusely throughout the hypothalamus rather than within a discrete nucleus.[1] Control of GnRH secretion is complex, including the kisspeptin ligand-receptor system described in detail below. Neuropeptide Y (NPY) facilitates GnRH release and gonadotropin responsiveness to GnRH. Substance P, beta-endorphin, leuenkephalin, and other endogenous opiates inhibit hypothalamic GnRH release, both acutely and tonically (in the case of beta-endorphin).[2,3] Stress-related surges in corticotrophin-releasing hormone (CRH) suppress GnRH gene transcription as well as GnRH release, as do inflammatory cytokines, such as tumor necrosis factor-α (TNF-α).[4] This CRH-induced suppression may be mediated by endogenous opiates.[5,6] The effects of catecholamines (norepinephrine, epinephrine, dopamine) are more controversial and likely depend on the prevailing endocrine milieu and the stage of sexual maturation.[2] Neurotransmitters, such as gamma-aminobutyric acid (GABA), have been shown to have both excitatory[7,8] and inhibitory[9,10] effects in animal studies, and use of the GABA-ergic drug valproic acid (VPA) in women did not affect hypothalamic–pituitary hormones.[9] Such conflicting data on the role of GABA in modulating GnRH release illustrate the challenges inherent in using rodent models to understand GnRH regulation in humans.[2]

Integration of these multiple signals ultimately results in neuronal release of GnRH, which then travels via the hypothalamic–hypophyseal portal circulation to the anterior pituitary gland, where it binds to the GnRH receptor 1 and up-regulates synthesis and secretion of two pituitary hormones—luteinizing hormone (LH) and follicle-stimulating hormone (FSH). GnRH secretion is pulsatile, with discrete bursts of GnRH effecting the release of pulses of LH and FSH by the pituitary. Moreover, the frequency of GnRH secretion has been shown in animal models to differentially affect the synthesis of LH and FSH, with rapid-frequency GnRH pulses (1 pulse/hour) favoring LH synthesis and slow-frequency GnRH pulses favoring the synthesis of FSH.[10] The secretion of LH and FSH is also regulated by direct negative feedback from gonadal products (estradiol [E_2], inhibin A and B). Once released from the pituitary, LH and FSH travel through the systemic circulation to stimulate sex steroid production and gametogenesis by the gonads. The patterns of hypothalamic, pituitary, and gonadal activity are responsible for the transition from childhood to adulthood, as well as for normal ovulatory cycles in postmenarchal women and normal sexual function in males.

The presence of appropriate quantities of these hormones is not enough to maintain a normal reproductive axis. Frequent sampling of plasma hormone concentrations has led to the belief that most hypothalamic hormones are secreted episodically, and often in a circadian rhythm. Hormonal release may be linked primarily to the sleep–wake cycle, synchronized with food ingestion, or related to the dark–light cycle. Thus, integrity of the hypothalamic suprachiasmatic nucleus, which maintains both the circadian rhythm and the sleep–wake cycle, is an important factor for regulating gonadal function in men and women.

Patients with abnormalities of this complex hypothalamic–pituitary axis often show undetectable or inappropriately low levels of pituitary gonadotropins (FSH and

LH) in combination with low sex steroid levels (testosterone <100 ng/dL in males and E_2 <20 pg/mL in females). This combination of laboratory findings defines the condition *hypogonadotropic hypogonadism*. In contrast, patients with primary gonadal pathology have elevated FSH and LH levels in combination with low testosterone or E_2 levels, a disorder referred to as *hypergonadotropic hypogonadism*. The clinical presentation of hypogonadotropic hypogonadism varies with age of onset and degree of hormonal deficiency. Males may present with micropenis and cryptorchidism. Testicular function can be completely impaired, with Leydig cell atrophy, or testicular size can approach normal, with only mild Leydig cell impairment. The phenotype of hypogonadotropic hypogonadism in women is also quite variable, ranging from a classic eunuchoid appearance in some women (lower body segment [floor to *pubis*] >2 cm longer than the upper body segment [*pubis* to crown] and arm span >2 cm longer than height) to moderate breast development in others.[11] Amenorrhea, whether primary or secondary, frequently is the reason why women seek medical attention. The degree of ovarian follicular development depends on the duration of gonadotropin deficiency; in cases of congenital hypogonadotropic hypogonadism, few follicles beyond the primordial stage may be present.[12] The administration of exogenous gonadotropins (or exogenous pulsatile GnRH, when it was available) can effect ovulation and pregnancy.[13]

Although some patients with hypogonadotropic hypogonadism have no evidence of pulsatile LH secretion, others have detectable LH secretory pulses that are of insufficient frequency and amplitude to trigger gonadal steroid synthesis. A small number of patients show nearly normal patterns of LH secretion, but the LH molecules are inactive and consist only of the uncoupled α subunit.[10] This heterogeneity of basal LH secretion in patients with hypogonadotropic hypogonadism is mirrored in their responses to exogenous GnRH stimulation. Complete unresponsiveness to GnRH is rare,[14] but many patients show subnormal increases of FSH and LH. In other cases, FSH or LH levels may rise in isolation, or both may increase normally.[13,15]

Hypogonadotropic hypogonadism may be physiological, as occurs during puberty and lactation, or it may be a manifestation of congenital or acquired pathology. Congenital hypogonadotropic hypogonadism usually occurs in the absence of other pituitary hormonal deficits, whereas acquired GnRH deficiency may be caused by tumors, infiltrative diseases, infection, trauma, or radiation—all of which can also cause other hormonal deficiencies. Epilepsy is frequently associated with reproductive dysfunction, often polycystic ovary syndrome (PCOS). Abnormalities of other hormones (i.e., thyroid hormone, cortisol, prolactin [PRL]), overnutrition and undernutrition, exercise, stress, and medications can also cause functional hypogonadotropic hypogonadism. Hypogonadotropic hypogonadism commonly occurs with pituitary disease due to tumors and apoplexy, as well as other autoimmune and inflammatory disorders.

Hypothalamic Dysfunction

Reproductive integrity requires an intact hypothalamus, which secretes GnRH from neurons that are distributed diffusely throughout the hypothalamus rather than in a discrete nucleus.[1] As discussed earlier, GnRH is secreted in a pulsatile fashion, the frequency of which differentially affects the pulsatile secretion of the gonadotropins. Moreover, the frequency of GnRH secretion is known to affect gene expression, with rapid-frequency GnRH pulses (1 pulse/hour) favoring LH synthesis, and slow-frequency GnRH pulses favoring FSH synthesis. Pituitary LH and FSH secretion are also regulated by direct negative feedback from gonadal products (E_2, inhibin A and B). The patterns of hypothalamic, pituitary, and gonadal activity are responsible for the transition from childhood to adulthood, as well as for normal ovulatory cycles in postmenarchal females and sexual function and spermatogenesis in males. Disruption of hypothalamic GnRH secretion at any point during development can have transient or permanent effects on fertility. Such disturbances can result from congenital, structural, or functional abnormalities of the central nervous system (CNS)-hypothalamic component of the reproductive axis.

Congenital Disease of the Hypothalamus

Hypogonadotropic hypogonadism resulting from abnormal development of GnRH neurons is relatively rare, affecting 1:10,000 males and 1:50,000 females.[16] GnRH neurons originate during embryonic life outside of the CNS in the nasal placode. Olfactory neurons have a similar embryonic origin in humans and many other vertebrate species. Migration of olfactory axons toward the olfactory bulb anlage is required for normal olfactory bulb (OB) development.[17,18] GnRH neurons then migrate across the cribriform plate toward the OB in two phases—one before OB formation and one in association with OB formation.[19] The latter wave of migration occurs in association with olfactory, vomeronasal, and terminal nerves as well as neural cell adhesion molecules, ultimately resulting in GnRH neuronal cell dispersion in the arcuate nucleus of the medial basal hypothalamus by 14 weeks of gestation.[20,21] The mature GnRH axonal neuron network eventually coordinates pulsatile secretion of GnRH into the hypothalamic–hypophyseal portal circulation.[22] Disruption of this complex series of events can result in varying degrees of hypothalamic dysfunction, which manifests clinically as hypogonadotropic hypogonadism.

Congenital hypogonadotropic hypogonadism is usually divided into two categories: that which is accompanied by olfactory deficits (anosmic idiopathic hypogonadotropic hypogonadism [IHH] or Kallmann syndrome [KS]) and that which is associated with an intact sense of smell (normosmic IHH). Exciting progress has been made in identifying genetic causes for both anosmic and normosmic IHH,[23] as summarized in Figure 21.1 and Table 21.1. Some genes are necessary for the correct embryonic differentiation of the GnRH-secreting neurons (*fibroblast growth factor receptor 1 [FGFR1], fibroblast growth factor 8 [FGF8], negative elongation factor [NELF], heparin sulfate* 6-O-*sulfotransferase [HS6ST1]*), others are essential for the migration of the GnRH neurons to the hypothalamus (*KAL1, Prokineticin 2/Prokineticin 2 receptor 2[PROK2/PROKR2], chromodomain-helicase-DNA-binding protein 7 [CHD7]*),[24] and others are involved in the upstream signals which participate in the activation

of the GnRH neuron *(tachykinin 3/tachykinin 3 receptor [TAC3/TACR3], Kisspeptin1/Kisspeptin1 receptor [KISS1/KISS1R]*). The candidate genes include also GnRH, GnRH receptor, and the gonadotropins. However, most cases of GnRH deficiency in humans are sporadic. In the cohort of 106 patients with GnRH deficiency with and without anosmia reported by Waldstreicher and colleagues only 30% of cases were familial.[25] Because IHH predominantly impairs fertility, families with multiple affected members are few, but the availability of gonadotropin therapy to induce fertility in both affected males and females may increase vertical transmission of the condition.

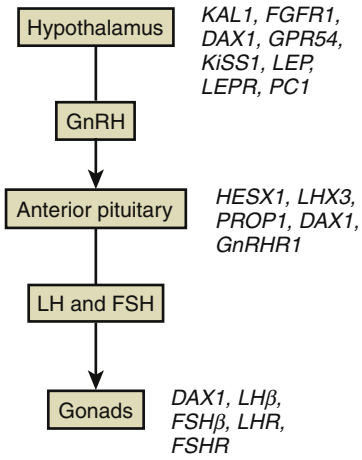

FIGURE 21.1 Schematic diagram of the hypothalamic–pituitary–gonadal axis showing genetic mutations that are responsible for some cases of hypogonadotropic hypogonadism. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone. *(Modified from Cadman SM, Kim SH, Hu Y, Gonzalez-Martinez D, Bouloux P. Molecular pathogenesis of Kallmann's syndrome.* Horm Res *67:231, 2007. With permission from S. Karger AG, Basel.)*

Anosmic Idiopathic Hypogonadotropic Hypogonadism

KAL 1 *Mutation*

The pathological association between IHH and olfactory dysfunction was originally recognized in the 19th century, but Kallmann and Schoenfeld first suggested a genetic basis for this group of patients in 1944.[26] In 1989, Schwanzel-Fukuda and colleagues discovered a tangle of GnRH neurons on the surface of the cribriform plate in a human fetus with X-linked KS.[27] The finding of the neurons in this location rather than in the typical location in the hypothalamus established defective GnRH neuronal migration as the cause of hypogonadotropic hypogonadism in KS.[27,28] Because the initial differentiation and migration were normal, research then focused on factors affecting axonal growth, pathfinding, and maturation. The *KAL1* gene on the X chromosome (Xp22.3) was subsequently identified in 1991 by two groups, and both deletions and point mutations have since been found in patients with KS.[29,30] The product of *KAL1*, anosmin-1, is transiently expressed in numerous tissues of the developing human fetus, including the OB and along the migratory pathway for GnRH neurons. In the absence of anosmin-1 (with the *KAL1* mutation), OB differentiation and early olfactory axon navigation are impaired. Without olfactory nerve synaptogenesis in the OB, GnRH neurons have no migratory pathway to follow to the forebrain, resulting in the anosmia and hypogonadotropic hypogonadism typical of KS.[31] *KAL1* expression also occurs in the mesonephric tubules, ureteric bud, and corticospinal tract by 7 weeks of age, and in the retina and kidney by 11 weeks of age.[32] This tissue-specific expression accounts for the high prevalence of renal, neurological, and midline facial abnormalities in patients with KS. Unilateral renal agenesis is believed to occur because of developmental failure of the collecting duct system in the absence of mesonephric tubule anosmin-1. Synkinesia ("mirror movements," or

Table 21.1 Genes and Idiopathic Hypogonadotropic Hypogonadism

Clinical Features	Condition	Gene	Localization	Inheritance	Site of GnRH Impairment
HH + anosmia	Kallmann syndrome	*KAL1*	Xp22.3	X-linked	Hypothalamus (incomplete GnRH neuronal migration)
HH ± anosmia ± midline facial defects	Kallmann syndrome	*KAL2*	8p11.2	Autosomal dominant	
HH + anosmia	Kallmann syndrome			Autosomal recessive	
HH		*GnRH-R*	4q21.2	Autosomal recessive	Pituitary (↓ GnRH-R activity)
HH		*GPR54*	19p13	Autosomal recessive	Hypothalamus
HH + adrenal insufficiency	Adrenal hypoplasia congenital	*AHC*	Xp21	X-linked	Hypothalamus Pituitary
HH		*LHβ*	19q13.3	Autosomal recessive	Pituitary

the involuntary movements of one extremity when an individual is asked to perform rapid, repetitive motions with the other extremity) results from abnormal fast–conducting ipsilateral corticospinal tract projections.[3] Absence of anosmin-1 expression in the facial mesenchyme leads to a high incidence of cleft palate in patients with *KAL1* mutations. Renal agenesis and synkinesia were present in 31% and 85% of patients, respectively, of a British cohort of patients with KS.[33] These abnormalities were not present in any patients with KS without the *KAL1* mutation or in patients with normosmic IHH.

As is the case with all forms of hypogonadotropic hypogonadism, KS is much more common in males, with prevalence estimated at 1:7500 males versus 1:70,000 females.[34] The *KAL1* mutation accounts for only 3% to 15% of cases of anosmic IHH[16,35] and no more than one third of familial cases of IHH,[25] but it is highly penetrant. No cases of *KAL1* mutations have been described in female patients or in normosmic males.[35] Patients with KS usually do not undergo puberty, but a minority may have some degree of testicular growth or breast development, suggesting that GnRH deficiency is not always complete. Additional reproductive features may include cryptorchidism and microphallus. As is the case with other genetic defects discussed later, there is no clear genotype-to-phenotype relationship in those with a *KAL1* mutation,[34] illustrating the importance of modifier genes and environmental factors.

KAL 2 *Mutation*

Mutations in the gene encoding fibroblast growth factor receptor 1 *(FGFR1)*, a tyrosine kinase receptor, also referred to as *KAL2*, appear to be inherited in an autosomal dominant pattern and are seen in 7% to 10% of individuals with KS.[35] Fibroblast growth factor signaling is involved with the formation, growth, and shaping of a variety of tissues and organs, including the OB.[36] Fibroblast growth factor (FGF) receptor-1 *(FGFR1)* has been detected in both the nasal placode and the developing OBs of mice as well as along the migratory pathway for GnRH neurons and in the mature hypothalamus. Studies in rodents with targeted abolition of *FGFR1* signaling resulted in aplasia of the OB. Both *FGFR1* and anosmin-1 are coexpressed in the olfactory placode of human embryos by 4.5 weeks' gestation, and again at 8 weeks in the terminal nerve portion that guides GnRH neuronal migration to the hypothalamus.[28] Studies suggest that *FGFR1* is a ligand for anosmin-1.[24] Loss-of-function mutations in the *FGFR1* gene located on chromosome 8p11.2 can cause IHH, with or without anosmia.[37,38] At least 12 missense mutations have been identified in this gene thus far, and loss of function of the isoform *FGFR1c* is present in approximately 10% of male and female patients with KS.[22] Isoform *FGFR1c* is also important for palate morphogenesis as well as olfactory development.[39]

Unlike *KAL1* mutations, *KAL2* mutations are not always associated with a severe reproductive phenotype. A minority of patients may have delayed puberty or normal reproductive function, suggesting that the *KAL2* mutation may not prevent GnRH migration entirely, but may affect neuronal maturation in the hypothalamus. This variable expressivity of *KAL2* suggests a role for other genes or the environment in modifying the phenotypic expression of this mutation. It also raises the possibility that *KAL2* mutations account for other reproductive phenotypes associated with hypothalamic dysfunction, such as hypothalamic amenorrhea and delayed puberty.[37]

Congenital hypogonadotropic hypogonadism (CHH) is less severe in patients with *KAL2* muations than in those with *KAL1* mutations, and mean LH levels are significantly lower in *KAL1* patients compared to *KAL2* patients.[40] Identification of *KAL2* mutations and the relationship between FGF signaling and anosmin-1 may explain the male predominance of hypogonadotropic hypogonadism despite the low prevalence of the X-linked form of the disease. Females have two copies of the *KAL1* gene and, therefore, higher levels of anosmin-1, which may compensate for inadequate *FGFR1* function in the presence of a *KAL2* mutation. Thus, women with *KAL2* mutations often have a milder, if not a normal, reproductive phenotype. On the other hand, males have a lower level of *KAL1* or anosmin-1 expression and are unable to compensate for impaired FGF signaling in the presence of a *KAL2* mutation. Thus, their reproductive phenotypes tend to be more severe.[22]

Other Candidate Genes

As is the case for IHH as a whole, most cases of KS are sporadic and cannot be traced to familial transmission. Autosomal recessive transmission of KS does exist, but the responsible gene has yet to be cloned. Multiple other candidate genes that may be involved in cases of anosmic IHH without *KAL1* mutations have been identified in the past decade. Mutations of *CHD7*, which can cause CHARGE syndrome (coloboma, congential heart disease, choanal atresia, mental and growth retardation, genital hypoplasia, and ear malformations or deafness) have been seen in KS patients. Heterozygous mutations in *NELF* have been reported in a few patients with KS; the murine form of *NELF* is involved in olfactory and GnRH neuronal migration.[41] Mutations in *Pkr2*, which encodes a G-protein–coupled receptor critical for OB and reproductive organ development in mice.[25] have been found, as have mutations in the heparan sulfate 6-O-sulfotransferase 1 *(HS6ST1)* gene. The enzyme is involved in the modulation of extracellular matrix components, such as heparin sulfate polysaccharides, thought to modulate cell-cell communication, which is required for neural migration.[42] Heterozygous mutations of WD repeat domain 11*(WDR11)* have been found in a small number of patients with Kallmann syndrome. The *WDR11* gene encodes a protein which interacts with the transcription factor EMX1. The interaction between both factors is important for the development of olfactory neurons.[43] FGF receptor mutations have also been identified in normosmic individuals with IHH, suggesting that anosmic IHH and normosmic IHH are part of a spectrum of disease rather than distinct clinical entities.[22,38]

Normosmic Idiopathic Hypogonadotropic Hypogonadism

Not all patients with hypogonadotropic hypogonadism have an impaired sense of smell. Those with a normal sense of smell are given the diagnosis of IHH. In the American cohort reported by Waldstreicher and colleagues, approximately half of patients with hypogonadotropic hypogonadism were

normosmic.[25] Nasal mucosal biopsy specimens from patients with normosmic IHH showed immunologically recognizable GnRH, providing evidence that the GnRH gene itself was intact and that defective GnRH synthesis was not the cause of IHH in these patients.[21]

GnRH Mutations

There are also patients with IHH manifesting with severe hypogonadism who do have isolated GnRH deficiency. It was not until 2009 that a homozygous frameshift mutation in the GnRH1 gene in such patients was reported. GnRH1 encodes the preprohormone of GnRH. These patients had severe hypogonadism, suggesting that isolated GnRH deficiency can be a rare cause of IHH.[44,45] Other etiologies for IHH have since been identified in this group of patients, in whom the frequency of cryptorchidism[33] and nonreproductive phenotypes (synkinesia, palate abnormalities, hearing loss) is much less common than in anosmic IHH.[37]

GnRH Receptor Mutations

Attempts to identify congenital defects that would explain normosmic IHH have led to the discovery of loss-of-function missense mutations in the gene encoding the GnRH *receptor* (*GnRH-R*) on chromosome 4q21.2. These mutations are transmitted in an autosomal recessive pattern. The GnRH receptor is a G-protein–coupled transmembrane receptor involved with signal transduction. Mutations in this protein were initially considered unlikely because patients with normosmic IHH showed increased FSH and LH secretion in response to exogenous GnRH stimulation. However, in the study by de Roux and colleagues,[46] the index cases both had partial IHH and likely responded normally to GnRH stimulation because the exogenous dose was high enough to overcome their partial receptor defects. *GnRH-R* mutations are estimated to occur in 40% of autosomal recessive cases of normosmic IHH and in 10% to 15% of sporadic cases.[47,48] Heterozygotes are unaffected.[28]

Identical mutations can produce different clinical phenotypes, suggesting that gonadotroph function depends on other genes as well. The clinical presentation of patients with *GnRH-R* mutations can include microphallus, cryptorchidism, gynecomastia, and delayed puberty in males, and primary amenorrhea, incomplete thelarche, and delayed puberty in females.[48] Phenotypes can also be milder, as in men with normal adult-sized testes as well as intact spermatogenesis, but impaired LH-dependent Leydig cell testosterone secretion ("fertile eunuch syndrome").[49] It is now believed that GnRH secretion in these cases is sufficient to trigger enough Leydig cell testosterone production locally to maintain spermatogenesis and testicular growth, but insufficient to generate systemic testosterone levels capable of achieving full virilization.[50]

Screening for *GnRH-R* mutations at the time of diagnosis of IHH is not clinically useful unless fertility is an immediate treatment goal. In these cases, knowledge of a *GnRH-R* mutation would guide one toward gonadotropin therapy and away from pulsatile GnRH therapy (when it was available for clinical use), as the latter was less effective in restoring reproductive function. As with other confirmed genetic abnormalities, identification of a *GnRH-R* mutation would also allow screening and treatment of family members.[48]

GPR54 Mutations

Homozygous deletions in the gene *GPR54* on chromosome 19 (19p13) were first reported in 2003 in a large consanguineous family with multiple members affected by IHH but with normal GnRH receptors. *GPR54* encodes an orphan G-protein–coupled receptor that is expressed widely across the reproductive axis, including the hypothalamus, pituitary, gonads, and placenta.[51] The ligand for *GPR54* is kisspeptin (formerly metastin), which is derived from kisspeptin-1. Kisspeptin was originally discovered because of its ability to inhibit metastatic melanoma and breast cancer cell lines. Continued study of this protein suggests that it may play an important role in regulating central puberty through its ability to signal through *GPR54* and stimulate GnRH release. *GPR54* mutations account for 2% to 5% of normosmic IHH.[52] Both male and female *GPR54*-deficient mice had a hypogonadotropic hypogonadal phenotype (males with small testes, females with delayed vaginal opening and delayed follicular maturation), but had normal levels of hypothalamic GnRH and responded to exogenous GnRH.[46,53] Similarly, spermatogenesis and successful ovulation have been achieved in *GPR54*-deficient patients treated with exogenous GnRH. *GPR54* does appear to have tissue-specific effects, because the *in vitro* administration of kisspeptin metastin did not have the same stimulatory effects on pituitary gonadotrophs as it did on the hypothalamus, and homozygous mutations in *GPR54* did not affect spermatogenesis or ovarian steroidogenesis.[51] The exact mechanism by which *GPR54* regulates puberty remains the subject of ongoing investigation.

TAC3 Mutations

Homozygous mutations in tachykinin 3 (TAC3), which encodes neurokinin B and its heptahelical transmembrane G-protein-coupled receptor *TACR3*, have been described in patients with normosmic IHH. Patients with this mutation have very low basal LH secretion with a nonpulsatile pattern, while pulsatile GnRH treatment normalizes LH release.

Gonadotropin Mutations

Both FSH and LH are composed of a common α subunit and a β subunit that is unique to FSH, LH, thyroid-stimulating hormone (TSH), and human chorionic gonadotropin (hCG). Alpha subunit mutations have not been reported and likely are not compatible with life.[28] However, beta subunit mutations in both the LH[54] and FSH molecules[46] have been identified and are associated with delayed puberty.

Pituitary Transcription Factor Mutations

Mutations in various homeobox transcription factors involved with normal adenohypophyseal development have been reported. Homozygous mutations in *LHX3* have been described in two consanguineous families who presented with combined pituitary hormone deficiencies, including deficits in LH and FSH.[55] LHX3 encodes a protein which is required for pituitary development and motor neuron specification. Mutations in *PROP1* are also associated with variable degrees of FSH and LH insufficiency and other pituitary hormone deficiencies.[56,57] PROP1 has both DNA-binding and transcriptional activation ability. Its expression leads to ontogenesis of homozygous and heterozygous

mutations of *HESX1* and has been implicated in some cases of septo-optic dysplasia, a disease that includes optic nerve hypoplasia, pituitary gland hypoplasia, and midline CNS anomalies. Children with septo-optic dysplasia can have either precocious puberty or pubertal failure.[58,59]

Hypogonadotropic Hypogonadism and Adrenal Failure

Normosmic hypogonadotropic hypogonadism can occur in association with adrenal failure due to loss-of-function mutations in *DAX1* (adrenal hypoplasia congenital). *DAX1* encodes an orphan nuclear receptor on chromosome Xp21 and is critical for the development and function of both the adrenal gland and the hypothalamic–pituitary–gonadal axis. In the presence of *DAX1* mutations, adrenal failure usually presents in male infants or boys, and is followed by impaired pubertal development due to failure of hypothalamic and pituitary gonadotropin production. Males with this mutation are often resistant to gonadotropin stimulation because of impaired spermatogenesis. Steroidogenic factor 1 (SF1), another nuclear receptor that regulates gene transcription in both the adrenal gland and the gonads, caused both adrenal and gonadal agenesis when knocked out in a murine model.[60] Human SF1 mutations were associated with XY sex reversal and adrenal failure.[61] It is now thought that *DAX1* represses transcription of nuclear receptors, including SF1, and that loss of *DAX1* function causes a variety of adrenal, pituitary, and hypothalamic abnormalities.[50]

Hypogonadotropic Hypogonadism and Obesity Syndromes

Mutations in leptin[62] and the leptin receptor[63] have been identified in morbidly obese patients with normosmic IHH. It is leptin's effects on the release of NPY that are likely responsible for its effects on GnRH secretion.[64] Mutations in prohormone convertase 1 (PC1) also cause morbid obesity and hypogonadotropic hypogonadism, as well as hypocortisolemia (with elevated proopiomelanocortin) and hypoinsulinemia (with elevated proinsulin).[65]

Adult-Onset Idiopathic Hypogonadotropic Hypogonadism

An acquired form of GnRH deficiency was described in 1997 in 10 men who presented with decreased libido, impotence, and infertility at a mean age of 35 years, after undergoing normal puberty. None had features of congenital GnRH deficiency (anosmia, synkinesia, cleft palate, or a family history of GnRH deficiency), and none had a tumor, a history of radiation, infection, or infiltrative disease that might have explained their abnormal gonadotropin and sex steroid levels. Treatment with pulsatile GnRH reversed the hypogonadism and restored fertility in the subset of men who received long-term therapy.[66] Recent data show that some men with IHH, carry a mutation in the *FGF8* gene, and have normal reproductive function before onset of hypogonadism[67] suggesting a combination of genetic and environmental infuences.

Diagnosis of Idiopathic Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism should be included in the differential diagnosis for any patient with absent or incomplete pubertal development. In males, this can include microphallus, cryptorchidism, absence of facial hair, and small testes; and in women, incomplete or absent breast development, amenorrhea, or a eunuchoid body habitus. Obtaining a family history can also be helpful when considering a diagnosis of IHH. Whereas the incidence of delayed puberty in the general population is less than 1%, the incidence of delayed puberty among relatives of a series of 106 patients with IHH was 12%.[50] Because the GnRH pulse generator is quiescent until the onset of puberty (after an initial period of activation during infancy), the diagnosis of hypogonadotropic hypogonadism is usually not made until the age of 18 years, when such physical findings might prompt laboratory evaluation. Characteristic findings include low sex steroid levels (testosterone <100 ng/dL; $E_2 < 20$ pg/mL) in association with low or inappropriately "normal" gonadotropin levels. Assessment of other pituitary hormones should also be performed when hypogonadotropic hypogonadism is initially discovered. To exclude structural causes of GnRH deficiency, magnetic resonance imaging (MRI) is indicated in the evaluation of such patients. When laboratory studies and negative findings on imaging studies offer no other explanation for hypogonadotropic hypogonadism, a diagnosis of IHH or isolated GnRH deficiency is appropriate.

Management of Idiopathic Hypogonadotropic Hypogonadism

Therapy for patients with IHH depends on the degree of sexual maturity and the desire for fertility. For men with severe gonadotropin deficiency who have yet to complete puberty, hCG is used as a surrogate for LH to stimulate Leydig cell testosterone secretion, typically using an intramuscular dose of 2000 IU three times weekly. Plasma testosterone and sperm counts are followed every 4 to 8 weeks, and hCG doses are adjusted to maintain normal testosterone levels. Recombinant FSH (75-150 IU three times weekly) is often required to improve the quality of the sperm produced, although it may not be required for initiation of spermatogenesis in men with partial IHH and those with postpubertal onset of hypogonadism. Inability to achieve a normal sperm count after 6 months of hCG treatment alone and declining sperm count despite hCG are indications to add FSH.[68-70] Success with this combination is possible, regardless of previous exposure to testosterone, although individuals differ in the timing of their response to induction of spermatogenesis.[71,72] Restoration of fertility occurs as early as 4 months in some men, but can take more than 1 year in others. Even if spontaneous pregnancy does not occur, adequate sperm are usually present after combined hCG and FSH therapy such that assisted reproductive techniques, including *in vitro* fertilization with intracytoplasmic sperm insertion, are good options. Subcutaneous or intravenous administration of GnRH via pump has been shown to achieve spermatogenesis more rapidly than treatment with gonadotropins, but it is no longer available.[73] Once pregnancy is achieved, hCG but not FSH should be continued to maintain normal serum testosterone and some spermatogenesis to facilitate future pregnancies. Men who only desire virilization can be given intramuscular or topical testosterone, depending on their preferred mode of administration.[35]

Cyclic estrogen and progesterone should be given to female patients to induce normal sexual development and

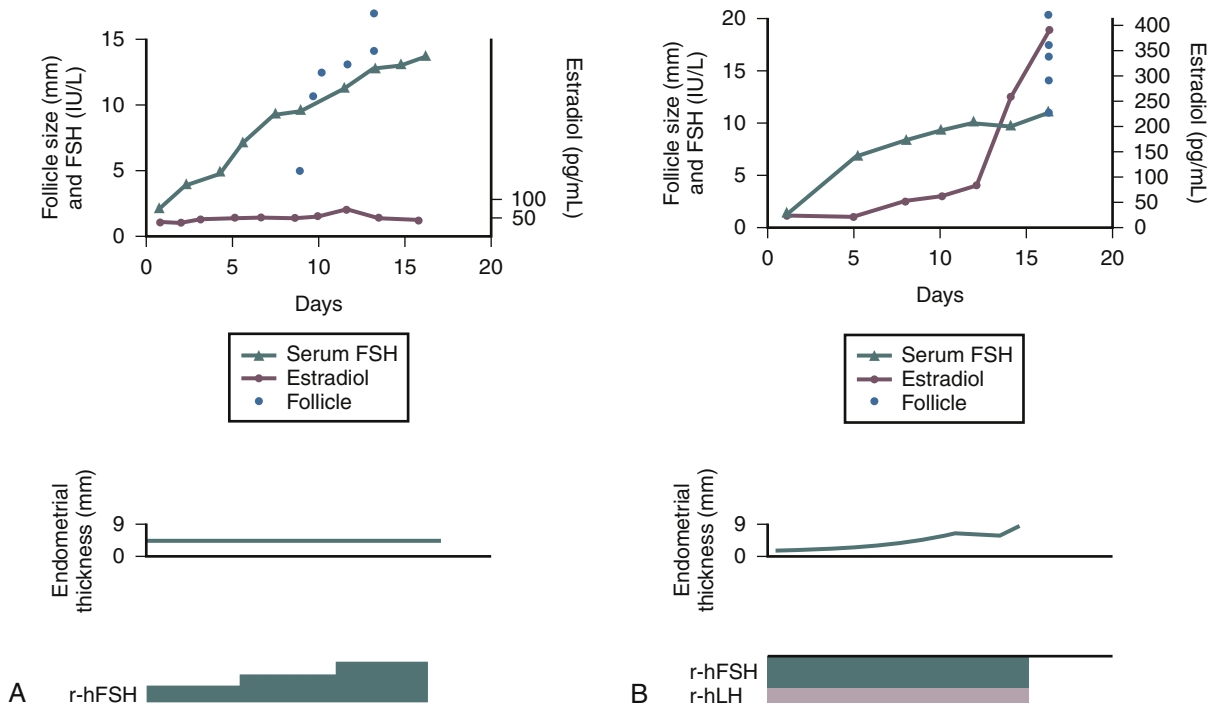

FIGURE 21.2 Ovarian response to recombinant follicle-stimulating hormone (r-hFSH) **(A)** or a combination of recombinant FSH and luteinizing hormone (r-hLH) **(B)** in women with severe hypogonadotropic hypogonadism. Follicle size and endometrial thickness were monitored by transvaginal ultrasonography. *(Modified from Shoham Z, Mannaerts B, Insler V, Coelingh-Bennink H. Induction of follicular growth using recombinant human follicle-stimulating hormone in two volunteer women with hypogonadotropic hypogonadism.* Fertil Steril *59:738, 1993.)*

preserve normal bone mineral density (BMD), although progesterone should not be added until breast development is complete.[48] Women who desire fertility should receive exogenous gonadotropins to stimulate ovulation. Recombinant FSH alone can induce follicular growth, as shown in Figure 21.2A, and has been shown to be as effective as highly purified FSH in achieving pregnancy, with a lower risk of ovarian hyperstimulation.[74] However, women with severe hypogonadotropic hypogonadism require some source of LH to generate adequate androgen precursors for aromatization to E_2, as illustrated in Figure 21.2B.[75] E_2 is required for endometrial proliferation and creation of a uterine environment optimal for implantation.[76,77]

Treatment with hCG (75 IU daily) may be used in such cases to maintain adequate E_2 concentrations. In women with baseline LH levels of greater than 1.2 IU/L, FSH alone may be sufficient to stimulate follicular growth as well as ovarian steroidogenesis. Once adequate follicular development and E_2-induced endometrial proliferation have occurred, exogenous recombinant hCG (250 μg) can be used to induce ovulation and is as effective as urinary hCG.[78] Recombinant formulations of LH are available, but their shorter half-life and higher cost preclude their widespread clinical use. Provision of luteal-phase progesterone is also recommended. When using FSH and hCG in combination, a woman's chance of conception is approximately 70% after six cycles. Such treatment does carry a risk of ovarian hyperstimulation and multiple gestations, and these risks are higher than those associated with pulsatile GnRH therapy when it was available.[79] For this reason, close monitoring with transvaginal ultrasound is required in women receiving gonadotropin therapy. In addition, pregnancies in women with hypopituitarism should be considered high risk because they are associated with higher rates of spontaneous abortion, possibly reflecting a uterine environment devoid of important endocrine growth factors.[80]

In addition to issues surrounding hormone replacement therapy and fertility treatment, there are other considerations when treating patients with IHH. Those with anosmic IHH and a family history suggestive of an X-linked mode of inheritance should have an abdominal-pelvic ultrasound at the time of diagnosis to assess for possible renal agenesis, given the relatively high frequency of this nonreproductive abnormality in patients with a *KAL1* mutation. Genetic testing is not routinely employed in patients with IHH because the majority of cases are sporadic. However, limited genetic testing is available for patients suspected of carrying a *KAL1* mutation. Research laboratories can also investigate for point mutations in *KAL1* or *FGFR1* and *GnRHR* gene mutations.[35]

Prognosis for Recovery

Until recently, it was believed that lifelong hormone therapy was required to maintain secondary sex characteristics and sexual function in men with IHH, but recent reports of testicular growth in men receiving maintenance androgen replacement therapy led to the identification of a minority of patients (10%) in whom reversal of IHH occurs. Such reversal can occur in men who underwent partial puberty or who were prepubertal at the time of diagnosis, and in men with either anosmic or normosmic IHH. It is believed that exposure to sex steroids promotes plasticity of the GnRH neuronal network, such that gradual reversal of IHH is possible, even in the face of genetic defects in men who

are treated with androgen replacement therapy. Thus, men being treated for IHH should have their hypothalamic–pituitary axis reassessed periodically so that such reversal can be identified.[81,82]

Structural Disease of the Hypothalamus

Mass lesions in the hypothalamus can also disrupt the secretion of GnRH into the hypothalamic–hypophyseal portal circulation and cause hypogonadotropic hypogonadism. Such cases usually cause other pituitary hormone abnormalities as well. Distinguishing hypothalamic mass lesions from pituitary mass lesions requires MRI. Dynamic testing with hypothalamic-releasing hormones is not used clinically, with the exception of CRH, which is used in combination with inferior petrosal sinus sampling (IPSS) to determine whether hypercortisolemia is of pituitary or ectopic origin.

Tumors

Craniopharyngioma

Craniopharyngiomas are rare, almost always benign, epithelial tumors arising from remnants of the craniopharyngeal duct that occur with an annual incidence of 0.13 cases per 100,000 person-years.[83,84] They are the most common lesions involving the hypothalamic–pituitary region in children, and account for 5.6% to 15% of the intracranial neoplasms in this population (2% to 5% in adults).[85,86] Craniopharyngiomas affect men and women at equal rates, and no genetic susceptibility has been identified.[83] They are histologically benign lesions, usually cystic or mixed (84% to 99%) rather than solid (1% to 16%).[87] Two subtypes have been identified adamantinomatous and papillary. The adamantinomatous type is more common in children and often contains calcification. Although tumor margins are usually sharp, adamantinomatous craniopharyngiomas tend to generate significant reactive gliosis in the adjacent normal brain tissue, making complete surgical resection difficult. Cysts may be multiloculated and contain viscous fluid rich in desquamated squamous epithelial cells and cholesterol.[84] Because of its sometimes brown-green appearance of this cystic fluid, the term "motor oil" has been used to describe it. A recent preliminary study showed that nuclear accumulation of b-catenin is present in adamantinomatous craniopharyngiomas, but not in papillary craniopharyngiomas.[88] The strong beta-catenin expression indicates the reactivation of the Wnt signaling pathway, which is involved in the development of several neoplasms.[89] The papillary subtype is seen almost exclusively in adults and is rarely associated with calcification. Papillary craniopharyngiomas tend to be solid or mixed rather than purely cystic, and they are less likely to infiltrate surrounding normal brain tissue, making surgical resection easier.[90] Papillary craniopharyngiomas usually lack the peripheral palisading of epithelial cells, cystic change, calcification, and the cholesterol depots found in the adamantinomatous type.

Craniopharyngiomas almost always have a suprasellar component and are rarely purely intrasellar,[91] as the images in Figure 21.3 show. Because of their proximity to vital neural structures and their significant size at the time of diagnosis (58% to 76% are between 2 and 4 cm), they frequently present with headache, nausea, vomiting, visual disturbances, growth failure (in children), and hypogonadism (in adults), although the rate of tumor growth also determines the severity of symptoms.[84,90] Bitemporal hemianopsia is the most common visual complaint, occurring in almost 50% of cases. Hydrocephalus can be present, occurring more frequently in children than in adults for unclear reasons (41% to 54% versus 12% to 30%).[84] With the exception of hydrocephalus and its associated symptoms, there was no difference in symptom duration or extent of hormone deficiency between children and adults with craniopharyngiomas.[91]

Both computed tomography (CT) and MRI can be helpful in diagnosing craniopharyngiomas. CT can show calcification that is characteristic of the adamantinomatous subtype, whereas MRI with gadolinium enhancement provides better structural analysis. The appearance of the craniopharyngioma depends on the proportion of solid and cystic components and the content of the cyst.[92] The solid tumor part is iso-or hypointense compared to the brain on precontrast T1 sequences and shows enhancement after contrast. On T2 sequences the signal is mixed, hypo- or hyperintense.[93] The cystic component is hypointense on T1 and hyperintense on T2. If there is protein, cholesterol, or methemoglobin present, then there may be a high T1 and a low T2 signal.[94] The cyst can show a peripheral contrast-enhancing rim in the T1 postcontrast images.[93] When the findings of imaging studies are consistent with craniopharyngioma, surgical resection is usually the initial therapy, although radiation therapy (RT) has been used for small lesions not causing pressure-related visual, neurological, or endocrinological damage. The surgical approach depends on tumor size, location, and degree of calcification, and the experience of the surgeon, but often involves craniotomy and sometimes a two-stage process. Preoperative drainage of large cystic components in the days before surgery can relieve pressure-related symptoms and make surgical resection easier, although cyst cavities refill if surgery is delayed by weeks. Gross total resection is the goal in all cases, but it often cannot be achieved because of tumor size and adherence to vital neurovascular structures.[84]

Unfortunately, craniopharyngiomas often recur even after gross total resection has been achieved and confirmed radiographically. Recurrence rates at 10 years vary from 0% to 62%, but improve with use of adjuvant RT. Recurrence-free survival correlates best with extent of surgical removal; age, sex, location (intrasellar versus suprasellar), and size of the tumor at the time of surgical resection do not predict recurrence. Some reports suggest that recurrent craniopharyngiomas show a higher microvessel density, lower levels of galectin-3 and macrophage migration inhibiting factor, and lower levels of retinoic acid receptor beta and higher levels of retinoic acid receptor gamma.[84] Management of recurrent disease usually involves RT rather than repeated surgery because of the perioperative morbidity and mortality associated with the latter. In fact, surgery for recurrent disease is only recommended in the event of acute pressure-related symptoms.[84] The 10-year progression-free survival rate from the time of the first recurrence was 72% in a series of 25 patients who received RT.[95] Other options for the management of recurrences include brachytherapy (for predominantly cystic lesions), bleomycin installation via an Ommaya reservoir, and stereotactic radiosurgery.[84,96]

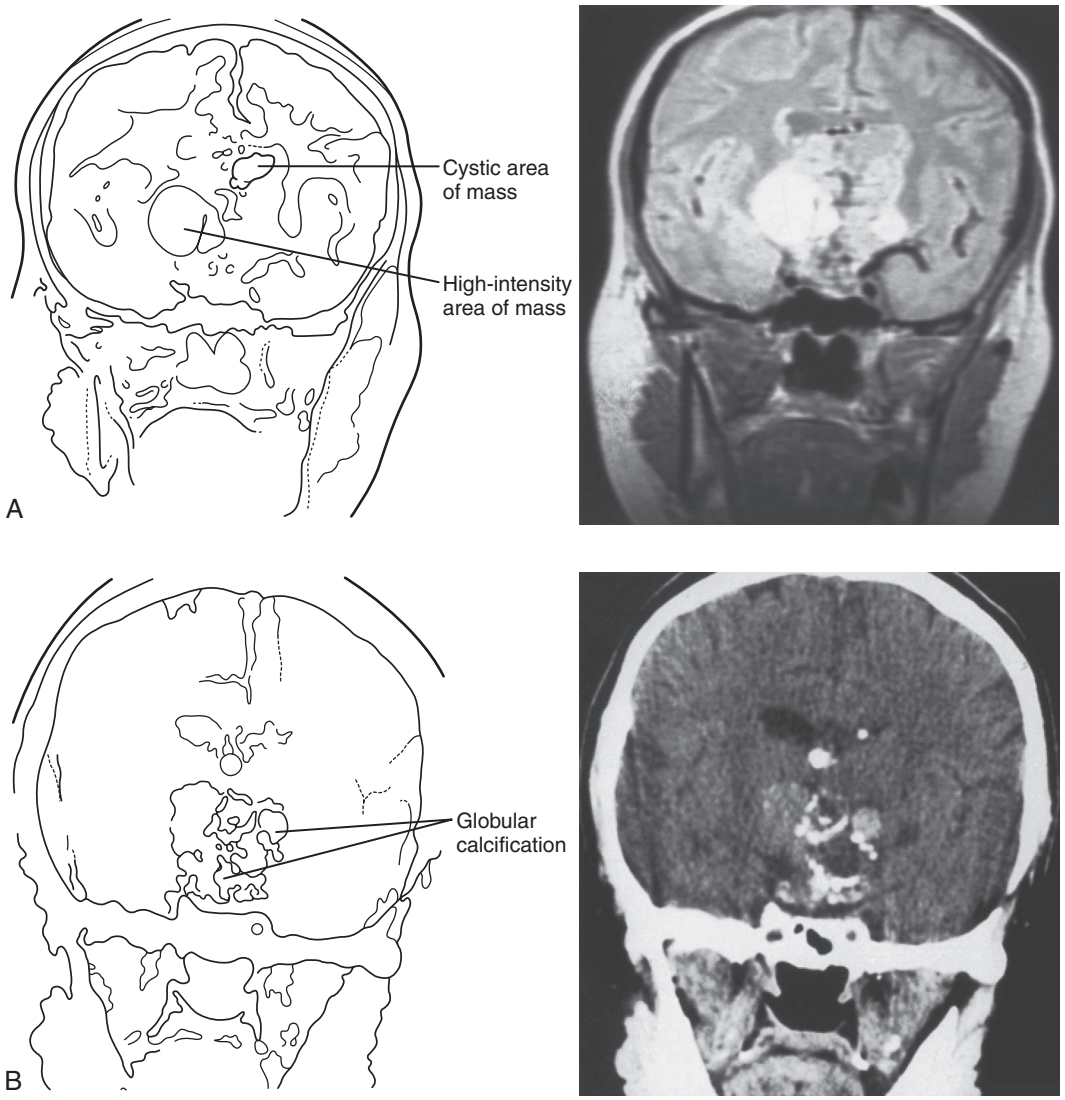

FIGURE 21.3 **A,** Schematic and proton-density–weighted coronal magnetic resonance imaging showing a cystic area and a high-intensity signal area in a large sellar-suprasellar mass, typical of craniopharyngiomas. **B,** Characteristic globular calcification is apparent on a coronal computerized tomography image of the same patient. *(Modified from Peebles T, Haughton VM. Neuroradiology and endocrine disease. In Besser GM, Thorner MO [eds].* Comprehensive Clinical Endocrinology, *3rd ed. London, Elsevier, 2002.)*

The endocrine, visual, and neuropsychological morbidities associated with craniopharyngiomas are significant. At the time of presentation, 35% of the patients in Van Effenterre's cohort had one to three hormone deficits.[97] After treatment, the frequency of individual hormone deficits varies significantly across studies (88% to 100% for growth hormone [GH], 80% to 95% for FSH and LH, 55% to 88% for adrenocorticotropic hormone [ACTH], 39% to 95% for TSH, and 25% to 86% for antidiuretic hormone [ADH]) and is not affected by the type of therapy. Unlike pituitary adenomas, it is very unusual for patients with pretreatment hormone deficits to experience restoration of those axes after treatment, but pituitary hormones can be replaced relatively easily. Visual defects (i.e., quadrantanopia or worse) are present in the majority of patients after surgery with or without adjuvant RT.[98] Potentially more disabling are the consequences of hypothalamic damage that occur so commonly in patients with craniopharyngiomas. Obesity secondary to hyperphagia affects 26% to 61% of patients who undergo surgery with and without adjuvant RT.[84] Diabetes insipidus (DI), with an impaired sense of thirst resulting in water and electrolyte imbalances, was present in 14% of a pediatric cohort.[99] Neuropsychological and cognitive functions often decline in patients with craniopharyngiomas. At follow-up 7 years after initial treatment, 16% of the adults and 26% of the children in Van Effenterre's cohort were not living independently and had not returned to their previous jobs or schools.[97] Mortality rates three to six times higher than those of the general population have been reported in patients with craniopharyngiomas.[84]

Rathke Cleft Cyst (RCC)

RCCs are the most common incidentally discovered sellar lesion. They are found in 13% to 33% of normal pituitary glands. They are discovered usually later in life with a peak between the 4th and 6th decades, which is most likely due to the fact that they grow slowly[100-102] and symptoms occur later in life. RCC originates from embryonic remnants of

the Rathke pouch which extends cranially to form the craniopharyngeal duct. The pouch is derived from the ectodermal stomadeum (primitive oral cavity). The Rathke pouch cells proliferate and form the pars anterior of the pituitary and the cells from the posterior wall differentiate into the pars intermedia. The pouch involutes and the craniopharyngeal duct obliterates. If the obliteration of the lumen does not occur, then a cyst develops and the remnants in the craniopharyngeal canal develop into cystic lesions ranging from simple RCCs to complex craniopharyngiomas.[102] RCCs are benign lesions which can range from a few milimeters to 5 cm. The content of the cyst is mostly thick and can consist of cholesterol and proteins. The cyst wall is lined by cuboid or columnar epithelium and occasionally with goblet cells secreting mucous into the cyst. RCCs and craniopharyngiomas have overlapping pathological features and are sometimes difficult to distinguish. Co-existence of RCCs with pituitary adenomas has been shown in 0.5% to 1.7%. Of these adenomas, GH secreting pituitary adenomas and prolactinomas are the most frequently described coexisting with RCCs. Location of RCCs are usually in the pars intermedia sometimes with suprasellar extension. Symptoms usually do not occur until the cyst is large enough to put pressure on the surrounding structures. The most common symptom includes headaches. The presence of headaches does not correlate with the cyst size, but seems to be related to either high or isointense content on T1-weighed MRI, mucous cyst content or cystic wall inflammation. Major visual field defects are present in up to 75% of cases and anterior pituitary hormone deficits are present in 19% to 81% of patients. Hypogonadism because of hyperprolactinemia is the most frequent hormonal manifestation. MRI often shows a hypointense lesion with rim enhancement and a hyperintense signal in the T-2 weighted images. Hyperintensity on T1-weighted images and isointensity on T2-weighted images suggests mucoid material is present in the cyst; hyperintensity in both T1- and T2-weighted images suggests the presence of blood. Cysts with high protein content show a high T1 signal intensity.[102] Only 13% of RCCs show calcification on CT. Asymptomatic, small RCCs are treated conservatively without surgery. If symptomatic, the aim is to drain the cyst content and to remove as much of the capsule as possible. Radiation is usually not used routinely for treatment with the exception of recurrent cysts. The 4-year recurrence rate has been reported to be 48%; the presence of squamous metaplasia in the cyst wall is associated with a higher risk of recurrence.

