Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the Authors, Contributors, or Editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Remembrance

Samuel S. C. Yen, MD, DSc
1927–2006

In 2006, endocrinology in general, and reproductive endocrinology in particular, lost a giant in clinical and translational reproductive endocrinologic research, Samuel S. C. Yen. He was insightful and a visionary and demanded excellence from his trainees, but no more so than from himself. He was arguably the leading clinical reproductive neuroendocrinologist of his time.

He and I coedited the first four editions of this textbook, which has since been translated from English into five languages—including a pirated version from China. The genesis of our textbook was crystallized during our time at the magnificent, idyllic Rockefeller Foundation retreat, the Villa Serbelloni, at the nexus of the three legs of Lake Como in Italy. It was there, surrounded by scholars from a panoply of disciplines and countries (Sam and I were the only physicians in the group), that we had the time and freedom to finalize the chapters. We mutually selected the authors, most of whom were outstanding investigators and clinicians in the areas about which they wrote (albeit not all as expeditiously as we had hoped).

Fortunately, our first editor, John Hanley, was a true scholar who shared our passion for quality and excellence. Our original publisher, W. B. Saunders, shared that same passion.

Sam continued his insistence on excellence for each edition, and he cajoled several of our authors until they did the same.

Sam's chapters on neuroendocrine regulation of the brain and of the hypothalamic-pituitary-ovarian axis are classic. His extensive and productive collaboration with his very close friend, the Nobel Laureate Roger Guillemin, who characterized many of the hypothalamic secretagogues that Sam used in his clinical studies, enabled him to base many of his comments in the textbook on his own laboratory's studies.

Sam was hard-driving, yet charming, as demanding of himself and our authors as he was of the myriad investigators with whom he worked and trained. His was a rich, full, productive, and creative life. He was a unique and colorful individual.

His like comes along very rarely.

Preface

A centerpiece of reproductive endocrinology is the utilization of assisted reproductive technologies, including *in vitro fertilization* (IVF), to build healthy families. In 1978, the first baby born from IVF, Louise Brown, was proof of the concept that successful human pregnancy was possible following *in vitro* fertilization. In the same year, the first edition of Yen and Jaffe was published and represented the birth of a field with a strong research foundation, whose findings had direct applicability to health. Three decades later, the 2010 Nobel Prize in Medicine or Physiology was awarded to Sir Robert G. Edwards, Ph.D. (b. 1925, d. 2013), for his seminal contributions to the field of reproductive endocrinology and infertility. The publication of the 7th edition of Yen and Jaffe is dedicated to Dr. Edwards and all the pioneers who have devoted their energies to advancing the field.

In the first years of the development of the field, a major focus was on the endocrine mechanisms that supported the optimal development of oocyte and sperm, their interaction and the implantation of an embryo in the developmentally prepared endometrium. Today, interest in germ cell development and germ cell biology has gained great prominence, raising the possibility of application of stem cell-based therapeutics to treat infertility and gene disorders. Fertility preservation through the cryopreservation of sperm and oocytes has emerged as a key element of care for the cancer patient and others who face concerns regarding retention of reproductive potential. The importance of these translational advances is recognized by the addition of new chapters to this edition.

The completion of the sequencing of the human genome and the reduction in cost in whole genome analysis have opened new opportunities for finding genes that affect different aspects of reproduction, such as genes that affect the age of menarche and the age of menopause; genes that predispose to endometriosis, uterine fibroids, and polycystic ovary syndrome; and genes that influence ovarian reserve and spermatogenesis. These important discoveries, which will shed light on pathophysiology and new avenues for diagnosis and treatment, are highlighted in the present edition.

Since the publication of the last edition of this text, we have achieved a better understanding of environmental factors influencing fertility, including obesity. These contemporary issues have been addressed in this edition. Epigenetic factors are thought to mediate the impact of environmental exposures on gametes and embryos and the developing fetus. They are also believed to be responsible for intergenerational effects. Although still in its infancy, the science of epigenetics holds promise for explaining reproductive phenotypes and reproductive outcomes.

We appreciate the collaboration of past and new authors for their critical evaluation of the state of their respective fields. Their contributions have enriched this text and we are grateful for their efforts. They have helped carry forward the tradition of excellence that Drs. Jaffe and Yen created when they brought forward the first edition of this text.

Acknowledgments

The Editors thank William Drone, Kel McGowan, Stefanie Jewell-Thomas, and Steven Stave of Elsevier; and Karen Olinger and Deborah Weir of Virginia Commonwealth University, for their assistance in the preparation of this volume.

CHAPTER 1

Neuroendocrinology of Reproduction

Christopher R. McCartney
John C. Marshall

The Central Control of Reproduction

Successful reproduction is essential to the survival of a species. The reproductive system represents a highly-complex functional organization of diverse tissues and signaling pathways that, when properly functioning, ensures a number of key endpoints, the most important of which are the adequate production of gametes (ova and sperm); successful delivery of gametes for fertilization; and, in women, physiological preparation for possible pregnancy. Neuroendocrine systems are the principal drivers of reproductive function in both men and women. In particular, hypothalamic gonadotropin-releasing hormone (GnRH) is the primary, if not exclusive, feedforward signal to gonadotrope cells of the anterior pituitary, stimulating the synthesis and secretion of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Together, these two gonadotropins direct the primary functions of the reproductive axis: gametogenesis and gonadal sex steroid synthesis.

Given its critical importance to a species, the reproductive system must be robust, continuing to function properly in the face of various internal and external influences. In contrast, in settings of marked physiological stress (e.g., significantly reduced energy availability), mechanisms that temporarily limit fertility—the usual outcome of which is metabolically expensive in women—are biologically advantageous for the individual and, ultimately, the species. Appropriate function (or quiescence) of the reproductive system is governed by a number of intricate relationships. For example, feedback signals from the gonads (e.g., sex steroid concentrations) communicate the status of gonadal function to the hypothalamic-pituitary axis; these signals in turn influence GnRH and gonadotropin output, rendering a coordinated and tightly regulated feedback system that maintains gonadal function within narrow limits. The reproductive system also has extensive interactions with other neuroendocrine systems, such as those involved with energy balance and adaptations to stress. The reproductive neuroendocrine network integrates these myriad feedback signals, and the GnRH-secreting neuronal network represents the final common pathway for the central control of reproduction. Thus, the regulation of GnRH secretion represents a major focus of reproductive neuroendocrinology.

Much of our understanding of reproductive neuroendocrinology has emerged from the study of rodents, sheep, and non-human primates, which largely reflects the ethical boundaries inherent to human research. Since many neurobiological principles are similar among all mammals, these animal studies have been (and continue to be) indispensable. Nonetheless, certain aspects of reproductive neuroendocrinology may differ markedly among species. Thus, when available, human data will be prioritized throughout this chapter, but animal studies will also be discussed when appropriate, recognizing that specific findings may or may not be generalizable to humans.

Neuroendocrinology: The Interface Between Neurobiology and Endocrinology

Endocrinology is the study of cell-to-cell signaling that occurs via specific chemicals (hormones) that travel through the bloodstream to influence remote targets. The term "neuroendocrinology" refers to the involvement of the central nervous system—the hypothalamus in particular—in this process. This field of study has traditionally focused on hypothalamic neuron-derived factors that influence various target tissues, either directly, as with the hormones of the neurohypophysis, or indirectly, as with hypothalamic releasing factors that control anterior pituitary hormone secretion. Neuroendocrine systems direct a wide variety of critical biological processes such as growth and development, energy and fluid homeostasis, responses to stress, and reproduction.

Neurons are highly specialized and morphologically diverse cells that transmit information via electrical impulses called action potentials. Neurons have a cell body containing the cell nucleus, mitochondria, and synthetic organelles. Neurons also have cell processes that participate in the reception and delivery of electrical impulses (Fig. 1.1). Dendrites are short processes—often extensively branched to increase surface area—that typically receive information (afferent electrical impulses). The axon is a single cell process that generally transmits efferent electrical impulses away from the cell body in a process called "neuronal firing."

In unstimulated neurons, the inner portion of the neuronal membrane is negatively charged compared to the outer membrane surface (e.g., this "resting membrane potential" is typically between -50 to -75 mV in GnRH neurons). Such electrical polarization reflects transmembrane ionic differences, which are maintained by protein channels that govern transmembrane passage of specific ions (e.g., sodium, potassium, chloride). Regulated changes of transmembrane ion differences may cause the membrane potential to become more or less negative (hyperpolarization and depolarization,

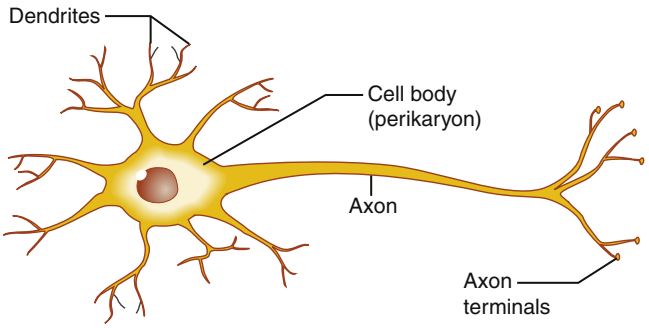

FIGURE 1.1 Morphological components of a neuron.

respectively). Depolarization to a certain threshold results in a rapid and temporary reversal of membrane potential (an action potential), which is propagated along the neuronal membrane. Notably, the amplitude of the action potential does not vary with the strength of stimulation; instead, once a threshold is reached, a full action potential occurs—the so-called "all-or-none" phenomenon. However, the degree of neuronal stimulation can alter the frequency of action potentials generated. In this way, neurons transmit information to other neurons and effector tissue cells.

Neuronal signals are transferred across neuron-to-neuron connections (synapses) via chemical neurotransmitters. This process begins with bursts of neuronal firing, which results in the opening of voltage-gated calcium channels at the axonal terminal. The influx of calcium promotes exocytosis of neurotransmitter-containing synaptic vesicles, releasing neurotransmitters into the synaptic cleft. Neurotransmitters then bind to specific ligand-dependent ion channels in the postsynaptic membrane, which can stimulate an action potential in the postsynaptic cell membrane. A wide variety of factors serve as neurotransmitters, including amino acids (e.g., acetylcholine, glutamate, γ-aminobutyric acid [GABA]), biogenic amines (e.g., norepinephrine, epinephrine, dopamine, serotonin), and neuropeptides (e.g., kisspeptin, neurokinin B, dynorphin, β-endorphin, somatostatin, proopiomelanocortin [POMC], neuropeptide Y [NPY]).

Bursts of neuronal firing can also elicit release of neuronal products into the bloodstream to influence remote targets (i.e., "neurosecretion" of "neurohormones"). Hypophysiotropic neurons are specialized hypothalamic neurons that secrete peptide releasing factors—GnRH, corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), and growth hormone-releasing hormone (GHRH)—into the hypophyseal portal circulation. These releasing factors in turn stimulate specific anterior pituitary cell populations. In contrast, hypothalamic release of dopamine into the portal circulation provides tonic inhibition of prolactin secretion. Hypothalamic neurosecretion of vasopressin and oxytocin, which are released directly into the systemic circulation, alter the function of distant tissues such as the renal tubules and uterus, respectively.

Neuroglial cells (e.g., astrocytes, ependymal cells, oligodendrocytes, and microglia) represent approximately 90% of cells in the central nervous system (CNS). Neuroglia do not conduct action potentials, but they perform critical supportive functions. For example, astrocytes form the supportive framework of the CNS; help isolate synaptic junctions (to prevent nonspecific spread of neuronal impulses); facilitate nutrient delivery to neurons; and contribute to the blood-brain barrier. In addition, astrocytes have been implicated in the control of GnRH secretion and the mechanisms underlying pubertal onset.[1] For example, astrocytes may impact neuronal activity via secretion of numerous growth factors, and astrocytes abundantly appose GnRH neurons; these contacts can influence synaptic input, and they may be influenced by estrogen in both rodents and nonhuman primates. Similarly, specialized ependymal cells (tanycytes) in the median eminence appear to modify access of GnRH neuron terminals to the hypophyseal portal blood.

Anatomy of the Reproductive Hypothalamic-Pituitary Axis

Portions of the hypothalamus and anterior pituitary gland constitute the primary effector arm of the central reproductive axis. In particular, hypothalamic neural systems regulate GnRH release into the hypophyseal portal veins, with GnRH being the signal to gonadotropes (anterior pituitary) to secrete LH and FSH. In turn, these gonadotropins direct gonadal (ovarian and testicular) function.

Hypothalamus

The hypothalamus is located at the base of the brain (Fig. 1.2). Although small (approximately 10 grams, less than 1% of total brain weight), it performs critical functions for maintenance of whole-organism homeostasis. In particular, primary functions include regulation of hunger and weight maintenance, various aspects of metabolism, growth, thirst and renal water handling, body temperature, autonomic function, sleep, circadian rhythms, and emotion. Importantly, the hypothalamus is also a primary control center for reproduction and influences sexual behavior.

As an anatomical structure, the hypothalamus does not have discrete borders; but in general, it forms the floor and inferior lateral walls of the third ventricle (Fig. 1.3). The medial portions of the hypothalamus are primarily made up of cell bodies, while the lateral portions are mostly composed of neuron fibers (axons), such as those connecting the medial hypothalamus to other areas of the brain. (Note that the hypothalamus is extensively interconnected with other brain areas.) By convention, closely associated collections of neuron cell bodies are called nuclei; and the paraventricular, dorsomedial, ventromedial, and arcuate nuclei (the latter can be called the infundibular nucleus in humans) contain a majority of the neurons that secrete hypophysiotropic hormones into the portal circulation. GnRH cell bodies do not form discrete nuclei, but are instead diffusely located throughout the preoptic area and the mediobasal hypothalamus (Fig. 1.4); the latter is situated caudal to the preoptic area, extending from the retrochiasmatic area (i.e., the area situated behind the optic chiasm) to the mamillary bodies, and including both the arcuate (infundibular) nucleus and the median eminence.

Median Eminence

Positioned at the base of the third ventricle, the median eminence is part of the anatomical link between the hypothalamus and anterior pituitary. The internal zone of the median eminence is located along the ventral floor of third ventricle

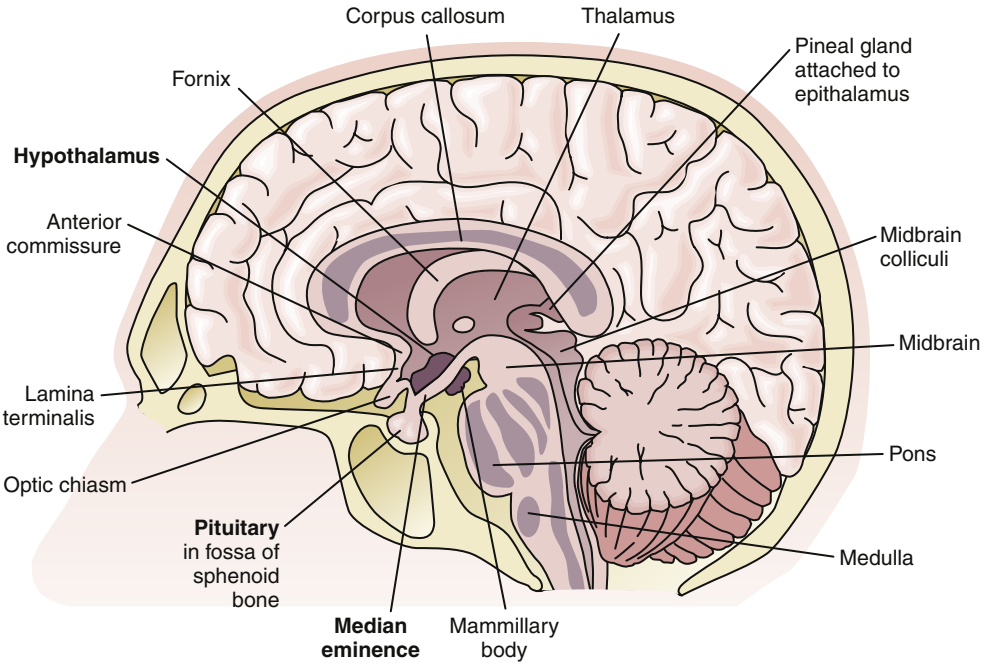

FIGURE 1.2 Cross-sectional representation of the human brain (sagittal plane), including hypothalamus, median eminence, and pituitary gland. *(Adapted from Johnson MH, Everitt BJ.* Essential reproduction*, ed 5. Blackwell Science, 2000, Fig. 6.1.)*

and is largely composed of axonal fibers from both magnocellular neurons (larger neurons that secrete vasopressin and oxytocin) and hypophysiotropic neurons as they travel from hypothalamic nuclei/areas to their final destinations—the neurohypophysis (posterior pituitary) and the external zone of the median eminence, respectively (Fig. 1.5). The external zone contains hypophysiotropic neuron terminals, which release hypophysiotropic hormones into an extensive capillary plexus—the proximal end of the hypophyseal portal system. Some nerve terminals in this zone act on other nerve terminals to influence hormone release (e.g., kisspeptin neurosecretion at GnRH neuron terminals appears to influence GnRH release).

The ependymal layer lining the third ventricle includes a population of specialized ependymal cells called tanycytes, which have a short process extending toward the ventricular surface and a long process extending into the median eminence toward areas around portal capillaries. The latter tanycyte projections envelope or retract from GnRH nerve terminals during high and low GnRH neuronal activity, respectively. Thus, tanycytes may influence GnRH secretion by physically isolating GnRH neuron terminals from portal capillaries, a regulated process.[2] Tanycytes have also been proposed to be a link between cerebrospinal fluid and events at the external zone (e.g., by transporting substances from the third ventricle to portal blood).

The median eminence is among the so-called circumventricular organs, which lie adjacent to the ventricular system and represent openings in the blood-brain barrier. While lipid-soluble molecules can diffuse in and out of the CNS relatively easily, and cellular transport mechanisms allow selective entry of ions, the blood-brain barrier functions to protect certain regions of the brain and hypothalamus from larger charged molecules, with physical protection provided by (a) tight junctions between endothelial cells and (b) neuron-capillary separation by both astrocyte foot processes and microglia. However, the CNS requires feedback signals—including hormonal, metabolic, and toxic—via macromolecules of peripheral origin that would otherwise be excluded by the blood-brain barrier; accordingly, capillaries of the circumventricular organs are fenestrated and permit transcapillary exchange of larger charged molecules (e.g., proteins, peptide hormones). Thus, the median eminence represents a key access point for central sensing of peripheral cues. Similarly, fenestrated vessels readily allow entry of hypothalamic releasing factors into portal blood.

Hypophyseal Portal Circulation

No direct neuronal connections exist between the hypothalamus and the anterior pituitary. However, the hypophyseal portal circulation (hypothalamic-hypophyseal portal system, pituitary portal system) represents the functional connection between the median eminence and anterior pituitary (Fig. 1.4). The superior hypophyseal artery (a branch of the internal carotid artery) subdivides to form an extensive capillary network in the external zone of the median eminence, with loops that reach into the inner zone. Capillary blood then drains into sinusoids that converge into the hypophyseal portal veins. Traversing the pituitary stalk to reach the anterior pituitary, the hypophyseal portal system forms the primary blood supply of the anterior pituitary. The direction of blood flow is primarily, but not exclusively, from the hypothalamus to the anterior pituitary; some retrograde flow allows for short-loop hypothalamic feedback.

Pituitary Gland (Hypophysis)

The pituitary gland appears as an extension at the base of the hypothalamus and resides cradled within the sella turcica, a saddle-like structure of the sphenoid bone (Fig. 1.2). The adenohypophysis (anterior pituitary) is of ectodermal origin, derived from an upward invagination of pharyngeal epithelium (Rathke pouch) during embryological development. The adenohypophysis is comprised primarily by the anterior lobe (pars distalis), which contains specialized

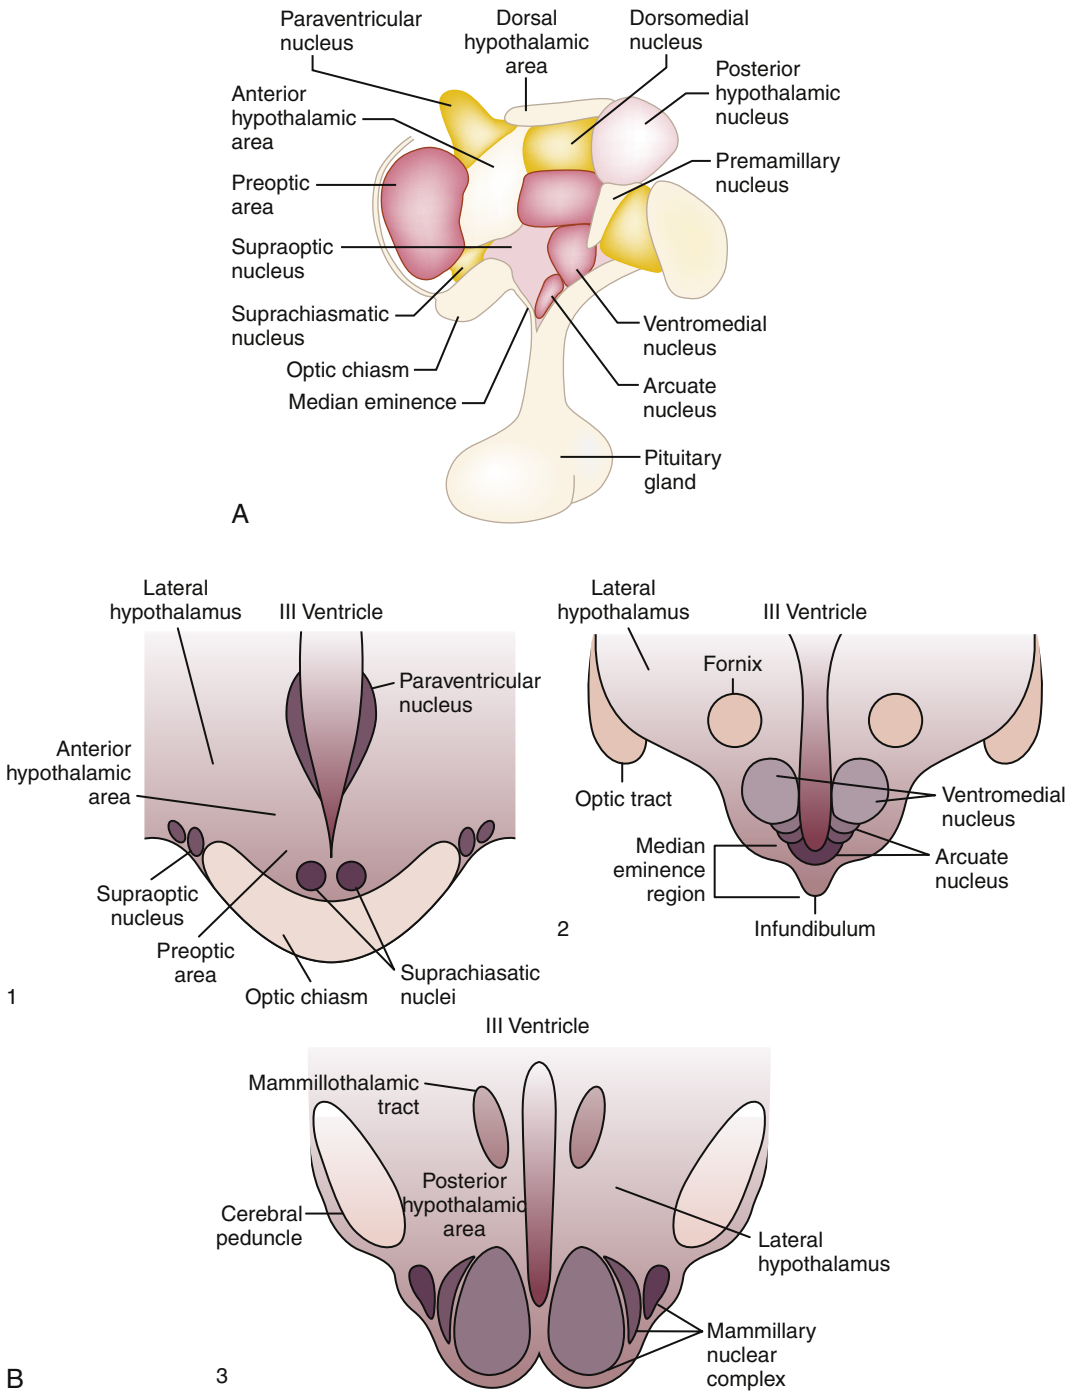

FIGURE 1.3 Nuclei and areas of hypothalamus. **A,** By custom, the nuclei and areas of the hypothalamus are often divided into three groups according to their location along the anterior-posterior plane: the anterior group, the tuberal group, and the posterior (or mamillary) group. The anterior group is formed by the paraventricular, supraoptic, and suprachiasmatic nuclei along with the anterior hypothalamic and preoptic areas. The tuberal group—so-called because of its position above the tuber cinereum (from which the infundibulum or pituitary stalk extends)—contains the dorsomedial, ventromedial, and arcuate nuclei along with the median eminence. Along with the paraventricular nucleus, the nuclei of the tuberal group contain a majority of the neurons that secrete hypophysiotropic hormones (i.e., hypothalamic hormones regulating hormone synthesis and release from cells in the anterior pituitary). Finally, the posterior group includes the posterior hypothalamic nucleus and mamillary nuclei. **B,** Cross-sectional representations (coronal planes) of the rostral (1), mid (2), and caudal (3) portions of the human hypothalamus. *(Section B is adapted from Johnson MH, Everitt BJ.* Essential reproduction*, ed 5. Blackwell Science, 2000, Fig. 6.3.)*

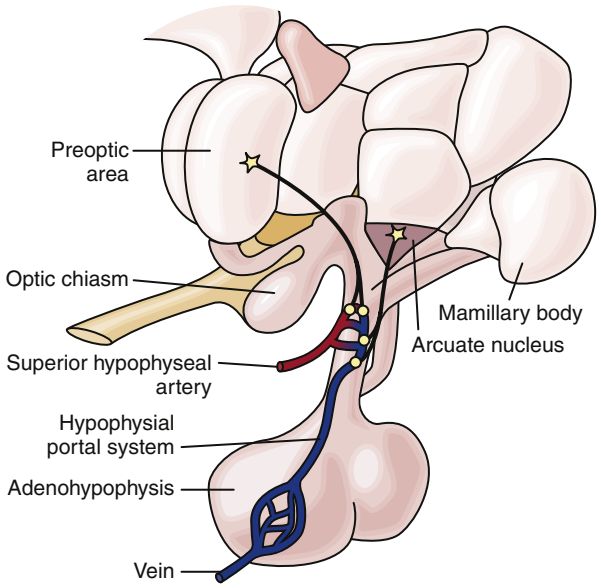

FIGURE 1.4 Anatomical relationship between hypothalamic GnRH neurons and their target cell populations in the adenohypophysis (anterior pituitary). GnRH neuron cell bodies are located in the preoptic area and the mediobasal hypothalmus. GnRH axonal projections terminate at the median eminence, where GnRH is secreted into the hypophyseal portal system. *(Adapted from Johnson MH, Everitt BJ.* Essential reproduction*, ed 5. Blackwell Science, 2000, Fig. 6.4.)*

cell populations that produce specific hormones: gonadotropes (the gonadotropins LH and FSH), mammotropes (prolactin), corticotropes (adrenocorticotropic hormone), thyrotropes (thyroid stimulating hormone [TSH]), and somatotropes (growth hormone). The intermediate lobe is vestigial in adult humans, but includes a small population of cells (e.g., POMC cells) in contact with the posterior lobe; and the pars tuberalis is a slender layer of tissue (e.g., LH-producing cells and TSH-producing cells) surrounding the infundibulum and pituitary stalk.

In contrast to the adenohypopysis, the neurohypophysis (posterior pituitary) is comprised of neural tissue and forms as a downward extension of neuroectodermal tissue from the infundibulum during embryological development. It is thus a direct extension of the hypothalamus. The neurohypophysis includes the infundibular stalk and the pars nervosa (posterior lobe of the pituitary). The supraoptic and paraventricular nuclei include magnocellular neurons that produce oxytocin and arginine vasopressin ([AVP]; also known as antidiuretic hormone [ADH]) respectively; these axons project to the posterior lobe of the pituitary, where oxytocin and AVP are secreted into a capillary network that drains into the hypophyseal veins (i.e., directly into the general circulation). The posterior lobe also includes specialized glial cells called pituicytes, which envelope or retract from magnocellular nerve terminals during high and low neuronal activity, respectively.

Gonadotropin-Releasing Hormone: The Final Common Pathway for the Central Control of Reproduction

Gonadotropin-releasing hormone, previously called luteinizing hormone-releasing hormone (LHRH), is synthesized

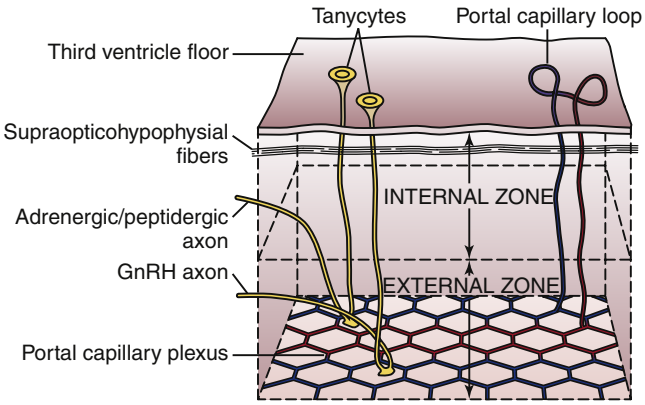

FIGURE 1.5 Diagram of the median eminence.

and released from a relatively small population of specialized hypothalamic neurons. GnRH was initially isolated from porcine hypothalami and shown to stimulate pituitary gonadotropin release.[3] Although the primary function of GnRH is to regulate pituitary gonadotropin secretion, GnRH also appears to have autocrine and paracrine functions in diverse tissues (e.g., ovary, placenta).[4]

The regulation of GnRH secretion is complex and involves overlapping pathways, which likely increases the robustness of central reproductive function. However, there are no known parallel or backup pathways for the stimulation of gonadotropin secretion. Thus, natural fertility is absolutely dependent on appropriate GnRH secretion. For example, mice with mutations of the GnRH-1 gene are hypogonadal, but reproduction can be restored via GnRH-1 gene therapy[5] or transplantation of fetal GnRH neurons.[6] Similarly, a variety of human conditions associated with absent (or near-absent) GnRH secretion lead to pubertal failure, hypogonadotropic hypogonadism, and infertility, all of which can be fully reversed with exogenous GnRH therapy.[7]

GnRH secretion is influenced by numerous factors including sex steroids, energy availability, and stress. In some mammalian species, GnRH secretion is also affected by circadian rhythms, photoperiod (e.g., seasonal breeders such as sheep), social cues, and pheromones.

GnRH Structure

Gonadotropin-releasing hormone (GnRH-1 in particular) is a decapaptide, with the amino acid structure (pyro)Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2. The amino acid structure of GnRH is identical in essentially all mammalian species; and with the exception of the central Tyr-Gly-Leu-Arg segment, the amino acids of GnRH are highly conserved among vertebrate species.[8] The GnRH-1 gene *(GNRH1)* is located on human chromosome 8 (8p11.2-p21) and produces a 92 amino acid precursor peptide called prepro-GnRH, which includes a signal sequence (23 amino acids), GnRH (10 amino acids), a proteolytic processing site (3 amino acids), and GnRH-associated peptide (56 amino acids) (Fig. 1.6). The latter peptide can stimulate gonadotropin secretion and inhibit prolactin secretion, although its precise physiological role, if any, remains unclear. The actions of GnRH are mediated through the GnRH type I receptor.

Another form of GnRH (GnRH-2) and its receptor have been identified in a variety of animal species including

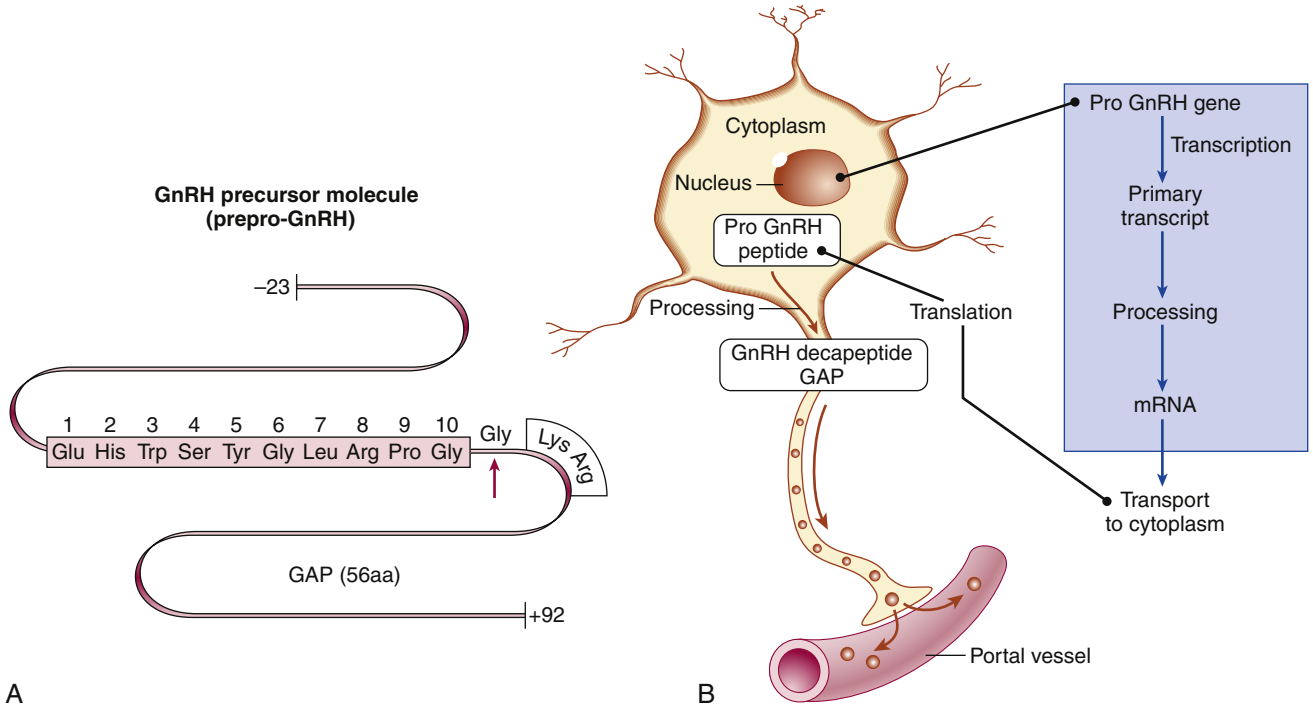

FIGURE 1.6 Schematic of GnRH synthesis. **A,** Representation of prepro-GnRH, including a 23 amino acid signal sequence, GnRH, a proteolytic processing site (Gly-Lys-Arg), and GnRH-associated peptide (GAP). The arrow indicates the site of proteolytic cleavage and C-amidation. **B,** Schematic of neuronal GnRH synthesis and secretion.

humans.[9] GnRH-2 is a decapeptide with similar structure to GnRH-1: (pyro)Glu-His-Trp-Ser-His-Gly-Trp-Tyr-Pro-Gly-NH_2 (underlined amino acids denote differences compared to GnRH-1). However, the gene for GnRH-2 is located on human chromosome 20 (20p13). GnRH-2 is widely expressed in the CNS and extra-CNS tissues, and it may contribute to reproductive behavior regulation in some species. In lower animals, GnRH-2 can act via its own receptor, which is structurally and functionally distinct from the GnRH type I receptor. Although a homologue of the GnRH-2 receptor gene has been detected in the human, it includes a frameshift and premature stop codon. Thus, GnRH-2 signaling in humans may act through the GnRH type I receptor, although the physiological role of GnRH-2 in humans remains unclear.

Anatomy of GnRH-Secreting Neurons

GnRH neurons are a heterogeneous population of hypothalamic neurons. They are relatively few, numbering approximately 1500 to 2000, and the majority of GnRH neuronal cell bodies are located in the arcuate (infundibular) nucleus (part of the mediobasal hypothalamus) and the medial preoptic area.[10] Although GnRH neurons are rather loosely affiliated anatomically, they are functionally integrated and form a complex network with numerous interconnections, in addition to connections to other neuronal populations. The GnRH neurons in the mediobasal hypothalamus appear to be requisite for gonadotropin secretion, and GnRH neuronal axons project to the median eminence via the GnRH tuberoinfundibular tract. The physiological function of other GnRH neurons, which arise from the anterior and posterior hypothalamus, and project to the limbic system and posterior pituitary, respectively, remains unclear, although some of these circuits may possibly be involved with various behavioral responses.

Embryological Development of the GnRH Neuronal Network

The ontogeny of GnRH neurons in vertebrate species is unique among neuronal systems of the CNS: nascent GnRH neurons are initially identified outside of the CNS in the nasal placode (sometimes called the olfactory placode). However, GnRH cells migrate during embryological development, as directly observed in embryonic nasal explant cultures and in embryonic head slices (mouse model).[11,12] The specific migratory pathway of GnRH neurons was first demonstrated in mice by documenting the presence of GnRH-immunoreactive cells in different areas at different stages of embryonic development (Fig. 1.7).[13-15] Specifically, GnRH expression is first observed within the nasal placode circa embryonic day 10 or 11. By embryonic day 13, GnRH cells are primarily located around the cribiform plate, and GnRH cells begin to reach the hypothalamus by embryonic day 14, approaching their final positions around embryonic day 16. This migratory pathway has been confirmed in both nonhuman primates[16] and humans.[17]

Successful migration of GnRH neurons is inextricably intertwined with olfactory system development, likely reflecting the close functional relationship between reproduction and the olfactory system (e.g., pheromones) in mammalian phylogeny. The nasal placode gives rise to nasal epithelium and olfactory sensory neurons, the latter of which extend axonal projections to the olfactory bulb. Vomeronasal neurons are a subset of olfactory neurons

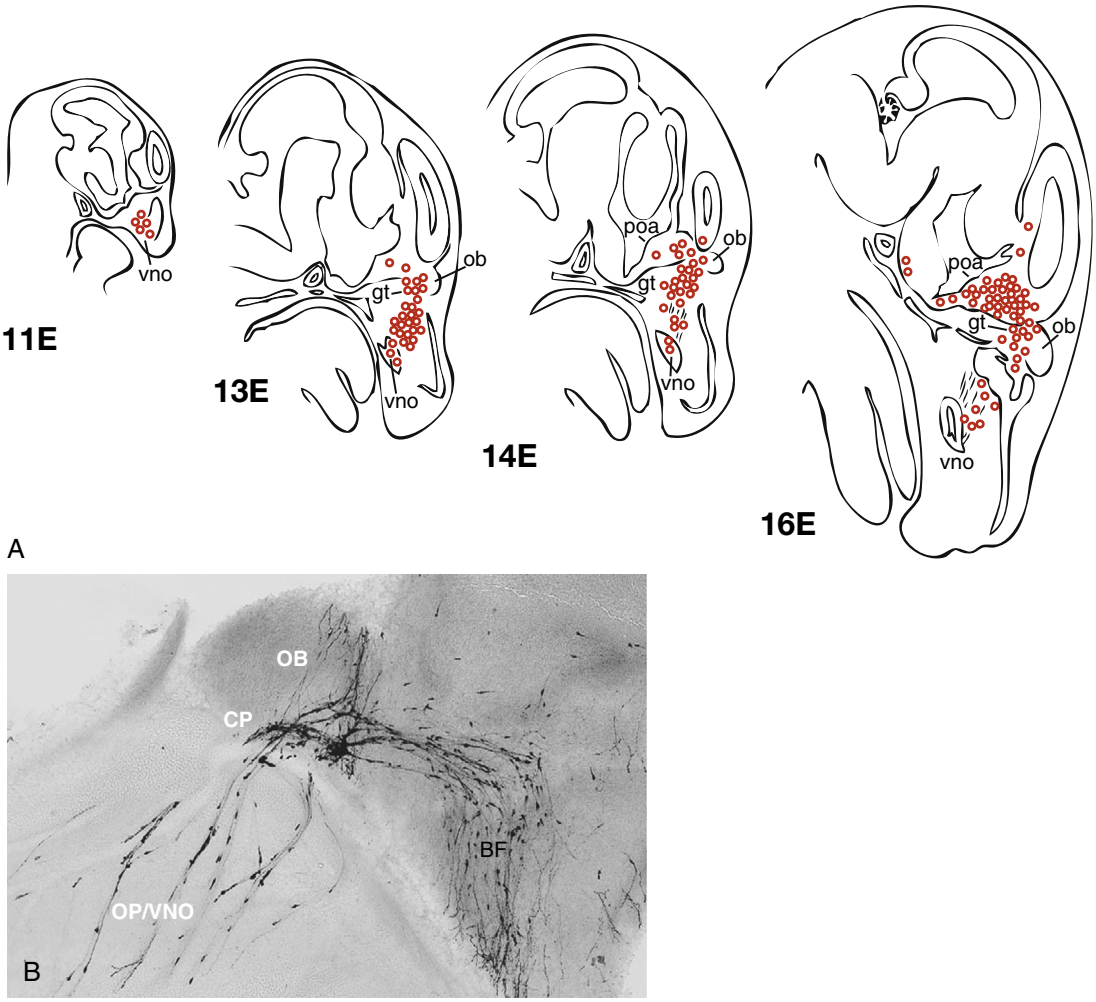

FIGURE 1.7 GnRH neuron migration during embryogenesis. **A,** Location of GnRH-immunoreactive cells (red circles) as a function of embryological age (mouse). On embryological day 11 (11E), GnRH cells are located in the nasal (olfactory) placode and presumptive vomeronasal organ (vno). GnRH cells migrate across the cribiform plate toward the olfactory bulb (ob). GnRH neurons then follow the caudal branch of the vomeronasal nerve toward the forebrain and hypothalamus. By day 16 (16E), GnRH neurons largely reside in the preoptic area (poa) of the hypothalamus. Abbreviations: gt, ganglion terminale. *(Adapted from Schwanzel-Fukuda M, Pfaff DW. Origin of Luteinizing Hormone-Releasing Hormone Neurons.* Nature *338:161-164, 1989.)* **B,** Sagittal brain slice (mouse, embryonic day 15) demonstrating the migratory route of GnRH-immunoreactive cells. Staining is for GnRH and peripherin (a neuronal intermediate filament). OP/VNO, olfactory placode-vomeronasal organ; CP, cribriform plate (CP); OB, olfactory bulb; BF, basal forebrain. *(Adapted from Wierman ME, Pawlowski JE, Allen MP, et al. Molecular mechanisms of gonadotropin-releasing hormone neuronal migration.* Trends Endocrinol Metab *15:96-102, 2004.)*

believed to be involved with pheromone detection; these axons originate in the vomeronasal organ and largely extend to the accessory olfactory bulb. At the level of the cribiform plate, some olfactory (vomeronasal) axons separate and form a branch that extends caudally into the forebrain. Of great importance, migrating GnRH neurons maintain adhesion to these axons; thus, these olfactory neurons form a critical guidance track for GnRH neuronal migration across the nasal epithelium and through the forebrain toward the hypothalamus.[18,19]

The dependence of GnRH neuronal migration on normal olfactory system development is exemplified by Kallmann syndrome, a form of congenital hypogonadotropic hypogonadism accompanied by absent sense of smell (anosmia). In this syndrome, faulty development of the olfactory system renders an inadequate guidance infrastructure for migrating GnRH neurons, leading to failure of GnRH neurons to reach the hypothalamus. The first identified cause of Kallmann syndrome was deletion of the Kallmann syndrome 1 sequence (*KAL1* gene), which is located on the X chromosome (Xp22.3) and encodes anosmin-1, a secreted matrix glycoprotein expressed in the presumptive olfactory bulb. Although precise mechanisms are unclear, anosmin-1 is believed to be important for the formation of olfactory elements that provide migratory guidance to GnRH neurons as they move out of the nasal placode. Evaluation of a 19-week-old human fetus with X-linked Kallmann syndrome demonstrated GnRH-immunoreactive cells within a tangle of olfactory and vomeronasal nerves at the dorsal surface of the cribiform plate, along with the absence of olfactory tracts and bulbs.[20] In a second human fetus (16 weeks) with X-linked Kallmann syndrome, GnRH was detected along terminal nerve fascicles in the nasal mucosa only.[21] This syndrome illustrates that, without the guidance framework provided by the olfactory neuronal system, GnRH neurons fail to migrate into the hypothalamus

and thus cannot release GnRH into the hypophyseal portal system.