Germ Cell Tumors

Germ cell tumors (GCTs) are believed to result from malignant transformation and abnormal migration of primordial germ cells. They are characterized by their secretion of hCG and alpha-fetoprotein (αFP). Intracranial GCTs occur most commonly in the pineal region (50%) and in the anterior hypothalamus (30%).[103] They account for 2.9% of all intracranial tumors in children and have a peak incidence between ages 10 and 14 years old.[104] Presenting symptoms depend on tumor location: nausea, vomiting, diplopia, and paralysis of upward gaze (Parinaud syndrome) occur with pineal gland tumors, whereas suprasellar lesions can cause hypopituitarism, DI, and visual deficits.[103] Histologically, GCTs are often cystic and are classified as germinomatous GCT (GGCT) or nongerminomatous GCT (NGGCT). NGGCTs account for the minority of intracranial GCTs and include choriocarcinomas, teratomas, embryonal carcinomas, and yolk sac tumors. Serum hCG and AFP levels tend to be elevated in NGGCTs, whereas only a minority of patients with GGCTs have an abnormal serum hCG.[105] Stereotactic biopsy is indicated when the diagnosis is unclear from imaging studies and serum hCG and AFP levels. If a diagnosis of GGCT is made, therapy usually consists of radiation rather than resection, given the radiosensitivity of GGCTs and the neurological morbidity associated with surgery. Chemotherapy is an alternative therapy, but is associated with a higher recurrence rate when used in the absence of RT.[106] NGGCTs are less radiosensitive and, therefore, carry a poorer prognosis. However, platinum-based chemotherapy, in combination with craniospinal RT, is often used, followed by surgical resection if a residual mass persists.[107,108]

Other lesions occurring in the pineal region include pineal parenchymal tumors, astrocytomas, meningiomas, metastases, cysts, and vascular malformations. Hypothalamic–pituitary function can be disturbed by any of these.

Infiltrating Diseases

Sarcoidosis

Sarcoidosis is a multisystem disease of activated T lymphocytes and noncaseating granulomas that commonly affects the lungs, lymph nodes, eyes, and skin, but can involve the CNS and peripheral nervous system in 10% to 20% of cases. Neurological symptoms can be the presenting sign of disease in 50% of the latter group of patients and can increase morbidity and mortality. CNS lesions can appear as subdural plaques or infundibular plaques, infiltrating intraparenchymal pseudotumoral masses, or as multiple nodules on MRI studies. Although hypothalamic–pituitary lesions may not be evident on MRI, 25% to 33% of patients with neurosarcoidosis have DI and autopsy studies in such patients show extensive granulomatous inflammation of the hypothalamus, with little pituitary involvement. DI results from vasopressin deficiency and destruction of neurons in the neurohypophysis, but damage to the osmoreceptor controlling thirst also contributes to polyuria and polydipsia. Other symptoms of hypothalamic disease include somnolence, body temperature dysregulation, hyperphagia, and obesity.[109,110] Impaired secretion of anterior pituitary hormones also occurs; GH and gonadotropin deficiencies occur more commonly than TSH or ACTH deficiency.[110] In Murialdo and Tamagno's Italian series of 91 patients, 39% had hypogonadotropic hypogonadism, and 59% of the women in the study ($n = 46$) reported amenorrhea.[109]

As with other forms of sarcoidosis, confirmation of neurosarcoidosis requires histological evidence of noncaseating granulomas and lymphocyte infiltration of affected tissue, but obtaining nervous system tissue can be difficult. However, a probable diagnosis can be made with the proper clinical picture and imaging studies (i.e., MRI; Fig. 21.4). PRL elevation can be a useful screen for hypothalamic involvement. Results of cerebrospinal fluid (CSF) analysis are abnormal in 80% of patients with CNS sarcoid, and can include elevations in protein, lymphocytes, or angiotensin-converting enzyme levels.[109]

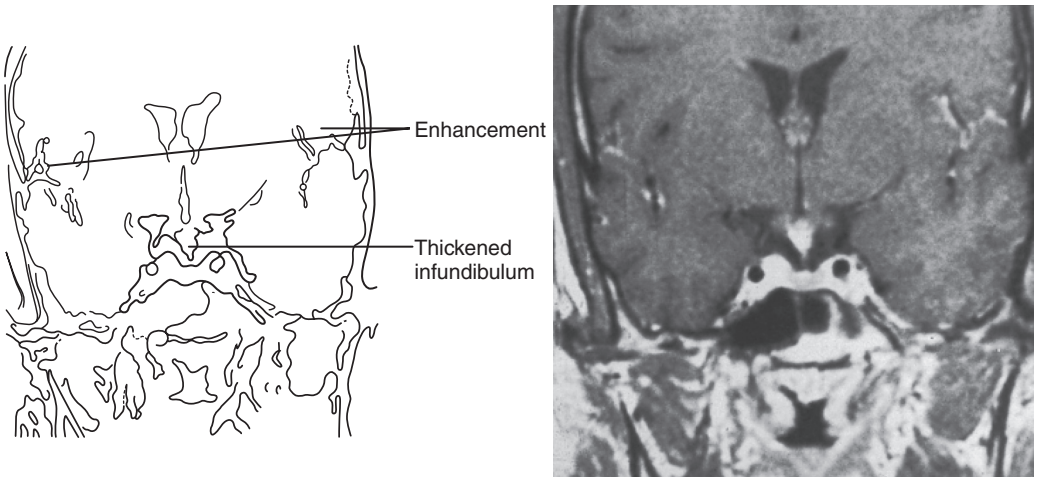

FIGURE 21.4 Schematic and T1-weighted magnetic resonance imaging after contrast administration showing a thickened, enhancing infundibulum typical of granulomatous disease, such as sarcoidosis. Enhancement in the sylvian fissure on the *left* and near the inner table on the *right* identifies leptomeningeal involvement. *(Modified from Peebles T, Haughton VM. Neuroradiology and endocrine disease. In Besser GM, Thorner MO [eds].* Comprehensive Clinical Endocrinology, *3rd ed. London, Elsevier, 2002.)*

Prednisone (up to 40 to 80 mg daily) is the mainstay of treatment for neurosarcoidosis, as it is for other forms of the disease, although therapy is often intensified in CNS disease. Cyclosporine A (4 to 6 mg/kg) is often added to minimize glucocorticoid requirements. RT is employed in patients who do not respond to oral medications. Unfortunately, anterior pituitary deficiencies usually are not restored, despite treatment. Dopaminergic agents can be used to decrease PRL levels, but they will not restore fertility if hypogonadotropic hypogonadism is also present.[109]

Sarcoidosis can also infiltrate the epididymis and testes, resulting in painless epididymitis or a scrotal mass, both of which respond to glucocorticoids. Granulomatous involvement of the uterus and fallopian tubes has also been reported in women with sarcoidosis who present with amenorrhea or menorrhagia.[110] Thus, reproductive dysfunction in patients with sarcoidosis can be both primary and secondary to CNS disease.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is another multisystem disease of unknown etiology that has a predilection for the hypothalamus and pituitary. It is characterized by the clonal accumulation and proliferation of abnormal dendritic histiocytes, with accompanying lymphocytes, eosinophils, and neutrophils. These cellular infiltrative lesions can destroy a variety of tissues, including skin, bone, lymph nodes, liver, spleen, lungs, and bone marrow. Known previously as *Letterer-Siwe disease, Hand-Schüller-Christian disease, eosinophilic granuloma,* and *histiocytosis X,* LCH primarily affects children between the ages of 1 and 3 years old. It can remit spontaneously or disseminate, even resulting in death in rare cases.[111] Adults make up fewer than 30% of all reported cases of LCH, with an incidence of 1.8 cases per million people. LCH in adults more commonly affects the skin, lung, and bones.[112]

The hypothalamic–pituitary axis is involved in 5% to 50% of children with LCH,[94] with 15% to 50% of these children presenting with DI.[113,114] The incidence of DI increases over time. It is usually seen within 5 years of diagnosis, and occurs more often in the setting of multisystem disease.[115] DI was also the earliest hormonal abnormality in the adult cohort reported by Kaltsas and colleagues, 33% of whom presented with DI.[112] Anterior pituitary hormone deficiency occurs in approximately 20% to 35% of patients and is usually associated with DI. In a large pediatric cohort, the estimated 5- and 10-year risks of pituitary involvement with LCH were 22% and 24%, respectively. GH deficiency is the most common pituitary endocrinopathy, occurring in 10% of patients with LCH and increasing in frequency over time. Ear, nose, and throat involvement increases the risk of GH deficiency.[114] GH deficiency in the absence of DI is unusual,[113] but 54% of patients with DI who were followed for 10 years ultimately had GH deficiency.[114] GH replacement effectively improves the final height in children with GH deficiency, although midparental height is usually not achieved because children have fairly severe growth restriction at the time therapy is initiated.[113,114] Importantly, GH therapy did not increase the risk of LCH disease activity.[114] GH replacement in adults with LCH has not been well studied.

Gonadotropin deficiency also occurs in LCH, almost always in association with other anterior pituitary hormone deficiencies. Because most patients are prepubertal at the onset of disease activity, those with gonadotropin deficiency require exogenous sex steroids to induce and maintain puberty.[113] Fifty percent of the cohort of 12 patients reported by Kaltsas and colleagues had gonadotropin deficiency at a median of 7 years old after diagnosis of LCH, and exogenous gonadotropins successfully restored fertility in 1 male patient.[112]

Findings on MRI are abnormal in the majority of patients with LCH and endocrinopathy. Loss of the posterior pituitary bright spot on T1-weighted images and infundibular enlargement are the most common abnormalities, with the former observed in 100% of patients with DI.[113] As shown in Figure 21.5, other less common radiological abnormalities include a thickened infundibular stalk, a partially or completely empty sella, and lesions in the hypothalamus.[111]

Both children and adults with LCH and DI are at high risk for anterior pituitary deficits and should be followed

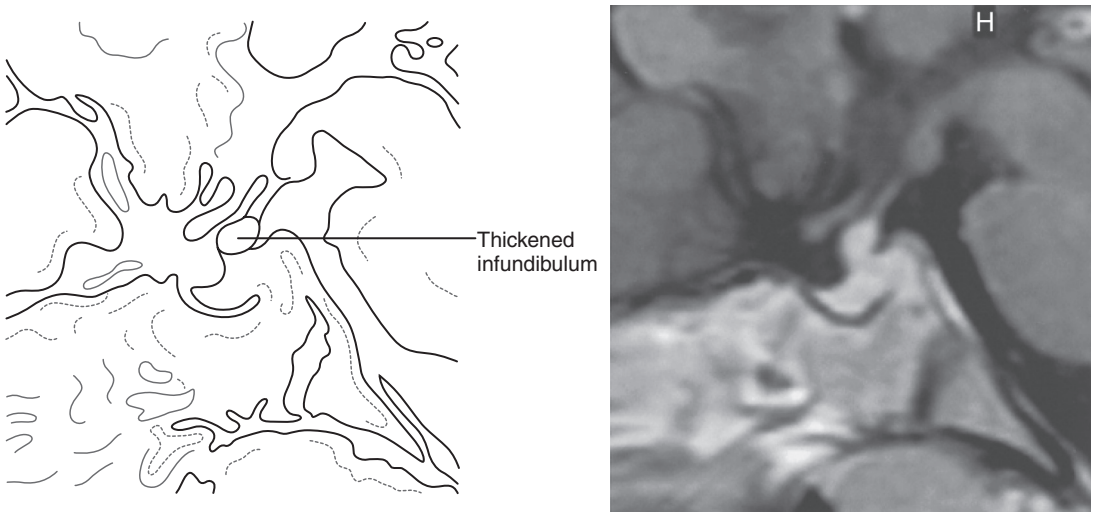

FIGURE 21.5 Schematic and sagittal T1-weighted contrast-enhanced magnetic resonance imaging showing a thickened enhancing infundibulum from known Langerhans cell histiocytosis (H). *(Modified from Peebles T, Haughton VM. Neuroradiology and endocrine disease. In Besser GM, Thorner MO, [eds].* Comprehensive Clinical Endocrinology, *3rd ed. London, Elsevier, 2002.)*

closely. Unfortunately, dynamic evaluation of pituitary function was not a useful predictor of later endocrinopathies.[116] DI and other hormonal deficiencies tend to be permanent once established, despite treatment of LCH lesions with radiation therapy, chemotherapy, or both. RT may be helpful for controlling localized disease and mass effects, however. Chemotherapy was not helpful in long-term disease management in adults.[112]

Other infiltrating diseases that can cause hypothalamic infiltration with resulting reproductive dysfunction include hemochromatosis (which more commonly affects the pituitary; discussed later in the chapter),[117] leukemia,[118,119] lymphoma,[120-122] and Wegener granulomatosis.[123-125] Central DI is often the presenting feature, and treatment of the underlying condition sometimes results in resolution of this and other associated hormonal abnormalities.[124,125] When associated with malignancies (leukemia, lymphoma), hypothalamic involvement is a poor prognostic feature and usually does not respond to treatment.[126]

Infections

Infections are a rare cause of hypothalamic–pituitary disease affecting the reproductive axis. They usually present acutely with fever, headache, meningismus, and change in mental status or seizure, and can be identified using culture, polymerase chain reaction, or detection of antibodies to viral antigens. Tuberculosis and atypical mycobacterial infections, viral encephalitis, mycotic infections, and bacterial meningitis can all cause infiltration of the hypothalamus or pituitary and result in hormonal deficiencies. Box 21.1 summarizes the classification of infiltrative, infectious, and other nontumoral diseases involving the hypothalamus that can cause hypogonadotropic hypogonadism.

Box 21.1 Classification of the Infiltrative, Infectious and Other Nontumoral Diseases Involving the Hypothalamus Causing Hypogonadotropic Hypogonadism

INFILTRATIVE OR AUTOIMMUNE DISEASES
- Sarcoidosis
- Langerhans' cell histiocytosis
- Lymphomatous diseases
- Castelman disease
- Wegener granulomatosis
- Vasculitis

INFECTIOUS DISEASES
- Tuberculosis
- Atypical mycobacterial infections
- Bacterial meningitis
- Encephalitis (viral)
- Mycotic infections

OTHERS
- Trauma
- Pituitary stalk section
- Radiation therapy
- Hydrocephalus and pseudotumor cerebri

Head Trauma

Head trauma has been recognized as a cause of neuroendocrine dysfunction for many years, but assessment of hypothalamic–pituitary function during acute and long-term management of patients with traumatic brain injury (TBI) occurs infrequently. TBI is most common in males between the ages of 11 and 29 (5:1 male-to-female ratio), and is the leading cause of death and disability among young adults.[127] Road accidents account for 75% of cases of TBI.[128] Most patients who have post-head trauma hypopituitarism (PHTH) were comatose for a period after their injuries, and all had Glasgow Coma Scale scores of less than 13. PHTH can result from structural injury to the hypothalamus or pituitary, but a vascular insult leading to cerebral swelling is the most likely mechanism in most cases.[129] Such localized edema increases intracranial pressure in the sellar or suprasellar regions and can temporarily impair hypothalamic–pituitary function. PHTH may also be an adaptive mechanism to the acute illness often associated with TBI.[127,130]

One third of patients studied 3 months to 23 years after head injury had at least one pituitary hormonal deficiency: 18% had an inadequate GH response to insulin tolerance testing, and 20% to 25% had insufficient responses to GnRH stimulation.[129] The frequency of gonadotropin deficiency was even higher (80% to 90%) when defined by low early morning testosterone or E_2 levels and inappropriately low FSH and LH levels.[127] TBI-associated neuroendocrine dysfunction only presents with DI in the minority of cases (25% to 30%). PRL elevation occurs in approximately 50% of patients and correlates negatively with Glasgow Coma Scale score, likely because it is a marker of pituitary stalk or hypothalamic damage.[127,128]

Unfortunately, PHTH is usually not diagnosed during hospitalization unless a patient has acute ACTH deficiency or DI. Because pituitary hormone deficiency eventually recovers in approximately 60% of patients with moderate to severe head injury, some deficiencies (i.e., GH, gonadotropin) may never be recognized.[129,130] Gonadotropin secreting cells appear to be the most sensitive to TBI, and patients with PHTH often present after hospital discharge with amenorrhea, erectile dysfunction, and infertility.[128] FSH and LH in such patients may be inappropriately low. Most hormonal deficits (75%) appear within 1 year after injury, but diagnosis can be delayed by 5 or more years in 15% of patients.[128] In patients with a known history of TBI whose anterior pituitary function is initially normal, repeat evaluation during follow-up care may be indicated, given the delayed appearance of hypopituitarism in some cases.

Radiaton Therapy

Hypothalamic–pituitary dysfunction after cranial irradiation has long been recognized to occur in survivors of childhood cancer and in patients who receive high-dose RT for nasopharyngeal carcinoma[131,132] or pituitary disease.[133] However, not until recently has the high frequency of endocrine dysfunction in adult survivors of nonpituitary brain tumors who receive RT been recognized.[134] This frequency is only likely to increase with the improvements in prognosis for both children and adults with primary brain malignancies. Of a cohort of 56 patients with primary brain tumors who had received their last dose of RT at least 1 year before the time of study, 23 (41%) showed evidence of hypopituitarism with multiple (25%) or single (16%) hormone deficiencies. GH deficiency was most common, followed by gonadotropin, ACTH, and TSH deficiency.[135] DI is rarely associated with radiation-induced hypopituitarism. The risk of hormonal deficiency depends on the total dose, fraction size, number of fractions received, and total duration of RT. Panhypopituitarism can occur when the total dose exceeds 60 gray (Gy), but this risk can be reduced by administering more fractions of smaller dose, thereby extending treatment time.[136]

The rates of gonadotropin and GH deficiency in adults are significantly lower than those observed in pediatric studies, in which 20% to 50% of patients eventually have partial or severe gonadotropin deficiency[134,137] and GH deficiency occurs in 80% to 100%.[135] It is thought that the hypothalamic–pituitary axis is more radiosensitive in children than in adults.[135,138,139] Doses exceeding 50 Gy in childhood can cause gonadotropin deficiency, but smaller doses can result in precocious puberty. In low-dose cranial irradiation used prophylactically in children being treated for acute lymphocytic leukemia, girls are more susceptible to early puberty than boys, but this sexual dichotomy disappears when higher doses (25 to 50 Gy) are used to treat primary brain tumors.[136] In a pediatric cohort with preexisting GH deficiency, the relationship between age at time of irradiation and age at onset of puberty was linear.[140] The severity of gonadotropin deficiency varies in postpubertal subjects, from low normal to frankly low sex hormone levels.

The site of radiation-induced injury is the hypothalamus, and postradiation studies show normal responses to hypothalamic-releasing hormones, including GnRH.[141] The mechanism of this radiation-induced damage is unclear, but may involve direct damage to hormonally active cells or to their surrounding microvasculature. Alternatively, radiation may damage the vascular connections between the hypothalamus and the pituitary.[134,135] Hormone deficiencies may not become evident for many years,[142] because the radiation-induced damage takes its toll on the slowly dividing cells of the hypothalamus and secondary pituitary atrophy occurs after previous hypothalamic damage.[134-136] The delayed appearance of these deficits mandates that such patients be followed annually for these late effects of radiation.

Gonadal damage is also a concern in patients treated for primary brain tumors, but usually occurs as a result of adjuvant chemotherapy or spinal RT. Alkylating agents, procarbazine, cisplatin, and vinblastine are chemotherapeutic agents often associated with gonadal toxicity, whereas gonadal damage secondary to spinal RT occurs from radiation scatter.[136] Sixty-four percent of girls who received craniospinal irradiation but no chemotherapy had evidence of primary ovarian failure over 8 years of follow-up.[143] Sex steroids and germ cells are both lost in female patients treated with RT or chemotherapy, whereas males may present with infertility with normal levels of testosterone as a result of a differential effect of cancer therapy on Leydig cell function and spermatogenesis.[136]

Treatment for radiation-associated infertility secondary to disruption of the hypothalamus or pituitary requires replacement of gonadotropins. Physiological exogenous pulsatile GnRH therapy restored ovulation in the majority of women when it was clinically available.[144] Theoretically, cryopreservation of embryo, sperm, oocyte, or ovarian tissue can be used to preserve fertility when cancer treatment is expected to cause gonadal damage. However, each has significant drawbacks and none is routinely employed.[145,146]

Seizure Disorders

Epilepsy is a relatively common condition, with a prevalence of 5:1000 to 9:1000 and has been associated with subfertility in numerous epidemiological studies. The background rate of menstrual dysfunction (50% to 60%) far exceeds that of the general adult female population.[147] PCOS is the most common form of reproductive dysfunction in this population and affects up to 25% of epileptic women, although hypothalamic amenorrhea and luteal phase deficiency (LPD) can also occur.[148] The diagnosis of PCOS was unrelated to the type of epilepsy.[148]

Both seizures themselves and the antiepileptic drugs (AEDs) used to treat them have been implicated as the cause for reproductive dysfunction in patients with epilepsy. Epileptiform discharges transiently increase PRL and may disrupt GnRH pulsatility, a hypothesis suggested by observations of altered LH pulse frequency in regularly menstruating women with epilepsy who were not taking AEDs.[148,149] The similar rates of PCOS among medicated and unmedicated women with epilepsy also provide evidence that seizure activity itself interferes with normal reproductive function.[147,148] In addition, the use of AEDs (specifically, VPA) in normal women and those with other conditions (bipolar affective disorder) does not increase the risk of PCOS or affect baseline LH pulse dynamics, gonadal hormones, or rates of oligomenorrhea,[150-152] arguing for the position that epilepsy itself is responsible for interfering with reproductive function in some women.

Antiepileptic drug therapy, especially VPA, appears to worsen the central reproductive dysfunction caused by epilepsy itself. VPA has been shown to augment LH secretion in response to GnRH in healthy women, presumably via its stimulatory effects on glutamic acid decarboxylase and its inhibitory effects on GABA transaminase, ultimately leading to an increase in brain GABA activity.[150,153] No association between PCOS and the use of any specific AED was apparent in a relatively lean cohort of epileptic women reported by Bilo and colleagues,[154] but polycystic ovaries and hyperandrogenism were observed in 70% of a Finnish cohort receiving VPA monotherapy.[155] The frequency of menstrual disorders, polycystic ovaries, and hyperandrogenism was increased in both lean and obese women, but was higher in the latter.[156] Anovulatory cycles occurred in 43% of women who were currently using VPA or had done so within the previous 3 years, whereas only 10% of cycles were anovulatory in women with generalized epilepsy who had never taken VPA.[157] Although VPA is associated with weight gain, the changes observed in serum androgens (testosterone, androstenedione) occurred as early as 1 to 3 months after initiation of VPA and before any significant changes in body weight.[158] These observations suggest that VPA-associated PCOS in women with epilepsy is likely multifactorial in origin, with genetic and environmental factors playing some role.[148,159,160] In addition, the initiation of VPA before the age of 20 years was a risk factor for future development of PCOS.[155] Although VPA has never been shown to increase LH secretion, it may have direct ovarian effects, which in combination with the GnRH pulse generator dysfunction described earlier, ultimately lead to the hyperandrogenemia characteristic of many epileptic women receiving VPA.[160]

Ovulatory dysfunction related to AEDs may also arise as a result of alterations in cytochrome P450 activity. Phenytoin, phenobarbital, and carbamazepine induce cytochrome P450 activity, thus increasing sex hormone–binding globulin (SHBG) synthesis and reducing bioavailable testosterone and E_2 levels.[160] VPA inhibits cytochrome P450 enzyme activity and increases androgen concentrations.[157] However, these changes in bioavailable hormone levels are not always significant enough to alter reproductive function, and women taking carbamazepine have never been shown to have a higher risk of menstrual dysfunction, hyperandrogenemia, or PCOS.

Unfortunately, anovulatory cycles can be the only sign of epilepsy-associated reproductive dysfunction. Thus, an awareness of the effect of the disease and its treatment on patients' reproductive health should be part of routine care for women with epilepsy.[157] Menstrual cycle duration and body weight should be monitored regularly in women taking AEDs, especially VPA, so that reproductive abnormalities are not overlooked.[160] When such changes develop, switching women to other AEDs, such as lamotrigine, in consultation with their neurologist, can reverse the adverse reproductive and metabolical phenotype associated with AED treatment.[161]

Men with epilepsy also have reproductive endocrine abnormalities and are 36% less likely than unaffected male siblings to be biological fathers.[162] Approximately one third of men with temporolimbic epilepsy have hypogonadism,[163] and reductions in sperm count or motility as well as abnormal sperm morphology are observed in 8% to 90% of men, regardless of AED use.[164,165]

Functional Alterations and Disorders of the Hypothalamus

Physiological Hypogonadotropic Hypogonadism

Pubertal Transition

Hypogonadotropic hypogonadism can be physiological during certain phases of life. GnRH neurons are temporarily activated during infancy, producing midpubertal levels of either testosterone or E_2. After 6 months of age, however, GnRH neurons become quiescent, and gonadotropin levels and sex steroid levels fall. This *physiological hypogonadotropic hypogonadism of prepuberty* persists until approximately 8 to 9 years of age, when serum LH, FSH, and E_2 levels begin to rise, primarily overnight.[50,166] Over the course of puberty, mean LH increases 116-fold, FSH increases 7-fold, and E_2 increases twelvefold.[167] These changes are shown in Figure 21.6.

These gonadotropin changes directly reflect hypothalamic GnRH release because they can be simulated by exogenous GnRH administration,[168] can be blocked by GnRH antagonist administration,[166] and can occur in the absence of functioning gonadal tissue.[169] The factors mediating this reactivation of the GnRH pulse generator in early puberty are still unclear,[169] as are the factors permitting the progressive increase in daytime LH that occurs during puberty. Because hypogonadotropic hypogonadism is normal during puberty, distinguishing it from pathological causes of hypogonadotropic hypogonadism becomes difficult during adolescence. Both are characterized by absent or incomplete sexual maturation, low gonadotropin concentrations, low sex steroid levels (testosterone <100 ng/dL; $E_2 <20$ pg/mL), and no evidence of other hypothalamic–pituitary axis abnormalities. The α subunit response to GnRH injection was used in the past to separate these two conditions; adolescents who ultimately had the former condition had little α subunit production after GnRH, indicating pituitary disease.[170] However, the current unavailability of GnRH forces clinicians to rely on clinical features and family history rather than laboratory data to distinguish constitutional delay of growth and puberty (a normal variant characterized by hypogonadotropic hypogonadism) from more sinister causes of delayed puberty.

In Besser GM, Thorner MO [eds].* Comprehensive Clinical Endocrinology, *3rd ed. London, Elsevier, 2002.)*

Postpartum Period

The postpartum period is another time in life in which hypogonadotropic hypogonadism is physiological. Amenorrhea occurs in all women after childbirth. High levels of E_2 and progesterone during pregnancy are initially responsible for this hypothalamic–pituitary suppression. However, amenorrhea persists for varying durations into the puerperium and is prolonged further in women who breastfeed.[171] FSH levels remain low (similar to those seen in the early follicular phase), mean LH and LH pulse frequency are reduced, and serum E_2 and progesterone are low.[172] The mechanisms responsible for this continued suppression of the hypothalamic–pituitary–gonadal axis are unknown.[173,174] PRL has been implicated because it is universally elevated in the immediate postpartum period and suppresses GnRH release. However, PRL declines long before menstrual cyclicity returns in lactating women, arguing that mechanisms other than hyperprolactinemia must be responsible for lactational amenorrhea.[175] The suckling stimulus itself increases PRL, as shown in Figure 21.7, but also increases the sensitivity of the GnRH pulse generator to the negative feedback effects of E_2, such that GnRH and LH pulse activity are nearly absent in the immediate postpartum period.[176] Both of these effects of suckling diminish with time, however.

Once they reappear, LH pulse patterns are initially erratic and are augmented by sleep, similar to the pattern observed in early puberty.[173,176] Follicle growth and associated E_2 production often return to normal before ovulation resumes because suckling impairs the normal positive feedback of E_2 that is required for the preovulatory LH surge. Thus, menses may return, but cycles may be anovulatory until the suckling stimulus decreases further and normal ovulatory cycles resume.[171,176] Additional evidence suggesting a hypothalamic etiology for lactational amenorrhea comes from studies in lactating women exposed to pulsatile exogenous GnRH. Midcycle LH surges occurred in these women, luteal phases were normal, and FSH declined appropriately in response to increasing levels of ovarian steroids.[177] The hypothalamic hypogonadism of lactation can persist for more than 12 months, depending on the frequency and intensity of suckling.[176] This endogenous contraception allows women to cope with the physiological demands of the postpartum period before considering additional pregnancies. Both puberty and the postpartum period illustrate the neuroendocrine control mechanisms that govern GnRH, and abnormalities can be seen in a number of pathophysiological states.

Pathophysiological Hypogonadotropic Hypogonadism

Hypogonadotropic Hypogonadism Associated with Altered Secretion of Thyroid Hormone, Cortisol, and Prolactin

The neuroendocrine components of the reproductive axis are highly sensitive to disturbances in other hormones, including thyroid hormone, cortisol, and PRL. Within this context, menstrual irregularity occurs in approximately 25% of women with any degree of *thyroid hormone deficiency*, although the prevalence increases with the severity of hypothyroidism. Oligomenorrhea and menorrhagia are the most common menstrual disturbances, and sexual dysfunction (hypoactive sexual desire, erectile dysfunction, and delayed ejaculation) is observed in the majority of men with hypothyroidism.[178,179] Men with hypothyroidism often have low free testosterone levels that improve with initiation of thyroid hormone replacement.[180] Hypogonadotropic

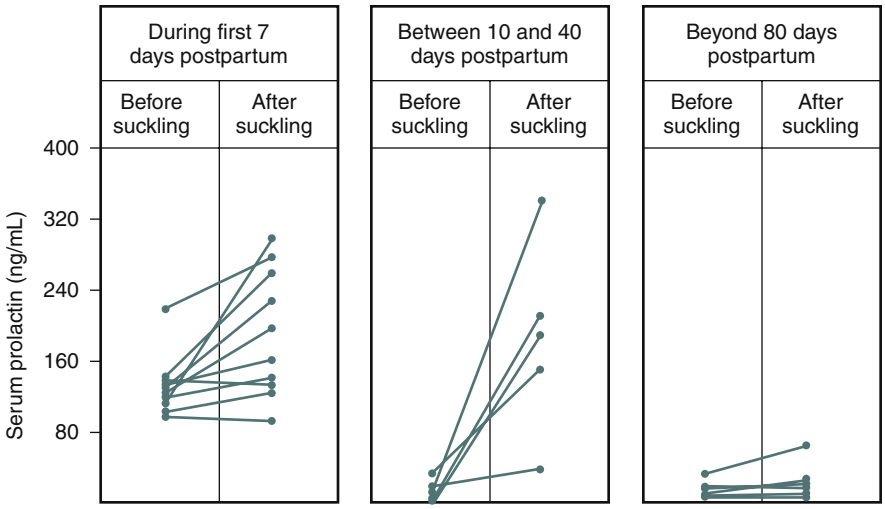

FIGURE 21.7 Serum prolactin concentrations basally and in response to suckling as a function of time after delivery. Within the first week after delivery, the basal value is high relative to the nonpregnant state, and there may be a further increase in response to suckling. Several weeks after delivery, the basal value is close to that of the nonpregnant state, but there is still a pronounced increase in response to suckling. Three months after delivery, the basal value is similar to that of the nonpregnant state, and there is a minimal response to suckling, if any. *(From Tyson JE. Studies of prolactin secretion in human pregnancy.* Am J Obstet Gynecol *113:14, 1972.)*

hypogonadism (low FSH and LH) may be present, but the clearance rate of the gonadotropins and sex steroids is reduced in the presence of hypothyroidism.[180-183] Pituitary sensitivity to GnRH may be reduced in hypothyroid children, but appears normal in hypothyroid women.[181,183] Fewer than 10% of patients with newly diagnosed hypothyroidism (TSH > 4 mU/L) have associated hyperprolactinemia that resolves with initiation of thyroid hormone replacement. However, correction of hyperprolactinemia in these patients does not correct the menstrual dysfunction. Only with restoration of a euthyroid state does menstrual function normalize, assuming it was secondary to thyroid dysfunction originally.[184]

Thyroid hormone excess, as occurs in Graves disease, is also associated with menstrual irregularities, anovulation, and infertility in women and sexual dysfunction in men.[179,185] Amenorrhea may be present in severe hyperthyroidism. Excess thyroid hormone increases gonadotropin sensitivity to GnRH[186-188] and may impair aromatase activity.[189] Hepatic SHBG production is also increased in hyperthyroidism, resulting in higher total testosterone and E_2, but normal free testosterone.[186-188] This increase in E_2 can cause gynecomastia in men with severe hyperthyroidism. Spermatogenesis may be impaired in men with thyroid hormone excess, but normalizes after restoration of a euthyroid state.[187,188]

Reproductive dysfunction frequently accompanies *abnormalities of cortisol secretion*. Amenorrhea develops in 25% of patients with *adrenocortical insufficiency*, although the etiology of such a severe reproductive disturbance is likely multifactorial, with chronic illness, weight loss, or autoimmune ovarian failure contributing.[190] Appropriately treated patients with autoimmune adrenal insufficiency (Addison disease) have basal LH levels and LH pulse patterns similar to those of normal healthy adults. During experimental periods with low cortisol replacement, patients with Addison's disease showed elevated CRH and ACTH levels, but normal sex steroid levels (testosterone and E_2). Gonadotropin alterations were gender-specific; mean LH concentrations and LH pulse amplitudes were suppressed in men in the setting of insufficient cortisol replacement for 47 hours, whereas similar conditions had no effect on LH dynamics in premenopausal and postmenopausal women. These differences may reflect higher opioid receptor activation in men than in women because opioids mediate the inhibitory effects of glucocorticoids on LH release.[191] Responses to low-dose GnRH stimulation did not vary in either sex under low cortisol conditions,[191] although higher doses of GnRH did alter stimulated FSH and LH concentrations.[192] These experimental conditions do not replicate the effects of long-term hypocortisolism, however, and clinical observations would suggest that maintaining physiological cortisol levels is crucial for preserving a normal hypothalamic–pituitary–gonadal axis.

Menstrual irregularities (amenorrhea, oligomenorrhea, polymenorrhea) are present in the majority of women with *cortisol excess* (Cushing syndrome), with only 20% reported to have normal menses in one large cohort.[193] GnRH neurons possess cortisol receptors,[194] and hypercortisolemia blocks both GnRH release and the action of gonadotropins on the gonad.[193] Gonadotropin levels are low or inappropriately normal in the presence of glucocorticoid excess, although GnRH testing showed normal or slightly increased gonadotropin reserve in hypercortisolism.[193,195,196] Thus, impaired GnRH release from the hypothalamus rather than pituitary dysfunction likely explains the reproductive pathology seen in Cushing syndrome. This reduction in gonadotropin secretion explains the radiographic appearance of the ovaries in women with Cushing syndrome, which tend to be smaller, with few primordial follicles and stromal hyperplasia.[197] Plasma E_2 and free and total testosterone are low in hypercortisolism, consistent with hypogonadotropic hypogonadism.[193,198,199] E_2 correlates inversely with the degree of cortisol elevation.[193] This hypogonadism can be reversed by restoration of normal serum cortisol levels.[196,198]

Although excess cortisol itself could explain these abnormalities of the hypothalamic–pituitary–gonadal axis, other hormones have been implicated, including *corticotrophin-releasing hormone*, *PRL*, and *androgens*. CRH is an important inhibitor of gonadotropin release in settings of acute stress, but it is suppressed by negative feedback in states of cortisol excess and is therefore unlikely to play a role in menstrual dysfunction in patients with Cushing disease. Similarly, hyperprolactinemia is present in the minority of patients with Cushing disease, but does not correlate with the severity of the reproductive disturbance and is unlikely

to be causative. Androgens were long believed to mediate Cushing-associated menstrual abnormalities. However, in a cohort of 45 premenopausal women with newly diagnosed Cushing disease, serum testosterone and androstenedione concentrations were elevated in only 29% and 39%, respectively, and there was no correlation between androgen levels and cortisol.[193] Metyrapone treatment of women with Cushing syndrome restores regular menses despite the increase in androgen levels associated with this drug.[200,201] These data suggest that hypothalamic GnRH release is suppressed by excess cortisol itself rather than by its adverse effects on other hormonal parameters.

Hyperprolactinemia is a common cause of reproductive dysfunction in premenopausal women, and is usually caused by pituitary lactotroph adenomas that are less than 1 cm in diameter (microadenomas). Hyperprolactinemia accounts for 10% to 20% of cases of amenorrhea (after pregnancy is excluded). Menstrual disturbances of varying degrees were present in 87% of a cohort of premenopausal women with hyperprolactinemia, whereas galactorrhea, another manifestation of hyperprolactinemia, was only present in 47%.[202] The severity of menstrual disturbance is related directly to the degree of hyperprolactinemia. Mild hyperprolactinemia (20-50 ng/mL) may impair progesterone secretion by the corpus luteum, resulting in a shortened luteal phase, but no menstrual irregularities. Moderate increases in PRL (50-100 ng/mL) can result in oligomenorrhea, whereas amenorrhea and overt hypogonadism occur when PRL is significantly elevated (>100 ng/mL). Any degree of hyperprolactinemia can contribute to infertility, however.[203,204] The severity of reproductive dysfunction in men also relates to the degree of hyperprolactinemia and can include decreased libido, infertility, gynecomastia, and galactorrhea.[205,206] The diagnosis of hyperprolactinemia is often delayed in postmenopausal women because they are already hypoestrogenic; such patients often present with compressive symptoms related to PRL-secreting adenomas, including headache, visual symptoms, or abnormalities of other pituitary hormones.

The mechanism of PRL-associated amenorrhea is suppression of hypothalamic GnRH release, resulting in low or inappropriately normal gonadotropin levels and low sex steroid levels. This reduction in hypothalamic GnRH release results in decreased LH pulse frequency, but LH pulse amplitude is higher.[207,208] The sleep-associated slowing in LH pulse frequency that occurs in normal adults is also lost in those with hyperprolactinemia. These effects of PRL on the hypothalamus are not mediated by increased hypothalamic opioid activity, and can be overcome with provision of exogenous pulsatile GnRH, which has resulted in pregnancy.[209,210] These observations and others show that hyperprolactinemia, whether due to normal physiological states (lactational amenorrhea) or pathophysiological causes, does not interfere with pituitary–gonadal feedback mechanisms or with the actions of LH and FSH on the ovary.[209,210] Restoration of normal PRL levels, either medically or surgically, allows LH pulse frequency and amplitude to recover, thereby normalizing menses, correcting hypogonadism, and restoring fertility.[202,211]

Evaluation of any woman with menstrual dysfunction or any man with symptoms consistent with hypogonadism should include measurement of a serum PRL level. Mild increases in PRL can occur with intense breast or chest wall stimulation, strenuous exercise, and emotional or physical stress. Thus, mild elevations should be confirmed before further evaluation for a cause of hyperprolactinemia. PRL secretion is normally inhibited by tonic hypothalamic dopamine secretion; thus, use of any drug that inhibits hypothalamic release or transport of dopamine to the pituitary or that blocks pituitary dopamine receptors can cause hyperprolactinemia. Such agents include metoclopramide, phenothiazines, butyrophenones, risperidone, verapamil, and rarely, the selective serotonin reuptake inhibitors. Discontinuation of potentially offending agents should be attempted, if possible, for at least 72 hours to determine whether hyperprolactinemia is drug-induced. In the absence of drug-induced hyperprolactinemia, hypothalamic lesions (craniopharyngiomas, granulomatous infiltration) must also be considered in the differential diagnosis. Such processes can cause hyperprolactinemia by compressing the pituitary stalk and thus interfering with dopamine transport. PRL levels greater than 200 ng/mL should also be repeated after dilution to avoid the "hook" effect, which can artificially lower actual PRL values by interfering with both immunoradiometric and chemiluminescent assays.[212] Once the presence of non–drug-induced hyperprolactinemia is confirmed, pituitary imaging with MRI is preferred for identification of adenomas.

Effects of Nutrition on the Neuroendocrine Components of the Reproductive Axis

States of Undernutrition: Effects of Fasting

Nutritional status is an important regulator of reproductive health. Individual and species survival are at stake when food is scarce; thus, reproductive potential is appropriately reduced in the setting of undernutrition. The effects of undernutrition on the reproductive axis have been studied experimentally by fasting normal subjects. These studies have suggested that the hypothalamic–pituitary axis in men may be more sensitive to the effects of starvation than that in women. Mean LH and FSH decrease within 48 hours of fasting in men.[213,214] Although the mechanisms involved remain unclear, similar reductions observed in animal studies did not appear to be opioid-mediated.[215] The data on LH pulse frequency and amplitude are less consistent, however. Within this context, Veldhuis and colleagues did not detect any change in LH pulse frequency in healthy men during a 5-day fast, although LH pulse amplitude was attenuated.[214] In contrast, the results of Cameron and colleagues in healthy men who fasted for 48 hours showed a significant reduction in LH pulse frequency, but no change in pulse amplitude.[213] Serum testosterone decreased in both studies.[213,214] The GnRH pulse generator in men may be more sensitive to the effects of fasting because of the sensitizing effects of gonadal steroids.[216] Older men, whose sex steroid levels have declined with age, do not show the same fasting-induced changes in LH pulsatility that are seen in younger men.[217] Animal studies have also shown that these effects of sex steroids on neuroendocrine function may vary with the type of stressor.[218-220]

The GnRH pulse generator in women appears less susceptible to the effects of acute fasting. Despite minor perturbations in LH pulse frequency and mean LH, at the end of a 72-hour follicular-phase fast, follicle development in fasting women was similar to that in women who were fed, as illustrated in Figure 21.8 and Figure 21.9.[221-223]

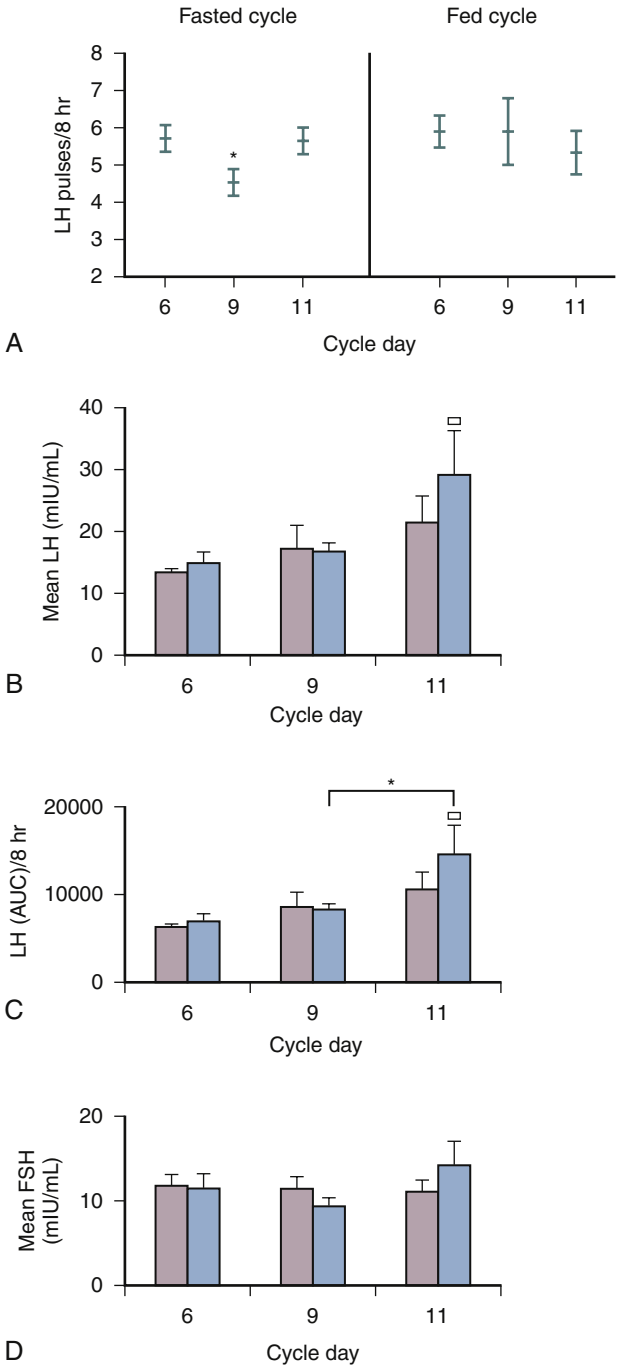

FIGURE 21.8 Cumulative 8-hour luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion on cycle days 6, 9, and 11 in women fasted on cycle days 7 to 9 (purple bars, $n = 10$) or fed (blue bars, $n = 7$). **A,** Mean number of LH pulses for each woman during the study for fasted *(left)* and fed *(right)* cycles. **B,** Mean LH value for the groups. **C,** LH area under the curve (AUC). **D,** Mean FSH values. FIGURE 21.9 Patterns of daily follicle growth in five women during fed *(green)* and fasted *(purple)* cycles beginning on cycle day 6 and lasting until the day before the collapse of the dominant follicle. The *interrupted line* in subject E in both fed and fasted curves represents the loss of the largest measured follicle not associated with a luteinizing hormone surge. A 5-day hiatus in measurements occurred before the last point in the fed cycle. *(Adapted from Olson BR, Cartledge T, Sebring N, Defensor R, Nieman L. Short-term fasting affects luteinizing hormone secretory dynamics but not reproductive function in normal-weight sedentary women.* J Clin Endocrinol Metab *80:1187, 1995. With permission from The Endocrine Society.)*

This resistance of the GnRH pulse generator to the acute effects of fasting occurs despite documented changes in cortisol and melatonin, both of which have been proposed to be critical regulators of the GnRH axis.[221] Body weight may mediate the effect of fasting on GnRH drive, and LH pulse frequency declined by 20% in lean women compared with normal weight women.[224] Attempts to determine the effects of acute undernutrition on GnRH activity during the luteal phase in women have proven more difficult, and exogenous administration of E_2 and progesterone to simulate the luteal phase also suppresses LH. As in their male counterparts, however, women showed alterations in both cortisol and melatonin when fasted during a simulated luteal phase, with dramatic increases in cortisol and duration of nocturnal melatonin secretion with fasting, evidence that this nutritional stress was not without some hormonal perturbation.[221]

Fasting can only be maintained in healthy subjects for short periods. The effects of more sustained caloric deprivation have been assessed in healthy women maintained on 800 to 1100 kcal/day diets for one menstrual cycle. Such caloric restriction was sufficient to cause weight loss[225,226] and resulted in anovulation in some women.[207,209] Dieting reduced follicular-phase LH secretion as well as follicular-phase LH pulse frequency, but luteal-phase LH patterns and FSH were unaffected.[225] Sex steroids (testosterone, androstenedione) were decreased, SHBG increased, and dehydroepiandrosterone sulfate did not change with dietary restriction.[226] These data in healthy, regularly ovulating women suggest that cortisol and melatonin may be the first hormones affected by short-term fasting,[221,227] but that continued caloric deprivation reduces GnRH activity within weeks. Amenorrhea can develop with loss of approximately 10% of body weight, regardless of initial body weight.[227]

States of Undernutrition: Anorexia Nervosa

Anorexia nervosa (AN) is an extreme example of the effects of undernutrition on the reproductive axis. It is difficult to separate the neuroendocrine effects of this nutritional deprivation itself from the hormonal alterations caused by the comorbid psychiatric illnesses that are frequently associated with AN. However, the effects of long-term caloric deprivation alone are also difficult to discern in other states of chronic undernutrition, such as protein–calorie malnutrition in hospitalized patients. Thus, AN has been best studied as a model of the reproductive consequences of severe caloric restriction. AN is defined by weight loss of greater than 15% for height, an intense fear of gaining weight, a disturbance in one's body image, and amenorrhea for at least 3 months. It is estimated to affect 0.5% of young women, with an even lower prevalence in males. Both primary and secondary amenorrhea can occur in AN, depending on the time of onset of the condition. A loss of 10% to 15% of normal weight for height is enough to delay the onset of menarche (primary amenorrhea), and a similar amount of weight loss disrupts normal menstrual cycles in postmenarchal girls (secondary amenorrhea). However, amenorrhea precedes weight loss in a significant percentage of patients with anorexia,[228,229] evidence that psychological stress and excessive exercise can also play a role. Other organ systems affected by AN include the cardiovascular and peripheral vascular (hypotension, arrhythmias), hematological (anemia), dermatological (lanugo hair), and renal systems (hypokalemia).[229]

Menstrual disturbances in anorexia result from hypothalamic rather than pituitary or ovarian dysfunction. Mean serum LH concentrations are lower than those of regularly menstruating women studied in the follicular phase,[230] and the LH secretory pattern is prepubertal, even in previously menstruating adolescents.[231] Responses to exogenous GnRH are blunted; the degree of response is greater in women who are closer to ideal body weight and in those who will ultimately resume normal menses after restoration of body weight.[232-234] Positive feedback from E_2 on the hypothalamus is also impaired in anorexic patients, as shown by studies with clomiphene citrate and exogenous estrogen that did not augment gonadotropin secretion.[235,236] The reduction in gonadotropin stimulation of the ovaries results in low estrone (E_1), E_2, progesterone, testosterone, and androstenedione levels.[232] Reduction in aromatase activity as a result of low body fat also contributes to the hypoestrogenism seen in anorexia, as does the preferential synthesis of catecholestrogen over E_2. Catecholestrogen is an endogenous antiestrogen that is capable of binding to estrogen receptors without having any biological action. Catecholestrogen also competes with dopamine for the enzyme catechol-O-methyltransferase, thus increasing dopamine levels, further inhibiting GnRH pulsatility, and potentiating hypoestrogenism.[228] These alterations in E_2 metabolism result from changes in body weight and are not specific to anorexia.[237] Additional evidence that anorexia-associated amenorrhea is the result of hypothalamic dysfunction is the induction of menses in anorexic women with the use of pulsatile GnRH.[238]

The biochemical factors responsible for the hypothalamic amenorrhea in anorexia are unclear. Increased opioid tone is unlikely to be the only operative mechanism because administration of naloxone increased LH secretion in some,[239] but not all, studies.[233,240] Women who had reached ideal body weight and those with the highest basal LH levels had the most significant responses to opiate antagonists (naloxone).[233,239] Dopamine can also inhibit LH release, but the use of the dopamine agonist metoclopramide did not result in a significant increase in LH in a cohort with anorexia.[241] Metabolites of serotonin, such as 5-hydroxyindolacetic acid, which stimulate hypothalamic GnRH release and increase pituitary sensitivity to GnRH,[242] are low in patients with anorexia and increase during recovery, as shown in Figure 21.10.[243]

Selective serotonin reuptake inhibitors, which restore CNS serotonin levels, have been shown to be effective in reversing abnormal eating behaviors in some patients with anorexia. Thus, disturbance of the serotonin system may also play some role in anorexia-associated hypogonadotropic hypogonadism.[228,243] Another potential factor is leptin, which is secreted by adipocytes and is critical for energy homeostasis. Leptin receptors have been identified in the hypothalamus, pituitary, endometrium, ovary (granulosa, theca, and interstitial cells), and testes (Leydig cells). Leptin indirectly stimulates GnRH release, acting in concert with other molecules involved in appetite control (NPY, melanocortin). It also directly stimulates LH and FSH release from anterior pituitary cells. Leptin gene expression is promoted by estrogen and insulin. Anorexia and other states of hypoinsulinemia are characterized by reduced leptin concentrations, which correlate with body fat. Weight restoration in anorexia is associated with increases in leptin, changes that correlate with increases in serum LH and FSH. Thus, leptin may serve as a peripheral signal of adequate adipose stores that is capable of reactivating the hypothalamic–pituitary–gonadal axis and restoring menses during recovery from AN.[244] The changes in leptin in AN are also accompanied by changes in ghrelin, another peptide intimately involved in control of feeding behavior. Ghrelin is increased in anorexic females compared with age-matched control subjects and constitutionally thin women without AN. Ghrelin correlates negatively with body mass index (BMI) and leptin,[245,246] and partial weight recovery results in a 25% decrease in ghrelin levels in patients with anorexia.[245]

Dehydroepiandrosterone sulfate and androstenedione are reduced in women with anorexia, but serum and urine cortisol levels are higher than normal. This preferential synthesis of cortisol over adrenal androgens is similar to that seen normally in prepubertal children and reflects relative 17, 20-desmolase deficiency.[247] The resulting hypercortisolemia is augmented by the prolonged plasma half-life of cortisol in AN.[248] In spite of elevated cortisol, ACTH levels are not elevated at baseline or in response to CRH, as illustrated in Figure 21.11.

These findings show that the negative feedback effects of this hypercortisolemia remain intact at the level of the pituitary, and that excess secretion of CRH and decreased clearance of CRH contribute to this hypercortisolemia.[249] The lack of clinical signs of hypercortisolemia may result from diminished tissue expression of glucocorticoid receptors in patients with anorexia.[250] Importantly, these alterations of the hypothalamic–pituitary–adrenal (HPA) axis resolve with long-term weight recovery.[230,249] The hypothalamic–pituitary–gonadal axis also recovers with restoration of ideal body weight, as shown in Figure 21.12.[231]

Although no absolute BMI or percentage of body fat has been found to correlate with the resumption of menses, more than 85% of patients who achieve a weight that is 90% of their ideal body weight note return of menses within 6 months.[251] However, amenorrhea persists in a minority of women (10% to 30%), despite weight gain. Of the latter, many admit to restricting their fat intake and score higher on questionnaires designed to detect anorexic behaviors.[229] Hypoestrogenemia in such women correlates with the degree of ovarian dysfunction, and ovarian ultrasound shows small, amorphous ovaries. However, small multifollicular ovarian cysts appear once weight gain starts, with the return of a dominant ovarian follicle once premorbid weight is achieved.[252] Those who recover from anorexia, resume regular menses, and have normal eating behaviors can successfully conceive and bear healthy children.[229]

Recovery from AN and restoration of ideal body weight requires both emotional and nutritional rehabilitation, and remains quite challenging, despite improvements that have been made in understanding the pathophysiology of AN during the last century. Standardized mortality rates in patients

with AN are increased tenfold to thirteenfold when patients are followed for ten years.[253] The crude death rate in large meta-analyses, including more than 3000 patients with AN, was 5.9%.[254] The percentage of patients who recover entirely is less than 50%, whereas a significant proportion of patients have binge-eating behaviors at some point during their illness.[253] At least 10% still meet the criteria for AN after long-term follow-up. Factors associated with poorer outcomes included longer duration of illness before the first inpatient treatment and a lower BMI, illustrating the importance of early diagnosis and intervention.[255]

Unfortunately, the effects of severe undernutrition on other body systems can persist, even when anorexic patients restore their body weight. Osteopenia and osteoporosis are the most serious long-term consequences of AN, and they result from both decreased bone formation (related to energy deprivation) and increased bone resorption (related to hypoestrogenism). The majority of patients presenting with amenorrhea and anorexia have some degree of low bone density, and bone mass can decline by as much as 2% to 6% per year during periods of undernutrition.[229] Unfortunately, BMD does not always normalize after restoration of a healthy body weight and menstrual cyclicity, often because peak bone mass was not achieved during the adolescent and young adult years. The declines in bone density have been shown to correlate with the duration of anorexia and the age of onset of the disease.[228,229] Treatment of anorexia-associated osteopenia appears to require more than hormone replacement, likely because the osteopenia results from various nutritional and hormonal factors, not just estrogen deficiency.[256] For example, patients who received recombinant human insulin-like growth factor-1 (IGF-1) in combination with oral contraceptives had higher BMD than those who received oral contraceptives alone.[257]

Males account for only 5% of the anorexic population, but the diagnosis of AN in males is often delayed because the signs of reproductive dysfunction are harder to identify. Anorexia in men is strongly associated with depression and other underlying psychiatric disturbances, although the rate of comorbid substance abuse is higher than it is in women. Other features more prevalent in males with anorexia include a history of obesity, sexual identity concerns, and excessive exercising.[228] Boys are at higher risk for malnutrition-induced delays in growth and pubertal development, because they enter puberty later than girls. Studies in males with anorexia have shown abnormalities in the hypothalamic–pituitary–gonadal axis similar to those in women. Serum testosterone concentrations are often below

normal, as are mean 24-hour LH concentrations.[214,234] GnRH-stimulated gonadotropin levels are also lower than those of normal control male subjects. Unlike gonadotropin levels in anorexic females, basal LH and FSH do not correlate with BMI (and degree of weight loss) in males with anorexia.[234] This hypogonadotropic hypogonadism is likely the result of severe caloric restriction itself because caloric restriction in obese men had similar effects on sex steroid and gonadotropin levels.[258]

States of Undernutrition: Bulimia Nervosa

Bulimia nervosa (BN) is another eating disorder characterized by irregular feeding patterns, specifically binge eating, in individuals of normal body weight, many of whom aspire to body weight far below normal. These episodes of binge eating are followed by periods of self-induced vomiting, laxative abuse, or extreme exercise, all driven by an abnormal body image. BN affects approximately 2% of the general female population, and approximately one third of patients with BN who present for treatment have a history of anorexia. Both anorexia and bulimia are more common in patients with coexisting low self-esteem, depression, and anxiety.[226] Disturbances in the reproductive axis can be seen in patients with bulimia, but they do not define the condition, as in anorexia. Amenorrhea occurs in 30%.[259] Approximately half of women with bulimia show hypogonadotropic hypogonadism and no evidence of follicular development associated with decreased LH pulse frequency,[260,261] whereas others have normal gonadotropin secretion and normal follicular development, but impaired luteal-phase progesterone levels.[260] Patients with purging behaviors showed more severe reductions in LH responses to GnRH infusion than nonpurging patients with bulimia and control subjects.[262] As in women with anorexia, serum cortisol is higher in bulimic women than in control subjects,[261,263] possibly related to increased CRH stimulation.

States of Overnutrition

Overnutrition and *obesity* pose a much greater threat to human health in most parts of the world than does food scarcity. Associated morbidities, including diabetes, obstructive sleep apnea, cardiovascular disease, and osteoarthritis, often remain undiagnosed until later in adulthood, although their foundations are established in young adulthood. However, men and women of reproductive age can have obesity-associated reproductive dysfunction that brings them to medical attention much sooner than these other conditions. For example, the most common endocrinopathy in reproductive-age women is PCOS, which affects 5% to 10% of women in this age group and is associated with reproductive as well as cardiovascular and cosmetic complications.[264,265] Many patients with PCOS are obese, and adiposity correlates linearly with testosterone levels in these women.[266] Weight reduction can restore menstrual regularity and, therefore, fertility in many patients with PCOS.[265] Both lean and obese women with PCOS show rapid LH pulse frequencies, but increasing body weight is associated with decreases in LH pulse amplitude in women with PCOS.[267] This neuroendocrine dysfunction is a product of and contributes to hyperandrogenemia, thus creating a vicious cycle in women with PCOS.

Obesity itself in the absence of PCOS-associated hyperandrogenemia also affects the hypothalamic–pituitary axis. Historical analysis of menstrual cycle data shows a higher percentage of menstrual abnormalities or hirsutism in women who were heavier.[268] The number of menstrual cycles with evidence of luteal activity was lower in overweight or obese women than in normal-weight participants in the Study of Women's Health Across the Nation (SWAN) study. Women with BMI of 25 kg/m^2 or greater also had statistically longer follicular phases and shorter luteal phases.[269] Consistent with these population studies, detailed hormonal sampling studies have shown that excess body weight suppresses gonadotropins. LH amplitude was reduced by 50% in morbidly obese women (mean BMI, 48.6 kg/m^2) with regular cycles studied before gastric bypass surgery, although pulse frequencies did not differ. Nevertheless, the marked attenuation of pulse amplitude resulted in a lower mean LH compared with normal-weight control subjects.[270] This reduction in LH drive also results in deficient luteal stimulation and corpus luteum progesterone production, as reflected by lower urinary excretion of the progesterone metabolite pregnanediol glucuronide, illustrated in Figure 21.13.[269,270] Plasma E_2 and androstenedione concentrations are lower in obese women with regular cycles,[271] although E_1 does not change with body weight in most studies.[269,270]

Multiple factors are likely responsible for these obesity-associated neuroendocrine changes. The response to exogenous physiological-dosed GnRH was inversely related to body weight in women with PCOS, but not in normally cycling women, suggesting that obesity may blunt the pituitary response to GnRH.[272] Insulin may also interfere with pituitary gonadotropin secretion, although no clear relationship between LH and insulin has been identified. Hyperinsulinemia clearly suppresses hepatic secretion, however, thereby increasing free E_2 levels. Free E_2 may exert more negative feedback on the pituitary because it is more biologically active, thus decreasing gonadotropin production.[269] Leptin, an adipose-derived hormone, increases hypothalamic GnRH pulsatility and pituitary gonadotropin release,[244] although obesity is often associated with leptin resistance. Leptin also inhibits granulosa cell responses to hCG and may interfere with oocyte maturation. Thus, the exact relationship of leptin to the neuroendocrine changes described earlier is not fully understood. Similarly, the role of other adipose-derived substances, including TNF-α and interleukin-1β, is an area of active investigation because both have the ability to reduce pituitary response to GnRH as well as to impair corpus luteum function.[270]

Obesity in men is also associated with reductions in circulating gonadotropin and sex steroid concentrations. The hyperinsulinemia-associated decrease in hepatic SHBG decreases binding affinity for testosterone and results in greater aromatization of testosterone to E_2. The subsequent increase in free E_2 and the reduction in the testosterone-to-E_2 ratio have important implications for male sexual function.[273-275] Total testosterone is lower in obese men compared with normal-weight men, but free testosterone does not change.[274,276,277] Mean LH, LH pulse frequency, and LH pulse amplitude are suppressed in severely obese men (BMI > 35), again reflecting the negative feedback effects of elevated free E_2. More moderate degrees of adiposity (BMI 30 to 35) do not affect gonadotropin secretion.[277,278] These alterations in the hypothalamic–pituitary–gonadal axis can

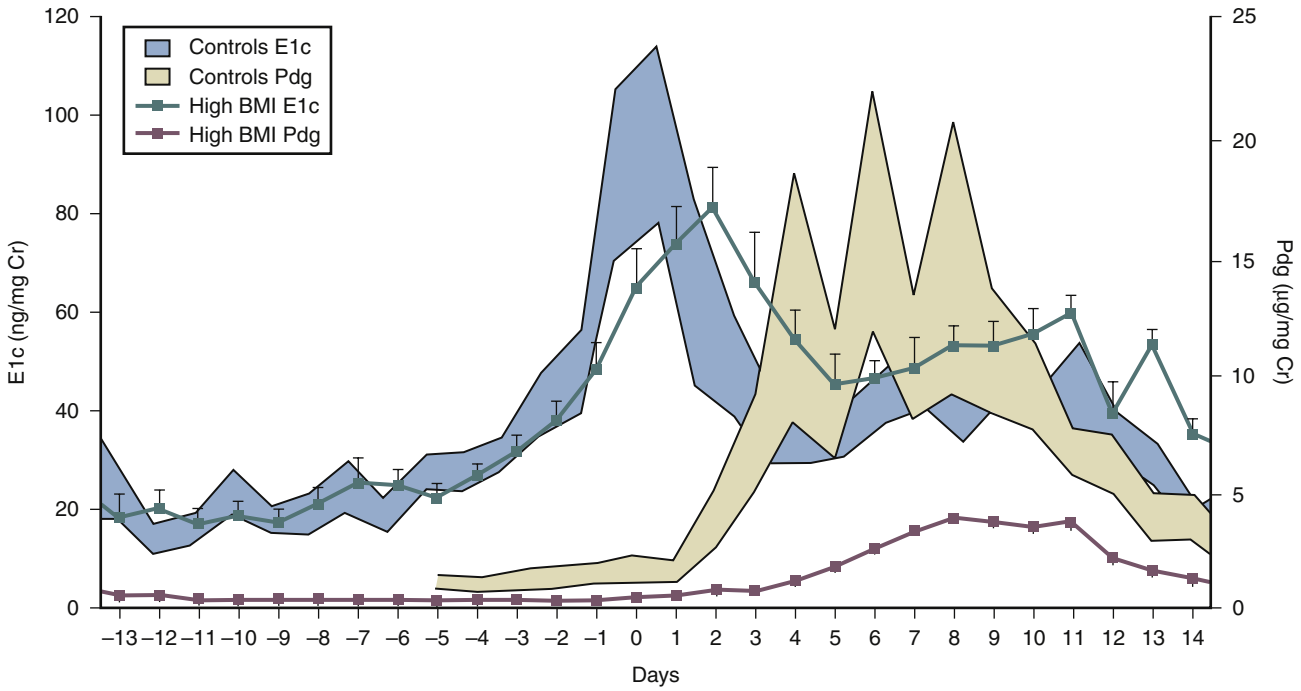

FIGURE 21.13 Daily urinary estrone conjugate (E1c) and pregnanediol glucuronide (Pdg) in women with a high body mass (BMI) versus mean values of control women ±1 standard deviation. Data are standardized to day 0, 13 days before ovulation. *(Modified from Jain A, Polotsky AJ, Rochester D, Berga SL, Loucks T, Zeitlian G, Gibbs K, Polotsky HN, Feng S, Isaac B, Santoro N. Pulsatile luteinizing hormone amplitude and progesterone metabolite excretion are reduced in obese women.* J Clin Endocrinol Metab *92:2468, 2007. With permission from The Endocrine Society.)*

decrease sperm concentrations.[273] Importantly, reducing hyperinsulinemia through weight loss allows for restoration of normal testosterone and LH levels.[278]

Effects of Exercise on the Neuroendocrine Components of the Reproductive Axis

Excessive exercise in the absence of eating disorders can result in hypogonadotropic hypogonadism due to hypothalamic dysfunction ("athletic amenorrhea"). The clinical manifestations of the reduced GnRH activity are varied and may include amenorrhea, oligomenorrhea, LPD, or anovulation. Menstrual cycle length is not a good marker of ovarian function in athletic women because it may be normal during cycles characterized by anovulation or LPD. In addition, one woman's cycle will differ over time, depending on the volume of her exercise and other environmental factors.[279] Exercise-associated menstrual dysfunction has been reported in women engaged in a variety of athletic activities, including long-distance running, rowing, skiing, tennis, gymnastics, ballet, fencing, and volleyball.[280] Dancers and long-distance runners have especially high rates of menstrual dysfunction (60% to 70%), but divers, cheerleaders, and gymnasts also have rates of amenorrhea (22%) that far exceed those in the general population.[264] Even recreational athletes are susceptible to exercise-associated menstrual dysfunction; 78% of such women had LPD or anovulation in at least one of three menstrual cycles.[279]

Risk factors for exercise-associated menstrual irregularities include the volume of training, eating behaviors, and gynecological age. Studies of distance runners have illustrated the effect of exercise volume on menstrual function, with the prevalence of amenorrhea increasing from 3% to 60% as weekly training mileage increased.[281] Surveys of eating behaviors among female collegiate athletes show relatively low rates of diagnosed eating disorders among this population (3.3% with AN; 2.3% with bulimia nervosa). Importantly, however, almost one third may be "at risk" for eating disorders, based on assessments of their attitudes toward eating, and these athletes are the ones most likely to report menstrual irregularities or bone injuries.[282] Although all menstruating females are susceptible to the disruptive effects of exercise on the reproductive axis, those who are younger and closer to the time of menarche (i.e., lower gynecological age) are more sensitive, regardless of body size, body composition, training mileage, or years of training.[280,283,284] This sensitivity of the hypothalamic–pituitary–gonadal axis appears to be maximal in the first 15 years after the onset of menses and wanes thereafter.[284]

Exercise-induced menstrual dysfunction is characterized by low gonadotropin and E_2 concentrations.[285] Whereas athletic women with normal cycles had 20% to 30% reductions in LH pulse frequency compared with regularly cycling sedentary women, amenorrheic athletes experienced an additional 20% reduction in LH pulse frequency,[286-288] as shown in Figure 21.14.[286]

Reductions in LH pulse amplitude and loss of sleep-associated changes in LH pulsatility also occur in the amenorrheic group.[286,289] FSH secretion is impaired during the follicular–luteal phase transition. These gonadotropin changes may be subtle enough that menses remain regular, but they likely contribute to the high rates of anovulation (12%) seen in recreational athletes. Ultimately, ovarian steroid production is reduced in the absence of appropriate gonadotropin stimulation and corpus luteum function is impaired. The former is reflected in Figure 21.15 *(top)*[286] by a reduction in urinary E_1 (E_1G) excretion in amenorrheic

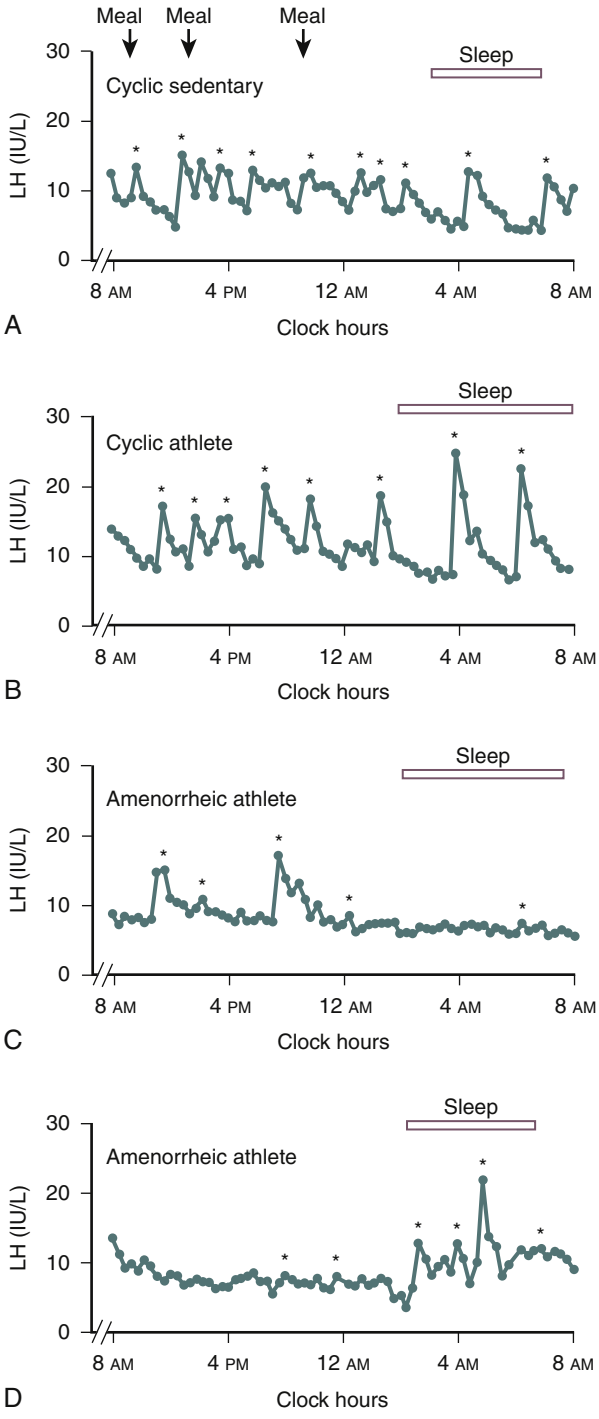

FIGURE 21.14 Serum luteinizing hormone (LH) levels at 20-minute intervals for 24 hours in a cycling sedentary women **(A),** a cycling athletic woman **(B),** and two amenorrheic athletic women (**C** and **D**). *Asterisks* indicate pulses, as identified by the Cluster pulse analysis program using a 2 × 1 cluster size and balanced T criteria of 2.1. *(Modified from Loucks AB, Mortola JF, Girton L, Yen SSC. Alterations in the hypothalamic-pituitary-ovarian and the hypothalamic-pituitary-adrenal axes in athletic women.* J Clin Endocrinol Metab *68:402, 1989. With permission from The Endocrine Society.)*

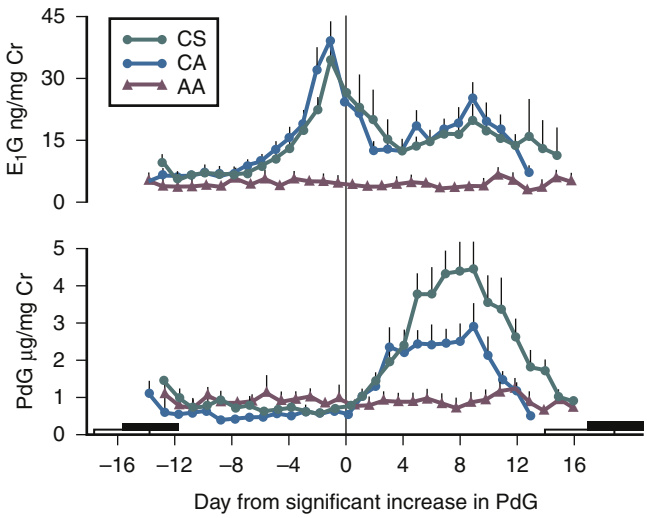

FIGURE 21.15 Mean (± standard error) daily urinary excretion of estrone glucuronide (E_1G) *(top)* and pregnanediol glucuronide (PdG) *(bottom)* in cycling sedentary (CS), cycling athletic (CA), and amenorrheic athletic (AA) women. Days are oriented from a significant increase in urinary PdG excretion, with day 1 being the day of the first significant increase. For urinary E_1G, 1 ng/mg creatinine (Cr) = 2.134 pmol/mg Cr; for PdG, 1 µg/mg Cr = 2.014 nmol/mg Cr. *(Modified from Loucks AB, Mortola JF, Girton L, Yen SSC. Alterations in the hypothalamic-pituitary-ovarian and the hypothalamic-pituitary-adrenal axes in athletic women.* J Clin Endocrinol Metab *68:402, 1989. With permission from The Endocrine Society.)*

athletes, whereas Figure 21.15 *(bottom)* shows urinary excretion of the progesterone metabolite prenanediol glucuronide (PdG) in these women. Reductions in PdG define luteal phase deficiency (LPD) and characterize 43% of the menstrual cycles in regularly cycling athletic women and can contribute to infertility.[286]

Provision of exogenous GnRH to women with exercise-induced amenorrhea illustrated that the etiology of this disorder is reduced hypothalamic GnRH secretion, rather than impaired pituitary or ovarian responsiveness. Submaximal graded doses of GnRH (2.5 µg, 5 µg, 10 µg, 25 µg) elicited exaggerated LH responses in athletic women compared with sedentary control women, whereas supraphysiological doses of GnRH (100 µg) in amenorrheic athletes resulted in greater LH secretion compared with regularly menstruating athletic women.[290]

Exercise also causes hypogonadotropic hypogonadism in men, with reductions in both gonadotropins and total and free testosterone levels that correlate with the intensity of endurance exercise.[291,292] High-mileage endurance exercise can also affect sperm count, density, motility, and morphology on semen analysis.[292-294] Unlike endurance exercise, resistance exercise is associated with transient increases in androgens and dehydroepiandrosterone sulfate in men.[295] Because hypogonadism in males is less often recognized by both medical providers and patients themselves, literature on the effects of exercise on the male reproductive axis is more limited.

Physical activity is associated with hypogonadotropic hypogonadism in some, but not all, female athletes. A prospective study of previously eumenorrheic women who engaged in distance running (65 miles/week) at or above the lactate threshold for 12 months or longer detected no

significant changes in menstrual cycle length, follicular and luteal phase length, or integrated serum progesterone and E_2 concentrations compared with control women who were not exercise-trained. Body weight, percentage of body fat, lean body mass, and caloric intake did not change during the 12-month training period, and none of the women had oligomenorrhea or amenorrhea. Only luteal phase length was shorter in the group exercising above the lactate threshold. This stability of the reproductive axis occurred despite significant increases in oxygen consumption in the training groups.[280] Importantly, the women in this study had few risk factors for exercise-induced reproductive dysfunction because their mean gynecological age was 17 years and they were carefully screened for coexisting psychiatric disease or eating disorders. Nevertheless, critics of this study note that the trained women may have been exercising enough at baseline to alter reproductive hormone secretion,[296] although there was little evidence that intensifying their exercise adversely affected their reproductive function.

The mechanisms whereby some women lose menstrual cyclicity when they initiate an exercise regimen are complex. Loss of body fat with intense exercise, with or without an underlying eating disorder, has long been thought to explain exercise-induced amenorrhea. Maintenance of a minimal percentage of body fat and a minimal weight for height was believed to be necessary to prevent menstrual dysfunction or restore menses in athletic women experiencing amenorrhea.[297] However, this theory has been disproved in multiple studies, none of which has been able to differentiate normally cycling athletes from oligomenorrheic or amenorrheic athletes by anthropometric features alone.[283,288,298,299] In addition, the changes in LH pulsatility are evident within 5 days,[300] much sooner than changes in adiposity appear.[301]

An imbalance between caloric intake and the amount of energy expended with exercise more likely explains the reduced hypothalamic GnRH drive observed in women with exercise-associated menstrual dysfunction.[287,302] Energy availability can be defined by the difference between energy intake and energy expenditure, with exercise being one component of energy expenditure. When energy availability is low, reproductive function suffers, as do thermoregulation, growth, and cellular maintenance.[303] Detailed nutritional assessments of athletic women who were expending 900 to 1000 kcal/day exercising showed that their daily caloric intake was similar to that of sedentary women. Thus, energy availability was significantly lower in the former, although none of these athletes had been formally diagnosed with an eating disorder. Fat and protein accounted for a smaller percentage of calories in the athletic women, and the athletic women with amenorrhea consumed 50% less fat than their regularly menstruating counterparts. This negative energy balance was reflected in insulin–glucose dynamics, with amenorrheic athletes showing marked hypoinsulinemia throughout the 24-hour observation period and glucose levels that were 10% lower. Women with more significant hypoinsulinemia had the lowest dietary fat intake and experienced greater reductions in LH pulse frequency.[287]

These effects of energy availability on hypothalamic GnRH secretion occur relatively quickly. When a negative energy balance is created experimentally, by restricting calories,[304] increasing expenditure,[305] or combining the two,[302] declines in LH pulse frequency occur within 1 week. Detailed studies in women whose energy availabilities were gradually decreased while they maintained a constant energy expenditure of 15 kcal/kg lean body mass (LBM)/day (kcal/kg LBM × day) illustrated that 30 kcal/kg LBM × day is the threshold of energy availability required to maintain normal reproductive function.[300] When energy availability falls below this threshold, LH pulse frequency declines and amplitude increases, as illustrated in Figure 21.16.[300]

The sensitivity of GnRH neurons to energy availability appears to decline with increasing gynecological age, suggesting that hypothalamic centers become desensitized to these metabolical signals over time. Caloric restriction combined with vigorous daily aerobic exercise altered LH pulse frequency in adolescents, but not adults, changes that appeared within 5 days of energy deprivation, as shown in Figure 21.17.[284] Correction of this negative energy balance in amenorrheic exercising monkeys who continued vigorous training was achieved with overnutrition, and the rapidity of recovery was directly related to energy consumption.[306,307]

These experimental data suggest a role for a peripheral marker of adequate energy stores that can also act centrally to regulate the reproductive axis. Derived principally from adipose tissue, leptin is one such hormone whose receptors have been identified in the hypothalamus, pituitary, ovary, and testes. Its effects are stimulatory in the CNS and inhibitory at the gonads.[244] Leptin concentrations in amenorrheic athletic women are significantly reduced compared with those in eumenorrheic athletic women,[308] and the normal diurnal pattern of leptin secretion is lost in the former.[309] Opposing the actions of leptin, ghrelin is an orexigenic hormone that stimulates the release of NPY and agouti-related protein from the arcuate nucleus of the hypothalamus. Exercise does not appear to alter ghrelin levels in the short term. Chronic exercise over 1 year in overweight sedentary women was associated with increases in ghrelin when the exercise was accompanied by weight loss. Not surprisingly, amenorrheic athletes had 85% higher levels of ghrelin than did women who were ovulatory and sedentary, ovulating and exercising, or exercising with an LPD.[310] Thus, both leptin and ghrelin are likely involved in the metabolical signaling cascade that mediates the reproductive effects of exercise.[311]

Exercise may also impair the hypothalamic–pituitary–gonadal axis in some women by acting as a chronic stressor and activating the HPA axis. This activation mobilizes fuel stores in an attempt to maintain metabolical homeostasis. Ultimately, however, this HPA activation impairs other hypothalamic–pituitary axes, including the hypothalamic–pituitary–gonadal axis, through changes in CRH, proopiomelanocortin, ACTH, endogenous opiates, adrenal corticosteroids, or neurotransmitters. Both regularly menstruating and amenorrheic female athletes demonstrated higher plasma cortisol levels compared with regularly menstruating nonathletes with preservation of a diurnal pattern.[286,287] The degree of hypercortisolism correlated negatively with the magnitude of reduction in LH pulse frequency.[287] Administration of carbohydrates during prolonged exercise was shown to attenuate these increases in cortisol in both rodents[312] and humans,[313] suggesting that

this HPA axis activation may occur in response to inadequate energy availability and that dietary energy restriction is more disruptive to the reproductive axis than energy expenditure through exercise.[289]

Alterations in the somatotroph axis also occur as a result of exercise-associated metabolical changes. Both GH pulse frequency and mean 24-hour mean GH are augmented in amenorrheic athletes,[287,314] changes also observed in states of nutritional deficiency, such as AN.[315] These increases in GH levels do not effect a rise in circulating serum IGF-1, which directly stimulates LH release in rodent studies.[316] This lack of increase in IGF-1 likely reflects the increases in its binding protein (IGF binding protein-1 [IGFBP-1]), which is the most metabolically response IGF-binding protein. In the prevailing hormonal milieu associated with exercise (low endogenous insulin, elevated cortisol), IGFBP-1 increases and serves as another peripheral signal of fuel shortage, slowing hypothalamic GnRH release. Unlike IGFBP-1, the concentrations of other GH-binding proteins (GHBPs) fall 35% in amenorrheic athletes and are unchanged in regularly cycling athletes, demonstrating the role that nutrient availability plays in the regulation of hepatic GHBP synthesis. Exercise-associated variations in circulating catecholamine and free fatty acid levels may also contribute to this complex regulation of hypothalamic–pituitary GH secretion.[287]

Given its role in metabolism, it is not surprising that thyroid hormone is affected by the hypothalamic dysfunction that occurs with exercise of moderate intensity. Energy imbalance as a result of carbohydrate restriction causes triiodothyronine (T_3) to decline, the result of reduced 5′-diodinase activity. In men, increased energy expenditure through moderate exercise results in a rise in reverse T_3 and a fall in serum free T_3, changes similar to those seen in the "low T_3 syndrome."[317] Exercise in women is associated with significant reductions in T_4 and T_3, although only amenorrheic athletic women have alterations in free T_3 and reverse T_3 levels, both of which are significantly decreased compared with regularly menstruating athletes or sedentary women. Mean 24-hour TSH levels are not affected by this reduction in thyroid hormone negative feedback. Thyrotropin-releasing hormone (TRH) deficiency with exercise could explain these differences in women.[318] Alternatively, the nocturnal hypermelatoninemia observed in amenorrheic athletes[319] could modulate thyroid hormone levels because melatonin secretion from the pineal gland reduces serum thyroid hormone levels in animals and humans.[318,320,321] Finally, some studies suggest a genetic predisposition which contributes to the susceptibility to inhibition of the reproductive axis by stressors such as exercise, nutritional deficits, and psychological stressor.[322]

In summary, multiple metabolical signals are clearly involved with signaling to the GnRH pulse generator. Exercise can temporarily alter these metabolical signals if it creates an imbalance in energy availability. Such an imbalance can be prevented by supplementing dietary intake. Although most female athletes do not intentionally restrict their intake, few consume the additional calories needed to maintain a healthy energy balance. The exact nature of these interactions is complex and continues to be the subject of multiple investigations, but appears to be independent of body weight.

Long-Term Complications of the Hypoestrogenism Associated with Exercise

The complications associated with hypoestrogenism and exercise include infertility, lipid abnormalities, and premature bone loss.[303] Infertility results from poor or absent ovarian follicular development, impaired ovulation, or insufficient luteal-phase progesterone concentrations to support implantation. Amenorrheic athletes frequently have elevated low-density lipoprotein cholesterol levels[323] and endothelial dysfunction, despite their lack of body fat and low dietary fat intake.[324] Although the long-term effects of these cardiovascular risk factors in this population are not known, the adverse effects of amenorrhea on the skeletal system in young female athletes are well established. Estimates of the prevalence of osteopenia among female athletes range from 22% to 50%, whereas the prevalence of osteoporosis is much lower (0% to 13%).[325] Reductions in BMD are the result of increased bone resorption secondary to estrogen deficiency and decreased bone formation resulting from reduced energy availability.[303] Exercise itself may have differential effects on BMD, depending on the site examined. BMD at weight-bearing sites containing predominantly cortical bone, such as the femoral neck, was normal or increased in adolescent ballet dancers, whereas BMD was reduced at sites with predominantly trabecular bone, such as the spine and ribs. Sedentary amenorrheic girls with anorexia whose percentage of body fat was similar to the ballet dancers had lower BMD at all sites compared with regularly menstruating girls. Thus, weight-bearing exercise may offset the adverse effects of exercise-associated hypogonadism on cortical bone.[326] The skeletal effects of milder degrees of reproductive dysfunction, such as LPD, are unknown, and increasing evidence suggests that the declines in BMD associated with exercise-induced hypogonadotropic hypogonadism may not be reversible.[327]

The American College of Sports Medicine uses the term "the female athlete triad" to refer to the association of menstrual dysfunction, disordered eating, and osteoporosis in female athletes. Figure 21.18 illustrates the importance of

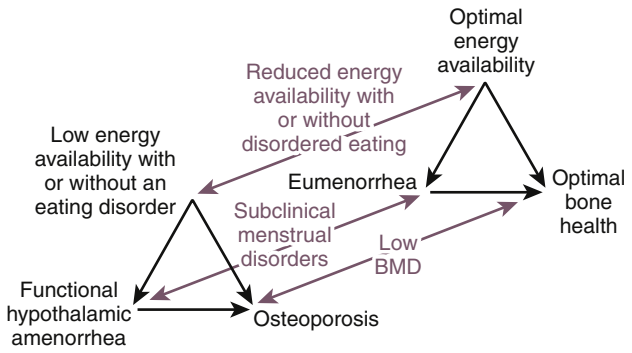

FIGURE 21.18 Female athletic triad. The spectrums of energy availability, menstrual function, and bone mineral density (BMD) along which female athletes are distributed *(purple arrows)*. An athlete's condition moves along each spectrum at a different rate according to diet and exercise habits. Energy availability, defined as dietary energy intake minus exercise energy expenditure, affects bone mineral density both directly via metabolical hormones and indirectly via effects on menstrual function and thereby estrogen *(black arrows)*. *(From Nattiv A, Loucks AB, Manore MM, Sanborn CF, Sundgot-Borgen J, Warren MP. The female athlete triad.* Med Sci Sports Exer *38:1867, 2007.)*

optimal energy availability for both reproductive and skeletal health.[303]

Caloric intake that is adjusted for the energy expended during exercise maintains normal hypothalamic–pituitary–gonadal function (eumenorrhea), while also providing nutrients for normal bone formation. Athletes who maintain such homeostasis often have BMD 5% to 15% above those of age-matched individuals. However, even mild but sustained reductions in energy availability can induce subtle degrees of menstrual dysfunction. Eventually, such dysfunction impairs estrogen-mediated bone resorption and BMD begins to fall below that expected. Not surprisingly, eumenorrheic athletes have higher BMD than amenorrheic athletes, and eumenorrheic athletes with disordered eating but no formal eating disorder have lower BMD.

Identifying adolescents and women with the female athlete triad can be difficult, especially when overt amenorrhea has not developed. Even in the absence of a clinical eating disorder, restrictive eating behaviors should raise concern and should be investigated further, potentially with the help of a mental health professional. A history of multiple stress fractures or fractures with minimal trauma might also be the first clinical manifestations of nutritional deficits.[326] Healthcare providers should be especially mindful of menstrual dysfunction in adolescent females engaged in sports where leanness is emphasized (i.e., gymnastics, cheerleading, diving). Such athletes should be encouraged to optimize their nutrition and vitamin D status to prevent exercise-induced menstrual dysfunction.[303] Exercise-associated menstrual dysfunction is a diagnosis of exclusion, however, and women should still be evaluated for pregnancy, hyperprolactinemia, thyroid dysfunction, premature ovarian failure, and anatomical abnormalities of the uterus, even if the history is consistent with exercise as the cause of oligomenorrhea or amenorrhea.

Treatment

Treatment of adolescents and adults with exercise-associated reproductive dysfunction requires a modification in diet or exercise behavior to increase energy availability, an intervention that is often difficult to implement.[328,329] Such nonpharmacological approaches are also more effective at increasing bone density than is hormone replacement therapy (HRT).[327,324] In the absence of weight gain, HRT has not been consistently effective at increasing BMD in patients with exercise-induced hypogonadotropic hypogonadism,[330] likely because it does not correct the abnormal metabolical milieu that may be contributing to premature bone loss. In addition, many athletes refuse to take estrogen because of the associated weight gain. HRT may be indicated in a woman with continued loss of BMD on serial bone densitometry scans, despite adequate nutritional intake and body weight. Bisphosphonates are not used for the bone loss associated with exercise-induced amenorrhea because of their long residence time in bone and the harm they may cause to future developing fetuses. Recombinant IGF-1 used in combination with HRT in the form of oral contraceptive pills may be better than oral contraceptives alone at increasing BMD, but is not currently used clinically.[257]

Infertility related to exercise-induced alterations of the hypothalamus can be treated with exogenous gonadotropins, but more conservative interventions, such as restoration of body weight, are much preferred. Women with low body weight and borderline nutritional status before conception may not augment their intake enough during pregnancy to sustain normal fetal growth, thus placing them at higher risk for spontaneous fetal loss. Progesterone can be prescribed for those women with LPD that does not correct, despite increases in energy intake or decreases in exercise.[303]

Stress and Functional Hypothalamic Amenorrhea

Undernutrition, overnutrition, and exercise are well-recognized causes of functional hypothalamic amenorrhea (FHA), which is defined by hypothalamic hypogonadism in the absence of any structural hypothalamic or pituitary abnormality. The mediators of this hypothalamic dysfunction are multiple and likely include insulin, leptin, ghrelin, CRH, and cortisol. FHA accounts for 34% of cases of secondary amenorrhea in adults, making it the most common cause of this disorder.[331] FHA also exists in women who do not meet the criteria for an eating disorder and do not exercise; such cases are often attributed to stress or are termed *idiopathic*. Life-threatening stress (i.e., experiencing refugee or concentration camps, wars, air raids) has long been known to cause amenorrhea in the majority of women; it resolves once environmental conditions improve.[332] Less severe stressors also contribute to menstrual dysfunction in some women. Characterization of women with such stress-associated menstrual dysfunction is complicated by the heterogeneity of the condition.

Stress is difficult to define objectively,[333] but Selye noted in 1939 that it was accompanied by activation of the HPA axis and that it reduced reproductive capacity.[334] This physiological response makes sense teleologically because it allows for preservation of adrenocortical function in the case of emergency at the expense of gonadal activity. Acute stress results in a brief increase in LH and testosterone, possibly as a result of a decrease in the metabolical clearance rate rather than a change in the secretory rate. However, this initial stimulatory phase is short-lived and is not nearly as clinically relevant as the response to prolonged stress, which has consistently been shown to inhibit hypothalamic GnRH secretion, to interfere with GnRH-induced LH production, and to impair gonadal response to LH and FSH. Stress-related increases in CRH, pro-opiomelanocortin, ACTH, endogenous opiates, adrenal corticosteroids, or neurotransmitters may modulate these central and peripheral effects on the reproductive axis. The interactions of each of these factors with each other and with the hypothalamus, pituitary, and gonads are extremely complex, as shown in Figure 21.19 and, therefore, difficult to distinguish experimentally.[335]

The decreased GnRH activity characteristic of FHA reflects CNS and hypothalamic responses to perceived or actual stressors. Different stressors elicit different neuromodulatory responses in different people, and the magnitude of these responses may be determined early in life by events that permanently influence the sensitivity of the HPA axis.[336] The severity of patients' self-reported psychomatic disturbance has been shown to correlate with the degree of gonadotropin suppression.[337] Most women are able to maintain normal menstrual cycles throughout stressful life events, periods of weight loss, and periods of intense exercise. In those who have amenorrhea, some degree of

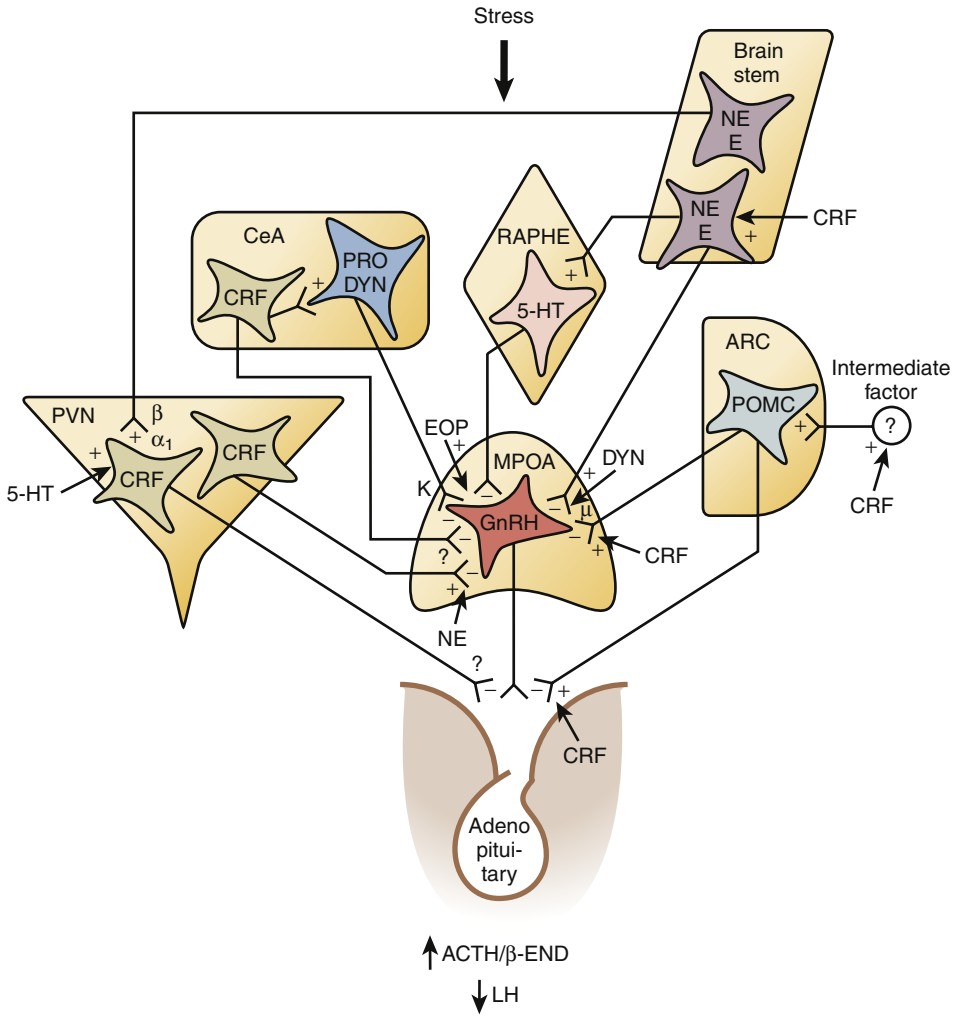

FIGURE 21.19 The main effects of physical stress on different brain areas, and peptidergic or aminergic pathways directly or indirectly involved in alteration of the activity of gonadotropin-releasing hormone (GnRH) neurons. Effect of stress on the activity of the hypothalamic-pituitary-gonadal axis: peripheral and central mechanisms.* Biol Reprod *45:523, 1991.)*

menstrual irregularity often precedes the complete cessation of menses, whereas women with amenorrhea related to Cushing syndrome, hypothyroidism, Sheehan syndrome, or pituitary tumors usually have no history of menstrual dysfunction.[331] Similarly, athletes who have amenorrhea during periods of intense exercise often have a history of menstrual irregularity.[338] Clearly, in some individuals, the hypothalamic–pituitary–gonadal axis is more sensitive to disturbances in homeostasis than it is in others. Men are also susceptible to stress-associated reproductive compromise, but identifying functional declines in GnRH pulsatility is quite difficult in males. Asthenospermia (decline in sperm motility) may be the mildest manifestation of altered GnRH drive, but is usually only diagnosed in the workup of infertility.[339]

Gonadotropin secretion in women with FHA is inappropriately low, but the pattern of secretion varies during the course of illness. Studies in women with FHA who were of normal weight for height, who were not being treated for an eating disorder, and who were not exercising excessively at the time of sampling showed low-frequency LH secretion in 43%, low-frequency and low-amplitude secretion in 27%, low-amplitude secretion in 8%, apulsatile secretion in 8%, and an unclassified pattern in 14%, as shown in Figure 21.20.[340]

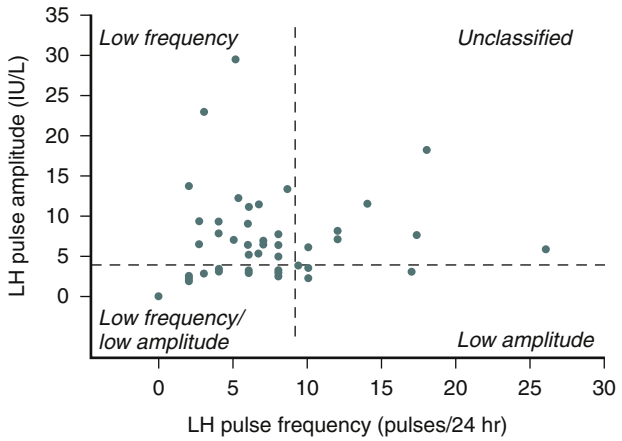

FIGURE 21.20 Classification of subjects with hypothalamic amenorrhea by luteinizing (LH) pulse frequency and amplitude, defined by mean –1 standard deviation in normally cycling women *(hatched lines)*. Low pulse amplitude was defined as less than 4 IU/L. Low pulse frequency was defined as fewer than 9 pulses/24 hr. *(Adapted from Perkins RB, Hall JE, Martin KA. Twelve patients participated in two to eight overnight sampling studies each, and LH secretory patterns changed in 75% of these women on repeated study. The majority of these women responded to naloxone infusion with increases in LH pulse frequency, implicating enhanced opioid tone as a cause of hypothalamic amenorrhea in a subset of patients. This naloxone response occurred in women regardless of their baseline neuroendocrine patterns, and has been supported by previous studies.[341] Thus, women with FHA do not appear to have a static defect of GnRH secretion. Rather, their hypothalamic sensitivity to endogenous opioids and other stress-associated factors is heightened, resulting in GnRH concentrations that rise and fall with changes in endogenous opioid levels. Such disordered GnRH pulsatility is unable to support follicular development and ovulation.[340]

Metabolical signals may also be responsible for inhibiting GnRH activity in idiopathic and stress-induced FHA. Specifically, both leptin and ghrelin have been implicated as markers of inadequate nutrition stores that are capable of signaling to the hypothalamus and suppressing the reproductive axis. In nonathletic women of normal weight with FHA, adipose-derived leptin levels are reduced compared with age-, weight-, and body fat–matched eumonorrheic control subjects, suggesting that energy deprivation may underlie menstrual dysfunction in these patients, as it does in patients with eating disorders and excessive exercise.[342,343] Administration of exogenous leptin to a small group of women with FHA increased maximal follicular diameter, ovarian volume, and endometrial thickness, as well as the number of dominant follicles, as shown in Figure 21.21.[344] LH pulse patterns normalized, and E_2, thyroid hormone, and IGF-1 levels increased in the majority of these women, despite the fact that they lost weight and experienced a decline in their percentage of body fat.[344]

Treatment with leptin over 36 weeks in women with FHA resulted in recovery of menstruation and also changes in markers of bone metabolism.[345]

Unlike the anorexigenic leptin, ghrelin is an orexigenic molecule that stimulates food intake. Ghrelin acts on the same neurohormonal pathways as leptin and is secreted by gastric oxyntic cells. Ghrelin levels correlate well with feelings of hunger and are higher in women with eating disorders and in exercising women who lose weight.[246] In addition, in animal studies, ghrelin has been shown to suppress LH pulse frequency in monkeys,[346] which has been confirmed for LH and FSH in human studies.[347] It may not be surprising that ghrelin levels are significantly higher in women with FHA, whose scores on tests of eating disordered behaviors were significantly higher than those of control women. Ghrelin elevation may be another mechanism that the body uses to stimulate appetite and suppress reproduction in the face of a negative energy balance.[348] Studies of male Army Rangers engaged in an elite combat leadership course also support the hypothesis that low energy availability is an important mediator of FHA. In these men, alterations in metabolical

and reproductive hormones during periods of semistarvation resolved after *ad libitum* refeeding, despite continued exposure to other stressors (heat, cold, sleep deprivation, extreme exercise, illness, injuries).[349] Thus, whether a reduction in energy availability occurs as the primary homeostatic insult, as it does in AN, or whether it is a secondary response to stress, it may be the proximate causes of the majority of reproductive disorders.[333] The hypogonadotropic hypogonadism associated with FHA may be the final common pathway by which the body serves to protect itself from additional stressors, such as childbearing.