A number of additional single-gene defects have been associated with Kallmann syndrome, including mutations of prokineticin 2 (PROK2) and its receptor (PROKR2),[22] fibroblast growth factor-8 (FGF8) and its receptor (fibroblast growth factor receptor 1 [FGFR1]),[23] nasal embryonic LH-releasing hormone factor (NELF),[24] and chromodomain helicase DNA binding protein 7 (CHD7).[25] The importance of these genes in GnRH neuronal development is corroborated by mouse studies. For example, in fetal mice lacking either PROK2 or PROKR2, GnRH neurons are trapped in a tangled web of olfactory/vomeronasal axons, with few, if any, reaching the forebrain.[26] Although these gene products are clearly important for GnRH neuron ontogeny, their precise roles remain uncertain.

Mouse studies suggest other important factors underlying GnRH neuron migration during prenatal development. For example, the chemokine (C-X-C motif) receptor 4 (CXCR4) is expressed on murine GnRH neurons and interacts with a secreted chemokine stromal cell-derived factor-1 (SDF-1), which is present as a gradient in the nasal mesenchyme. This gradient, with highest concentrations at the cribriform plate, provides directional information as GnRH neurons migrate toward the cribiform plate; and GnRH cell migration across the nasal compartment is markedly impaired in CXCR4 knockout mice.[27] As another example, extension of the caudal branch of the vomeronasal nerve toward the ventral forebrain involves chemoattraction via interactions between netrin-1—a chemokine expressed as a gradient in the forebrain—and its receptor, deleted in colorectal cancer (DCC). In mice without either DCC or netrin-1, the caudal branch of the vomeronasal nerve extends toward the cerebral cortex rather than the ventral forebrain; GnRH neurons follow this path, ultimately residing in the cerebral cortex.[28,29] A number of such interactions have been implicated in (a) guidance of olfactory neurons toward the forebrain and (b) the association between migrating GnRH neurons and axons of olfactory/vomeronasal nerves, but their specific roles in humans remain unclear. For example, no human mutations affecting DCC or netrin-1 have been described to date.

After reaching the hypothalamus, GnRH neurons detach from olfactory nerve axons and may disperse further before resting. A critical next step is extension of GnRH neuronal axons to the median eminence, where GnRH may gain access to the hypophyseal portal system.

GnRH Neuronal Firing and GnRH Secretion

GnRH neuronal activity is marked by bursts of action potentials (burst firing), the patterns and rates of which change across time. Changes of GnRH secretion are presumably related to changes of GnRH neuron firing rates, although the precise relationship between these events is unclear. Variable firing rate patterns (e.g., times of high and low firing rates) appear to be intrinsic to GnRH neurons, but they can also be altered by neurotransmitters and neuromodulators (e.g., glutamate, GABA, kisspeptin). Although sex steroids can markedly influence GnRH neuronal firing rates, GnRH neurons lack the primary receptors mediating sex steroid feedback (i.e., estrogen receptor alpha, progesterone receptor, androgen receptor); however, many studies suggest that sex steroid actions on GnRH neuronal activity are mediated primarily by afferent neurons (e.g., those secreting glutamate, GABA, kisspeptin, etc.).

GnRH neuron cell bodies are relatively scattered across the mediobasal hypothalamus and preoptic area, yet GnRH is secreted into the hypophyseal portal system in a coordinated, pulsatile fashion. Specifically, GnRH secretion is marked by episodic bursts of hormone release into the portal system, as demonstrated in rats,[30] sheep,[31] and monkeys.[32] Once released into the portal vascular compartment, GnRH is rapidly degraded via enzymatic proteolysis, and the half-life of GnRH in the blood is very short—approximately 2 to 4 minutes. Thus, GnRH presentation to gonadotrope cells is intermittent.

Pulsatile GnRH secretion is absolutely required for long-term stimulation of gonadotropin synthesis and secretion. Yet there is a relatively narrow window of GnRH pulse frequency and amplitude that will optimally stimulate gonadotropin secretion. Intermittent GnRH stimulation of gonadotrope cells can increase (or maintain) GnRH receptors on gonadotropes—the "self-priming" or "autopriming" effect. Thus, intermittent GnRH stimulation facilitates or maintains gonadotrope responsiveness to GnRH. However, more frequent exposure to GnRH pulses can reduce gonadotropin responses to GnRH[33]; at one extreme, continuous GnRH receptor stimulation leads to marked desensitization of gonadotropin synthesis and secretion. In a classic experiment involving rhesus monkeys with hypothalamic lesions that abolished GnRH secretion, intermittent (once an hour) exogenous GnRH administration restored pituitary gonadotropin secretion. However, changing from intermittent to continuous GnRH administration resulted in marked desensitization of gonadotropin release (Fig. 1.8).[34] This desensitization is largely related to reduced GnRH receptor expression on gonadotropes (i.e., receptor downregulation).

The foregoing phenomenon can be exploited therapeutically with the use of long-acting GnRH receptor agonists. Such agonists are peptides with structures very similar to that of GnRH, but with amino acid substitutions that enhance receptor binding affinity, increase resistance to proteolytic degradation, or both (Fig. 1.9), thus providing continuous GnRH receptor stimulation. Although initial GnRH receptor agonism temporarily increases gonadotropin release (gonadotropin "flare"), continued agonism leads to desensitization of gonadotropin secretion with accompanying reductions of gonadal sex steroid concentrations to castrate levels ("medical oophorectomy," "medical castration," "pseudomenopause"), usually over 4 to 8 weeks. These agents are useful in the therapy of gonadotropin-dependent disorders such as central precocious puberty, endometriosis, and prostate cancer.

Peptide GnRH receptor antagonists are also available for clinical use. These antagonists reversibly bind to, but do not stimulate, the GnRH receptor (i.e., competitive antagonism). Thus, these agents do not cause an initial "flare" of gonadotropin secretion, and they reduce gonadotropins more rapidly than GnRH agonists—usually within 24 to 72 hours.

GnRH Stimulation of Gonadotrope Cells

The specialized cells that synthesize and secrete gonadotropins (i.e., gonadotropes) are located mainly in the lateral

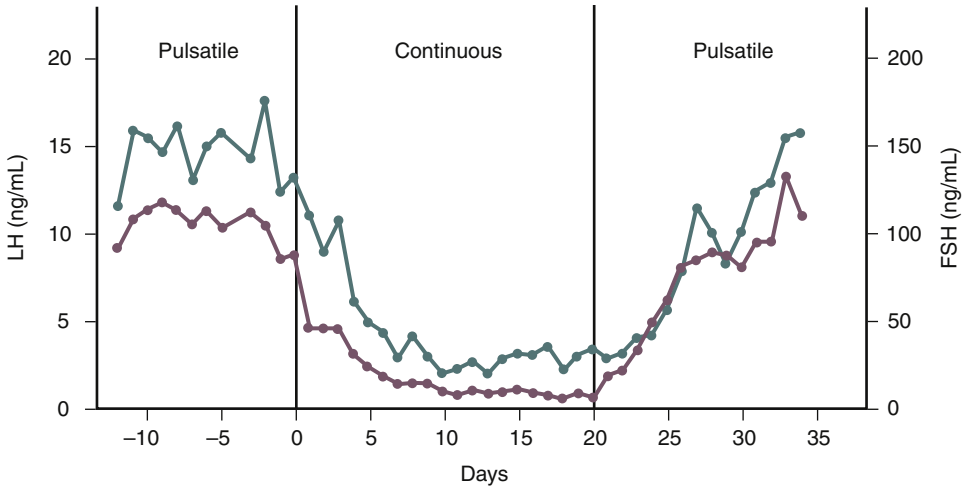

FIGURE 1.8 The influence of pulsatile vs. continuous GnRH administration to GnRH-deficient monkeys. Intermittent exogenous GnRH administration reconstitutes normal gonadotropin secretion. However, continuous GnRH infusion leads to a marked reduction (downregulation) of luteinizing hormone (green) and follicle-stimulating hormone (purple) concentrations. Resumption of pulsatile GnRH administration restores LH and FSH secretion. *(Adapted from Belchetz PE, Plant TM, Nakai Y, et al. Hypophysial responses to continuous and intermittent delivery of hypothalamic gonadotropin-releasing hormone.* Science *202:631–633, 1978.)*

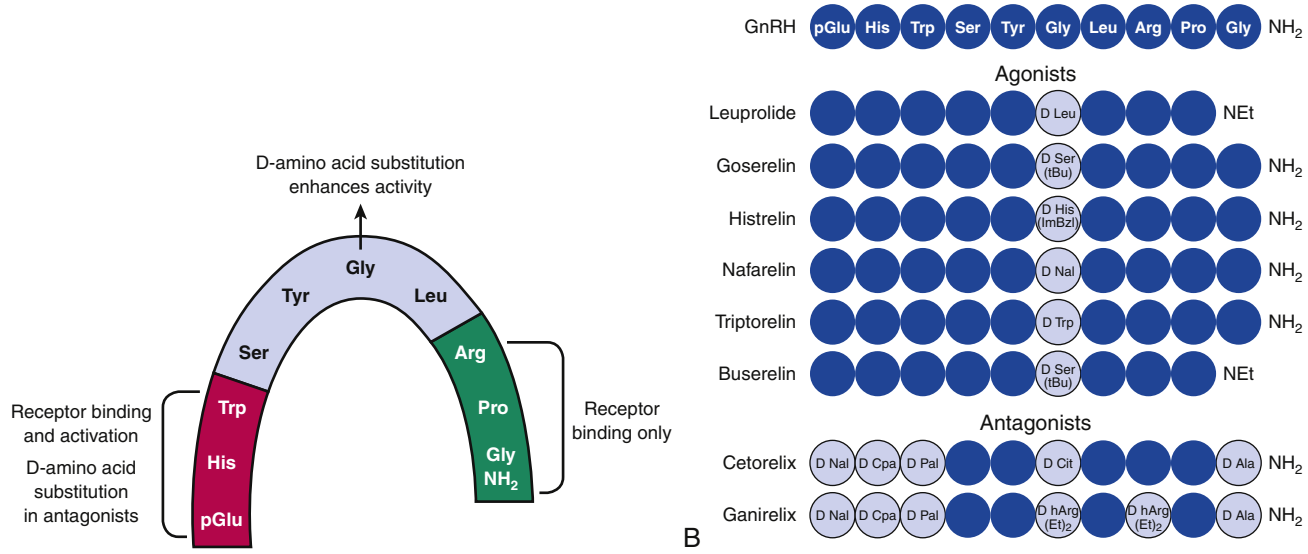

FIGURE 1.9 Structure of GnRH and GnRH receptor agonists and antagonists. **A,** Schematic of GnRH-1 in its folded conformation. Folding around the glycine in position 6 enhances GnRH receptor binding. Substitution of the glycine in position 6 with D-amino acids stabilizes the molecule in the folded conformation, which increases affinity for the GnRH receptor and reduces metabolic clearance. The amino-terminal (red) is involved with receptor binding and activation, and GnRH antagonists involve modifications of these residues that prevent receptor activation. The carboxyl-terminal (green) participates in receptor binding, but not activation. Substitution at position 10 (e.g., replacement of glycinamide by ethylamide) can increase binding affinity. **B,** Amino acid structure of GnRH along with selected GnRH receptor agonists and antagonists. Solid black circles represent amino acids that are unchanged compared to native GnRH. *(From Millar RP, et al. Gonadotropin-releasing hormone receptors.* Endocr Rev. *25:235–275, 2004.)*

portions of the anterior pituitary gland and constitute 7% to 10% of the adenohypophysis cell population. GnRH action at the pituitary gonadotrope begins with GnRH binding to the GnRH type I receptor on the plasma membrane.[8] The GnRH type I receptor is a member of the seven-transmembrane receptor family, a G protein-coupled receptor, and encoded on chromosome 4. GnRH receptor density varies in different physiological conditions and exhibits a positive correlation with gonadotrope responsiveness to GnRH (e.g., with both being high in rodents during preovulatory gonadotropin surges[35]). GnRH receptor density appears to be modulated primarily by GnRH, with intermittent GnRH stimulation leading to increased GnRH receptor expression; this is a central facet of the self-priming effect of GnRH, and an important mechanism by which GnRH action is modulated in different physiological states.

A majority of gonadotropes synthesize and secrete both LH and FSH. A detailed description of intracellular mechanisms of GnRH action on the gonadotrope is provided in Chapter 2. Briefly, GnRH receptor binding activates the guanosine

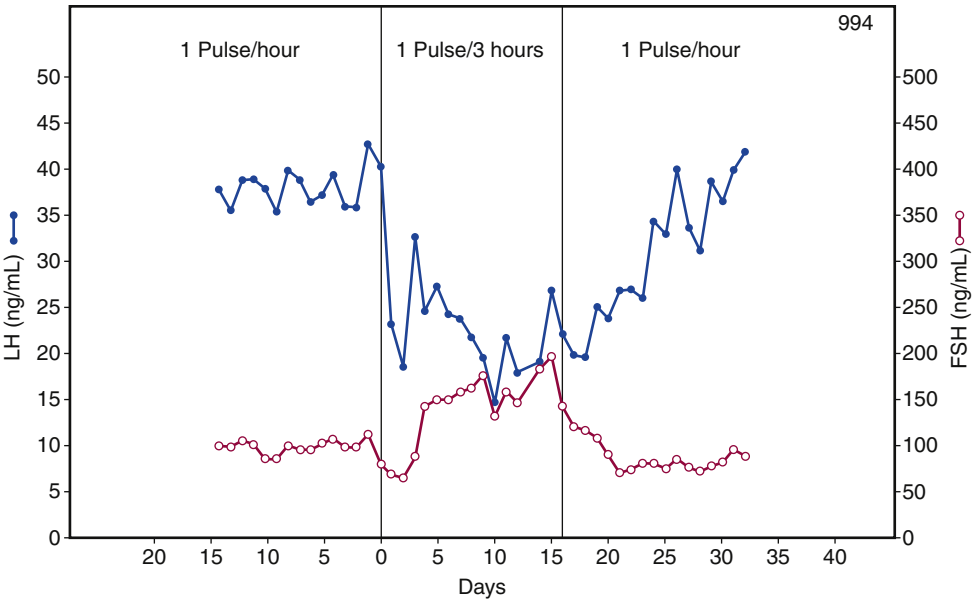

FIGURE 1.10 LH and FSH concentrations in gonadectomized (but sex steroid-replaced) monkeys after arcuate nucleus ablation—a model of isolated GnRH deficiency. Exogenous GnRH administered in a pulsatile fashion every hour reconstituted LH and FSH secretion. Changing GnRH pulse administration from a relatively high frequency (hourly) to a relatively low frequency (every 3 hours) resulted in decreased LH but increased FSH secretion. *(Adapted from Wildt L., et al., Frequency and amplitude of gonadotropin-releasing hormone stimulation and gonadotropin secretion in the rhesus monkey.* Endocrinol *109:376–385, 1981.)*

triphosphate (GTP)-binding protein $G_{q/11}$ leading to an increase of second messengers inositol 1,4,5-triphosphate (IP_3) and 1,2-diacylglycerol (DAG). Further intracellular signaling involves increased intracellular calcium and activation of various protein kinase C (PKC) isoforms, mitogen-activated protein kinases (e.g., extracellular signal-regulated kinase [ERK], c-Jun NH_2-terminal kinase [JNK], and p38), calcium/calmodulin-dependent kinase II (Ca/CaMK II), and adenylate cyclase.

Each gonadotropin consists of two protein subunits, α and β. The 92 amino acid α-subunit is common to both LH and FSH—in addition to human chorionic gonadotropin (hCG) and TSH. β-subunits for LH (LHβ) and FSH (FSHβ) are 121 and 117 amino acids in length, respectively, and account for the biological specificity of these two hormones. GnRH stimulates gene expression of LHβ, FSHβ, and α-subunit, and the latter noncovalently dimerizes with either LHβ or FSHβ to form LH or FSH, respectively. Gonadotropins also undergo variable post-translational modification, primarily glycosylation (addition of oligosaccharide moieties to specific amino acids), which influences bioactivity and elimination half-life.[36] The gonadotropins are then packaged into secretory granules for eventual secretion.

Although GnRH is the primary stimulus for LH and FSH synthesis and release from a common cell type, concentrations of these two gonadotropins vary differentially throughout ovulatory cycles, with FSH predominance in the early follicular phase and LH predominance in the late follicular phase. This sequential pattern of FSH and LH predominance is important for normal follicular maturation, ovarian steroid production, and subsequent ovulation. At least two mechanisms govern differential gonadotropin secretion throughout ovulatory cycles. First, both estradiol and inhibins selectively inhibit FSH release from gonadotropes during the midfollicular and luteal phases.[37,38] Second, different patterns of pulsatile GnRH release differentially affect gonadotropin synthesis and secretion. Specifically, rapid (high frequency) GnRH pulses favor LH, while slower (low frequency) GnRH pulses favor FSH synthesis and secretion. For example, studies in ovariectomized, GnRH-deficient monkeys

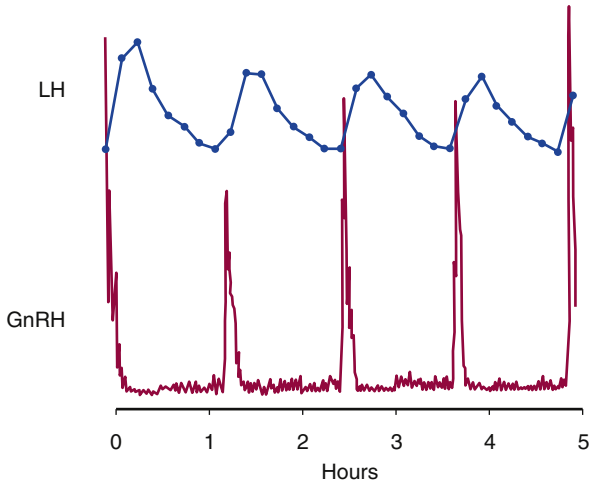

FIGURE 1.11 Close temporal relationship between pulses of LH (jugular vein) and GnRH (pituitary portal system) in the sheep model. *(Adapted from Moenter SM et al. Dynamics of gonadotropin-releasing hormone release during a pulse.* Endocrinology. *130:503–510, 1992.)*

reveal that a decrease in the frequency of exogenously-administered GnRH pulses from one pulse per hour to one pulse every 3 hours results in a 65% increase in plasma FSH, despite a 50% decrease in LH (Fig. 1.10).[33] Similar findings have been described in sheep[39] and humans.[40,41] Detailed studies in rats demonstrate that rapid GnRH pulse stimulation favors α-subunit and LHβ mRNA expression, while slow GnRH pulses favor FSHβ mRNA expression.[42] The mechanisms effecting differential LH and FSH expression in response to changes of GnRH pulse frequency include variations of GnRH receptor number on the gonadotrope cell surface[43] and alterations of gonadotrope activin β_B and follistatin expression (discussed later in the chapter).[44]

A pulse of GnRH release stimulates a pulse of LH release on a one-to-one basis, and LH (or α-subunit) pulse patterns, as assessed by frequent sampling of peripheral blood, accurately mirror GnRH pulse patterns in animal studies (Fig. 1.11).[31,45] Similarly, exogenous GnRH pulses elicit LH

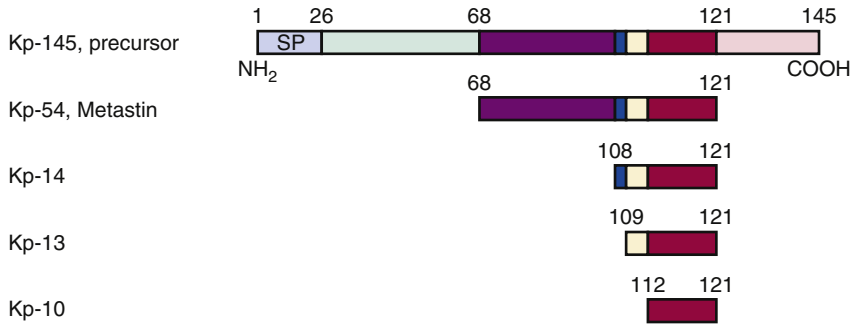

FIGURE 1.12 Schematic of the precursor kisspeptin-145 and the functional kisspeptin (Kp) fragments, including size and cleavage sites. Note that all functional kisspeptin fragments maintain amino acids 112-121. SP, signal peptide. *(From Roseweir AK, Millar RP. The role of kisspeptin in the control of gonadotrophin secretion.* Human Reproduction Update *15:203–212, 2009.)*

pulses in GnRH deficient patients. Since measurable GnRH is effectively confined to the hypophyseal portal system, which is inaccessible in humans, GnRH pulse frequency is inferred from LH pulse frequency (or α-subunit pulse frequency[46,47]) in human studies. While pulses of GnRH stimulate pulsatile release of FSH, the longer serum half-life of FSH renders FSH pulses more difficult to identify via frequent sampling of peripheral blood. Also, while short-term LH secretion is very closely tied to continued GnRH stimulation, FSH secretion is less acutely dependent on GnRH stimulation.[48,49] For example, with GnRH antagonism, the percentage reduction of LH exceeds that of FSH.[50]

Neuronal Inputs into GnRH Neurons

The governance of GnRH neurons is highly complex and involves numerous interacting neural systems utilizing various neurotransmitters and neuromodulators. The neuronal populations upstream of the GnRH neuron play key roles in puberty and are important mediators of sex steroid feedback and the influence of nutritional cues and stress on the GnRH pulse generator. Numerous neurotransmitters appear to be involved in the regulation of GnRH secretion, including dopamine, norepinephrine, glutamate, GABA, and nitric oxide. The control of GnRH secretion has been the subject of intense investigation, and the recent discovery of several neuronal populations upstream of the GnRH neuron (e.g., kisspeptin neurons) has markedly enhanced our understanding of reproductive neuroendocrinology.

Kisspeptin

The kisspeptin system is believed to be requisite for normal GnRH secretion, serving as a "gatekeeper" of puberty and helping to mediate the effects of sex steroids and metabolic cues on GnRH secretion. Kisspeptin was originally called metastin because of its ability to suppress metastatic spread of human melanomas and breast carcinomas. However, in recognition of its discovery at Pennsylvania State University in Hershey, Pennsylvania, it was later named kisspeptin after Hershey's chocolate KISSES®. Herein we will use the following abbreviations[51]: *KISS1* and *Kiss1*, the human and nonhuman kisspeptin genes, respectively; *KISS1R (Kiss1R)* and KISS1R (Kiss1R), the human (nonhuman) kisspeptin receptor genes and gene products, respectively.

The *KISS1* gene product is a 154 amino acid precursor protein (kisspeptin 1-145). Variable proteolytic modification yields kisspeptins of different lengths: kisspeptin-54, -14, -13, and -10, with the numbers referring to the amino acid length of bioactive kisspeptin fragments (Fig. 1.12). Importantly, all functional kisspeptins maintain the 10 amino acids of the carboxy-terminal (kisspeptin amino acids 112 to 121), which are important for receptor binding and function. Kisspeptin is the natural ligand of KISS1R—also known as the G-protein coupled receptor 54 (GPR54)—a seven transmembrane domain, G protein-coupled receptor.

The importance of the kisspeptin system in reproduction was initially revealed by members of two consanguineous families with *KISS1R* mutations leading to pubertal failure and normosmic hypogonadotropic hypogonadism.[52,53] Inactivating *KISS1* mutations leading to pubertal failure and normosmic hypogonadotropic hypogonadism have also been described in four sisters.[54] Mouse models with targeted knockouts of *Kiss1* and *Kiss1R* exhibit hypogonadotropic hypogonadism with impaired sexual maturation, reduced gonadal size, failure of estrous cyclicity (females), impaired spermatogenesis (males), and infertility.[53,55,56] However, the notion that kisspeptin is an absolute requirement for puberty and reproductive function in mice is somewhat controversial.[57,58] *KISS1R* and *KISS1* mutations neither interrupt GnRH neuron migration to the hypothalamus nor impair GnRH synthesis.

Single boluses of kisspeptin markedly stimulate LH release in rodents, sheep, monkeys, and humans. This effect of kisspeptin is mediated by stimulation of GnRH neurons, as supported by the following: kisspeptin fibers appear to project to and form synaptic contacts with GnRH neurons[59,60]; the kisspeptin receptor is expressed by a majority of GnRH neurons[61]; kisspeptin can directly depolarize GnRH neurons[62,63]; and kisspeptin stimulation of gonadotropin secretion is completely blocked by GnRH antagonists.[64,65] However, kisspeptin may also work indirectly, as kisspeptin increases GABAergic and glutamatergic postsynaptic currents onto GnRH neurons in the presence (but not absence) of estrogen in the mouse model.[66] Kisspeptin does not stimulate LH secretion in Kiss1R knockout mice,[56] suggesting that kisspeptin acts exclusively through its cognate receptor.

It remains unclear to what degree kisspeptin acts at GnRH cell bodies versus nerve terminals, but some studies suggest that kisspeptin neurons can form synapses with GnRH neuron terminals in the external zone of the median eminence, and that kisspeptin can stimulate GnRH release (exocytosis) from GnRH neuron terminals.[67,68] Although kisspeptin may possibly have direct effects on gonadotropes, available data suggest that this does not play a major role in kisspeptin's ability to stimulate gonadotropin secretion. For example, pulsatile GnRH can restore normal reproductive function in patients with *KISS1R* mutations.[69]

The numbers of kisspeptin neurons are high in the human arcuate (infundibular) nucleus, similar to findings in monkeys.[65,70,71] Extensive study in the rodent model discloses two primary populations of kisspeptin-expressing neurons in the hypothalamus: one in the arcuate nucleus (mediobasal hypothalamus) and the other in the anteroventral periventricular nucleus (AVPV) of the preoptic area.[72] Of interest, kisspeptin expression in the AVPV is much higher in female compared to male rodents, which appears to reflect organizational effects of sex steroids during early development[73,74]; and the kisspeptin neurons in the AVPV appear to be specifically important for LH surge generation in rodents. Sexual dimorphism of kisspeptin expression has also been described in sheep[75] and humans.[71] However, in primates, including humans, the majority of the kisspeptin cell bodies reside in the arcuate nucleus; and although a study of adult women revealed rare kisspeptin neurons in the medial preoptic area, a population homologous to the rodent AVPV has not been identified.[70]

Neurokinin B

Neurokinin B (NKB), a peptide encoded by the tachykinin 3 gene (*TAC3*), is a member of the tachykinin family—a family that also includes substance P and neurokinin A (products of the *TAC1* gene). There are several neurokinin receptors (NK1R, NK2R, NK3R), and although NKB can produce some agonism at NK1R and NK2R, NKB binds preferentially to and acts primarily via its cognate receptor NK3R (*TACR3* gene).[76] Studies of patients with idiopathic hypogonadotropic hypogonadism from consanguineous families revealed that homozygous loss-of-function mutations of either *TAC3* or *TACR3* can cause pubertal failure and severe hypogonadotropic hypogonadism—highlighting the importance of NKB in human reproduction.[77,78] In contrast to *Kiss1* and *Kiss1R* knockout mice, *Tacr3* knockout mice remain fertile, although they can demonstrate reproductive defects.[79,80]

Animal studies demonstrate that a selective NK3R agonist (senktide) stimulates LH secretion in the rat,[81] sheep,[82] and monkey,[83] albeit not as potently as kisspeptin. This effect appears to be influenced by the sex steroid milieu. For example, senktide administration to ewes increases LH secretion during the follicular phase, but not during the luteal phase.[82] In addition, senktide increases LH release in the presence of physiological estradiol in rodents, but it reduces LH release in estradiol-deficient animals.[81] Mechanisms underlying these apparently paradoxical observations are unclear.

Stimulation of LH secretion by NKB is mediated by GnRH secretion, as GnRH receptor antagonism abolishes LH responses to senktide in the monkey.[83] Yet, there are few or no NKB receptors on GnRH neurons, and LH is not rapidly stimulated with central senktide administration. However, kisspeptin neurons express NK3R; and in ovariectomized and estradiol-replaced rats, senktide increases c-fos expression in kisspeptin neurons.[81] Additionally, desensitization of Kiss1R markedly reduces GnRH responsiveness to senktide in monkeys, while similar desensitization of NK3R does not impair GnRH responsiveness to kisspeptin.[84] Moreover, a recent study suggests that continuous kisspeptin infusion can restore pulsatile LH secretion in patients with loss-of-function mutations of *TAC3* or *TACR3*.[85] Taken together, these studies support the contention that NKB primarily influences pulsatile GnRH secretion indirectly by stimulating kisspeptin release.[86,87]

Endogenous Opioid Peptides

Endogenous opioid peptides (EOP), which include endorphins, enkephalins, and dynorphins, participate in myriad processes such as motor activity, cognitive functions, water and food intake, and regulation of neuroendocrine function.[88] Most active EOPs share a common sequence (Tyr-Gly-Gly-Phe-[Met or Leu]) at the amino-terminal, although endorphins, enkephalins, and dynorphins are derived from different precursor proteins that undergo regulated post-translational processing (Fig. 1.13).[89] Endorphins such as β-endorphin are products of the precursor protein proopiomelanocortin (POMC). POMC can be preferentially processed to produce adrenocorticotropin hormone (ACTH) and β-lipotropin, as occurs in corticotropes (adenohypophysis) under the control of corticotropin-releasing hormone (CRH). However, in the hypothalamus, POMC processing primarily yields β-endorphin and α-melanocyte-stimulating hormone. Hypothalamic β-endorphin participates in the regulation of reproduction, temperature, and cardiovascular and respiratory functions, and it acts primarily via μ (micro)-opioid receptors. Enkephalins are derived from proenkephalin, and their primary functions appear to relate to autonomic nervous system modulation, mainly via δ (delta)-receptor activation. Dynorphins are products of the precursor prodynorphin and act chiefly at κ (kappa)-opioid receptors. Importantly, while β-endorphin, enkephalins, and dynorphins acts primarily via μ-, δ-, and κ-opioid receptors, each can act as agonists at more than one receptor subtype.

Numerous studies provide evidence that hypothalamic opiates partly mediate sex steroid negative feedback on GnRH release. For example, GnRH neurons express few if any progesterone receptors, but β-endorphin concentrations increase in hypophyseal blood during the luteal phase—when sex steroids suppress GnRH secretion—in monkeys.[90,91] Moreover, naloxone and naltrexone (opiate receptor antagonists acting primarily at μ- and κ-opioid receptors) increase LH pulse frequency when administered to luteal phase women[92] or progestin-treated postmenopausal women.[93] Similarly, morphine suppresses GnRH secretion from mediobasal hypothalami isolated from fetal and adult humans—an effect that is reversed by naloxone[94]; and chronic high-dose opiate administration can cause hypogonadotropic hypogonadism by suppressing GnRH and LH secretion.[88]

Several animal studies implicate dynorphin as a principal mediator of progesterone negative feedback on GnRH pulse frequency in females.[95] For example, dynorphin neurons in the arcuate nucleus co-localize with progesterone receptors in ewes,[96] and dynorphin-containing varicosities are closely associated with GnRH neuron cell bodies in the mediobasal hypothalamus.[97] Progesterone treatment in ewes increases dynorphin A concentrations in third ventricle cerebrospinal fluid,[98] and central infusion of dynorphin in goats reduces volleys of multiple-unit activity in the mediobasal hypothalamus and reduces LH pulses.[87] In luteal phase ewes, specific κ-opioid receptor antagonists—but not antagonists to δ- or μ-opioid receptors—reversed progesterone inhibition of LH secretion and LH frequency when locally administered into the mediobasal hypothalamus.[97] However, other EOPs (e.g.,

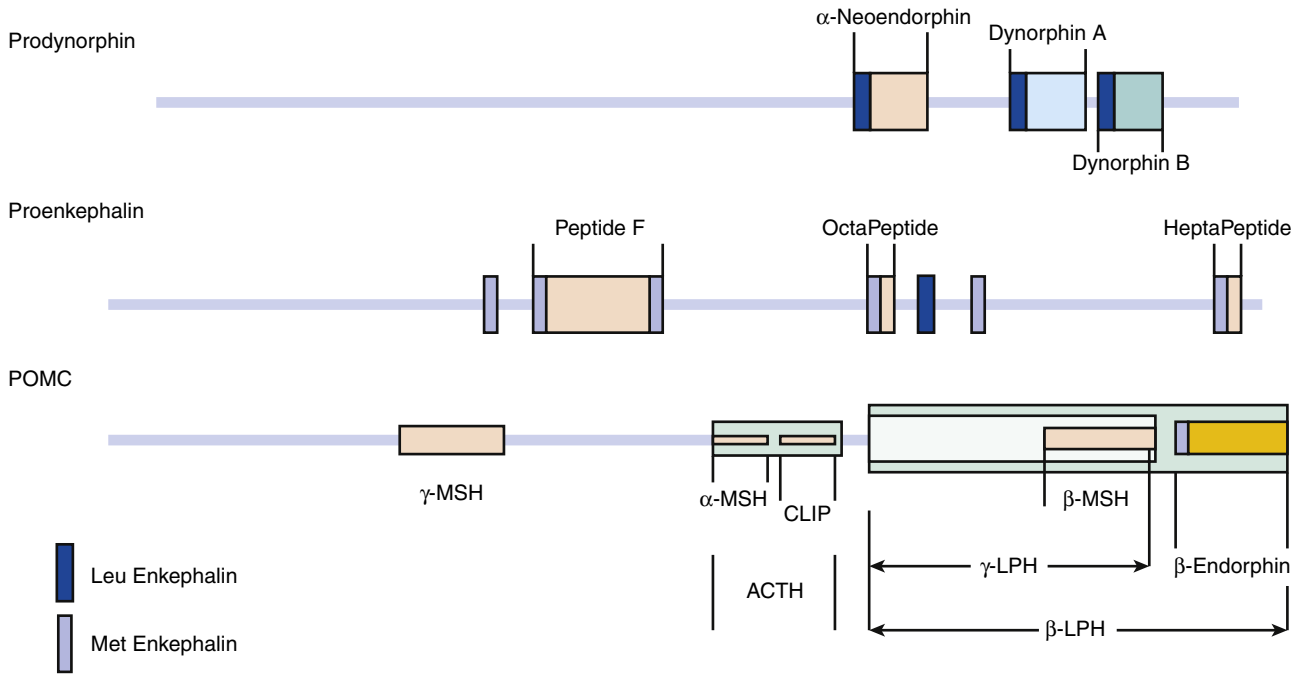

FIGURE 1.13 Schematic of endogenous opiate precursors. POMC, proopiomelanocortin; MSH, melanocyte-stimulating hormone; CLIP, corticotropin-like intermediate lobe peptide; ACTH, adrenocorticotropic hormone; LPH, lipotropin. *(From Akil H, et al. Endogenous opioids: overview and current issues.* Drug Alcohol Depend. *51:127–140, 1998.)*

β-endorphin) in other hypothalamic areas may be involved as well; for example, in the aforementioned study,[97] κ- and μ-receptor antagonists locally administered into the preoptic area increased LH and LH pulse frequency.

Kisspeptin, Neurokinin B, Dynorphin (KNDy) Neurons

In the arcuate nucleus, kisspeptin, NKB, and dynorphin are frequently coexpressed in the same neuron. For example, kisspeptin neurons in the arcuate nucleus have been found to coexpress NKB and dynorphin in mice,[86] goats,[87] and sheep.[99] For convenience, and as a playful nod to kisspeptin (namesake of Hershey's chocolate KISSES®), such neurons are increasingly being called KNDy neurons (Kisspeptin, Neurokinin B, Dynorphin). Available data from human autopsy studies are consistent: 77% of kisspeptin cell bodies (and 56% of kisspeptin axon fibers) in the arcuate (infundibular) nucleus coexpress NKB.[71]

Kisspeptin, Neurokinin B, Dynorphin (KNDy) neurons in the arcuate nucleus form an extensively interconnected network surrounding the third ventricle. KNDy axons also appear to project to the median eminence: in rats, Kiss1/NKB fibers from the arcuate nucleus project to the internal zone of the median eminence where they are in close proximity to GnRH fibers.[100] As with kisspeptin neurons, KNDy neuron neuroanatomy exhibits sexual dimorphism in sheep, possibly related to perinatal sex steroid exposure.[75]

As discussed further below, KNDy neurons appear to be intimately involved with sex steroid feedback on GnRH secretion, and some investigators have suggested that the KNDy neuronal network represents a fundamental component of the GnRH pulse generator, with NKB stimulating and dynorphin inhibiting kisspeptin release.

Gonadotropin-Inhibitory Hormone

The role of gonadotropin-inhibitory hormone (GnIH) and its orthologues, also called RF-amide related peptides (RFRP), in the central control of reproduction has been recently reviewed.[101] Briefly, GnIH immunoreactive cells have been identified in hypothalami of a number of species including monkeys, and GnIH-immunoreactive fibers can be found in close proximity to GnRH neurons and in the median eminence. GnIH can reduce GnRH neuronal activity, and GnIH also appears to have hypophysiotropic actions to directly inhibit pituitary gonadotropin release. A recent study in sheep revealed reduced GnIH expression in the preovulatory period in ewes, suggesting a reciprocal relationship with GnRH release, and infusion of GnIH blocked the estrogen-induced LH surge.[102] GnIH has also been implicated in the regulation of food intake (increase), sexual motivation (decrease), and the influence of stress on reproduction. In sum, a growing body of data suggests that GnIH is an important factor controlling GnRH and gonadotropin secretion in a number of animal species, although an understanding of its role in humans awaits further investigation.

The GnRH Pulse Generator

As described above, intermittent GnRH receptor stimulation is an absolute requirement for physiological maintenance of gonadotropin secretion. Although the precise basis of pulsatile GnRH release remains unclear, a number of observations support the concept that neuronal systems within the mediobasal hypothalamus effect pulsatile release of GnRH into the hypophyseal portal system. In animal models, volleys of multiple unit electrical activity (i.e., detection of activity in multiple neurons near an electrode)

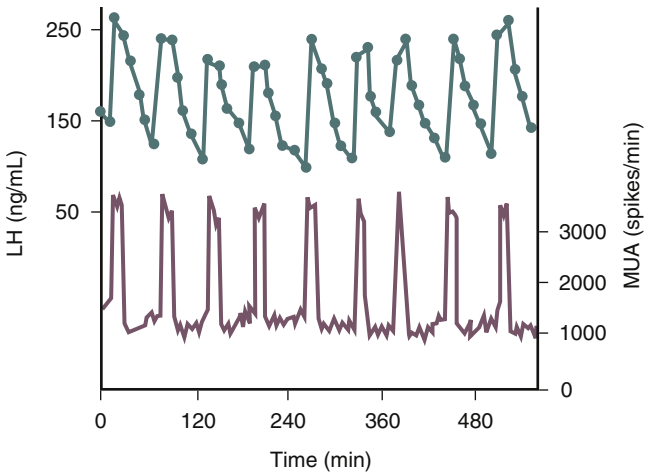

FIGURE 1.14 Temporal association between volleys of multiple unit activity (MUA) in the hypothalamus and luteinizing hormone (LH) pulses (green) detected in peripheral blood in an ovariectomized monkey. *(Adapted from Knobil E. The electrophysiology of the GnRH pulse generator in the rhesus monkey.* J Steroid Biochem *33:669–671, 1989.)*

in the mediobasal hypothalamus coincide with the initiation of LH pulse secretion (Fig. 1.14).[103] Similarly, electrical stimulation via electrodes placed in the mediobasal hypothalamus stimulates GnRH release into the hypophyseal portal system in monkeys.[104] Mediobasal hypothalami isolated from fetal (20 to 23 weeks gestation) and adult humans release GnRH in discrete pulses, with a frequency of approximately one pulse per 60 to 100 minutes[94]; and mediobasal hypothalami separated from the remainder of the brain can maintain pulsatile LH secretion in monkeys.[105] Lastly, selective radiofrequency ablation of the arcuate nucleus (part of the mediobasal hypothalamus) in adult female monkeys obliterates gonadotropin secretion.[106] These data suggest that the mediobasal hypothalamus, the arcuate nucleus in particular, houses all requisite components for GnRH pulse generation (i.e., the GnRH pulse generator) and that pulsatile GnRH release does not require innervation from outside of the mediobasal hypothalamus. Nonetheless, mechanisms underlying episodic GnRH pulse generation, and what neuroanatomical components constitute the GnRH pulse generator, are uncertain.