Detailed overnight hormonal sampling studies in women with FHA showed the expected changes in gonadotropins. Mean serum LH concentrations, LH pulse frequency, and FSH were reduced by 30%, 53%, and 19%, respectively. Importantly, however, abnormalities in other hypothalamic–pituitary axes were also apparent. In addition, 24-hour cortisol secretion was 17% higher in women with FHA compared with eumenorrheic women,[350] but this hypercortisolemia did not suppress CSF CRH levels, suggesting hypothalamic resistance to cortisol negative feedback.[351] In addition, 24-hour PRL was lower, and nocturnal GH secretion was higher and more disordered. TSH was unchanged, but serum T_3 and T_4 were lower in the women with FHA. Administration of hypothalamic-releasing factors (GnRH, CRH, GH-releasing hormone [GHRH], TRH) showed normal pituitary responses in both groups, evidence that global hypothalamic dysfunction occurs in women with FHA.[350]

Treatment of Stress-Associated FHA

Restoring reproductive function in cases of stress-associated FHA is not as straightforward as the treatment of exercise-induced amenorrhea or anorexia-associated amenorrhea, in which case the pathological behaviors are obvious and potentially reversible. Women with all three types of amenorrhea tend to be perfectionists who desire social approval and who possess abnormal attitudes toward eating.[352,353] Detailed questioning is often required to uncover these unhealthy eating behaviors, which tend to be of the bulimic type in adult women and of the restrictive type in adolescents.[337,343] Women and adolescents with FHA tend to have lower self-esteem and a higher prevalence of psychological disturbances compared with eumenorrheic control subjects and women with amenorrhea due to other causes.[337,354] Cognitive behavioral therapy (CBT) can help to identify stressors and maladaptive attitudes toward eating and provide patients with problem-solving techniques to better cope with stress-inducing circumstances. CBT has also been shown to restore ovulation in up to 75% of women who were previously anovulatory, whereas observation alone was effective in only one of eight women during the 20-week study period. Responses to CBT occurred relatively quickly after CBT initiation (mean, 11.2 ± 3.3 weeks)[355] and were preceded by normalization of the hypercortisolemia characteristic of FHA.[356] Such psychological intervention is also more likely to allow for recovery of all endocrine and metabolical disturbances than is targeted treatment of the hypothalamic–pituitary–gonadal axis alone with sex steroid replacement.[357] Sex steroids can be considered after amenorrhea has persisted for 6 months or more despite lifestyle changes; lumbar spine BMD may improve in such patients.[358] Recombinant leptin may also have a potential role in preventing FHA-associated bone loss in the future, either alone or in combination with E_2, although leptin's suppressive effects on appetite are concerning in this population, which is already predisposed to altered eating behaviors.[359] Exogenous gonadotropins can be used to induce ovulation and achieve pregnancy in FHA, but they will not reverse the hypothalamic hypothyroidism and hypercortisolism that often accompany the hypogonadism. If pregnancy is achieved, obstetric and fetal outcomes may be adversely affected by failure to correct these other hormonal disturbances.[357,360]

Establishing recovery rates in cases of FHA unrelated to weight loss or exercise is complicated by the difficulty in defining this subset of patients. FHA of idiopathic etiology confers a poorer prognosis, with recovery rates in small longitudinal studies of 6 to 10 years' duration ranging from 29% to 61%. FHA related to stress almost always resolves once the causal factor is reversed, especially if there is associated weight loss that improves concurrently.[361,362] No neuroendocrine pattern was predictive of recovery.[361] The fact that few women with FHA of defined etiology do not experience recovery of menses, even after correction of the inciting factor, shows that both physiological and environmental insults are important.[361]

Medication-Associated Hypogonadotropic Hypogonadism

A variety of medications can interfere with the hypothalamic–pituitary axis as a result of their tendency to increase PRL.[363-385] Given that PRL release is under tonic inhibition by hypothalamic dopamine secretion, medications that interfere with hypothalamic release or transport of dopamine or that block pituitary dopamine receptors can raise serum PRL. The degree of PRL elevation in such cases is usually less than 100 ng/mL, a range that overlaps that seen with PRL-secreting microadenomas and with stalk deviation caused by other pituitary lesions.[385] More detailed description on the effects of medications on prolactin levels is described in Part 1, Chapter 3 of this edition.

Pituitary Dysfunction

Pituitary Tumors

Development of Pituitary Tumors: Etiological Considerations

Currently available information suggests that the majority of pituitary tumors develop from monoclonal tumor cell expansion of a mutated somatic cell.[386] Such mutations can occur in a familial setting within the germ cell line or may be sporadic. The development of a pituitary adenoma within a familial setting is known to occur in multiple endocrine neoplasia type 1 (MEN 1) and Carney complex (CNC)[387,388] as well as in familial acromegaly.[389] As discussed later, the MEN 1 syndrome is caused by mutations in the tumor suppressor gene *MEN1*, which is located on chromosome 11q13 and encodes a 610–amino acid nuclear protein. In patients with the *MEN1* gene, pituitary adenomas occur in approximately 40% of cases. Other mutations, such as that in the *CDKN1B* gene (which encodes for the cyclin-dependent kinase inhibitor $p27^{Kip1}$), are also considered to be possibly involved in the MEN 1 syndrome. CNC is associated with mutations in the protein kinase A1 alpha regulatory subunit gene on chromosome 2p16 in 60% of cases.[390,391]

Isolated familial somatotropinoma (IFS) is defined as more than two cases of acromegaly in a family in the absence of MEN 1 or CNC. The genetic pathophysiology is still unclear, even though a mutation in the gene encoding the aryl-hydrocarbon receptor–interacting protein has been found in some cases, including four Northern Irish families.[392-394] Somatic mutations in the $G_s\alpha$ gene *(GNAS1)* are found in a subset of GH-secreting tumors, with a prevalence ranging from 40% in white populations to 10% in Japanese populations. The oncogenic gsp mutation correlates with constitutively increased cyclic AMP response element–binding protein phosphorylation and activity, which then leads to increased Pit-1 transcription and GH synthesis.[391] An example of a sporadic mutation associated with pituitary cell tumors is the activating mutation in *GNAS1*, which is seen in McCune-Albright syndrome, a condition with multiple endocrine manifestations, including hyperplastic pituitary lesions.[395] Several *in vivo* and *in vitro* lines of evidence suggest that the clonal expansion of the mutated pituitary cell requires a secondary event for tumor progression.

This secondary event may be an additional somatic mutation or overexpression of genes in pituitary adenomas. Somatic mutations of the Ras oncogene have been associated with increased aggressiveness of prolactinomas and have been detected in metastasis of pituitary carcinomas.[396] Increased expression of cyclin E is associated with ACTH-producing pituitary adenomas. Overexpression of the pituitary tumor–transforming gene *(PTTG)* has been thought to be involved in pituitary tumorigenesis as all pituitary adenoma subtypes, and particularly invasive adenomas express *PTTG*. *PTTG* is a member of the securin family that regulates the separation of chromatids during mitosis.[397] Overexpression of *PTTG* is thought to be at least partly responsible for the aneuploidism often observed in pituitary tumors. Promotor methylation of the retinoblastoma gene and p16INK4a and low expression of the p27Kip1 protein all cause loss of tumor suppressor gene function and have been associated with the development and the aggressiveness of pituitary adenomas.[398,399]

Several growth factors have been shown to induce pituitary hyperplasia, with or without adenoma development. FGF-β, which is expressed in the pituitary and is a potent mitogen for neuroectoderm cells and their synthesis, is induced in NIH3T3 cells overexpressing *PTTG*. The heparin-binding secretory transforming gene *hst* seems to be associated with the aggressiveness of the tumor,[400,401] and pituitary TGF-α has been associated with estrogen-induced lactotrophic hyperplasia.

Few data concerning the effect of environmental factors on the development of pituitary tumors are available. However, the presence of the aryl hydrocarbon receptor on pituitary tumors, which is believed to mediate cell responses to toxins, such as dioxin,[402] suggests that such mechanisms may play a role in tumor development.

From both a morphological and a mechanistic perspective, pituitary hyperplasia must be distinguished from pituitary adenomas. Mechanisms subserving hyperplasia certainly include overstimulation of particular pituitary cell types by hypothalamic factors, such as GHRH and CRH, which may be secreted ectopically and lead to somatotrophic and corticotrophic hyperplasia. Moreover, situations in which negative feedback on the hypothalamic–pituitary system is absent as well may result in hyperplasia. For example, and as discussed later, untreated hypothyroidism may result in thyrotrophic hyperplasia, and inadequate glucocorticoid replacement after adrenalectomy is thought to be involved in the development of corticotrophic hyperplasia (Nelson syndrome).[391]

Pituitary Adenomas

Nonfunctioning Adenomas and Gonadotroph Adenomas

Nonfunctioning tumors of the pituitary either do not secrete hormones or do so at such a low level that clinical syndromes of hormone excess do not develop. The majority of these tumors are microadenomas (<1 cm) and clinically lead to no significant symptoms. Most of the nonfunctioning adenomas that do come to medical attention are macroadenomas that compress both pituitary and nonpituitary tissues and result in hypopituitarism.

In 70% of patients with a nonfunctioning macroadenoma, visual field defects are present.[403] More than 90% of patients have at least one pituitary hormone deficiency before surgery, most commonly, GH deficiency followed by hypogonadism. In 80% of these patients, secondary hypothyroidism occurs, and in 60%, secondary adrenal insufficiency is present before surgery.[404] In the rare case in which an adenoma secretes biologically active FSH, amenorrhea, high E_2 concentrations, and multiple ovarian follicles can occur.[405] In pubertal girls, these events may result in premature breast development and vaginal bleeding.[406]

Typically, the clinical diagnosis of a *gonadotroph adenoma* is made by an absence of symptoms that would suggest a different type of pituitary adenoma (e.g., of somatotrophic, corticotrophic, lactotrophic, or thyrotrophic origin) and by basal and stimulated secretion of gonadotrophins and their subunits. Approximately 80% of clinically nonfunctioning pituitary tumors are gonadotroph adenomas, and hypersecretion of more than one monomeric subunit, with or without LH or FSH secretion, is common. β-FSH is elevated in approximately 30% of patients, whereas the α subunit is elevated in approximately 20% of patients. Intact FSH hypersecretion occurs less frequently. In rare cases, LH hypersecretion is present, but seldom is sufficient to result in abnormally elevated testosterone levels.

In the setting of primary gonadal failure in general and in postmenopausal women in particular, serum concentrations of the gonadotropins and free subunits are also increased in the absence of an adenoma. Under those conditions, intravenous administration of TRH has been reported to help distinguish a normal hypothalamic–pituitary response to gonadal failure from a pituitary tumor. In approximately 40% of male patients and 69% of postmenopausal women with nonfunctioning pituitary adenomas, intravenous TRH results in an increase in serum concentrations of the gonadotropins or the free α/β subunit. In a study by Daneshdoost and colleagues, none of the healthy postmenopausal women had LH-β, LH, or FSH[407] responses to TRH. Unfortunately, TRH is not currently available for clinical use in the United States. Few data exist about the utility of measuring pituitary glycoprotein hormones or their free subunits, although some literature suggests that a postsurgical decrease in

circulating FSH concentration correlates with tumor size reduction. The final determination of the cellular basis of nonfunctioning pituitary tumors is based on immunohistochemistry. In most nonfunctioning tumors, immunostaining detects either intact pituitary glycoprotein hormones (FSH, LH, TSH) or the free subunits of these glycoproteins (α subunit, β-FSH, β-LH, β-TSH). In rare cases, PRL, ACTH, or GH is found. In fewer than 30% of nonfunctioning adenomas, no immunoreactive hormone or hormone subunit is seen (*null cell* pituitary tumors).[408]

Treatment. With regard to therapeutic strategies, nonfunctioning pituitary adenomas may express receptors for TRH, GnRH, and dopamine, but treatment with somatostatin analogs, GnRH agonists, GnRH antagonists, and dopamine agonists have shown inconsistent results.[409] In a small number of patients, 6-month combination therapy with cabergoline and octreotide resulted in a 30% tumor size reduction, but only in those patients who had detectable baseline or stimulated LH, FSH, and α subunit levels.[410] Temozolamide (an alkylating agent) has been reported to lead to a reduction in pituitary size in some cases in nonfunctioning pituitary adenomas.[411]

Nonfunctioning pituitary adenomas often are found as unsuspected pituitary lesions, discovered on an imaging study which was performed for unrelated reasons, so called incidentalomas. Based on the 2011 Endocrine Society Clinical Practice Guideline, surgical treatment is recommended when there is a visual deficit due to the pituitary lesion, other visual abnormalities, such as opthalmoplegia due to compression by the lesion exist, the lesion abuts or compresses the optic nerves or chiasm on MRI or in case of pituitary apoplexy with visual disturbance. The guideline suggests that surgery should be considered if there is significant growth of the pituitary lesion, in case of loss of endocrinological function, unremitting headache and if the lesion is close to the optic chiasm and the patient plans to become pregnant. Patients who do not meet criteria for surgical removal need to be followed with regular clinical assessments with imaging, laboratory tests, and visual field testing if necessary.[412]

Prolactin-Secreting Adenomas

Under physiological conditions, the regulation of PRL is inhibitory, mediated by dopamine through the type 2 isoform (D2) of the dopamine receptor. Dopaminergic neurons are primarily located in the arcuate nucleus (tuberoinfundibular system), but also in the rostral caudate and paraventricular nuclei (tuberohypophysial system).[413] Pituitary stalk injury or stalk compression interrupts these inhibitory circuits and results in increased PRL levels, which usually do not exceed 250 ng/mL.

Prolactin-secreting pituitary tumors include both prolactinomas and GH-producing pituitary tumors, which in 25% of cases cosecrete PRL. The latter observation reflects the fact that lactotroph and somatotroph cells derive from a common progenitor GH-expressing stem cell. Prolactinomas are classified as microadenomas (<10 mm) or macroadenomas (≥10 mm), with the risk of progression from microadenoma to macroadenoma estimated at 4% to 7% over a period of 8 years.[414] High PRL levels, larger tumor size, cavernous sinus invasion, and resistance to dopamine agonists are associated with increased aggressiveness. A serum PRL cutoff level of 3300 ng/mL predicts an invasive tumor with a specificity of 91%.[415] Specific clinical symptoms of prolactinomas in premenopausal women include hypogonadism, which may present as infertility, oligomenorrhea, or amenorrhea,[416,417] and galactorrhea. However, it cannot be overemphasized that galactorrhea may also occur in normoprolactinemic women. Kleinberg and colleagues reported that 86% of women with idiopathic galactorrhea without amenorrhea had normal PRL levels.[418] Regardless of its cause, the degree of PRL elevation correlates with the severity of hypogonadism. Serum PRL levels greater than 100 ng/mL are associated with hypogonadism and low E_2, which result in amenorrhea, hot flashes, and vaginal dryness. PRL levels of 50 to 100 ng/mL can be associated with both oligomenorrhea and amenorrhea, and levels of 20 to 50 ng/mL can result in a shortening of the luteal phase and resultant infertility.[186] Women with hyperprolactinemia and amenorrhea exhibit lower spine and forearm BMD compared with women with hyperprolactinemia and normal menses.[419] In men, sexual dysfunction is the main clinical manifestation of prolactinomas. Galactorrhea occurs in approximately 15% to 25% of men with microprolactinomas or macroprolactinomas and is less frequent compared with women. Osteoporosis can also occur in men with increased PRL levels.[420-422]

Besides PRL-producing pituitary adenomas, other causes of hyperprolactinemia include medications as well as hypothyroidism, chest wall trauma,[423] estrogens, chest wall tumors, herpes zoster of the chest, chronic renal failure, alcoholic cirrhosis, pregnancy, nipple stimulation, and the postictal state.[424] Idiopathic hyperprolactinemia is the diagnosis when no cause can be found. In a study by Sluijmer and Lappohn,[425] only 1 of 59 patients with idiopathic hyperprolactinemia who were followed for an average of 6.5 years had a pituitary adenoma.

In approximately 10% of patients with hyperprolactinemia, *macroprolactinemia* may be diagnosed. This condition is characterized by a predominance of high–molecular-mass circulating prolactin, which represents PRL complexed with anti-PRL immunoglobulins.[426] The cause of immunoglobulin production (mainly immunoglobulin G) is unclear. In a study that included more than 100 cases, dopaminergic treatment did not always result in normalization of serum PRL concentrations. Clinical symptoms associated with macroprolactinemia are sometimes absent because of the weak *in vivo* biological activity of macroprolactin. In patients with increased serum PRL levels and few or no symptoms related to PRL excess, this condition should be considered.[426] While gel-filtration chromatography (GFC) is currently considered the gold standard for macroprolactin measurement, this method is labour intensive and for routine use polyethylene glycol (PEG) precipitation is preferred.[427]

Falsely low PRL measurements can be encountered in the presence of very high PRL levels, reflecting the hook effect. In this case, the antigen (PRL) is present in the serum in excess and there is not enough antibody to bind both sides of the antigen. The assay value is significantly lower than the real value. Dilution of the samples will resolve the problem. The hook effect should be considered in the presence of a large pituitary tumor and low levels of circulating PRL.[428]

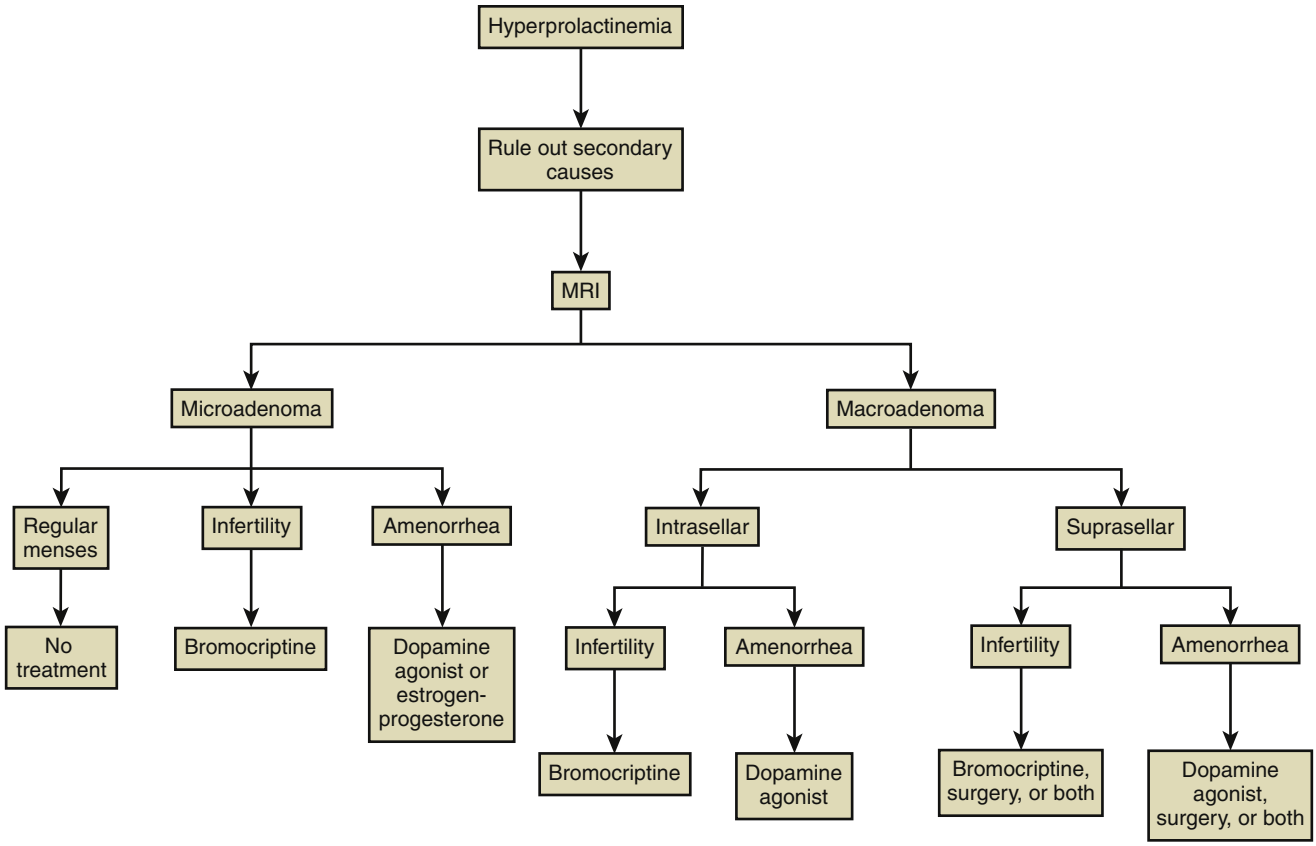

FIGURE 21.22 Algorithm for the management of prolactinoma in women. *(Reproduced from Schlechte JA. Clinical practice. Prolactinoma.* N Engl J Med *349:2035, 2003, with permission.)*

Treatment. The primary treatment objectives in patients with PRL-secreting pituitary adenomas include normalization of PRL levels, restoration of gonadal function, reduction of tumor size, and recovery of pituitary function. Both surgical and medical approaches to achieve these goals are available (Fig. 21.22).[429] For a detailed description of treatment options the reader is referred to Part 1, Chapter 3 of this edition.

Growth Hormone–Secreting Adenomas

Growth hormone is secreted in a pulsatile fashion by somatotrophic cells within the anterior pituitary gland. GH pulses can be detected every 3 to 4 hours and are primarily regulated by the interaction between the hypothalamic peptides somatostatin and GHRH. Most GH pulses occur at night. Somatostatin determines the trough levels of GH, whereas GHRH stimulates the release of GH from the pituitary as well as the increase in GH gene transcription.[430] Approximately 75% of pituitary GH circulates in the 22-kDA form, with 5% to 10% in the 20-kDA form.[431]

Growth hormone–secreting pituitary tumors represent approximately 2.8% of all pituitary tumors,[432] and are monoclonal in origin, suggesting intrinsic genetic alterations as the cause for their development. In a subset of GH-secreting tumors, a mutation of the *gsp* gene has been found, with the prevalence ranging from 40% in whites to 10% in Japanese. Other candidate genes associated with GH adenomas include *PTTG*, *H-ras*, *MEN1*, and *P16INK4a*. *PTTG* overexpression in pituitary tumors has been shown to correlate with tumor size. In 25% of GH-secreting pituitary adenomas, PRL is cosecreted.[433,434] Adenomas with plurihormonal secretion often have no apparent clinical symptoms and are called *silent somatotroph adenomas*, with increased IGF-1 and PRL levels.

In very rare cases, *ectopic GHRH secretion* is the cause of increased GH secretion. In such cases, MRI shows a normal or mildly enlarged pituitary because GHRH leads to hyperplasia of the somatotrophs.[435] Sources of increased GHRH secretion include hypothalamic tumors, bronchial carcinoids, and tumors of the pancreas, gastrointestinal tract, thyroid, and adrenals. Ectopic GH secretion by nonendocrine tumors has also been reported.[436]

Growth hormone–producing adenomas are phenotypically diverse, with two predominant histological forms, *densely granulated* and *sparsely granulated*. The two forms differ in their morphological features and respective growth patterns. *Densely granulated* GH cell adenomas show slow, expansive growth without invasion, resulting in the gradual development of acromegalic features. Such adenomas exert pressure on the surrounding nontumorous gland, resulting in the formation of a pseudocapsule, which helps with surgical removal. The *sparsely granulated* GH cell adenoma grows more rapidly and diffusely and is often invasive. Mixed adenomas expressing both GH and PRL are also more likely to invade surrounding tissues.[437]

Table 21.2 compares the most frequent symptoms found in acromegalic patients with symptoms found in patients with nonfunctioning pituitary tumors and prolactinomas.

Table 21.2 Comparison of Symptoms Between Acromegalic Patients and Patients with Nonfunctioning Pituitary Tumors and Prolactinomas

Many of the signs and symptoms of acromegaly develop slowly and insidiously, and patients are often treated for seemingly nonendocrine conditions long before the diagnosis of acromegaly is made. The average time between the onset of recognized symptoms and diagnosis is approximately 10 years.[432] Consequently, more than 70% of GH-secreting adenomas are macroadenomas at the time of diagnosis.[438] Besides the compressive symptoms of pituitary tumors, such as headache, visual field defects, and cranial nerve palsies, clinical symptoms of GH hypersecretion include hyperhidrosis, acral enlargement, thickness of the soft tissues of the hands and feet, prognathism, jaw malocclusion, macroglossia, arthralgias and arthritis, bilateral carpal tunnel syndrome, proximal myopathy, frontal bossing, skin tags, colon polyps, cardiomyopathy, hypertension, diabetes mellitus, sleep apnea, and visceromegaly. Cardiac disease is the primary cause of death in untreated acromegaly, with 50% of patients dying before the age of 50 years. Hypertension occurs in approximately 40% of patients, and left ventricular hypertrophy is present in more than 50% of normotensive acromegalic patients.

The serum IGF-I level is the best biochemical marker of clinical disease activity in acromegaly. Both GH and IGF-I correlate with mortality and when GH and IGF-I levels are controlled, mortality is close to the level expected in the general population.[439] Before the availability of IGF-I assays, dynamic tests were used and the oral glucose tolerance test ([OGTT] 75-g oral glucose load with serum GH sampling every 30 minutes over 2 hours) was the recommended test for the diagnosis and assessment of therapeutic outcome postoperatively. The OGTT may help diagnostically when there is a discrepancy between GH and IGF-I data, but it does not add additional diagnostic value when IGF-I levels are clearly elevated. A GH nadir during OGTT of less than 1 μg/L theoretically excludes acromegaly and indicates postoperative remission. However, the results of the OGTT must be interpreted with caution in conditions such as puberty, pregnancy, hepatic and renal disease, AN, and diabetes mellitus, all of which may cause inadequate GH suppression. A random GH level of 0.4 μg/L or less and an IGF-I level in the age-matched and sex-matched reference range excludes the diagnosis of acromegaly.[440]

Treatment. Treatment options for GH-secreting adenomas include surgery (with or without presurgical medical treatment), medical treatment, and RT. Data on postsurgical cure rates and recurrence rates must be interpreted by carefully reviewing the specific cutoff levels used for defining cure or recurrence and the assays used to measure IGF-I and GH.[441] Surgical cure rates also depend on the experience and workload of the surgeon.[442] Frank and colleagues[443] defined remission by a basal GH level of less than 2.5 ng/mL, a normal sex- and age-adjusted IGF-I level, and a GH nadir of less than 1 ng/mL after OGTT, and reported a cure rate of 83% in microadenomas and 64.5% in macroadenomas. Intraoperative invasiveness of the tumor decreased the cure rate to 44%, which was similar to the findings of other studies that reported that GH is controlled in approximately 80% of microadenomas. In macroadenomas, on the other hand, IGF-I and GH are controlled in fewer than 50% of cases. Using these criteria, long-term surgical remission rates range from 42% to 62% and multimodality (surgery followed by RT or medical treatment) remission rates vary from 52% to 97%.[438] When comparing the microscopic surgery with the endoscope approach, the latter provides the advantage of enhanced visualization of the suprasellar compartment and cavernous sinus walls.[444] In a series of 60 acromegalic patients who underwent endoscopic transsphenoidal surgery, Jane and colleagues[445] report that remission was achieved in 100% of microadenomas and 61% of macroadenomas with endoscopic transsphenoidal surgery in acromegalic patients. Interestingly, prior to transsphenoidal surgery, age and gender were not predictive of remission. Remission was defined as a normalized IGF-I, a post OGTT GH level below 0.4 ng/mL and a random GH of less than 1 ng/mL. Independent of which cutoff levels are used, both GH and IGF-I should be measured 3 months after surgery, although stabilization of IGF-1 levels can take up to 12 months. In addition, preoperative treatment with long-acting somatostatin analogs can have a prolonged suppressive effect on GH of up to 3 months postoperatively.[435] The postoperative GH level is the most important determinant of mortality outcome, with published data suggesting that a random GH level of less than 2 μg/L measured by radioimmunoassay is associated with the reversal of increased mortality and continued suppression of GH. Based on the

analysis of Jane and colleagues[445] a postoperative day 1 or day 2 morning GH level of less than 2.5 ng/mL is a strong predictor of remission. The risk for all-cause mortality in patients with acromegaly is increased by 32%[439] and persistence of disease (using the less stringent criteria of 5 μg/L) is associated with a 2.4- to 4.8-fold enhanced mortality.[446] If GH and IGF-I are normal 3 months postsurgery, annual follow-up measurements are recommended. The postsurgical serum GH level during the OGTT should be as low as 0.3 μg/L measured by a current two-site assay.[447] The IGF-I level should be within the age-adjusted reference interval according to the latest consensus statement of the Joint Consensus Conference of the Growth Hormone Research Society and the Pituitary Society, published in 2004.[440] Residual pituitary function should be assessed no later than 3 months postsurgery.[440]

Medical therapy includes *dopamine agonists* (e.g., cabergoline, bromocriptine), *somatostatin analogs* (e.g., octreotide, lanreotide), and the *GH receptor antagonist* pegvisomant. Dopamine agonists can provide adequate control in a minority of patients with acromegaly, and it may take 3 months to achieve maximal suppression of GH and IGF-I. Measurements should be performed annually after normalization. Vilar and colleagues[448] reported normalization of PRL and IGF-1 and 70% to 90% tumor shrinkage with cabergoline in two cases of somatotroph macroadenomas cosecreting PRL and GH. Cabergoline in combination with somatostatin receptor ligands may improve the responsiveness of patients with acromegaly that is otherwise resistant to maximal doses of somatostatin receptor ligands.[449] High-dose dopamine agonists used alone lead to a GH level of less than 5 ng/mL in only 15% of patients and normalize IGF-I levels in fewer than 10%. The advantage is the relatively low cost of the drugs, but disadvantages include the incidence of side effects in approximately 30% of patients.

Satisfactory GH and IGF-I levels are achieved in approximately 65% of patients, and IGF-I levels are normalized in 70% with somatostatin analogs. The effects are inversely related to pretreatment GH levels. Approximately 50% of patients show 30% average tumor volume shrinkage. Transient gastrointestinal symptoms, such as nausea, vomiting, and diarrhea, can occur during the first 2 weeks of therapy, and 25% of patients have gallbladder sludge and gallstones, which are usually diagnosed within the first 2 years after the start of treatment. Somatostatin analogs inhibit insulin secretion and may cause deterioration of glucose metabolism. Therefore, fasting blood glucose and hemoglobin A_{1C} should be measured annually. Although octreotide is given subcutaneously three times daily, there are also long-term depot somatostatin preparations (octreotide long-acting release) available that are given every 3 months.[450]

The GH receptor antagonist pegvisomant directly inhibits GH action in the periphery without inhibiting GH secretion. It normalizes circulating IGF-I levels in more than 95% of the patients treated for up to 36 months, whereas circulating GH values may rise during the first weeks, but then plateau. Pegvisomant is indicated after failure of other therapy options. Of 160 patients, 2 exhibited progression of tumor growth under pegvisomant therapy; therefore, patients should have an MRI every 6 months during the first year of pegvisomant therapy and annually thereafter. Therapy is monitored with IGF-I measurements every 6 months. In addition, liver enzymes should be monitored over the initial 6 months of therapy, given the potential transaminitis that can occur with GH antagonist therapy.[451] Observation of 1288 acromegalic patients over 2.1 years on pegvisomant showed that it is effective and safe. There was a low incidence of pituitary size increase (3.2%) and liver enzyme elevations (2.5%).[452]

Indications for the use of RT in acromegaly include conditions in which surgery or medical therapy does not lead to GH and IGF-I normalization. RT techniques include external radiation with a cyclotron or cobalt 60 source, proton-beam therapy, and stereotactic ablation by gamma knife radiosurgery. Whereas RT decreases GH levels to less than 5 ng/mL in 90% of patients within 18 years, fewer than 5% show a normalization of IGF-I.[453] An overall reduction in GH levels of 30% to 50% can be expected in the first 1 to 2 years, with a slower rate of decline after that. Pituitary deficiency develops in 50% of patients within 10 years of RT. GH and IGF-I should be measured 2 years after conventional multiple-dose RT, and pituitary function should be assessed annually. After gamma knife therapy, GH and IGF-I should be measured after 1 year and residual pituitary function measured at 6-month intervals.[440]

ACTH-Secreting Adenomas

In 70% of cases, hypercortisolism (Cushing syndrome) is caused by excessive ACTH secretion from the pituitary (Cushing disease).[454] Cushing disease is almost always caused by a solitary corticotroph adenoma[455] and presents more often in women than in men. The reported incidence is between 0.7 and 2.4 cases per million inhabitants per year, and patients have a fourfold higher mortality rate compared with age-matched and sex-matched peers as a result of cardiovascular complications.[456] Approximately 90% of the adenomas are microadenomas (<1 cm in diameter). The etiology of Cushing disease is unclear. Monoclonal tumor cell expansion is one possibility. Based on the findings in a patient with generalized glucocorticoid resistance due to a missense mutation of the glucocorticoid receptor preceding the development of Cushing disease,[457] others speculate that decreased negative feedback might also play a role in corticotroph adenoma formation. The cyclin-dependent kinase inhibitor p27 *(Kip1)* is believed to be involved in corticotroph tumorigenesis, and cytogenetic studies show loss of chromosomes 2, 15q, and 22. Brg 1 and histone deacetylase 2 (HDAC2) are considered candidates for glucocorticoid resistance and are also believed to be involved in the tumorigenic process of the adenoma.[458]

Symptoms of Cushing disease result from excessive cortisol production, with its widespread systemic effects. One of the earliest signs of Cushing disease is weight gain, often associated with increased abdominal, supraclavicular, facial, and dorsocervical fat.[459,460] However, proximal muscle weakness, with preservation of distal strength, plethora, and ecchymoses are considered the most discriminant indicators of hypercortisolism.[461,462] Such muscle weakness affects the upper arms and legs and results from cortisol-induced mobilization of amino acids from the muscle. If hypokalemia is present, muscle weakness is significantly more prominent. Cutaneous atrophy leads to wrinkling of the skin, which is especially obvious at the dorsum of the hands and elbows. The skin also can show striae around the hips, abdomen,

shoulders, and breasts. These striae are purple, in contrast to the white or pink striae found in generalized obesity, and the width of hypercortisolism-associated striae often is greater than 1 cm. The skin frequently shows increased bruisability as a result of increased fragility of the capillaries. Vellus hair, especially on the upper cheeks and forehead, can also be found. Other skin manifestations include those associated with fungal infections. Many patients have emotional and cognitive changes that correlate well with the degree of hypercortisolism and include depressed mood, irritability, tearfulness, insomnia, and anxiety.[463] Osteoporosis is present in 40% to 80% of patients, and a history of fractures of the feet, ribs, and vertebrae is not unusual. Hypertension occurs in approximately 80% of patients, and type 2 diabetes is present in 20% to 30%.[464,465] Menstrual and sexual dysfunction occurs in up to 75% of patients. A summary of the clinical manifestations of Cushing disease is shown in Table 21.3.

The diagnosis of Cushing disease does not rely on a single test, but often requires the combination of several biochemical tests. The procedures used to confirm the diagnosis are based on the fact that, in hypercortisolism (Cushing syndrome), the normal circadian rhythm of cortisol is no longer present and the normal feedback characteristics of glucocorticoids on the HPA axis are disturbed. To confirm hypercortisolism, the consensus statement by Arnaldi and colleagues stated that the 24-hour urinary free cortisol (UFC) measurement should be the initial screening test.[461] The 24-hour UFC is reported to have specificity of 100%, but sensitivity ranges from 45% to 71%. The authors suggest that up to three 24-hour UFC measurements should be obtained. When measuring urinary cortisol high-performance liquid chromatography, interfering substances, such as carbamazepine and digoxin, can produce false-positive results. Therefore, the preferred method for measurement of 24-hour UFC is tandem mass spectrometry, which is less likely to produce false-positive results. Of note, if the glomerular filtration rate is less than 30 mL/min, urinary cortisol excretion is decreased, resulting in a false-negative result.[466]

Another first-line diagnostic procedure is the low-dose (1 mg) overnight dexamethasone suppression test (DST). The recommended level for a normal plasma cortisol level after a low-dose overnight DST is less than 1.8 µg/dL (50 nmol/L), with a required cortisol assay sensitivity of 1 µg/dL.[461] Some centers suggest the 2-day low-dose DST as a

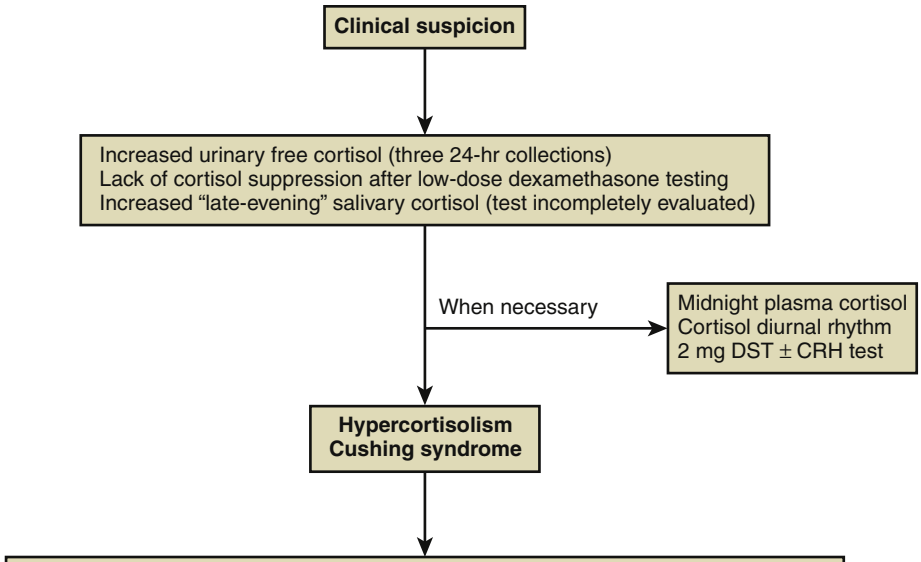
From Newell-Price J. Clinical manifestations of CD. *Endocr Rev* 19:647, 1998.

first-line screening test[467] in which the patient takes 0.5 mg dexamethasone orally every 6 hours. Urine is collected for UFC on 2 baseline days and is measured on the second day of dexamethasone administration, or cortisol is measured at 9 AM and 48 hours after the first dose. A normal response consists of a decrease in UFC to less than 10 μg/24 hours on the second day after dexamethasone administration or a plasma cortisol level of less than 1.8 μg/dL on the morning of the last dose of dexamethasone.[461]

Findling and Raff[468] suggested that measurement of a late-night or bedtime salivary cortisol level is an excellent surrogate for documenting an increased midnight serum cortisol level and is the test of choice. The assay has sensitivity and specificity of greater than 90% to 95%. Although this approach may be the most useful for the practicing endocrinologist, false-positive findings may be encountered in certain conditions, such as hypertension and advanced age, and in the setting of psychiatric disease.

Exogenous hypercortisolism always must be considered in the evaluation of patients for Cushing syndrome. The use of all prescription and over-the-counter medications and herbal remedies must be assessed, including injections into joints. This diagnosis is suggested by findings of suppressed ACTH and cortisol with no response to CRH or ACTH. Screening for synthetic glucocorticoids in serum or urine may be useful. Factitious hypercortisolism due to exogenous ACTH injections shows similar laboratory data as Cushing disease, but attention to the patient's history and a search for injection sites may show the cause.[469]

Other factors to consider include the effects of *exogenous compounds*, such as *estrogens*, *antiepileptic drugs*, and *glycyrrhetinic acid*, on cortisol measurements. Estrogen administration increases corticosteroid-binding globulin levels, with a concomitant increase in total plasma cortisol levels.[470] However, free cortisol levels and 24-hour UFC levels are normal. Pharmacological agents, such as phenytoin, barbiturates, and rifampicin, have an effect on the metabolism of dexamethasone by increasing its hepatic conjugation and biliary excretion. Thus, measurement of urinary free cortisol rather than a DST is suggested in these patients.[471,472] Glycyrrhetinic acid, an extract from licorice, has been shown to increase UFC by inhibiting 11β-hydroxysteroid dehydrogenase, which converts cortisol to cortisone. As a result, there is a cortisol excess, especially in the kidney, with increased concentrations in the urine, but not in the plasma. Therefore, urinary cortisol measurements can be misleading in patients taking licorice.[473]



Once the diagnosis of Cushing syndrome is made, the next challenge is to determine whether the hypercortisolism is ACTH-dependent or ACTH-independent. The interpretation of circulating ACTH levels depends on proper preanalytical sampling and on the use of an assay that can reliably detect plasma ACTH values of less than 10 pg/mL. ACTH values of greater than 10 pg/mL suggest ACTH-dependent Cushing syndrome (Cushing disease), whereas values of less than 10 pg/mL are most often consistent with ACTH-independent Cushing syndrome. However, caution is warranted in the interpretation of ACTH levels, given that Cushing disease can occur with ACTH values of less than 10 pg/mL in rare cases,[474] and adrenal hypercortisolism can be present with values of greater than 20 pg/mL. Values of 10 to 20 pg/mL are considered indeterminate, and it is prudent to repeat measurements of ACTH or perform a CRH test. If the ACTH response to CRH is greater than 20 pg/mL, Cushing disease is very likely.

If the diagnosis of an ACTH-dependent pituitary adenoma seems probable, MRI may help to locate the adenoma. In 65% of cases, MRI shows a pituitary tumor. However, the diagnosis of Cushing disease cannot be based on MRI imaging alone, given that some ACTH-secreting adenomas may not be visible, even after gadolinium enhancement, and nonsecreting incidentalomas may be present and misinterpreted as the source of ACTH.

Cushing's disease accounts for 70% to 90% of cases of ACTH-dependent hypercortisolism. However, ectopic ACTH production must be excluded. Currently, the procedure of choice to exclude ectopic ACTH production is IPSS. In experienced centers, bilateral IPSS has very high sensitivity (95% to 99%) for diagnosing Cushing disease. The test is recommended in patients with ACTH-dependent Cushing syndrome who have clinical, biochemical, or radiological findings that are discordant or equivocal.[475] An IPPS-to-peripheral cortisol ratio (IPSS/P) greater than 2 in the basal state and 3 after CRH administration suggests the diagnosis of Cushing disease. False-negative results with IPSS can occur as a result of unsuccessful catheterization or anomalous venous drainage; the additional measurement of PRL can be helpful in such cases.[476] IPSS has limited utility in lateralization of ACTH-producing pituitary adenomas within the gland. In a literature review of 313 cases, the diagnostic accuracy ranged from 50% to 100%, and a gradient of 1.4 or greater across both sides of the pituitary predicted the tumor location in 78% of cases. In the case of asymmetrical drainage, IPSS predicted the lateralization of the adenoma in only 44% of patients. Cavernous sinus sampling has been proposed as an alternative to IPSS for lateralization because the cavernous sinuses are closer to the pituitary. Accurate localization was reported in 73.3% of cases without CRH and in 93.3% of cases with CRH stimulation.[477]

A less invasive test for distinguishing ectopic ACTH production from pituitary-dependent Cushing syndrome is the single-dose, 8 mg overnight DST, which has 92% sensitivity and 100% specificity for Cushing disease when morning plasma cortisol is suppressed by 50%, according to Tyrrell and colleagues.[478] Aron and colleagues reported sensitivity of 81% and specificity of 66.7%, with both the 2-day, high-dose DST (2 mg dexamethasone every 6 hours for 48 hours) and the 8 mg, single-dose overnight test using the 50% threshold.[479] Patients with ectopic ACTH secretion were significantly older (mean, 51 years versus 40.2 years), were more likely to be male (58.8% versus 27.4%), had a shorter duration of clinical findings (11.6 months versus 39.9 months), and were more likely to have hypokalemia (50% versus 8.6%). Such patients also had higher baseline 24-hour UFC levels (mean, 3015 μg/day versus 422 μg/day) and higher plasma ACTH levels (210 pg/mL versus 78 pg/mL)[479] compared with patients with Cushing disease. Figure 21.23 describes a possible diagnostic approach to determine the source of hypercortisolism.[461]

Special mention should be made of differentiating patients with Cushing syndrome from those with the much more common PCOS. Women of reproductive age who have hypercortisolism have symptoms similar to those of women with PCOS, including oligomenorrhea or amenorrhea,

	Adrenal	Pituitary	Ectopic
ACTH	Low	Normal/high	Normal/very high

Diagnosis and complications of Cushing's syndrome: a consensus statement.* J Clin Endocrinol Metab *88:5593, 2003, with permission.)*

adrenal hyperandrogenism with acne or hirsutism, and metabolical syndrome.[461] Kaltsas and colleagues speculated that PCOS may be one manifestation of Cushing syndrome. In their small group of women, they found that 46% had ovaries with morphological features of PCOS.[480] Because the prevalence of PCOS is significantly higher than that of Cushing syndrome, the latter should always be considered in the differential diagnosis of PCOS. Especially in the case of mildly elevated cortisol levels, an endocrine profile suggestive of PCOS can be present (estrogen sufficiency, normal or increased androgen levels, enlarged ovaries). Kaltsas and colleagues also found that patients with proven Cushing syndrome had significantly higher blood pressure (both systolic and diastolic) than women with PCOS.[480]

Treatment. The treatment of choice of Cushing disease is selective transsphenoidal adenoma resection. The procedure has a mortality rate of less than 1%, and the most common postsurgical complication is transient DI, which may be present in up to 28% of patients.[481] The goal of surgery is selective adenomectomy and preservation of as much normal pituitary tissue as possible. If it is not possible to identify the tumor, hemihypophysectomy on the side of the gland with the ACTH gradient on IPSS is often performed. Recovery of the HPA axis after successful surgery rarely occurs before 3 to 6 months and commonly is not confirmed until 1 year after the procedure. Until recovery is confirmed, patients are treated with glucocorticoid replacement.

The definition of cure of Cushing disease is still under debate. Several reports suggest that serum morning cortisol levels of less than 5 μg/dL measured at day 1 or day 2 after surgery (first surgery) are associated with sustained remission in 93% of patients after 32 months.[482] Others suggest that postsurgical remission is likely if serum cortisol levels are 2 μg/dL or less within 72 hours of surgery.[483,484] When applying a serum cortisol threshold of 1.8 μg/dL or less measured 5 to 14 days after surgery and at least 24 hours after the last dose of hydrocortisone, the reported surgical remission rate was between 40% and 65%, and the 10-year incidence of recurrence was 25%.[482] Other studies reported postoperative remission rates of 60% to 90%.[485] Of note, postoperative detectable serum cortisol levels above those suggested earlier may still be compatible with cure and can decrease within 2 weeks. However, the absence of secondary adrenal insufficiency 4 to 6 weeks postoperatively suggests that the patient has persistent hypercortisolism or will have a recurrence.[468] When no histological confirmation of tumor removal can be made, remission is achieved in only 50% of patients.[486] Reasons for surgical failure include residual tumor within the pituitary gland, tumor located ectopically in the intrasellar or perisellar region, and residual invasive tumor within the dura mater of the sella turcica or the cavernous sinus[487,488] suggests that the lateral invasion of the tumor into the medial wall of the cavernous sinus may be caused by the anatomy of the lateral venous drainage of the pituitary gland. The confluent pituitary veins that penetrate the pituitary capsule and the dura of the cavernous sinus produce an anatomical route of least resistance. When surgery is unsuccessful, additional therapeutic options include repeated transsphenoidal surgery, medical treatment, RT, and bilateral adrenalectomy. A report by Locatelli and colleagues[485] suggests a favorable effect on remission in patients with initial surgical failure when the repeat surgery is done within 15 days. Figure 21.24 summarizes their suggested management of Cushing disease.[485]

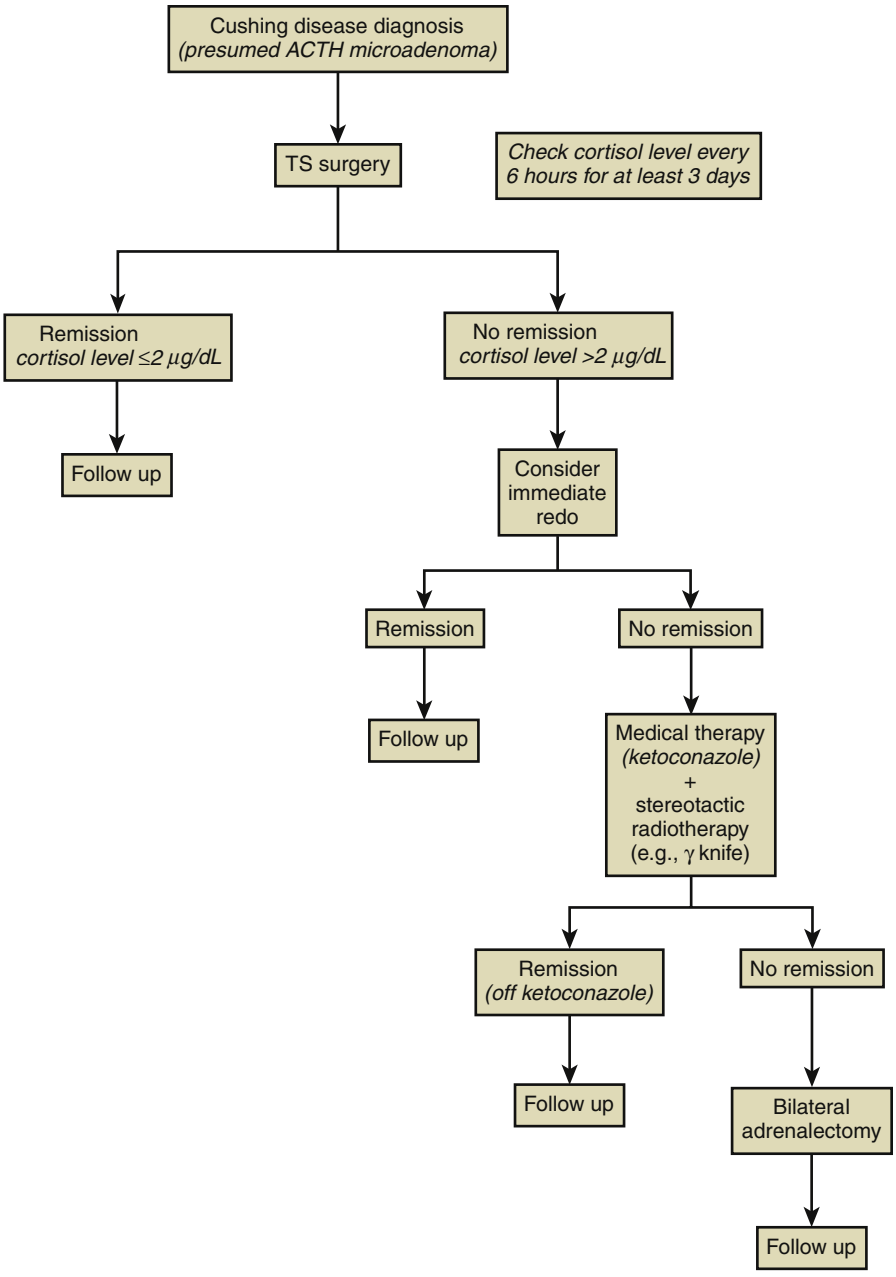

FIGURE 21.24 Therapeutic algorithm for the management of Cushing disease. ACTH, adrenocorticotropic hormone TS, transsphenoidal. *(Reproduced from Locatelli M, Vance ML, Laws ER. Clinical review: the strategy of immediate reoperation for transsphenoidal surgery for Cushing's disease.* J Clin Endocrinol Metab *90:5478, 2005, with permission.)*

When surgical intervention fails or is likely to be unsuccessful (e.g., in patients with cavernous sinus or dural invasion), pituitary radiation—either conventional or gamma knife—is recommended. Remission rates of 76% have been reported for gamma knife RT.[489,490] The expected normalization of cortisol levels occurs 12 to 36 months after RT; thus, adrenostatic therapy is required in the interim.[489,490]

Medical treatment targets adrenal steroid secretion and includes ketoconazole, metyrapone, aminoglutethimide, mitotane, and etomidate. *Ketoconazole* is an imidazole antifungal agent and an inhibitor of cytochrome P450 enzymes that blocks adrenal steroid synthesis at several points. The principal side effects of ketoconazole include hepatic toxicity, skin rash, gastrointestinal upset, and gynecomastia.[491,492] *Metyrapone* blocks the cortisol synthetic pathway by inhibiting the enzyme 11β-hydroxylase. The drug achieves cortisol trough levels 2 hours postdose and is given in three to four doses per day. However, the drug is not approved by the U.S. Food and Drug Administration for this use and has been withdrawn from the U.S. market. The main side effects include hirsutism, acne, edema, hypertension, and gastrointestinal upset.[201] *Aminoglutethimide* blocks the conversion of cholesterol to pregnenolone and causes a reduction in the synthesis of all hormonally active steroids, including corticosteroid production. Its side effects include a morbilliform rash, fever, and dizziness. *Mitotane* blocks adrenal cortisol synthesis and has direct cytotoxic effects on the adrenals. In high doses, it can achieve remission in up to 83% of patients. In lower doses and in combination with RT, remission can be achieved in up to 80% of patients.[493] The onset of effect can take up to 6 to 8 weeks, and effects can last for weeks and even months after discontinuation due to its lipophilic activity. Major side effects are related to gastrointestinal and neurological toxicity. Elevated liver enzyme levels, abnormal

platelet function, and hypercholesterolemia are other side effects. High doses are used for adrenocortical carcinoma and can cause anorexia and ataxia. *Etomidate* is an imidazole-derived anesthetic agent that inhibits adrenocortical 11β-hydroxylase. Given as a nonhypnotic low-dose infusion (0.1 mg/kg/hour or lower), it has been shown to control cortisol levels in severe hypercortisolemia.[494] It acts rapidly, but its use is limited because it must be given parenterally. *Mifepristone*,[495] a type 2 glucocorticoid receptor antagonist, which is currently under investigation has been shown to rapidly decrease circulating cortisol levels in malignant and benign hypercortisolism. Another agent, *Pasireotide*, has a unique, broad somatostatin-receptor-binding profile, with high binding affinity for somatostatin receptor subtype 5. In a double blind, phase 3 study, urinary free cortisol levels decreased by approximately 50% by month 2 and remained stable for 12 months. The combination of *pasireotide* with a dopamine agonist and low dose ketoconazole induced biochemical remission in 88% of patients with Cushing disease.[496,497]

In cases of persistent hypercortisolism or intolerable side effects related to the adrenostatic therapy, bilateral adrenalectomy is an option. It has no risk of hypopituitarism and may be chosen over RT in younger patients who worry about postradiation hypopituitarism and loss of reproductive function. Disadvantages of bilateral adrenalectomy include the lifelong requirement to take glucocorticoid and mineralocorticoid replacement therapy as well as a 50% risk of Nelson syndrome (discussed later in the chapter). Prophylactic pituitary radiation before adrenalectomy can reduce this risk to 25%.[498]

Nelson Syndrome

The first case of Nelson syndrome (NS) was reported in 1958.[499] Since that time, various criteria have been used to define this syndrome, including: (1) the presence of a pituitary macroadenoma, and (2) the presence of high ACTH levels after bilateral adrenalectomy. Nelson and colleagues suggested that the definition need not include the presence of a pituitary adenoma.[500] More recently, others have used the term *corticotroph tumor progression* for NS.[501]

The pathogenetic mechanisms underlying the development of a Nelson tumor are not fully understood. NS is believed to be in part the result of lack of cortisol feedback after adrenalectomy. Other findings support a role for mutations in regulatory genes.[457,502] Some studies suggest that ACTH stimulation after CRH infusion is greater and more prolonged in NS compared with Cushing's disease.[503] Studies of the ACTH secretion profile in NS show an altered secretion profile compared with patients with Cushing disease.[504] Immunohistochemically, tumors stain strongly positive for ACTH.

Published data suggest that the prevalence of NS after adrenalectomy ranges from 8% to 50%.[498,505] The interval between adrenalectomy and the diagnosis of NS ranges from 0.5 year to 24 years. According to Assie and colleagues,[506] a shorter duration of Cushing disease and a relatively high plasma ACTH concentration in the year after adrenalectomy are predictive of corticotrophic tumor progression. In their study, tumor progression was first diagnosed as early as 3 years after adrenalectomy. Others found a relationship between pretreatment urinary cortisol levels and the occurrence of NS.[507] Kelly and colleagues[508] reported that a shorter duration of the disease before adrenalectomy is also predictive of tumor progression.

The clinical features of NS are caused by the mass effects of the tumor on surrounding structures, secondary loss of other pituitary hormones, and the effects of the high serum alpha-melanocyte–stimulating hormone (α-MSH) concentration (a derivative of proopiomelanocortin) on the skin. Cutaneous hyperpigmentation of hand lines, scars, gingivae, and areolae is present.[509] The degree of pigmentation reflects the level of serum α-MSH.

Treatment. Treatment strategies for Nelson syndrome include surgical intervention and RT, which rarely cure the disease. There have also been therapeutic approaches with drug treatment. Because the peroxisome proliferative-activated receptor (PPARγ) is expressed in corticotroph adenomas, the effect of PPARγ agonists on tumor growth has been documented. Using a rodent model, some studies have suggested that PPARγ agonists have a favorable effect on retarding tumor growth and lowering ACTH and cortisol levels.[510,511] However, studies in humans that have focused on the effects of rosiglitazone (given over 8 weeks) have not shown a reduction in ACTH. Longer-duration studies and the evaluation of PPARγ agonists with stronger agonist activity warrant consideration.[512] Other neuropharmacologic approaches, such as treatment with valproate or dopamine agonists, are rarely effective. Studies investigating neurosurgical interventions show success rates of 10% to 70%.[513] RT of the pituitary after adrenalectomy has been shown to reduce the risk of NS by 50% in some studies.[498]

Thyrotropin-Secreting Tumors and Thyrotroph Hyperplasia

The term *thyrotropin-producing pituitary tumors* describes two distinct clinical conditions: true thyrotroph neoplasia, which results in secondary hyperthyroidism, and pituitary hyperplasia, resulting from long-standing hypothyroidism.[514] It is important to distinguish one from the other because the therapeutic approaches are different.

Thyrotrophic adenomas (TSHomas) account for 0.5% to 1% of all pituitary adenomas, with a prevalence of one to two cases per million. They have no sex preference. TSHomas are almost always benign but are, in approximately 90% of cases, macroadenomas, which are highly invasive.[515] Such tumors have been shown to be monoclonal in origin.[516] Previous thyroid ablation appears to have deleterious effects on the size of the pituitary adenoma. Approximately 72% of tumors secrete TSH alone. In 28% of cases, hypersecretion of TSH is associated with hypersecretion of the α subunit and can also be associated with hypersecretion of GH and PRL and, in rare cases, with gonadotropins. No association with ACTH is known.

Clinically, patients present with symptoms of hyperthyroidism (goiter and clinical thyrotoxicosis) and with mass effects of the pituitary adenoma (visual field defects, headache). However, the size of the tumor in the imaging study does not correlate with serum TSH levels.[514] Clinical characteristics of patients with TSHomas are shown in Table 21.4. More than 90% of patients present with a goiter. Approximately one third had an inappropriate thyroidectomy or radioiodine thyroid ablation before the

TSH-secreting pituitary adenoma was discovered. Typically, the concentration of thyroid hormone is elevated in the presence of detectable TSH. Some reports suggest that TSH molecules in patients with TSHomas have increased bioactivity.[517] It has been suggested that an α subunit or TSH ratio above 1 indicates a TSHoma.[518] The TSH inhibition test using T_3 (80 to 100 μg) given for 8 to 10 days can be used to confirm the presence of a TSHoma. The lack of suppression confirms the autonomy of the TSH secretion by the adenoma, but the test is contraindicated in the elderly and patients with coronary heart disease.[514] In the rare cases when no pituitary adenoma is present, resistance to thyroid hormone must be considered.

Treatment. The primary approach to treatment of TSHomas is surgical removal of the pituitary tumor. Approximately two thirds of TSHomas respond to surgery or irradiation.[514] An undetectable TSH level 1 week after surgery typically indicates successful surgery. A measurable TSH level after the T_3 suppression test suggests the need for additional treatment after surgery. If surgery is not an option, RT followed by somatostatin analog administration can be considered.

Pituitary Hyperplasia

Pituitary hyperplasia as a consequence of untreated hypothyroidism is rarely symptomatic, but may present with hypothyroidism, headache, visual defects, hyperprolactinemia, amenorrhea, or galactorrhea. A goiter is present in 16% of cases. In children, presenting signs and symptoms include abnormal puberty, delayed bone age, and short stature.

Treatment. Treatment is medical, with adequate thyroid hormone replacement resulting in total tumor regression in 62% and partial regression in 29% of cases,[514] occurring sometimes within 1 or 2 months. In children, initial therapy can lead to pseudotumor cerebri; such a complication should be considered when symptoms worsen after initiation of thyroid hormone replacement.

Adenomas of Multiple Endocrine Neoplasia Type 1

The combined occurrence of tumors of the parathyroid gland, pancreatic islet cells, and the anterior pituitary is characteristic of *multiple endocrine neoplasia type 1* (MEN 1; also called *Wermer syndrome*). The *MEN1* gene is located on chromosome 11q13 and encodes the protein MENIN. More than 90% of tumors from patients with MEN 1 have loss of heterozygosity, suggesting that the *MEN1* gene is a tumor-suppressor gene. The overall incidence of MEN 1 is 0.25%. It is 1% to 18% in patients with primary hyperparathyroidism and less than 3% in patients with pituitary tumors.[519,520] All forms of MEN 1 are either inherited as autosomal dominant syndromes or occur sporadically. A patient may be considered to have MEN 1 if two of the three principal related tumors (parathyroid, pancreatic islet [e.g., gastrinoma, insulinoma, glucagonoma, VIPoma], and anterior pituitary [prolactinoma, GH-producing, ACTH-producing, nonfunctioning]) are diagnosed.[521] Associated tumors include carcinoid tumors, adrenocortical tumors, lipomas, facial angiofibromas, and collagenomas, as well as thyroid tumors.[522] The incidence of pituitary tumors in patients with MEN 1 ranges from 15% to 90%. The majority of the pituitary tumors are microadenomas, and approximately 60% secrete PRL. Fewer than 25% secrete GH, and 5% secrete ACTH. The rest are nonfunctioning and secrete glycoprotein subunits.

Treatment. The treatment of these pituitary tumors is identical to that of other isolated pituitary tumors. Because of its autosomal dominant inheritance,[523] distinction between sporadic and familial forms is important for first-degree relatives who have a 50% risk of having the disease.

Carcinoma of the Pituitary

Pituitary carcinomas are rare neoplasms that can be distinguished from invasive adenomas by the presence of craniospinal or systemic metastasis. An unresolved question is whether pituitary carcinomas develop from pituitary adenomas or occur *de novo*. Studies addressing this question have been limited by the small number of patients and the lack of sufficient follow-up.[524] Pituitary carcinomas are defined by metastases. Whether extensive invasion of the brain by a pituitary tumor is a further criterion is a matter of controversy.[525] Adenomas that meet these criteria should be followed carefully.

Immunohistochemically, MIB-1 (Ki-67) and p53 staining correlate with the aggressiveness of pituitary tumors.[526] Studies of molecular markers suggest that the *Ras* oncogene may play a role in the anaplastic progression of GH-producing tumors. Expression of the *p53* gene has been shown to be increased during the transformation of a pituitary adenoma to a pituitary carcinoma.[527] Loss of heterozygosity on autosomes 1p, 3p, 10q26, 11q13, and 22q12 has also been shown to be present in ACTH-producing pituitary carcinomas.[528] Other factors, such as telomerase and its subunits, have been shown to be increased in PRL-producing pituitary carcinoma.[529] Animal studies have suggested a connection between the loss of the retinoblastoma gene *(Rb)* and the development of pituitary carcinomas, observations that could not be confirmed in benign ACTH-positive adenomas in humans.[530]

The prevalence of pituitary carcinoma is 0.2% of all adenohypophysial neoplasms,[531] with the majority of such tumors being endocrinologically active (88%). Available data suggest that 12% are null cell pituitary tumors, 33% are PRL-producing tumors, 42% are ACTH-producing tumors, 22% are associated with Nelson syndrome, 6% are GH-producing pituitary tumors, 5% are gonadotroph-producing tumors, and approximately 1% are TSH-producing tumors.[531,532] PRL-producing pituitary tumors (71%) and ACTH-producing tumors (57%) have the highest propensity to metastasize.[533] An average 15.3-year interval between adenoma diagnosis and the development of carcinoma has been reported in cases of Nelson syndrome.[531]

The prognosis of pituitary carcinoma is poor. In a study of 15 patients with pituitary carcinoma, 80% died of metastatic disease within 7 days to 8 years after diagnosis. Sixty-six percent of the patients died within 1 year.[531] Sironi and colleagues reported a mean survival time for patients with PRL-secreting carcinomas of 2.4 years.[534]

The majority of pituitary carcinomas are hormone-secreting, are invasive, and result in symptoms from local mass effect. Sites of pituitary tumor metastasis include the brain, spinal cord, bone, liver, lymph nodes, ovary, heart, and lung. In ACTH-secreting pituitary carcinomas, ACTH levels range from 145 to 280,000 pg/mL.[535] Serum PRL levels associated with PRL-secreting pituitary carcinomas range from 6 to 22,000 ng/mL, and increased levels are associated with tumor recurrence and metastasis.[531,536]

Treatment. Treatment options for pituitary carcinomas include medications specific for the pituitary tumor as well as RT and chemotherapy. Dopamine agonists have a role in the treatment of PRL-producing pituitary tumors, but control serum PRL levels for a limited time. Neither adjuvant RT to the sella and distant metastases nor stereotactic radiation has been shown to have an effect on long-term outcome. Similarly, different chemotherapy protocols with agents such as carmustine, hydroxyurea, and 5-fluorouracil have not improved outcomes.[532]

Temozolamide, a lipophilic imidazotetrazine derivative that is converted to a methylating alkylator agent, MITC (methy-triazene-1-yl)-imidazole-4-carboxide) which induces DNA damage, has shown to be effective in pituitary carcinoma and is generally well tolerated.[537-540]

Metastatic Disease Involving the Pituitary

Metastatic disease to the pituitary has been found in 1% to 3.6% patients at the time of pituitary resection.[541] If both the pituitary and the surrounding sella turcica are evaluated, metastases are found in 27% of patients with malignant tumors.[542] Of tumors known to metastasize to the pituitary, cancer of the breast is the most common (accounting for up to 33% to 40%), followed by cancer of the lung (33% to 36%). Others include prostate, colon, and other gastrointestinal tumors; lymphoma; leukemia; and thyroid tumors.[543] Most metastatic disease is found in the posterior pituitary gland (57%), followed by the anterior gland (13%), and both lobes (12%). This preference for the posterior pituitary is probably explained by its direct arterial blood supply.[544] Of interest, metastases from breast cancer seem to occur most often in the anterior as opposed to the posterior pituitary. Perhaps surprisingly, most metastases to the pituitary are clinically silent and only 7% have been found to have produced symptoms in an autopsy series. Clinical features include DI, followed by ophthalmoplegia, visual impairment, headache, and anterior hypopituitarism. Kimmel and O'Neill[545] suggested that 14% to 20% of patients presenting with DI may have pituitary metastases.

Although there are no imaging characteristics that are specific for pituitary metastases, Fassett and Couldwell[543] have suggested that thickening of the pituitary stalk, loss of the high-intensity signal of the posterior pituitary, isointensity of T1- and T2-weighted MRI scans, invasion of the cavernous sinus, and sclerotic changes around the sella turcica may make metastatic disease more likely.

Treatment. Treatment includes surgery, RT, and chemotherapy, which do not change the mean survival rate in most cases, which ranges from 6 to 22 months.[546]

Pituitary Apoplexy and Sheehan Syndrome

Pituitary Apoplexy

Pituitary apoplexy is a potentially life-threatening condition that results from acute expansion of an infarcted or hemorrhagic pituitary adenoma. Symptoms typically associated with pituitary apoplexy include sudden severe headache, visual field defects, decreased visual acuity, and ophthalmoplegia.[547] Other symptoms are nausea, vertigo, meningismus, facial pain, and in some cases, hemiparesis and Horner syndrome. Headache occurs in nearly 100% of cases and is believed to be a consequence of meningeal irritation from blood or dural stretching. In cases of extension to the lateral wall of the sinus, cranial nerve damage can occur in association with ophthalmoplegia. The accompanying

hypopituitarism and possible pressure on the brain stem can result in decreased consciousness. The symptoms are often similar to those of other disease entities, such as ruptured intracranial aneurysms and bacterial or viral meningitis.

All types of pituitary tumors have a similar risk of apoplexy, and the incidence of apoplexy within pituitary tumors has been estimated at 2% to 7%.[548,549]Approximately 50% to 80% of cases of apoplexy occur in patients who were unaware of the presence of pituitary tumors before the apoplectic event. The ratio of men to women presenting with apoplexy is 2:1, and most patients present in the fifth or sixth decade.[547] Precipitating factors described in the literature include hypertension, hypotension, bromocriptine therapy, anticoagulation, surgery, diabetic ketoacidosis, RT, and pregnancy.[550-555]

The most reliable method to diagnose pituitary apoplexy is MRI. Early MRI images show predominant hyperintensity on T1 images and predominant hypointensity on T2-weighted images.[556] Whereas pituitary apoplexy can be confirmed by MRI in essentially all cases, CT scans may not show this disorder in 54% to 79% of patients.[547] Because vascular emergencies are more common than pituitary apoplexy, head CT is often the first procedure performed to evaluate the symptoms that are common to both conditions. Thus, the low sensitivity of CT scanning for the diagnosis of pituitary apoplexy must not be overlooked when no aneurysm is identified.

Treatment. Usually timely surgical intervention to provide decompression is essential. Although the outcome of pituitary apoplexy is unpredictable, cranial nerves III, IV, and VI seem to recover more easily than do the chiasmal and optic nerves, especially if decompression is achieved within 7 days. DI occurs in only 2% to 3% of patients, whereas reports show that 88% of patients are GH-deficient, 76% do not secrete LH, and 66% have secondary adrenal insufficiency.[547] Verrees and colleagues reported that decompression within 3 days after the onset of symptoms resulted in full return of pituitary function in 73% of patients.[547]

Indications for conservative treatment of pituitary apoplexy should be made by a multidisciplinary team of experts in neurosurgery, endocrinology, and ophthalmology. This approach can be tried in patients, who are without neuroophthalmic signs or with mild and stable signs. Management includes steroid administration and careful monitoring, including repeated formal assessment of visual fields and acuity and neurological assessment, as well as evaluation of the pituitary function.[557]

Sheehan Syndrome

Sheehan syndrome is a form of pituitary apoplexy that results from hypotension secondary to severe postpartum uterine hemorrhage. In rare cases, it is seen without massive bleeding or after normal bleeding. It has been suggested that the enlarged pituitary during pregnancy is more prone to have ischemic necrosis after postpartum bleeding. The presence of a small sella has also been proposed as a potential risk factor for Sheehan syndrome.[558] It may be difficult to distinguish Sheehan syndrome from postpartum autoimmune hypophysitis (AH), given that pituitary antibodies have been described in both disorders.[559] In the early stage of Sheehan syndrome, MRI shows an enlarged pituitary, and in later stages, an empty sella can be present.[560] Clinical manifestations include failure of postpartum lactation and failure to resume regular menstrual cycles postpartum, together with the loss of pubic and axillary hair. Other symptoms of anterior hypopituitarism can be present. In the case of hypopituitarism, replacement therapy (especially glucocorticoids) must be initiated as soon as possible. Partial or complete spontaneous recovery has been reported.[561]

Empty Sella Syndrome

Primary Empty Sella Syndrome

Primary empty sella syndrome is a radiological finding. It refers to the anatomical state that occurs as a result of intrasellar herniation of the subarachnoid space through an opening in the diaphragma sellae, allowing spinal fluid to enter the sella. The result is a compressed and often posteriorly displaced pituitary gland. The term *primary empty sella syndrome* is used when no identifiable cause can be found. The majority of patients are asymptomatic. Of those who have symptoms, 80% are middle-aged women who are overweight and hypertensive.[562] Chronic headache is the most common symptom and often the only one. Elevated intracranial pressure is believed to be an important contributing factor, and 10% of patients with benign intracranial hypertension also have empty sella syndrome.[563] In 5% of patients, moderate hyperprolactinemia resulting from stalk compression is evident. In 10% of patients, CSF rhinorrhea is present and is the result of CSF pulsation-associated thinning of the sella floor.[564]

Secondary Empty Sella Syndrome

Secondary empty sella syndrome can be the consequence of previous surgery, radionecrosis, or pituitary apoplexy. In contrast to primary empty sella syndrome, there is no association with body habitus or sex. Visual symptoms are not uncommon and are usually the result of chiasmal prolapse. Panhypopituitarism or selective pituitary hormone deficiencies can occur. Having established the diagnosis, the treatment is primarily based on the complications (endocrinological, ophthalmological, CSF rhinorrhea).

Lymphocytic Hypophysitis

Autoimmune hypophysitis, also referred to as *lymphocytic hypophysitis*, is the most common form of chronic inflammation that primarily affects the pituitary gland. AH is a rare disease that should be part of any differential diagnosis of a nonsecreting pituitary mass during pregnancy or postpartum. Outcomes of this disease range from spontaneous recovery to death. Women are affected much more commonly than are men (9:1 occurrence rate, and symptoms include those of sellar compression, such as headache and visual disturbance, pituitary deficiency, and DI).[565] DI can be masked by coexisting glucocorticoid deficiency, given that glucocorticoids inhibit the secretion of ADH from the paraventricular nucleus and suppress the synthesis of aquaporin 2, which is an ADH-dependent water channel in the renal collecting tubules.[566-568] In AH, the anterior pituitary corticotrophin-secreting cells are most frequently impaired, whereas the least common finding is hyperprolactinemia. The clinical diagnosis of AH may be difficult.

Indeed, 40% of cases are misdiagnosed preoperatively as pituitary adenomas. AH should always be considered when there is a temporal relationship with the identification of pituitary pathology and pregnancy or the postpartum state. The strong association between pregnancy and AH might be explained by the presence of low-titer serum antibodies, which are directed against alpha-enolase, a 49-kDa cytosolic pituitary protein that is expressed in the placenta.[569,570] However, others have found a similar association between these antibodies and nonfunctioning pituitary adenomas, thus calling into question the specificity of these antibodies. Other autoantibodies have been associated with the disease as well. AH has been associated with other autoimmune diseases, such as Hashimoto thyroiditis, polyglandular syndrome type 2, Graves disease, and systemic lupus erythromatosis.[565] Imaging studies often show an enlarged pituitary, sometimes with suprasellar extension and occasionally with thickening of the infundibulum. In rare cases, an empty sella is present.[571] The histopathology of lymphocytic hypophysitis shows lymphoplasmacytic infiltrates.

Treatment. Visual loss related to AH can necessitate surgical intervention. If surgery is not urgently needed, medical treatment with corticosteroids and sequential MRI are recommended. There are also reports of successful treatment with azathioprine[572] and methotrexate[573] after unsuccessful glucocorticoid therapy. RT has been used successfully in patients who have failed medical treatment or had repeated recurrences.[574,575]

The differential diagnosis of hypophysitis should also include sarcoidosis, fungal infections, tuberculosis, Langerhans cell granulomatosis, IgG4-related hypophysitis, Wegener's granulomatosis, Tolosa-Hunt syndrome, CTL4 blockade-related hypophysitis.[576]

Pituitary Hemochromatosis

Primary hemochromatosis is the most common form of hemochromatosis. It is an autosomal recessive disorder caused by a single site mutation of the *HEFE* gene.[577] This gene is located near the human leukocyte antigen complex and produces the *HEFE* glycoprotein, which binds to the transferrin receptor and decreases the affinity of this receptor for iron-bound transferrin. *Secondary hemochromatosis* may result from disorders including thalassemia, aplastic anemia, blood transfusion, long-term kidney dialysis, and chronic liver disease. Patients with hemochromatosis of both types have increased iron deposition in different organs, including the liver, skin, heart, joints, pancreas, hypothalamus, and pituitary. The most common feature of hemochromatosis is fatigue; other symptoms include arthritis, heart failure, diabetes mellitus, hepatic cirrhosis, hyperpigmentation, hypothyroidism, and hypogonadism.[578]

Iron has been found as aggregates of ferritin and hemosiderin in the cytoplasm of all five anterior pituitary cell types, but with a propensity for the gonadotrophs. The cytotoxic effect seems to correlate with the quantity of iron stored. The most common consequences of deposition of iron in the pituitary gland and hypothalamus are hypogonadotropic hypogonadism and GH deficiency.[579] Thirty percent of men with hemochromatosis have low gonadotrophin and testosterone levels resulting from impaired LH and FSH response to GnRH by the damaged gonadotrophs.[580] Siminoski and colleagues[117] described a patient with idiopathic hemochromatosis with no LH or FSH response after clomiphene administration, suggesting that a defect in the hypothalamic GnRH response can also occur. In patients with iron overload, MRI shows low signal intensity,[581] and some authors suggested that the MRI T2 relaxation rate of the pituitary correlates with the extent of pituitary siderosis.[582]

Treatment. Treatment options include phlebotomy and desferrioxamine, which is a chelating agent.[583]

Iatrogenic Pituitary Dysfunction

Hypopituitarism has been described in patients after *radiation therapy* for nonpituitary disorders, such as primary brain tumors and nasopharyngeal carcinoma, as well as in children who undergo prophylactic cranial irradiation for leukemia. GH is usually the first pituitary hormone affected by cranial RT, followed by the gonadotropins ACTH and TSH.[133] The total dose of radiation administered determines the severity of the pituitary deficiencies.[133] Children and adults differ with regard to the threshold dose for the risk of hypopituitarism.[138] Agha and colleagues reported that 41% of adult patients who had irradiation of a nonpituitary brain tumor had hypopituitarism.[135] After RT, regular evaluation is mandatory to check for recurrence and pituitary function, even though the site of radiation may have been distant from the hypothalamic–pituitary region.[134]

Radiation of the pituitary, most often used to treat residual disease after pituitary surgery or recurrent pituitary tumors, typically uses either gamma knife or linear accelerator–based radiosurgical techniques. Gamma knife treatment delivers a high dose (25 Gy to the periphery of secretory tumors and 12 to 20 Gy to the periphery of nonsecretory tumors) in a single fraction. Hypopituitarism occurs in approximately 30% of patients postradiation, with thyroid and GH deficiencies being the most common.[584] Data on the outcome of treatment with linear accelerator–based treatments are comparable to those for gamma knife treatment, with 20% to 40% of patients requiring hormone replacement 10 to 20 years after linear accelerator radiation.[585] Additional longer-term studies are needed to evaluate the hormonal effects of both treatment options.

Chemotherapy, alone or in combination with RT, can affect the hypothalamic–pituitary axis. Patients treated with chemotherapy (e.g., vincristine, vinblastine) may have syndrome of inappropriate antidiuretic hormone secretion as a result of cytotoxic effects on the paraventricular and supraoptic neurons, leading to increased vasopressin release.[586] Autopsy findings have related cyclophosphamide therapy to vasopressin depletion of the posterior pituitary as well as to infundibular necrosis.[587]A rare case of pituitary apoplexy after treatment with vinblastine, cisplatin, and methotrexate for squamous cell carcinoma was reported by Davies and colleagues.[588] Prolonged high-dose exogenous glucocorticoid therapy in children with leukemia or lymphoma can lead to secondary adrenal insufficiency via suppression of the HPA axis. Children treated with chemotherapy often exhibit growth retardation after which "catch-up growth" occurs. When catch-up growth does not occur after 1.5 to 2 years, such children should be tested for GH deficiency.

CHAPTER 22

Polycystic Ovary Syndrome and Hyperandrogenic States

R. Jeffrey Chang

Understanding the clinical significance and pathophysiology of polycystic ovaries and polycystic ovary syndrome has evolved over more than 150 years. The first description of enlarged, polycystic ovaries surrounded by a smooth capsule was reported in 1844.[1] This was followed by similar observations, including a description on hyperthecosis in 1897.[2] In the early 1900s, there was a growing awareness that dysfunctional uterine bleeding was associated with multiple cystic follicles of the ovary, which in part, led to the therapeutic recommendation of bilateral ovarian wedge resection. In 1926, it was demonstrated in rodents that gonadotropic extract derived from the urine of pregnant women was capable of inducing multiple ovarian cyst formations.[3] This finding suggested that abnormal secretion of anterior pituitary hormones may be responsible for the morphological changes in the ovary. Subsequently, in 1935, the classic description of polycystic ovaries was reported by Stein and Leventhal, which codified the association with hyperandrogenism, amenorrhea, and infertility as well as established the syndrome named for the authors.[4] As investigators began to study the pathogenesis of this disorder and the number of relevant publications increased, there followed a gradual and distinct terminological conversion to what has become known as *polycystic ovary syndrome* (PCOS).

Currently, the term polycystic ovary syndrome refers to a multi-system reproductive-metabolical disorder that has evolved over decades and stands to be further defined in years to come. The principal clinical manifestations are hyperandrogenism and irregular menstruation, the latter of which leads to infertility. The ovaries of women with these symptoms are polycystic and conform to a specific anatomical appearance that may be detected on ultrasound imaging, although the ovarian morphology can exist in women without the overt clinical manifestations. The associated metabolical dysfunction includes insulin resistance, dyslipidemia, and, in the United States, an increasing prevalence of obesity. The intriguing nature of PCOS rests with the underlying mechanism(s) responsible for the juxtaposed abnormalities of hypothalamic-pituitary-ovarian-adrenal function with those of altered metabolical physiology. All of these factors may contribute to the clinical phenotype, pose increased long-term health risks, and serve as targets for therapeutic intervention in women with PCOS.

Epidemiology

Prevalence

It is estimated that the prevalence of PCOS is 4% to 12% of women in their reproductive years of life,[5-7] which designates this disorder as the most common reproductive endocrinopathy of women. Estimates may vary among reports based on the study population and whether ultrasound imaging of the ovary was included in the diagnostic criteria. In a study of 277 unselected women undergoing employee entrance physical examinations, 4.6% were found to have PCOS.[5] Of the 11 women with PCOS, all had oligomenorrhea and of 9 women in whom androgen levels were assessed, 8 exhibited hyperandrogenemia. These results confirmed earlier reports in which the diagnosis of PCOS was highly likely in women with hirsutism and oligomenorrhea.[8,9]

In the absence of hirsutism, it has been demonstrated that women with anovulation have a high incidence of PCOS. In 206 non-hirsute women, biochemical assessment revealed elevated androgens consistent with the diagnosis in 87% of those with oligomenorrhea and 32% with amenorrhea.[10] In contrast, women with hirsutism alone were reported to have ultrasound findings of polycystic ovaries regardless of whether the patient had oligomenorrhea, amenorrhea, or regular cycles.[9,11] In these women, increases in circulating androgen levels may have facilitated the development of polycystic ovaries. This notion is supported by studies in which female to male transsexuals treated with androgen acquire the typical appearance of polycystic ovaries.[12]

While the sonographic demonstration of polycystic ovaries in the presence of typical clinical features is regarded as confirmatory for the syndrome, a small portion of women with PCOS have been shown to have regular ovulation accompanied by normal follicle development as determined by serial ultrasound.[13] Moreover, it has been clearly demonstrated that polycystic ovaries can be found in normal ovulatory women without a history of hyperandrogenism.[14] In a study of 104 young Danish women with polycystic ovaries, only 43 were found to have other symptoms that fulfilled the criteria for PCOS.[15] Thus, 58% of women with polycystic ovaries were essentially normal without menstrual abnormalities or evidence of hyperandrogenism. Similarly,

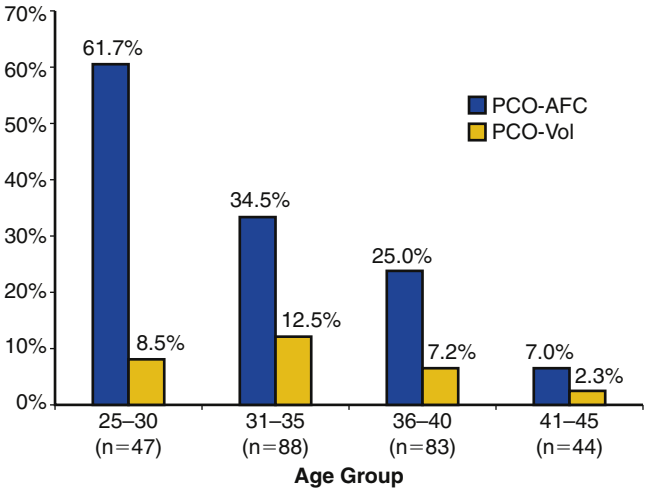

FIGURE 22.1 Percentage of subjects by age group meeting PCO antral follicle count (AFC) and volume (vol) according to Rotterdam criteria. *(Adapted from Johnstone EB, Rosen MP, Neril R, et al. The polycystic ovary post-Rotterdam: a common, age-dependent finding in ovulatory women without metabolic significance.* J Clin Endocrinol Metab *95:4965–4972, 2010.)*

polycystic ovaries were recently shown to be a relatively common finding in a large series of well characterized normal women from age 25 to 45 years old.[16] Of 257 women, polycystic ovaries were identified in 32% overall with the greatest percentage, 62%, occurring in women 25 to 30 years old followed by progressive decline in older groups (Fig. 22.1). The physiological relevance of polycystic ovaries in normal women is not clear, although a longitudinal study suggested that such individuals are not at increased risk for PCOS.[17] Thus, while the requisite identification of polycystic ovaries to establish the diagnosis appears to be clinically appropriate, the morphogenesis of the polycystic ovary may not necessarily be unique to the disorder.

Familial Occurrence

It has been well documented that PCOS tends to aggregate within families.[18] Moreover, several studies have addressed the prevalence of PCOS among first-degree relatives. Based on clinical evidence and laboratory confirmation of hyperandrogenism, anovulation, and polycystic ovaries, the likelihood of PCOS in sisters and mothers of affected women has been reported to be considerably higher than those of normal controls. In a study of 115 sisters of 80 probands, PCOS was demonstrated in 22% of reproductive-aged siblings whereas hyperandrogenemia was found in an additional 24%.[18] Additional studies of families with PCOS have revealed that 32% to 66% of sisters and 24% to 52% of mothers had the syndrome.[19,20] In contrast, in a study of sisters and mothers of Turkish women with PCOS revealed rates of 16% and 8%, respectively.[21] In most of these studies the prevalence of insulin resistance and impaired glucose tolerance was considerably greater in the relatives compared to normal controls.

A PCOS phenotype for men and male siblings of affected women with PCOS has not been established. However, circulating dehydroepiandrosterone sulfate (DHEA-S) levels in first-degree male relatives have been shown to be significantly higher than those of unrelated body mass index (BMI)-matched controls.[22] Serum testosterone (T), sex hormone binding globulin (SHBG), luteinizing hormone (LH), and follicle stimulating hormone (FSH) were similar between groups.

Collectively, these results indicate that first-degree relatives of PCOS women are at significant risk for having PCOS. The findings support a genetic basis for hyperandrogenemia, which may account, at least in part, for the familial clustering of this disorder.

Clinical Description

Hirsutism

The most distinctive and visible clinical feature of PCOS is hirsutism, the degree of which is variable from mild to severe. The rate of hair growth is important clinically as gradual and progressive growth indicates a functional etiology, whereas the rapid appearance of thick, pigmented hair often suggests a neoplastic source of androgen production. In PCOS, increased hair growth is commonly found on the side of the face, upper lip, and chin extending down to the neck region (Fig. 22.2). This pattern of hirsutism may be accompanied by extension of pubic hair growth towards the umbilicus and include excess hair on the extremities, abdominal flank, and back, although these areas are not considered specific sites of sexual hair growth. More severe cases include the appearance of hair on the chest. Progressive hyperandrogenism may be associated with temporal balding and male pattern baldness.

In PCOS, the amount of hirsutism has been correlated to serum androgen concentrations. However, individual variation in hair growth may reflect ethnic differences, which may account for slight variations of prevalence of PCOS in different parts of the world.[7,23-25] Coexisting conditions that alter the bioactivity of androgens, such as hypothyroidism and obesity may also give rise to excessive hair growth. These conditions are associated with lowered sex-hormone binding globulin (SHBG), which provides increased availability of free testosterone. Sequence variations within the coding region of separate SHBG alleles were identified in a heterozygous woman who presented with severe hyperandrogenism during pregnancy.[26] Serum SHBG levels were barely detectable and non-protein bound testosterone concentrations markedly higher than the normal reference range. A single nucleotide polymorphism within an allele encoded a missense mutation that permitted normal steroid hormone binding, but caused abnormal glycosylation and decreased serum SHBG.

Menstrual Irregularity

In PCOS, menstrual dysfunction is primarily characterized by irregular, infrequent, or absent menstrual bleeding. Typically, this pattern of bleeding is an extension of postmenarchal irregularity and monthly menstrual cyclicity is never established. In some women, the onset of chronic anovulation emerges beyond adolescence, but this is unusual. Prolonged heavy bleeding should raise consideration of abnormal endometrial hyperplasia and even endometrial adenocarcinoma. In approximately 20% of women, there is

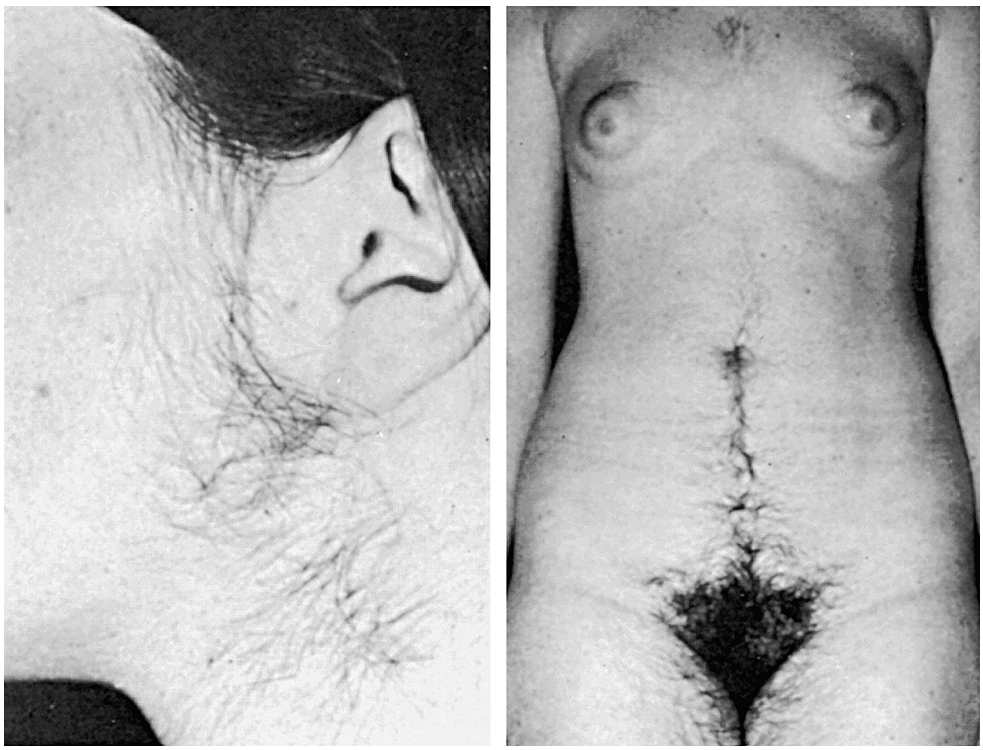

FIGURE 22.2 Moderately severe hirsutism in a young woman. Note the male pattern of hair distribution.

complete absence of menses, whereas 5% to 10% of cases demonstrate regular ovulatory function. Recognition of normal ovulation in PCOS is significant in that a history of regular menstrual cycles does not exclude the diagnosis. It has been reported that in late reproductive life, PCOS women begin to experience regular ovulation for unknown reasons.[27] Aging PCOS women with regular menstrual cycles appear to have a smaller follicle cohort, higher serum FSH levels and lower androgen levels compared to age-matched PCOS with persistent anovulation.[28] Whether changes in the follicle population or alterations in the ovarian endocrine milieu may be responsible for resumption of ovulation in late-age PCOS women remains to be determined.

Ovarian Morphology

Classically, women with PCOS have enlarged ovaries with numerous peripheral small antral follicles and increased central stroma (Fig. 22.3). While the process that leads to this morphological appearance is not completely understood, it has been proposed that normal follicular growth appears to occur up to the midantral stage, after which maturation ceases and progressively, the majority of follicles undergo atresia.[29] As the follicle reaches the midantral stage, the granulosa cell layer becomes progressively degenerative and the entire structure may have the appearance of a thin-walled cyst. In contrast, the theca cell layer that surrounds the follicle becomes substantially hyperplastic and thickened compared to that of normal follicles and is responsible for increased androgen production (Fig. 22.4). However, that follicle development becomes arrested at the midantral stage does not necessarily signal the immediate onset of atresia. In granulosa cells from unstimulated ovaries of women with PCOS, viability measures have indicated robust cell survival with substantial steroidogenic potential compared to cells obtained from ovaries of normal women.[30] It was concluded that the majority of follicles in PCOS are not apoptotic, but retain ample functional capacity. These findings were consistent with a recent study in which PCOS granulosa cells exhibited decreased apoptotic nuclei and proteins and increased anti-apoptotic protease gene expression compared to that of normal cells.[31] After midantral arrest, there appears to be a progressive accumulation of follicular fluid that results in expansion of the antrum which gives rise to the classical appearance of cystic follicles. As the follicle enlarges, the granulosa cell layer becomes progressively degenerative and thin.

The ovarian follicle population in PCOS also is distinctive in that histomorphometric studies have revealed a twofold to threefold increase in the numbers of primary, secondary, and tertiary follicles compared to those of the normal ovary.[32] Whether the ovaries are endowed with a greater number of follicles or whether the rate of programmed cell death is decelerated compared to the normal ovary has not been systematically studied. In the classical description of the polycystic ovary, the central ovarian stroma appears abnormally increased occupying at least 25% of the medullary portion of the ovary. This hyperplastic stroma may be responsible for displacing the cystic follicles towards the periphery.

A mechanism for the morphogenesis of the polycystic ovary has not been established, although a role for androgen excess on follicle growth and development has been suggested from ovarian morphology in hyperandrogenic women with congenital adrenal hyperplasia and androgen producing ovarian tumors.[33-35] In particular, polycystic ovaries have been demonstrated in male to female transsexuals receiving long-term androgen treatment.[12,36] Nonhuman primates treated with subcutaneous silastic capsules containing testosterone were observed to develop enlarged

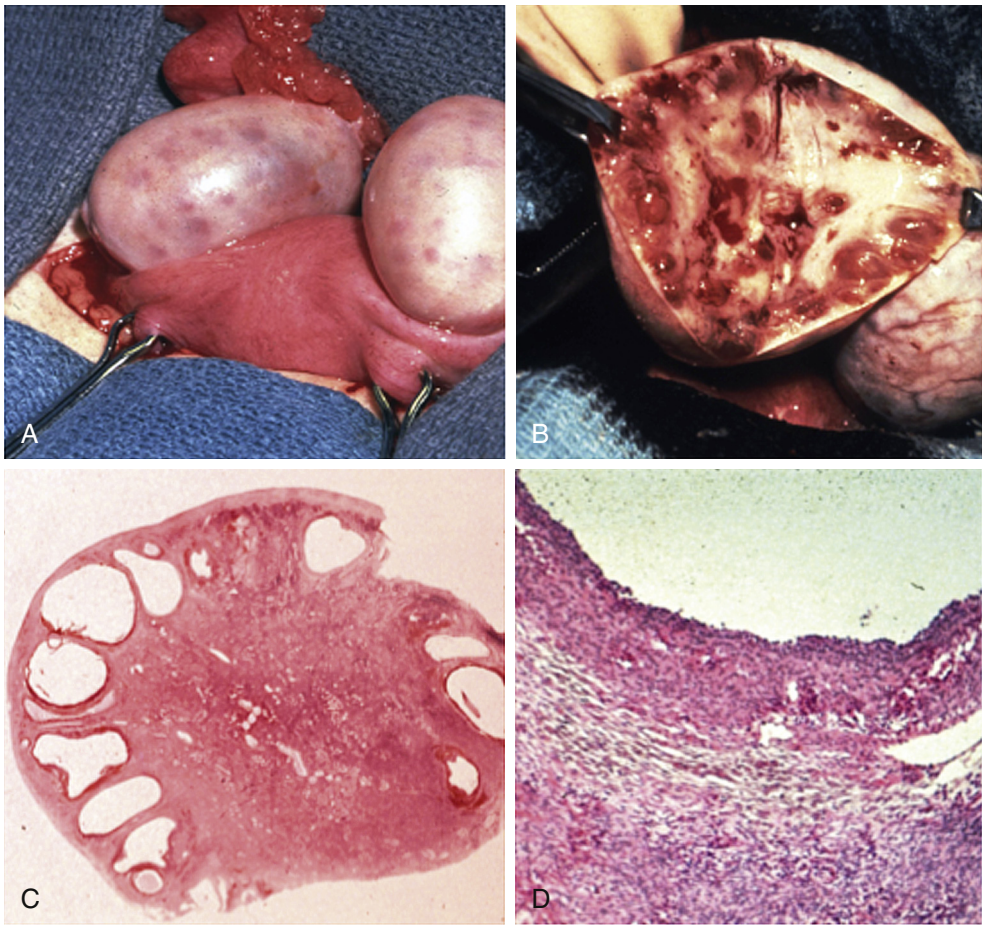

FIGURE 22.3 The gross and microscopic characteristics of the polycystic ovaries. **A**, Bilateral enlarged ovaries with a smooth and thickened capsule. **B**, On cut section, multiple follicular cysts surrounded by abundant ovarian stroma are found throughout the cortex of the ovary. **C**, Subcapsular antral follicles arrested at midstage of development. **D**, Hyperplasia of theca cell layer; note relative thin granulosa cell layer.

ovaries and increased follicle number.[37] *In situ* hybridization studies revealed that androgen receptor (AR) messenger ribonucleic acid (mRNA) was expressed primarily in healthy small- and medium-sized antral follicles compared to large preovulatory follicles.[38] Moreover, AR mRNA was found to colocalize with that of the FSH receptor and testosterone treatment increased the expression of FSH receptor mRNA.[39]

Alternatively, there is evidence to suggest that antimüllerian hormone (AMH) may be involved with the morphogenesis of the polycystic ovary. AMH is a product of the granulosa cell and mRNA expression is initially detected in primary follicles. With subsequent growth, the concentration of AMH intensifies and the greatest expression is observed in large preantral and small antral follicles.[40-42] Thereafter, the expression declines and is not observed in

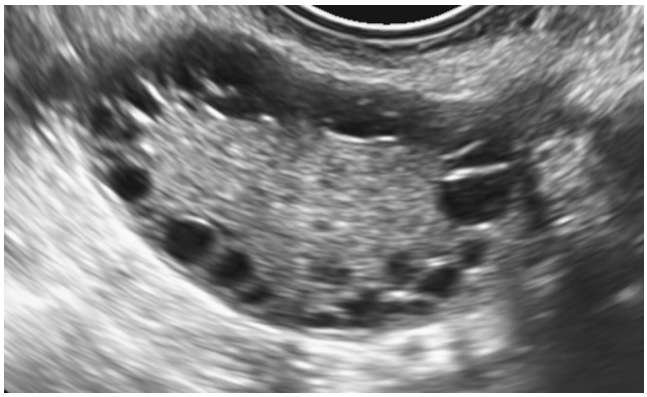

FIGURE 22.5 Polycystic ovary on ultrasound. *(Courtesy of Dr. G. Garzo.)*

late stage antral follicles, preovulatory follicles, or the corpus luteum. It has been proposed that AMH has two potential functions. First, AMH may serve to inhibit recruitment of primordial follicles into the pool of growing follicles to prevent early depletion.[42,43] Second, AMH may decrease follicle sensitivity to gonadotropin stimulation to control the number of large preantral and small antral follicles that reach the preovulatory stage.[43,44] These proposed actions of AMH are consistent with the report of decreased AMH expression in preantral and early antral follicles of women with PCOS compared to values observed in normal women.[45] In addition, the number of small antral follicles in PCOS women and normal women has been positively correlated to circulating levels of AMH.[46,47] With two functions so critical to folliculogenesis, the regulation of AMH is paramount in understanding its role. However, the regulation of AMH production by granulosa cells is not well understood.

The polycystic ovary has been characterized by ultrasound examination (Fig. 22.5). At a consensus conference in Rotterdam, Netherlands in 2003, a polycystic ovary was described as having 12 or more follicles per ovary or an ovarian volume of greater than 10 cm^3.[48] This description should not be confused with the ultrasound appearance of an ovary in women recovering from hypogonadotropic hypogonadism. In these individuals, multiple small antral follicle growth is common and may appear similar to a polycystic ovary. In women undergoing ovulation induction, multiple follicles formation may occur as result of ovarian stimulation. Thus, implication of a multi-follicular ovary or polycystic ovary should be considered within the realm of the clinical setting.

Obesity

Early studies of the clinical features of PCOS demonstrated that obesity was present in a little more than 50% of cases.[49] However, there is epidemiological evidence that the incidence may be greater, at least in the United States, than that previously described. Commonly, an increase in the upper body or central distribution of fat gives rise to an increased waist to hip ratio as compared to obese women without PCOS.[50] This fat distribution pattern has been termed android obesity and can be found in other hyperandrogenic states, diabetes, and hyperlipidemia. Notably, there is a preponderance of visceral fat compared to peripheral fat not unlike the distribution of adipose tissue in individuals with insulin resistance.[51] In contrast, women with gynecoid obesity generally have an enhanced accumulation of normal fat in the hips, buttocks, and thighs. As to whether PCOS patients are predisposed to obesity has not been clarified. It has been shown that postprandial thermogenesis may be decreased in PCOS, thereby contributing, at least in part, to weight gain.[52] However, resting energy expenditure in PCOS appears to be equivalent to that of normal weight-matched control, which suggests a relative disparity of increased caloric intake and decreased total energy expenditure.[53]

Insulin Resistance

It has been well-documented that women with PCOS are insulin resistant and have compensatory hyperinsulinemia as a result of their disorder.[50,54,55] The prevalence of insulin resistance in PCOS has been reported to range between 20% to 40%.[56,57] That insulin resistance is common in obesity may account, in part, for the rather wide prevalence. Nevertheless, independent of obesity, the presence of a defect in insulin action in PCOS has been clearly established.[50] Generally, the degree of insulin resistance is mild, although the prevalence of glucose intolerance and subsequent diabetes has been reported to be as high as 31% and 7.5% respectfully.[57] Moreover, in these individuals the progression to diabetes appears to be relatively rapid.[58,59] Commonly, fasting hyperglycemia is not evident; instead there is a primary dysfunction of postprandial glucose uptake that results in severe peripheral insulin resistance.[60,61]

Not only are women with PCOS predisposed to insulin resistance and risk for diabetes, but evidence exists that first-degree relatives also exhibit disordered glucose metabolism and insulin secretion. Importantly, this predisposition includes both sisters and brothers of affected individuals.[62,63] Aside from the increased risk for diabetes, there is indirect evidence to indicate that insulin resistance may worsen the clinical manifestations of PCOS. Administration of insulin lowering drugs has been shown to improve insulin sensitivity, reduce androgen levels, and restore ovulation in some, but not all patients with this disorder.[64-67] Insulin resistance may also contribute to metabolical dysfunction in PCOS, including an increased likelihood of lipid abnormalities.[68,69] In addition, the association of insulin resistance with visceral fat distribution is underscored by the displacement of central fat to the peripheral compartment with improvement of insulin sensitivity following administration of insulin lowering drugs or weight reduction.[66,70]

The discovery and documentation of insulin resistance in PCOS has been achieved by time-consuming and complex procedures conducted in the course of clinical investigation. By comparison, identification of insulin resistance in the clinical setting has been difficult as most patients exhibit normal fasting blood glucose levels and increased circulating insulin levels are not common. As a result, effective and convenient screening tests to determine evidence-based therapeutic modalities have been limited.