Several studies suggest that pulsatility is an intrinsic property of GnRH neurons. For example, pulsatile GnRH release is exhibited by immortalized GnRH-secreting neurons[107,108] and by cultured GnRH neurons obtained from fetal rats, sheep, and monkeys.[109-111] If GnRH pulse generation is an intrinsic property of GnRH neurons, then coordination of GnRH release could be facilitated by cell-to-cell interconnections among GnRH neurons.[112,113]

Recent data suggest that afferent inputs (e.g., kisspeptin neurons) are important for normal GnRH secretion, and some investigators have suggested that kisspeptin (KNDy) neurons represent a key component of the GnRH pulse generator, with NKB and dynorphin influencing kisspeptin stimulation of GnRH neurons. As described above, volleys of multiunit activity in the arcuate nucleus are temporally associated with LH pulses; however, in addition to GnRH neurons, the arcuate nucleus contains numerous kisspeptin (KNDy) neurons. Also, kisspeptin release into the hypophyseal portal circulation appears to be pulsatile in sheep and monkeys. Although these kisspeptin pulses were not clearly coincident with peripheral LH pulses in ovariectomized ewes,[114] kisspeptin pulses occurred approximately once per hour and corresponded to GnRH pulses 75% of the time in midpubertal rhesus monkeys.[115]

Although kisspeptin administration did not influence the frequency of LH pulses or volleys of multiple unit electrical activity in the arcuate nucleus in one rat study,[116] administration of a selective kisspeptin antagonist into the arcuate nucleus suppressed LH pulse frequency in another.[117] Also, central administration of dynorphin in goats inhibits both MUA volleys in the mediobasal hypothalamus and pulsatile LH release, whereas NKB provokes MUA volleys.[87] Human studies also imply that kisspeptin may play a role in the GnRH pulse generator. For example, continuous intravenous infusion of a relatively low-dose of kisspeptin can increase LH pulse frequency in adult men.[118] Another recent study in adult men suggested that a single injection of kisspeptin may reset the GnRH pacemaker.[119] In the latter study, the interval between the kisspeptin-induced LH pulse and the immediately preceding endogenous LH pulse was variable, but on average shorter than the normal LH interpulse interval (as expected). In contrast, the interval between the kisspeptin-induced LH pulse and the subsequent endogenous LH pulse was similar to normal interpulse intervals (circa 2 hours), suggesting that kisspeptin administration reset the hypothalamic GnRH clock.

Hypothetical models regarding how KNDy neurons may be involved with GnRH pulse generation are shown in Figure 1.15. However, some data suggest that kisspeptin may not be requisite for GnRH pulse generation. In particular, frequent sampling studies reveal that humans with *KISSR* mutations demonstrate pulsatile LH release, albeit at low amplitude.[53,120] Similarly, a recent study suggested that puberty occurs and fertility is preserved in female mice with either (a) congenital absence of kisspeptin neurons or (b) congenital absence of neurons expressing Kiss1R.[57] When taken as a whole, available data imply that kisspeptin action may not be an absolute requirement for pulsatile GnRH secretion, but that kisspeptin is required for normal GnRH pulse secretion and normally exerts an important influence on GnRH pulse generation.

Physiologic Development of Reproductive Neuroendocrine Function

Patterns of GnRH secretion change markedly across human development. Reproductive neuroendocrine events throughout early maturation, including both before and during the establishment of reproductive competence, are discussed in detail in Chapter 18. Briefly, GnRH and gonadotropin secretion is robust in utero, peaking in midgestation. In males, gonadotropin secretion markedly stimulates testicular androgen secretion, which is important for normal genital differentiation. The gestational increase of sex steroid (e.g., estradiol) production from the fetoplacental unit provides negative feedback to limit fetal GnRH and gonadotropin secretion. Birth is followed by a marked but transient (3 to 9 month) increase of GnRH and gonadotropin secretion (the "mini-puberty of infancy"), perhaps related to the withdrawal of fetoplacental sex steroids.

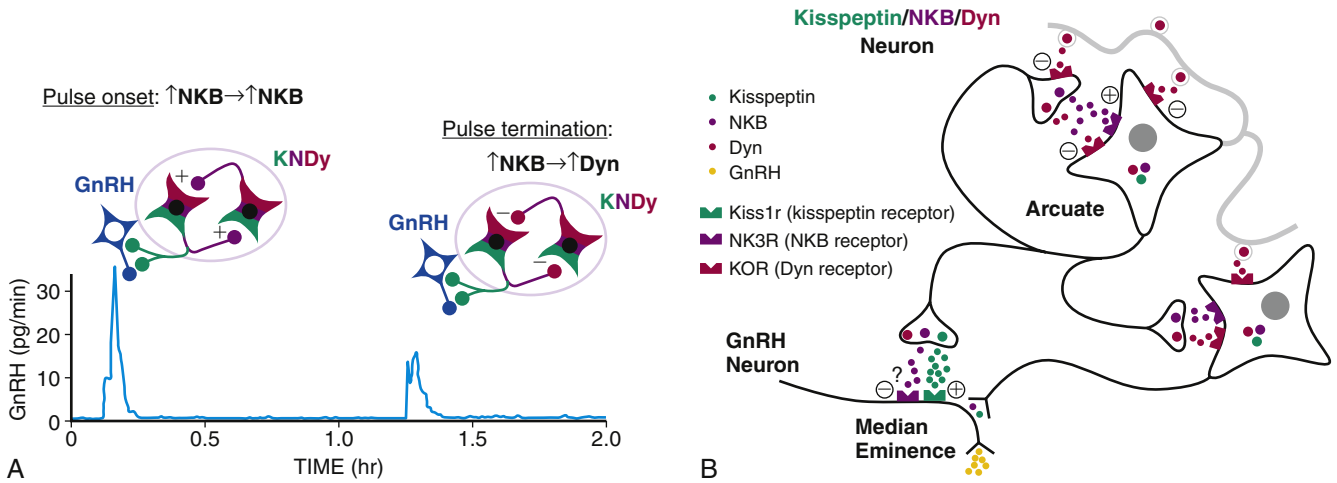

FIGURE 1.15 Working model regarding how KNDy neurons may participate in the generation of GnRH pulses proposed by Lehman and colleagues **(A)** and Wakabayashi and colleagues **(B)**. **A,** By this model, neurokinin B (NKB, magenta) stimulates and dynorphin (DYN, red) suppresses kisspeptin release, with kisspeptin (green) stimulating GnRH neuronal firing. The onset of a GnRH pulse is triggered by an initial increase of NKB, which stimulates further NKB release (positive feedback loop) and increases kisspeptin output. NKB stimulation of KNDy neurons also stimulates DYN release; and after a short period of time, the increase of DYN suppresses kisspeptin (and NKB) release. This withdrawal of kisspeptin stimulation terminates the GnRH pulse. *(From Lehman MN, Coolen LM, Goodman RL. Minireview: kisspeptin/neurokinin B/dynorphin (KNDy) cells of the arcuate nucleus: a central node in the control of gonadotropin-releasing hormone secretion.* Endocrinology. *151:3479–3489, 2010.)* **B,** By this model, KNDy neurons in the arcuate nucleus form a neural circuit, within which neurokinin B (NKB, magenta) accelerates and dynorphin (Dyn, red) reduces KNDy neuron activation. These reciprocal effects of NKB and Dyn produce episodic activation of KNDy neurons, with KNDy neuronal activation increasing kisspeptin release at the median eminence. Kisspeptin in turn stimulates GnRH release into the hypophyseal portal system. KOR, kappa opiate receptor. *(Adapted from Lehman MN et al. Minireview: kisspeptin/neurokinin B/dynorphin (KNDy) cells of the arcuate nucleus: a central node in the control of gonadotropin-releasing hormone secretion.* Endocrinology, *151:3479-3489, 2010; and Wakabayashi Y et al. Neurokinin B and dynorphin A in kisspeptin neurons of the arcuate nucleus participate in generation of periodic oscillation of neural activity driving pulsatile gonadotropin-releasing hormone secretion in the goat.* J Neurosci. *30:3124-3132, 2010.)*

A marked sex difference of gonadotropin release is evident at this time, with LH concentrations being higher in males and FSH levels higher in females. The possibility that kisspeptin is important for the minipuberty of infancy is suggested by a patient with a compound heterozygote mutation of *KISSR*, who had micropenis, undescended testes, and undetectable serum gonadotropins at 2 months of age—a time usually marked by robust gonadotropin secretion.[121]

By late infancy or early childhood (earlier in boys than in girls), GnRH and gonadotropin secretion markedly decreases, leading to a hypogonadotropic phase of childhood marked by low sex steroid concentrations—the "juvenile pause." Studies of gonadotropin secretion in children reveal low LH and FSH concentrations, a high FSH-to-LH ratio, and low LH pulse amplitude and frequency.[122] Mechanisms accounting for low GnRH secretion during this time appear to include inhibition of the GnRH pulse generator ("neurobiological brake") by higher-order neuronal systems (e.g., involving γ-aminobutyric acid [GABA]- and neuropeptide Y-secreting neurons) and a developmental removal of stimulation (e.g., involving neurons secreting glutamate and norepinephrine).

Near the close of the first decade, a marked nocturnal amplification of pulsatile LH secretion indicates the neuroendocrine beginnings of puberty. A majority of studies suggest that early pubertal subjects demonstrate sleep-entrained increases of LH (GnRH) pulse frequency and amplitude.[123] Gonadotropin concentrations rise across puberty,[124,125] stimulating gametogenesis, gonadal sex steroid secretion, and the development of secondary sexual characteristics. Mechanisms underlying puberty are poorly understood, but likely reflect developmental remodeling of inhibitory and stimulatory neural circuits in the hypothalamus. For example, puberty has been associated with reductions of GABAergic inhibitory neurotransmission and an increase of excitatory neurotransmitters such as glutamate. Kisspeptin and NKB also appear to play important roles in human puberty, as inactivating mutations of *KISS1*, *KISS1R*, *TAC3*, or *TACR3* result in pubertal failure; and a gain of function *KISS1R* mutation has been reported as a cause of central precocious puberty.[126] In addition to these transsynaptic mechanisms, neuroglial cells may contribute to the pubertal reactivation of GnRH secretion (e.g., by secretion of growth factors).[1]

Patterns of Pulsatile GnRH Secretion in Adults

Human studies employing frequent blood sampling and pulse detection analysis have documented significant changes of LH (and by inference GnRH) pulse frequency throughout ovulatory cycles. Briefly, average LH (GnRH) pulse frequency is around one pulse every 90 minutes in the early follicular phase, and this gradually increases to approximately one pulse per hour by the late follicular phase. Although monkey studies suggest that GnRH pulse frequency slows during the mid-cycle surge,[127] human studies suggest no change in either LH or α-subunit pulse frequency at midcycle.[128,129] LH pulse frequency slows markedly during the luteal phase, approximating one pulse every 3 to 8 hours. These day-to-day changes of GnRH pulse frequency appear to be important for normal hormonal changes across ovulatory cycles.[130,131]

In adult humans and nonhuman primates, GnRH pulses occur approximately once per hour in the (near) absence of sex steroid negative feedback (e.g., after surgical or natural menopause).[132-134] Similarly, the isolated human mediobasal hypothalamus secretes GnRH pulses every 60 to 100 minutes,[94] and LH pulses do not appear to exceed a once hourly frequency during any phase of the cycle.[133,135] These findings have contributed to the concept that a pulse frequency of approximately one per hour (a "circhoral" frequency) may be an inherent characteristic of the adult GnRH pulse generator, and that day-to-day changes of GnRH pulse frequency in women reflect the imposition or removal of sex steroid (primarily progesterone) negative feedback.

LH pulse amplitude also changes across the menstrual cycle. LH pulse amplitude decreases slightly across much of the follicular phase, but it is greatly amplified at the midcycle LH surge. During the luteal phase, LH pulse amplitude is variable, but in general approximately twofold higher than that of the follicular phase. It is important to note that the amplitude of LH pulses can be modulated centrally via changes of GnRH released per pulse, at the pituitary gonadotrope via changes of gonadotrope responsiveness to GnRH, or both. Also of interest, LH pulse amplitude varies inversely with the preceding LH interpulse interval.[136]

In women, dynamic changes of gonadotropin secretion are required to achieve follicular development, ovulation, and preparation for possible pregnancy. In contrast, young men demonstrate consistent daily patterns of GnRH and gonadotropin secretion, with GnRH pulse frequency approximating 1 pulse every 2 hours. This achieves continuous spermatogenesis, and healthy men are prepared for fertilization at all times. Additionally, day-to-day testosterone secretion remains relatively constant, although testosterone concentrations may exhibit diurnal changes with peaks in the morning.

Feedback Regulation of GnRH and Gonadotropin Secretion

After puberty, gonadal hormones continually relay information about the state of gonadal function to the hypothalamo-pituitary unit. Hypothalamic areas involved with the regulation of GnRH secretion (and pituitary gonadotropes) express receptors for estrogen, progesterone, and androgen; and sex steroid feedback plays a predominant role in the physiological modification of GnRH and gonadotropin secretion. These steroid feedback signals can in turn alter gonadotropin feedforward signals to the gonads by influencing GnRH secretion, modulating pituitary (gonadotrope) responses to GnRH, or both. Under normal circumstances, these regulatory feedback loops maintain appropriate gonadal function. The negative feedback actions of pharmacological doses of sex steroids (e.g., combined oral contraceptives) suppress gonadotropins and can be employed for temporary contraception in women; similar strategies are being developed for men.

Negative Feedback Regulation of GnRH and Gonadotropin Secretion in Women

In women, estradiol concentrations correspond to follicular development during the follicular phase and corpus luteum function in the luteal phase. When concentrations are relatively low (i.e., excluding preovulatory concentrations), estrogens inhibit gonadotropin secretion. This effect is most dramatically illustrated by markedly increased gonadotropin secretion in states of estrogen deficiency (i.e., the open loop condition) such as menopause[137] and aromatase deficiency.[138] The negative feedback effects of estradiol appear to be mediated primarily at the hypothalamus.[139] GnRH release (by direct measurement) is increased in ovariectomized sheep and monkeys, and this is reversed with estrogen replacement.[140,141] In human studies, GnRH release can be estimated using GnRH antagonists, with the premise that the degree of LH suppression after incomplete GnRH antagonism is inversely related to endogenous GnRH secretion. In postmenopausal women, the percent reduction of LH concentrations after incomplete GnRH receptor blockade is increased by estradiol replacement.[142]

Overall, studies indicate that estradiol reduces GnRH pulse amplitude, but not GnRH pulse frequency.[141,143] Although one study in ovariectomized monkeys suggested that estradiol reduces the frequency of both hypothalamic multiple unit electrical activity and LH pulses,[144] available studies in postmenopausal women imply that estrogen replacement primarily reduces LH pulse amplitude rather than LH pulse frequency.[134,145] In addition, LH pulse frequency is maximal at 1 pulse per hour during the late follicular phase in women, when estradiol concentrations are relatively high.

Estrogens may also decrease pituitary LH responses to GnRH, although available data are mixed. For example, although estradiol acutely reduces LH release in GnRH-deficient monkeys and sheep receiving fixed-dose exogenous pulsatile GnRH,[146,147] relatively low (i.e., not preovulatory) doses of estradiol do not markedly influence LH release in GnRH-deficient women receiving fixed-dose exogenous pulsatile GnRH.[37] Interestingly, initial reductions of LH release with estradiol may be followed by increased LH release[148]; this biphasic pattern presumably reflects initial negative feedback and later positive feedback.

Progesterone is the primary negative feedback regulator of day-to-day GnRH pulse frequency in women. LH pulse frequency slows in tandem with increases of progesterone (from the corpus luteum) in the early luteal phase,[135] and LH pulse frequency is inversely correlated with progesterone (but not estradiol) concentrations during the luteal-follicular transition.[149] Moreover, administration of progesterone to women during the follicular phase, when progesterone concentrations are usually low, slows LH pulse frequency.[150] Similarly, progesterone plus low-dose estradiol (but not estradiol alone) slows LH frequency in postmenopausal women.[134,145] Importantly, the ability of progesterone to slow GnRH pulses appears to require the permissive presence of estradiol,[151,152] which likely reflects the ability of estrogen to increase hypothalamic progesterone receptor expression.[153,154] In contrast, progesterone inhibition of GnRH pulse frequency appears to be antagonized by androgens. For example, androgens increase GnRH neuronal firing rates in the mouse model[155]; and in hyperandrogenic women with polycystic ovary syndrome (PCOS), high GnRH pulse frequencies are relatively resistant to negative feedback suppression by progesterone and estradiol[156]—a defect that can be reversed by androgen receptor blockade.[157] These findings may be a consequence

of androgen-mediated reductions of hypothalamic progesterone receptor expression.[158]

Positive Feedback and the Mid-Cycle Gonadotropin Surge

Most examples of endocrine feedback regulation involve negative feedback loops. However, the ovulatory menstrual cycle is unique in that it also depends on the positive feedback effects of sex steroids on the hypothalamic-pituitary unit. Specifically, high estradiol concentrations from the dominant ovarian follicle can produce a marked increase in gonadotropin release—a midcycle (or preovulatory) gonadotropin surge. In effect, estradiol from the preovulatory follicle signals to the hypothalamo-pituitary unit that follicular development is adequate for ovulation. Estradiol positive feedback appears to be related to both achieved estradiol concentrations and the duration of estradiol elevation, as demonstrated in both monkeys[159] and women.[160] Although the midcycle surge is characterized by a marked discharge of both gonadotropins, the increase of LH release exceeds that of FSH, with blood concentrations increasing approximately tenfold vs. fourfold, respectively; thus, it is often called the LH surge.

The mid-cycle gonadotropin surge uniformly involves positive feedback at the pituitary, markedly increasing gonadotrope responsiveness to GnRH stimulation.[161,162] However, whether the gonadotropin surge involves positive feedback at the hypothalamus is likely species dependent. GnRH secretion is augmented during the LH surge in rats[163] and sheep[164]; such "GnRH surges" appear to be physiologically important in these species. Similarly, GnRH release appears to increase in response to estradiol positive feedback in female monkeys.[165,166] However, LH surges can be induced by high estradiol concentrations in GnRH-deficient monkeys receiving constant dose (exogenous) GnRH delivered as once hourly pulses,[167] implying that a GnRH surge is not essential for LH surge generation in these animals.

One study using incomplete GnRH receptor antagonism to estimate GnRH secretion in women suggested that GnRH secretion may actually be reduced at midcycle compared to the late follicular and early luteal phases.[168] Similarly, pulsatile administration of constant-dose exogenous GnRH produces LH surges in GnRH-deficient women[162]; indeed, LH surges can occur in such women even when pulsatile GnRH doses are reduced at midcycle.[169] Also, while pituitary metabolic activity (by positron emission tomography) increases in women at midcycle, hypothalamic metabolic activity does not.[170] Thus, although continued GnRH stimulation plays a critically important permissive role in LH surge generation in women (e.g., the surge can be prevented with GnRH receptor antagonists[171,172]), available data do not suggest that the gonadotropin surge is accompanied by increased GnRH release in women.

Progesterone increases pituitary gonadotropin responses to GnRH[173,174]; when given in the luteal phase, the progesterone receptor antagonist mifepristone decreases mean LH and LH amplitude[175,176] and reduces LH responses to exogenous GnRH.[176] Nonetheless, progesterone by itself is unable to induce gonadotropin surges; indeed, progesterone can block LH surge generation when administered before estradiol in postmenopausal women.[177] However, progesterone augments gonadotropin secretion in estradiol-primed women.[160,178] Although estradiol alone can provoke an LH surge, the late follicular rise in progesterone, which begins approximately 12 hours before the LH surge,[160,179] may be important for the full expression of the midcycle gonadotropin surge. For example, progesterone may increase the duration of the surge,[160] and the progesterone-receptor antagonist mifepristone can delay the surge.[180] Some studies suggest that progesterone may be important for the increase of FSH at midcycle,[177,178] while others suggest that estradiol alone is sufficient to produce an FSH surge.[160,181]

Of interest, although humans demonstrate sexual dimorphism of hypothalamic neuronal populations (e.g., kisspeptin), the circuitry required for LH surge-like activity appears to be present in male primates. For example, in male monkeys orchiectomized after puberty, estradiol administration can induce LH surges,[182] and ovarian transplants can induce LH surges and other neuroendocrine changes that maintain cyclic function of the transplanted ovary.[183] Estradiol and progesterone positive feedback can be experimentally induced in adult men,[184,185] but this is not a normal occurrence in male physiology.

Negative Feedback Regulation of GnRH and Gonadotropin Secretion in Men

In contrast to cyclic changes in women, normal postpubertal males demonstrate a relatively constant average LH pulse frequency of approximately one pulse every 120 minutes, related to relatively stable day-to-day sex steroid concentrations and corresponding negative feedback effects (tonic inhibition). In male monkeys, bilateral orchiectomy increases mean LH, LH pulse frequency, and LH pulse amplitude—effects that are prevented by physiologic testosterone replacement.[186] Similarly, testosterone deficient men (e.g., related to either primary testicular failure or "medical castration" with ketoconazole) exhibit elevated mean LH, LH pulse frequency, and LH pulse amplitude; changes that are at least partially reversed by testosterone replacement.[187-189]

The importance of the androgen receptor in mediating testosterone negative feedback of LH secretion is suggested by elevated LH concentrations in the setting of androgen insensitivity[190] and androgen receptor blockade.[191,192] Moreover, mean LH is reduced in men by administration of dihydrotestosterone (DHT), a potent androgen that cannot be aromatized to estradiol.[193-195] However, a portion of synthesized testosterone is aromatized to estradiol, either in testicular Leydig cells or in nongonadal tissues, and estrogens can exert negative feedback actions at the hypothalamo-pituitary unit. For example, estradiol administration reduces LH secretion in normal and agonadal men.[191,193,196,197] Taken together, these findings suggest that both androgens and estrogens exert negative feedback actions at the hypothalamo-pituitary unit. However, the relative roles of androgen and estrogen binding at their respective receptors at the hypothalamus and anterior pituitary remain controversial.

Many studies suggest that sex steroid negative feedback on the GnRH pulse generator is partly mediated by the androgen receptor. For example, DHT can reduce LH pulse frequency in men,[195] and some[191,192] but not all[198] studies suggest that androgen receptor blockade increases

LH pulse frequency in men. Similarly, the marked increase of LH pulse frequency with high-dose ketoconazole (which inhibits both testicular/adrenal steroidogenesis and aromatase activity) is completely reversed by testosterone replacement despite low estradiol concentrations, while LH frequency is only partly normalized with estradiol add-back (with persistently low testosterone concentrations).[189] On the other hand, aromatase inhibitors[199] and antiestrogens[196,200-202] increase LH pulse frequency in normal men, and estrogen treatment in men with aromatase deficiency reduces LH pulse frequency.[203] Overall, these data suggest that both androgens and estrogens mediate negative feedback of hypothalamic GnRH secretion.

In contrast to dual (androgen, estrogen) steroid feedback on GnRH pulse secretion, a number of studies suggest that estradiol is a primary mediator of negative feedback at the pituitary in men.[189,193,197,204] For example, androgen receptor blockade does not alter LH responses to exogenous GnRH in some studies,[192,198] and aromatase inhibition appears to prevent testosterone's ability to reduce GnRH-stimulated LH and FSH secretion.[188] Perhaps the most compelling studies were performed in GnRH-deficient men receiving pulsatile exogenous GnRH in constant doses. Under this "GnRH clamp" paradigm, testosterone alone and estradiol alone (but not DHT alone) reduced LH and FSH concentrations.[204] In another "GnRH clamp" study, LH amplitude and mean LH increased after high-dose ketoconazole, and LH parameters were normalized with estradiol, but not testosterone, add-back.[189] Overall, these study results imply that estradiol is the primary mediator of testosterone negative feedback at the pituitary gonadotrope.

Kisspeptin and KNDy Neurons as Mediators of Sex Steroid Feedback

Evidence in rodents, sheep, and monkeys suggests that sex steroid feedback on GnRH secretion is mediated by KNDy neurons and kisspeptin, at least in part. For example, kisspeptin and KNDy neurons show a high degree of colocalization with estrogen receptors,[72] progesterone receptors,[96] and androgen receptors.[205] The numbers of kisspeptin neurons are high in the arcuate nucleus of humans and monkeys.[65,70,71] In the monkey, kisspeptin expression is markedly reduced by estrogen or estrogen plus progesterone.[70] Also, in animal models and in postmenopausal women, sex steroid deficiency is associated with increased kisspeptin expression in the arcuate nucleus (in parallel with circulating gonadotropins), and this is reversed by estradiol or testosterone replacement.[70,72] In addition to influencing kisspeptin expression, estrogen modulates neuronal responsiveness to kisspeptin in mice.[63] A model regarding the influence of KNDy neurons in negative feedback is shown in Figure 1.16.

Kisspeptin also appears to play a key role in the midcycle LH surge in the female rodent. *Kiss1* and *Kiss1R* null mice do not exhibit LH surges,[206] and the LH surge can be prevented by a kisspeptin antagonist[207] or a monoclonal antibody to kisspeptin.[208] Of particular interest, available data in rodents suggest that kisspeptin neurons in the AVPV are stimulated by estradiol, while those in the arcuate nucleus are inhibited by estradiol.[72] Also, estradiol administration directly into the medial preoptic area (location of the AVPV) induces LH surges, while estradiol administration directly into the mediobasal hypothalamus—which also raises estradiol levels in the pituitary—does not.[209] These and other findings in rodents have led to a model in which kisspeptin neurons in the arcuate nucleus regulate tonic GnRH release by mediating estrogen negative feedback, while kisspeptin neurons in the AVPV mediate the positive feedback effects of estrogen (Fig. 1.17).

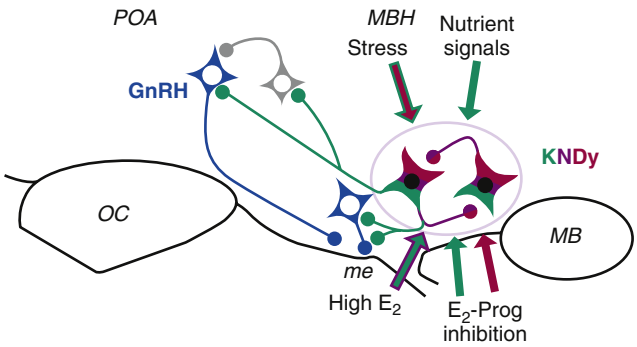

FIGURE 1.16 Model of KNDy signaling to GnRH neurons, largely based on data obtained in sheep. KNDy peptides are kisspeptin (green), which stimulates GnRH neurons; neurokinin B (NKB, magenta); and dynorphin (red). The major influences on GnRH secretion are shown, with putative effects on KNDy peptides denoted by the color of the arrow. For example, estradiol (E_2) inhibition may involve reductions of kisspeptin (green arrow), while progesterone (Prog) inhibition likely involves an increase of DYN. Arrows with two colors signify that more than one KNDy peptide may mediate a given effect (e.g., in the ewe, stimulation of GnRH secretion by high E_2 may involve an increase of both kisspeptin and NKB). The possibility that kisspeptin stimulation of GnRH neurons is mediated by interneurons is shown by the gray cell. POA, preoptic area; MBH, mediobasal hypothalamus; MB, mammillary bodies; ME, median eminence; OC, optic chiasm. *(Adapted from Lehman MN, Coolen LM, Goodman RL. Minireview: kisspeptin/neurokinin B/dynorphin (KNDy) cells of the arcuate nucleus: a central node in the control of gonadotropin-releasing hormone secretion.* Endocrinology. *151:3479–3489, 2010.)*

It remains unclear whether a population of kisspeptin neurons homologous to those in the AVPV of rodents plays a similar role in primates. While LH surge generation requires an intact preoptic area in rodents,[210] monkeys retain the ability to produce LH surges after isolation of the mediobasal hypothalamus from the remainder of the brain.[105] Also, LH surges persisted after destruction of the preoptic area, which included the AVPV and suprachiasmatic nuclei, in one monkey study,[211] but not in another.[212] While human and monkey studies suggest the presence of kisspeptin neurons in the preoptic area,[70,71,213] it is unclear whether these are truly analogous to those of the AVPV in rodents. Of interest, kisspeptin expression increases in a caudal portion of the arcuate nucleus during the preovulatory period in both monkeys and sheep,[213-215] and some have suggested that kisspeptin neurons in this region could possibly represent a special population important for surge generation. Regardless, it is not certain that a unique population of kisspeptin neurons need be invoked in women, as increased GnRH secretion at mid-cycle (i.e., a GnRH surge) does not clearly occur in women (described earlier in the chapter). Thus, how these intriguing observations in animal models relate to human neurophysiology during midcycle remains unclear.

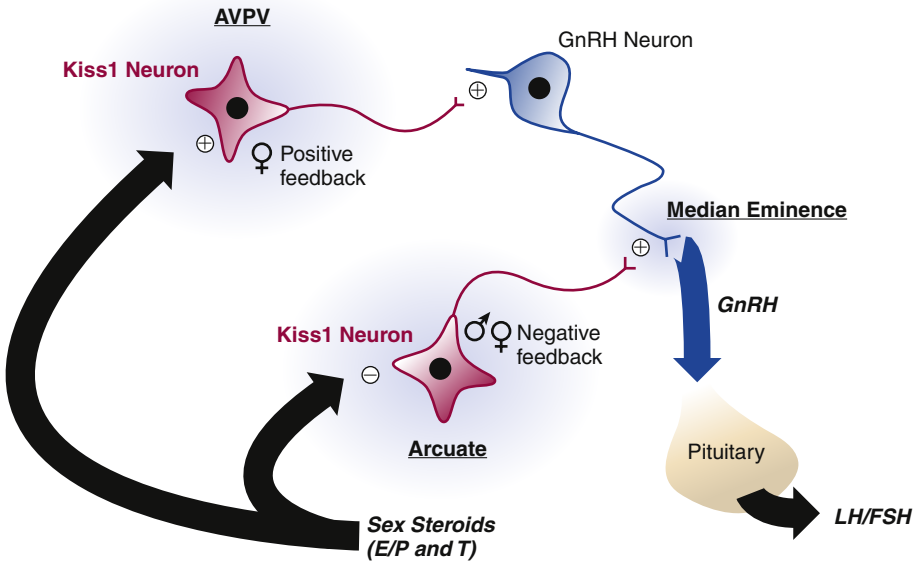

FIGURE 1.17 Model of kisspeptin-mediated feedback regulation of GnRH and gonadotropin secretion in rodents. By this model, kisspeptin (Kiss1) neurons in the arcuate nucleus of males and females project to and stimulate GnRH neurons. This population of kisspeptin neurons is inhibited by sex-appropriate gonadal steroids (i.e., estradiol [E], progesterone [P], and testosterone [T]). Thus, tonic GnRH secretion is primarily regulated by relatively low concentrations of estradiol via kisspeptin neurons in the arcuate nucleus. Females have another population of kisspeptin neurons in the anteroventral periventricular nucleus (AVPV) that also projects to and stimulates GnRH secretion. However, estradiol stimulates kisspeptin neurons in the AVPV—in contrast to estradiol inhibition of kisspeptin neurons in the arcuate nucleus. Thus, while high estradiol concentrations inhibit arcuate kisspetin neurons in females, they stimulate AVPV kisspeptin neurons, resulting in a GnRH surge. LH, luteinizing hormone; FSH, follicle-stimulating hormone. *(From Oakley AE, Clifton DK, Steiner RA. Kisspeptin signaling in the brain.* Endocrine Reviews *30:713–743, 2009.)*

Selective Regulation of Pituitary FSH Secretion

Inhibins, activins, and follistatin preferentially influence FSH secretion and contribute to divergent release of LH and FSH throughout the menstrual cycle.[38] During the midfollicular to late follicular phase and the luteal phase, both estradiol and inhibins selectively inhibit FSH release from gonadotropes. Inhibins are heterodimer peptide members of the transforming growth factor (TGF)-β superfamily with two isoforms, inhibin A and inhibin B, which contain identical α-subunits but different β-subunits (βA for inhibin A, βB for inhibin B). Most inhibin is derived from the ovaries: inhibin B is secreted by ovarian granulosa cells, mainly during the early follicular phase in response to FSH stimulation; and inhibin A is primarily produced by the corpus luteum during the luteal phase in response to LH stimulation. The chief function of both inhibins is to inhibit FSH release from pituitary gonadotropes. In men, inhibin B is produced from Sertoli cells and is a key negative feedback regulator of pituitary FSH release, although estradiol also inhibits pituitary FSH release.[216]

Activin is a dimer peptide with three isoforms: activin A (βAβA), activin B (βBβB), and activin AB (βAβB). The activin β-subunits and the inhibin β-subunits are identical. Activin produced in pituitary gonadotropes stimulates production of FSH in a paracrine fashion. Follistatin is a monomer peptide synthesized by the anterior pituitary (including folliculostellate cells); it inhibits pituitary FSH secretion by binding activin, thus rendering it inactive. Of interest, gonadotrope follistatin production varies in parallel with GnRH pulse frequency, one of the mechanisms contributing to the differential effects of GnRH pulse frequency on LH and FSH release.[44,217] In contrast to inhibins, which act primarily via endocrine signaling, activin and follistatin produced in the pituitary influence FSH secretion via autocrine-paracrine signaling.

Interface Between Reproduction and Energy Availability

Organisms require metabolic energy to support a number of processes, including maintenance of cellular function, muscle contraction (e.g., cardiac function, locomotion), thermogenesis, and growth. For various reasons, energy availability can be limited—sometimes severely so. For example, low energy availability may result from short-term or long-term reductions of calorie intake (e.g., famine, anorexia nervosa), insufficient calorie intake for metabolic demands (e.g., in the setting of significant exercise loads), or reduced ability to utilize energy sources (e.g., as may occur in severe diabetes). In such situations, energy use has opportunity costs: energy used for one process is no longer available for another. Thus, energy-requiring processes are prioritized to favor those that are life-sustaining.

Reproduction in women, pregnancy and lactation in particular, is metabolically demanding. For example, pregnancy requires an estimated additional 80,000 kilocalories.[218] Since reproduction is not imperative for individual survival, it is metabolically gated: reductions of energy availability can suppress reproductive function (nutritional infertility). This is biologically advantageous for the individual and, ultimately, the species. As such, it can be seen as an appropriate adaptive response. This process is believed to

be at the center of functional hypothalamic amenorrhea, a reversible condition of suppressed hypothalamic-pituitary function occurring in the absence of anatomical or organic abnormalities and often accompanied by reduced body weight, disordered eating (e.g., restrictive eating patterns), excessive exercise, and/or psychological stress. Prototypical examples include the amenorrhea of anorexia nervosa, a disorder marked by weight loss, altered body image, and fear of weight gain; and the "female athletic triad," which classically refers to the clinical association of amenorrhea, osteoporosis, and reduced energy availability related to vigorous exercise and disordered eating. The functional relationships between metabolic status and reproductive function are mediated by neural systems located in the hypothalamus.

Functional hypothalamic amenorrhea is characterized by impaired GnRH and gonadotropin secretion. Although a majority of women with functional hypothalamic amenorrhea demonstrate low LH pulse frequency,[219,220] such patients may demonstrate variable LH pulse patterns as a group—including absent pulses, low frequency and amplitude, low frequency only, low amplitude only, and normal frequency and amplitude; and patterns can change across time in the same woman.[7,219,220] In these patients, GnRH and gonadotropin secretion is inadequate for normal follicular development, estrogen production, and mid-cycle gonadotropin surges, but cyclic ovulation and fertility can be restored with pulsatile administration of exogenous GnRH.[7]

Some investigators have proposed that reduced reproductive function in functional hypothalamic amenorrhea primarily reflects insufficient body fat stores—the "critical fatness hypothesis."[221] This idea has been controversial, and a substantial body of data suggests that reduced energy availability, rather than body fat per se, is a primary variable driving reduced reproductive function in these settings. For example, there is marked variability of body fat percentage in athletes with and without amenorrhea, and body fat does not reliably distinguish amenorrheic from eumenorrheic athletes.[222] Also, calorie restriction can result in amenorrhea before weight loss; and in those with a history of eating disorders, amenorrhea can persist after weight restoration.[223] Likewise, findings consistent with functional hypothalamic amenorrhea can be observed shortly after bariatric surgery for severe obesity; importantly, the onset of amenorrhea can occur while still obese (e.g., body mass approximately 35 kg/m^2), albeit in the setting of negative energy balance.[224] Moreover, altered LH pulsatility is observed very quickly (within 5 days) of controlled reductions of energy availability.[225] Overall, these findings suggest that altered reproductive function in this setting reflects altered energy availability rather than body composition. It is also important to note that energy balance (and thus body weight) can be maintained in the face of calorie restriction by reducing metabolic rate[226]; this situation involves reduced energy availability for "noncritical" functions such as reproduction. Also of interest, experiments in women and monkeys suggest that reproductive function may not be impaired until energy availability is reduced by more than 30% (Fig. 1.18).[225,227]

While some have posited a specific influence of exercise, calorie supplementation to maintain adequate energy availability appears to prevent alterations of LH secretion despite significant daily exercise loads.[228] Similarly, while amenorrhea can be induced in monkeys by gradually increasing daily exercise in the setting of constant food intake,[229] providing supplemental calories reverses amenorrhea despite continued exercise.[230]

The neurobiological mechanisms underlying functional hypothalamic amenorrhea, and mechanisms underlying the influence of nutritional status on the reproductive system in general, remain poorly understood. Chronic energy deprivation is associated with myriad neuroendocrine adaptations and hormonal changes, including reductions of leptin, insulin, insulin-like growth hormone-1 (IGF-1), and thyroid hormone concentrations; increases of growth hormone and ghrelin levels; and activation of the hypothalamic-pituitary-adrenal axis.[231] A number of these alterations can influence GnRH and gonadotropin secretion and may mediate the influence of low energy availability on reproductive function. Much interest has centered on the permissive role of leptin, a hormone derived from adipose tissue that functions to signal metabolic status to central systems, influencing feeding, energy expenditure, and reproduction. Humans and mice lacking leptin or the leptin receptor (LepR) (e.g., ob/ob and db/db mice, respectively) have pubertal failure and infertility; in the setting of leptin deficiency, these manifestations can be reversed with leptin administration.[232,233] Low leptin levels have also been observed in women with functional hypothalamic amenorrhea,[234] and a specific role for leptin was suggested by a small study in which recombinant human leptin administration improved LH pulse secretion and parameters of ovarian function (e.g., estradiol concentrations) in women with functional hypothalamic amenorrhea; leptin administration was also associated with ovulation in a subgroup of these subjects.[235] While serum leptin concentrations generally correlate with fat mass, leptin levels can change rapidly in response to reduced energy availability; and leptin concentrations are suppressed with maneuvers known to suppress LH secretion, such as marked short-term energy restriction.[236] Of interest, exogenous leptin administration prevents the fall of LH release and testosterone concentrations associated with short-term fasting in men.[237] Although the precise role of leptin in regulating reproductive neuroendocrine function is unclear, it is believed that leptin has an important permissive role in normal GnRH secretion.