Acne and Acanthosis Nigricans

Women with PCOS may experience increased skin oiliness secondary to excessive stimulation of the pilosebaceous

FIGURE 22.6 Acanthosis nigricans. Note the darkened, velvety plaque along the nape of the neck giving the appearance of hyperpigmentation in a patient with severe insulin resistance, hirsutism, and polycystic ovaries.

unit by increased androgen production. However, increased sebaceous gland activity in PCOS is not associated with acne nor is acne correlated with increased ovarian androgen production. Therefore, as an isolated symptom, acne should not be considered a sign of PCOS.

Perhaps, more common is the finding of acanthosis nigricans, which has been observed in 5% to 50% of hyperandrogenic women and is related to the presence and severity of hyperinsulinemia.[71] This dermatological condition features symmetrical, darkened, velvety plaques that may appear most commonly appear on the nape of the neck, in the intertriginous areas of the body such as skin folds, and on pressure bearing surfaces such as knuckles and elbows (Fig. 22.6). Acanthosis nigricans originates from epidermal hyperkeratosis and dermal fibroblast proliferation. There is no evidence of an increased number of melanocytes or melanin deposition despite apparent increased pigmentation. Acanthosis nigricans is considered a potential marker for insulin resistance and diabetes in adults. Reduction of hyperinsulinemia is associated with improvement in the darkened skin areas.

Infertility

A significant number of patients will offer infertility as a presenting feature of PCOS.[49] Clearly, anovulation would appear to be the primary defect responsible for the failure to achieve pregnancy in this disorder. However, other potential considerations may exist which may preclude fertility. There is evidence that women with PCOS have a higher incidence of spontaneous pregnancy loss, the mechanism of which remains unclear.[72] It has been reported in a small series of women that the prevalence of polycystic ovaries in women with recurrent miscarriage was 56%.[72] Subsequently, in a much larger study, it was observed that polycystic ovarian morphology was not predictive of pregnancy loss among women with recurrent pregnancy loss.[73] Clearly, additional research is necessary to determine the prevalence of recurrent pregnancy loss in PCOS as well as the underlying mechanism.

PCOS in Adolescence

Ovarian Morphology in Adolescence

An early attempt to estimate the prevalence of polycystic ovaries in a general adolescent population revealed that 28% of 119 girls had 10 or more follicles per ovary.[74] More recently, in a large cohort from Australia it was demonstrated in 230 adolescents that the median antral follicle count was 11 with an interquartile range of 7 to 14.[75] From this cohort it was shown that 35% had polycystic ovaries using Rotterdam criteria.[76]

In normal adolescent girls with regular cycles and no hirsutism, it was reported that 9% exhibited polycystic ovaries using older criteria.[74] Later, using Rotterdam criteria, ultrasonography in 74 nonobese girls with regular menstrual cycles and no evidence of hyperandrogenism revealed a 34% prevalence of polycystic ovaries.[77] A similar rate, 40%, was reported in 20 postmenarchal girls with regular menstruation function and in whom hyperandrogenism had been excluded.[78] Collectively, the data suggest that polycystic ovaries are relatively common in the normal adolescent population. The precise rate of polycystic ovaries in this group is unclear due to the limited numbers of subjects studied to date. Nevertheless, an increased prevalence in adolescence is not dissimilar to that reported for normal young adults.[15,16]

There is little information about ovarian morphology in adolescent girls with PCOS. Ibanez and colleagues identified polycystic ovaries in only 38% of adolescent and young women who presented with evidence of androgen excess or irregular bleeding.[79] Similar findings were reported in adolescent PCOS girls who had been referred for oligomenorrhea and hirsutism.[80] Polycystic ovaries were identified in 35% of these individuals.

Recently, Brown and coworkers studied ovarian morphology in normal high school students and adolescents with PCOS based on the presence of hirsutism and oligomenorrhea.[81] Employing magnetic resonance imaging, 17 of 21 normal individuals (81%) had 12 or more follicles per ovary (Fig. 22.7). In 5 of 21 normal adolescents, ovarian volume was larger than 10 mL. Of 19 girls with PCOS, each had polycystic ovaries by follicle count and ovarian volume. While the number of subjects in this study was small, the difference between these findings and those of others may have been due to magnetic resonance technique and improved visualization of small antral follicles. A direct comparison between magnetic resonance and ultrasound of the ovary has not been conducted in this population.

In adolescent girls with irregular menstrual cycles, the prevalence of polycystic ovaries is significant. In a study of nonobese adolescent girls with oligomenorrhea, polycystic ovaries were demonstrated in 45%.[74] Similarly, it was reported in healthy girls with menstrual irregularities that the ultrasound appearance of the ovary was polycystic in

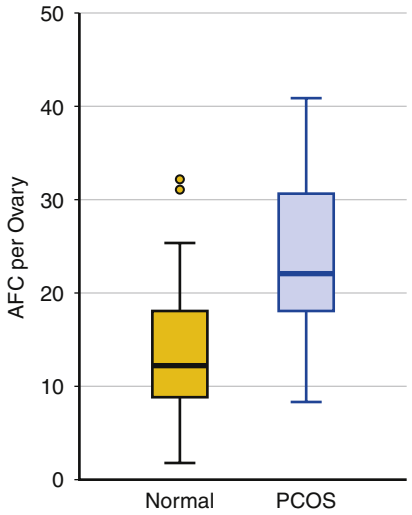

FIGURE 22.7 Box-and-whisker plot showing antral follicle count (AFC) per ovary in normal adolescent girls and adolescent girls with polycystic ovary syndrome (PCOS) assessed by magnetic resonance imaging. Horizontal small bars represent the 5th to 95th percentile range and the boxes indicate the 25th to 75th percentile range. The horizontal line within each box corresponds to the median. O, values beyond the 95th percentile. *(From Brown M, Park A, Shayya R, et al. Detailed morphometric analysis of the ovary in adolescent girls with polycystic ovary syndrome and age-matched controls.* J Magn Reson Imaging. *Jan 4. doi: 10.1002/jmri.23992. [Epub ahead of print] 2013.)*

41% of cases.[82] Subsequent examinations performed 2 to 7 years later showed that the percentage of individuals with polycystic ovaries increased despite no change in the rate of anovulation. In contrast, 40% of oligomenorrheic girls with elevated LH levels and enlarged ovaries were shown to spontaneously normalize ovarian function and size during longitudinal follow-up.[83] These results point out that the polycystic ovary is a common finding in adolescent girls with abnormal menstrual cycles and suggest that the likelihood of spontaneous restoration to normal ovarian morphology is relatively small as long as menstrual irregularity persists.

Clinical Presentation

Characteristically, the symptoms of PCOS emerge insidiously coincident with changes that accompany normal pubertal development (see Chapter 18). That the emergence of PCOS can commonly be traced to the events of puberty suggests that this disorder may be related to an abnormal expression of those factors that initiate and regulate the process of puberty. Because the duration of menstrual irregularity that accompanies normal puberty may be variable, it is difficult to rely solely on this historical feature as a basis for diagnosis. Moreover, with the recognition that some PCOS women may exhibit normal ovulatory function, evidence of regular cyclic bleeding does not preclude the disorder in adolescence. Rather, early detection of PCOS in adolescent girls is predicated primarily on hyperandrogenic symptoms such as hirsutism and acne. In the obese individual, associated metabolical-reproductive abnormalities may create uncertainty as to the mechanism of hyperandrogenism. Reduction in SHBG is directly correlated to obesity, thus giving rise to increased free testosterone levels. In addition, obese adolescents, particularly those with evidence of acanthosis nigricans, are highly likely to have insulin resistance with compensatory hyperinsulinemia, which is known to suppress SHBG and probably contributes to excess ovarian androgen production. An ultrasound image of a polycystic ovary virtually confirms the diagnosis. However, the utility of ultrasonography is often limited by the necessity of an abdominal versus vaginal approach and the difficulty securing adequate imaging in obese girls.

It has been well-documented that adolescent girls with PCOS have increased levels of circulating androgens as well as elevated LH levels.[74,83] Previous studies have shown that hyperandrogenic girls with likely PCOS exhibited changes in gonadotropin secretion patterns that were similar to those found in adult PCOS.[74,82-84] Increased concentrations of serum LH are accompanied by an increase in pulse frequency and amplitude. In addition, mean serum levels of testosterone and androstenedione were elevated. Twenty-four hour pulsatile LH secretion studies have revealed that premenarchal hyperandrogenic girls demonstrated higher LH levels while awake whereas the sleep entrained increases were minimal compared to those of developmentally matched control subjects.[84] In post-menarche, there was greater LH pulse activity during waking hours whereas pulse frequency was slowed with sleep (Fig. 22.8). By comparison, in postmenarchal normal girls, LH levels were lower and the pulse frequency reduced while awake whereas during sleep LH pulse frequency was significantly less than that of hyperandrogenic girls. Thus, the pattern of gonadotropin secretion in the postmenarchal normal control resembled that of the younger premenarchal hyperandrogenic girl. These findings suggest that the transition through neuroendocrine puberty may be accelerated in hyperandrogenic girls compared to normal puberty. Moreover, the data pose the question as to whether there is a chronological difference in the onset of increased LH levels and pulse frequency between hyperandrogenic and normal pubertal girls.

Role of Obesity

The effect of obesity on androgen levels and gonadotropin secretion in adolescents has recently been examined. In a cross-sectional study, McCartney and colleagues showed that during early puberty obese girls at Tanner stage 1-3 had significantly increased serum testosterone levels compared to nonobese controls accompanied by corresponding decreases of circulating LH concentrations.[85,86] In addition, obese girls exhibited hyperinsulinemia and increased HOMA values compared to that of normal weight controls which may have accounted, in part, for hyperandrogenemia in the presence of lowered serum LH. In early pubertal girls, diurnal variation was observed for both testosterone and progesterone with levels lower at night and rising in the early morning hours. The incremental change in both hormones was significant in nonobese girls, but failed to achieve statistical significance in obese girls likely because of too few numbers. Nevertheless, the heightened level of progesterone in obese girls may have contributed to reduced LH levels in early puberty.

This concept relates to responsiveness of the GnRH pulse generator to progesterone negative feedback. In normal adult women, progesterone administration inhibited LH pulse frequency whereas in women with PCOS, LH secretion was unaltered.[87] However, after androgen blockade by anti-androgen treatment, rapid LH release was

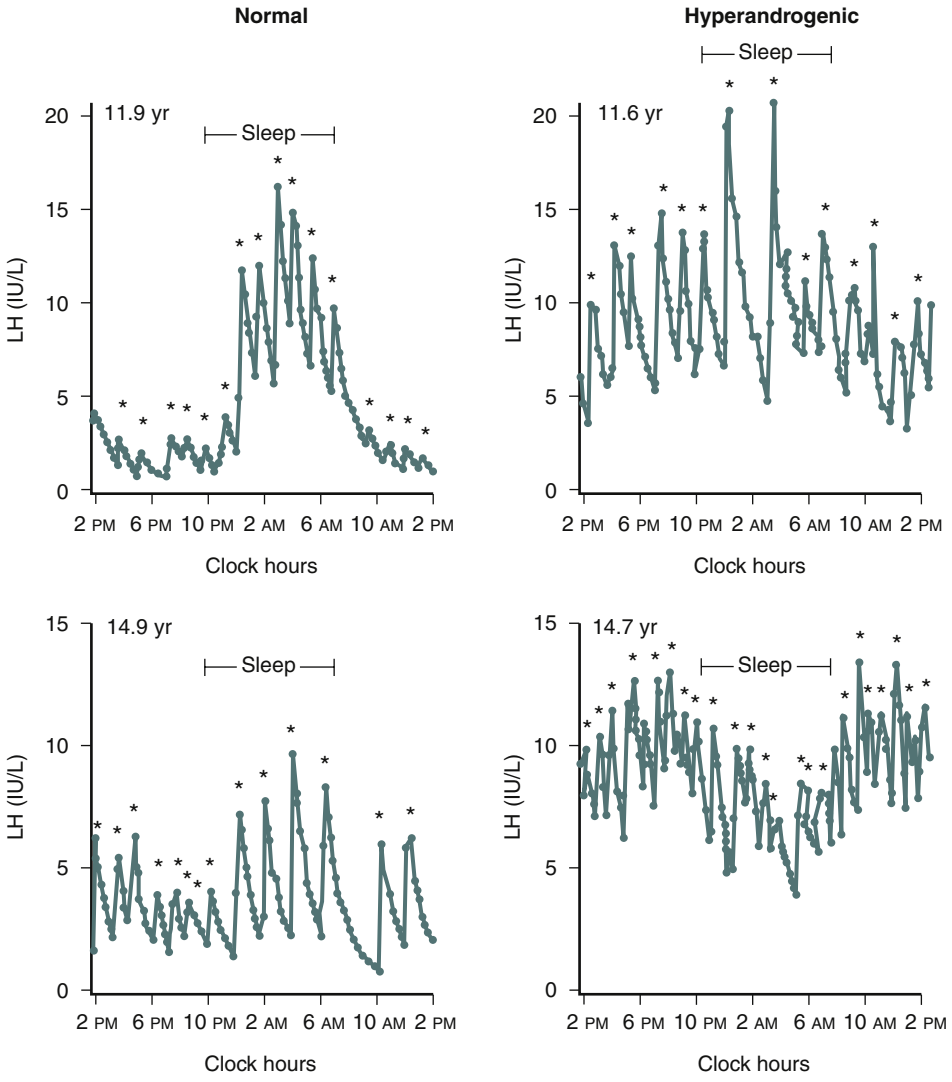

FIGURE 22.8 Twenty-four-hour pulsatile luteinizing hormone patterns in premenarchal and postmenarchal hyperandrogenic girls *(right)* and two developmentally matched healthy girls *(left)*. Asterisks indicate significant pulses. Open bars represent sleep periods. *(Adapted from Apter DA, Butzow J, Laughlin GA, et al. Accelerated 24-hour luteinizing hormone pulsatile activity in adolescent girls with ovarian hyperandrogenism: relevance to developmental phase of polycystic ovarian syndrome.* J Clin Endocrinol Metab *79:119–125, 1994.)*

reduced by progesterone administration which implied that hyperandrogenemia may have contributed to increased LH secretion.[88] This proposed mechanism is suggested in young adolescents as some girls with PCOS treated with progesterone failed to exhibit a reduced rate of LH release.[89]

Evidence for this was provided by an intensive and vigorous examination of 24-hour LH secretion in nonobese and obese girls through puberty.[90] The 24-hour pattern of LH secretion in nonobese girls during early adolescence (Tanner stage 1-3) was characterized by greater release during sleep than that observed while awake. The nighttime rise of LH declined in the very early morning hours and was correlated to a corresponding increase of serum progesterone. In contrast, in obese girls, LH secretion was unaltered during the sleep-wake cycle and there was no relationship to circulating progesterone levels. With advanced development (Tanner stage 3-5) obese adolescents exhibited increasing day and night time LH secretion that was greater than that observed in nonobese individuals, although pulse amplitude remained significantly higher in nonobese girls. The pattern of LH secretion in the obese group was essentially equivalent to those with PCOS. Similar findings were reported in a study of LH secretion during early puberty.[91] Normal weight girls at Tanner stage 3 demonstrated a sleep related rise of mean circulating LH that was significantly greater than that observed in an obese group of adolescents.

Thus, in the absence of hyperandrogenemia, diminished LH secretion in early puberty may be a consequence of obesity during this stage of development. However, in general, obesity confers acceleration of puberty or, in some instances, precocity in young girls. This being the case, another factor or mechanism associated with and separate from obesity may be involved with regulation of gonadotropin secretion in early puberty.

Oligomenorrhea and PCOS Risk

Among postmenarchal girls with irregular bleeding, it has been estimated that approximately 50% of oligomenorrheic adolescent girls have increased levels of serum LH associated with mild elevations of circulating androgens.[82,83,92] In addition, we and others have shown that these individuals exhibited an increased rate of LH release as determined from frequent sampling studies, which suggested a diagnosis of PCOS.[92,93] Notably, in a long-term follow-up study of oligomenorrheic girls, those with normal serum LH values

eventually developed regular ovulatory function compared to more than half of those with elevated LH levels in which the gonadotropin abnormalities persisted along with hyperandrogenism.[83,94] These intriguing findings suggest that oligomenorrhea in early adolescence may be associated with an endocrinological phenotype of PCOS in the absence of overt signs of hyperandrogenism. Whether the transitory nature of elevated LH and androgens represents an extension of normal hypothalamic-pituitary development remains to be determined.

Abnormal Metabolical Function

Similar to their adult counterparts, hyperandrogenic girls, with likely adolescent PCOS, exhibit abnormal insulin responses to glucose loading.[95] Correspondingly, assessment of 24-hour patterns of insulin revealed greater release in hyperandrogenic girls than that observed for normal girls whereas a reciprocal relationship was found for IGFBP-1 secretion. Pulsatile growth hormone secretion was not altered in adolescent PCOS.[95] The lipid profile in the girls with increased androgen indices demonstrate higher low-density lipoprotein cholesterol (LDLC) to high-density lipoprotein cholesterol (HDLC) ratios in conjunction with lowered SHBG levels.[96] These data suggest that any risk for long-term health consequences may be established early in reproductive life for these girls.

Prepubertal Disposition

It has been reported that girls with premature pubarche are at increased risk for functional ovarian hyperandrogenism and polycystic ovaries following puberty.[96] Moreover, with subsequent development of hyperandrogenism and hyperinsulinemia, there was a corresponding reduction in birth weight of these individuals.[96] The link between low birth weight and insulin resistance in children appears to be persistent throughout life as indicated by studies performed in early and late adulthood.[97,98] This relationship may be of particular relevance to a possible mechanism for PCOS in this population. Low birth weight is commonly associated with hypoplasia of the fetal adrenal and correspondingly low serum DHEA-S levels.[99] DHEA-S secretion also serves as a marker for adrenarche, which is independent of and precedes gonadarche by several years. It has been demonstrated in pairs of discordant siblings who achieved similar weight in childhood that DHEA-S levels were higher in those of low birth weight compared to those born with normal weight.[100] Thus, if as proposed, fetal growth modulates adrenarche, then increased DHEA-S may have reflected an exaggerated adrenarche in these children. The resultant increased androgen pool may set in motion a cycle of altered physiology characteristic of PCOS. This notion is further reinforced by the presence of hyperinsulinemia and insulin resistance, which may enhance androgen production in adolescent girls at risk for PCOS.[101] In addition, elevated levels of circulating insulin coincide with a reciprocal decline of SHBG, thereby allowing for increased availability of free testosterone. Thus, the detection of hyperinsulinemia in postmenarchal girls with hyperandrogenism relates temporally to physiological insulin resistance during puberty and may be of critical importance in the genesis of PCOS.

While premature pubarche may increase the risk for PCOS after puberty, exposure to androgen prepubertally may also provoke features of the disorder. In a study conducted in nonhuman primates, prepubertal female rhesus macaques at 1 year of age were administered silastic testosterone implants resulting in fourfold rise of circulating levels.[102] This level of induced hyperandrogenemia was maintained long-term throughout the course of study. At age 5 when the monkeys were in early adulthood, testosterone-treated animals had a significantly greater LH pulse frequency during the early follicular phase compared with controls given cholesterol filled implants. No differences were seen in insulin sensitivity, although there was suggestion of multiple follicle formation in the ovaries as determined by magnetic resonance. Ovulation rates were similar in both groups. These results show that increased androgen exposure over the course of pubertal development may enhance the neural drive to the reproductive axis that resemble those of obese hyperandrogenemic girls in early adulthood and are characteristic of PCOS. Moreover, the findings suggest that the prepubertal hypothalamic-pituitary-ovarian axis may be vulnerable to endocrinological insult such as excess androgen production.

Fetal Predisposition

It has been shown that adult, female rhesus monkeys exposed to testosterone *in utero*, at concentrations equivalent to those found in males, may exhibit increased LH secretion, impaired insulin secretion, hyperandrogenic anovulation, and enlarged ovaries with multiple cystic follicles.[103] Similar outcomes have been observed in female adult sheep following *in utero* exposure of high doses of testosterone at various phases of pregnancy.[104,105] These observations have led to the hypothesis that the clinical phenotype of PCOS may be the result of intrauterine androgen exposure during pregnancy. In human pregnancy, it has been reported that high maternal serum testosterone levels do not confer this clinical consequence in female offspring.[106] This is likely due to increased circulating levels of SHBG as well as the metabolical capacity of placenta aromatase to neutralize maternal androgen production. Rather, an *in utero* effect of hyperandrogenism may occur in the presence of abnormal steroidogenesis by the fetal ovary or adrenal gland. In support of this concept, it has been reported that women with 21-hydoxylase deficiency also display excessive ovarian androgen production and polycystic ovaries.[35] The possibility exists that androgenic programming in fetal life may predispose select individuals to the clinical features of PCOS.

Altered Physiology

Hypothalamic-Pituitary Interaction

In adult women with PCOS, LH secretion is characterized by increased pulse frequency and amplitude, elevated 24-hour mean serum concentrations, and greater responses to gonadotropin releasing hormone (GnRH) compared to those found in normal women (Fig. 22.9).[107] The mechanism(s) responsible for this increased release of LH are not well understood. A particular characteristic of LH secretion in PCOS is increased pulse frequency, the periodicity of which

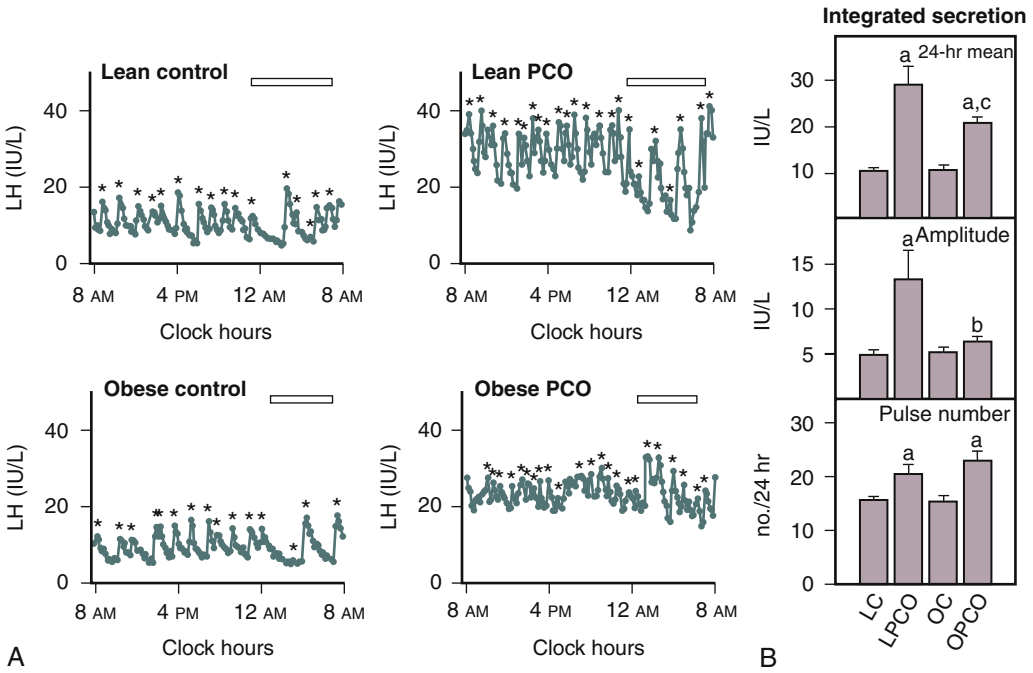

FIGURE 22.9 **A**, Representative 24-hour luteinizing hormone (LH) pulsatile patterns in lean and obese control women during the follicular phase of the menstrual cycle and in lean and obese women with polycystic ovary syndrome (PCOS). *Asterisks* indicate LH pulses. *Open bars* signify sleep times. **B**, Twenty-four-hour mean (±SE) LH levels, pulse amplitude, and pulse frequency in lean and obese women with PCOS (LPCO, OPCO) and their respective controls (LC, OC: n = 8 for each group. a, $P < 0.001$ versus corresponding control group; b, $P < 0.01$; c, $P < 0.001$ versus corresponding lean group. *(Adapted from Morales AJ Laughlin CA, Butzow T, et al. Insulin, somatotropic, and LH axes in lean and obese women with polycystic ovary syndrome: common and distinct features.* J Clin Endocrinol Metab *81:2854–2864, 1996.)*

is approximately 1 hour. This rapid rate of LH release does not appear to be altered by experimental manipulation or physiological change.[108,109] These observations imply that corresponding pulsatile release of hypothalamic GnRH is increased. In PCOS, the relationship between GnRH pulse frequency and gonadotrope responsiveness may be a key issue relative to inappropriate gonadotropin secretion. Previous studies in rodents have demonstrated preference for LHβ gene expression in response to rapid rates of GnRH delivery.[110] Not only does GnRH drive the release of LH but also it has been shown, in normal women, to self-prime the pituitary and thereby contributes to increased LH sensitivity to subsequent GnRH stimulation.[111] Collectively, these findings have led to the suggestion that the profound abnormality of gonadotropin secretion in PCOS may be a primary consequence of increased hypothalamic GnRH activity.[112]

In humans, progressive increases in the frequency of GnRH stimulation have resulted in corresponding increases in the rate of LH release as well as elevated basal concentrations.[113] In GnRH-deficient women, an increase in the rate of GnRH administration from every 90 minutes to every 60 minutes was not associated with corresponding increases in serum LH or changes in pulse amplitude, whereas GnRH given at 30-minute intervals resulted in elevated LH levels and reduction of pulse amplitude.[112] While consistent with the primacy of increased hypothalamic GnRH, an LH pulse frequency of 1 hour may represent a physiological limit beyond which more frequent pulses in women do not occur. In normal ovulatory women during the late follicular phase and at midcycle, as well as in postmenopausal women, it has been documented that LH pulse frequency approximates 60 minutes.[114,115] In addition, previous studies have shown that GnRH release from the medial basal hypothalamus of the fetus and adult has a periodicity of about 1 hour.[116] Thus, in PCOS women, the tempo and to some degree magnitude of pulsatile gonadotropin secretion, are probably established by hypothalamic GnRH activity. However, beyond the requisite need for GnRH, LH responsiveness to GnRH and, accordingly, maximal increases in LH pulse amplitude, are probably reliant upon other factors.

It has been suggested that the positive feedback effects of chronic estrogen secretion associated with this disorder may bring about an increase of LH either by a direct effect on gonadotrope sensitivity to GnRH or indirectly by facilitating GnRH pulse frequency.[107,117] *In vitro*, estrogen has been shown to increase the fraction of individual gonadotropes responding to GnRH which is consistent with amplification of LH responses to GnRH in normal women receiving estradiol benzoate.[118] However, prolonged administration of estrone to PCOS patients failed to raise circulating levels of LH beyond baseline values or increase GnRH stimulated LH responses.[117] Alternatively, in animals it has been demonstrated that estrogen enhances GnRH pulse frequency and in women with PCOS serum GnRH levels are increased.[119,120] That estrogen may exert an effect at the hypothalamus in PCOS is supported by the strong positive correlation of mean serum estradiol levels to GnRH pulse frequency.

Hyperandrogenemia has also been implicated as a potential cause of increased LH secretion in PCOS. *In vitro*, it has been shown that androgen administration resulted in

increased GnRH pulse generator activity.[121] Examination of LH secretion in hyperandrogenic patients with congenital adrenal hyperplasia revealed that mean LH levels and LH responses to GnRH were increased, which tended to normalize with the onset of treatment and corresponding lowering of androgen levels.[35] By comparison, other studies have not been able to detect an increase in LH following the administration of androgen. Short-term infusion of androgen to both normal women and women with PCOS failed to alter basal LH secretion.[122] Moreover, high dose androgen infusion in normal women appeared to result in an acute reduction of serum LH levels.[36,123]

Notwithstanding these past findings, other studies have indicated that excess androgen production may have a profound influence on LH pulse frequency in women with PCOS. Progesterone administration, either alone or in combination with estrogen (oral contraceptive) suppressed mean LH and LH pulse frequency in both PCOS and normal women.[87] The lowering of LH release was more pronounced in normal women compared to those with PCOS and suggested an effect of increased androgen production.[87] In subsequent studies, pretreatment with an androgen blocking agent prior to physiological estrogen and progesterone administration resulted in restoration of LH pulse frequency to that observed in normal women (Fig. 22.10).[88] These findings suggested that in PCOS, high circulating levels of androgen prevent the negative feedback effects of estrogen and progesterone on LH pulse release as noted in earlier studies. Moreover, the physiological relevance in women regards a rapid rate of spontaneous hypothalamic GnRH activity, which is regulated by the feedback effects of ovarian steroids.

Efforts to determine an effect of insulin in PCOS women have not documented consistent alterations in LH secretion or LH release following GnRH stimulation.[50,124] Reduction of hyperinsulinemia by administration of insulin-lowering drugs to PCOS patients resulted in decreased mean serum levels of androgens and LH in some cases, whereas in others an accompanying fall of LH was not found.[50,65-67,125-127] We have explored the role of insulin on gonadotropin secretion in PCOS and normal women.[128] Our results demonstrated that episodic gonadotropin secretion and LH responses to multi-dose GnRH stimulation were not altered by insulin infusion over an interval of 12 hours in both groups. In particular, endogenous serum LH levels were unchanged prior to and immediately following initiation of the insulin clamp (Fig. 22.9). These findings confirm and clarify previous studies, which have been unable to document consistent alterations in LH secretion or LH release following GnRH stimulation following insulin administration in women with PCOS.[50] In addition, the results may explain why changes in serum LH were not observed in PCOS women treated with insulin-lowering drugs despite significant reductions in circulating androgen levels. Alternatively, interpretation of these clinical trials is potentially confounded by several factors. First, most of the patients studied were obese and it has been shown recently that obesity is inversely correlated to LH secretion in PCOS (Fig. 22.11).[109] Second, hyperinsulinemia is positively correlated with the BMI in women with this syndrome. Third, the occurrence of ovulation in PCOS is associated with a lowering of LH levels into the normal range.

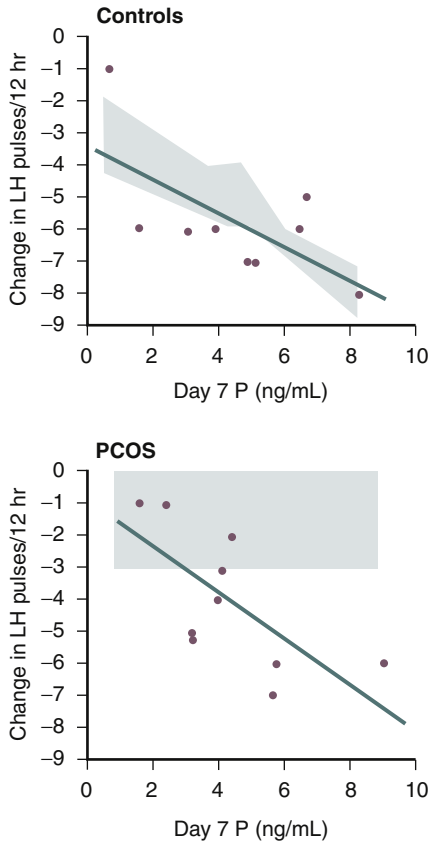

FIGURE 22.10 The change in luteinizing hormone pulse frequency between flutamide treatment alone and after estradiol (E_2) and progesterone (P) administration for 7 days during continued flutamide treatment. Data are shown as a function of the mean plasma P level during E_2 and P administration with flutamide for controls and polycystic ovary syndrome (PCOS) patients. Shaded area shows the range of responses in an identical protocol performed in the absence of flutamide. The slopes for the linear regression analysis are as follows: controls (with flutamide), –0.53; controls (without flutamide), –0.76; PCOS (with flutamide), –0.72; and PCOS (without flutamide), 0.07. *(Adapted from Eagleson CA, Gingrich MB, Pastor CL, et al. Polycystic ovarian syndrome: evidence that flutamide restores sensitivity of the gonadotropin-releasing hormone pulse generator to inhibition by estradiol and progesterone.* J Clin Endocrinol Metab *85:4047–4052, 2000.)*

Recently, we re-examined the relationship of insulin to composite basal LH secretion and LH responses to GnRH in normal and PCOS women using rigorous analytical methods.[129] In normal women, insulin was negatively correlated to mean LH levels. In contrast, in women with PCOS multivariable modeling revealed that insulin had a suppressive effect on baseline LH and LH responses to GnRH dosing. These observations provided evidence for a role for insulin in modulating LH levels.

Increased LH pulse frequency and other features of polycystic ovary syndrome have been described in women with epileptic disorders or women treated with antiepileptic drugs.[130,131] The link between epileptic and postseizure ictal states may involve stimulation of excitatory neurotransmitters, the receptors of which exist in hypothalamic nuclei that influence GnRH release. Thus, the consequences of epileptic activity may result in increased GnRH activity and simulate the pattern of increased LH secretion in PCOS.[132] In addition to altered LH secretion, polycystic ovaries and

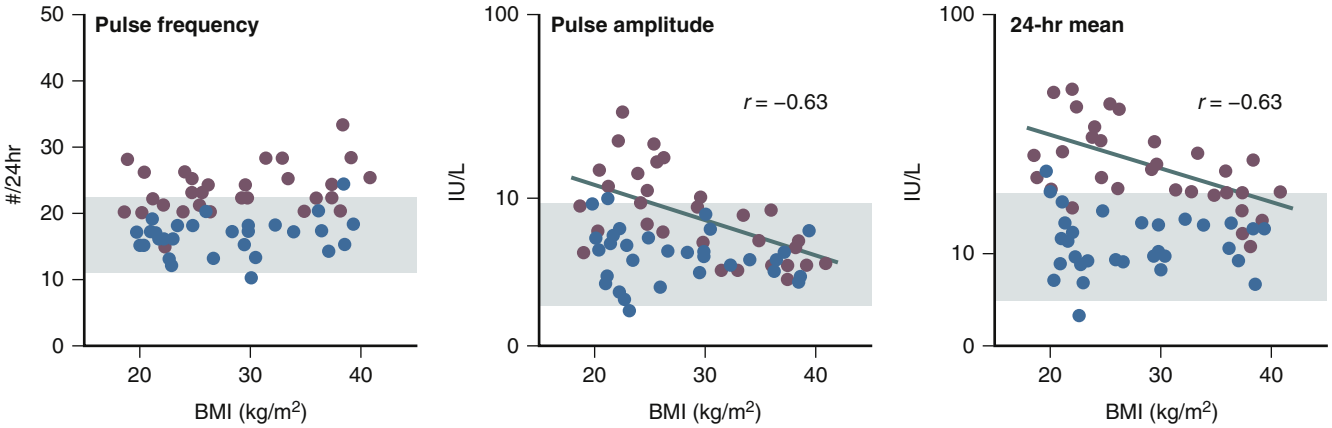

FIGURE 22.11 Regression of body mass index (BMI) for polycystic ovary syndrome (PCOS, purple dots) and normal control (NC, blue dots) women against luteinizing hormone (LH) pulse frequency (PCOS and NC, P = ns), LH pulse amplitude (PCOS: r = –0.63, P < .001; NC: P = ns), and 24-hour mean LH levels (PCOS: r = –0.63, P < .001; NC: P = ns). Values for LH pulse amplitude and 24-hour mean are log-transformed. Shaded area represents 95% confidence interval for NC (frequency, 11-22 pulses/24 hours; amplitude, 2.6-9.2 IU/L; 24-hour mean, 6.1-18.2 JU/L). *(Adapted from Arroyo A, Laughlin CA, Morales AJ, Yen SSC. Inappropriate gonadotropin secretion in polycystic ovary syndrome: influence of adiposity.* J Clin Endocrinol Metab *82:3728–3733, 1997.)*

hyperandrogenism have been reported in untreated and treated women with epileptic seizures, which strengthen the possible association between PCOS and epilepsy.[133] A mechanistic role for antiepileptic medication, including sodium valproate, in the development of excess androgen production or follicle cyst formation in treated subjects has not been elucidated.

In contrast to pituitary LH, FSH secretion in PCOS is decreased as indicated by significantly lower serum concentrations compared those found in normal women during the early follicular phase of the menstrual cycle.[107] In addition, FSH responses to GnRH stimulation are reduced as shown in some, but not all studies.[134,135] The precise underlying basis for decreased FSH secretion in PCOS has not been determined, although the negative feedback effect of chronic unopposed estrogen secretion in these women has been implicated as a mechanism.[117,136] The reduction in serum FSH may also reflect the activity of hypothalamic GnRH. As mentioned earlier, increased frequency of pulsatile GnRH predisposes to a preference for LHβ gene expression at the expense of the FSHβ gene.[110]

Theca Cell Function

The most notable clinical feature of PCOS is hirsutism, which is the result of excessive androgen production. Both the ovary and adrenal glands contribute to the pool of increased circulating androgens. However, in PCOS the major bioactive serum androgens, androstenedione and testosterone are produced by the ovary, whereas elevated concentrations of DHEAS are derived from the adrenal glands.[55] Within the polycystic ovary, numerous antral follicles are surrounded by hyperplastic theca cells which are the predominant site of androgen overproduction. There is firm evidence to indicate that excess ovarian androgen is driven by the abnormally increased secretion of pituitary LH acting on theca cells.[137] Nonetheless, the rather broad range of LH secretion in PCOS suggests that other mechanisms may be instrumental in the excessive production of androgens, including increased theca cell sensitivity to LH and the presence of cogonadotropic growth factors.

In vitro studies have established that theca cells from PCOS ovaries in culture produce significantly more androgen following LH stimulation than that generated by theca cells from normal ovaries.[138,139] In these studies the rate of androgen production in PCOS theca cells was greater than of normal cells but the magnitude of response was similar in both groups, reflecting higher basal production of androgen in PCOS cells. Clinically, stimulation of ovarian androgen production by a GnRH agonist revealed significant increases in serum 17-hydroxyprogesterone and androstenedione concentrations in PCOS compared to those of normal women.[140] Differences in testosterone responses between the two groups were not found. These results suggested an overexpression of *CYP17A1*, which encodes both 17-hydroxylase and C-17-20-lyase activities. Moreover, these findings suggested that differential androgen production in PCOS may arise *de novo* within the theca cell. To further examine this issue, steroid responses to hCG were examined in PCOS subjects and normal subjects prior to and following administration of a GnRH agonist, which effectively suppressed and eliminated any disparity in basal LH secretion and ovarian androgen production.[141] Serum 17-hydroxyprogesterone responses to hCG were not abrogated by agonist treatment which provided further evidence that in PCOS the magnitude of androgen responsiveness to LH may have been due to a primary abnormality of theca cell steroidogenesis.

Rosencrantz and colleagues performed a dose-response study in PCOS women and normal women to determine theca cell androgen production following intravenous administration of multiple doses of human chorionic gonadotropin (hCG).[142] In PCOS women, 17-hydroxyprogesterone responses to hCG increased in a dose dependent manner and were greater than those observed in normal women (Fig. 22.12). A shift in the response curve was not observed, which indicated greater theca cell responsiveness and not increased sensitivity to hCG. Notably, peak androstenedione and testosterone responses in PCOS women occurred

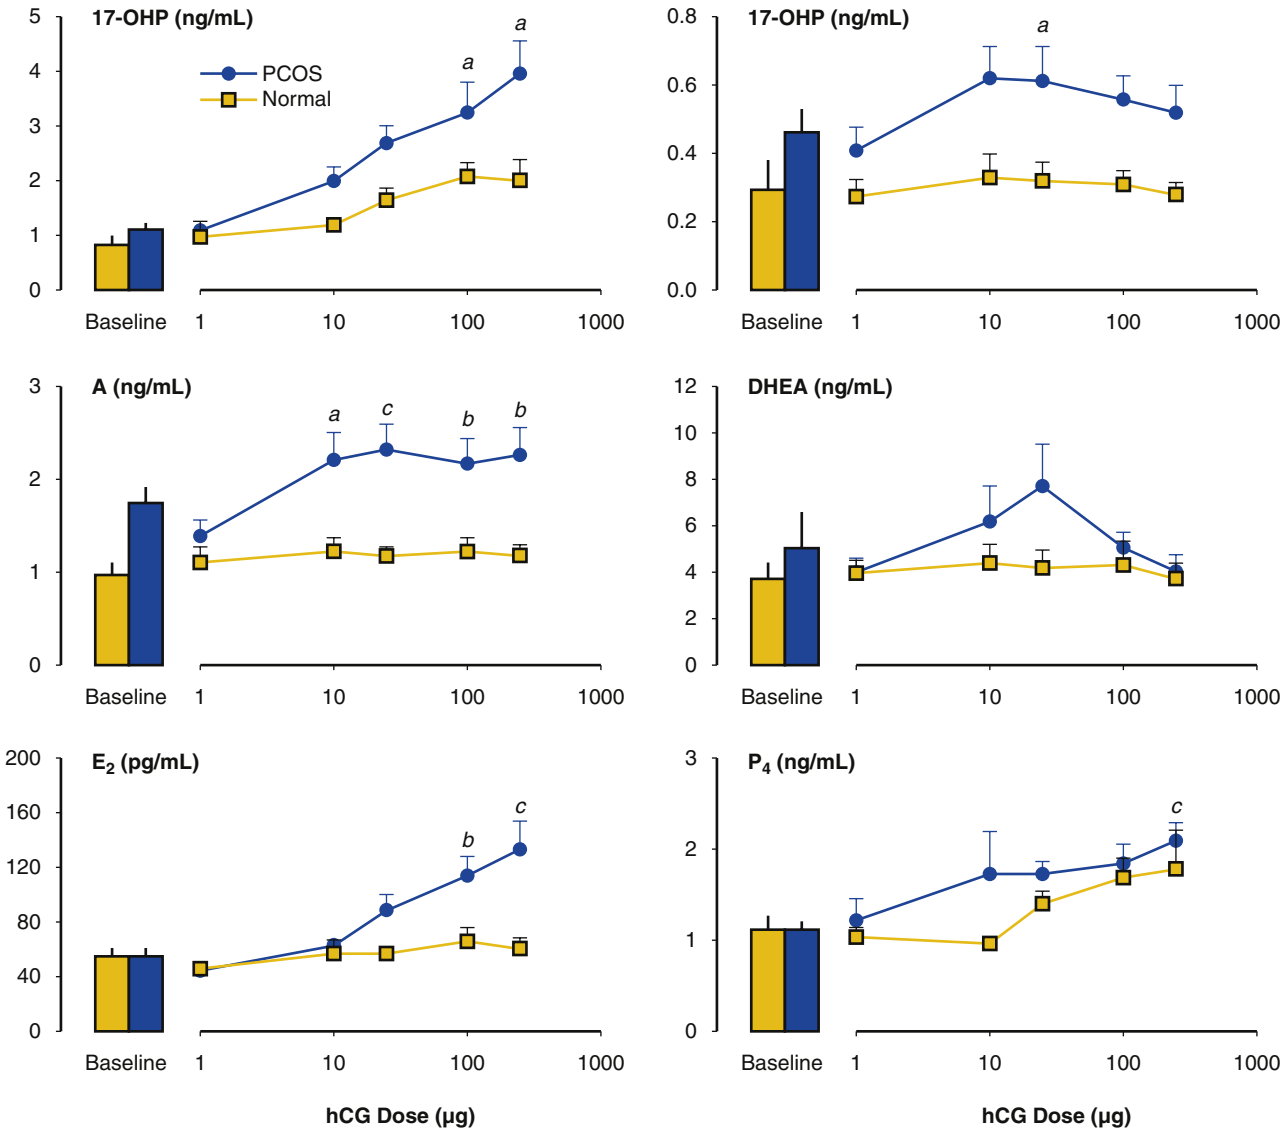

FIGURE 22.12 Mean (±standard error SE) baseline and 24-hour serum 17-OHP, A, T, DHEA, E_2, and P_4 responses to IV administration of 1, 10, 25, 100, and 250 μg of r-hCG in polycystic ovary syndrome (PCOS) and normal women. Using linear mixed-effect repeated measure model (MMRM) analyses, significant increases of 17-OHP, E_2, and P_4 were observed in both groups. By comparison, incremental A responses were significant only in PCOS women. Between groups, 17-OHP and A responses were significantly greater in PCOS women. Serum T responses were also higher compared to normal women, but the difference did not achieve statistical significance. As determined by MMRM, significant differences between groups in response to a fixed dose of human chorionic gonadotropin (hCG) are indicated by a ($P < 0.05$), b ($P < 0.01$), and c ($P < 0.001$). *(Adapted from Rosencrantz MA, Coffler MS, Haggan A, et al. Clinical evidence for predominance of delta-5 steroid production in women with polycystic ovary syndrome,* J Clin Endocrinol Metab *96:1106–1113, 2011.)*

at a low dose of hCG whereas maximal 17-hydroxyprogesterone responses were observed at higher doses of hCG. In contrast, hCG-stimulated responses of androstenedione and testosterone in normal women were not observed. These results suggested exquisite theca cell responsiveness to hCG in PCOS women compared to minimally stimulated androgen production in normal women. Previous clinical studies had suggested a lack of 17, 20-lyase activity based on GnRH-stimulated rises of androstenedione that were relatively less than that of 17-hydroxyprogesterone.[143] However, it was later shown in PCOS theca cells that radiolabeled pregnenolone was more rapidly metabolized to 17-hydroxyprogesterone, pregnenolone and DHEA and, eventually, to androstenedione compared to normal cells.[144] This increased steroid output was accompanied by greater enzymatic activities of cholesterol side-chain cleavage enzyme (CYP11A1), 3-beta, hydroxysteroid dehydrogenase (3β-HSD), and 17β-HSD, reflecting an overall upregulation of ovarian steroid production. Inefficiency of delta-4 17, 20-lyase activity may explain, at least in part, the discordant dose-responses of 17-hydroxyprogesterone compared to those exhibited by androstenedione and testosterone in our PCOS women. The accumulation of androstenedione and testosterone with minimal 17-hydroxyprogesterone production at a low dose of hCG is compatible with hyperactivity of the delta-5 steroid pathway combined with increased 3β-HSD enzyme activity, a stable property of the PCOS theca cell.[144] At higher doses of hCG, incremental changes

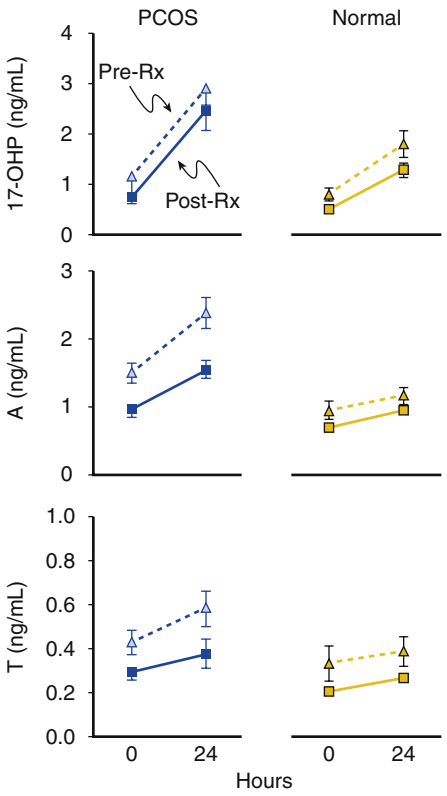

FIGURE 22.13 Mean (±SE) serum androgen levels following administration of hCG, 25 μg IV, prior to and after treatment with gonadotropin releasing hormone (GnRH) antagonist in women with polycystic ovary syndrome (PCOS) and normal controls. The rise from baseline values is significant ($p < 0.05$) for all pretreatment and posttreatment responses in both groups except for the T response in normal women before GnRH antagonist *(Rosencrantz MA, unpublished observation).*

in 17-hydroxyprogesterone responsiveness likely arose from combined over-expression of both 17-hydroxylase and 3β-HSD enzymes.

It is clear that LH is necessary to sustain circulating androgen levels. However, the extent to which endogenous LH contributes to theca cell androgen production is not completely obvious. To address this issue, we examined theca cell response to intravenous hCG stimulation in PCOS and normal women prior to and 2 days following administration of a GnRH antagonist. In both groups, antagonist treatment significantly lowered LH and moderately reduced FSH which was accompanied by decreased basal androgen levels (Fig. 22.13). Corresponding androgen responses to hCG were also lower in each group. However, the incremental fold-change for both PCOS women and normal women was not different from responses observed before agonist treatment. Our results extend the findings of other previously reported studies.[141,145] Collectively, these results suggest that endogenous gonadotropin secretion contributes to basal androgen secretion and, even in the presence of lowered gonadotropin levels, maintains ovarian androgen synthesis and responsiveness to gonadotropin stimulation. This is consistent with primary theca cell dysfunction leading to excessive ovarian androgen production in women with PCOS. Collectively, these results suggest that endogenous gonadotropin secretion contributes to basal androgen secretion and, even in the presence of lowered gonadotropin levels, maintains ovarian androgen synthesis and responsiveness to gonadotropin stimulation. This is consistent with primary theca cell dysfunction leading to excessive ovarian androgen production in women with PCOS.

Exclusive of the direct stimulus-response dynamic of ovarian androgen production, the human theca cell is also subject to the effects of co-gonadotropic growth factors, the most notable of which are insulin and insulin-like growth factors (IGF). Receptors for insulin, IGF-I and IGF-II have been localized to the theca compartment of ovaries from both normal women and PCOS patients.[146] Accordingly, *in vitro* studies of normal human theca tissue have demonstrated that these growth factors are capable of enhancing androgen responses to LH as well as independently stimulating androgen production themselves.[138,147-149] By comparison, studies performed on theca cells from hyperandrogenic women including PCOS have not demonstrated a synergistic effect between LH and insulin or IGF-I.[149] Nevertheless, the observation that reduction of hyperinsulinemia has been associated with significant decreases of serum androgens without corresponding changes in LH in women with PCOS treated with insulin-lowering drugs indirectly suggests a role for insulin in LH stimulated androgen synthesis.

Granulosa Cell Function

In PCOS, the mechanism(s) responsible for the persistence of ovulatory failure are not well understood. Earlier studies had implicated a deficiency of aromatase activity to explain the lack of follicle development as estradiol concentrations were low in follicular fluid and granulosa cells contained little measurable aromatase enzyme.[150] However, subsequent *in vitro* studies have demonstrated that these cells are, indeed, vital and exhibit substantial capacity for steroidogenesis.[13,30,151] We have previously shown that cultured granulosa cells obtained from women with PCOS exhibit a significantly greater rise of estradiol following FSH stimulation compared to that observed in normal granulosa cells, which indicated that the inherent capacity of these cells to respond to FSH was ample.[151] Clinical studies have corroborated these *in vitro* findings. In women with PCOS the capacity for estradiol production in response to the stimulatory effects of FSH was clearly enhanced compared to that of normal women.[152] Notably, this difference was dose-dependent and only manifested at 150 IU, as increases in circulating estradiol after 37.5 and 75 IU of FSH were similar in both PCOS and normal women (Fig. 22.14). The amplification of estradiol responses beyond an apparent FSH threshold dose range indicated greater *in vivo* granulosa cell responsiveness in PCOS in the presence of an abundance of aromatase substrate as profiles of circulating FSH levels at each dose were essentially identical in both groups. This heightened estradiol response may have reflected greater follicle number in the PCOS ovary compared to that of the normal ovary.[32] This explanation is consistent with the report in which comparative estradiol responses to FSH in PCOS and normal women during ovulation induction were more likely related to the number of stimulated ovarian follicles rather than differences in the FSH threshold.[74]

While these results may reflect increased numbers of stimulated follicles or increased granulosa cell sensitivity

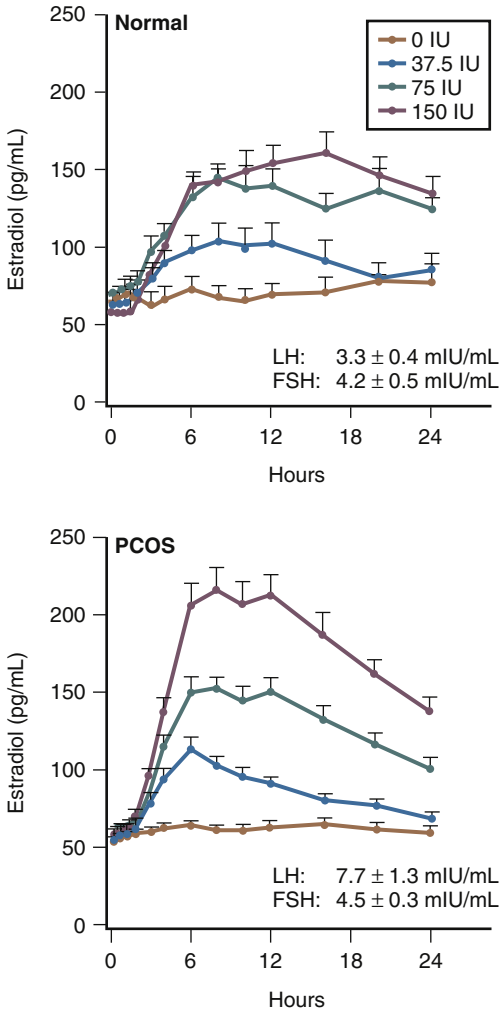

FIGURE 22.14 Mean (±SE) serum estradiol levels following intravenous administration of the indicated doses of recombinant follicle-stimulating hormone (rFSH) to subjects with polycystic ovary syndrome (n = 16) and normal controls (n = 7) at t = 0 hours. The 0-IU dose of rFSH is saline control. Mean (±SE) baseline levels of serum LH and FSH are also shown. *(From Coffler MS, Patel KS, Dahan MH, et al. Evidence of abnormal granulosa cell responsiveness to follicle-stimulating hormone in women with polycystic ovary syndrome,* J Clin Endocrinol Metab *88:1742–1747, 2003.)*

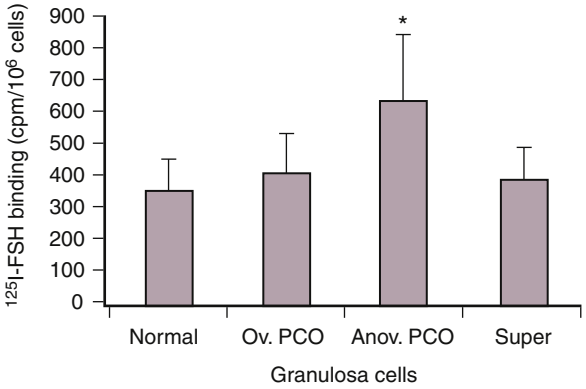

FIGURE 22.15 Binding of human recombinant ^{125}I-follide stimulating hormone to granulosa cells from different groups of patients. Follicle stimulating hormone binding per cell number was significantly (*P < .05) increased in anovulatory polycystic ovary syndrome. Functional integrity of granulosa cells from poly-cystic ovaries,* Clin Endocrinol *44:571–580, 1996.)*

to FSH or both, it is evident that women with PCOS are susceptible to ovarian hyperstimulation in response to gonadotropin stimulation. Whether increased granulosa cell sensitivity may arise primarily or secondarily as a result of intraovarian or extra ovarian factors is unknown. Studies have shown that in granulosa cells obtained by aspiration of follicles from unstimulated anovulatory PCOS ovaries, binding of radio-labeled FSH was significantly higher compared to that detected in cells from ovaries of ovulatory PCOS or normal women (Fig. 22.15).[30] These findings link granulosa cell sensitivity to increased FSH receptor binding in granulosa cells from PCOS ovaries and provide insight into a possible mechanism for increased estradiol responsiveness to FSH stimulation.

Insulin and insulin-like growth factors appear to act as co-gonadotropins within the ovary. Previous studies have shown that these peptides significantly amplify steroid production in PCOS granulosa cells.[153-155] In addition, this facilitory action of insulin was likely mediated through its own receptor.[156] Efforts to clinically demonstrate a role for insulin on granulosa cell function in women with PCOS have been limited. Following treatment with insulin lowering drugs, PCOS women have been shown to improve insulin sensitivity and resume ovulation, which indirectly links insulin resistance to chronic anovulation in this disorder.[64-67] In studies that evaluated granulosa cell function, measurement of serum estradiol levels did not reveal any particular pattern of response in women who became ovulatory or remained anovulatory. In women undergoing weight reduction, initiation of regular menses was associated with improved insulin sensitivity as reflected by increased SHBG.[126] In these studies, because the rate of ovulation improved during treatment, it was unclear whether an alteration of estradiol levels was a direct result of lowered circulating insulin levels or secondary to restoration of ovarian steroidogenesis. Insulin-lowering drugs, such as thiazolidinediones and metformin, have been shown to exert direct effect on ovarian steroid enzymes.[157-159] The potential effect of hyperinsulinemia on granulosa cell function has been examined by assessing estradiol responses to FSH stimulation.[160] In women with PCOS treated with a thiazolidinedione, pioglitazone, for 5 months, estradiol production following FSH during insulin infusion was significantly increased compared to responses observed prior to treatment (Fig. 22.16). Amplification of the estradiol response was associated with an improvement in insulin sensitivity that suggested in PCOS women granulosa cells may be insulin resistant. Moreover, these findings may account for the apparent paradoxical effect of insulin on granulosa cell function in that, *in vitro*, insulin enhances estradiol production whereas, *in vivo*, treatment with insulin-lowering drugs induces ovulation. Whether granulosa cells in PCOS women may be insulin resistant on a primary basis or secondarily has not been addressed.

That PCOS granulosa cells may be insulin resistant, could, at least in part, account for decreased estradiol responsiveness to FSH observed in PCOS women undergoing

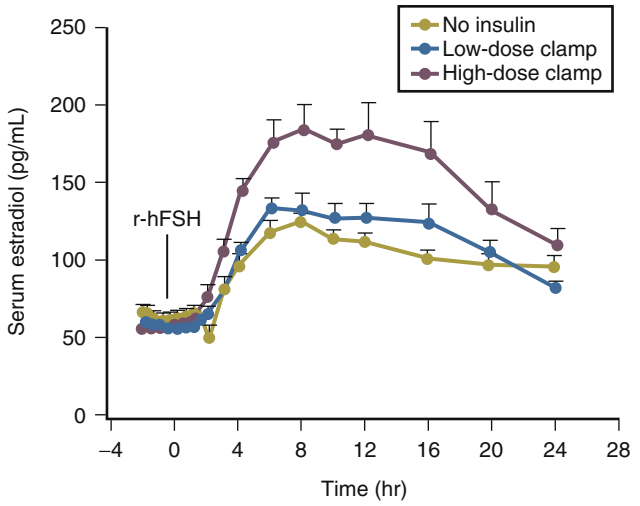

FIGURE 22.16 Time-course of mean (± standard error SE) 24-hour serum estradiol responses following injection of intravenous recombinant follicle stimulating hormone, 75 IU, to women with polycystic ovary syndrome treated with pioglitazone without insulin infusion and 2 hours following initiation of low-dose (30 μ/min/m^2) and high-dose (200 mU/min/m^2) hyperinsulinemic-euglycemic clamps administered for 10 hours. The integrated estradiol response as determined by area under the curve was significantly greater ($P < .02$) in subjects receiving high-dose insulin infusion compared with those observed for women without insulin or with low-dose insulin infusion. *(Adapted from Coffler MS, Patel KS, Dahan MH, et al. Enhanced granulosa cell responsiveness to follicle stimulating hormone during insulin infusion in women with polycystic ovary syndrome treated with pioglitazone,* J Clin Endocrinol Metab *88:5624–5631, 2003.)*

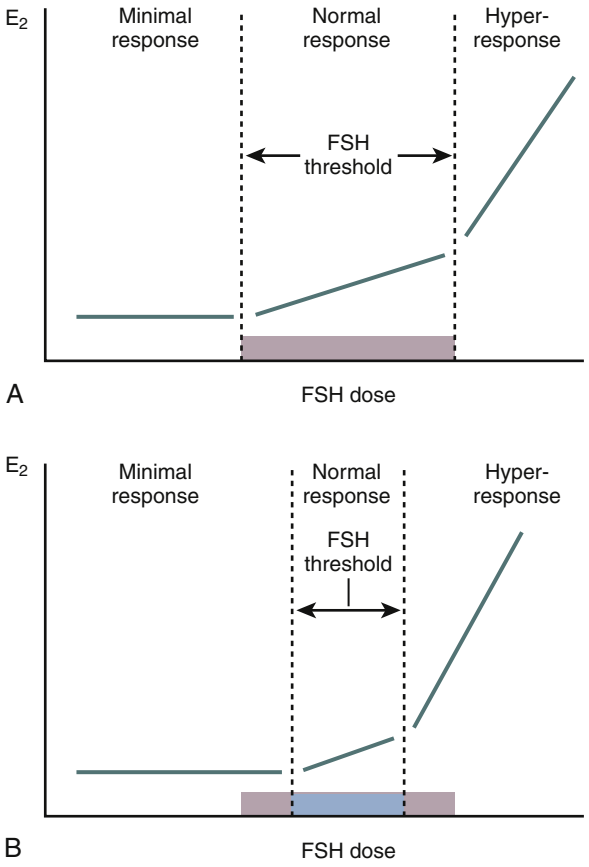

FIGURE 22.17 Conceptualized model of granulosa cell responses to a range of follicle stimulating hormone (FSH) doses administered during ovulation induction in normal women (**A**) and women with polycystic ovary syndrome (PCOS, **B**). Note the narrowed FSH threshold in women with PCOS, which may explain the minimal response to initial gonadotropin stimulation as well as the comparative hyperresponsiveness at higher threshold doses.

controlled ovarian hyperstimulation.[107,161] Clinical experience has indicated that this reduced follicle responsiveness may be overcome with progressive increases in the dose or duration of FSH. Protracted administration of low-dose FSH has been particularly useful as the risk of ovarian hyperstimulation syndrome is considerably diminished with this method of ovulation induction.[162] The gradual accumulation of constant low-dose FSH over time is preferred to an escalation of the daily dose because of follicular hyperresponsiveness to FSH in PCOS women and an increased risk of ovarian hyperstimulation syndrome.[163] These observations combined with our previous report describing greater estradiol responsiveness in PCOS women compared to normal women at a 150 IU dose of FSH suggests a bidirectional narrowing of the FSH threshold range in this disorder (Fig. 22.17).

In the past it appeared that the effect of insulin on FSH stimulated follicle development may have involved the IGF system as both IGF-I and IGF-II were shown to enhance granulosa cell responses to FSH.[151,164] In PCOS granulosa cells, exposure to both IGF-I and FSH resulted in significantly greater estradiol production compared to incubation with each hormone separately. The actions of IGFs are likely mediated by their receptors which have been identified on granulosa cells of both PCOS and normal follicles.[146] However, despite *in vitro* studies in which IGF-I clearly amplified FSH induced aromatase activity, most studies have failed to detect or shown very little of the protein in human granulosa cells.[146,165,166] By comparison, IGF-II mRNA message has been located in all compartments of the human ovary and is strongly expressed in granulosa cells.[146,165] Consistent with this observation are recent studies of human PCOS ovarian tissues which demonstrated that estrogen responses to IGF-II were significantly enhanced in granulosa cells preincubated with insulin than without insulin.[13] These findings point out the potentially critical relationship between insulin and IGF-II in the regulation of granulosa cells function. In particular, in PCOS excess insulin secretion may down regulate insulin receptors, which would prevent translocation of subcellular IGF-II receptors to the plasma membrane and deprive granulosa cells of the stimulatory effect of a potent cogonadotropin.[167,168]

IGFs are complexed with IGF binding proteins (IGFBPs) that regulate their bioactivity. In PCOS serum, IGFBP-1 has been shown to be decreased as a result of hyperinsulinemia which implies an increase in the levels of free IGF-I. This notion is supported by the demonstration of increased circulating levels of free IGF-I in PCOS women.[169] Additionally, IGFBPs may be critical in regulating IGF bioactivity at the level of the ovary. IGFBP-2 and -4 have been shown to be increased in follicle fluid derived from androgenic follicles including those of PCOS patients.[170,171] IGFBP-4 protease was not detectable in these follicles.[172] These results are in stark distinction to those found in healthy antral follicles of

normal women in which IGFBP-2 and -4 were decreased and IGF-II concentrations were increased in the follicular fluid.[173] The impact of the androgenic environment on follicular fluid IGF bioavailability has been documented in transsexuals treated with high-dose androgens. In the follicular fluid of these individuals, IGF-II levels were decreased, IGFBPs increased, and IGFBP-4 protease was non-detectable, thus accounting for decreased bioavilable IGF-II.[174] Whether this IGF-IGFBP profile is a consequence of follicular fluid androgen levels is not clear although the association is compelling and suggests that androgen excess in PCOS, driven in part by insulin mediated theca cell androgen production, may be instrumental.

The potential role of the oocyte in abnormal follicle growth in women with PCOS has not been investigated. Studies have demonstrated that oocyte-derived growth factors may be important to follicle development and function. In particular, growth differentiation factor-9 (GDF-9) and bone morphogenetic protein-15 (BMP-15) appear to have major roles on folliculogenesis and female fertility.[175] *In vitro* studies have shown that these genes are selectively expressed in developing oocytes during folliculogenesis.[176,177] In addition, in GDF-9 deficient female mice, disruption of reproductive function has been associated with arrested follicle growth at the primary stage, decreased granulosa cell proliferation, inappropriate theca cell development, ovarian cyst formation, and infertility.[178,179] We have examined mRNA expression of GDF-9 and BMP-15 in ovaries obtained from women with PCOS and found that the GDF-9 signal was decreased in oocytes throughout folliculogenesis compared to GDF-9 message in oocytes from normal ovaries.[180] By comparison there was no difference in BMP-15 mRNA expression between groups. These results suggest that the expression of GDF-9 is delayed in oocytes of developing PCOS follicles. Because of the apparent growing importance of GDF-9 in folliculogenesis and fertility, it is suggested that dysregulation of GDF-9 expression may contribute to aberrant folliculogenesis in PCOS women.

Intrafollicular Paracrine Interaction

In 2008, Wachs and coworkers reported that in PCOS women, intravenous administration of FSH resulted in significant increases in serum 17-hydroxyprogesterone, androstenedione, and DHEA levels (Fig. 22.18).[181] By comparison, androgen levels in normal women remained unchanged after FSH stimulation. In PCOS women, serum estradiol responses were also greater than those of the normal group. These findings suggested that theca cell androgen production in women with PCOS may be, in part, regulated by granulosa cells. Both *in vitro* and *in vivo* studies conducted in animals have indicated that FSH may amplify LH-induced ovarian androgen production.[182,183] In cultured human theca cells, androstenedione responses to LH in the presence of inhibin were clearly increased compared to those without inhibin.[184,185] In addition, inhibin was able to negate the inhibitory effect of activin on human theca cell androgen production. Accordingly, in our study the significant increases in ovarian androgens exhibited by PCOS women were accompanied by similar significant increments in FSH-stimulated inhibin B levels compared to those of normal women (Fig. 22.19). A direct effect of inhibin B on theca cell androgen production is unlikely as a receptor for this protein has not been identified. Rather, it has been shown that inhibin B binds to membrane bound binding protein, β-glycan, to form a complex that has high affinity for activin type II receptors.[186] The sequestration of activin type II receptors prevents formation of the activin type II

or type I receptor complex required for activin signaling and eventual inhibition of CYP17A1 within the theca cell.

Another granulosa cell-derived growth factor, kit ligand, has also been shown to stimulate theca cell androgen production. In cultured bovine theca cells, kit ligand significantly increased androstenedione synthesis in the absence of gonadotropins.[187] Moreover, kit ligand is stimulated by FSH and its receptor, c-kit, is increased by LH which potentially creates a vigorous forward feedback loop for androgen production.[188,189] Together, these findings provide a possible mechanism for FSH-stimulated androgen production in PCOS women. Consideration of an intrafollicular paracrine model of androgen production challenges the long-held two-cell, two-gonadotropin concept of ovarian steroidogenesis. However, documentation of this interaction in human ovarian tissue and whether inhibin or activin signaling and kit ligand or c-kit interaction is altered in theca cells of PCOS women has not been studied.

Adrenal Function

The role and significance of increased adrenal androgen production in women with PCOS continues to be vague. Previous studies have not consistently shown that excess adrenal androgen contributes primarily to increased T and A4 production in PCOS women despite increased serum DHEAS in 20% to 30% of cases.[55,190,191] This suggests that the mechanism for adrenal hyperandrogenemia may arise from either altered adrenal responsiveness to ACTH or abnormal adrenal stimulation by factor(s) other than ACTH. Studies to address this issue have produced varied results. Increased 17-hydroxyprogesterone responses to ACTH, following dexamethasone, have been observed in women with PCOS and functional ovarian hyperandrogenism, which suggested dysregulation of P450c17.[192,193] However, other studies have not been able to confirm these results.[194,195] These latter studies did not employ dexamethasone suppression prior to ACTH stimulation, which may have accounted for the disparate results. Alternatively, separation of PCOS women on the basis of 17-OHP responses to GnRH agonist revealed that basal androgen levels of high responders were minimally affected by dexamethasone while the percent inhibition in normal responders was equivalent to that of normal women.[196] This suggested that adrenal androgen production may contribute significantly to hyperandrogenemia in the normal responder group although studies that address this notion have not been performed. In PCOS women, *in vitro* and *in vivo* studies have shown that serum 17-hydroxyprogesterone and androstenedione responses to ACTH were significantly greater in the presence of hyperinsulinemia compared to those in the absence of elevated insulin levels.[197,198] In addition, it has been demonstrated that in individuals with PCOS, ACTH administration during insulin infusion was associated with a significantly higher 17-hydroxypregnenolone and 17-hydroxyprogesterone responses than those measured during saline infusion.[199] This facilitory effect of insulin appeared to result in a relative lowering of 17-20 lyase activity as indicated by higher 17-hydroxypregnenolone to DHEA and 17-hydroxyprogesterone to androstenedione ratios. These findings are consistent with reports that demonstrate a reduction in serum DHEA-S in women during administration of insulin infusion or a glucose tolerance test.[124,200] Whether adrenal hyperandrogenemia is contributory to the perpetuation of PCOS is not clear. However, that an exaggerated adrenarche may be an inciting event in the pathogenesis of PCOS warrants further investigation of adrenal gland function in adolescent girls with hyperandrogenism.

Pancreatic β-Cell Function and Insulin Receptor Binding

In women with PCOS, severe peripheral insulin resistance is accompanied by compensatory hyperinsulinemia. That insulin responses are exaggerated in women with PCOS following a glucose load belies a distinct abnormality of beta cell function in this disorder. Early studies had shown that in PCOS first-phase insulin secretion was equivalent to that of normal women.[201] However, first-phase insulin release is relevant to the magnitude of ambient insulin resistance in each individual. Consequently, the product of these measures can be calculated (disposition index) and related to the hyperbolic relationship of these measures established in normal women.[202] Employing this technique, it has been reported that the disposition index was significantly decreased in both obese and nonobese PCOS women compared to BMI matched normal controls (Fig. 22.20).[203] In addition, in a subset of PCOS women with a family history of diabetes the disposition index as quantitated by the

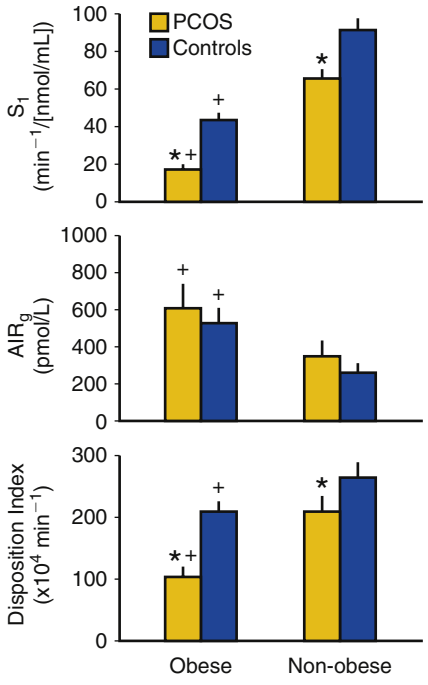

FIGURE 22.20 Insulin sensitivity index (S1) acute insulin response (AIRg), and disposition index in obese and nonobese PCOS and control women. *, Significantly different in PCOS compared to normal women; +, significantly different in obese compared to nonobese women. The S_1 is decreased in PCOS and obese women (both $P \leq 0.001$). The AIR_g is significantly increased in obese women ($P \leq 0.005$), and the disposition index (S_1 X AIR_g) is significantly decreased in PCOS and obese women (both $P \leq 0.005$). *(Modified from Dunaif A, Finegood DT. Beta-cell dysfunction independent of obesity and glucose intolerance in the polycystic ovary syndrome,* J Clin Endocrinol Metab *81:942–947, 1996.)*

insulin secretory response to graded doses of insulin infusion was in the eighth percentile whereas in those without a similar family history, the index was in the 33rd percentile.[204] Thus, women with PCOS and a family history of type 2 diabetes exhibit impaired insulin responses compared to those without a family history, particularly when expressed in relation to the degree of insulin resistance.

In PCOS, insulin receptor binding and affinity have been shown to be normal. However, studies of adipocytes from PCOS women have revealed decreases in glucose transport and lipolysis indicating an impairment of insulin signaling (Fig. 22.18).[205,206] Evidence for decreased tyrosine phosphorylation and increased insulin-independent serine phosphorylation has been demonstrated in cultured skin fibroblasts removed from women with PCOS.[207] Serine phosphorylation inhibits tyrosine kinase activity of the insulin receptor and may be responsible for the observed insulin resistance in PCOS.[208,209] Notably, increased serine phosphorylation was observed in only 50% of PCOS women studied as the remainder exhibited insulin-stimulated insulin receptor autophosphorylation which was similar to that found in normal control women.[207] Thus, these findings may be applicable to a subset of women with PCOS, whereas in others, the mechanism still remains unknown. Importantly, while a defect in insulin receptor phosphorylation may exist for some PCOS women, the potential for abnormalities beyond the receptor is suggested by apparent alterations in other downstream signaling events.[210] Moreover, different pathways may be affected to greater or lesser degrees in various insulin-sensitive tissues which reflect the complexity of the mechanism of insulin resistance in this disorder.

Genetics of PCOS

The familial predisposition of PCOS implies a disorder of inheritance, although the mode of transmission has not been established despite a number of studies. Much of the difficulty resides with methodological limitations due to small numbers of families and the inability to establish phenotypes among family members. The latter reflects the variable criteria used to designate individuals with PCOS. Studies of twin sisters have not demonstrated a substantial genetic component for polycystic ovaries, although concordance was found in affected twins relative to biochemical markers including fasting insulin levels and serum androgen concentrations.[211-213] Similarly, efforts to detect chromosomal abnormalities among PCOS subjects have not revealed alterations in number or structure.[214-216] In pursuit of the genetics of PCOS, most studies to date have focused on identifying candidate genes that are linked to recognized abnormalities of steroid hormone production and action, carbohydrate and fuel metabolism, and gonadotropin secretion. To date, only a few genes have emerged that may be reasonably related to PCOS.

Of the genes involved in steroidogenesis, there is evidence to suggest that allelic variants of *CYP11A1* may have a potential role in excess androgen production and hirsutism in PCOS.[217-220] Gharani and colleagues demonstrated association between an allele of *D15S520* that is located in the promoter region of *CYP11A1* and PCOS.[217] However, these findings were not replicated in other studies.[219,220] The androgen receptor (AR) gene persists as a possible candidate for PCOS in light of the inverse relationship between the number of trinulceotide (CAG) repeats and androgen action.[221] The AR gene is X-linked and in women one copy of the X chromosome is inactivated. Thus, the manner in which X-inactivation occurs may influence AR bioactivity. This was suggested in a study by Hickey and colleagues which showed sister pairs with the same AR CAG repeats genotype were more often associated with similar patterns of X-inactivation and like phenotypes compared to sister pairs with the same genotype, but different X-inactivation and varying clinical phenotypes.[222]

Given the predisposition of PCOS women to insulin resistance, genes that are related to carbohydrate metabolism have been the subject of considerable investigation. Of particular note is the insulin receptor gene, a mutation of which leads to severe insulin resistance, marked hyperandrogenism, and acanthosis nigricans (type A syndrome of insulin resistance). Two studies have identified the region near the insulin receptor gene locus as being associated with PCOS.[219,223] In contrast, abnormalities in the tyrosine kinase domain of the insulin receptor gene in PCOS women were not detected.[224] Additionally, molecular analysis of the coding region of the insulin receptor gene conducted on the deoxyribonucleic acid (DNA) of women with PCOS failed to detect any missense or nonsense mutations suggesting that mutational defects on the insulin receptor gene are highly unlikely.[225] As for the insulin gene or *VNTR*, there are conflicting reports linking this marker to PCOS.[219,226,227] As a regulator of transcription, *VNTR* is related to hyperinsulinemia, risk of type 2 diabetes, and development of childhood obesity.[228] Several studies have shown a modest association between *VNTR* and women with PCOS.[226,229] However, other investigators have been unable to demonstrate evidence of a link between PCOS and the insulin gene.[219,230,231] Collectively, these findings suggest that involvement of this gene locus with PCOS is uncertain.

It has been shown that variation in the gene encoding the cysteine protease, calpain-10, influences susceptibility to type 2 diabetes.[232,233] However, two subsequent studies in women with PCOS of African-American and European descent were unable to establish associations with multiple DNA polymorphisms in the calpain-10 gene.[234,235] Nevertheless, the 112/121 haploid combination in African-Americans with PCOS was found to be significantly associated with increased circulating insulin levels in response to a glucose challenge. Another potential susceptibility locus was identified from a screen of 37 PCOS candidate genes that found evidence for a strong association of an allele of *D19S884* on chromosome 19p13.2.[219] This association was strengthened by a similar outcome in a subsequent study by the same investigators involving a larger number of families.[236] While the *D19S884* allele may be a distal enhancer of the insulin receptor gene, its functional role has not yet been determined. Recently, other susceptibility variants in the gene for transcription factor-7 like-2, which is a significant risk factor for type 2 diabetes, were associated a PCOS cohort. In addition, these alleles were linked with β-cell dysfunction in PCOS women with impaired glucose tolerance.[237,238]

All these studies reflect efforts to assign a single gene marker to PCOS. However, the phenotype of this syndrome

has multiple clinical alterations that imply a highly complex genetic disorder. Thus, it was anticipated that genome wide association studies (GWAS) would provide a more comprehensive approach with fruitful outcomes. Indeed, in a large GWAS conducted in Han Chinese involving 744 PCOS cases and 895 controls in the discovery set and 3338 PCOS and 5792 controls in the replication set, there was evidence of strong associations between three PCOS susceptible loci on chromosomes 2p16.3 (luteinizing hormone-chorionic gonadotropin receptor *[LHCGR]*), 2p21 (thyroid adenoma associated protein *[THADA]*), and 9q33.3 (DENN-MADD domain containing 1A *[DENND1A]*).[239] In a subsequent large study of women with PCOS of European descent, similar findings emerged for *DENND1A* and *THADA*, which gave credence to the previous GWAS study.[240] Almost simultaneously, a third study largely confirmed the association of *DENND1A* susceptibility loci in a cohort of PCOS women from Iceland and the United States.[241] These findings warrant further investigation, although currently it appears that *DENND1A* and, possibly, *THADA* confer increased risk for PCOS.

Pathophysiological Concept

A clear explanation of the pathogenesis for PCOS has not been established. Several concepts have emerged that await confirmation. A growing body of evidence suggests that excessive androgen production may be essential in the evolution of this disorder (Fig. 22.21). Notably, it has been demonstrated that administration of androgen to nonhuman primates alters ovarian morphology by increasing the size of the ovary, thickness of the capsule, and number of preantral and antral follicles.[37] These data are consistent with the polycystic ovaries of hyperandrogenic women with 21-hydroxylase deficiency and female to male transsexuals administered long-term androgen therapy.[154,165-168,170,171] The mechanism that dictates these morphological changes has not been elucidated, although in rhesus monkeys, androgen receptor mRNA is colocalized with that of the FSH receptor in granulosa cells and androgen treatment increases the expression of FSH message.[39] The presence of increased FSH binding in granulosa cells of antral follicles from women with PCOS compared to binding in normal follicles suggests that local exposure of excess androgen may drive this process and account for increased follicle number and size in this disorder.[30]

An androgen-induced increase of FSH receptors on granulosa cells of PCOS women may also explain the robust follicular response to FSH observed *in vitro* and relate to heightened granulosa cell responsiveness to gonadotropin stimulation.[29,151,152] Similar to studies in nonhuman primates, women with PCOS treated with androgen exhibited intense nuclear staining for androgen receptor in granulosa cells.[172] In rat granulosa cell culture, studies have shown that testosterone acts at a site upstream from cyclic adenosine monophosphate c-AMP, which suggests involvement of the FSH receptor, whereas other studies have been unable to determine whether changes in c-AMP are induced by androgen treatment.[141,147,148] Despite these inconsistent findings, it is likely that the effect of androgen on the FSH receptor and subsequent granulosa cell function is mediated through its receptor. However, the precise mechanism for this interaction remains to be defined. An

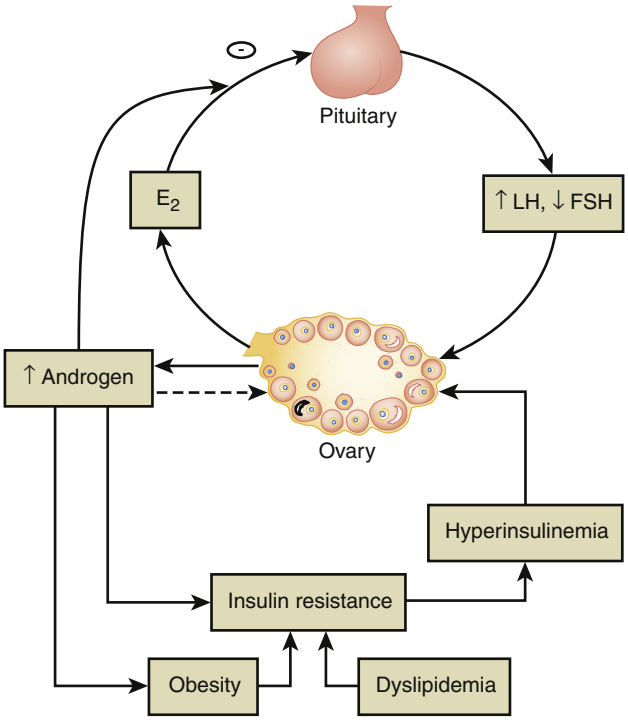

FIGURE 22.21 Pathophysiological concept of polycystic ovary syndrome (PCOS): Increased luteinizing hormone (LH) secretion together with enhanced theca cell responsiveness drives the production of excess ovarian androgen. Increased androgen production may inhibit steroid negative feedback effects on hypothalamic gonadotropin-releasing hormone pulse generation to account for the rapid LH pulse frequency observed in PCOS women. In addition, increased androgens are associated with android obesity, visceral fat deposition, and dyslipidemia, all of which may contribute to insulin resistance. Independently, hyperandrogenemia, obesity, and hyperinsulinemia may decrease sex hormone-binding globulin, thereby increasing bioactive testosterone. Finally, increased androgen may have direct effects on the ovary to increase follicle number, follicle size, and, possibly, enhance granulosa cell responsiveness to follicle stimulating hormone.

amplification of granulosa cell responsiveness to FSH is not unique to androgens as estrogens have long been known to enhance FSH-stimulated estradiol production.[242] In rodent granulosa cells, synergy between estradiol (E_2) and FSH has been demonstrated with regards to increased FSH receptor binding, induction of LH receptors, increased aromatase activity, and progestin synthesis.[243-245] The mechanism for this synergy has not been completely elucidated, although estrogen-induced granulosa cell proliferation or increased FSH-binding capacity per granulosa cell have been suggested.[244,246,247] Alternatively, both processes may serve to amplify FSH receptor number in granulosa cells of developing follicles. Thus, these findings strongly suggest that in normal and PCOS granulosa cells, estrogen as well as androgen may enhance FSH-stimulated estradiol release through a mechanism that involves the FSH receptor.

Increased androgen production may have a significant impact on inappropriate gonadotropin secretion in PCOS. The critical feature of LH secretion in PCOS is increased LH pulse frequency, which remains intact in the face of physiological and most pharmacological manipulations. Until recently, it was difficult to exclude altered GnRH

release as an instigating factor in PCOS. However, that the rate of rapid LH release in PCOS women may be normalized with administration of physiological doses of estrogen and progesterone following treatment with an anti-androgen suggests an inhibitory effect of increased androgen bioactivity on steroid negative feedback.[88] This notion is underscored by the appearance of increased LH pulse release in young adult female monkeys that had received chronic androgen administration prior to and through puberty.[102] These results suggest that hyperandrogenism may be responsible for or, at least, contribute to increased LH pulse frequency in this disorder. The prevention of steroid negative feedback may be a unique effect of androgen as estradiol and insulin, the secretion of which are both abnormal, have not been shown to alter LH pulse frequency. Further studies are necessary to elucidate primary and secondary mechanisms of increased GnRH pulse generator activity in PCOS.

The apparent central role of androgen excess in PCOS underscores the importance of the process by which hyperandrogenism is achieved. That the theca cell is the primary source of hyperandrogenism in PCOS is undeniable. Furthermore, there is evidence to demonstrate increased theca cell responsiveness to LH stimulation compared to normal theca tissue, which suggests a primary defect in this cell.[138,139] As previously mentioned, in PCOS women, increased 17-hydroxyprogesterone dose-responses to hCG were accompanied by significantly greater increases of both androstenedione and testosterone.[142] The androgen responses were achieved at a much lower stimulatory dose of hCG than that required to induce significant increments of 17-hydroxyprogesterone. These results were consistent with *in vitro* studies using propagated PCOS theca cells in which stimulated progesterone, 17-hydroxyprogesterone, and testosterone production were greater than that observed for normal cells.[144,248] The pronounced increase of *CYP11A1* expression and 3β-HSD and 17β-HSD enzyme activities subserve an overall upregulation of steroid formation in the PCOS ovary. In addition, the production of androgen is driven by pituitary LH, which has a bimodal dose effect on the enzyme activities encoded by *CYP17A1*.[249,250] At low doses, LH primarily stimulates 17-hydroxylase activity, whereas at high doses LH down-regulates the 17-20 lyase activity of *CYP17A1*, which would account for the greater incremental change in 17-hydroxyprogesterone.

Notwithstanding the physiological impact of increased theca cell production of androgens, the bioavailability of testosterone is largely influenced by the production of sex hormone binding globulin, the reduction of which may lead to significant hyperandrogenism. Decreases in circulating SHBG concentrations have been observed in women with hyperinsulinemia, excessive weight gain, or hyperandrogenism with the clinical outcome resulting in various degrees of hirsutism. In PCOS, all of these conditions may coexist simultaneously, thereby amplifying the clinical manifestations of excess androgen production. To illustrate the impact of SHBG, marked elevation of serum free testosterone levels and severe hirsutism have been recently reported during pregnancy in a woman who essentially lacked the capacity to produce bioactive SHBG. The deficiency in SHBG production was caused by a single nucleotide polymorphism within an allele that encoded a missense mutation.[26]

As previously stated the role of the adrenal in the genesis of PCOS is unclear. Nevertheless, elevated DHEAS in approximately 20% to 30% of cases indicates an adrenal contribution to excess androgen production that may impact pathophysiological alterations. Moreover, it remains to be determined whether the emergence of adrenal hyperactivity at the time of or just prior to puberty provokes the onset of this syndrome. In girls that experience pubic hair growth prior to age 8, premature pubarche, the risk of PCOS is increased.[251] Similarly, it has been hypothesized that an exaggerated adrenarche at puberty, marked by increased production of DHEA and its sulfate, leads to abnormal androgen exposure and eventual PCOS.[252] These considerations raise the possibility that the genesis of PCOS may be critically linked to the onset of adrenal androgen production at or shortly before puberty.

The role of insulin resistance and hyperinsulinemia in PCOS as a primary cause has not been established. However, there is clear evidence to suggest that hyperinsulinemia may perpetuate the altered reproductive and metabolical physiology in this syndrome. *In vitro* studies have demonstrated that insulin enhances LH-induced androgen production from normal theca cells.[138,147,148,253] Moreover, improvement in insulin sensitivity through the administration of insulin lowering drugs has been accompanied by reduction of serum androgen levels without an effect on circulating LH concentrations. In the granulosa cell, insulin has been shown to enhance estradiol responses to FSH *in vitro* and there is indirect *in vivo* evidence to suggest that insulin may facilitate FSH stimulated estradiol release.[64-67,125,155,254] At the level of gonadotropin secretion, evidence for a role of insulin is inconsistent and remains to be determined. Insulin may have a suppressive or minimal effect on pituitary LH and FSH release whereas results obtained *in vitro* in the rat model would suggest otherwise.[128] However, overall these data suggest that the role of insulin resistance in PCOS is directed primarily, but not exclusively, at the level of the ovary. Concomitantly, hyperinsulinemia may also effect a reduction of serum SHBG as well as reflect a consequence of obesity in these individuals. Whether insulin resistance is etiological is unclear as not all women with this disorder have been found to exhibit abnormal insulin secretion. In addition, defining cellular defects in insulin signaling and insulin related cell function have not been consistent within similar or different tissues of women with PCOS.[255]

Aside from the effects of increased LH secretion on theca cell androgen production, it has been suggested in PCOS that ovarian follicles undergo premature luteinization as a result of the atretogenic action of LH on the granulosa cell. This concept has been supported by evidence that demonstrates increased LH-induced progesterone production from medium-sized follicles (<9 mm diam.) of granulosa cells from PCOS ovaries compared to those observed with normal granulosa cells.[256] In addition, PCOS granulosa cells have been documented to express significantly greater LH receptor mRNA message than cells from normal follicles.[257] These findings together with the increase in LH secretion provide a compelling argument for such a process. Whether this mechanism can explain the arrest of follicle development at the midantral stage of growth in women with PCOS remains to be shown. Moreover, it is not clear how pervasive is the effect of increased LH secretion on granulosa

cell viability. Indeed, it has been demonstrated that most granulosa cells derived from unstimulated follicles of PCOS ovaries are extremely vital and exhibit great capacity for steroidogenesis.[30] Moreover, in 2008 it was reported that in PCOS granulosa cells that markers for apoptosis were decreased and anti-apoptotic gene expression increased compared to those of normal granulosa cells.[31] It may be the case that only the very terminal granulosa cells become quickly atretic and suffer demise.

PCOS continues to remain a pathophysiological enigma with several components of altered physiology unexplained. While a unifying concept seems currently elusive, there is reason to invoke a crucial role for excess androgen exposure in the perpetuation and, perhaps, pathogenesis of this disorder. This approach would account for the diversity of clinical situations which may give rise to the PCOS phenotype including primary and secondary causes of increased androgen production as well as conditions in which androgen bioactivity is increased.

Long-Term Consequences

In PCOS the reproductive-metabolical alterations that are responsible for the immediate concerns of hirsutism, acne, and anovulatory infertility may also pose significant long-term risks to a woman's general health and well-being. These concerns have principally been attributed to chronic anovulation, insulin resistance, and obesity, all of which are salient features of the disorder.

Cancer

Beyond the immediate problem of anovulatory infertility in PCOS, persistent stimulation of the endometrium by chronic unopposed estrogen may lead to endometrial hyperplasia or adenocarcinoma in some women, particularly those with obesity. In a long-term follow-up study of women with PCOS based on ovarian wedge resection, the odds ratio for developing endometrial carcinoma was 5.3 (95% CI: 1.55-18.6) compared to controls.[258] The relationship of endometrial cancer with PCOS was evident in a case-control study, which showed that elevated androstenedione levels were associated with 3.6-fold and 2.8-fold increased risks of carcinoma in premenopausal and postmenopausal women, respectively.[259] Conversely, it has been documented that in young women with endometrial cancer a history of menstrual irregularities consistent with anovulation and the diagnosis of PCOS is common.[260] This problem is compounded by the presence of obesity and the associated decrease of sex-hormone binding globulin resulting in an increase of circulating free estradiol. In cases of endometrial cancer found in PCOS women, the lesion is usually well-differentiated as compared to poorly-differentiated or undifferentiated forms noted for older postmenopausal women. It is not clear whether the histological pattern of endometrial cancer in young PCOS patients might alter consideration of definitive therapy. However, expression of estrogen and progesterone receptors was more commonly encountered in the endometrial tissues of premenopausal versus postmenopausal women.[260]

Studies of the association between PCOS and breast cancer have generally not revealed increased risk. However, many of these studies were limited by conditions of design or subject selection. For instance, increased risk was not found among a cohort of chronic anovulatory women from the Mayo Clinic.[261] It was presumed that these women had PCOS and the study was retrospective. Subgroup analysis of postmenopausal breast cancer showed a significantly increased risk, although the affected cohort was comprised of only five subjects. The Cancer and Steroid Hormone Study, involving 4730 women with breast cancer and 4688 controls failed to identify an increased risk for breast cancer.[262] Moreover, there was actually a 50% reduced likelihood of developing breast cancer. Unfortunately, the diagnosis of PCOS was self-reported and no laboratory documentation was performed. Similarly, the Iowa Women's Health Study, which did not demonstrate increased risk for breast cancer also relied on self-reporting of PCOS.[263] In a study in which the diagnosis of PCOS was based on histological appearance and clinical features, no association could be determined in a cohort of 786 women.[264] In 2003 it was reported that PCOS women were found to have a statistically significant family history of breast cancer compared to that of controls, suggesting a familial association.[265] This study suffered from a lack of enrolled participants, as there were 41 women with PCOS and 66 controls. Thus, of the studies conducted to determine the relationship of PCOS to breast cancer, the vast majority have not been able to define a positive association.

A link between PCOS and ovarian cancer has been suggested from the findings of the Cancer and Steroid Hormone Study, in which women with epithelial ovarian cancer had a significantly higher likelihood of reporting a diagnosis of PCOS compared to that of controls.[266] Moreover, after adjusting for age, parity, oral contraceptive use, infertility and education, the odds ratio, 2.4 (95% CL, 1.0-5.9), for a history of PCOS remained statistically significant. In contrast, longitudinal follow-up studies have not been able to corroborate an increased risk of ovarian cancer in PCOS women. The Mayo Clinic cohort of 1270 subjects with presumed PCOS revealed no concurrent or subsequent risk of ovarian cancer.[261] Similarly, the mortality from ovarian cancer in 768 women with histologically identified PCOS ovaries followed for an average of 30 years was comparable to an expected rate of 2.6 deaths.[264] Recently, in a large population-based case-control study from Australia, women with a history of PCOS or excess androgen exposure were not associated with an increased rate of ovarian cancer.[267]

Diabetes Mellitus

The discovery that women with PCOS have insulin resistance and are at risk for diabetes mellitus has had an enormous impact on the long-term health implications of this disorder. While insulin resistance has been described as being relatively mild, it has been estimated that 20% to 40% of these patients will develop glucose intolerance or type 2 diabetes mellitus by the fourth decade of life.[268,269] Conversely, premenopausal women with type 2 diabetes appear to be at increased risk for PCOS. It is apparent from several studies that PCOS is a leading factor for type 2 diabetes in women.[57,255,270] Not only are women with PCOS at increased risk for impaired glucose tolerance and diabetes, but increased circulating concentrations of insulin have been

reported to be common in first degree relatives.[271] Recently, it has been reported that the combined prevalence rates for impaired glucose tolerance and diabetes in mothers and fathers of women with PCOS were 46% and 58%, respectively, which are considerably greater than rates encountered in families without a history of PCOS.[21] In addition, affected sisters of PCOS women were shown to have higher insulin to glucose ratios than their unaffected female siblings.[272] Collectively, these findings illuminate the trend towards abnormalities of glucose metabolism and diabetes in PCOS women and their immediate family members.

Dyslipidemia

Lipid abnormalities in PCOS are characterized by significant increases of circulating total cholesterol, LDL-cholesterol and triglycerides compared to normal matched controls.[273] Conversely, serum levels of total HDL cholesterol and HDL_2 are significantly lower in PCOS than that of normal women. While it has been shown that in PCOS this lipid profile may exist independently of several risk factors, the impact of these factors on lipid metabolism may be considerable. Previous studies have clearly demonstrated that obesity and impaired glucose tolerance are associated with adverse lipid profiles. The effect of androgen excess on lipid metabolism is less well understood in PCOS.[274] Compared to age-matched normal women, the dyslipidemia of PCOS appeared to be less distinctive when the data were adjusted for body weight. Moreover, serum concentrations of lipoprotein-a and possibly PAI-1 were reduced by testosterone whereas DHEA increased insulin sensitivity.

Regardless of the mechanisms which predispose to the lipid abnormalities in PCOS, these patients should be at risk for plaque generation in coronary vessels.[275] Through the action of hepatic triglyceride lipase, very low density lipoprotein (VLDL) and intermediate density lipoprotein (IDL) are converted to LDL cholesterol. LDL cholesterol appears to be the most atherogenic lipoprotein. Another lipoprotein, lipoprotein-a, is also atherogenic and has the most pronounced effect when LDL cholesterol is elevated. Hepatic triglyceride lipase is also responsible for converting HDL_2, which is rich in cholesterol, to cholesterol poor HDL_3. While the atherogenic properties of LDL cholesterol are well established, there is evidence to suggest that low HDL cholesterol and high triglycerides may be more predictive of coronary artery disease in women than men.

Cardiovascular Disease

It is generally believed that women with PCOS are at increased risk for the development of cardiovascular disease. This is based on the presence of several risk factors which predispose to heart disease. These include impaired glucose tolerance, android obesity, hyperandrogenism, dyslipidemia, and hypertension. Whether PCOS itself constitutes a risk factor independent of known risk factors is not absolutely clear. Evidence to support this association was provided by a case-control study in which 206 women with PCOS and corresponding controls matched for age and race were compared.[276] The PCOS group was found to have significantly higher levels of total cholesterol, LDL-cholesterol, and triglycerides than normal controls. Adjusting for confounding variables such as BMI, fasting insulin, exogenous hormones, oral contraceptives, and age by multiple regression analysis, the lipid abnormalities in PCOS women remained highly significant. In addition, the dose-response relationship between insulin and PCOS was examined within individual cases and only about 20% of the variance could be attributed to insulin. Of note, androgens also did not contribute to the variance in lipids. These findings suggest that dyslipidemia in PCOS involves pathways separate from those of insulin and androgens. To determine whether the risk of cardiovascular disease may be demonstrated clinically in PCOS, a comparison of carotid ultrasonography was performed in PCOS patients and their matched controls.[277] The intima-media thickness, which has been directly correlated with cardiovascular disease, was significantly greater in PCOS than in controls. In addition, atherosclerotic plaque formation was found to be twofold greater in the PCOS group.

Retrospective studies exist which have suggested that women with PCOS or at least the stigmata of PCOS have increased arterial lesions in their coronary vessels.[275,278] In an analysis that employed a statistical risk factor model, it was determined that PCOS women had a significant increased risk of myocardial infarction compared to controls.[279] Unfortunately these studies were limited by their retrospective design, lack of controls for obesity, and insufficient categorization of patient groups. Nevertheless, the current literature clearly indicates that women with PCOS cluster risk factors for premature morbidity and mortality regarding heart disease.[280] Despite the suggestive evidence of greater cardiovascular risk, measurement of actual death from myocardial injury has yet to be established. In 2 studies which examined the long-term health consequences in 786 women with PCOS, increased risk for coronary heart disease was identified, but mortality and morbidity did not differ from the age-matched control group.[258,264]

Hypertension

It has been reported in a retrospective study that postmenopausal women with a history of PCOS, corroborated with pathological conformation, have an approximate fourfold increase in rate of hypertension compared to control subjects.[281] In addition, PCOS women tended to exhibit elevated blood pressure when compared to age-matched controls. However, increases in blood pressure in both obese and nonobese PCOS do not appear to be greater than that of control subjects after adjusting for weight and body composition.[282,283] Thus, despite the presence of insulin resistance in PCOS, particularly in obese women, hypertension may not be a common accompaniment of the disorder. Currently, the relationship of hypertension to PCOS is under investigation.

Differential Diagnosis

The lack of a specific diagnostic test for PCOS combined with the broad clinical spectrum resulting from anovulation and hyperandrogenism warrant consideration of related conditions with similar presentations. These include both functional and neoplastic processes. Among the functional disorders are ovarian hyperthecosis, congenital adrenal hyperplasia, and Cushing disease. Included in the neoplastic

group are androgen producing tumors of the ovary and adrenal gland.

Ovarian Hyperthecosis

Hyperthecosis refers to an unusual proliferative condition in which the ovary contains nests of luteinized theca cells scattered throughout the stroma.[284] The extent of theca cell involvement may vary from minimal to extensive. Severe hyperthecosis may be accompanied by extensive and dense fibroblast growth resulting in an enlarged ovary of extremely firm texture, findings which are clearly distinct from those found in PCOS. Interestingly the degree of hyperthecotic transformation in the ovary is not correlated to the severity of disease.[285] This observation would suggest that the hyperthecotic tissue may be hypersensitive to gonadotropin stimulation since serum LH levels are commonly in the normal range of values. Due to markedly high serum androgen concentrations, these individuals suffer from severe hirsutism and a significant percentage of patients exhibit virilizing signs such as clitoromegaly, temporal balding, a male body habitus and a deepening of the voice. The androgen production may be resistant to conventional forms of long-term ovarian suppression such as oral contraceptive therapy, although administration of gonadotropin releasing hormone agonists have been shown to dramatically decrease androgen production. There usually is marked insulin resistance with substantial elevations of circulating insulin levels. In addition, these patients are often obese and exhibit acanthosis nigricans.