Similarly, a number of neuropeptides have been implicated in the influence of energy availability on reproductive function, including kisspeptin, neuropeptide Y (NPY), galanin-like peptide (GALP), beta-endorphin, corticotropin-releasing hormone (CRH), ghrelin, and polypeptide YY. While metabolic signals could potentially act directly on GnRH neurons, many studies suggest that afferent neural circuits are involved. For example, recent studies in mice suggest that metabolic signals can be relayed to the GnRH pulse generator from different areas in the brain, such as the ventral premammillary nucleus (e.g., leptin effects)[238] and the area postrema (e.g., in the absence of utilizable glucose).[239] Some studies suggest that increased opioid tone may contribute to slow GnRH pulses in functional hypothalamic amenorrhea.[220,240-242]

Even though successful reproduction is not metabolically costly for males, male reproductive function can also be affected by metabolic stress. For example, healthy young

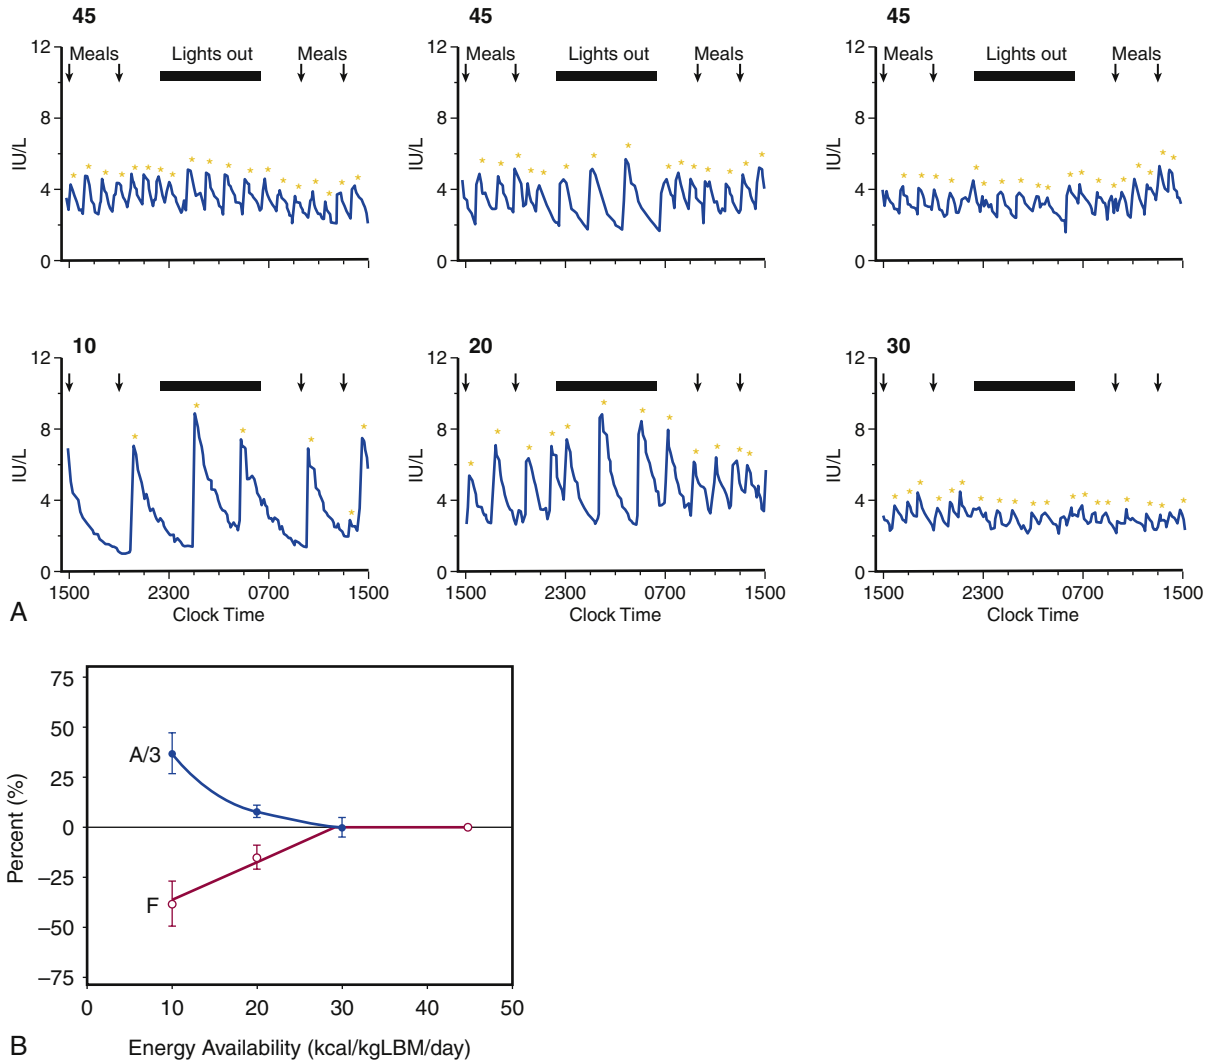

FIGURE 1.18 Influence of energy availability on LH pulsatility in healthy women. **(A)** Representative 24-hour LH time series in three women under different conditions of energy availability. These studies were designed to assess the effects of exercise and reduced energy availability in habitually sedentary women with regular menstrual cycles. In this study, exercise energy expenditure was substantial for all participants at approximately 840 kcal/day, and energy availability was altered via variable calorie intake. When energy availability is defined as dietary energy intake minus exercise energy expenditure—an estimate of the energy available for non-exercise related functions—and normalized to fat-free mass (thus expressed as kcal/kg lean body mass [LBM] per day), 45 kcal/kg LBM per day approximates balanced energy availability, and LH profiles under this condition are shown on top. Conditions of restricted energy availability (i.e., 10, 20, and 30 kcal/kg LBM per day) are shown along the bottom. Significant LH pulses are denoted by asterisks; arrows denote the timing of meals; and black bars denote lights out periods. **(B)** Association of energy availability and LH pulse characteristics. Energy availability is shown on the x-axis; on the y-axis, LH pulse amplitude (solid circles) and LH pulse frequency (open circles) are expressed as changes relative to values observed at 45 kcal/kg LBM per day. (Note that changes of LH pulse amplitude are divided by three.) While energy availability reductions to 30 kcal/kg LBM per day did not alter LH pulse characteristics, reductions below 30 kcal/kg LBM per day were associated with progressive reductions of LH pulse frequency and corresponding increases of LH pulse amplitude. *(Adapted from Loucks AB, Thuma JR. Luteinizing hormone pulsatility is disrupted at a threshold of energy availability in regularly menstruating women.* J Clin Endocrinol Metab *88:297–311, 2003.)*

men participating in U.S. Army Ranger training, which involves multiple stressors including intermittent extreme calorie restriction and weight loss (10 to 12 kg on average), can experience reductions of LH and suppression of testosterone concentrations to near castrate levels.[243] Of interest, increased calorie intake allowed prompt recovery of testosterone in this study, even without altering other associated stressors (e.g., exercise, sleep deprivation). Additionally, anorexia nervosa in adolescent boys and men can be associated with marked hypogonadotropic hypogonadism.[244] Energy-sensitive reproductive function in males would also be expected to delay reproduction during times of reduced energy availability; these regulatory pathways may have developed in males because of advantages imparted to other members of the species (e.g., mates and offspring).

Impact of Stress on Reproductive Function

Functional hypothalamic amenorrhea in the setting of reduced energy availability represents a particular form of stress-related reproductive suppression. A "stressor" represents a real or potential threat to homeostasis, such as

predator proximity, injury, illness (e.g., systemic infection), temperature extremes, reduced energy availability (e.g., fasting), and situations that provoke psychological distress. The nature of the stress response depends on the precise nature of the stressor, but typically involves both neural and neuroendocrine responses. A group of neurons in the hypothalamic paraventricular nucleus project to the median eminence, where they secrete corticotropin-releasing hormone (CRH) into the hypophyseal portal system. CRH (and, to some degree, cosecreted arginine vasopressin [AVP]) stimulates corticotrope cells in the anterior pituitary to release adrenocorticotropic hormone (ACTH), which in turn stimulates adrenal glucocorticoid (cortisol) production. A subset of paraventricular neurons is also involved with the regulation of the autonomic sympathetic nervous system, which includes neural pathways linked to the brain stem, spinal cord, and adrenal medulla (e.g., sympathoadrenal axis). Other components of the stress response include central arousal systems and the locus ceruleus, a nucleus in the brainstem involved with emotional and cognitive responses to stress. Thus, stressors trigger integrated neural, endocrine, and behavioral responses that promote short-term maintenance of homeostasis and survival. For example, activation of the sympathoadrenal axis leads to increased epinephrine secretion—an important component of the "fight-or-flight" response—while activation of the hypothalamic-pituitary-adrenal (HPA) axis with increased cortisol secretion enhances energy mobilization.

Chronic stress and marked acute stress can inhibit reproductive function—an appropriate adaptive response when homeostasis is threatened. For example, critical illness is associated with a reversible hypogonadotropic hypogonadism.[245,246] Mechanisms underlying the suppression of reproductive function during stress are highly complex; and while suppression of GnRH secretion is a major component, direct pituitary and gonadal effects may occur as well. Notably, the specific effects of stress on various aspects of reproductive function appear to depend on a number of factors including species, sex, hormonal milieu (e.g., intact vs. castrate), and the specific type of stress experienced.

A number of mediators have been implicated in stress-related inhibition of GnRH secretion, including CRH (which activates the HPA axis but also appears to have central effects), CRH-like peptides called urocortins, AVP, ACTH, endogenous opioid peptides (e.g., β-endorphin), and cortisol, in addition to noradrenergic, GABAergic, and serotoninergic neural pathways. For example, intracerebroventricular injection of CRH reduces multiple unit electrical activity in the mediobasal hypothalamus in monkeys[247]; and CRH antagonists can prevent some forms of stress-related LH suppression.[248] Naloxone can block CRH-related LH suppression in monkeys,[249] suggesting the involvement of endogenous opioid peptides as well. Noradrenergic afferents from the locus ceruleus have also been implicated in GnRH pulse generator suppression.

Notably, some data suggest that stress plays a role in functional hypothalamic amenorrhea. For example, amenorrheic athletes and women with anorexia nervosa demonstrate evidence of HPA axis activation (e.g., elevated cortisol concentrations).[231,250] Also, functional hypothalamic amenorrhea in women may be associated with evidence of higher psychological stress, including perfectionism, a history of unfavorable childhood experiences, and difficulty coping with stressors[251,252]; and reproductive function may be improved in some with cognitive behavioral therapy[253] or hypnotherapy.[254] Studies in female monkeys provide corroborating evidence: in one study, while very few monkeys demonstrated altered reproductive function when exposed to either (a) psychosocial stress (relocation to new housing setting with unfamiliar monkeys) or (b) mild dietary restriction plus daily exercise, the combination was associated with altered cycle length or anovulation in a majority.[255]

For unclear reasons, the degree to which stressors (e.g., reduced energy availability) interrupt reproductive function is variable among individual women and in female monkeys (i.e., "hypothalamus robustus" vs. "hypothalamus fragilis," "stress sensitive" vs. "stress resilient"). As suggested above, it is likely that a number of factors (e.g., reduced energy availability, stress) can interact to impact GnRH secretion. Also, a recent study suggested that mutations in genes associated with hypogonadotropic hypogonadism, including Kallmann syndrome 1 sequence gene *(KAL1)*, fibroblast growth factor receptor 1 gene *(FGFR1)*, prokineticin receptor 2 gene *(PROKR2)*, and the GnRH receptor gene *(GNRHR)*, are more likely to be identified in women with functional hypothalamic amenorrhea compared to normally cycling women.[256] Thus, it seems likely that genetic variants (e.g., those related to GnRH neuron biology), and perhaps epigenetic modifications as well, play a role in reproductive susceptibility to reduced energy availability and stress.

Lactation

High prolactin concentrations during pregnancy and suckling in the postpartum period stimulate milk production, which, for much of human history, was effectively the only source of nutrition for infants. Suckling also leads to posterior pituitary release of oxytocin, which stimulates contraction of myoepithelial cells within mammary gland acini, causing milk ejection. Lactation is also associated with amenorrhea and subfertility. The likelihood of pregnancy during the first 6 months postpartum is low (less than 2%) in fully-breastfeeding, amenorrheic women,[257] and some lactating women may remain amenorrheic for years. Since a short interval between births can place infant well-being at risk, lactational amenorrhea has ostensibly been an important adaptation enhancing infant survival in many cultures both past and present.[258]

During pregnancy, high placental sex steroid (estradiol, progesterone) and prolactin concentrations markedly suppress GnRH and gonadotropin secretion and prevent follicular development. In the absence of lactation, cyclic hypothalamic-pituitary-ovarian activity typically resumes in the 8 weeks after parturition. In the setting of lactation, however, pulsatile GnRH remains suppressed (e.g., low frequency pulses), with consequent impairment of LH secretion and estradiol production.[259] The reduction of GnRH secretion during lactation is suggested by a marked reduction of multiple unit electrical activity in the mediobasal hypothalamus in nursing monkeys,[260] and by the ability of pulsatile exogenous GnRH to restore ovarian function in amenorrheic lactating women.[261]

Mechanisms underlying lactational amenorrhea are incompletely understood. Lactation is associated with a very high metabolic cost: daily production of 750 to 1000 mL of human milk requires approximately 500 to 600 kilocalories a day,[262] some of which is obtained from fat stores and increased food intake. Nonetheless, the high energy requirements of lactation—which are approximately twice that of pregnancy—may induce some or all of the aforementioned mechanisms that inhibit pulsatile GnRH secretion in the setting of reduced energy availability. As recently reviewed,[263] animal (chiefly rodent) studies reveal that lactation is associated with activation of orexigenic neural systems (e.g., neuropeptide Y [NPY]) and inhibition of anorexigenic neural systems within the hypothalamus—changes that may partly relate to alterations of peripheral metabolic cues (e.g., leptin, insulin). Such alterations increase food intake and may suppress GnRH neuronal activity, either by direct effects on the GnRH neuronal network or by modification of key afferent systems such as kisspeptin. As an example of the former, NPY neuronal activation during lactation may directly inhibit GnRH neuronal activity.[264] As an example of the latter, expression of both kisspeptin and NKB in the arcuate nucleus is reduced in lactating rodents.[100,265]

Hyperprolactinemia suppresses GnRH pulsatility, at least in part via increased hypothalamic opioids,[266] and suppression of GnRH secretion during periods of lactation may partly reflect high prolactin concentrations. However, prolactin levels gradually decrease to normal despite continued breastfeeding; thus, the activity of the hypothalamic-pituitary-ovarian may not correlate well with circulating prolactin concentrations. Importantly, the intensity (e.g., frequency, duration) of suckling appears to be an important determinant of contraceptive effectiveness in women, and the suckling stimulus may inhibit the hypothalamic-pituitary-ovarian axis through additional (e.g., neural) mechanisms.

Miscellaneous Physiological Influences on GnRH Secretion

Circadian Changes

Diurnal rhythms (i.e., those that cycle once a day) are frequently observed in endocrinology, and this includes the reproductive system. Diurnal rhythms are called circadian rhythms if they are internally (endogenously)-driven rhythms, although such rhythms are usually entrained (synchronized) to environmental cues (e.g., light-dark cycle). Circadian rhythms are dictated by a "master clock" located in the suprachiasmatic nucleus of the hypothalamus and are derived from complex intracellular interactions involving the so-called "clock genes," which participate in feedback interactions that generate recurring cyclic activity.[267] Such clocks in the suprachiasmatic nucleus can be synchronized by light-dark signals received from the retina and transferred to the suprachiasmatic nucleus via the optic nerve (retinohypothalamic tract).

Depending on factors such as species and sex, both basal gonadotropin secretion and LH surges may exhibit diurnal rhythms. As a prominent example, LH surges in female rats are specifically confined to the late afternoon, which is shortly before rats become active (i.e., when copulation is most likely).[268] It is believed that this reflects a daily stimulus generated by the suprachiasmatic nucleus, but only relayed to the GnRH neuronal network in the presence of preovulatory estradiol concentrations. Thus, ovulation in rats is optimally timed to coincide with sexual opportunity and receptivity.

In contrast to rodents, LH surges do not appear to be constrained to a specific time of day in monkeys; for example, LH surges can be advanced by 12 to 18 hours with supraphysiological estradiol administration.[159] Some studies in women suggest that LH surges tend to be initiated in the morning. For example, in one study of 19 ovulatory women, LH surges were initiated in the early morning hours (circa 0400 to 0800 hours)[269]; and in one study of 155 spontaneous cycles, the estimated time of LH surge initiation was between midnight and 8:00 AM in 85% of cycles.[270] These studies do not confirm a true circadian signal, and putative confinement of ovulation to the morning hours could reflect diurnal environmental cues. In addition, the potential relevance of a specific daily timing of ovulation in women is uncertain since ovulation typically occurs some 36 hours after the LH surge; and the likelihood of conception when sexual intercourse occurs on the day before ovulation (circa 40%) is similar to conception rates when intercourse occurs on the day of ovulation.[271] Although humans demonstrate clear diurnal changes of gonadotropins, recent studies in women who were carefully assessed during the early follicular phase[272] or after menopause[273] suggest that LH and FSH secretory parameters (including LH pulse frequency and amplitude) do not exhibit circadian changes after controlling for sleep status, body position, light exposure, activity level, and nutritional cues.

Sleep

Although precise mechanisms are unclear, sleep can have a major influence on pulsatile LH (and presumably GnRH) secretion. For example, the nocturnal amplification of LH pulsatility during puberty is specifically related to sleep: it generally begins within an hour of sleep onset, and it follows sleep reversal.[274,275] Although the data relating LH pulses to sleep stage are incomplete, sleep-related pulses during puberty appear to occur primarily during non-rapid eye movement (REM) sleep.[274,275]

Sleep also influences LH pulse secretion in adults, primarily in the form of sleep-related slowing of LH pulse frequency, which is most prominent during the early follicular phase,[133,135,276,277] but also occurs in the late follicular phase.[225,278] Nocturnal slowing of LH pulse frequency in women during the early follicular phase is specifically related to sleep, as it follows sleep reversal.[279] During this time, LH pulses are uncommon during REM and slow wave sleep, and more common following brief awakenings.[279] Such slowing may be mediated by hypothalamic opioids, since naloxone prevents the sleep-associated decrease of LH pulse frequency.[280]

Taken together, these data imply that sleep influences LH pulse frequency, and that the effect of sleep can be modulated by factors such as developmental stage and sex steroid milieu. The physiological relevance of sleep-associated changes of GnRH secretion remains unclear, but such changes have been postulated to contribute to normal gonadotropin production across puberty[123] and to the early follicular prominence of FSH secretion in postpubertal women.[279]

Pheromones

Pheromones are chemicals transmitted through the air that can influence reproductive function and sexual behavior (e.g., to produce stereotyped behaviors, neuroendocrine changes) in other individuals within many mammalian species. For example, the presence of a novel and sexually mature male mouse can synchronize estrous cycles among female mice; this so-called "Whitten effect" is presumably mediated by pheromones.[281] Similarly, pheromones produced by male sheep and goats can induce out-of-season ovulation in females—the "male effect."[282]

The role of pheromones in humans remains unclear. Menstrual synchrony (sometimes called the McClintock effect) is a putative phenomenon in which menstrual cycles of women living in very close proximity become synchronized.[283] This has been cited as physiological evidence of pheromone functionality in humans, and axillary secretion from late follicular women has also been reported to advance ovulatory timing in recipient women.[284] However, supportive research has been criticized on methodological grounds, and the existence of this phenomenon remains controversial.[285] Also, while the vomeronasal organ—believed to be responsible for pheromone detection in animals—develops in utero in humans, it subsequently regresses and is largely believed to be nonfunctional in adults.[286]

CHAPTER 2

The Gonadotropin Hormones and Their Receptors*

Mario Ascoli
Prema Narayan

Gonadal functions, gametogenesis and steroidogenesis, are regulated by a hypothalamic decapeptide, gonadotropin-releasing hormone (GnRH), and two anterior pituitary gonadotropins: luteinizing hormone (LH) and follicle stimulating hormone (FSH). Along with placental-derived human chorionic gonadotropin (hCG), these three gonadotropins regulate androgen, estrogen and progesterone synthesis, oogenesis, spermatogenesis, ovulation, and the maintenance of early pregnancy.

Structurally, the three gonadotropins, and the highly related thyroid-stimulating hormone (TSH) exist as heterodimers; sharing a common α subunit and homologous hormone-specific β subunits. They are highly elongated molecules with two intertwined subunits that have similar conformations. They are also members of the larger cystine knot-containing growth factor family that includes transforming growth factor β (TGFβ), activin and others.

The three gonadotropins act via two G protein-coupled receptors (GPCRS). The gonadotropin receptors (as well as the TSH receptor [TSHR] and several others) are characterized by the presence of a large extracellular domain containing several leucine-rich repeats (LRR). This large extracellular domain is responsible for the recognition and high-affinity binding of the appropriate hormones. The luteinizing hormone receptor (LHR) recognizes both LH and hCG, and the follicle stimulating hormone receptor (FSHR) is specific for FSH. The LHR is expressed in Leydig, theca, granulosa, and luteal cells whereas the FSHR is expressed in granulosa and Sertoli cells. Expression of the gonadotropin receptors in non-gonadal tissues has also been reported but these findings are still controversial and the physiological significance, if any, of the extragonadal expression of the gonadotropin receptors is debatable.

This chapter focuses on the three gonadotropins and their two receptors.

Gonadotropins

Gonadotropin Proteins (LH, hCG, and FSH)

Amino Acid Sequences and Three-Dimensional Structures

The three gonadotropin proteins (LH, hCG, and FSH) and TSH comprise the better characterized members of a family of complex proteins known as the glycoprotein hormones.[1] They are non-covalently bound heterodimers composed of a common α subunit and distinct β subunits. The common α gonadotropin subunit (α-GSU), encoded by the *CGA* gene contains 92 amino acid residues, and LHβ, FSHβ, and hCGβ are, respectively, 121, 110, and 145 amino acid residues in length. The additional length of hCGβ is due to a carboxy-terminal extension arising from a frameshift mutation in an ancestral LHβ gene resulting in a read-through into an untranslated region of LHβ and an extension of the open reading frame.[2-4] This extension is known as the carboxy-terminal peptide (CTP). The amino acid sequences of the human (h) subunits are shown in Figure 2.1, and it can be seen that the α and β subunits are relatively rich in Cys residues and that considerable homology exists in the β subunits.

Crystal structures are available for deglycosylated hCG,[5,6] glycosylated, antibody-bound hCG,[7] a partially deglycosylated hFSH[8] and a partially deglycosylated complex of a single chain hFSH bound to a large N-terminal fragment (residues 1-268) of the hFSHR ectodomain (ECD).[9] Figure 2.2 shows the crystal structures of hCG and hFSH.

The conformations of hCG and hFSH are quite similar, each being highly elongated molecules with the two subunits intertwined one with another in a slightly twisted manner. Despite the absence of any striking sequence homology, the two subunits in both heterodimers have similar folds, characterized by three major loops, and each subunit contains a cystine knot motif, consisting of three disulfides located in the core of each subunit. The α and β subunits contain, in addition to the three disulfides in the cystine knot, two and three disulfides, respectively. A 20-amino acid residue region of the β subunit, denoted as the seatbelt, wraps around and latches a portion of the α subunit. A major difference in the structures of hCG and hFSH is in the C-terminal portions of the seatbelts that exhibit distinct conformations. In both hCG and hFSH, the two subunits are associated in a head-to-tail arrangement (Fig 2.2). Although there are no structures available for LH and TSH, the similarities of the hCG and FSH structures engender confidence that the overall conformations of LH and TSH will be closely related to the known structures. Solution structures have also been obtained for deglycosylated human α-GSU[10,11] using nuclear magnetic resonance (NMR) spectroscopy. The overall ensemble of

FIGURE 2.1 Amino acid sequences of human α *gonadotropin subunit* (α-GSU), luteinizing hormone (LH)β, chorionic gonadotropin (CG)β, and follicle-stimulating hormone (FSH)β. Amino acid sequences were obtained from the Ensembl web site *(http://www.ensembl.org/index.html),* and the β subunits are aligned to maximize homology. Identical, highly conserved, and semiconserved residues among the three β subunits are highlighted by the blue, green, and yellow boxes, respectively. All cysteines participate in disulfide bond formation in the native proteins. hCG, human chorionic gonadotropin; hFSH, human follicle-stimulating hormone; hLH, human luteinizing hormone. *(Copyright © 1999–2008 The European Bioinformatics Institute and Genome Research Limited, and others. FIGURE 2.2 Crystal structures of human chorionic gonadotropin (hCG; *left*) and human follicle-stimulating hormone (hFSH; *right*). The structures[5-8] show that the two subunits are highly elongated and intertwined (hCGα, *yellow;* hCGβ, *green;* and hFSH, *blue*), forming a relatively large contact surface area. As discussed in the text, there are several interesting features associated with the structures: each subunit contains a cystine knot motif; the β subunit wraps around a portion of the α subunit, forming what is termed a seatbelt (shown in *white*); although having little sequence homology, the two subunits adopt similar folding patterns; hCG and hFSH form very similar structures, but the respective subunits of each exhibit subtle differences in their conformations. C, C-terminus; N, N-terminus.

structures determined for α-GSU is similar to that obtained in the crystal structures of hCG and hFSH.

With crystal structures available for FSH[8] and an FSH-FSHR ECD complex[9] (discussed elsewhere in this review), it is possible to delineate the conformational changes of the free heterodimer, and that bound to receptor. The unbound form of the hormone is more flexible than that of the bound form. It is the C-terminal region of the α-GSU, however, that undergoes the greatest change in conformation. In addition, the two C-terminal residues in α-GSU are unordered in the crystal structure of FSH, but in the complex with receptor they are fully ordered.

Glycosylation

The gonadotropins are trafficked from the endoplasmic reticulum to the cis-Golgi and undergo glycosylation as they traverse the Golgi reaching the trans-Golgi, to yield the mature hormones. The human subunits contain N-linked glycans: two on α-GSU at Asn52 and Asn78, two on CGβ (Asn13 and Asn30), two on FSHβ (Asn7 and Asn24), and one on LHβ at Asn30. In addition, hCGβ contains four mucin-type O-linked glycans at serines 121, 127, 132, and 138, located on the CTP (Fig. 2.3). The carbohydrate moieties appear to be important in subunit assembly and stabilization, secretion, and circulatory half-life. Although earlier studies suggested a role of the N-linked glycan at Asn52 on α-GSU in receptor activation, more recent evidence indicates that the glycan acts more as a conformational or stabilizing determinant of the protein.[12,13] Moreover, there is growing evidence that the particular type of glycosylation may influence biological activity.[14-20]

The biantennary N-linked glycans on hFSH and hCG terminate in sialic acid (and to a lesser extent sulfate), although the number of such moieties varies from zero to two, accounting in large part for the microheterogeneity of these glycoprotein hormones. In LH the biantennary N-linked structures tend to terminate mainly in sulfate. These are but generalizations since, for example, hFSH also contains triantennary and tetrantennary N-linked glycans, and some hFSHβ subunits lack N-linked structures completely.[21-24] A variety of glycosyltransferases are responsible for N- and O-glycan biosynthesis; notably, sulfation in the pituitary requires N-acetylgalactosamine transferase and sulfotransferase, both of which are missing in the placenta.[21,22] Also, fucose is often found in the glycoprotein hormones. As summarized, nearly 50 different N-linked and O-linked glycans have been reported in hCG α and β preparations.[25-27] The major gonadotropin N-linked and C-linked glycans are shown in Figure 2.3.

Folding and Assembly

Investigations into the kinetic folding pathways of the hCG subunits led to the interesting suggestion that disulfide

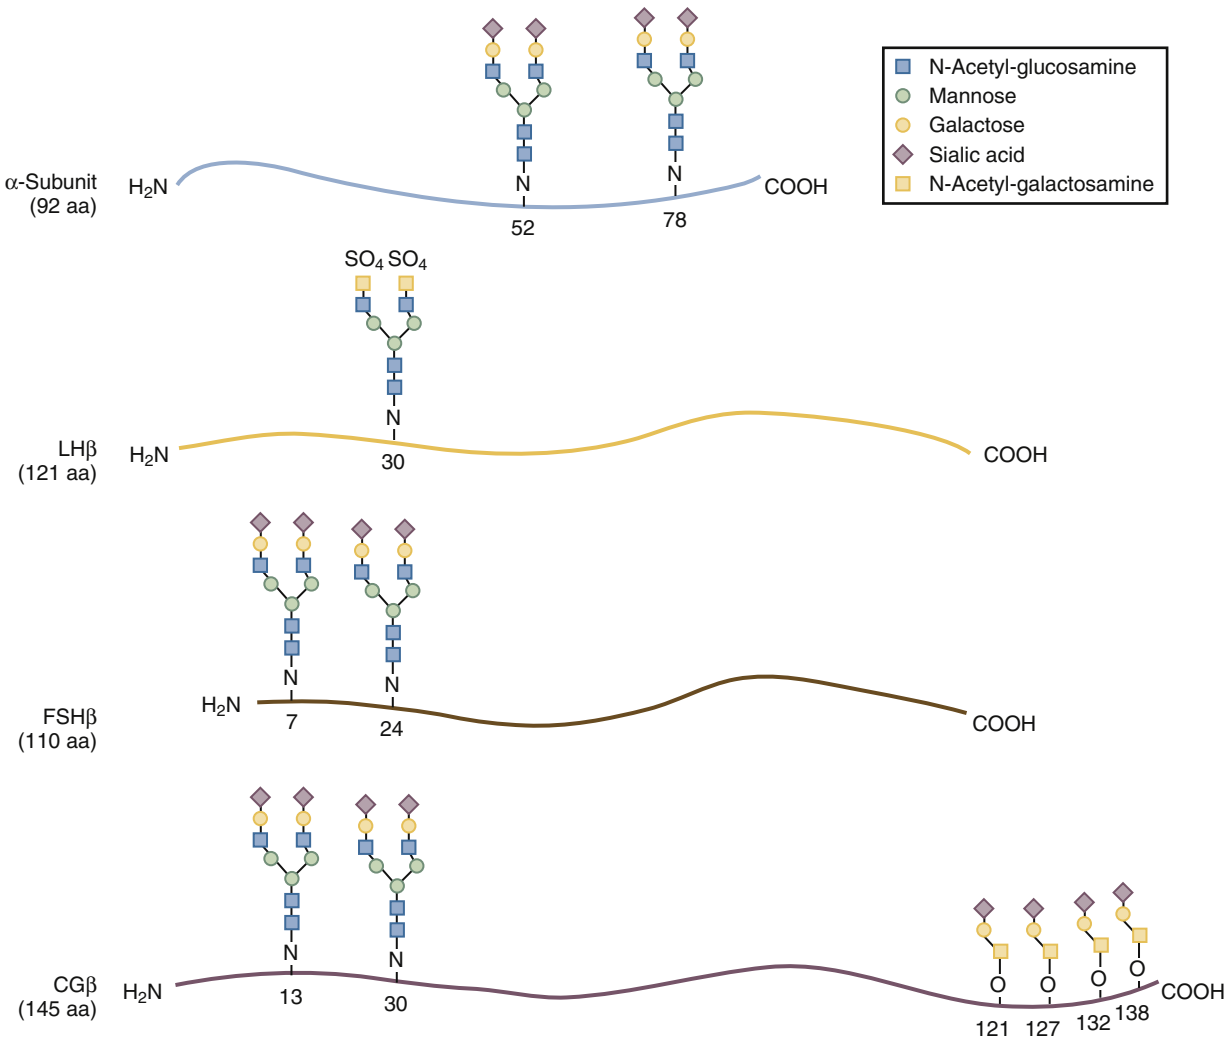

FIGURE 2.3 Location and typical structures of the N-linked and O-linked glycans on the gonadotropins. The sites of glycosylation on each of the gonadotropin subunits and representative structures of the various N-linked glycans on human luteinizing hormone (hLH), human chorionic gonadotropin (hCG), and human follicle-stimulating hormone (hFSH). As discussed in the text, scores of different structures have been identified, often with fucose present; moreover, some sites are devoid of glycosylation in various gonadotropin preparations. A representative structure of type 1 O-linked glycans on the carboxy-terminal peptide of hCGβ is shown; type 2 structures have been reported as well, and some sites show no glycosylation in various gonadotropin preparations. *Blue squares,* GlcNAc; *yellow squares,* GalNAc; *green circles,* mannose; *yellow circles,* galactose; *purple diamonds,* sialic acid.

exchange occurs during the maturation process and that subunit association occurred before completion of protein folding and disulfide formation.[28-32] Moreover, it was posited that subunit association occurred before the seatbelt was latched by closure of Cys26 and Cys110. In contrast to these reports, a different mechanism in which subunit assembly involved closure of the seatbelt latch, followed by threading of α loop 2, has been proposed.[33-37] Others have also studied the folding patterns of hCG and reported that subunit association occurred between an almost completely folded α subunit and an immature β subunit.[38-41]

In addition to the heterodimeric nature of the hormones, homodimers have also been found for LHβ,[42,43] and for the α subunit.[40,41,44] Whether these homodimeric forms of the glycoprotein hormones have any associated bioactivity remains to be shown, although it has been reported that the free α subunit potentiates progesterone-mediated decidualization.[45]

Other Heterodimeric Glycoproteins Related to the Gonadotropins

A search of the human genome revealed two glycoproteins, GPA2 and GPB5, similar to the glycoprotein hormone α and β subunits, respectively.[46] Heterodimers can be formed between GPA2 and GPB5, and the complex is capable of stimulating the TSH receptor. This heterodimer, named thyrostimulin, is postulated to act in a paracrine manner to activate the pituitary TSHR.[47] Comparative structure analysis of the glycoprotein hormone subunits and GPA2 and GPB5 suggests that GPA2 and GPB5 cannot form stable heterodimers at low concentration in circulation as they lack the cystine residues potentially involved in the cystine knot structure and GPB5 does not possess the sequence homologous to the seat belt.[48] This suggests a paracrine, rather than endocrine role for thyrostimulin. Phylogenetic studies suggest that the thyrostimulin may in fact be an "old" hormone

with the subunits appearing with the emergence of bilateral metazoa more than 500 million years ago.[46,49] In the basal chordate, amphioxus, thyrostimulin appears to play a role in embryonic development and heterodimerization may not be required for its activity.[49] A recent study suggests that thyrostimulin, expressed in the oocyte, is a paracrine regulator of TSHR in the granulosa cells of the rat ovary.[50]

Structure-Function Studies

Amino Acid Mutations

As discussed elsewhere in this review, only a limited number of naturally occurring mutations have been identified in the α and β subunits of the glycoprotein hormones. In contrast, there is a wealth of information available from site-directed mutagenesis followed by biological characterization of the mutant hormones. Few mutants have been described in which there was a significant increase in bioactivity; most mutations either have no effect or induce a loss-of-function, either disrupting folding, subunit assembly, or receptor binding/activation. Gain-of-function mutations in hCG were obtained by replacing single or multiple amino acid residues at the N-terminal region of the α subunit with Lys.[51] A 2-fold increase in potency of hCG was obtained with a single replacement of Phe with Thr at position 18 of α-GSU.[52] Mutant forms of α-GSU missing the N-linked oligosaccharide at Asn52 are capable of associating with the hCGβ or FSHβ subunit giving a heterodimer that binds to the cognate receptor but has diminished signaling efficacy.[53] Although still controversial, it appears that the role of N-linked glycosylation at Asn52 is to stabilize the active conformation of the heterodimer by formation of a hydrogen bond with a Tyr on the β subunit.[8] Mutations in the central region of α-GSU[54-56] and at the C-terminus[57,58] yielded mutants that associated with the β subunits of hCG and hFSH, but displayed compromised functionality in receptor binding.

A large number of β subunit mutations have been prepared and characterized.[59-67] As with mutations in α, many interfere with folding, subunit assembly, or receptor binding. The data, overall, being consistent with the structures of hCG and FSH. Unlike α-GSU mutants, however, there have been no reports of β mutants that retain the ability to form heterodimers and bind to receptor, yet do not signal.

Protein Engineering

Protein engineering has been used to produce a variety of subunit deletion derivatives, single chain hormones and chimeric hormones yielding interesting results. As mentioned earlier, C-terminal deletion mutants of the α subunit result in large N-terminal fragments that retain the ability to bind to the β subunit, but the resulting heterodimers exhibit minimal, if any, receptor binding capability. Deletion mutants at the N- and C-termini of hCGβ have been reported by several groups,[59,60,63,68] and the shortest form that retains minimal functionality in subunit assembly and subsequent receptor binding and activation is a fragment consisting of residues 8-100.[63]

A number of glycoprotein hormone chimeras have been designed and characterized, providing useful information on specific amino acid residues involved in receptor binding and activation.[69-75] In general, these results emphasize the role of the β subunit seatbelt region in receptor binding, although different portions are important in receptor specificity.

A novel approach to the study of gonadotropin structure-function relationships involved the design of single chain hormones (i.e., fusion proteins of the α and β subunits). The first reports of a yoked or tethered hCG demonstrated that the single chain gonadotropin, in the configuration N-hCG β-α-C, was bioactive.[76,77] Subsequently, similar fusion proteins of LH and FSH were also found to be bioactive.[78,79] Later, single chain proteins of hCG in the N-α-hCGβ-C configuration and proteins with different linkers were expressed and characterized, in many cases with interesting mutations in one or both subunits.[80,81] From these studies it was concluded that the N-α-hCGβ-C configuration was also bioactive and, quite surprisingly, that, each disulfide of the subunits could be eliminated without a loss of activity.[82-84] The single chain hormones also displayed increased stability and heat resistance *in vitro* compared to their heterodimeric counterparts.[78] Extending the approach of covalently linking the two subunits, others designed and expressed disulfide-linked heterodimers.[85-89] These results further substantiated the possibility that α-Asn52 contributed to heterodimer stability and was not involved directly in signal transduction,[12] and also led to suggestions that the C-terminus of the α-GSU is not required for LHR binding. This latter finding is consistent with the observation that the five C-terminal residues can be removed from α-GSU without a loss of LHR binding. The use of single chain gonadotropins, particularly in the N-α-β-C configuration, also raises interesting questions about the role of the C-terminal region of α-GSU in FSH where the structure of the FSH-FSHR ECD complex shows a large movement of α-GSU in the receptor complex compared to the heterodimer.[9] Of great interest was the report that single chain hCGβ-βhomodimers bind to LHR with an affinity about three times lower than wild type hCG; this engineered homodimer does not elicit a biological response and blocks hCG binding to LHR.[90] A second single chain hCG antagonist was designed by mutating three of the four N-linked glycosylation sites that are associated with LHR activation (Asn 13 and 30 in the β subunit and Asn 52 in the α subunit). Asn 78 in the α subunit, associated with receptor binding, was left intact. This analog behaved as a competitive antagonist and suppressed ovarian hyperstimulation syndrome in rats.[91]

The approach of converting glycoprotein hormones to single chains has been extended to produce fusion proteins with dual and triple activities. For example, a three domain fusion protein of the form, N-FSHβ-hCGβ-α-C, exhibited both LH and FSH activities.[92-94] Interestingly, the bifunctional gonadotropin is secreted from cells as two species, one with LHR, and the other with FSHR activities.[95] A four domain fusion protein, N-TSHβ-FSHβ-hCGβ-α-C, although secreted inefficiently, was found to exhibit three distinct bioactivities both in cellular and whole animal studies.[96,97] These results raise intriguing questions regarding subunit association and conformation as manifested in receptor binding and activation. A most provocative finding was based on a bifunctional, triple domain fusion protein of the form: N-FSHβ-hCGβ-α-C.[84] These investigators showed that disruption of heterodimer formation by mutation of either Cys10-Cys60 or Cys32-Cys84 did not

eliminate bioactivity, and thus concluded that αβ contacts are not required for receptor binding and activation. These selected results, along with others not covered here, indicate that single chain glycoprotein hormones exhibit some properties distinct from those in heterodimers. The single chain proteins with increased stability, the single chain hCG antagonists and single chain molecules with dual LH/hCG-like and FSH-like bioactivities, are attractive candidates for clinical utility.

The concept of single chain gonadotropins was extended to produce fusion proteins of hCG and LHR (i.e., covalent attachment of a single chain hCG to LHR) which when expressed, led to constitutive receptor activation in transfected cells and transgenic mice.[98-102] This model was also used to demonstrate that the individual subunits are devoid of bioactivity.[103]

Gonadotropin Subunit Genes and Transcripts

Gonadotropin Subunit Genes

The three gonadotropins, LH, CG, and FSH, are encoded by one gene each for the common α subunit and the β subunits of LH and FSH; in contrast, the CGβ subunit, expressed in primates and equids, is encoded by six genes.[104,105] It has been suggested that the glycoprotein hormone α and β subunits diverged from a common ancestral gene over 900 million years ago[104] with the β gene undergoing duplications and mutations to yield the current family. In humans, the gene encoding the common alpha subunit is on chromosome 6, that for FSHβ on chromosome 11 and those for LHβ and CGβ on chromosome 19 (http://www.ensembl.org). The gene for human α is 9.4 kb and contains four exons and three introns; that for FSHβ is 4.2 kb with three exons and two introns; for LHβ the gene is 1.1 kb with three exons and two introns; and those for CGβ are variable in length.

The seven genes for LHβ and CGβ exist in a large cluster spanning about 52 kbp.[104,105] The six genes encoding the β subunit of CG (i.e., *CGB*, *CGB1*, *CGB2*, *CGB5*, *CGB7*, and *CGB8*) exist as tandem and inverted repeats.[106] The genes for CGβ have been analyzed in detail.[104,105] Four of the CGβ genes, *CGB*, *CGB5*, *CGB7*, and *CGB8*, exhibit 97%-99% sequence identity while their identity with LHβ is 92%-93%. These gene similarities lead to protein amino acid sequences that are 98%-100% identical for the four CGβ genes and 85% identical with LHβ. The genes for *CGB*, *CGB5*, *CGB7*, and *CGB8* encode proteins with a carboxy-terminal extension (CTP), that appears to have arisen from the LHβ gene by frameshift mutations leading to a read-through into a previously untranslated region, thus extending the reading frame.[2,3,107] The CTP contains mucin-type O-glycans (Fig. 2.3), resulting in properties of hCG not found in LH.[4]

Gonadotropin Subunit Transcripts

The available evidence indicates single transcripts for the gonadotropin genes, with the exception of the human *FSHB* gene for which four messenger RNA mRNA species have been described, arising from alternate splicing and the utilization of two polyadenylation sites.[108] The CGβ family is interesting in that all six genes appear to be expressed giving transcripts of varying lengths. *CGB5* and *CGB8* are highly expressed in the placenta.[104,105,109] Although expressed in placenta,[104,105] pituitary,[110] testis,[111] and breast cancer,[112] no proteins have yet been identified for the *CGB1* and *CGB2* genes. The predicted sizes of CGβ1 and CGβ2 are smaller than that of hCGβ; this observation, coupled with the distinct amino acid sequences predicted, suggests that these proteins, if biosynthesized, may have quite different functions than those of hCG. Using transgenic mice expressing a 36 kb cosmid insert that contained the six *CGB* genes, transcripts of *CGB1* and *CGB2* genes were found to be present in brain at levels comparable to those of the other four *CGB* genes.[113]

Naturally Occurring Mutations in *CGA*, *LHB*, and *FSHB* Genes

The only mutation reported in the *CGA* gene is that from a human carcinoma, Glu56Ala, resulting in a mutant form of α-GSU that does not associate with LHβ.[114] In contrast, there are several reports of mutations in the genes encoding the β subunits, resulting in loss-of-function and thus hypogonadism.[105,115,116] The first report of a mutation in the *LHB* gene was that of a missense mutation in a male presenting with delayed puberty and hypogonadism.[105,115,116] This mutant led to a replacement of Gln54 with Arg; while subunit assembly could occur, the heterodimer was unable to bind to LHR. Other studies showed that LHβ and hCGβ subunits with Gln54 replacements formed heterodimers with α-GSU, but these heterodimers exhibited reduced binding to LHR.[64,67] Another missense mutation reported in LHβ was that of Gly36 to Asp, reported on a male with delayed puberty and infertility.[105,115,116] Gly36 is part of the CAGYC sequence in LHβ that is critical to the formation of the disulfide knot; presumably, an Asp at this position prevents at least one of the disulfides from forming.

Two additional mutations in the *LHB* gene were recently reported. The first reported mutation,[117] a G-C substitution at the +1 position of intron 2 (a 5′ splice-donor site), leads to a hypothetical aberrant protein with a 79 amino acid residue insert beginning after Met41 and a frameshift in exon 3, thus removing the essential seat belt loop of β and important cysteines. The offspring of consanguineous parents (second cousins) who were heterozygous for the mutation were analyzed. Three homozygous siblings presented with hypogonadism and infertility, and interestingly, the sister underwent normal pubertal development and menarche at age 13 years. Three heterozygous siblings were fertile. Analysis of serum hormone concentrations of the three siblings homozygous for the LHβ gene mutation showed undetectable levels of LH and high levels of free α-GSU; the two males had elevated FSH and low testosterone while the female had FSH, estradiol and progesterone values in the normal range, albeit on the low end of normal for the sex steroids.

The second recently reported mutation[118] was a 9 bp deletion in exon 2 resulting in deletion of amino acid residues 10-12 of LHβ in a man and his sister. Both were homozygous for the deletion while two additional unaffected siblings were heterozygous. In spite of undetectable levels of LH, low serum and intratesticular testosterone, the man had complete spermatogenesis and normal sperm count. Presumably, the low activity by the mutant LH detected *in vitro* was sufficient for normal spermatogenesis. The sister underwent normal puberty and menarche, but subsequently had amenorrhea, infertility, ovarian cysts, and low estradiol levels.

Recently, rare missense heterozygous mutations in the hCGβ subunit have been identified in a Northern European population.[105,119,120] The Val56Leu mutation in the *CGB5* gene was identified in a patient with recurrent miscarriage (RM). Although the amount of mutant hCGβ subunit assembled into the heterodimer was very low, it elicited a strong signaling response on binding to the receptor.[119] Arg8Trp mutation, also found in an RM patient did not affect assembly. The Pro73Arg mutation found in five individuals (three RM and two controls) caused about half of the secreted β-subunits to acquire an alternate conformation, but did not affect biological activity. Individuals homozygous for these mutations have not been identified, perhaps because such genotypes would result in complete pregnancy failure and suggests that only mutations with mild functional consequences can be tolerated in the major *CGB* genes.

Several mutations have been described in exon 3 of *FSHB* that lead to an absence of pubertal development, amenorrhea, and infertility in females and azoospermia in males.[105,115,116] The first report was on a 27-year-old woman presenting with the above symptoms and undetectable serum FSH both before and after administration of GnRH. She was found to be homozygous for a two base-pair deletion at codon 61 (Val61Stop) of *FSHB* causing a frameshift, namely an alteration of codons 61-86, and premature termination of the β subunit. A similar mutation was found in an 18-year-old male who was evaluated for delayed puberty.

Other reports identified a compound heterozygous mutation at codon 51 leading to a Cys51 to Gly replacement and Tyr76Stop nonsense mutation.[105,115,116] A missense mutation was found in a 28-year-old male who presented with infertility and was found to have Cys82 replaced with Arg[105] and recently a frameshift at codon 79 (Ala79Stop) caused by a 1 bp deletion and premature termination.[121] One case of hypoglycosylation was reported for FSH, resulting in a hormone with diminished activity.[122]

Overall, the observed phenotypes associated with the naturally occurring mutations in *LHB*, *CGB*, and *FSHB* are consistent with the known structures and actions of the gonadotropins, although fertility in men is not totally dependent on FSH as it is in women.

Polymorphisms in *LHB, CGB,* and *FSHB* Genes

A fairly well characterized polymorphism in LHβ appears in variable frequencies in ethnic groups throughout the world and results from two single nucelotide polymorphisms (SNPs) leading to replacements of Trp8 with Arg and Ile15 with Thr.[105,115,116] There is, however, no association of this polymorphism with assessed phenotypes of infertility, polycystic ovarian syndrome or cancer,[105,115,116] although biopotencies are increased *in vitro* with altered half-life in circulation.[123,124] Individuals harboring this double polymorphism appear to exhibit low, if detectable, levels of immunoreactive LH, but this results from the use of antibodies that do not recognize the altered LH. The Thr15 mutant has an additional site of glycosylation, but Arg8 may be responsible for most of the altered properties.

Another LHβ variant is a replacement of Gly102 with Ser, resulting in reduced LH biopotency *in vitro*.[105,115,116] The frequency of this polymorphism, however, seems to be quite low.

An unusual polymorphic variant of LHβ involves an Ala to Thr replacement three residues before the signal peptide cleavage site.[115,116] Using *in vitro* assays, it was found, rather surprisingly, that the mature protein from the variant appears less potent than wild type LH in cAMP production, but more potent in inositol phosphate production. The SNP-related alteration may interfere with proper processing of the β subunit, although studies have not addressed this possibility.

A polymorphism has been reported in exon 3 of *CGB5*, resulting in a Val79 replacement with Met.[105,115,116] This SNP results in a β subunit deficient in folding and interaction with the α subunit. The frequency and physiological consequences of this polymorphic variant are unknown; one sampling of just under 600 samples from four European groups failed to detect a single case.[115,116] Other polymorphic variants have been detected, but these were silent or located in intron regions.[115,116] A case study in which the *CGB5* and *CGB8* genes were analyzed in RM (n=184) and control fertile (n=195) patients from Estonia and Finland, 71 polymorphisms were identified of which 48 were novel.[120] A protective effect against RM was associated with two single nucleotide polymorphisms located at identical positions in *CGB5* and *CGB8* and with four *CGB5* promoter variants. These findings suggested that polymorphisms in the *CGB* gene might contribute to the susceptibility to RM. These polymorphisms can be found in the SNP database (http://www.ncbi.nlm.nih.gov/SNP/), accession nos. ss105106983-ss105107053.

A very limited number of silent polymorphic variants of *FSHB* have been reported.[105,115,116] Recently, a *FSHB* promoter polymorphism (-211G/T) identified in a cohort of Estonian men has been associated with reduced serum FSH levels in GT heterozygotes and TT homozygotes.[125] This polymorphism was found to be more prevalent among infertile men.[126] The *LHB* and *FSHB* polymorphisms can be found at the SNP database: (www.ncbi.nlm.nih.gov/projects/SNP/snp_ref.cgi?geneId=3972 and www.ncbi.nlm.nih.gov/projects/SNP/snp_ref.cgi?geneId=2488).

Regulation of Expression and Secretion of the Gonadotropins

Transcriptional Regulation

The neurocrine reproductive axis, composed of the hypothalamus, anterior pituitary and gonads, is now known to be regulated, apparently in large part, by kisspeptin, a product of *KISS1*, acting via the G protein-coupled receptor, GPR54, located on GnRH neurons.[127,128] The three gonadotropin subunit genes in the pituitary are differentially responsive to GnRH pulse frequency and magnitude: *CGA* being preferentially transcribed at high GnRH pulse frequencies, *LHB* at intermediate frequencies, and *FSHB* at lower frequencies.[129] Sex steroid-mediated regulation of the gonadotropin genes may result from direct effects on the hypothalamus and pituitary, and recent evidence suggests a critical role of the kisspeptin-GPR54 system in sex steroid action.[130-132]

Binding of GnRH to its receptor in the gonadotropes primarily activates $G\alpha_{q/11}$ resulting in the activation of phospholipase Cβ, calcium influx, activation of protein kinase C (PKC), and calcium-calmodulin kinase II.[133,134] PKC

mediates the downstream activation of the mitogen activated protein kinase (MAPK) cascades: extracellular signal regulated kinase (ERK1/2), jun N-terminal kinase (JNK) and P38.[134-136] The MAPK pathway can also be activated by GnRH stimulation of $G\alpha_s$[137,138] and while both the $G\alpha_s$ and $G\alpha_{q/11}$ pathways are responsive to pulses of GnRH, only the $G\alpha_{q/11}$ pathway is responsive to constant GnRH.[138] A recent study suggests that the different G proteins regulate the pattern of FSH and LH expression by GnRH. FSHβ induction depends predominantly on $G\alpha_{q/11}$ while LHβ expression depends on $G\alpha_s$. Interestingly, $G\alpha_s$ signaling induced inhibin α, which acted as an autocrine regulatory factor to suppress FSHβ expression.[139]

Our understanding of the mechanisms that mediate transcription of the pituitary gonadatropin genes has primarily come from studies on the rodent genes in two murine immortalized gonadotrope cell lines, αT3-1 and LβT2[134,140] and several excellent recent reviews on the regulation of these genes are available.[134,141-146] GnRH activation of the MAPK signaling cascade increases transcription of the immediate early genes including *Egr1*, *Jun*, and *Atf3* which encode the DNA proteins early response protein 1 (EGR1), JUN and activating transcription factor 3 (ATF3), respectively. The orphan nuclear receptor, steroidogenic factor 1(SF1), ATF3/JUN heterodimer, LIM homeobox protein 3 (LHX3), and paired-like homeodomain transcription factor 1 (PITX1) are required to activate C*ga*.[145,146] EGR1, SF1, and PITX1 form a tripartite complex that bind to a highly conserved proximal promoter sequence to synergistically activate the *LHB/Lhb* gene and βcatenin serves as a co-activator of SF1 to maximally activate the *Lhb* gene in response to GnRH.[134,144,145] Activator protein 1 (AP1), SF1, nuclear factor Y, PITX1, and LHX3 bind to and activate the *Fshb* promoter.[134,141,143,145,146]

Activin induces *Lhb* and *Fshb* gene expression by interaction of the Smads with the activin response elements. Binding of FOXL2, a member of the forkhead family of transcription factors, to the *Fshb* promoter is essential for activin responsiveness and the runt-related transcription factors RUNX are negative regulators of *Fshb* gene expression.[147]

The gonadal steroids can act on gonadotropin promoters in the pituitary to positively or negatively regulate their expression. The ligand-bound estrogen receptor α (ERα) indirectly binds to the *Lhb* promoter sequence through interactions with SF1 and PITX1 to induce expression.[134,145] There is little evidence to support regulation of *Fshb* expression by estrogen in rodents. Androgens suppress transcription of *Lhb* and increase transcription of *Fshb* via interactions of the androgen receptor (AR) to the hormone response elements on the promoter sequences.[134,145] Progesterone suppresses *Lhb* gene expression in gonadotrope cells and this is thought to be mediated by indirect binding of the progesterone receptor (PR) to the promoter.[134] In contrast, progesterone induces the expression of *Fshb* in gonadotrope cells by binding of PR directly to the *Fshb* proximal promoter. Recent studies have shown that activin and progesterone act synergistically to mediate *Fshb* transcriptional regulation in gonadotrope cells[134] and FOXL2 is necessary for the full synergistic response.[148]

It has been proposed that in the trophoblast layer of the placental villous, association of the cAMP response binding protein (CREB) and v-ets erythroblastosis virus E26 oncogene homolog 2 (ETS2), augmented by protein kinase A, regulates C*GA* expression. An upstream regulatory element (URE) on C*GA* contains binding sites for several transcription factors, and a second control element, alpha-activating elements (αACT), binds a GATA factor and AP2γ. The C*GB5* promoter binds both CREB and ETS2, and an AP1-like site has been identified.[149-151]

Post-Translational Regulation (Glycosylation)

It is now well established that the glycosylation patterns of at least some of the glycoprotein hormones change during various physiological states.[14] Examples include a shift in the structures of hCG N-linked oligosaccharides during pregnancy in the differentiation of cytotrophoblasts to syncyciotrophoblasts,[18,152-155] changes in LH and FSH N-linked glycosylation during the menstrual cycle[156] and alterations in FSH N-linked glycans during adolescence in boys.[14,17] Indeed, a portion of FSH contains a non-glycosylated β subunit.[24,157]

The circulatory half-life of the sulfated gonadotropins, notably LH, is invariably less than that of the sialic acid-containing hormones. This arises from an hepatic receptor that recognizes the terminal N-acetyl galactosamine-sulfate, rapidly removing it from circulation.[158] Indeed, ablation of the gene encoding GalNAc-4-sulfotransferase, the enzyme responsible for modifying the terminal GalNAc in LH with sulfate, resulted in mice with increased half-life and circulating levels of LH.[159]

Various laboratories have shown that the hyperglycosylated variant of hCG is produced in early pregnancy, i.e., from cytotrophoblasts, and in gestational trophoblastic diseases whereas hCG is secreted by syncytiotrophoblast.[153,154,160,161] Hyperglycosylated hCG molecules have enhanced branching into triantennary and unusual biantennary N-linked oligosaccharides and a prevalence of the more complex Core 2, as opposed to Core 1 O-linked sugars.[161,162] In clinical studies, hyperglycosylated hCG is identified by the binding of a monoclonal antibody B152 that specifically recognizes the Core 2 O-linked sugars at Ser 132.[163,164] It has been suggested that in addition to the canonical physiological function of "rescuing" the corpus luteum, hyperglycosylated hCG acts in an autocrine/paracrine manner to promote trophoblast invasion of the placenta.[18,19,165,166] There are also data suggesting that the hCG produced by cytotrophoblasts and choriocarcinoma have distinct carbohydrate moieties.[167] The N-linked oligosaccharides on hCG from invasive mole and testicular cancer are characterized by both biantennary and triantennary structures and often more heavily fucosylated glycans, while the four O-linked units tend to have more core-2 type structures.[27]

Samples from patients with choriocarcinoma, testicular cancer and invasive mole showed interesting differences in their glycans. Triantennary N-linked glycans increase in choriocarcinoma[161] at Asn30 but not at Asn13,[27] while the reported increase in monoantennary N-linked glycans was observed at both Asn13 and Asn30.[27] The status of hCG fucosylation in pregnancy and cancer patients has been investigated by several groups[168] with some conflicting results. In malignancies,

fucosylation was recently reported to increase at Asn13, but not at Asn30.[27]

Regulation of Secretion

The pathways of secretion and polarity of hormone release are different for the various gonadotropins. Although LH and FSH are synthesized by the same cell, LH is packaged in dense storage granules[169] with regulated secretion occurring from the basolateral surface under the control of the pulsatile secretogogue, GnRH.[170-172] In contrast, FSH secretion is constitutive, linked to its synthesis and exhibits no apparent polarity of secretion.[170-173] The sorting determinant for the regulated secretion of LH lies in the hydrophobic heptapeptide at the carboxy terminus of LH[174,175] and a single leucine residue at position 118 contributes to the sorting of LH via the regulated pathway. Recent studies have demonstrated that sulfation of LH does not play a role in its regulated secretion,[176] but may be important for its extracellular bioactivity.[159]

Although LHβ and CGβ share 85% sequence identity and are functionally interchangeable, hCG is not stored in granules, but rather is secreted constitutively into the maternal circulation at the apical side of trophoblasts.[177] The CTP sequence, unique to hCG, is the important determinant in the constitutive secretion[178] and the O-linked oligosaccharides in the CTP are essential for the apical release of hCG.[179]

Expression in Physiological and Pathophysiological Conditions

The accepted physiological action of hCG is in the initiation and maintenance of pregnancy. In the gonads it maintains functionality of the corpus luteum and progesterone production, particularly during the first trimester of pregnancy. It also mediates multiple placental, uterine, and fetal functions including trophoblast invasion; development of syncytiotrophoblast cells, uterine growth and differentiation; placental development and localized suppression of the immune system.[180] In addition, hCG is located in pituitary,[181] but its physiological significance is unknown. As with pituitary hCG, there are reports of small amounts of glycoprotein hormone synthesis in various non-pituitary and non-placental tissues,[44,182] but specific functions have not been ascribed to these ectopically produced hormones. The major forms of circulating LH and hCG have been delineated, along with their patterns in normal physiological conditions and various disorders.[156]

There is ample evidence supporting ectopic production in a variety of disorders. It is well known that hCG is expressed in malignant forms of gestational trophoblastic disease, e.g., invasive mole and choriocarcinoma.[155,168,183,184] In men and women, hCGβ, hyperglycosylated hCGβ, and only occasionally intact hCG, is expressed in a variety of other malignancies, including breast, bladder, colorectal, gynecological, head and neck, hematological, lung, neuroendocrine, oral/facial, pancreatic, prostate and testicular cancer.[184-188] The detection of free CGβ subunit in these malignancies is generally associated with poor prognosis.

In an analysis of human *GCA*, *LHB*, and *CGB* gene expression in breast cancer, studies showed that most normal tissues expressed only *CGB7*, while *CGB3*, *CGB5*, and *CGB8* were expressed in trophoblastic tissues and correlated with the malignant transformation of breast cancer and other non-trophoblastic malignancies.[112,189] Human *CGA*, *LHB*, *CGB1*, *CGB2*, and *CGB7* were not, however, up-regulated in breast cancer.

A possible role of LH in the etiology and progression of Alzheimer disease has been postulated.[190-193] Of interest was the observation that LH modulates the processing of the amyloid-β precursor protein yielding deposition of amyloid-β peptide.[194] Genetic ablation of *Lhcgr* in amyloid precursor protein transgenic mice improved the amyloid pathology suggesting that chronic elevation of LH may promote the amyloid β plaque formation.[195]

Diagnostic and Therapeutic Applications of the Gonadotropins

Immunoassay-based measurements of the serum concentrations of pituitary-derived gonadotropins have been used extensively to monitor functionality of the hypothalamic-pituitary-gonadal axis, and measurements of urinary concentrations of hCG are widely used for pregnancy determinations and management, as well as monitoring trophoblastic malignancies. Hyperglycosylated hCG is the preferable form for the early detection of pregnancy or its complications.[163] In addition, studies have shown that hyperglycosylated hCG can be used to detect Down syndrome pregnancies,[164,196] particularly when coupled with other serum markers, α-fetoprotein and estradiol.[197] hCGβ and hyperglycosylated hCGβ are used as tumor markers for the detection of malignancies.[168,184] Immunocytochemistry is also commonly used in evaluating expression of hCGβ in suspected tumor tissue sections. It has been recognized for decades, that multiple variants of hCG are present in normal pregnancy, giving rise to microheterogeneity and macroheterogeneity.[198] These include intact or heterodimeric hormone, nicked hCG, heterodimeric hormone with bond cleavages in the hCGβ 43-48 region, free α and β subunits, nicked hCGβ core fragment (i.e., free β subunit with bond cleavages in the 43-48 region), and hCGβ core fragment, consisting of two disulfide-linked fragments, 6-40 connected to 55-92.[154] Hyperglycosylated hCG can present with a similar number of derivatives. Some of these variants may be useful diagnostic tools for germ cell and gynecological malignancies.[168] Therefore, hCG, assays must be capable of distinguishing the variants. Several reviews, workshop proceedings, and reports have addressed this issue and the challenges of obtaining and using appropriate standards.[18,167,168,183,198] The preparation and adoption of universal standards, coupled with complete characterization and disclosure of antibody specificities, will greatly facilitate standardization of glycoprotein hormone immunoassays.

While immunoreactivity is the primary technique for determining hormone concentrations in body fluids, it is often necessary to measure bioactivity. The earlier cumbersome *in vivo* assays for the glycoprotein hormones have, by and large, been replaced with radioreceptor and signaling assays in transfected cells. Such measurements provide quantitative data on hormone-receptor binding and efficacy of signal transduction, but they give no information on circulatory half-life and, thus, *in vivo* potency. For this, animal and human studies are obviously required.

Therapeutically recombinant gonadotropins expressed in Chinese hamster ovary cells are used in the treatment of infertility. The longer circulatory half-life of hCG, attributed to the β subunit, CTP, has been utilized most effectively in producing long acting analogs of FSH and TSH with a CTP engineered to the β C-terminus.[199-202] Another approach that has proven successful in extending the half-life of FSH is an engineered extension at the α N-terminus with two sites of N-glycosylation.[203] The resulting analog was glycosylated as judged by mobility on sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and exhibited increased circulatory half-life and *in vivo* potency.

Recently, a number of reports have appeared suggesting that hCG, in particular, could be used therapeutically in the treatment of cancer. A recent phase I clinical trial has shown that administration of hCG to postmenopausal breast cancer patients led to a reduction in the proliferative index (Ki67) and the levels of estrogen and progesterone receptors.[204] In contrast, female transgenic mice overexpressing hCG or LH exhibit multiple sites of tumorigenesis.[205] A conjugate of the lytic peptide, hecate (a 23-amino acid residue peptide, similar to bee venom mellitin, that disrupts cell membranes), to a 15-amino acid residue peptide from hCGβ (residues 81-95) was found to kill cultured prostate and ovarian cancer cells and reduce the tumor xenografts in nude mice.[206-209] In a transgenic mouse model, it was found that the hecate-hCGβ 15-amino acid residue peptide reduced malignant Leydig and granulosa cell tumors via necrosis or necrosis-like cell death.[210] While it is surprising that such a short hCGβ peptide is capable of LHR binding, the results are quite dramatic and may lead to specific therapies of LHR-positive tumors.

Gonadotropin Receptors

Gonadotropin Receptor Proteins

Amino Acid Sequences and Three-Dimensional Structures

The fully processed human LHR and FSHR (http://www.ncbi.nlm.nih.gov/gene/3973, and http://www.ncbi.nlm.nih.gov/gene/2492) are 675 and 678 amino acid residues long, respectively. By convention, the amino acid residues of the hLHR and hFSHR have been numbered from the initiator methionine of their precursor sequences obtained by virtual translation of the open reading frames of the cognate DNA (cDNA).[211,212] Algorithms that predict the most likely site of cleavage of signal peptides predict these to be between residues 24 and 25 of the hLHR and residues 17 and 18 of the hFSHR. Therefore the N-terminus of the mature hLHR and hFSHR are predicted to be Leu25 and Cys18 respectively. An alignment of the amino acid sequences of the hLHR and hFSHR is presented in Figure 2.4.

When grouped with the TSH receptor, the gonadotropin receptors form the glycoprotein hormone receptor family. One can readily recognize three distinct domains in this family of receptors, a large N-terminal domain that contains about 300 residues and is predicted to be extracellular, a serpentine region containing seven transmembrane segments connected by three extracellular loops and three intracellular loops, and a C-terminal tail that is predicted to be located intracellularly (Fig. 2.4). The presence of seven transmembrane segments suggests that the gonadotropin receptors are members of the superfamily of G protein-coupled receptors (GPCRs). The GPCR superfamily can be readily divided into several major subfamilies and the glycoprotein hormone receptors belong to the rodhopsin/β_2-adrenergic receptor-like subfamily of GPCRs.[213]

The amino acid sequences of the ECD of the gonadotropin receptors are 46% identical and this region is of particular interest because it is responsible for the recognition and high affinity binding of the hormones to their cognate receptors.[211,214,215] It can be divided into three subregions: an N-terminal cysteine-rich region, a region composed of several copies of a structural motif rich in leucine and other hydrophobic residues (the leucine-rich repeat, LRR), and a C-terminal cysteine-rich domain also known as the hinge region (Fig. 2.4).

The crystal structures of a large portion of the ECD of the hFSHR (residues 1-268, Fig. 2.4) complexed with a single chain hFSH analog has provided much needed light into the three dimensional structure of this important receptor region and its involvement in ligand binding.[9] The nine LRRs predicted from the primary structure form nine parallel β sheets as expected but an additional β sheet is comprised of residues in the N-terminal cysteine rich region. The first seven β sheets form a fairly flat structure but the last three have a horseshoe-like curvature that gives the ECD the overall shape of a slightly curved tube (Fig. 2.5A). The individual LRRs are irregular in length and conformation but they each have a β strand that collectively form the concave surface and a coiled structure that collectively form the outer surface of the LRR domain (Fig. 2.5A). FSH is bound to the concave surface of the ECD of the FSHR like two hands clasping each other with the receptor wrapping itself around the middle section of the hormone (Fig. 2.5A). All 10 β strands (as well as additional structures) of the LRRs of the hFSHR are in contact with the hormone and many of these contacting amino acid residues of the hFSHR are also conserved in the other two glycoprotein hormone receptors (Fig. 2.5A and B). The contact surface area between the hormone and the receptor is large and highly charged.

As expected both hormone subunits participate in receptor binding. Important points of receptor contact for the hormone involve the C-terminal portions of the α and β subunits as well as the α and ββ L2 loops (Fig. 2.5C and D). A comparison of the crystal structure of free hFSH[8] with that of the receptor-bound hormone[9] revealed that the structures of the free and bound hFSH are quite similar but the hormone is more rigid when bound to the receptor. The most obvious change in the hormone is on the C-terminus of FSHα which becomes buried at the receptor interface where it forms contacts with receptor residues that are highly conserved among the three glycoprotein hormone receptors.[9]

The crystal structure of large region of the ECD of the TSHR in complex with a TSHR autoantibody has also been solved.[216] Although the number of LRRs is different between the TSHR and the FSHR the overall structure of the ECD of the TSHR is very similar to that of the ECD

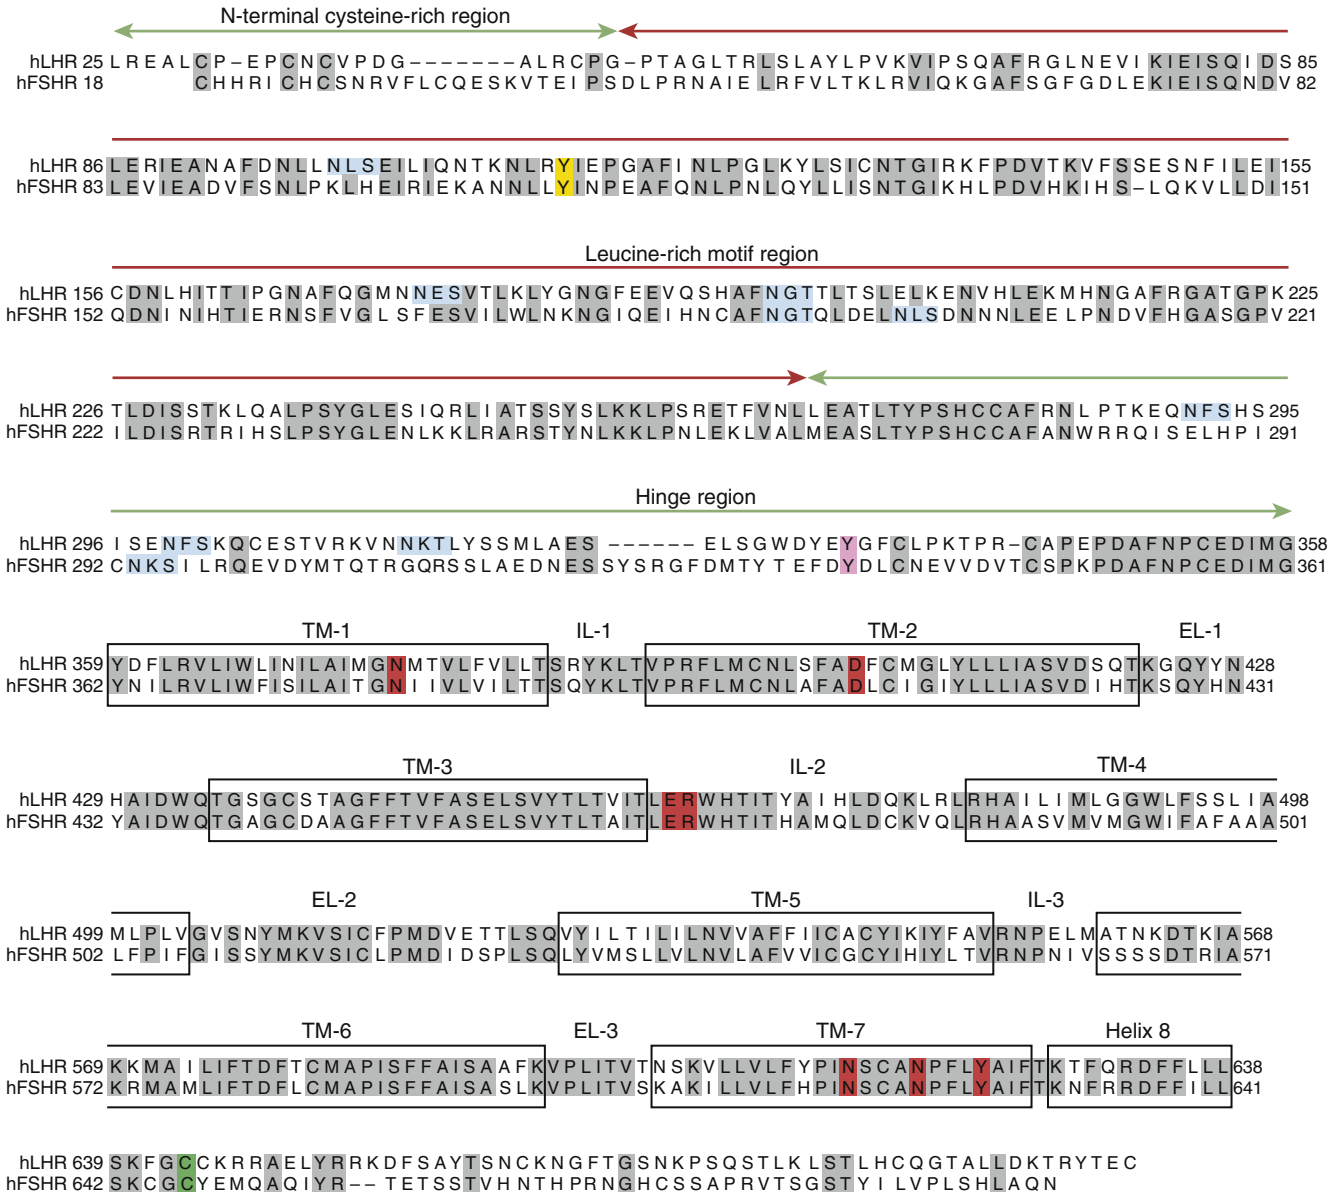

FIGURE 2.4 Amino acid sequence alignment of the human luteinizing hormone receptor (hLHR) and human follicle-stimulating hormone receptor (hFSHR). Amino acid sequences were obtained from a public Web site (www.ensembl.org/index.html). The boundaries of the three distinct regions of the extracellular domain discussed in the text (N-terminal cysteine-rich region, leucine-rich motif region, and hinge region) are marked with *green, red,* and *green arrows,* respectively. The seven transmembrane (TM) helices and the putative cytoplasmic helix 8 are delineated by *black boxes* and labeled TM-1 through TM-7 and helix 8, respectively. The three extracellular (EL) and four intracellular (IL) loops that connect the transmembrane regions are labeled EL-1 through EL-3 and IL-1 through IL-4, respectively. Identical residues between the two receptors are shown with *gray boxes*. The consensus sequences for N-linked glycosylation are shown with *blue boxes*. The tyrosine that participates in dimer formation for the FSHR and is conserved in the hLHR is shown in *yellow*. The conserved tyrosines that may be sulfated are shown in *pink*. The conserved cysteines that are believed to be palmitoylated are shown with the *green box*. Residues that are highly conserved among the rhodopsin/β2-adrenergic family of G-protein–coupled receptors are shown in *red. of the FSHR.[216] Interestingly the TSHR surface that binds the autoantibody is remarkably similar to the surface of the FSHR that binds FSH.[216]

The crystal structure also revealed that the FSH/FSHR complex forms a dimer using the outer surface of LRRs 2-4 in the hFSHR. Mutation of one of the residues predicted to be on this surface (Tyr110, highlighted in yellow in Figure 2.4) did not affect the dimerization of the hFSHR expressed in heterologous cell types, however.[217] The crystal structure of the TSHR in complex with a TSHR antibody did not show any dimers.[216]

Since the hinge region is missing from the two ECD crystal structures, nothing is known about its contribution to the overall conformation of the ECD or the receptors. The finding that residues 1-268 of the hFSHR (the fragment used for the crystal structure) binds hFSH with high affinity suggests that the hinge region of the hFSHR is not involved in binding. Likewise, a number of laboratory-designed and

The α and β chains of FSH are shown in *green* and *blue,* respectively, and the ECD of the FSHR is shown in *red*. Disulfides are shown in *black,* and the N-linked carbohydrates (of the hormone and the receptor) present in the crystal structure are shown in *yellow*. **B** to **D,** Sequence alignments and secondary structure of portions of the ECD of the two gonadotropin receptors **(B),** the β-subunits of the three gonadotropins **(C),** and the common α subunit **(D)**. *Arrows* designate β strands and *cylinders* designate α helices. For the receptor ectodomains **(B),** β strands located on the concave face of the FSHR ectodomain are shown in *red,* and those located in the convex face are shown in *beige*. The FSHR ectodomain residues shown in *green, blue,* or *pink* are buried at the receptor–ligand interface by the α subunit, the β subunit, or both, respectively. The residues in FSHβ shown in *blue* **(C)** and those shown in green on FSHα **(D)** are buried at the receptor interface. hCG, human chorionic gonadotropin; hLH, human luteinizing hormone; LHR, luteinizing hormone receptor. *(Modified from Fan QR, Hendrickson WA. Structure of human follicle-stimulating hormone in complex with its receptor.* Nature *433:269–277, 2005. © The Nature Publishing Group [2005].)*

naturally-occurring mutations of the LHR show that the hinge region of the hLHR is not necessary for the high-affinity binding of hLH or hCG.[211] Nevertheless, the high degree of conservation of some hinge region residues in the glycoprotein hormone receptor family (Fig. 2.4) suggests that this region plays an important role in other aspects of receptor function such as activation (addressed later in the text). A highly conserved Tyr present in this region (Fig. 2.4) was shown to be sulfated in the cell surface TSHR and mutation of this Tyr impairs TSH binding and activation.[218] Sulfation of the equivalent Tyr in the LHR or FSHR has not been demonstrated, but mutations of this residue in the

gonadotropin receptors also impair hormone binding and activation.*[218]

The serpentine domain of the gonadotropin receptors is characterized by the canonical GPCR structure containing seven transmembrane (TM) segments joined by three alternating intracellular and extracellular loops (Fig. 2.4). The amino acid sequences of this region of the hLHR and hFSHR are 72% identical (Fig. 2.4). A three dimensional structure of the transmembrane domain of the gonadotropin receptors is lacking but the three dimensional structure of several other GPCRs with short extracellular domains have now been solved[213] (also see http://gpcr.scripps.edu) and the transmembrane domain of the gonadotropin receptors is likely to be very similar. Transmembrane domain residues that are highly conserved among the rodhopsin/β_2-adrenergic receptor-like subfamily of GPCRs are also highlighted in Figure 2.4.

Surprisingly, the intracellular domains of the gonadotropin receptors are the most divergent of the three domains (~27% identity, Fig. 2.4). An intracellular cysteine residue present in the juxtamembrane region of the C-terminal tail of the rodhopsin/β_2-adrenergic receptor-like subfamily of GPCRs is, however, among the most highly conserved residues of this subfamily of GPCRs and all members of this subfamily examined to date have been shown to be palmitoylated at this site. This cysteine is towards the C-terminal end of a cytoplasmic helical segment of other GPCRs that is referred to as helix 8 (http://gpcr.scripps.edu) and the palmitate present at this highly conserved position is thought to be embedded in the membrane. The LHR is unusual in having two adjacent cysteines in this position (Fig. 2.4). Although the palmitoylation of the hLHR has not been studied, the mature form of the rLHR expressed in 293 cells, has been shown to be palmitoylated at both of these residues.[211] The equivalent cysteine in the hFSHR is also palmitoylated.[219]

Glycosylation

The ECDs of the hLHR and hFSHR have six and three consensus sites for N-linked glycosylation, respectively (Fig. 2.4). Although it is clear that the hLHR and hFSHR contain N-linked carbohydrates, studies determining whether all potential sites for carbohydrate attachment are utilized have not been performed with the human receptors. This question has only been addressed for both the recombinant rat rLHR and rFSHR expressed in heterologus cell lines as well as the endogenous porcine (p) LHR. In the LHR at least five, or perhaps all six of the glycosylation sites have been reported to be glycosylated.[211] A single study done with the recombinant rFSHR expressed in mammalian cells concluded that only two of the three glycosylation sites are glycosylated.[220]

The FSHR/FSHR complex used in the crystallography studies is partially deglycosylated and full carbohydrate structures are therefore not available. It is clear, however, that carbohydrate residues are present in all four potential glycosylation sites of the hormone (αAsn52, αAsn78, βAsn7, and βAsn24) as well at the first potential glycosylation site of the receptor (Asn191). It is also clear that these are not part of the hormone/receptor interface (Fig. 2.5). Similarly, the potential glycosylation sites of the TSHR are located on the surface of the TSHR that is not involved in binding autoantibodies.[216] These data are consistent with the findings that glycosylation of the gonadotropins or the receptors are not required for hormone binding.[211]

Folding, Maturation, and Transport to the Plasma Membrane

Mammalian cells expressing the recombinant hLHR display several distinct glycoprotein species with molecular masses (estimated from SDS SDS gels) ranging from 65 to 240 kDa.[211] The mature LHR present at the cell surface has been identified as an 85-95 kDa protein whereas a 65-75 kDa band has been identified as an immature, partially glycosylated precursor that is located in the endoplasmic reticulum.[211] The higher molecular weight bands ranging from 165-240 kDa are oligomers of the immature or mature receptors.[211,221] Precursor, mature, and oligomerized forms of the hFSHR can also be detected in transfected cells, but there is more variation on the reported molecular weights of these products. Estimates for the molecular mass of the mature cell surface FSHR range from 74 to 89 kDa whereas estimates for the molecular mass of the immature intracellular precursor range form range from 67 to 82 kDa.[220,222-224] Higher molecular weight forms of the FSHR (~170 kDa) have also been identified and appear to be oligomers of the immature intracellular precursor.[224]

Two different studies using the hLHR or rLHR and site directed mutagenesis, removal of carbohydrate moieties by glycosidase treatment or pharmacological inhibition of carbohydrate attachment, suggest that the nonglycosylated LHR can fold properly, transit to the cell surface (albeit at reduced levels), bind hormone and transduce signals.[211] A similar series of studies done with the rFSHR suggests that one of the two carbohydrate moieties present in this receptor (as stated earlier in the text) is required for the proper folding of the nascent receptor into the conformation that can bind FSH with high affinity.[220] Interestingly the intracellular precursor of the LHR can bind LH and hCG with high affinity,[211] but the intracellular precursor of the FSHR cannot bind FSH.[225]

Many of the studies on the sizes and nature of the different forms of gonadotropin receptors have been done by immunological detection of the epitope-tagged receptors expressed in heterologous cell lines. Immunological detection of the endogenous gonadotropin receptors expressed in

*Shortly after the submission of this Chapter the crystal structure of the entire ectodomain of the FSHR in complex with FSH was published (see paper by Jiang et.al. in the list of recommended readings). This important publication showed that the ectodomain of the FSHR is composed of a short N-terminal region followed by 12 leucine-rich repeats and a short C-terminal region. Importantly, there is a hairpin loop between the 11th and 12th repeats. This overall structure of the ECD hormone complex resembles a right hand holding an American football where the hairpin loop is the thumb of the hand. This structure now suggests that FSH first binds to a hormone binding subdomain composed of LRRs 1-8 and that this interaction induces a conformational change in the L2β loop of FSH that promotes the formation of a second binding site where this loop interacts with LRR 8 and 9 as well as the insertion of a sulfated tyrosine residue in the receptor (Y335, highlighted in yellow in Fig 2.4) between the α and β subunits of FSH. This interaction of the sulfated receptor tyrosine with the hormone is now thought to be essential to the activation of the receptor and the initiation of signal transduction.

the testes or ovaries has been much more difficult because they are expressed at low densities and because of the nature of the gonadotropin receptor antibodies available. Using monoclonal or polyclonal antibodies that have been rigorously validated, the mature and immature forms of the LHR and FSHR described above can indeed be immunologically detected in target tissues.[211]

Low Molecular Weight Gonadotropin Receptor Agonists and Antagonists

Since there is a physical separation between the region of the gonadotropin receptors that binds the hormones (ECD) and the region involved in receptor activation (TM domain, introduced earlier in the text) there must be a way by which binding of the hormones to the ECD transmits a signal that induces conformational changes in the TM domain. In contrast to what is known about conformational changes in the TM domain of other GPCRs, however,[213,226] little is known about these potential changes in the gonadotropin receptors. Nevertheless, the importance of the TM domain of the gonadotropin receptors in receptor activation is underscored by the discovery of a number of low molecular weight (LMW) compounds that interact with the TM domain of the gonadotropin receptors and either serve as allosteric agonists or antagonists.

The first LMW non-peptide gonadotropin receptor agonists and antagonists were identified using high-throughput screening approaches.[227,228] One of the compounds identified in these screens was Org 43553 (molecular weight ~500), a nanomolar potent, allosteric LHR agonist that interacts with the endodomain of LHR and selectively activates the adenylyl cyclase pathway.[229,230] This is in contrast to LH/CG, which bind to the extracellular domain of the LHR (introduced earlier in the text). Org 43553 exhibited a shorter circulatory half-life than hCG, stimulated testosterone production in primary Leydig cells, and was able to induce ovulation in female mice and rats after a single-dose oral administration.[231] Org 43533 also did not induce ovarian hyperstimulation syndrome (OHSS), in preclinical rodent models.[232] Dimeric ligands based on the parent, Org 43533, are also effective, allosteric LHR agonists.[233] Lastly, as discussed below, another allosteric, LMW LHR agonist, Org 42599, functionally rescued the cell surface expression of intracellularly retained LHR mutants that caused Leydig cell hypoplasia in men.[234]

LMW FSHR antagonists capable of inhibiting ovulation and the steroidogenic response *in vitro* have been developed and may have potential as non-steroidal contraceptives.[227,235] LMW agonists that specifically activate the FSHR through allosteric mechanisms have also been described.[236,237] Oral administration of two recently developed LMW FSHR agonists with a short circulatory half-life resulted in surge-like profiles and induced formation of luteinized unruptured antral follicles thereby preventing ovulation in several animal models without affecting cyclicity.[236] Inhibition of follicular rupture was shown to be reversible within one cycle. These studies present a novel approach for reversible female contraception using the short-acting LMW FSHR agonists.

These LMW compounds[238] appear to have great potential for future clinical applications in the treatment of infertility and perhaps as non-steroidal contraceptives. They offer advantages over current therapies utilizing gonadotropins in that they can be administered orally and the LMW compounds can be synthesized at reduced cost and without the variability seen among the preparations of recombinant hormones.

Other Receptors Related to the Gonadotropin Receptors

The LHR, FSHR, and TSHR are the founding members of a subfamily of GPCRs characterized by the presence of a large N-terminal ECD containing several LRRs (stated earlier in the text). This glycoprotein hormone receptor family, which has been renamed the leucine-rich repeat-containing G-protein-coupled receptor (LGR) family, has been expanded to include five additional LGRs designated LGR4-8.[239] Some of these are also now known as the relaxin family peptide receptors (RXFP).[240] Interestingly, LGR8 (RXFP2) is a receptor for insulin-like peptide 3, which is involved in testicular descent.[241]

The Gonadotropin Receptor Genes and Transcripts

Genes

The human lutropin and follitropin receptors are encoded by single genes located about 200 Kb apart in the short arm of chromosome 2 *LHCGR*; http://www.ncbi.nlm.nih.gov/gene/3973 and *FSHR*; http://www.ncbi.nlm.nih.gov/gene/2492.