Congenital Adrenal Hyperplasia

Among the several enzymatic defects that comprise congenital adrenal hyperplasia (CAH), the incomplete form of 21-hydroylase deficiency best simulates PCOS (see Chapter 25). This deficiency is manifested by an accumulation of 17-hyroxyprogesterone which leads to abnormal elevations of the hormone compared to circulating values found in the follicular phase of the menstrual cycle. As 17-OHP is an androgen precursor, expression of this defect is associated with increased production of androstenedione and testosterone with resultant hyperandrogenism. Notably, the clinical presentation may be indistinguishable from that of PCOS. However, there are several aspects of CAH-21-hyroxylase deficiency which may suggest the diagnosis. These include severe hirsutism, clitoromegaly, familial tendency and short stature. The condition is transmitted by an autosomal recessive inheritance pattern whereas an explanation for short stature is unknown. Morphologically, the ovaries have been reported to appear similar to those of PCOS. The capsule generally is dense and thickened although the presence of peripheral cystic follicles has been an inconsistent finding. The second most common enzyme deficiency is 11-β-hydroxylase which gives rise to a mild hirsutism due to increases in 17-hydroxyprogesterone as well as 11-deoxycortisol, the immediate precursor for this enzyme. The accompanying hypertension often distinguishes this disorder from the 21-hyroxylase form of CAH.

Cushing Syndrome

The clinical features of Cushing syndrome primarily result from excessive cortisol production by an adrenal neoplasm or from excessive adrenocorticotropin (ACTH) production. In most cases, ACTH overproduction is due to a pituitary tumor, although, rarely, ectopic sources of ACTH may be encountered such as in adenocarcinoma of the lung. The preponderant findings are obesity, hirsutism, acne, and menstrual irregularity. These suggest the diagnosis of PCOS. However, additional evidence of moonlike facies, buffalo hump, hypertension, muscle wasting, abdominal striae, and osteoporosis indicate a primary problem of cortisol excess. While circulating androgen levels are elevated, there is also abnormal cortisol secretion characterized by increased basal levels, loss of circadian rhythmicity and failure of suppression in response to dexamethasone. In contrast to CAH, careful examination of the ovaries does not reveal changes typical of PCOS in the vast majority of cases.

Androgen Producing Neoplasms

Androgen producing tumors may arise from the ovary and the adrenal gland. In contrast to the gradually evolving clinical presentation associated with functional hyperandrogenism, the neoplastic process can be quite dramatic. Within a matter of months these lesions may induce severe hirsutism, a male body habitus and virilization marked by clitoromegaly. In addition, there may be acne and a lowering of the voice. Despite the severity of androgenic manifestations, the early stages of development of these tumors can mimic PCOS or other functional hyperandrogenic syndromes. Occasionally, the hormone production may be mixed to include excess production of cortisol and progesterone.[286] Disruption of menstrual cyclicity varies from irregular bleeding to amenorrhea. The rapid onset of symptoms provides an important clue to the diagnosis. In some instances, a pelvic or abdominal mass can be palpated, which suggests an ovarian tumor.

Evaluation

Laboratory Evaluation

Basically the laboratory diagnosis of PCOS is one of exclusion. Traditionally, it has been recommended that patients suspected of having PCOS on a clinical basis undergo a minimum endocrine evaluation consisting of serum total testosterone or free testosterone and, if indicated, 17-hydroxyprogesterone (see Chapter 25). Measurement of DHEAS is likely to be of low yield unless indicated by clinical findings of severe hirsutism and suspicion of a neoplasm. Individuals with moderate to severe hirsutism may be harboring a hyperplastic or neoplastic lesion. Ethnic considerations are also important as Asians often do not or only minimally manifest androgen excess. Measurements of testosterone and DHEA-S that exceed 200 ng/dL and 7000 ng/dL, respectively, may be associated with an androgen-producing tumor of the ovary or adrenal gland. Should circulating concentrations exceed these threshold levels for tumor, then imaging studies such as ultrasound and MRI are warranted to locate the lesion. Occasionally, high circulating androgen levels may not be associated with a distinct lesion, but rather bilateral non-cystic ovarian enlargement. If accompanied with a gradual onset of symptoms, this presentation would suggest the diagnosis of hyperthecosis.

Commonly, these patients will exhibit severe insulin resistance and acanthosis nigricans.

Determination of 17-hydroxyprogesterone is useful as a screening test for the detection of CAH due to 21-hydroxylase deficiency. It has been proposed that a threshold concentration of basal 17-hydroxyprogesterone of 3 ng/mL provides the maximal cost-benefit.[287] A very high level of 17-hydroxyprogesterone is indicative of the disorder. A circulating level of less than 3 ng/mL obtained at random in anovulatory individuals or during the follicular phase in women with regular menstrual cycle excludes the diagnosis. Values in excess of 3 ng/mL warrant further evaluation by an ACTH stimulation test. Following an overnight fast, ACTH (1-24), 250 μg, is injected intravenously. After 1 hour, a serum 17-hydroxyprogesterone is measured and an increase of greater than 20 ng/mL is indicative of the enzyme defect. Genetic testing may also be used, but this is usually for cases in which the diagnosis is uncertain.

Women with Cushing syndrome may also present with a clinical picture consistent with PCOS. The optimal screening test is a 24-hour urinary free cortisol, for which the normal value is less than 100 mcg/24 hour. Abnormal responses require further testing to determine the mechanism and site of excess cortisol production. These include low dose, high dose dexamethasone suppression tests as well as imaging studies to determine the existence of adrenal hyperplasia, Cushing disease, adrenal adenoma or ectopic ACTH production.

As part of the assessment of oligoamenorrhea due to anovulation, measurements of prolactin and TSH may be desirable. In PCOS, serum elevations in prolactin have been reported to range between 20% and 40% and probably relates to lactotrope stimulation by chronic estrogen exposure.[288,289] Coexistence of a prolactinoma and PCOS is uncommon. Disorders of thyroid secretion have been associated with irregular menstrual bleeding, although there usually are other accompanying clinical features that suggest the diagnosis.

Some comment is warranted regarding the measurement of serum gonadotropin levels and free testosterone concentrations. Despite the widespread practice of measuring serum LH and FSH, the circulating levels of these glycoproteins really do not contribute significantly to the diagnosis of PCOS. Increased pituitary LH secretion cannot always be determined by measurement of the serum concentration, as approximately one-third of patients will have circulating levels of LH in the normal range. Circulating endogenous LH levels are positively correlated to body mass index, which suggests that normal LH levels are not uncommon in obese women with the disorder. Similarly, the LH to FSH ratio probably has little additive value in determining the diagnosis. The measurement of free testosterone does not contribute significantly to the identification of women with PCOS. Rather, its principle utility may be applied to determining the efficacy of treatment for hirsutism.

The observation that women with PCOS are insulin resistant and have compensatory hyperinsulinemia raises the question of whether assessment of glucose metabolism and insulin secretion should be evaluated in these patients. Unfortunately, at the present time, the ability to determine insulin resistance is limited by tests, which lack sensitivity or are impractical for implementation. Based on fasting levels of glucose and insulin, a variety of indices have been designed to establish insulin resistance.[60,290,291] While a reasonable correlation exists between each model and provocative glucose tolerance tests, normal values do not preclude the presence of insulin resistance. However, the fasting level of glucose may be used to distinguish glucose intolerance or diabetes and an elevated fasting insulin level will confer insulin resistance. An oral glucose tolerance test also provides valuable information, particularly if glucose measurements are accompanied by circulating insulin values. However, a reliable and reproducible assay for insulin is mandatory. Whether determination of insulin resistance is essential to the diagnosis of PCOS seems unlikely. Nevertheless, with the availability of insulin lowering drugs, ascertainment of insulin resistance is warranted, particularly in high-risk individuals.

Imaging Studies

In women with PCOS, ultrasound imaging of the ovaries usually reveals bilateral or unilateral enlargement and 12 or more antral follicles per ovary.[48] As this appearance is unique to the syndrome, ultrasound evidence of polycystic ovaries virtually confirms the diagnosis in women with anovulation and hyperandrogenism. However, that the vast majority of PCOS may be determined solely from clinical symptomatology and polycystic ovaries may be demonstrated in normal women makes the routine use of pelvic ultrasound for the diagnosis optional. Considerable information regarding the endometrial response to chronic estrogen exposure may be achieved with ultrasound.

Treatment

Oral Contraceptives

Notwithstanding infertility, the most problematic issue for women with PCOS is excessive hair growth. Thus, one of the primary goals of treatment includes ameliorating the clinical effects of hyperandrogenism, which may be achieved by suppression of ovarian steroidogenesis, interruption of androgen action at the target tissue, and reduction of hyperinsulinemia. Administration of an oral contraceptive containing combination estrogen-progestin has proven to be an effective treatment for hirsutism, although the range of response is variable depending on the severity of hair growth at the time of treatment. In addition to suppression of ovarian androgen production, oral contraceptives increase SHBG as well as facilitate the metabolical clearance rate of testosterone. This modality of treatment also has the advantage of instituting regular cyclic withdrawal bleeding and providing sufficient progestin to prevent excessive endometrial proliferation and hyperplasia.

Anti-Androgens

In many instances, anti-androgenic agents have been in conjunction with oral contraceptives to maximize clinical benefit. Spironolactone is an aldosterone antagonist which, along with its major metabolite, canrenone, competes for testosterone binding sites, thereby exerting a direct anti-androgenic effect at the pilosebaceous unit. In addition,

spironolactone appears to interfere with cytochrome P450, thereby inhibiting steroid enzyme action and resultant androgen production.[292] In the past, it was used to treat mild hypertension and may exert a mild diuretic effect. Because this medication opposes the action of aldosterone, serum potassium levels may increase and therefore should be monitored. Other anti-androgens include flutamide and finasteride. Flutamide competes for the androgen receptor whereas finasteride inhibits 5α-reductase. Both agents have been shown to be effective for the treatment of hirsutism.[293] In a few cases, flutamide has been associated with liver toxicity particularly in women that are obese.[294,295] Clinical studies have determined that these compounds exhibit comparable effectiveness in reducing hair growth.

Insulin Lowering Drugs

Insulin lowering drugs have been shown to improve insulin sensitivity in PCOS women with insulin resistance, which warrants their consideration in the management of this disorder. Most studies have detected a significant decrease in serum testosterone levels whereas others, which have included patients with severe obesity, were unable to demonstrate a similar effect.[64-67,125,254] Metformin, a biguanide, increases insulin sensitivity in the liver to reduce gluconeogenesis and hyperinsulinemia. Clinical studies have shown that administration of metformin to PCOS women resulted in decreased androgen levels, increased rates of spontaneous ovulation, and enhanced ovulatory responses to clomiphene.[65,67] Studies have shown that metformin may have direct effects on ovarian steroidogenesis independent of insulin action. Incubation of human ovarian theca-like tumor cells with metformin inhibited the mRNA expression of steroidogenic regulatory protein and 17α-hydroxylase, whereas no effect was detected for 3β-hydroxysteroid dehydrogenase (3βHSD) or cholesterol side chain cleavage.[296] In contrast, metformin was not associated with changes in 17α-hydroxylase or 3βHSD in studies of yeast cells.[158] The disparity between results may reflect differences in the cell systems employed. However, evidence for metformin ameliorating excessive hair growth is lacking. Side effects of metformin include gastrointestinal symptoms which are dose-related and tend to resolve after several weeks. A rare adverse effect of metformin therapy is lactic acidosis which may occur in individuals with systemic and debilitating diseases. Therefore, metformin should not be prescribed to patients with renal, hepatic, or major cardiovascular disease or hypoxia because these patients have a predisposition to elevated lactate levels. Precautionary temporal withdrawal of metformin is advised in patients undergoing radiological procedures involving intravascular iodinated contrast materials and surgery.

Thiazolidinediones comprise another group of insulin lowering drugs that include rosiglitazone and pioglitazone. These drugs act by binding to perioxisome proliferation activator receptor gamma which forms a heterodimer with retinoic acid receptor and binds to a promoter to increase the expression of genes that regulate glucose homeostasis. It has been well-documented that thiazolidinediones decrease androgen levels in women with PCOS.[125,127] In addition, in a large multi-center clinical trial, it was shown that improved insulin sensitivity was associated with resumption of ovulation following long-term treatment with troglitazone.[64] This effect was dose-dependent as determined by the rate of ovulation and the length of time required to achieve ovulation. Similar to metformin, thiazolidinediones have also been shown to have direct effect on steroidogenesis. In studies using yeast, the steroidogenic enzymes, 17α-hydroxylase and 3βHSD, were inhibited by troglitazone and to a lesser extent rosiglitazone and pioglitazone.[158] Similar results have been achieved in human granulosa cells. However, studies to determine whether troglitazone influences aromatase enzyme have not produced consistent results in human granulosa cells.[157,159] Liver toxicity was associated with first generation drugs of this class of compounds. However, both rosiglitazone and pioglitazone have been virtually devoid of liver effects. Nevertheless, thiazolidinediones should not be initiated in patients with evidence of liver disease. There have been some reports of increased cardiovascular risk with rosiglitazone whereas others have been unable to substantiate similar findings. Currently, it remains on the market in the United States and Europe.

Surgical Approach to Anovulation

In the formal description of PCOS in 1935, it was reported that several women undergoing wedge resection experienced a resumption of ovulation.[4] This was attributed to the removal of hyperplastic central stroma. As a result, for many years this technique was employed to treat anovulatory infertility in these women until the discovery and development of medical agents that stimulated the ovary and induced ovulation (clomiphene citrate, gonadotropins). Accordingly, enthusiasm for wedge resection waned and it was used sparingly. In 1984 it was reported that in women with PCOS, electrocautery of the ovarian capsule during laparoscopy resulted in a high rate of ovulation and pregnancy.[297] This led to multiple papers examining the utility of this method that showed ovulation rates of 70% to 90% and pregnancy rates of 50% to 70%.[298] The duration of spontaneous ovulation following LOD is variable, although some reports suggest an ovulatory pattern may persist for several years.[299]

Penetration of the ovarian capsule by diathermy or laparoscopic ovarian drilling (LOD) may be achieved using either cautery or laser, although the former appears to result in fewer post-operative pelvic adhesions. The technique involves puncture of the capsule with a unipolar coagulating current at about three to six different areas to a depth of 4 to 10 mm. The tendency is to perform this technique on both ovaries although one report showed that unilateral and bilateral ovarian drilling exhibited similar rates of ovulation.[300] The mechanism by which LOD induces ovulation is unknown. During the procedure there is a decrease of androgens and steroid hormones that have led to several theories including disruption of estrogen negative feedback on gonadotropin secretion, decrease of intraovarian androgens that inhibit follicle development, or activation of intraovarian growth factors that stimulate follicle growth. However, evidence for these considerations has not been convincing.

The application of LOD appears to be best suited for anovulatory women that are resistant or fail to respond to clomiphene citrate treatment. In contrast, recently it was

shown that clomiphene-resistant women exhibited slightly higher rates of ovulation with letrozole therapy compared to LOD.[301] These findings indicate that initial attempts at ovulation induction in untreated anovulatory PCOS women should employ medical treatment rather than surgery. Not all clomiphene-resistant women will respond to LOD as an estimated one-third will exhibit persistent anovulation. In these patients, past LOD may sensitize the ovary such that responsiveness to subsequent clomiphene citrate CC therapy may restore ovulatory function.[302]

Ovulation Induction

See Chapter 30 for a discussion of ovulation induction.

CHAPTER 23

Female Infertility

Robert L. Barbieri

Fertility is defined as the capacity to conceive and produce offspring. *Infertility* is the state of a diminished capacity to conceive and bear offspring. In contrast to sterility, infertility is not an irreversible state. The current clinical definition of infertility is the inability to conceive after 12 months of frequent coitus. Infertility prevalence among women aged 15 to 44 years was 8.5% in 1982 and 7.4% in 2002. More recent population-based studies from 2009 and 2012 reported a higher prevalence of infertility with estimates ranging from 12% to 24%.[1-3] Infertility prevalence is greater in older women, a factor which may contribute to the rising rate of infertility.[4] Since the fertility potential of the female partner decreases after 35 years of age, most authorities recommend initiating an infertility evaluation after 6 months of attempting conception in women 35 to 40 years of age and immediately in women over 40 years of age.[5,6] Women with known causes of infertility, such as amenorrhea, should immediately start an evaluation to assess the cause of the endocrine disorder.

A Statistical Model of Infertility

The clinical definition of infertility is relatively crude because it does not reflect the wide range of fertility potential in couples that have not conceived after 12 months. The clinical definition of infertility implies the existence of a dichotomous state, either a pregnancy is achieved in 12 months (infertility is not present) or a pregnancy is not achieved in 12 months and, by definition, infertility is present. The current clinical definition of infertility is similar to analyzing a continuous variable, such as height, by using a dichotomous variable: "short" and "tall." Height is clearly much better described by a continuous measure, such as centimeters, rather than by using a dichotomous variable like "short" and "tall."

Our clinical approach to fertility and infertility would be best advanced by the use of the statistical concept of fecundability. *Fecundability* is the probability of achieving a pregnancy in one menstrual cycle (approximately 0.25 in healthy young couples). A related concept, *fecundity*, is the ability to achieve a pregnancy that results in a live birth in one menstrual cycle. Fecundability, a population estimate of the probability of achieving pregnancy in one menstrual cycle, is a valuable clinical and scientific concept because it creates a framework for the quantitative analysis of fertility potential. Based on the clinical characteristics of a population of infertile couples, the estimated fecundability may range from 0.00 in couples with an azoospermic male partner to approximately 0.04 in couples where the female partner has early stage endometriosis.

In addition, fecundability provides a convenient quantitative estimate of the efficacy of various fertility treatments. An infertile couple with an estimated fecundability of 0.04 if left untreated, may have the choice of two approaches to the treatment of their fertility: a low-cost treatment (clomiphene plus intrauterine insemination) that will increase fecundability to 0.08, or an expensive treatment (*in vitro* fertilization) that will increase fecundability to 0.25. A clear quantitative presentation of the potential effect of each treatment on fecundability should assist the couple in choosing an optimal treatment plan. A practical problem with using fecundability as a central concept in infertility care is that the prediction models for estimating the fecundability of a couple are not well developed or validated. Factors that are important in estimating fecundability of a couple are age of the female partner, number of motile sperm, duration of subfertility, and presence of primary or secondary infertility.[7] Clinical care for infertile couples would be significantly advanced if discussions of infertility used the concept of fecundability. The "per cycle pregnancy rate" is the fecundability multiplied by 100. In this chapter, the terms "fecundability" and "per cycle pregnancy rate" are both used to mean the proportion of couples achieving pregnancy in one cycle. The concept of fecundability can be used to derive a simple statistical description of the fertility process.

Fecundability (f) is defined as the probability of conceiving during any one cycle. The probability of failing to conceive during any one cycle is 1–f. Over a short period of time, the fecundability of a population is often stable.[8] For a large group of couples, the probability of conception is f for the first month, $f \times (1–f)$ for the second month, $f \times (1–f)^2$ for the third month, and $f \times (1–f)^{N–1}$ for the Nth month. Using this model, the mean number of months required to achieve conception is 1/f. The cumulative probability of conception, F, through month N is calculated as follows: $F = 1–(1–f)^N$. Based on this simple statistical model, assuming a normal menstrual cycle fecundability of 0.25 and starting with 100 couples, approximately 98 couples should conceive within 13 cycles. If each cycle is 28 days, then 98% of couples should conceive within one calendar year (13 cycles × 28 days/cycle = 364 days).

Over short periods of follow-up, a population of couples attempting pregnancy behaves in a statistically stable manner, with a fixed proportion of the cohort becoming pregnant with each additional cycle of follow-up. As the follow-up

Table 23.1 Observational Studies Often Demonstrate That the Fecundability of the Cohort Decreases as Follow-up Progresses

Cycle	Number of Women Available for Study at Start of Cycle	Number of Pregnancies in Cycle	Per-Cycle Pregnancy Rate
1	200	59	0.30
2	137	41	0.30
3	95	16	0.17
4	78	12	0.15
5	66	14	0.21
6	52	4	0.08
7	48	5	0.10
8	43	3	0.07
9	40	2	0.05
10	38	1	0.03
11	37	2	0.05
12	35	1	0.03

Table 23.2 Pregnancy Occurrence and Outcome During Three Consecutive Menstrual Cycles in 200 Healthy Couples Desiring Pregnancy

	Cycle Numbers			
Cycle Outcome	1	2	3	Total
Not pregnant at start of cycle	200	137	95	
Pregnant during cycle	59	41	16	116
Chemical pregnancy	7	7	1	15
Spontaneous abortion	12	5	4	21
Live births	40	29	10	79
Dropped out, not pregnant	4	1	1	6
Lost to follow-up			1	

Age of female partner, 30.6 ± 3.3 (mean ± standard deviation [SD]).
From Zinaman MJ, Clegg ED, Brown CC, et al. Estimates of human fertility and pregnancy loss. *Fertil Steril* 65:503–509, 1996.

is extended, however, the fecundability of the nonpregnant couples declines and the cumulative pregnancy rate approaches an asymptote, which is less than 100%. This pattern is likely due to heterogeneity in the fecundability of the initial population. The couples with the highest per cycle pregnancy rate are rapidly culled from the population (they became pregnant), leaving the couples with the more severe infertility problem in the residual pool.

Conceptually, this issue can be managed by assuming that there is an asymptote to the cumulative pregnancy rate of the population, or by using complex mathematical modeling of the population fecundability based on the assumption that couples in the population have a range of per cycle pregnancy rates. This issue is of special importance in the analysis of fertility rates in populations over long periods of time, such as 2 years. This issue is of less practical importance in studies where the time period for analysis is three cycles or less.

Many studies report that the observed fecundability of a population diminishes with long-term follow-up. For example, Guttmacher[9] assessed the number of months to conception in 5574 women who achieved pregnancy between 1946 and 1956. During the first 3 months of observation, the fecundability was 0.25. During the next 9 months of observation, the fecundability was 0.15. Zinaman and colleagues[10] studied 200 healthy couples who desired to conceive. During the first 3 months of observation, the fecundability was 0.25. During the next 9 months of observation, the fecundability was 0.11 (Table 23.1). Other investigators have reported similar results.[11]

The drop in fecundability suggests that each large population consists of a heterogeneous mixture of couples. Some couples have completely normal fertility and achieve pregnancy at a high rate (>0.25 per cycle). The remaining couples have a lower fecundability (ranging from 0.00 to 0.15). Some of the couples in this pool will eventually present to a clinician for the treatment of infertility. At the end of 12 months of attempting conception, the couples that have not achieved conception have a fecundability in the range of 0.00 to 0.04 if left untreated (Table 23.1). Successful interventions to improve fertility must increase the per-cycle pregnancy rate over this background pregnancy rate.

Unfortunately, not all pregnancies produce a live birth. Many pregnancies are lost soon after implantation. The terms occult pregnancy and chemical pregnancy are often used to describe these early pregnancy losses. *Occult pregnancy* was defined by Bloch[12] as a pregnancy that terminates so soon after implantation that there was no clinical suspicion of its existence. In one recent study, approximately 13% of pregnancies were occult. Unlike occult pregnancies, a *chemical pregnancy* typically occurs in the presence of a clinical suspicion that a pregnancy may exist. A blood or urine human chorionic gonadotropin (hCG) assay demonstrates the presence of a pregnancy, but no clinical evidence of the pregnancy is detectable by ultrasound. Of all clinical pregnancies, approximately 20% result in a spontaneous abortion. Of all pregnancies, approximately 30% are lost—either as occult, chemical, or clinical spontaneous abortions (Table 23.2).[10] Women older than 40 years of age who become pregnant have a spontaneous abortion rate more than double that observed in women younger than 30 years of age.[13]

Diseases Associated with Infertility

Pregnancy is the result of the successful completion of a complex series of physiological events occurring in both the male and female that allows for the implantation of an embryo in the endometrium (Fig. 23.1). At a minimum, pregnancy requires ovulation and the production of a competent oocyte, production of competent sperm, proximity of the sperm and oocyte in the reproductive tract, transport of the embryo into the uterine cavity, and implantation of the embryo into the endometrium. Many disease processes can result in subfertility.

Some diseases, such as those that cause azoospermia, clearly have a *cause-effect relationship* with infertility. For other disease processes, such as stage I endometriosis as defined by the revised American Society for Reproductive Medicine criteria, there is no clear cause-effect relationship between the disease and the infertile state. In these

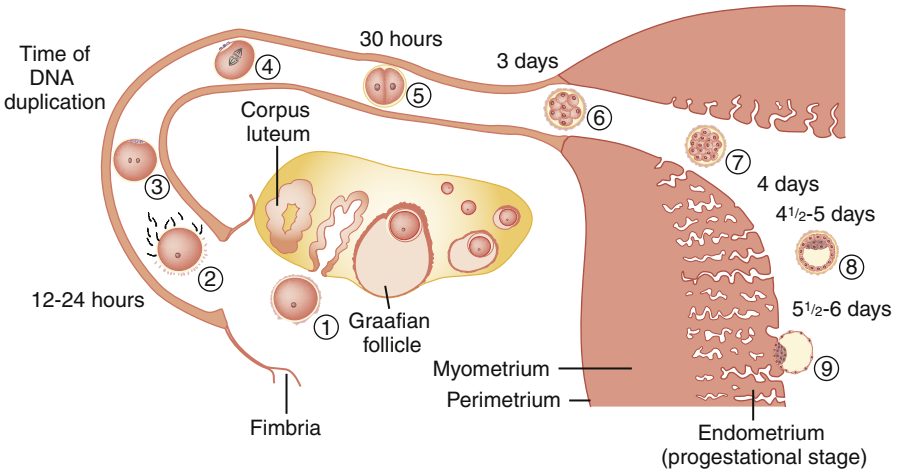

FIGURE 23.1 Schematic representation of the transport of the oocyte, sperm, and embryo in the female reproductive tract.

situations it is preferable to state that there is an *association* between the disease condition and the infertile state, but that causality has not been definitively established. Due to the limits of our current understanding of fertility in humans, it is often difficult to categorize disease conditions as either causal factors (azoospermia) or associated factors (stage I endometriosis) with infertility. Consequently, a discussion of the distribution of reproductive diseases that are diagnosed in infertile couples is not necessarily based on hard scientific data, but rather descriptive observations and assumptions about diseases that might *cause* or might be *associated* with infertility.

Most tabulations of the medical conditions that "cause" infertility divide the problem into male factors and female factors. The World Health Organization (WHO) task force on Diagnosis and Treatment of Infertility conducted a study of 8500 infertile couples using a standardized diagnostic protocol.[14] In developed countries, diseases that were identified as contributing to the infertile state were attributed to the female partner in 37% of couples, to the male partner in 8% of couples, and to both partners in 35% of couples. Five percent of the couples had no identifiable cause of infertility (unexplained infertility) and 15% of the couples became pregnant during the investigation. The diseases in the female most often identified were: ovulatory disorders (25%), pelvic adhesions (12%), tubal occlusion (11%), other tubal abnormalities (11%), hyperprolactinemia (7%), endometriosis (15%), and no identifiable disease in 20%.

In a review of 21 published reports containing 14,141 infertile couples, Collins[15] reported that the primary diagnoses in the couples were: ovulatory disorders (27%), abnormal semen parameter (25%), tubal defect (22%), endometriosis (5%), unexplained (17%), and other (4%), as shown in Figure 23.2. In another data set of 2198 infertile couples the distribution of primary diagnoses was: ovulatory disorders (18%), abnormal semen parameter (24%), tubal disease (23%), endometriosis (6.6%), unexplained (26%), and other (3%).[16] These observations can be broadly grouped into five major conditions that influence fecundability:

1. Abnormalities in the production of a competent oocyte (ovulatory factor, depletion of the oocyte pool, or poor oocyte function/quality)

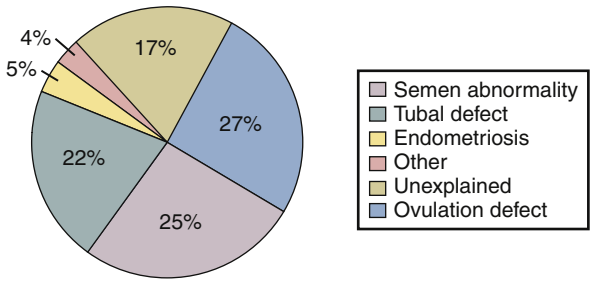

FIGURE 23.2 Primary clinical diagnoses in infertile couples. *(From Collins JA. Unexplained infertility. In Keye WE, Chang RJ, Rebar RW, Soules MR [eds].* Infertility: Evaluation and Treatment. *Philadelphia: WB Saunders, 1995, p 250, with permission.)*

2. Abnormalities in reproductive tract transport of the sperm, oocyte, and embryo (tubal, uterine, cervical, and peritoneal factors)
3. Abnormalities in the implantation process, including early defects in embryo development and embryo–endometrial interaction (embryo–endometrial factors)
4. Abnormalities of sperm production (male factor)
5. Other conditions, including immunological factors that can affect multiple components of the process

The initial infertility evaluation focuses on these five major processes (Box 23.1).

The Initial Infertility Evaluation

The standard components of the infertility evaluation include: a thorough history and physical examination (Table 23.3), a semen analysis (Box 23.1), documentation of competent ovulation, documentation of female reproductive tract and tubal patency, and assessment of the uterine cavity. The evaluation of the semen analysis is discussed in Chapter 24. As discussed in more detail below, ovulation may be presumptively documented based on a history of regular menses every 28 days or observation of a luteinizing hormone (LH) surge in the urine using an immunochemical method, and definitively diagnosed by a serum progesterone greater than 3 ng/mL or the histological demonstration of secretory changes on an endometrial biopsy. For women ≥35 years of age, a test of the size of

the ovarian follicle pool, also known as ovarian reserve, is warranted. Tests to assess the ovarian follicle pool include a menstrual cycle day 3 follicle stimulating hormone (FSH), antral follicle count, or antimüllerian hormone (AMH) measurement.[17]

Documentation of tubal patency should be accomplished early in the infertility evaluation by a hysterosalpingogram (HSG), a hysterosalpingo-contrast sonogram (HyCoSy), or a laparoscopy. Detection of uterine abnormalities can be accomplished by an HSG, HyCoSy, or hysteroscopy. An HSG is an excellent test of distal tubal patency with few false-positives, but it is associated with an approximately 15% false-positive rate for proximal tubal occlusion.[18] This means that if the HSG demonstrates that there is proximal tubal blockage, the finding should be confirmed by a second test (selective catheterization of each tube or laparoscopy). The HSG also provides evidence of the shape of the uterine cavity and will identify large intrauterine defects. As noted below (anatomical factors in the female), the hysterosalpingo-contrast sonogram is gaining in popularity as an initial test in the fertility work-up because it can detect tubal occlusion and is very sensitive for identifying small defects in the uterine cavity.[19] For the detection of uterine abnormalities, hysteroscopy remains the gold standard.[20]

Infertility tests that are probably not needed as part of the initial infertility evaluation include: the postcoital test, endometrial biopsy for luteal phase dysfunction, the hamster egg penetration test, routine *Mycoplasma* culture, and anti–sperm antibody testing. A major problem with the postcoital test is that it has low reproducibility, low interobserver reliability, and has not been reliably shown to help guide treatment recommendations.[21-23] In addition, there is little consensus on what constitutes an abnormal postcoital test. Given these limitations, there is little scientific rationale for performing a postcoital test. However, clinical experience suggests that clomiphene, acting as an anti-estrogen in the cervix, can cause abnormal cervical mucus production, both in quantity and quality. Some clinicians recommend performing a postcoital test to assess the impact of clomiphene on cervical mucus production in women receiving this drug for ovulation induction.

The endometrial biopsy is abnormal in many infertile women and in the past some clinicians believed that it was the gold standard for documenting ovulation and assessing endometrial preparedness for implantation. However, prospective studies demonstrate that the rates of abnormal (out-of-phase) endometrial histology are similar in fertile and infertile women.[24] Given the weak correlation between abnormal (out-of-phase) biopsies and fertility, most clinicians are not performing endometrial biopsy as a first line fertility diagnostic test.

Box 23.1 Initial Laboratory Approach to the Infertile Couple

PRIMARY TESTS FOR INFERTILITY

- Documentation of competent ovulation
  - Midluteal progesterone >3 ng/mL
  - Day 3 FSH or clomiphene challenge test (if female partner >35 years old)
- Semen analysis*
  - Volume ≥1.5 mL
  - Concentration ≥15 million/mL
  - Motility ≥32%
  - Morphology ≥4% (using "strict" criteria)
  - Terminology used to describe abnormal semen analysis: Low sperm concentration, oligospermia; low sperm motility, asthenospermia; sperm morphology abnormal, teratospermia; elevated white blood cells, leukocytospermia
- Documentation of tubal patency
  - Hysterosalpingogram or hysterosalpingo-contrast sonography
  - Assessment of the uterine cavity
  - Hysterosalpingogram, hysterosalpingo-contrast sonography, or hysteroscopy

SECONDARY TESTS FOR INFERTILITY

- Laparoscopy
- Hysteroscopy

*From Cooper TG, Noon E, von Eckardstein S, Auger J, et al. World Health Organization reference values for human semen characteristics. *Hum Reprod Update* 2010; 16: 231–245.

Table 23.3 History and Physical Examination Findings Relevant to the Infertility Evaluation in the Female Partner

History	Physical Exam Findings
Duration of infertility and results of previous tests and treatments.	Weight, height, body mass index.
Prior pregnancies and outcomes.	Evidence for hirsutism, acanthosis nigricans.
Pubertal Milestones: Adrenarche, Thelarche, and Menarche.	Thyroid size. Presence of thyroid nodules.
Menstrual cycle history from Menarche to present. Evidence for cycle irregularity.	Breast exam including palpation for breast masses and expression of nipple secretion.
Previous gynecological and abdominal surgery.	Tanner stage of the breasts.
Past contraceptive use.	Assessment of the anatomy of the clitoris, hymenal ring, vagina, and cervix. Assess for a vaginal septum. Assess for cervical stenosis or displacement of cervix from midline.
Coital frequency and sexual function.	Examination of position of the uterus and uterine size and mobility.
Relevant medical history of male partner.	Examination of adnexae for a mass or tenderness.
Current medications and allergies.	Examination of the uterosacral ligaments and cul de sac.
History of hirsutism, pelvic or abdominal pain, dyspareunia, thyroid disease, galactorrhea.	
Current occupation and exposure to environmental toxins.	
Use of tobacco, alcohol, and drugs.	
Exercise history and current pattern of exercise.	
History of stress, anxiety, depression.	

Abnormalities in Oocyte Production

Disorders of oocyte production are the most common cause of female infertility. The most common disorders of oocyte production are: anovulation, oligo-ovulation, depletion of the follicle pool, and aging of the ovarian follicle resulting in poor oocyte quality. Anovulation is typically associated with amenorrhea or severe oligomenorrhea. Oligo-ovulation is typically associated with oligomenorrhea (cycle lengths greater than 35 days). A depleted ovarian follicle pool is usually detected by a menstrual cycle day 3 FSH, antral follicle count or antimüllerian hormone measurement. Oocyte quality is difficult to assess. Poor oocyte quality should be suspected when the age of the female partner is older than 40 years of age, even if tests of the ovarian follicle pool indicate good ovarian reserve.[25]

Women who have monthly menses and report moliminal symptoms—such as breast tenderness and dysmenorrhea—are typically ovulatory.[26] The least expensive laboratory method for detecting ovulation is the measurement of the basal body temperature. For most women, the morning basal temperature obtained prior to rising from bed is less than 98°F before ovulation and over 98°F after ovulation. Progesterone production from the ovary appears to raise the hypothalamic set-point for basal temperature by approximately 0.6°F. The normal luteal phase is typically associated with a temperature rise, above 98°F, for at least 10 days in length. Occasionally basal body temperature recordings may appear monophasic even in the presence of ovulation. A biphasic pattern is almost always associated with ovulation. If the pattern is biphasic, coitus can be recommended every other day for a period including the 5 days prior to and the day of ovulation (Fig. 23.3).[27] In most developed countries the basal body temperature method is seldom used to detect or document ovulation in infertile women, with the sequential measurement of urine LH at the appropriate time in the menstrual cycle being the most common approach to detecting impending ovulation.

A serum progesterone level greater than 3 ng/mL is diagnostic of ovulation. In the midluteal and late-luteal phase, progesterone secretion is pulsatile due to the pulsatile nature of luteinizing (LH) secretion.[28] At a conceptual level, the pulsatile nature of progesterone secretion may make it difficult to reliably use a single progesterone measurement as a marker for the adequacy of ovulation. However, in most clinical situations, a single midluteal progesterone measurement appears to be a useful marker of the adequacy of ovulation. Hull and colleagues have suggested that a midluteal progesterone concentration less than 10 ng/mL is associated with a lower per-cycle pregnancy rate than progesterone levels above 10 ng/mL.[29]

An endometrial biopsy with histological secretory changes is a definitive test demonstrating ovulation. Although not currently in clinical use, it is likely that the endometrial biopsy could be used to detect endometrial proteins that can serve as useful markers of endometrial receptivity for implantation. Validation of the detection of implantation markers in endometrial biopsy specimens awaits future research.[30] An important point to emphasize is that in women without ovarian function, the administration of two hormones, estradiol and progesterone, are sufficient to prepare the endometrium for implantation.[31]

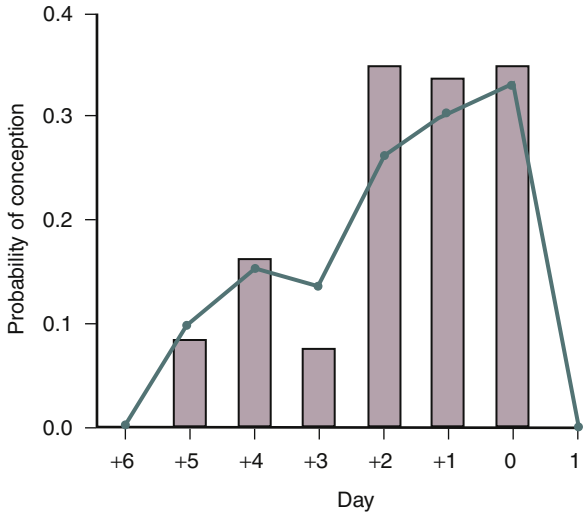

FIGURE 23.3 Probability of conception on specific days near the day of ovulation. The bars represent data reported by 129 women who had sexual intercourse on only 1 day in the 6-day interval ending on the day of ovulation (day 0). The solid line shows the probability of conception based on a statistical analysis of data from 625 cycles. *(From Wilcox AJ, Weinberg CR, Baird DD. Timing of sexual intercourse in relation to ovulation.* N Engl J Med *333:1517–1521, 1995, with permission.)*

Some authorities have suggested that a follicle may luteinize and differentiate into a corpus luteum (secreting progesterone and inducing a secretory endometrium) without rupturing and allowing the oocyte to escape the follicle.[32] The "luteinized unruptured follicle syndrome" may occur occasionally, but it is unlikely to be a major cause of infertility.[33,34] Sonographic examination of the ovary and serial measurement of LH or estrone-3-glucuronide can be used to demonstrate the growth of a dominant follicle, which is a necessary precondition to ovulation.[35] During menses, the follicles in the ovary are approximately 4 to 9 mm in diameter. Prior to ovulation, the dominant follicle reaches a diameter in the range of 20 to 25 mm. Demonstration of follicle growth and rupture of the dominant follicle is presumptive evidence that ovulation has occurred. The demonstration of an LH surge is also presumptive evidence of ovulatory cycles. Ovulation typically occurs about 36 hours after the onset of the LH surge and approximately 24 hours after the LH peak. In one large prospective study, the detection of a urine LH surge by patients using a home detection kit was associated with ovulation as demonstrated by a secretory endometrial biopsy in 93% of cycles.[36] In some infertile women, premature LH surges may occur that are not followed within 36 hours by ovulation. These premature LH surges may make it more difficult to precisely identify ovulation and the fertile part of the menstrual cycle.[37]

Many diseases can cause anovulation and infertility. The most common disorders are hypogonadotropic hypogonadism (WHO I), euestrogenic ovulatory dysfunction (WHO II), and hypergonadotropic hypogonadism (WHO III). The most common causes of adult-onset anovulation are hypothalamic dysfunction (35% of cases), pituitary disease (15%), and ovarian dysfunction (50%).[38,39] The most common causes of hypothalamic dysfunction are abnormalities in

weight and body composition, stress, and strenuous exercise (see Chapter 19). Less common causes of hypothalamic dysfunction are infiltrating diseases of the hypothalamus, such as lymphoma and histiocytosis. The pituitary disorders that cause anovulation (see Chapters 3 and 21) are prolactinoma, empty sella syndrome, Sheehan syndrome, Cushing disease, acromegaly, and other pituitary tumors. The most common ovarian causes of anovulation are ovarian failure (depletion of the oocyte pool) and ovarian hyperandrogenism (e.g., polycystic ovary syndrome [PCOS]). Occasionally thyroid disease can be associated with anovulation.

Evaluation of the various causes of anovulation can be complex. Typically, measurement of body weight and height, and measurement of serum follicle-stimulating hormone (FSH), prolactin, thyroid-stimulating hormone (TSH), and androgens, if indicated, can help identify the cause of the anovulation. A progestin withdrawal test may be helpful to evaluate the degree of hypogonadism present and may help guide treatment choices.

Patients with anovulation have the greatest success with infertility therapy. Treatment of anovulatory disorders can result in fecundability similar to that observed in normal couples (0.15-0.25). The choice of treatment is dependent on the cause of the anovulation. Common treatment choices include:

1. Interventions to modulate weight
2. Reduction in intensity of aerobic exercise
3. Clomiphene citrate
4. Clomiphene plus other hormone adjuvants
5. Gonadotropin treatment
6. Pulsatile gonadotropin-releasing hormone (GnRH)
7. Bromocriptine
8. Glucocorticoids

Weight Abnormalities Associated with Anovulation

Anovulation, oligo-ovulation, and subfertility are commonly observed in women above or below their ideal body weight (see also Chapter 19).[40] In one study of 597 cases of women with anovulatory infertility and 1695 fertile controls, overweight women (body mass index [BMI] greater than 27 kg/m^2) had a relative risk of anovulatory infertility of 3.1 compared with women of BMI 20 to 25 kg/m^2. Excessively thin women with a BMI less than 17 kg/m^2 had a relative risk of anovulatory infertility of 1.6. The investigators concluded that the risk of ovulatory infertility is highest in overweight women, but is also increased in underweight women.[41]

Anovulatory women far below their ideal body weight often have hypogonadotropic hypogonadism. Anovulatory women far above their ideal body weight often have PCOS. For women who are far below (hypogonadotropic hypogonadism) or far above (PCOS) their ideal body weight, appropriate management of dietary intake may be associated with resumption of ovulation.[42] For example, Pasquali and colleagues[43] demonstrated that anovulation in obese women with PCOS could be successfully treated with weight loss. Obese women with anovulation and PCOS were placed on a 1000-calorie to 1500-calorie diet for 6 months. The mean weight loss was 10 kg. After weight loss there was a 45% decrease in basal LH concentration and a 35% decrease in serum testosterone. Many of the women resumed ovulation and became pregnant. Similar results were reported by Clark and colleagues.[44] Thirteen obese anovulatory infertile women were entered into a program of diet and exercise and lost on average 6.3 kg over 6 months. Fasting insulin and testosterone levels decreased, and sex hormone-binding globulin concentrations increased. Twelve of 13 subjects resumed ovulation and 5 became pregnant without any other intervention.

Most studies of the impact of weight loss on reproductive function did not include a control group. Guzick and colleagues reported the results of a randomized, controlled trial of the impact of weight loss on reproductive function.[45] Twelve obese, hyperandrogenic, oligoovulatory women were randomized to either a weight reduction program or a "waiting list" observation control group. The six women randomized to the weight reduction program had a mean decrease in weight of 16 kg, a significant decrease in circulating testosterone, a decrease in fasting insulin, and no change in LH pulse frequency and amplitude. In the women who were randomized to the weight reduction program, four of six resumed ovulation. All of the women in the control group who were anovulatory before the study, remained anovulatory during the period of study observation.

Weight loss is difficult to achieve. Consultation with a nutritionist, encouragement by a physician, a hypocaloric diet, and initiation of an exercise program may be the most effective non-surgical interventions that can help a woman lose weight. Surgical methods of weight reduction can be very effective, especially in women with a BMI over 40 kg/m^2.[46]

Excessively lean women are at increased risk for anovulatory infertility. In experimental models, oligo-ovulation ensues following interventions that result in daily energy expenditure greater than daily calorie intake. In the captive female monkey, regular ovulatory cycles are observed with routine activity and a steady calorie intake at 300 kcal daily. When calorie intake is maintained at 300 kcal daily, but activity is increased to include 6 miles of additional ambulation daily, anovulation and amenorrhea ensue. Increasing calorie intake to up to 600 kcal daily while maintaining 6 miles of exercise daily results in resumption of ovulation and menses. In the exercising monkey, resumption of ovulation can also be initiated without an increase in calorie intake by administering pulses of GnRH.[47]

Women who exercise regularly have more anovulatory cycles than women who are sedentary.[48] In a study of sedentary women assigned to exercise plus calorie restriction or exercise plus a eucaloric diet, the exercise plus calorie restriction group produces greater declines in ovarian steroid production than exercise plus a eucaloric diet.[49] Hormones that help the brain assess the relative levels of calorie intake and energy expenditure include: leptin, insulin, thyroid hormones (thyroxine and triiodothyronine), growth hormone, insulin-like growth factor 1 (IGF1), cholecystokinin, glucagon-like pepetide-1, and ghrelin.

Women with hypothalamic amenorrhea (hypothalamic hypogonadism) often have low levels of leptin. Two clinical trials reported that the administration of exogenous leptin or a decapeptide leptin peptide (metreleptin) to lean women with hypothalamic amenorrhea, resulted in the resumption of ovulatory menses in some of the subjects.[50,51] In

addition, metreleptin administration for 36 weeks increased free triiodothyronine, IGF1, and osteocalcin.[51] Leptin may exert its effect on GnRH secretion by a direct action on kisspeptin releasing neurons.[52]

Lean women with anovulatory infertility are often reluctant to gain weight, alter their diet, or reduce their exercise regimen. However, in one study of 26 underweight women who practiced strict dieting and were infertile, the subjects were counselled by a dietician and given physician-directed advice to increase their BMI. After the intervention, the women gained a mean of 3.7 kg and 73% of the women became pregnant.[53] Interpersonal psychodynamic psychotherapy or cognitive behavior therapy may help WHO I anovulatory women resume ovulating.[54] It is important to try to achieve a normal BMI prior to initiating ovulation induction in excessively lean anovulatory women because pregnancy in women with a low BMI is associated with an increased risk of delivering infants with low birth weight, small head circumference, and microcephaly.[55]

Specific dietary factors may influence the risk of anovulatory infertility. For example, in one prospective study, women who consumed iron supplements were reported to have a 40% lower risk of anovulatory infertility.[56] In another prospective study, dietary patterns characterized by high consumption of monounsaturated rather than transfats, vegetable rather than animal protein, low glycemic carbohydrates, high fat dairy, and multivitamins was associated with a reduced risk of ovulatory infertility.[57] Myo-inositol, a new dietary supplement, is a precursor of D-chiro-inositol which is involved in the control of glucose metabolism and cell response to insulin stimulation. In one small observational study without a control group, oligo-ovulatory women with PCOS who took myo-inositol, 2 g twice daily, reported an increase in spontaneous menstrual cycles. Forty percent of the subjects became pregnant during 6 months of myo-inositol treatment.[58]

Clomiphene

Clomiphene, a non-steroidal triphenylethylene derivative estrogen agonist-antagonist related to tamoxifen and diethylstilbestrol, was first synthesized in 1956. In 1961, Greenblatt and colleagues[59] reported clomiphene to be effective in the induction of ovulation, and the drug was approved by the Food and Drug Administration (FDA) in 1967 (see also Chapter 30). Clomiphene citrate is marketed as a racemic mixture of enclomiphene (E, trans) and zuclomiphene (Z, cis) in a ratio of approximately 3 to 2. The Z-isomer may have greater ovulation-inducing properties than the trans isomer. An important recent observation is that nonsteroidal triphenylethylene compounds like tamoxifen and clomiphene may require bioactivation by the liver cytochrome P450 enzyme 2D6. In one study, liver microsomes containing active *CYP2D6*, metabolized clomiphene to two potent estrogen antagonist compounds, (E)-4-hydroxyclomiphene and (E)-4-hydroxy-N-desethylclomiphene.[60] These two compounds demonstrated 50% inhibition of estrogen receptor function at concentrations of 2.5 and 1.4 nM, respectively. The activity of *CYP2D6* shows significant variation among women, suggesting that allelic variation in this enzyme may contribute to the variability in the response to clomiphene.

Clomiphene has a half-life of approximately 5 days. It is metabolized by the liver and excreted in the feces. Fecal clomiphene can be detected up to 6 weeks after discontinuing the drug. In *normally cycling women*, the administration of clomiphene citrate, 150 mg daily for 3 days, resulted in an increase of serum concentration of LH and FSH of 40% and 50%, respectively.[61] In addition, LH pulse frequency increased from 3.3 to 6.8 pulses per 8 hours. The clomiphene-induced increase in LH pulse frequency indicates that clomiphene has an action at the hypothalamus. In women with PCOS who already have a high LH pulse frequency, clomiphene does not further increase LH pulse frequency, but it does increase LH pulse amplitude and serum levels of LH and FSH.[62] Successful induction of ovulation with clomiphene requires an intact hypothalamic-pituitary-ovarian axis. In contrast, exogenous gonadotropin treatment is effective even in the absence of a functional hypothalamus or pituitary.

Evidence that clomiphene has central nervous system effects includes the observation that clomiphene induces vasomotor symptoms,[63] increases LH pulse frequency,[61] and partially blocks the contraceptive potency of estrogen.[64] Studies in laboratory animals demonstrate that clomiphene can decrease estrogen stimulated hypothalamic tyrosine hydroxylase[65] and that clomiphene increases GnRH secretion from the rat medial basal hypothalamus.[66]

In addition to a hypothalamic site of action, clomiphene also has biological effects on the pituitary, ovary, endometrium, and cervix. In incubations of rat pituitary cells, both estradiol and clomiphene augmented GnRH-induced release of FSH and LH. Zhuang and colleagues[67] demonstrated that clomiphene, estradiol, and diethylstilbestrol all augmented gonadotropin induction of aromatase activity in rat granulosa cells. In hypoestrogenic women receiving exogenous estrogen, clomiphene can cause endometrial atrophy.[68] Clomiphene can diminish estrogen-induced cervical mucus quantity and quality, as demonstrated by decreased ferning and spinbarkeit formation.[69,70]