The *LHCGR* is about 70 Kb in length and is composed of 11 exons whereas the *FSHR* is about 190 Kb long and is composed of 10 exons. The transmembrane and C-terminal domains of the receptors are encoded by exon 10 for the *FSHR* and by exon 11 of the *LHCGR*. These exons also code for the C-terminal end of the hinge region of the extracellular domain of each receptor. The N-terminal cysteine-rich region, all of the leucine rich repeats, and the N-terminal end of the hinge region of the extracellular domain of these receptors arise from the splicing of the remaining exons.

The 5′ flanking regions of the *LHCGR* and *FSHR* are rich in GC and the proximal promoters of both genes are devoid of TATA boxes.[242,243] The cis- and trans-acting elements that control the transcription of the mouse, rat and human *LHCGR* have been examined in some detail and have been reviewed elsewhere.[242] Initial studies with transgenic mice harboring reporter genes driven by ~7, ~, or ~0.17 kb of the 5′-flanking sequence of the mouse *Lhcgr* express the transgene in adult Leydig cells, but not in fetal Leydig cells or ovarian cells.[244] More recent studies have shown that transgenic mice harboring reporter genes driven by 2-4 kb of the 5′-flanking sequence of the rat *Lhcgr* express the transgene in the gonads, adrenal glands, kidneys, and several areas of the peripheral and central nervous systems.[245,246]

Studies on the transcriptional control of the *FSHR* have been done mostly with the rodent genes and reviewed recently as well.[243]

Transcripts

There is controversial evidence regarding the number and nature of multiple FSHR transcripts.[243] Most of the studies on this issue have been done in sheep and mouse models, and as many as four different transcripts that arise

from alternative splicing and are presumably translated into functional proteins with distinct signaling properties have been reported.[247] Multiple transcripts of the LHR have also been identified and they arise from alternative splicing or from the use of two different polyadenylation domains present in the 3′ flanking region of the *LHCGR*.[242] Although the presence of these transcripts raises intriguing questions regarding their possible physiological roles, it is important to point out that for the most part, data that demonstrate the presence of proteins arising from such transcripts is lacking.

Naturally Occurring Mutations of the Gonadotropin Receptor Genes

A number of naturally occurring mutations of the *LHCGR* and *FSHR* associated with human reproductive disorders have been reported. These are shown in Figures 2.6 and 2.7 and have been extensively reviewed.[116,211,215,242,248,249]

Naturally occurring loss of function or inactivating mutations of the hLHR occur throughout the polypeptide chain as shown in Figure 2.6. These are all germ-line mutations and a phenotype is obvious only in individuals who are homozygotes or compound heterozygotes. In women, inactivating mutations of the hLHR are associated with low estrogen production and annovulatory disorders.[116,211,215,248,249] In men, the most severe phenotype is a complete absence of Leydig cells and pseudohermaphroditism. Other milder phenotypes in 46XY individuals include hypospadias and micropenis.[116,211,215,248,249]

The phenotype associated with the deletion of exon 10 deserves special mention. This mutant was initially found in a 46XY individual who failed to undergo puberty in spite of normal sex differentiation.[250] When expressed in a heterologous cell line a hLHR construct lacking the amino acids encoded by exon 10 (residues 290-316 in the hinge region of the ECD; Fig. 2.4) is transported properly to the cell surface and binds hLH and hCG with high affinity.[251] Interestingly, cells expressing this mutant respond to hCG normally but their sensitivity to hLH was reduced about 40-fold.[251] Therefore, the residues encoded by exon 10 of the hLHR do not participate in hormone binding, but appear to be involved in receptor activation by hLH but not by hCG. The LHR of the marmoset monkey provides an interesting evolutionary parallel to the hLHR variant lacking exon 10. The marmoset pituitary does not express LHβ[252] and exon 10 of the marmoset monkey *LHCGR* is spliced out of the

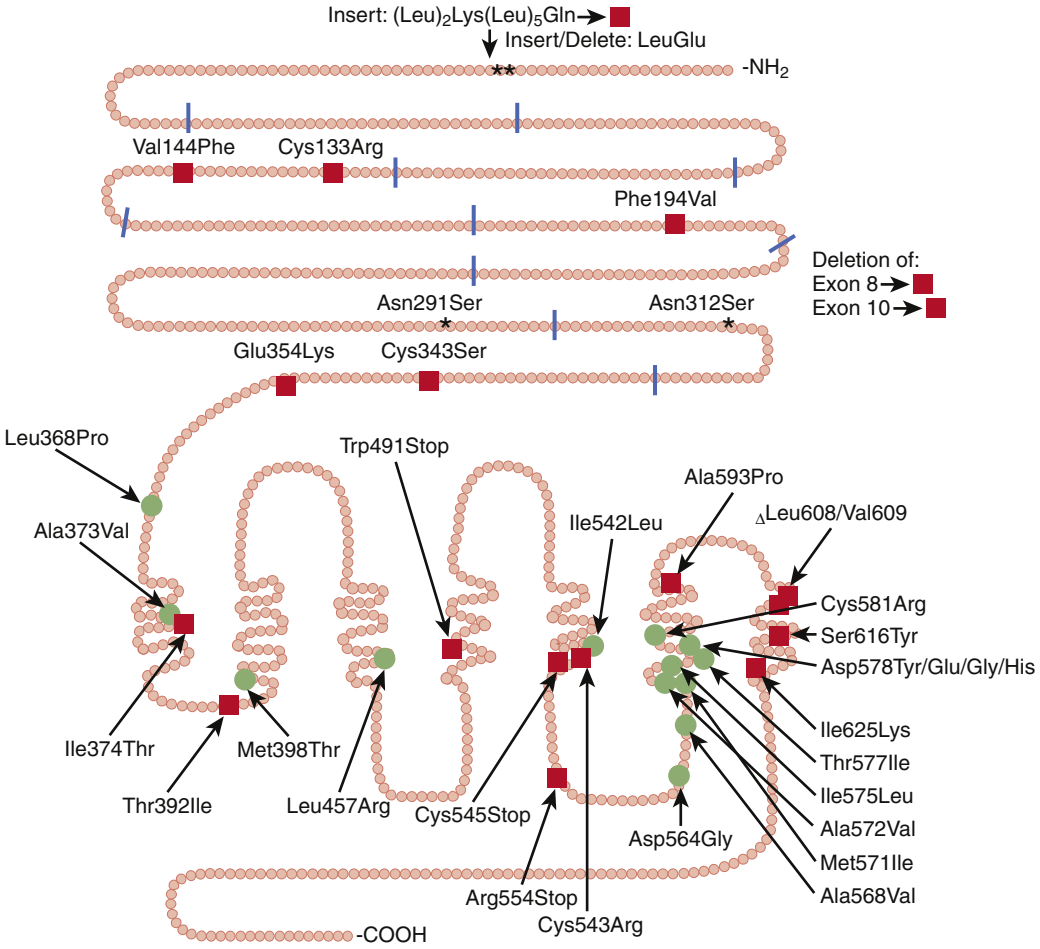

FIGURE 2.6 Location of naturally occurring polymorphisms, loss-of-function mutations, and gain-of-function mutations of the human luteinizing hormone receptor (hLHR). Polymorphisms are shown with *asterisks,* loss-of-function mutations are shown with *red squares,* and gain-of-function mutations are shown with *green dots*. The sequences coded for by the different exons are demarcated by vertical *blue bars. (From Themmen APN. An update of the pathophysiology of human gonadotrophin subunit and receptor gene mutations and polymorphisms.* Reproduction *130:263–274, 2005. © Society for Reproduction and Fertility [2005]. Reproduced by permission.)*

mature messenger ribonucleic acid mRNA[253] yet this receptor can bind hCG with a high affinity and respond to the bound hCG.[253] A recent study has begun to identify regulatory elements of the *LHCGR* that influence the usage of exon 10.[254]

As shown in Figure 2.6, the inactivating mutations of the hLHR can take many forms, ranging from single amino acid mutations, nonsense mutations that result in truncated receptors, small insertions or deletions as well as large insertions or deletions. Although some of these mutations prevent hormone binding or activation (as stated earlier in the text), many of them impair the maturation and/or transport of the hLHR precursor so that the expression of the mature hLHR at the cell surface is completely lost or a least partially reduced.[249] Therefore the phenotype of individuals harboring inactivating mutations of the hLHR is mostly due to a net loss of cell surface hLHR rather than to the expression of a receptor that binds hormone but cannot become activated.

In contrast to the heterogeneous location of the naturally occurring loss-of-function mutations of the hLHR, all naturally occurring gain-of-function mutations reported to date are localized in exon 11 which codes for C-terminal end of the hinge region of the extracellular domain as well as the transmembrane and intracellular regions of the hLHR (Fig. 2.6).[116,211,215,242,248,249] All of these are single point mutations and many of them cluster to transmembrane helix

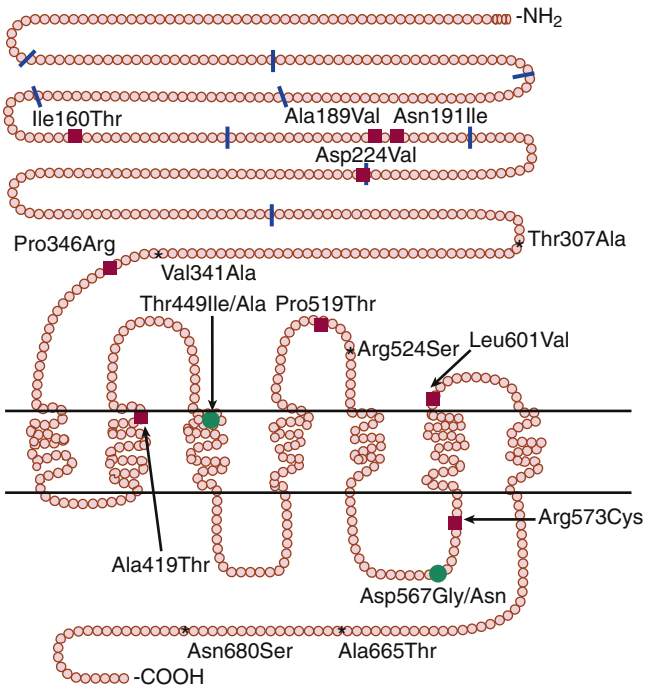

FIGURE 2.7 Location of the naturally occurring polymorphisms, loss-of-function mutations, and gain-of-function mutations of the human follicle-stimulating hormone receptor (hFSHR). Polymorphisms are shown with asterisks, loss-of-function mutations are shown with *red squares,* and gain-of-function mutations are shown with *green dots*. The sequences coded for by the different exons are shown with *vertical blue bars. (From Themmen APN. Reproduced by permission.)*

6 and intracellular loop 3 (Fig. 2.6). Four of these mutations are associated with a single residue (Asp578), which is found mutated to Gly, Glu, Tyr, and His (Fig. 2.6). Gain of function mutations of the hLHR are found in heterozygous boys with familial male limited precocious purberty, but there is no phenotype in female carriers.[116,211,215,242,248,249] All of these mutations are also germ-line, with the exception of the Asp578His mutation, which has only been found as a somatic mutation in the Leydig cells of several unrelated boys with precocious puberty and Leydig cell adenomas.[255-258]

When expressed in heterologous cell types these gain of function hLHR mutants display variable levels of constitutive (i.e., hormone-independent) activity, and addition of LH or hCG to cells expressing these mutants may or may not result in additional activation.[116,248,249,258-262]

Naturally occurring mutations of the *FSHR* are fewer in number but can be similarly classified (Fig. 2.7). The most severe phenotype in homozygous females harboring inactivating mutations such as Ala189Val and Ala419Thr is hypergonadotropic hypogonadism, arrest of follicular maturation beyond the primary stage, and complete lack of responsiveness to hFSH. Less severe phenotypes are observed in women who are homozygous or compound heterozygous for other mutations and they include secondary amenorrhea, gonadotropin resistance, and follicular development up to the antral stage.[116,263] The phenotype in homozygous males is not nearly as obvious. Sperm quality is reduced but fertility is maintained.[116,263] The functional properties of many of these hFSHR mutants have been studied by expressing the mutants in heterologous cell lines. As in the case of the hLHR many of these mutations impair the transport of the hFSHR to the plasma membrane thus inducing a complete lack of hFSH binding and therefore responsiveness.[116] At least one of them, however, (Ala419Thr in transmembrane helix 2) impairs signal transduction while having little effect or no effect on hFSH binding or the proper trafficking of the hFSHR to the plasma membrane.[264]

Only three activating mutations of the *FSHR* have been described and they are all located in exon 10 which codes for the transmembrane and intracellular domains (Fig. 2.7). The Asp567Gly in intracellular loop 3 was identified in a hypophysectomized male with undetectable gonadotropins who responded to testosterone treatment with normal spermatogenesis.[265] The activating nature of this mutation, however, is not readily apparent when the mutant receptor is expressed in heterologous cells.[265] The other two activating mutations of the *FSHR* (Fig. 2.7) were initially discovered in women with recurrent spontaneous ovarian hyperstimulation syndrome.[266-268] When these mutants are expressed in heterologous cell types, they display a weak but detectable level of constitutive activity; they also display increased sensitivity to hCG and to TSH while maintaining normal sensitivity to hFSH.[215] This latter change in binding specificity is responsible for the ovarian hyperstimulation experienced by the women harboring these mutations. In this context, it is worth mentioning that one naturally occurring mutation of the extracellular domain of the TSHR that renders it more sensitive to hCG was found in two women who experienced hyperthyroidism during pregnancy.[269]

Polymorphisms of the Gonadotropin Receptor Genes

Many single nucleotide polymorphisms (SNPs) of the *LHCGR* and *FSHR* have been identified: (http://www.ncbi.nlm.nih.gov/SNP/snp_ref.cgi?locusId=3973; http://www.ncbi.nlm.nih.gov/SNP/snp_ref.cgi?locusId=2492).

Only three SNPs of the *LHCGR* occur in exons. A six nucleotide in-frame insertion/deletion between codons 18 and 19 of exon 1 results in the expression of two hLHR variants that differ by the presence or absence of a Leu-Gln pair near the C-terminus of the signal peptide (Fig. 2.6)[270,271] The functional implications of the presence or absence of this insertion are unclear, however.[270,272,273] Two additional frequent SNPs in exon 10 of the hLHR gene code for either Asn or Ser in codons 291 and 312 in the hinge region of its extracellular domain. The presence of Asn or Ser at either of these positions does not appear to change the expression or functions of the hLHR.[274] This is interesting because codon 291 is a glycosylation site when Asn is present in this position (Fig. 2.4).

Only five of the *FSHR* SNPs are exonic. They are all located in exon 10 but only four cause a coding change (Ala307Thr, Arg524Ser, Ala665Thr, and Ser680Asn). The most common and best studied polymorphisms are Ala307Thr and Ser680Asn (Fig. 2.7). These two polymorphisms are in linkage disequilibrium and the most common allelic variants, Thr307/Asn680 and Ala307/Ser680, are almost equally distributed among Caucasians.[116] The Ala307Thr and Ser680Asn polymorphism appears to have predictive value for determining the optimal dose of FSH to use in controlled ovarian hyperstimulation protocols.[263,275-277] Women harboring the Ala307/Ser680 variant require higher doses of FSH. These variants may also be predictive of the responsiveness of PCOS patients to clomiphene.[275-277] Studies of the Ser680 or Asn680 hFSHR expressed in heterologous cells types have failed to reveal any differences in the functional properties of these receptors, however.[278,279] A polymorphism in the 5′ flanking region of the *FSHR* (-29 G/A) has also been reported to affect responsiveness to FSH stimulation because of its effect on the expression of the FSHR but there is no agreement on this finding yet.[275-277]

A more complete and up-to-date list of mutations and polymorphisms of the gonadotropin receptors can be found at: http://gris.ulb.ac.be.

Regulation of the Expression of the Gonadotropin Receptors

Transcriptional Regulation

In addition to directing the basal expression of the *LHCGR* and *FSHR*, transcriptional regulation of these genes is involved in the hormonal regulation of receptor expression in the ovary and perhaps the testes as well. For example, the increase in LHR that occurs during the growth and differentiation of rodent granulosa cells is accompanied by an increase in LHR mRNA that is mediated, at least in part, by an increase in the transcription of the *LHCGR*.[211] An exhaustive review of the hormonal regulation of the transcription of the *LHCGR* and *FSHR* is, however, beyond the scope of this chapter and the reader is referred to recent reviews of this important but complex area.[242,243,280] A summary of the regulatory elements that modulate basal expression of the *LHCGR* and *FSHR* has already been presented above.

Post-Transcriptional Regulation

Post-transcriptional regulation is also an important aspect of the regulation of the LHR mRNA and the LHR during the preovulatory LH surge.[280] This important level of regulation seems to be mediated by mevalonate kinase, an enzyme that is involved in cholesterol metabolism that is also an LHR mRNA binding protein.[280] The LH-induced activation of steroidogenesis and subsequent depletion of cholesterol triggers an increase in the transcription of genes that participate in cholesterol biosynthesis including mevalonate kinase. The increased levels of this protein may thus serve the dual role of enhancing cholesterol synthesis (an enzymatic function) and decreasing the levels of LHR mRNA by virtue of its ability to bind the LHR mRNA and enhance its degradation.[280]

Post-Translational Regulation

The processing and transport of the immature LHR from the endoplasmic reticulum to the cell surface have important implications to human disease because the majority of the naturally occurring mutations of the hLHR that cause gonadotropin resistance (as stated earlier in the text) are due to the intracellular retention of the misfolded hLHR.[281-283] Interestingly, when added to cells expressing some of the misfolded hLHR mutants, one of the low molecular weight agonists of the LHR (Org 42599, mentioned earlier in the text) partially rescues these naturally occurring mutants and enhances gonadotropin responsiveness.[284]

The gonadotropin receptors form oligomers in the endoplasmic reticulum and at the plasma membrane, in a process that is unrelated to receptor activation.[217,285] Importantly, co-expression of a misfolded gonadotropin receptor with its wild-type counterpart impairs the cell surface expression of the wild-type receptor and attenuates signaling.[217,221,285,286] Coexpression of splice variants of the LHR may also regulate the expression of the LHR and FSHR by forming intracellular oligomers that prevent the proper processing of the intracellular LHR precursor[287,288] For example, LHR transcripts lacking exon 9 are prevalent in normal human ovaries but the resulting protein is not able to bind hCG or to be adequately processed to be expressed at the cell surface.[289,290] When coexpressed with the wild-type hLHR or hFSHR the mutant lacking exon 9 associated with the immature forms of these receptors and decreased their cell surface expression.[289,290] Other studies have suggested that coexpression of a signaling inactive LHR with a binding inactive LHR leads to their dimerization and functional complementation such that, together, they can partially restore LH signaling,[291-294] but the interpretation of these results has been challenged.[295]

Some reports indicate that during development several rat tissues such as the gonads, adrenal glands, and kidneys express the immature form of the LHR whereas nervous tissues express both the mature and immature forms.[245,246] Interestingly, rodent gonads appear to express the mature LHR only after birth,[246] suggesting that the developing rat gonads are insensitive to the actions of LH. This finding is consistent with the phenotype of the LHR knockout mice which display arrested gonadal development only after

birth.[296,297] The expression of the mature LHR in rat tissues also seems to be under hormonal control as indicated by the finding that the mature LHR becomes detectable in the female adrenal glands and kidney during pregnancy.[246] Direct actions of gonadotropins on the kidneys are controversial, but expression of functional LHR that mediate direct actions on LH/CG in the pregnant adrenal gland have been well documented (discussed later in the text).

Another level of posttranslational regulation involves phosphorylation and regulated degradation of the mature gonadotropin receptors. This has been demonstrated for both, the LHR and the FSHR but most of these experiments have been done in heterologous cell types and their physiological significance is still debated.[260,298-307]

Phosphorylation of GPCRs is an important event for binding arrestins, a family of GPCR binding proteins that are involved in signaling, internalization, and desensitization.[308-310] The phosphorylation of the hLHR appears to be largely dispensable for arrestin binding and internalization,[259,260,311,312] whereas the phosphorylation of the rFSHR appears to be needed for arrestin binding and internalization.[305,311,313-315] It is also now accepted that some GPCRs can display "biased" signaling, either using arrestins or G proteins,[310,316] and recent reports suggests that partially deglycosylated equine LH and one of the inactivating mutants of the FSHR (Ala189Val, Fig 2.7) may signal through arrestins rather than G proteins.[310,317]

Hormone-induced internalization of the gonadotropin receptors is also dependent on arrestin binding and is an important process, because, depending on the fate of the internalized receptor, it can serve the function of preserving or preventing hormonal responsiveness. Interestingly, after hormone-induced internalization, the complex formed by hCG and the rodent or porcine LHR is largely routed to an intracellular degradation pathway[211] that is ultimately responsible for the degradation of hCG and a net loss of cell surface LHR and hormonal responsiveness.[211] The fate of the internalized hLHR is different, however, in that a substantial portion of the hCG-hLHR complex is routed to a recycling rather than a degradation pathway.[211] Cells expressing the hLHR recycle most of the internalized hormone and receptor and thus, the loss of hormonal responsiveness induced by gonadotropins is not as pronounced in cells expressing the hLHR as in those expressing the rLHR.[318] In contrast to the difference in the fates of the internalized hLHR and rFSHR, the internalized hFSHR and rFSHR are both routed mostly to a recycling pathway.[319] Cells expressing these receptors recycle most of the internalized FSH and FSHR and thus, the loss of hormonal responsiveness induced by FSH is relatively minor.[318]

Several amino acids present in the extreme C-terminus of the hLHR and one cellular protein that is important for recycling of the hLHR have been identified.[320-322] Amino acids of the FSHR that are important for recycling are also located in the extreme C-terminal tail.[319]

Expression of the Gonadotropin Receptors in Extragonadal Tissues

For many years, the LHR and FSHR were thought to localize strictly to gonadal cells. In the testes, the LHR and FSHR are thought to be restricted to Leydig and Sertoli cells, respectively. In the ovary, expression of the LHR occurs in theca, interstitial and, granulosa cells whereas the FSHR is localized to granulosa cells. Certainly, the main physiological roles of the gonadotropin receptors can be attributed to their actions in the ovaries and the testes as demonstrated by the phenotypes of individuals harboring activating or inactivating mutations of these genes (as stated earlier in the text) and by the phenotypes of mice with targeted inactivation of the *LHCGR*[296,297] or *FSHR*.[323,324]

There is a large but still controversial body of literature suggesting that functional LHR, may be present in a number of extragonadal tissues.[325,326] The suggestion of extragonadal LHR expression has been based in many cases upon the detection of fragments of the LHR mRNA. Attempts to detect immunoreactive LHR protein often result in the identification of a protein (or proteins) that do not match the expected molecular weight of the authentic gonadal LHR (as stated earlier in the text). A comparison of the actions of LH/CG in isolated cells or tissues from wild-type and LHR null mice would go a long way in shedding light on this controversy but curiously this has not been done often. In a recent study on the potential angiogenic activity of hCG it was shown that the proangiogenic effect of hCG was clearly ameliorated in blood vessels isolated from the LHR null mice.[327] This finding clearly shows that a functional, classical LHR is expressed in blood vessels.

Some of the clearest evidence for the extragonadal expression of a functional LHR comes from studies done on a woman who developed pregnancy-dependent Cushing syndrome and later developed it again after menopause.[328] After menopause there is clear evidence that the cortisol levels in this woman were controlled by LH because suppression of the hypothalamic/pituitary axis with leuprolide controlled the hypercortisolism.[328] Clinical findings in a number of other cases also seems to be explained by the inappropriate expression of the LHR in the adrenal cortex or in adrenocortical tumors.[329,330] Lastly, ectopic expression of functional LHR in the adrenal cortex seems to be a common finding in transgenic or knock-out mouse models with elevated levels of gonadotropins,[330] and expression of the mature LHR can be readily documented in the adrenal glands of pregnant rats.[246]

Studies on the potential extragonadal expression of the FSHR are more limited in nature but equally controversial. A recent study suggesting that FSH has direct actions in bone because of the expression of the FSHR in osteoclasts[331] has been challenged.[332-334] There is also some evidence for the expression of the FSHR in the prostate,[335] as well as tumor blood vessels.[334]

In spite of all this information, the phenotypes of genetically engineered mice with exaggerated or absent gonadotropin actions, as well as the phenotypes of men or women harboring activating or inactivating mutations of these gonadotropin receptors, it (as stated earlier in the text) appears to be explained entirely by the classical actions of LH and FSH in gonadal tissues.[205,326,336]

Signaling Pathways Activated by the Gonadotropin Receptors

Although most investigators agree that the effects of the gonadotropins on the differentiated function of their target

cells are mediated mostly (if not entirely) by the activation of the Gs/adenylyl cyclase/cAMP/PKA pathway, it is abundantly clear now that this is not the only pathway activated by these receptors. Additional pathways are activated as detailed below and these may be involved in other gonadotropin-dependent events such as the proliferation and/or differentiation of target cells.

The LHR was one of the first GPCRs shown to independently activate two G protein-dependent signaling pathways, adenylyl cyclase and phospholipase C.[337,338] This observation was initially made in heterologous cells expressing the recombinant mouse LHR but it has now been extensively reproduced by a number of investigators using a variety of cell lines transfected with either the rodent or human LHR.[211] The FSHR also activates both of these cascades when expressed in non-target[302-304] or target cells.[339,340] In general, however, the gonadotropin receptor-mediated activation of phospholipase C is detectable only when cells expressing a high density of receptors are exposed to high concentrations of gonadotropins[262,340] and there is no consensus on the physiological consequences of this activation.[339-342] In addition, the LHR has been reported to activate members of the other three families of G proteins[261,343,344] but again, little is known about the functional consequences of the activation of these G proteins.

The ovarian ERK1/2 cascade is also activated by the FSHR and LHR but the mechanisms involved in its activation are complex and poorly understood.[339,345-349] The importance of this cascade on the actions of LH is underscored by the finding that a granulosa cell specific deletion of ERK1/2 in mice results in infertility due to an ovulatory defect.[350,351] This study also showed that most of the ovarian genes that are up- or down-regulated by LH are targets of ERK1/2.[350,351]

More recently, the two gonadotropin receptors (but specially the LHR) have been shown to activate small GTPases such as Ras,[346,349,352] and tyrosine kinases such as members of the Src and/or ErB receptor family.[346,347,350] The molecular basis of the activation of these pathways are still actively being investigated, but the LHR-induced transactivation of the EGF network, which involves several EGF-like growth factors and several ErB receptors is now known to be an essential mediator of the LHR-provoked ovulatory response.[347]

CHAPTER 3

Prolactin in Human Reproduction

Mark E. Molitch

Prolactin (PRL), a hormone with roles in reproduction, lactation and metabolism, is made by the pituitary lactotrophs which, in the normal human pituitary, comprise about 15% to 25% of the total number of cells. Lactotrophs are similar in number in both sexes and do not change significantly with age.[1] During gestation and subsequent lactation there is considerable lactotroph hyperplasia due to the stimulatory effect of the hormonal milieu of pregnancy.[2,3] The hyperplastic process involutes within several months after delivery, although breast-feeding retards this process.[3] This stimulatory effect of pregnancy on the lactotrophs also holds true for prolactinomas, explaining why very significant tumor enlargement may occur during pregnancy. As described later in this chapter, the proliferation of lactotrophs and increase in PRL secretion is due, at least in part, to autocrine and paracrine mechanisms playing out within the pituitary gland. This chapter reviews the physiology of PRL and the pathophysiology of hyperprolactinemic states, their diagnosis, and management.

Anatomy and Physiology

Lactotroph Morphology and Ontogeny

During embryologic development, the ectodermal primordial cells of the anterior and intermediate lobes of the pituitary make contact with the neuroectoderm of the floor of the diencephalon. Inductive interactions between these tissues occur that are necessary for their subsequent interdependent development.[4,5] There are a number of transcription factors (Six-3, Hesx1, Lhx3, Lhx4, Sox2, Sox3, Pitx2, Otx2, Bmp2, Bmp4, and GLi2) that are sequentially expressed in the developing hypothalamus and pituitary that lead to the final determination of the five mature pituitary cell types and the functional integration of the hypothalamic-pituitary system.[4-6]

The POU homeodomain transcription factor, Pou1f1 (Pit-1), is necessary for the activation of the *PRL*, growth hormone *(GH)*, GH releasing hormone *(GHRH)* and thyroid-stimulating hormone β *(TSHβ)* genes as well as being necessary for the differentiation and proliferation of these cell lineages. Point mutations in the POU homeodomain of *Pou1f1* have been found to be the cause of the syndrome of combined GH, PRL, and TSH deficiencies found in humans, with absence of somatotroph, lactotroph, and thyrotroph cells.[4-6] A second paired-like homeodomain factor, known as Prophet of Pit-1 (Prop-1) has also been found to be necessary for the expression of Pit-1 and mutations of the *Prop-1* gene cause variable deficiencies of GH, PRL, TSH, luteinizing hormone (LH) and follicle-stimulating hormone (FSH).[4-6] Mutations in the *Lhx4* and *Hesx1* genes caused combined pituitary hormone deficiencies as well as other brain developmental defects.[5,6] Lactotrophs and somatorophs are thought to arise from a common progenitor, the mammosomatotroph, under the regulation of these and other transcription factors during embryologic development, but it is possible that some lactotrophs arise directly from a common pituitary progenitor cell without passing through this mammosomatotroph step.[7]

Prolactin Gene Structure and Regulation

The *PRL* gene in the human is located on chromosome 6.[8] The human *PRL* gene is approximately 10 kb long and consists of five coding exons, one non-coding exon, and four large introns.[9,10] In the 5′ flanking region there are specific regions responsible for tissue-specific Pou1f1 transcription activation. The transcription enhancement of the *PRL* gene by Pou1f1 can be modified by other factors, such as thyrotropin-releasing hormone (TRH), epidermal growth factor (EGF), cyclic adenosine monophosphate (cAMP),[11-13] glucocorticoids,[14] and estrogens.[15] Other areas of the 5′ flanking region have also been found to involved in the suppression of *PRL* gene transcription by thyroid hormone and stimulation by estrogen.[15-19] Estrogen also increases PRL by modulating the inhibitory effect of dopamine (DA) on *PRL* gene transcription.[20,21]

A number of factors affecting PRL secretion, including TRH and dopamine (DA), act through the phosphoinositide-signaling pathways with resultant release of calcium from the endoplasmic reticulum and an activation of membrane calcium channels.[22] Increases in intracellular calcium result in activation of protein kinase C, which phosphorylates downstream effector proteins.

A second transduction pathway involving membrane phospholipids is the arachidonate pathway. In vitro stimulation of membrane-bound phospholipase A_2 by TRH, angiotensin II, neurotensin and other direct stimulators releases PRL and arachidonic acid from pituitary cells.[23,24] This stimulated release of arachidonic acid release is blocked by inhibitors of phospholipase A_2[23] and by DA.[25] Arachidonic acid increases PRL release primarily by an increase in calcium influx, not through mobilization of intracellular calcium stores.[26]

In addition to effects on protein kinase C, calcium also binds to topoisomerase II, which then interacts with specific DNA binding sites and to calmodulin. In turn, calmodulin then binds to a number of different intracellular enzymes.[27] TRH appears to cause rapid release of PRL via activation of

protein kinase C and calcium store mobilization but not calcium channel-mediated transport, and its effects on *PRL* gene transcription and PRL synthesis involve all three processes.[27]

Dopamine, the primary PRL inhibitory factor (PIF), acts through the D_2 DA receptor, inhibiting adenyl cyclase, the cAMP/protein kinase A pathway and possibly other mechanisms.[28] DA inhibits the PRL release induced by activation of calcium channels and by mobilization of intracellular calcium stores.[29] Conversely, the calcium channel blockers nimodipine, verapamil, and diltiazem antagonize the inhibitory effect of DA *in vitro*.[30] However, administration of the calcium channel blocker verapamil to humans causes an *increase* in serum PRL levels[31,32] and does *not* inhibit the TRH-induced PRL rise.[32] This was shown to be due to a decrease in tuberoinfundibular generation of DA.[33] Dihydropyridine and benzothiazepine calcium channel blockers have no effect on PRL levels in humans,[33] and it is likely that the effect of verapamil is via action at N-type calcium channels present in neuronal tissues.[33]

Vasoactive intestinal peptide (VIP) stimulates PRL release primarily through stimulation of adenyl cyclase and the production of intracellular cAMP.[34,35]

Hormone Biosynthesis

The mature PRL mRNA formed after nuclear processing of the original heteronuclear RNA is only about 1 kb long and codes for a 227 amino acid sequence which includes an initial 28 amino acid signal peptide and the 199 amino acid structural peptide.[9,10]

There is considerable heterogeneity in the final PRL product, depending upon variations in the extent of post-translational modifications (which include cleavage, polymerization, glycosylation, phosphorylation, and degradation). About 80% to 90% of PRL extractable from pituitaries and in serum is monomeric, 8% to 20% is dimeric (molecular mass 45 to 50 kDa), and 1% to 5% is polymeric.[36,37] These larger molecular weight polymers have decreased binding to receptors and display decreased bioactivity in a variety of receptor assays[36,37] but have normal bioactivity in the Nb_2 lymphoma cell bioassay.[37] Some of the cleavage products of PRL have been found to have anti-angiogenic function but their physiologic significance is not clear.[38]

Several patients described as having elevated basal serum PRL levels but normal reproductive function were found to have elevated proportions of polymeric PRL. This "macroprolactinemia" presumably resulted in less PRL bioactivity.[39-42] In other cases, the larger molecular weight moieties consist of monomeric PRL bound to immunoglobulin[43]; however, in many such reported cases the proportion of monomeric PRL in the blood is still elevated (discussed later in the chapter).

Decidual Prolactin

PRL levels in maternal blood rise throughout gestation and are of pituitary origin.[44,45] However, PRL concentrations in amniotic fluid are 10- to 100-fold higher than either maternal or fetal blood levels.[44] Cultured human chorion and decidual cells synthesize and release a PRL into the amniotic fluid that is identical to pituitary PRL in structure and bioactivity.[46-49] Decidual PRL mRNA is indistinguishable from pituitary PRL mRNA except for four silent nucleotide differences and the decidual *PRL* gene is about 150 nucleotides longer in the 5′ untranslated region.[50-52]

The regulation of decidual PRL production differs from that of pituitary PRL. DA agonists[53] and antagonists[54] given to the mother respectively decrease and increase maternal serum PRL levels, but have no effect on amniotic fluid PRL levels. Decidual PRL production is increased by progesterone and progesterone plus estrogen (but not estrogen alone),[51,55] insulin, insulin-like growth factor 1 (IGF-1), and relaxin.[51,56,57] The function of decidual PRL in humans remains obscure, although there is some evidence from animal studies that it may contribute to the osmoregulation of the amniotic fluid, fetal lung maturation, uterine contractility, and modulation of the uterine immune system.[58] Recent evidence suggests that decidual PRL may silence the expression of genes detrimental to pregnancy.[59] Interestingly, in some animal species, a large number of PRL-related genes in trophoblastic tissue have evolved whose products involve the coordination of maternal, extraembryonic and fetal tissues including immunologic activity.[60]

Measurement Of Prolactin

With conventional assays there is considerable variation in different laboratories in the measurement of PRL levels and normal values need to be established for each laboratory.[61] Over the past decade, two-site immunoradiometric assays (IRMA) and chemiluminometric assays (ICMA) have come into wide use because of improved sensitivity and precision and short incubation periods.

Hook Effect

In patients with large prolactinomas, the very high PRL levels may saturate the antibodies in two-site assays, preventing the formation of the PRL-antibody sandwich. As a result, labeled antibody is lost and a falsely low PRL value may be reported.[62,63] St. Jean and colleagues noted this high end "hook effect" in 5.6% of 69 patients thought to have clinically nonfunctioning adenomas.[62] Therefore, in patients with large macroadenomas, PRL assessments should always be performed in both undiluted and 1:100 diluted serum to exclude the "hook effect" when two-site assays are used.

Macroprolactin

Normally, over 90% of PRL is present in serum as the 23 kDa monomer and less than 10% is in larger molecular weight forms (discussed earlier in the chapter). These large molecular forms are referred to as macroprolactin and are usually comprised of PRL bound to immunoglobulin (IgG), but sometimes it is in the form of oligomers.[64-66] The gold standard method of measurement is to put a serum sample on a gel chromatography sizing column.[65-67] However, another more easily done method is to add polyethylene glycol (PEG) to the serum; the larger molecular weight forms will precipitate and the monomeric form is left in the supernatant.[64-68] However, this method is very assay-dependent and not technically feasible on all commercial assays.[69]

Some investigators have stated that in a patient with hyperprolactinemia, if the amount of PRL left after PEG precipitation is less than 50% or 40%, then the hyperprolactinemia is due to macroprolactin.[68] However, others

have suggested that since some macroprolactin is present in normal serum and/or some monomer is precipitated with PEG, that the "normal" range should be recalculated from normal samples after PEG treatment; therefore, hyperprolactinemia can be attributed to macroprolactin only when the level of nonprecipitated PRL, i.e., monomeric PRL, is within the normal range.[70] It is clear that in many studies even when the amount of nonprecipitated PRL is less than 40% of the total, the level is still above the normal range.

An important issue is the bioactivity of the macroprolactin, as it is implied that it is of no biological significance. In most series looking at patients with macroprolactin, there tend to be fewer symptoms in those whose hyperprolactinemia has been attributed to macroprolactin than in those with true hyperprolactinemia.[67-71] When macroprolactin is put into the rat Nb2 lymphoma cell culture system, a standard *in vitro* prolactin bioassay system, macroprolactin tends to have the same bioassayable activity as monomeric PRL.[72] However, when bioassays are used in which the human PRL receptor was stably transfected and expressed in murine Ba/F-3 cells or human embryonic kidney-derived 293 (HEK-293) cells, the bioactivity of macroprolactin was shown to be decreased.[73,74]

In studies in which patients with hyperprolactinemia, thought to be due (often in retrospect) to macroprolactin, have been treated with dopamine agonists, galactorrhea, when present, has generally disappeared, but oligo-amenorrhea has been variably responsive.[67,68,70,71] Long-term follow-up studies of patients diagnosed with macroprolactinemia show considerable instability of levels (up to fivefold).[67]

In clinical practice, if a patient has relatively typical symptoms, such as galactorrhea, amenorrhea, or impotence and is found to have mild hyperprolactinemia, the usual exclusions should be looked for (medication history, hypothyroidism, elevated creatinine, pregnancy—discussed later in the chapter), and then the patient should have a Magnetic Resonance Imaging (MRI) scan, primarily to exclude a large lesion such as a craniopharyngioma or clinically nonfunctioning adenoma. If the patient has equivocal symptoms (such as headaches or decreased libido), but has normal menses and no galactorrhea and is found to have mild hyperprolactinemia, assessment for macroprolactin would seem reasonable using PEG precipitation. The decision that the hyperprolactinemia is due to macroprolactin would then depend on demonstrating an abnormal amount of PEG-precipitable PRL, and an absolute level of monomer that is within the normal range. Only in such a patient would an MRI scan not be indicated, but such patients should continue to be followed clinically and biochemically on a periodic basis.

Hormone Secretion Patterns

Episodic Secretion

Prolactin is secreted episodically. There are 13 to 14 peaks per day in young subjects, with a peak duration lasting 67 to 76 minutes, a mean peak amplitude of 3 to 4 ng/mL, and an interpulse interval of 93 to 95 minutes.[75,76] Disinhibition seen with hypothalamic tumors causes an increase in basal PRL levels due to an increase in pulse amplitude, not pulse frequency.[77] There is an increase in the amplitude of the PRL secretory pulses that begins about 60 to 90 minutes after the onset of sleep; the secretory pulses increase with non-rapid eye movement (REM) sleep and fall prior to the next period of REM sleep.[78] An increase in circulating PRL levels of 50% to 100% occurs within 30 minutes of meals[79] due to the amino acids generated from the protein component of the meals, with phenylalanine, tyrosine, and glutamic acid being the most potent.[80]

Changes in Prolactin with Age

Prolactin levels are elevated almost 10-fold in infants following delivery due to the stimulatory effect of maternal estrogen, but then gradually decrease so that levels are normal by 3 months of age.[81] PRL levels then rise modestly during puberty to adult levels.[81] PRL levels in women gradually fall by about 50% over the first 18 months after menopause, but this decrease is considerably less in women treated with estrogen replacement therapy[82] (although some studies have shown no change in PRL levels with hormone replacement therapy[83]). In hyperprolactinemic women, estrogen replacement therapy causes no change in PRL levels.[84] In men, mean serum PRL concentrations are about 50% lower in older men compared with younger men.[85]

Changes in Prolactin Levels during the Menstrual Cycle

Some, but not all, women have higher PRL levels at midcycle and lower levels in the follicular phase.[44,61,86-89] Some studies have shown that PRL and LH secretion are often synchronous in the luteal phase and that very small doses of gonadotropin-releasing hormone (GnRH) can cause the secretion of both PRL and LH at this time.[90]

Changes in Prolactin Levels during Pregnancy

Basal PRL levels gradually increase throughout the course of pregnancy.[44,45] This has generally been attributed to the stimulatory effect of the hormonal milieu of pregnancy (primarily estrogenic) causing lactotroph hyperplasia.[2,3] By term, PRL levels may be increased 10-fold to levels over 200 ng/mL,[44,45,81] preparing the breast for lactation.

Changes in Prolactin Levels with Postpartum Lactation

Within the first 4 to 6 weeks postpartum, basal PRL levels remain elevated in lactating women and each suckling episode triggers a rapid release of pituitary PRL.[44,91] Over the next 4 to 12 weeks, basal PRL levels gradually decrease to normal, while the PRL increase which occurs with each suckling episode is gradually extinguished.[44,91] The decreases in basal and stimulated PRL levels between 3 and 6 months postpartum are largely the result of decreased breastfeeding as formula is introduced into the baby's diet. If intense nursing behavior is maintained, basal PRL levels remain elevated and postpartum amenorrhea persists.[92] High intensity lactation-induced failure to ovulate and menstruate has long been used as a method of contraception in a number of developing countries.[92]

Breast stimulation may cause an increase in PRL levels in some healthy women who are not breastfeeding; such increases have not been found in men.[91] Chronic nipple stimulation with nipple rings has been reported to cause sustained galactorrhea.[93]

Changes in Prolactin Secretion with Stress

Prolactin is one of the pituitary hormones released by stress, along with adrenocorticotropic hormone (ACTH) and GH. The stress-induced rise in PRL in humans generally results in a doubling or tripling of PRL levels and lasts less than 1 hour.[94] However, prolonged critical illness does *not* cause a sustained elevation of PRL; rather there is a reduction in the pulsatile secretion with an overall lowering of levels.[95] Acute exercise has also been regarded as a form of stress and results in an acute, transient increase in PRL levels.[94] Although chronic, high-level exercise, such as occurs in runners training for a marathon, is often associated with menstrual disturbances, it is not associated with sustained hyperprolactinemia.[96]

Neuroendocrine Regulation

The hypothalamus exerts a predominantly inhibitory influence on PRL secretion through one or more PRL inhibitory factors (PIF) that reach the pituitary via the hypothalamic-pituitary portal vessels (Fig. 3.1). There are PRL-releasing factors (PRF) as well. Disruption of the pituitary stalk leads to a moderate increase in PRL secretion as well as to decreased secretion of the other pituitary hormones.

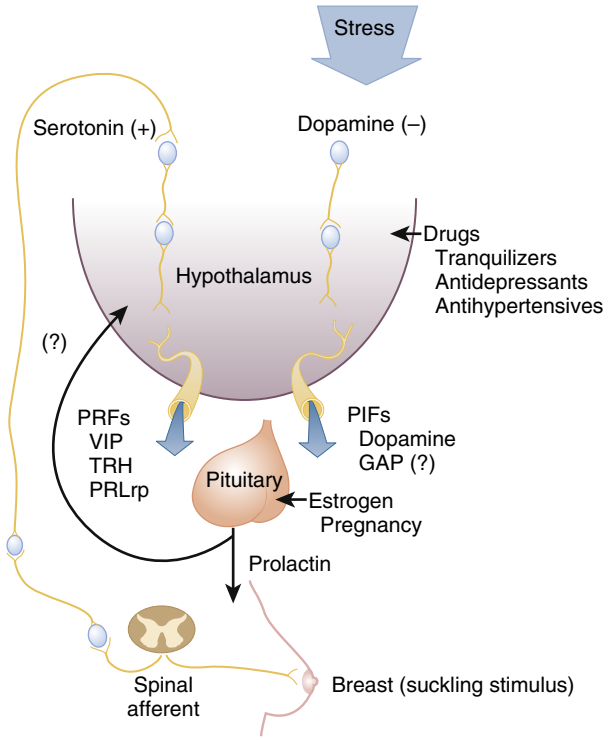

FIGURE 3.1 Regulation of prolactin secretion. Prolactin release is stimulated by a number of Prolactin Releasing Factors (PRF's), including Vasoactive Intestinal Peptide (VIP), Thyrotropin Releasing Hormone (TRH), and PRL releasing peptide (PRLrp), and is inhibited by Prolactin Inhibiting Factors (PIF's), predominantly dopamine but possibly also by the 56 amino acid peptide portion of the precursor to GnRH, known as GnRH Associated Peptide (GAP). Estrogens and the hormonal milieu of pregnancy are also stimulatory to prolactin production. The primary target organ for prolactin is the breast. Suckling activates neural afferent pathways to the hypothalamus where appropriate increases in PRF's and/or decreases in PIF's effect prolactin release in the puerperium. Within the hypothalamus serotoninergic pathways are stimulatory and dopaminergic pathways are inhibitory to prolactin release. *(Reproduced from Molitch ME. Disorders of prolactin secretion.* Endocrinol Metab Clin N Amer *30: 585–610, 2001, with permission.)*

Prolactin Inhibitory Factors

Dopamine

Dopamine is the predominant, physiologic PIF. The concentration of DA found in the pituitary stalk plasma (about 6 ng/mL) is sufficient to decrease PRL levels and is 5- to 10-fold higher than levels found in peripheral plasma.[97] Stimuli that result in an acute release of PRL usually also result in an acute decline in portal vessel DA levels.[98-100] In most physiologic circumstances that cause a rise in PRL, such as lactation, there is likely to be a fall in DA along with a simultaneous rise in PRFs (such as VIP).[101]

Experiments in mice in which the DA D_2 receptor or DA transporter have been "knocked out" (KO) with inactivating mutations have confirmed the results of earlier studies that employed pharmacologic methods or lesioning. DA D_2 receptor KO mice develop lactotroph hyperplasia with scattered multifocal prolactinomas and sustained hyperprolactinemia.[102-104] DA action within the synapse terminates as a result of DA reuptake by the DA-secreting neurons via the DA transporter. In contrast to the findings with the DA receptor KO mice, DA transporter KO mice have increased dopaminergic tone and lactotroph hypoplasia.[105] Although such mice have normal circulating levels of PRL, these levels cannot increase in response to various stimuli and the mice are therefore unable to lactate.[105]

In humans, infusion of DA causes a rapid suppression of basal and stimulated PRL levels.[106,107] Studies with low-dose DA infusions in humans have shown that DA blood concentrations similar to those found in rat and monkey hypothalamic-pituitary portal blood[97,108] are able to suppress PRL secretion.[109,110] Blockade of endogenous DA receptors by a variety of drugs causes a rise in PRL.[111,112]

The axons responsible for the release of DA into the median eminence originate in dorsal portion of the arcuate nucleus and inferior portion of the ventromedial nucleus of the hypothalamus. These axons terminate in the median eminence, a pathway known as the *tuberoinfundibular DA (TIDA) pathway*.[113,114] The DA that traverses the TIDA pathway binds to the D_2 DA receptors on the lactotroph cell membrane.[114]

The inhibitory action of DA on PRL secretion is partially blocked by estrogen administration. This is largely due to the direct action of estrogen on the estrogen response element of the PRL gene, as previously mentioned. Estrogen is able to partially block the inhibitory action of DA on PRL secretion; infusions of DA into women during the early follicular phase (when estrogen levels are low) result in a greater suppression of PRL than infusions during the late follicular or periovulatory phases (when estrogen levels are higher).[115]

Other Inhibitory Factors

Whether DA alone can account for all of the PIF activity of the hypothalamus has long been a question. Inhibitory

activity has been shown by GnRH-associated protein (GAP), a peptide in the carboxyterminal region of the precursor to GnRH[116] and γ-aminobutyric acid (GABA)[117,118] in various experimental studies but their physiologic importance in the human remains unknown.

Prolactin Releasing Factors

Thyrotropin-releasing hormone (TRH) causes a rapid release of PRL from pituitary cell cultures[119] and humans after intravenous injection.[120] The smallest dose of TRH that releases TSH also releases PRL in humans.[121] However, immunoneutralization of endogenous TRH with TRH antisera only causes suppression of basal PRL levels in rats in some studies,[122] but not in other studies[123,124]; mice with targeted disruption of the TRH gene (TRH KO) become hypothyroid but have normal PRL levels.[125] Suckling causes a rise in PRL but not TSH.[126] On the other hand, in hypothyroidism, basal TSH and PRL levels are elevated[127] with both being normalized by thyroxine treatment.[127,128] Conversely, in hyperthyroidism, PRL levels are not low basally but the PRL response to TRH is markedly blunted and returns to normal with correction of the hyperthyroidism.[127,128] These conflicting data support a role for TRH as a physiologic PRF, albeit not the primary one, or even one of major physiologic importance.

Vasoactive Intestinal Peptide and Peptide Histidine Methionine

Vasoactive intestinal peptide stimulates PRL synthesis and release from pituitary cell preparations, and humans in vivo.[129-133] VIP neuronal perikarya are present in the paraventricular nucleus with axons terminating in the external zone of the median eminence.[134] Passive immunoneutralization with anti-VIP antisera in rats partially inhibits the PRL responses to suckling, ether-induced stress[135,136] and estrogen.[137] This same type of VIP immunoneutralization in DA receptor-blocked rats suppresses PRL pulsatile secretion.[138] Similar results for suckling have been obtained with a VIP antagonist.[139]

Within the VIP precursor is another similarly sized peptide known as peptide histidine methionine (PHM).[140] PHM and VIP colocalize in the hypothalamus and median eminence.[141] PHM given to humans has caused a PRL increment in some experiments,[141] but not others.[133]

Complicating the role of VIP as a PRF is the finding that VIP is actually synthesized by anterior pituitary tissue.[142] Antisera to VIP inhibit basal PRL secretion from dispersed pituitary cells *in vitro*,[143,144] suggesting a local "autocrine" role for VIP in PRL regulation within the pituitary. The precise physiologic roles of VIP versus PHM and hypothalamic VIP versus pituitary VIP are still not clear.

Serotonin

Serotonin and its precursor, 5-hydroxytryptophan, cause a release of PRL in rats whether injected systemically[145] or into the third ventricle.[146] A variety of experiments using blockers of serotonin synthesis, receptors, or reuptake by nerve terminals, have shown that serotonin mediates, in part, the PRL elevations associated with suckling and proestrous.[147-149] In humans, infusion of the serotonin precursor, 5-hydroxytryptophan, results in a prompt increase in PRL levels.[150,151] Nocturnal PRL secretion is inhibited by cyproheptadine.[152] Fenfluramine, a serotonin releasing agent, caused a fourfold rise in PRL in humans that could be partially blocked by cyproheptadine.[153] Fluoxetine, a serotonin reuptake inhibitor, also increases PRL levels modestly (with levels remaining within the normal range).[154] Although it is possible that serotonin is a direct secretagogue for PRL, either through transport from the hypothalamus by the portal vessels or through an autocrine action within the pituitary, its role in this regard is still uncertain. Serotonin likely mediates, in part, the nocturnal surge of PRL; it may well participate in the suckling-induced rise in PRL through the ascending serotoninergic pathways from the dorsal raphe nucleus by causing VIP release.

Other Neuroactive Peptides and Neurotransmitters

Opioid Peptides

In rats, various opioid peptides cause release of PRL.[155,156] Studies employing specific agonists and antagonists have shown that the μ receptor is the predominant one involved in PRL release.[157,158] Most evidence suggests that the opioid peptides do not have a direct effect on the pituitary[156] and stimulate PRL release by inhibiting DA turnover and release by the TIDA pathway.[159,160] In humans, morphine and morphine analogs increase PRL release acutely[161] and chronically.[162] However, blockade of the μ receptor with naloxone has minimal to no effect on PRL levels either basally or with stimulation by hypoglycemia, exercise, sleep, TRH, or physical stress.[163,164]

In contrast to these findings, an increase in PRL levels in response to naloxone given in the late follicular and midluteal phases of the menstrual cycle has been reported.[165] The interpretation of these changes is not straightforward, but overall, it appears that the endogenous opioid pathways play, at most, only a minor role in the regulation of PRL secretion.[166]

Growth Hormone Releasing Hormone

A number of studies have found GH releasing hormone (GHRH) to have PRL releasing properties. The initial clue to this action of GHRH came when patients with acromegaly due to GHRH secreting tumors were found to be hyperprolactinemic and their PRL levels fell in parallel with GH after tumor excision.[167] GHRH has also been reported to release PRL *in vivo* in healthy humans[168] and chronic therapy with GHRH in children with GH neurosecretory dysfunction results in a sustained elevation of PRL levels.[169] Although large amounts of GHRH clearly can release PRL, the physiologic significance of these observations remains unknown.

Posterior Pituitary, Oxytocin, and Vasopressin

Studies in animals have shown that oxytocin, in levels found in the hypothalamic-pituitary portal vessels, can stimulate PRL release when added to the incubation medium of pituitary cells or when given intravenously, but it lowers PRL levels when directly injected into the third ventricle.[170] Studies in which endogenous oxytocin was eliminated by passive immunization with oxytocin antisera or by oxytocin antagonists show a reduction and a delay in the suckling induced PRL surges.[170] Very limited studies in humans suggest that oxytocin administered intravenously has no effect

on basal PRL levels and causes only a minimal increase in VIP-stimulated PRL levels.[171]

To date, there are no studies of the effects of vasopressin on PRL secretion in humans. Whether there are other PRF's in the posterior pituitary in addition to oxytocin, vasopressin, and their respective neurophysins has been a matter of controversy.

Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone releases PRL from rat pituitary cells *in vitro*.[172] GnRH has been found to cause a release of PRL in anovulatory women[173,174] and in women with infertility being treated with menopausal gonadotropins.[175] In 24% to 78% of normal women there is a PRL response to GnRH; this response is dependent upon the phase of the menstrual cycle, with the highest number of subjects responding in the periovulatory phase.[176]

Postmenopausal women also have a PRL response to GnRH that is augmented with estrogen supplementation.[177] There is no PRL release in response to GnRH in healthy, eugonadal males, but such a release does occur in transsexual men who receive high doses of estrogen.[178] Analysis of PRL and LH secretory pulses in women shows a high degree of concordance.[90] This cosecretion of LH and PRL suggests that the response to GnRH is physiological and is evidence against a physiological role for the inhibitory cosecreted GAP.

Prolactin-Releasing Peptide

Hinuma and colleagues discovered a 31-amino acid peptide capable of releasing PRL, that has been termed prolactin releasing peptide (PrRP); the discovery came while looking for endogenous ligands for an orphan receptor (termed HGR3) present in the human pituitary.[179] In pituitary cell preparations, PrRP released PRL with a potency equal to that of TRH.[179] However, although PrRP is found in neuronal perikarya in the paraventricular and supraoptic nuclei, PrRP-immunoreactive nerve fibers are found only in the internal zone of the median eminence and not the external zone,[180] casting uncertainty on the physiological significance of this peptide with respect to PRL secretion. Although PrRP has been shown to affect the hypothalamic-pituitary-adrenal axis stress response and feeding behavior, at present it is not thought that PrRP plays a significant role in PRL regulation in humans or any other species.[181]

Other Neuroactive Peptides and Neurotransmitters

There is evidence that several other neuropeptides and neurotransmitters affect PRL secretion in a variety of experimental paradigms in animals, including angiotensin, neurotensin, substance P, cholecystokinin, bombesin, secretin, gastrin, galanin, endothelin, somatostatin, relaxin, melatonin, basic fibroblast-growth factor, bradykinin, calcitonin, calcitonin gene-related peptide, histamine, norepinephrine, and acetylcholine. However, their physiological significance, especially in humans, is unknown.

Prolactin Short Loop Feedback

Experiments conducted in rats suggest that PRL is able to feed back negatively on its own secretion (short-loop feedback or autofeedback).[182] Most evidence suggests that such feedback occurs via augmentation of hypothalamic TIDA turnover.[183] Direct confirmation of the importance of short-loop feedback in rodents comes from recent studies using mice with targeted disruption of the PRL gene (*PRL* gene KO). Mice with the *PRL*-KO have no pituitary PRL and have markedly decreased DA in TIDA neurons along with hyperplasia of lactotrophs that do not make PRL.[184-186] Direct evidence for such PRL short loop feedback in the human has not been demonstrated. However, it has been suggested that altered regulation of gonadotropin and TSH secretion in hyperprolactinemic patients may constitute indirect evidence of PRL-induced augmentation of TIDA activity.[187]

Prolactin Action

PRL has a great diversity of actions in many species of animals, including osmoregulation, growth and developmental effects, metabolic effects, actions on ectodermal and integumentary structures and actions related to reproduction.[188] Its primary physiological action in humans, however, is the preparation of the breast for lactation in the postpartum period.[189] Elevated levels of PRL affect many tissues and PRL receptors are found in many tissues.

Prolactin Receptors

The PRL receptor is a member of the class 1 cytokine receptor superfamily. The human PRL receptor gene is located on chromosome 5p14-p13.2 and has 10 exons with exons 3 to 10 encoding the full length activating long form of the receptor.[190] Two isoforms of the PRL receptor result from alternative splicing and differ in the length and composition of the cytoplasmic tail, being referred to as the long and intermediate forms; the short form found in the mouse is not present in humans.[191,192]

PRL binds to its receptor with high affinity, the dissociation constant (K_d) being 10^{-10} mol/L.[192] Half-saturation of the receptor occurs at a hormone concentration of 7 ng/mL.[192] PRL binding causes dimerization of the receptor, a necessary step for signaling.[192]

PRL receptors are widely distributed throughout the body, being present in the breast, pituitary, liver, kidney tubules, adrenal cortex, prostate, ovary, testes, seminal vesicles, epididymis, intestine, skin, pancreatic islets, lymphocytes, lung, myocardium, and brain.[192] PRL release caused by suckling increases PRL receptor levels in the breast and liver, resulting in a much greater PRL binding activity in lactating animals than in those not lactating.[192] Signal transduction of the activated, dimerized receptor involves the JAK-STAT pathway.[192] Activation of the MAP kinase cascade has also been reported after receptor activation but whether this involves JAK 2 is unknown.[192]

The physiologic roles of PRL in most of the tissues in which receptors are present are not known. Although some have suggested that PRL may play a role in the development of breast and other cancers, this has not been firmly established. Future research with PRL receptor antagonists acting at the tissue level may allow a more clear delineation of additional physiological and pathological functions of PRL.[193]

Prolactin Effects on the Breast

Prolactin, GH, cortisol, insulin, estrogen, progesterone, and thyroxine all contribute to breast development. The high

concentrations of estrogen and progesterone produced by the placenta, coupled with the estrogen-induced high concentration of circulating PRL, and the high concentrations of placental lactogen cause development of the lobular, alveolar tissue during pregnancy.[189] Once the breast is fully developed and hormonally primed, PRL stimulates the production of milk proteins and other components.[189] Prior to term, the high estrogen levels suppress the effects of the high PRL levels on milk production, but the rapid fall off of estrogen levels following delivery allows milk production to proceed.[194] Bromocriptine-induced suppression of this physiological hyperprolactinemia in the puerperium causes a rapid cessation of milk production.[195] The key role of PRL in milk formation has been demonstrated by the finding that mice with either the *PRL* gene KO[184] or the PRL receptor KO[196] are unable to lactate.

Galactorrhea

The persistence of galactorrhea for more than 1 year after normal delivery and cessation of breastfeeding or its occurrence in the absence of pregnancy generally is taken as a definition of inappropriate lactation. The incidence of galactorrhea in healthy women has been reported as ranging from 1% to 45% of subjects tested.[197,198] This variability is probably the result of differences in the techniques used to express milk from the breast and the way in which nonmilky secretions are classified.

Inappropriate lactation may be an important clue to the presence of pituitary-hypothalamic disease, especially if accompanied by amenorrhea. Combined data from 14 published series suggest that 27.9% of galactorrheic women with normal menses have elevated PRL levels.[199] More recent experience, however, suggests that galactorrhea may be present in about 5% to 10% of normally menstruating women and basal PRL levels are normal in more than 90% of these women. Lowering of PRL levels will almost always lead to a marked decrease or abolition of lactation regardless of whether PRL levels are initially elevated or not.

Prolactin Effects on Gonadotropin Secretion

The effects of PRL levels in the normal range on gonadotropin secretion are not known. However, *PRL* gene-KO and PRL receptor-KO female mice are sterile and have disordered estrous cycles.[184,196] Females with the PRL receptor KO had fewer primary follicles, fewer eggs ovulated, fewer eggs fertilized, poorer progression of those eggs that were fertilized to the blastocyst stage, and uteruses that were refractory to implantation by the blastocyst.[196] Furthermore, they had decreased estradiol and progesterone levels.[200]

In healthy women treated with short-term bromocriptine to lower PRL levels to about 5 ng/mL, there was no change in the pulsatile secretion of LH and FSH but estradiol levels were higher the last 3 days of the follicular cycle. Progesterone levels were lower during the luteal phase.[201] Data are not available on reproductive function and prolactin levels for the new short-acting bromocriptine agent (Cycloset®) used for the treatment of diabetes.

Hyperprolactinemia has a number of effects on various steps in the reproductive axis. Hyperprolactinemia has been found in most studies to suppress LH pulsatile secretion (Fig. 3.2) by decreasing pulse amplitude and

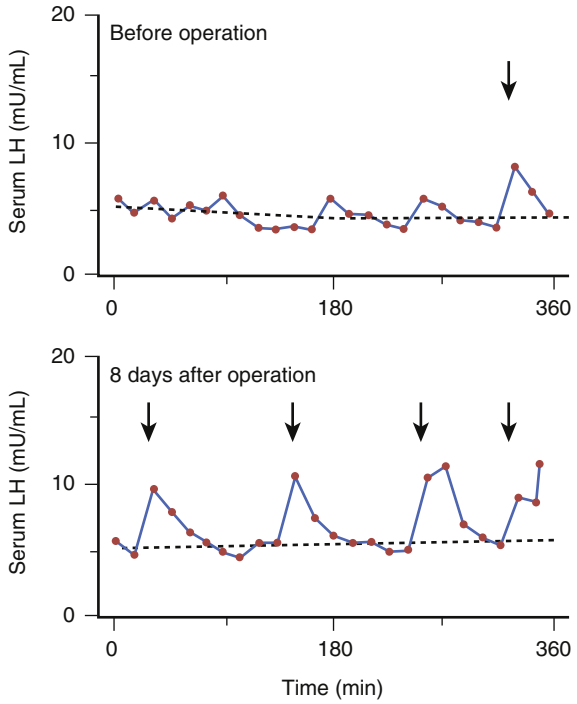

FIGURE 3.2 Pre- and postoperative serum luteinizing hormone (LH) concentrations following selective resection of a prolactinoma. The start of an LH pulse is indicated by an *arrow*. *(Adapted from Stevenaert et al., early normalization of luteinizing hormone pulsatility in women with microprolactinomas.* J Clin Endocrinol Metab *62:1044–1047, 1986.)*

frequency.[202-204] With menopause in humans, hyperprolactinemia can prevent the expected rise in gonadotropins[205]; normalization of PRL levels with bromocriptine results in a rise in gonadotropin levels and hot flashes.[205]

Hyperprolactinemia inhibits pulsatile gonadotropin secretion by a number of mechanisms. It had been postulated that the pulsatile gonadotropin secretion was directed by the hypothalamic GnRH pulse generator and that alteration of pulsatile secretion necessarily means a direct hypothalamic action of PRL. Consistent with that notion, PRL inhibits GnRH release from hypothalamic neuron cell lines through an action on PRL receptors expressed by these cells.[206] Measurement of portal vessel GnRH levels in rats showed a marked inhibitory effect of hyperprolactinemia in one study,[207] but not in another.[208]

The pituitary gonadotroph response to GnRH in hyperprolactinemia has generally been found to be decreased in rats[208,209]; in contrast, the response may be normal, increased or decreased in humans.[210,211] The number of GnRH receptors on gonadotroph cells in hyperprolactinemic rats is reduced[212] even when endogenous GnRH is replaced with intraarterial pulses of GnRH.[205,213] In addition to these effects, hyperprolactinemia in women has been associated with loss of positive estrogen feedback on gonadotropin secretion.[214]

Prolactin Effects on the Ovary

Prolactin is trophic to corpus luteum function in rats, giving rise to the name luteotrophic hormone.[215] The role of PRL in normal ovarian function in humans is not as

well established, however. McNatty and colleagues demonstrated that low physiologic concentrations of PRL are necessary for progesterone synthesis by human granulosa cells, but that high concentrations are inhibitory in vitro.[216] Other studies suggest that PRL can activate the expression of Type 2 3β-hydroxysteroid dehydrogenase, the final enzymatic step in progesterone biosynthesis.[217] Del Pozo and colleagues found no effect on luteal function in women treated with bromocriptine to lower normal PRL levels[218]; others, however, have found that such a decrease in PRL resulted in lowered progesterone levels and short luteal phases.[203,219,220] On the other hand, short luteal phases have also been reported in hyperprolactinemic women.[221]

In humans, plasma PRL levels greater than 100 ng/mL have been found to cause an increase of antral fluid PRL levels and reductions in antral fluid FSH and estradiol levels and a decrease in granulosa cell number.[222] Perfusion studies of human ovaries *in vitro* reveal a direct suppressive effect of PRL on progesterone and estrogen secretion.[223] PRL can inhibit estrogen formation by antagonizing the stimulatory effects of FSH on aromatase activity[224] and direct inhibition of aromatase synthesis has also been shown.[225]

In some but not all studies, PRL levels have been found to be elevated in women with polycystic ovaries (PCO).[226,227] Bromocriptine treatment of hyperprolactinemic patients with PCO usually resulted in a reduction of testosterone and LH levels, and often a resumption of ovulatory cycles. One hypothesis suggests that the increased estrogen levels found in PCO stimulate increased PRL secretion,[226] but the association between PCO and hyperprolactinemia has been questioned.[227,228]

When amenorrhea or oligo-amenorrhea is associated with galactorrhea, it usually is a manifestation of hyperprolactinemia. In combined series totaling 471 patients with galactorrhea-amenorrhea, 75.4% were found to have hyperprolactinemia.[199] Although the amenorrhea caused by hyperprolactinemia usually is secondary, it can also be primary if the disorder begins before puberty.[229,230] In two studies of 33 patients evaluated for primary amenorrhea and low gonadotropin levels, 9 (27%) were found to have hyperprolactinemia.[229,230] In patients with primary amenorrhea due to hyperprolactinemia, failure to develop normal secondary sexual characteristics may be the presenting problem. Galactorrhea is variable in this setting because the breast may not have been exposed to appropriate priming with estrogen and progesterone. Young women with hyperprolactinemia and primary amenorrhea tend to have macroadenomas more commonly than those with secondary amenorrhea; the reason for this difference remains uncertain.

Hyperprolactinemia has been found in many women with a short luteal phase, as noted previously. A short luteal phase is likely to be the first evidence of interference in the normal cycle by hyperprolactinemia.[231] In the initial period of shortened luteal phase, progesterone levels are subnormal, suggesting deficient corpus luteum function.

Infertility also may be a presenting symptom of patients with hyperprolactinemia and is invariable when gonadotropin levels are suppressed with anovulation. In women (367 women combined from multiple studies) studied for infertility, one-third were found to have hyperprolactinemia.[199] Most of the women had amenorrhea and galactorrhea as well, but in one series of 113 cases of infertility, 5 of the 22 hyperprolactinemic women had neither amenorrhea nor galactorrhea.[232] PRL excess may be important in this type of patient, as suggested by the finding that treatment of similar patients with bromocriptine restored fertility.[232] In some of these women, transient hyperprolactinemia lasting for 1 to 2 days during the cycle can be documented; this subset usually responded to bromocriptine, experiencing increased progesterone during the luteal phase and improved fertility.[233]

Reduced libido and orgasmic dysfunction are found in most hyperprolactinemic amenorrheic women when such complaints are specifically elicited.[210] Reduction of PRL levels to normal restores normal libido and sexual function in most of these women.[234]

Prolactin Effects on the Testes

The role of PRL in normal testicular function is not well understood. Half of the male rats with PRL receptor-KO mutations were fully fertile, but the remainder were either completely or partially infertile despite normal sexual behavior and normal spermatogenesis (as determined by histological evaluation of the testes).[196] Male mice with the *PRL* gene-KO were fully fertile and had normal plasma testosterone levels and normal testosterone release from the testes, despite decreased plasma LH levels and LH and FSH secretion from the pituitary *in vitro* and decreased weights of the seminal vesicles and ventral prostate.[235]

In studies of healthy men, bromocriptine-induced suppression of normal PRL levels for 8 weeks resulted in suppression of basal and hCG-stimulated testosterone levels.[236] This finding implies a physiologic role for PRL in normal testosterone production in humans. PRL is present in human semen in very high concentrations[237] and PRL has been shown to stimulate adenyl cyclase, fructose utilization, glycolysis, and glucose oxidation in human spermatozoa.[238]

Chronic hyperprolactinemia results in impotence and decreased libido in over 90% of cases.[239-247] Galactorrhea in men has been reported in 10% to 20% of cases and is virtually pathognomonic of a prolactinoma.[239-245,248] As previously noted, there is a decrease in the pulsatile secretion of LH and FSH in hyperprolactinemic men, and testosterone levels are low or are in the lower part of the normal range.[239-248] With normalization of PRL levels with cabergoline, testosterone levels normalize in about two-thirds of men and erectile function normalizes in 60%.[246,249]

The testosterone response to stimulation with hCG has been reported to be both decreased[243,250] and normal[239,251]; in those with decreased responses there is improvement in the response when PRL levels are lowered with bromocriptine.[243] If there is sufficient normal pituitary tissue, reduction of elevated PRL levels to normal usually results in a return of normal testosterone levels.[244-246,252,253] Although some studies in rats have suggested that drug-induced elevated PRL levels cause a partial block in the enzyme 5-α reductase, resulting in a decrease in dihydrotestosterone levels, this has not been

found in studies of men with prolactinomas.[250] Carter and colleagues noted that testosterone therapy of hyperprolactinemic men does not always correct the impotence until PRL levels are brought down to normal.[239] Whether or not this is due to a decrease in dihydrotestosterone levels has not been verified directly.

Sperm counts and motility are decreased with an increase in abnormal forms in hyperprolactinemic men.[246,249,251] Histological studies reveal abnormal seminiferous tubule walls and altered Sertoli cell ultrastructure.[254] The semen analysis does not always return to normal despite normalization of testosterone and PRL levels.[249,252]

A number of surveys have attempted to assess the frequency of hyperprolactinemia among men with complaints of impotence or infertility. Between 2% and 25% of males with impotence have been found to be hyperprolactinemic in various series.[232,243,245,255-258] However, only 1% to 5% of infertile men have been found to be hyperprolactinemic.[259-261] Although these frequencies are relatively low, the modest cost of measuring PRL is justified given that hyperprolactinemia is, in general, easily treatable.

Prolactin Effects on the Adrenal Cortex

Although PRL receptors are found on cells of the adrenal cortex, the physiological role of PRL in adrenal steroidogenesis is unknown. Plasma dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEAS) levels have been found to be mildly elevated in about 50% of women with hyperprolactinemia in some,[262] but not all, studies.[263] In most of these studies, however, the investigators did not try to correlate the androgen levels with the presence of hirsutism or other indices of hyperandrogenism. The abnormal androgen levels return to normal with correction of the hyperprolactinemia by bromocriptine.[232]

Prolactin Effects on Bones

PRL may have a physiological role in calcium and bone metabolism. The PRL receptor-KO mouse has a decrease in bone formation rate and bone mineral density in association with increased parathyroid hormone levels, but also had decreased estradiol and progesterone levels.[200] Thus, it is difficult to know how much of the abnormal bone metabolism is attributable to the inability to respond to PRL as opposed to estrogen deficiency.

Hyperprolactinemic women have decreased bone mineral density,[264-267] but whether this effect is mediated by estrogen deficiency[264] or is a direct effect of the hyperprolactinemia[265,266] has been debated. The decreased bone mass is accompanied by an increase in bone turnover makers[267] and fractures.[268] Correction of the hyperprolactinemia results in an increase in bone mass.[269,270] Studies of hyperprolactinemic women who were not amenorrheic and hypoestrogenemic have shown that their bone mineral density is normal,[271,272] confirming the initial hypothesis that estrogen deficiency mediates the bone mineral loss. A similar, androgen-dependent loss of bone mineral is found in hyperprolactinemic men,[273,274] is accompanied by an increase in vertebral fractures[275] and is reversible with reversal of the hypoandrogenic state.[273]

Prolactin Effects on the Immune System

Prolactin is produced by T- and B-lymphocytes but its synthesis is under control of an alternative upstream promoter.[276] In animal studies, lowering of normal PRL levels by bromocriptine or anti-PRL antibodies results in impaired lymphocyte proliferation and macrophage activating factor production[277] but in *PRL* gene-KO and PRL receptor-KO mice, PRL has not been found to be essential for normal immune function.[278,279] Conversely, in rat models of systemic lupus erythematosus, PRL levels are elevated and bromocriptine causes improvement in a variety of autoimmune parameters.[280-282]

Studies in humans have been conflicting. Some studies of patients with hyperprolactinemia have shown increased rates of autoantibodies (including antithyroid, anti-double-stranded DNA, anti-Ro, anticardiolipin, and antinuclear antibodies) without clinical evidence of disease.[283-285] Conversely, elevated levels of PRL have been found in patients with systemic lupus erythematosus, rheumatoid arthritis, psoriatic arthritis, multiple sclerosis, Reiter's syndrome, Sjögren's syndrome, and uveitis.[285-288] In some studies, conventional immunosuppressive treatment of these disorders resulted in a lowering of PRL levels and conversely treatment with bromocriptine resulted in clinical improvement in the autoimmune condition (see Chuang and Molitch for detailed review).[289] Although PRL appears to have an immunomodulatory function, at present, the relationship of pituitary vs. lymphocytic PRL to these autoimmune conditions in humans is still uncertain and treatment aspects remain to be established.

Pathologic States of Prolactin Secretion

Hypoprolactinemia

PRL deficiency may occur in the setting of panhypopituitarism, generally as a result of pituitary infarction or following pituitary surgery. When the cause of the hypopituitarism is hypothalamic or stalk dysfunction, PRL levels generally rise due to disinhibition of PRL secretion (which will be explained later in this chapter). However, when the pituitary tissue is actually destroyed, as in Sheehan's peripartum necrosis, PRL levels are usually low.[290] The finding of low PRL levels following surgery for a pituitary tumor usually is indicative of very severe hypopituitarism.[291] Idiopathic PRL deficiency has been described in only a single human.[292] Clinically, hypoprolactinemia manifests as an inability to lactate postpartum.

Hyperprolactinemia

The differential diagnosis of sustained hyperprolactinemia encompasses a spectrum of pharmacological and pathological entities (Box 3.1). This section discusses those causes of hyperprolactinemia other than prolactinomas.

Medications

Psychoactive medications

The antipsychotic agents (phenothiazines and butyrophenones) are dopamine receptor blockers and uniformly result in elevated PRL levels, generally no higher than 100 ng/mL, but some patients have been reported with levels as

IDIOPATHIC

high as 365 ng/mL.[111,112] PRL levels usually fall to normal within 48 to 96 hours of discontinuation of antipsychotic drug therapy.[293] Atypical antipsychotic agents that are combined serotonin-dopamine receptor antagonists, such as risperidone and molindone, cause similar elevations of PRL.[294] However, many of the other atypical antipsychotic agents, such as quetiapine, olanzapine, and aripiprazole do not cause hyperprolactinemia, and when feasible, hyperprolactinemic patients on risperidone or one of the phenothiazines may be switched to these drugs.[294-297] The lack of hyperprolactinemic effect of these other atypical antipsychotic agents is thought to be due to their being only transiently and weakly bound to the D_2 receptor and to their having agonist as well as antagonist activity at the D_2 receptor.[294]

Tricyclic antidepressants cause modest hyperprolactinemia in about 25% of patients.[298] Monoamine oxidase (MAO) inhibitors, when used chronically, may also cause a minimal elevation of PRL levels.[299] The mechanisms by which these drugs cause increased PRL levels are not certain and they likely facilitate several possible stimulatory pathways. Serotonin reuptake inhibitors, by increasing synaptic serotonin levels, very rarely cause hyperprolactinemia.[154,294,300,301] Other antidepressants including nefazodone, bupropion, venlafaxine, trazodone, and lithium do not cause hyperprolactinemia.[294] Chronic opiate abuse is associated with mild hyperprolactinemia and menstrual dysfunction.[294] Cocaine abuse has also been associated with chronic, mild hyperprolactinemia.[302]

Antihypertensive Drugs

Alpha-methyldopa causes moderate hyperprolactinemia by inhibiting the enzyme L-aromatic amino acid decarboxylase (which is responsible for converting L-dopa to dopamine) and by acting as a false neurotransmitter to decrease dopamine synthesis. Short-term and chronic verapamil therapy has been found to increase basal PRL secretion and the PRL response to TRH[31-33,303-305]; patients have been described with galactorrhea associated with sustained hyperprolactinemia from verapamil therapy.[303,304] In a survey of patients taking verapamil in an outpatient clinic, PRL levels were found to be elevated in 8.5% of patients.[305] Verapamil blocks the hypothalamic generation of dopamine.[33] Other calcium channel blockers such as the dihydropyridines and benzothiazepines have no action on PRL secretion, implying that the action of the phenylakylamine, verapamil, likely is acting on the neuronal N-type calcium channel.[33]

Protease Inhibitors

Although one report showed that some HIV positive patients treated with protease inhibitors developed galactorrhea and hyperprolactinemia,[306] a second report implied that the elevations of PRL seen in some patients can largely be attributed to other medications received and stress.[307] The mechanism and frequency of this are unknown.

Other Medications

Metoclopramide and domperidone, two drugs commonly used to increase gastrointestinal motility and help stomach emptying in patients with gastroparesis diabetocorum, are D_2 receptor blockers. These drugs cause hyperprolactinemia in over 50% of patients and commonly cause symptoms of amenorrhea and galactorrhea in women and erectile dysfunction in men.[294] Although there are isolated case reports of hyperprolactinemia being associated with H_2 blockers and protease inhibitors, more systematic studies of these classes of medications have failed to support an etiological role for them.[294]

Stress

As previously mentioned, physical stress (such as physical discomfort, exercise, and hypoglycemia) causes an acute, transient rise in PRL levels (discussed earlier in the chapter). Chronic hyperprolactinemia, due to prolonged physical stress, has not been reported and chronic illness generally suppresses PRL levels. Psychological stress may cause minimal increases of PRL but chronic hyperprolactinemia has not been reported with any chronic psychiatric state except in pseudocyesis; in this condition, PRL levels fall with psychotherapy.[308]

Kidney disease

Hyperprolactinemia occurs in 73% to 91% of women and 25% to 57% of men with end-stage renal disease.[309,310] This is due to decreased PRL clearance as well as autonomous production and bromocriptine results in suppression of PRL levels.[309] About one-quarter of individuals with renal insufficiency not requiring dialysis (serum creatinine ranging from 2.0 to 12.0 ng/mL) have PRL levels in the 25 to 100 ng/mL range.[310] When such patients take medications known to alter hypothalamic regulation of PRL (such as methyldopa or metoclopramide) PRL levels may rise to over 2000 ng/mL.[310] Correction of the renal failure with transplantation causes a return of PRL levels to normal.[310] Hyperprolactinemia plays a role in the hypogonadism of

chronic renal failure, but probably does not explain all of the abnormalities in every case.

Cirrhosis

Basal PRL levels are elevated in patients with alcoholic cirrhosis in frequencies varying from 16% to 100%[311-313] and in patients with nonalcoholic cirrhosis from 5% to 13%.[311] In one study, 50% of patients with hepatic encephalopathy were found to be hyperprolactinemic.[314] An underlying defect in hypothalamic dopamine generation has been hypothesized as the cause of the hyperprolactinemia in these encephalopathic patients.

Hypothyroidism

A modest increase in the level of PRL in 8% to 36% of patients with overt hypothyroidism and a smaller percentage with subclinical hypothyroidism; levels greater than 25 ng/mL are uncommon.[315] The mechanisms involved probably include increased TRH production, increased sensitivity of lactotrophs to TRH and possibly increased pituitary VIP generation. Therapy with L-thyroxine will cause the PRL levels to return to normal and can even result in a regression of pituitary size (which was due to thyrotroph hyperplasia).[315,316]

Adrenal insufficiency

Glucocorticoids have a suppressive effect on *PRL* gene transcription and PRL release. Rare cases of hyperprolactinemia have been reported in patients with adrenal insufficiency whose PRL levels return to normal with glucocorticoid replacement.[317,318]

Neurogenic Stimulation

Sexual breast stimulation and suckling cause a reflex release of PRL that is mediated, by afferent neural pathways going through the spinal cord. Chest wall and cervical cord lesions have been reported to result in elevated PRL levels and galactorrhea through stimulation of these afferent neural pathways.[319] Similar chronic elevations of PRL have been reported after mastectomy, nipple piercing rings, thoracotomy, and chronic spinal cord injuries.[320,321]

Ectopic Prolactin Secretion

Ectopic production of PRL is exceedingly rare[322]; however, there have been reported cases of symptomatic hyperprolactinemia due to well-documented PRL production from a renal cell carcinoma,[323] a gonadoblastoma,[324] and ectopic pituitary tissue in ovarian teratomas.[325,326] Given the great frequency of prolactinomas, "idiopathic hyperprolactinemia" and other causes of hyperprolactinemia, a search for an ectopic source of PRL secretion is not warranted unless some other tumor shows up coincidentally.

Hypothalamic-Pituitary Stalk Disease

Hyperprolactinemia caused by lesions of the hypothalamus and of the pituitary stalk is due to disturbance of the neuroendocrine mechanisms that control PRL secretion.[327] From hypothalamic lesion work in animals, it has been assumed that this PRL elevation is due to disinhibition of the tonic PIF (DA) acting at the level of the pituitary lactotrophs. However, many of these patients have normal TSH and ACTH function, implying that there still is significant transmission of hypothalamic releasing factors to the pituitary.

Generally, patients with total stalk section (in whom the PRL rise is due solely to dopamine deficiency), have lower PRL levels than those with partial stalk-hypothalamic dysfunction who have DA plus continued PRF activity. In a recent series of 226 patients with clinically non-functioning pituitary adenomas, 99% had serum PRL levels less than 84 ng/mL.[328] However, a number of cases have been reported in the literature by others with PRL levels between 104 and 219 ng/mL.[327-329] Irradiation of pituitary and non-pituitary brain tumors may also cause hyperprolactinemia along with hypopituitarism, presumably due to hypothalamic damage and dysregulation.[330]

Idiopathic Hyperprolactinemia

When no specific cause for hyperprolactinemia is found, it is designated as idiopathic. In many such cases, small prolactinomas may be present that are too small to be detected by current radiological techniques. In other cases, the hyperprolactinemia may be attributed to presumed hypothalamic regulatory dysfunction, but no dysfunction specific to idiopathic hyperprolactinemia has been definitively elucidated. Long-term follow-up of such patients has found that in about one-third, PRL levels return to normal; in 10% to 15% there is a rise in PRL levels to greater than 50% over baseline; and in the remaining patients, prolactin levels remain stable.[331,332] Over a 2 to 6 year follow-up of 199 patients, only 23 were found to have evidence of microadenomas and none developed macroadenomas.[331-335] In one study, about 25% of patients with idiopathic hyperprolactinemia are found to be anti-pituitary antibody positive, suggesting that there may be some element of subclinical hypophysitis present.[336]

Clinical Testing of Hyperprolactinemic Patients

Because PRL is secreted episodically and some PRL levels during the day may be above the upper limit of normal established for a given laboratory, the finding of minimally elevated levels in blood requires confirmation in several samples. As indicated in the previous section, there are a number of conditions that may cause moderate PRL elevations of less than 250 ng/mL. A careful history and physical examination, screening blood chemistries, thyroid function tests and a pregnancy test will exclude virtually all causes except for hypothalamic-pituitary disease.[337,338] In cases with less certain symptoms, macroprolactinemia should be looked for (discussed earlier in the chapter).

When there is no obvious cause of the hyperprolactinemia from the routine screening, a radiologic evaluation of the hypothalamic-pituitary area is mandatory to evaluate for a mass lesion.[337-339] This includes patients with even mild PRL elevations. At present, such an evaluation is generally done using magnetic resonance imaging (MRI) with gadolinium enhancement or computed tomography (CT) with intravenous contrast enhancement. For prolactinomas, there is a fairly good correlation between PRL levels and the size of the tumor.[339] Patients with microprolactinomas rarely have PRL levels of more than

250 mg/dL.[337,338] It should be emphasized here that it is very important to distinguish between a large nonsecreting tumor causing modest PRL elevations (usually <250 ng/mL) from a PRL secreting macroadenoma (PRL levels usually >>250 ng/mL), as the therapy may be quite different. It is important to have serum run at 1:100 dilution in patients with large macroadenomas to exclude the "hook effect." Stimulation and suppression tests give nonspecific results with regard to the differential diagnosis of hyperprolactinemia and reveal no more information than just measurement of basal PRL levels.[337,338]

Prolactinoma

Classification and Epidemiology

Prolactinomas are generally classified clinically by size: microadenomas are less than 10 mm in diameter; macroadenomas are greater than 10 mm in diameter; and macroadenomas with extrasellar extension. The direction and degree of extrasellar extension are of obvious clinical importance. Serum PRL levels usually parallel the size of the tumors. Malignant prolactinomas are exceedingly rare.

Prolactinomas are the most common of the secreting pituitary adenomas, older studies reporting an incidence of 6 to 10 cases per million and a prevalence of 60 to 100 cases per million.[340] However, recent series from Belgium, Switzerland, Finland, and the United Kingdom report incidences and prevalences about five times higher.[341-344] Prolactinomas occur more commonly in women, in whom they are generally microadenomas, whereas those in men are generally macroadenomas (discussed later in the chapter).

Natural History of Prolactinomas

Autopsy Studies

Pituitary adenomas have been found at autopsy in about 11% of subjects not suspected of having pituitary disease while alive.[345] In the studies in which PRL immunohistochemistry was performed, 40% stained positively for PRL.[345] In these postmortem studies, all but seven of the tumors (99.97%) were less than 10 mm in diameter; however, there are a number of clinical reports of incidentally found macroadenomas.[345]

Natural History of Untreated Prolactinomas

Six studies have been published in which patients with microadenomas were observed for long periods without treatment. In these studies, women with prolactinomas documented by sella computed tomography or CT who refused surgery or medical treatment were followed for a period of up to 8 years.[346-351] Of the 139 women observed, there was evidence of tumor growth by these methods in only 9 (6.5%). In retrospect, we now know the high false-positive and false-negative rates of polytomography.

One potential stimulus to growth of a microadenoma was hypothesized to be the use of oral contraceptives. However, careful case-control studies using normal or amenorrheic control women and long-term epidemiologic surveys have not shown such a relationship.[352] In other studies, estrogens have been administered for 2 to 4 years to women with microadenomas and idiopathic hyperprolactinemia, resulting in no tumor enlargement in any patients.[353-355] However, individual cases with enlargement of tumors during estrogen therapy have been reported,[356] so hyperprolactinemic patients treated with estrogens should be followed carefully with periodic monitoring of PRL levels.

Many other potential factors have been investigated to determine why some tumors grow to become macroadenomas and why some macroadenomas are extremely large and invasive. Histologically, invasive prolactinomas have a high Ki-67 labeling index, which reflects increased cell proliferation.[357] Altered expression of adhesion molecules, matrix metaloproteinases, and extracellular matrix components have also been found.[357] An increase in angiogenesis has also been found in these large tumors.[358]

Pathogenesis of Prolactinomas

A primary defect in hypothalamic regulation of PRL secretion, such as a defect in dopaminergic tone had earlier been hypothesized to either cause or facilitate the growth of prolactinomas.[359] However, most information now favors the hypothesis that prolactinomas arise *de novo* as intrinsic disorders of the pituitary due to a single cell mutation with monoclonal cell proliferation and that most changes in hypothalamic function in patients with tumors are secondary to the tumors.[360,361]

A large number of potential mutations that could be pathogenetic for prolactinomas in humans have been investigated. Mutations causing loss of function in the dopamine D_2 receptor or gain of function of the TRH receptor have been looked for without success.[362-364] Evaluation of prolactinomas for mutations in the G proteins coupling the D_2 receptor to adenyl cyclase and the TRH receptor to its intracellular activating pathways have also been unsuccessful,[365,366] although prolactinomas resistant to bromocriptine may have decreased levels of the $G_{i2\alpha}$ protein that couples the D_2 receptor to adenyl cyclase.[365] As noted below, bromocriptine-resistant prolactinomas also have a decrease in the short D_2 receptor isoform, resulting in decreased inhibition of adenyl cyclase.[367] Thus, these alterations in D_2 isoforms and $G_{i2\alpha}$ may play a role in the pathogenesis of dopamine resistant prolactinomas, but those tumors comprise only 8% to 15% of prolactinomas.[365]

Many other studies have examined prolactinomas for putative oncogenes and tumor suppressor genes. No evidence for amplification or rearrangements have been found for the putative oncogenes *Pit-1*, *Prop-1*, *N-ras*, *H-ras*, *K-ras*, *myc II*, *N-myc*, *c-myc*, *myb*, *blc1*, *h-SF1*, *p16*, *p27*, *p53*, *sea*, *nm23*, or *c-fos* or the *menin* tumor suppressor gene.[360,361,368] Investigations are ongoing regarding abnormalities of cell cycle regulation, various signaling pathways and transcriptional regulators,[360] but their roles in the pathogenesis of prolactinomas and the stimulation of their growth still remain unclear.

Prolactinomas in Multiple Endocrine Neoplasia Type I

Prolactinomas occur in about 20% of patients with Multiple Endocrine Neoplasia Type I (MEN-I).[369] The MEN-I

(MENIN) gene is thought to function as a constitutive tumor suppressor gene, so an inactivating mutation results in tumor development. As noted previously, similar mutations have not been found in sporadic prolactinomas. The fact that prolactinomas develop in only a subset of MEN-I patients suggests that there may be a secondary modifying gene at a different locus that acts with the *MENIN* gene to produce prolactinomas.[369] There is evidence that the prolactinomas in patients with MEN-I may be larger, more aggressive and more resistant to treatment than sporadic prolactinomas.[370,371]

When patients with apparently sporadic prolactinomas were screened for hypercalcemia, 14.3% in one series were found to have hyperparathyroidism, of whom one-third were found to have gastrinomas upon screening for pancreatic tumors.[372] This figure is higher than the 2% to 3% reported previously.[373,374] However, even a figure of 2% suggests that obtaining a careful family history and measuring calcium levels are useful in the evaluation of all prolactinoma cases.

Prolactinomas in Familial Isolated Pituitary Adenomas (FIPA)

Germline mutations in the aryl hydrocarbon receptor interacting protein *(AIP)* gene were identified in a Finnish population of patients with familial isolate pituitary adenoma (FIPA) associated with somatotropinomas and prolactinomas.[375] In the initial report, 8 out of 54 patients from several families with a predisposition to prolactinomas and somatotropinomas harbored one of three different *AIP* germline mutations.[375] AIP appears to be a classic tumor suppressor gene with tumors in affected patients showing somatic loss of the wild-type allele. The genetics are autosomal dominant with variable penetrance and within families different types of tumors may be present, i.e., prolactinomas, somatotropinomas, and somatolactotopinomas.[376] In FIPA families, prolactinomas tend to present during childhood, be aggressive, have high rates of extrasellar expansion, and are resistant to dopamine agonists.[374, 376]

Pathology

Prolactinomas can invade local tissues and may have varying histologic features, but they cannot be termed truly malignant unless metastases distant from the original tumor can be demonstrated. Fortunately, true malignant prolactinomas are exceedingly rare and just over 40 have been reported.[377,378]

PRL secreting tumors may also secrete other hormones. The most common combination is PRL plus GH, about 25% to 40% of GH secreting tumors being found to make PRL. One particular variant of these PRL-GH-secreting tumors is the *acidophil stem cell adenoma*. These tumors have irregular, elongated cells with irregular nuclei and may have oncytic changes with very large mitochondria. In contrast to the other tumors secreting both hormones, patients with these tumors have more marked elevations of PRL than GH and usually present with menstrual abnormalities, galactorrhea, decreased libido, or impotence. They may have little in the way of acromegalic features.[379] These tumors are usually macroadenomas at the time of presentation and generally have had a relatively short course.[379] Other hormone combinations include PRL and ACTH, PRL and TSH, and PRL and FSH.[380] Interestingly, these plurihormonal tumors are generally monoclonal in origin,[381] as are most pure prolactinomas (discussed earlier in the chapter).

Local Mass Effects

Local mass effects may well cause symptoms in patients with macroadenomas, depending upon size and extent of extrasellar extension. The frequency of such symptoms is much lower than in patients with nonsecreting tumors because prolactinoma patients usually present with symptoms of reproductive or sexual dysfunction (discussed later in the chapter). Visual field defects due to chiasmal compression depend upon the amount of suprasellar extension. Because of the great variation in how these tumors grow superiorly with respect to the location of the chiasm, visual field defects can range from the classical, complete bitemporal hemianopsia to small, partial quadrantic defects, to scotomas.[382] There are no specific types of visual field defects peculiar to prolactinomas compared to other types of tumors.

Ophthalmoplegias are relatively uncommon, due to invasion of the cavernous sinus with entrapment of cranial nerves III, IV, V_1, V_2, and VI. In some patients a cavernous sinus syndrome may develop, consisting of ophthalmoplegia and pain or hyperesthesia in the distribution of V_1.[383] The carotid artery may be encased within the tumor but narrowing of the artery is not seen.[384] Shrinkage of these very large, invasive tumors with dopamine agonists can be quite dramatic and satisfying,[383,385,386] as surgery rarely is curative and is potentially fraught with complications.[387-389]

Extensive invasion of the floor of the skull, with massive destruction of bone, may occur, but this rarely causes problems of entrapping cranial nerves or compressing vital brain structures.[385-389] Extrasellar extension in other directions may rarely cause temporal lobe epilepsy and hydrocephalus.[385,388] These large, invasive tumors are uncommon but not rare and should be differentiated from true carcinomas; a demonstration of metastases distant from the primary tumor is necessary for the latter diagnosis. Histologically, these invasive tumors have no specific features to differentiate them from noninvasive prolactinomas.[388] Many of these patients respond quite well to dopamine agonists, occasionally shrinking to the point where no tumor is even detectable on scan, and PRL levels are normal.[383,385,386] Rarely, these tumors function as a "cork" at the base of the skull so that cerebrospinal fluid leaks may occur with substantial tumor shrinkage; surgery is necessary to repair such leaks to avoid the risk of meningitis.[386] For some tumors that do not respond to medication, surgical debulking and irradiation may be necessary (discussed later in the chapter).[385]

Local mass effects may also cause hypopituitarism because of direct pituitary compression or hypothalamic/stalk dysfunction. The larger the tumor, the more likely there is to be one or more hormonal deficits.[253,385-389] All patients with macroadenomas need to be evaluated for possible deficits in pituitary function.[337]

Clinical Manifestations

The clinical manifestations due to hyperprolactinemia are discussed above. The frequencies with which various

clinical manifestations occur in patients with prolactinomas vary depending upon referral patterns.

Women

In older series, almost all premenopausal women presented because of symptoms of galactorrhea, amenorrhea, or infertility. In a summary of 21 series of 1621 women with prolactinomas undergoing transsphenoidal surgery, the frequency of oligo-amenorrhea was 92.9% and of galactorrhea was 84.7%.[390]

Although secondary amenorrhea is more common, primary amenorrhea may also occur. Presentation because of severe headaches or visual field disturbance due to large tumors is uncommon in women because they usually initially seek medical attention for menstrual dysfunction or galactorrhea (which generally occur even with minimal PRL elevations and long before the tumors have grown large).[391] Postmenopausal women with prolactinomas usually present with mass effects from large tumors,[383] although others are found simply because of a history of "premature" menopause.[392]

Men

Men with prolactinomas often seek medical attention because of symptoms related to the size of the tumor, rather than because of impotence, loss of libido or infertility.[393] Prostate volume is reduced when men are hyperprolactinemic, presumably due to their low testosterone levels; prostate size returns to normal when PRL levels are normalized.[394] In a summary of 16 series comprising 444 men with prolactinomas (not all of whom went to surgery) 77.9% were impotent, 36.6% had visual field defects, 33.8% had partial or complete hypopituitarism, 29.1% complained of headaches, and 10.9% had galactorrhea.[390] Thus, about one-third of men had symptoms due to tumor size. Radiologic investigation demonstrates a macroadenoma in 80% to 90% of cases in most studies.[390,393]

There has been much speculation about the possible reason why a considerably greater proportion of men have macroadenomas compared with women. One hypothesis suggests that men tend to ignore symptoms of sexual dysfunction longer than do women, writing off impotence and decrease in libido to aging.[395] Thus, the prolonged course without therapy permits tumors to grow large. This line of reasoning ignores the data from women regarding the rather uncommon occurrence of progression of size of microadenomas. This observation would point to a more fundamental biological difference in the growth of prolactinomas between the sexes. The difference is unlikely to be due to the differences in target organ sex hormones, (i.e., estrogens and testosterone), because estrogens tend to be strongly growth-promoting. Whether or not there are tumor growth factors that might have a differential effect on prolactinoma growth in the different sexes is unknown. Immunohistochemical studies of tumors using the Ki-67 (MIB-1) antibody, which correlates with tumor growth, showed no difference between the sexes when corrected for tumor size.[396] Further examination of these issues may yield important information regarding the pathophysiology of these tumors.

Children and Adolescents

Children and adolescents may present with growth arrest, pubertal delay, or primary amenorrhea, in addition to the more standard presentations of galactorrhea, oligo-amenorrhea, and mass effects such as headaches or visual disturbances.[397-401] Low bone mineral density is also commonly seen.[402] In contrast to adults, there is a disproportionately large number of patients who have macroadenomas.[397,399-401] Hypopituitarism may be present in those with macroadenomas.[399] Furthermore, the percentage of patients resistant to dopamine agonists may be higher than in adults; Colao and colleagues reported that PRL levels were normalized in only 10 of 26 children and adolescents taking bromocriptine, 5 of 15 taking quinagolide, and 15 of 20 taking cabergoline.[401] The reasons for the high percentage of large macroadenomas and the relative resistance to dopamine agonists are not known, but it is tempting to speculate that these peculiarities may be linked.

Treatment

The indications for therapy in patients with prolactinomas may be divided into two categories: effects of tumor size and effects of hyperprolactinemia. As noted above, in 93% of patients, microprolactinomas do not enlarge over a 4 to 6 year period of observation. Thus, the simple argument that therapy is indicated for a microadenoma to prevent it from growing is fallacious. On the other hand, if a documented adenoma exists, it needs to be followed closely to determine if it is growing. It is very unlikely for a prolactinoma to grow significantly with no increase in serum PRL levels, although this phenomenon has been reported.[403] Therefore, after an initial scan showing a microadenoma, most patients can just be followed with serial PRL measurements. If PRL levels rise or the patient develops symptoms of mass effects such as headaches, then repeat scanning is indicated. Certainly a microadenoma that is documented to be growing demands therapy, for the size change alone, as it may be one of the 7% that will grow to be a macroadenoma.

Macroadenomas have already demonstrated their propensity for growth. Therefore, observation alone is inappropriate unless there are specific contraindications to therapy. Local or diffuse invasion or compression of adjacent structures, such as the stalk or optic chiasm, are additional indications for therapy.

Other indications for therapy are relative, being due to the hyperprolactinemia itself. These include decreased libido, menstrual dysfunction, galactorrhea, infertility, hirsutism, impotence, and premature osteoporosis. If a woman with a microadenoma has normal menses and libido and she is not bothered by the galactorrhea, there is no specific reason for therapy. On the other hand, therapy is indicated for a woman with amenorrhea and anovulation who wishes to become pregnant. However, if such a woman did *not* wish to become pregnant, then therapy to prevent osteoporosis or to improve libido is only relatively indicated and there are potential alternative therapies besides lowering PRL levels.

The ability to follow a patient closely with PRL measurements, CT or MRI scans, and estimations of bone mineral density, coupled with rather precise estimates of the efficacy of various modes of therapy allow a highly individualized way of following patients and choosing the proper timing and mode of therapy.

Surgery

Transsphenoidal surgical success rates are highly dependent upon the experience and skill of the surgeon as well as the size of the tumor. An analysis of the surgical results from 50 published series shows that normalization of PRL levels was achieved in 1596 of 2137 (74.7%) microadenomas and 755 of 2226 (33.9%) macroadenomas.[393] Clearly, for the macroadenomas the lower success rate in large part was dependent on the size of tumors chosen for surgery. In many series, the object was, appropriately, debulking of a very large tumor rather than cure and in other series very large tumors were not operated upon.

From the series compiled, recurrence rates for microadenomas (147 of 809 = 18.2%) and macroadenomas (106 of 465 = 22.8%) were similar.[393] It should be stressed here, that for virtually all of these recurrences, the recurrence is that of hyperprolactinemia and not documented radiological evidence of tumor regrowth. With recurrence of the hyperprolactinemia there usually also is a recurrence of sexual/reproductive dysfunction that usually is an indication for medical therapy to reduce PRL levels. Based on the cure and recurrence rates cited earlier in the text, the ultimate, long-term surgical cure rates using a normal PRL level as the criterion, is 61.1% for microadenomas and 26.2% for macroadenomas.

In an analysis of 84 patients with macroadenomas (36 were prolactinomas), Nelson and colleagues found that of those with normal preoperative pituitary function, only 78% retained normal function postoperatively.[404] One-third with some pituitary deficits prior to surgery improved and one-third with such deficits had worsened pituitary function after surgery; none of the panhypopituitary patients improved following surgery.[404]

Complications from transsphenoidal surgery for microadenomas are quite infrequent, the mortality rate being at most 0.6%, the major morbidity rate being about 3.4% (visual loss, stroke/vascular injury, meningitis/abscess, oculomotor palsy) and cerebrospinal fluid (CSF) rhinorrhea occurring in 1.9%.[393,405-407] The mortality rate for transsphenoidal surgery for all types of secreting and nonsecreting macroadenomas ranges from 0.25% to 1.2%, the major morbidity rate is about 6.5% (visual loss, stroke/vascular injury, meningitis/abscess, and oculomotor palsy), and the rate of CSF rhinorrhea is about 3%.[393,405-407] Transient diabetes insipidus is quite common with transsphenoidal surgery for both micro- and macroadenomas and permanent diabetes insipidus (DI) occurs in about 1% of surgeries on macroadenomas.[405-407] Although visual field defects and reduction in visual acuity can be improved in 74% of patients whose macroadenomas abut the optic chiasm,[408] a small number of patients with normal visual fields may have a reduction of vision after surgery due to herniation of the chiasm into an empty sella, direct injury or devascularization of the optic apparatus, fracture of the orbit, postoperative hematoma, or cerebral vasospasm.[409] In general, complication rates fall with increasing experience of the neurosurgeon.[406,407]

In recent years, endoscopic, endonasal transsphenoidal surgery has evolved into a commonly used technique. This method gives a superior panoramic view with a shorter operating time and local complication rate. However, surgical remission rates are no better with this newer approach.[410,411]

Radiotherapy

Because of the excellent therapeutic responses to transsphenoidal surgery and medical therapy (described later in the chapter), radiotherapy is generally not considered to be a primary mode of treatment for prolactinomas. There are reports of just over 250 patients who have been treated with conventional radiotherapy alone, or in combination with bromocriptine, or after failure of surgical cure.[393] About 35% of patients can achieve normal PRL levels following surgery plus irradiation, usually between 5 and 15 years after irradiation.[393]

The major adverse effect of radiotherapy is hypopituitarism. This complication occurs with frequencies as high as 93%.[393,412] Additional complications that occur months to years after radiotherapy of pituitary adenomas include second malignancies, cerebrovascular accidents, optic nerve damage, radiation brain necrosis, neurologic dysfunction, and soft tissue reactions. Second malignancies have been reported to be significantly increased 15 to 20 years following the primary irradiation.[413-415] Radiation-induced optic atrophy occurs in 2% to 5% of patients and is due to ischemic damage to the optic apparatus.[416] Radiotherapy-induced encephalopathy is rare but can be devastating and occurs only with high doses.[417]

A new form of radiotherapy used increasingly in recent years, which allows the precise delivery of a single, necrotizing dose to the tumor with little radiation to surrounding tissue is referred to as "stereotactic" radiotherapy ("gamma knife" and linear accelerator).[393] Cranial nerves in the cavernous sinus are relatively radioresistant but the optic nerves, chiasm, and tracts are radiosensitive,[418] so that this type of treatment appears to be advantageous for postoperative tumor residing in the cavernous sinus. Data extending out to only 2 to 3 years on almost 300 patients suggests that this technique may be more effective at reducing hormone levels and tumor size in a shorter period of time with fewer complications than conventional radiotherapy.[393] However, only one study reported using stereotactic radiotherapy as primary therapy without dopamine agonist, finding that only 16 of 77 (21%) patients achieved normal PRL levels.[419] Although it is hoped that many of the complications from brain irradiation will be lower with focused radiotherapy compared to conventional radiotherapy, data thus far suggest that the frequency of hypopituitarism will likely be the same.[420]

Thus, with radiotherapy only small numbers of patients reach normal levels of PRL and then only after many years. Radiotherapy seems best reserved as adjunctive therapy for those patients with enlarging lesions who have not responded to either medical or surgical treatment, and the newer techniques of focused radiotherapy would appear to offer advantages of efficacy, rapidity of effect, and possibly less adverse effects, especially for residual tumor in the cavernous sinus. However, in patients who were intolerant or unresponsive to dopamine and who were still hyperprolactinemic following transsphenoidal surgery, normoprolactinemia was achieved in only 18% following stereotactic radiotherapy.[421]

Medical Therapy

Bromocriptine

Bromocriptine was the first D_2 DA receptor agonist to be used for the treatment of hyperprolactinemia. Because of its

short half-life, it usually must be taken two or three times daily. Bromocriptine is successful in normalizing PRL levels or causing return of ovulatory menses in 80% to 90% of patients.[422,423] When PRL levels and return of menses were studied in the same patients, it was found that substantially reducing PRL levels to slightly elevated levels was often enough to restore ovulation and menses despite the fact that normal PRL levels were achieved in only 70% to 80% of treated patients.

There is little intraindividual variability in the absorption and peak blood levels achieved but there is considerable interindividual variability.[424] There is also considerable variability in the PRL lowering effects of a given dose of bromocriptine that does not correlate with serum bromocriptine levels, implying differences in sensitivity to the drug.[425] Decreased response to bromocriptine *in vivo* has been shown to correspond to decreased numbers of DA receptors on lactotroph cell membranes and decreased inhibition of adenyl cyclase when the same tumors are studied *in vitro* following surgery.[426]

In vitro studies have shown that bromocriptine decreases not only PRL synthesis but also DNA synthesis, cell multiplication, and tumor growth.[427] The initial report that bromocriptine was able to reduce tumor size in humans was by Corenblum and colleagues.[428] An analysis of tumor size responses to bromocriptine from 24 different series of patients (totaling 302 patients) with macroadenomas showed that 76.8% had some tumor size decrease in response to bromocriptine with periods of observation ranging from 6 weeks to over 10 years (Fig. 3.3).[390] In 10 studies with 112 patients in whom the size change was quantified, 45 (40.2%) had a greater than 50% reduction in tumor size, 32 (28.6%) had a 25% to 50% reduction in tumor size, 14 (12.5%) had a less than 25% reduction, and 21 (18.7%) had no evidence of any reduction in tumor size.[390] In 15 patients with microadenomas, Bonneville and colleagues found that 6 tumors disappeared completely, 5 decreased approximately 50% in volume and 4 remained unchanged with treatment of 3 to 12 months.[429]

The time course of tumor size reduction is variable. Some patients may experience an extremely rapid decrease in tumor size, with significant changes in visual fields being noted with 24 to 72 hours and significant changes noted on scan within 2 weeks.[430] In others, little change may be noted at 6 weeks but scanning again at 6 months may show significant changes.[390,431] In many patients, progressive tumor size reduction can be noted over several years.[390,431,432]

Visual field improvement occurs in 80% to 90% of patients with defects.[253,390,431,433] The visual field improvement generally parallels and often precedes the changes seen on scan.[253,433] It is often difficult to determine before treatment whether visual defects are temporary or permanent and only the response to therapy provides a final answer. These studies with medical therapy are reassuring in that a relatively slow chiasmal decompression over several weeks provides excellent restoration of visual fields and that immediate surgical decompression is not necessary. Usually, when there is no significant change in visual fields despite significant evidence of tumor reduction on scan, subsequent surgery also does not improve these fields.[434] Reduction in tumor size may also be accompanied by improved pituitary function.[253,435] When the prolactinoma is present prepubertally, improved pituitary function allows resumption of normal growth and pubertal development.[436]

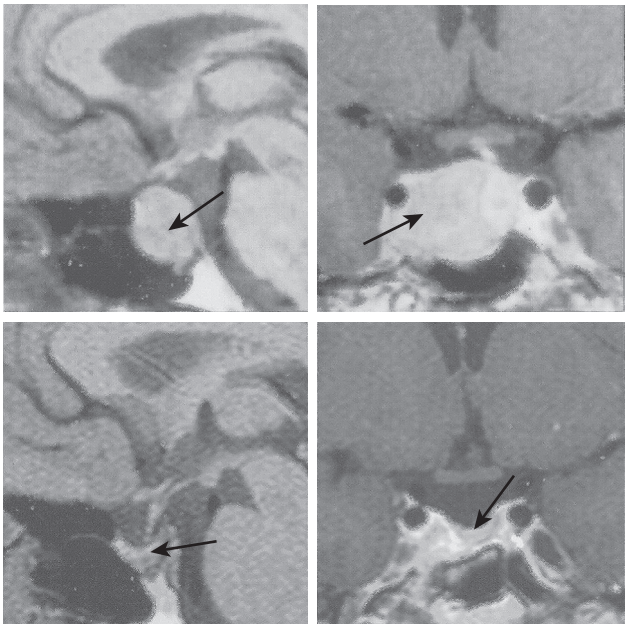

FIGURE 3.3 MRI scans of a patient with a macroadenoma before *(above)* and during *(below)* bromocriptine treatment. *Left:* sagittal view, *right:* coronal view. Note the marked decrease in tumor size.

The extent of tumor size reduction does not correlate with basal PRL levels, nadir PRL levels achieved, the percentage of PRL decrease, or whether PRL levels reached normal. Some patients have excellent reduction in PRL levels into the normal range but only modest changes in tumor size; others may have persistent, mild hyperprolactinemia (although suppressed greater than 88% from basal values) with almost complete disappearance of tumor.[253] A reduction in PRL levels always precedes any detectable change in tumor size, however; therefore patients whose PRL levels do not respond to therapy have no reduction in tumor size. Once maximum size reduction is achieved, the dose of bromocriptine can often be substantially reduced, gradually.[437]

Rarely, the prolactinoma serves as a "cork" and tumor size reduction with bromocriptine may cause CSF rhinorrhea.[387,438] Fibrosis has been reported in some tumors with marked shrinkage which may hinder later surgical cure of macroadenomas.[439,440] For most patients, however, continued dopamine agonist treatment is preferable to trying late surgery. Prolonged bromocriptine treatment for up to 10 years appears to be well tolerated[435,441-446] and the dose can often be reduced considerably.[437]

With discontinuation of short-term (several weeks to months) treatment, macroadenomas can re-expand within 2 weeks.[447] However, over 90% of tumors treated for several years with good size reduction, remain reduced in size when the drug is stopped, although PRL levels may increase to above normal levels and require treatment.[393,441,443,445] In a study of 69 patients with macroadenomas and 62 with microadenomas, Passos and colleagues found that 16% of patients with macroadenomas and 21% with microadenomas maintained normal PRL levels after stopping a median of 47 months of therapy.[448] In two more recent studies,

about 50% of patients with microadenomas maintained normal PRL levels after stopping therapy.[446,449]

Therapy discontinuation must be done very cautiously, if at all, in patients with very large tumors who have excellent tumor size reduction. The best approach is probably to reduce the dose gradually, following PRL levels, and only discontinue the drug if there are no increases in PRL levels or tumor size on low doses.

The most common adverse effects are nausea and sometimes vomiting; these are usually transient but may recur with each dose increase. Orthostatic hypotension usually is only a problem when initiating therapy and rarely recurs with dose increases. Limiting nausea and vomiting occurs in 5% to 10% of patients and digital vasospasm, nasal congestion, and depression occur rarely in patients when doses less than 7.5 mg/day are used.[422]

Side effects can be minimized by starting with one daily 1.25 mg dose taken with a snack at bedtime. The dose can then be gradually increased to 2.5 mg twice daily with meals over 7 to 10 days. PRL levels should be checked after 1 to 2 months; most patients who respond to this therapy will do so within this period. Dose higher than 7.5 mg per day are usually not necessary, except in some patients with very large tumors.

One other notable side effect is a psychotic reaction. Turner and colleagues noted psychotic reactions in 8 of 600 patients receiving either bromocriptine or lisuride for hyperprolactinemia or acromegaly.[450] Symptoms included auditory hallucinations, delusional ideas, and changes in mood. Rare reports of exacerbation of preexisting schizophrenia also exist; therefore the drug should be given cautiously to such patients.[451] Psychotic reactions usually resolve within 72 hours of stopping the drug. It should be noted that phenothiazines given to such patients may also blunt the action of bromocriptine on prolactinomas.[253]

One concerning problem is the tumor that initially shrinks in response to a dopamine agonist but then enlarges. This is usually due to noncompliance, which is further worsened by the tendency for the patient and physician to resume the full dose instead of gradually restarting. This tends to make side effects worse, further exacerbating the noncompliance. However, several case reports of tumor enlargement in compliant patients have been reported.[452-455] Pelligrini and colleagues have shown markedly fewer DA binding sites in tumors that grow during bromocriptine treatment compared with those that shrunk or remained unchanged in response to therapy.[455]

In other studies, Caccavelli and colleagues have shown that resistant cells express a decreased proportion of the shorter DA D2 receptor isoform which is coupled to phospholipase C more efficiently than the long DA D2 receptor isoform.[456] Recently, Peverelli and colleagues have found that this decreased D2 receptor expression is associated with a decrease in filamin, a cytoskeleton protein that associates with the receptor.[457] Prolactinomas that are resistant to bromocriptine are often sensitive to cabergoline.[458]

Although extremely rare, tumors that continue to enlarge while being treated with dopamine agonists may turn out to be carcinomas. A rare case of an adenoma transforming to a sarcoma during bromocriptine therapy has also been reported.[459]

An alternative method of giving bromocriptine has been found to be successful in some cases. Vermesh and colleagues reported that similar reductions in PRL levels are achieved with oral and intravaginal administration of oral bromocriptine tablets.[460] However, the drug effect lasts for up to 24 hours with a single dose and gastrointestinal side effects were much less with the intravaginal route. Katz and colleagues reported that a macroadenoma in a woman who was unable to tolerate oral bromocriptine responded well with tumor shrinkage to intravaginal bromocriptine.[461] Many women have now been treated with intravaginal bromocriptine with similar results, although some develop local irritation at the site of tablet placement. Thus, the gastrointestinal side effects appear to be caused by local effects rather than being mediated centrally.

Pergolide

Another dopamine agonist that has been demonstrated to have efficacy in the treatment of prolactinomas is pergolide, which had been approved by the U.S. Food and Drug Administration for the treatment of Parkinson's disease. Pergolide is comparable to bromocriptine with respect to tolerance and efficacy, including tumor size reduction.[462] However, pergolide was withdrawn from the U.S. market in 2007 because of an association with cardiac valvular lesions similar to those seen in patients with Carcinoid syndrome. These associations were seen only when it was used in the high doses needed for Parkinson's disease.[463,464] No such lesions were seen in patients treated with bromocriptine.[463,464] No cardiac valvular lesions have been reported in patients treated with the lower doses used for prolactinomas.

Quinagolide

Quinagolide (CV 205-502) is a non-ergot dopamine agonist that can be given once daily with similar tolerance and efficacy to bromocriptine and pergolide.[390,465] About 50% of patients who are resistant to bromocriptine respond to quinagolide.[390,465-467] Although side effects are similar, some patients appear to tolerate quinagolide better than bromocriptine.[390,465-467] In studies in which 105 patients were assessed for tumor size reduction in a semiquantitative way, 50 (48.1%) experienced greater than 50% tumor size reduction, 21 (20.2%) experienced a 25% to 50% size reduction, 18 (17.3%) experienced less than 25% reduction, and 15 (14.4%) had no change in tumor size.[390] Quinagolide is not approved for use in the U.S.

Cabergoline

Cabergoline is different from the other dopamine agonists in that it has a very long half-life and can be given orally once or twice weekly. The long duration of action stems from its slow elimination from pituitary tissue,[468] its high affinity binding to pituitary DA receptors,[469] and extensive enterohepatic recycling.[470] After oral administration, PRL lowering effects are initially detectable at 3 hours, then gradually increase so that there is a plateau of effect between 48 and 120 hours[470,471]; with weekly doses there is a sustained reduction of PRL.[472]

Several studies have shown that cabergoline is generally more effective than bromocriptine in lowering PRL levels and has substantially fewer side effects.[471-476] In a

prospective, double-blind comparison study of 459 women (279 microadenomas, 3 macroadenomas, 167 idiopathic hyperprolactinemia, 10 other), of women treated with cabergoline, 83% achieved normoprolactinemia, 72% achieved ovulatory cycles and 3% discontinued the medication because of adverse effects. Of women treated with bromocriptine, 59% achieved normoprolactinemia, 52% achieved ovulatory cycles, and 12% stopped the drug because of adverse effects.[475] In other studies, cabergoline treatment of men caused a rapid improvement of sperm number and quality.[476,477] Rare patients experience limiting nausea and vomiting with cabergoline, and they may be treated with intravaginal cabergoline as well.[478]

Several studies have assessed the effect of cabergoline on macroadenoma size.[472-474,479-485] A total of 130 patients in these series had their tumor size assessed in a semiquantitative way in studies ranging from 3 to 24 months duration of treatment. Of these 130, 33 (25.4%) experienced a greater than 50% tumor size reduction, 61 (46.9%) had a 25% to 50% reduction, 8 (6.9%) had a less than 25% reduction, and 28 (21.5%) had no change in tumor size. In many of these studies, many of the patients had been previously treated with other DA agonists, changing therapy because of intolerance or resistance, and this may color the findings. In a comparison of groups of patients, Colao and colleagues found that 25 of 26 (96%) patients who had never received prior dopamine agonists had tumor shrinkage of greater than 50%, whereas 13 of 19 (68%) who had been intolerant of prior bromocriptine, 21 of 33 (64%) who had been resistant to bromocriptine, and 14 of 20 (70%) who had been responsive to bromocriptine had similar reductions.[486] Thus, in the drug-naive patient, cabergoline clearly seems to be the most efficacious in reducing PRL levels to normal and in decreasing tumor size and has the least adverse effects. Visual defects tend to improve with the decreases in tumor size with cabergoline, similar to what has been seen with bromocriptine.[487]

In patients who have had normalization of their PRL levels for several years, cabergoline may be withdrawn gradually to see if hyperprolactinemia recurs. Colao and colleagues reported that after cabergoline withdrawal, of 105 normoprolactinemic patients with microadenomas, hyperprolactinemia recurred in 40% of those with tumors visible on MRI scan but in only 24% of those without visible tumors and of 70 normoprolactinemic patients with macroadenomas, hyperprolactinemia recurred in 58 of those with tumors still visible on MRI scan but in only 26% of those without visible tumors.[488] In a similar study of 67 patients with microadenomas, Biswas and colleagues found that only 31% remained free of recurrence of hyperprolactinemia.[447] More recently, Kharlip and colleagues found rates of recurrence of 52% in 31 patients with microadenomas and 55% in 11 patients with macroadenomas,[489] and Barber and colleagues found rates of recurrence of 64% in 45 patients with microadenomas and 93% in 15 patients with macroadenomas.[490] Overall, the rates of recurrence are lower for cabergoline compared to bromocriptine.[491] Interestingly, however, the amount of drug-induced tumor fibrosis is greater with bromocriptine use compared to cabergoline use.[492]

Some patients with macroprolactinomas are very resistant to even cabergoline and may require very high doses.[493,494] The dose of cabergoline can be gradually increased, as long as there is a stepwise fall in PRL with each stepwise increase in cabergoline dose and the patient is not experiencing side effects.[493-495] An additional approach involves adding an aromatase inhibitor to reduce testosterone-to-estrogen conversion in men.[495] In rare cases, the alkylating agent, temozolomide, has been found to be effective in reducing tumor size and PRL levels in invasive, giant prolactinomas that are not malignant.[496-498] Temozolomide has also been used successfully in some cases of the very rare PRL-secreting pituitary carcinomas.[499]

Cardiac valvular lesions similar to those seen in patients treated with pergolide have also been found in patients treated with cabergoline. As with pergolide, these associations were seen only when it was used in the high doses needed for Parkinson's disease.[463,464] Clinically significant cardiac valvular lesions have not been generally reported in patients treated with the lower doses generally used for treatment of prolactinomas, i.e., doses 2 mg per week or less.[494,500-503] However, in resistant patients who are receiving much greater than usual doses, it may be prudent to monitor them with echocardiograms. Given that mild, clinically insignificant valvular regurgitation is very common in the normal population, it may be difficult in a given individual without a prior echocardiogram to determine whether such a finding is of clinical significance.[494]

Conclusions Regarding Treatment

Microadenomas

The risk of progression of microadenoma to macroadenoma is under 7%, so the patient unconcerned with fertility has no pressing need for therapy. On the other hand, long-term hypogonadism due to hyperprolactinemia may be associated with premature osteoporosis in both sexes; treatment reverses the increased rate of bone loss. For the woman with continued menses and no hypoestrogenemia, the risk of osteoporosis is not increased. For the correction of gonadal function with prevention of osteoporosis and restoration of libido, most patients should be treated unless they have normal estrogen and testosterone function.

If fertility is not an issue, then estrogen replacement therapy or a DA agonist could be tried. Because of its efficacy in reducing PRL levels, its favorable adverse effect profile, and once- or twice-weekly dosing, cabergoline appears to be the initial drug of choice for most patients with prolactinomas. If fertility is the primary reason to restore ovulation, then some consider bromocriptine to be the better choice because of its more established safety profile (discussed later in the chapter).

The cost of treatment and the necessity of taking medications for many years make some patients choose transsphenoidal surgery as their primary option. Surgery may also be indicated for the 5% of patients who either cannot tolerate or do not respond to DA agonists. Initial surgical cure rates for microadenomas appear to be in the 65% to 85% range, with a later recurrence for hyperprolactinemia of about 20% (thus the ultimate cure rate is in the 60% range). Radiation therapy has a very restricted role in patients with microadenomas, being limited to those who do not respond to or are intolerant of DA agonists and who are not cured by surgery.

Macroadenomas

Because of their excellent results and the rather poor results of surgery in most patients, DA agonists are recommended as the initial therapy for patients with PRL-secreting macroadenomas. Surgery can be performed later in patients whose tumor responses to such medications are not optimal. Even if this subsequent surgery is necessary for tumor debulking, it rarely is curative and a DA agonist is usually necessary for treatment of the hyperprolactinemia. Because of its better tolerability and generally better efficacy, cabergoline is the DA agonist of choice. Radiation therapy again has a very limited role here, being used for those who have no response to or are intolerant to dopamine agonists, or whose tumor was documented to actually grow while on dopamine agonists and after incomplete surgical removal. Stereotactic radiotherapy appears to be the best form of radiotherapy at this point, although long-term complications have not yet been assessed fully.

When dopamine agonist therapy is stopped, the prolactinoma may return to its original size, often within days to weeks. However, most studies with longer-term treatment have found re-expansion in less than 10% of patients in whom dopamine agonists were withdrawn, despite recurrence of hyperprolactinemia in 80% to 85% of those treated with bromocriptine, but a considerably lower percentage with cabergoline. This potential return to pretherapy size dictates extreme caution when withdrawing dopamine agonist therapy, because rapid tumor expansion may produce far more clinical symptoms than slow tumor enlargement. Often, however, the dose can be gradually tapered once maximal size reduction has occurred and, in suitable cases, stopped entirely if no re-expansion occurs.

The anatomical response of tumors to dopamine agonist treatment must be monitored carefully by CT or MRI and by visual field examinations to detect tumors that do not respond, including the very rare carcinomas and cases of tumor re-enlargement.

Pregnancy in Women with Prolactinomas

Hyperprolactinemia is usually associated with anovulation and infertility; correction of the hyperprolactinemia with dopamine agonists restores ovulation in about 90% of cases. When a woman harbors a prolactinoma as the cause of the hyperprolactinemia, two major issues arise when ovulation and fertility are restored: the effects of the DA agonist on early fetal development, and the effect of the pregnancy itself on the prolactinoma.

Effects of Dopamine Agonists on the Developing Fetus

As a general principal, it is advised that fetal exposure to medications be limited to as short a period as possible. Most advise that mechanical contraception be used after institution of DA agonist therapy until the first two to three cycles have occurred, so that an intermenstrual interval can be established. In this way, a woman will know when she has missed a menstrual period, a pregnancy test can be performed quickly, and the dopamine agonist stopped. Thus, the drug will have been given for only about 3 to 4 weeks of the gestation.

When used in this fashion, compared to what would be expected in the normal population,[504-506] bromocriptine has not been found to cause any increase in spontaneous abortions, ectopic pregnancies, trophoblastic disease, multiple pregnancies, or congenital malformations (Table 3.1).[507,508] Long-term follow-up studies of 64 children between the ages of 6 months and 9 years whose mothers took bromocriptine in this fashion have shown no ill effects.[509] Experience with the use of bromocriptine throughout the gestation, however, is limited to only just over 100 women; no abnormalities were noted in the infants except for one with an undescended testicle and one with a talipes deformity.[507,510-512]

Pergolide has been shown to cross the placenta in mice[513] and limited data suggest that there is an unacceptable risk of congenital malformations.[514,515] Initially no detrimental effects on pregnancy or fetal development in women who became pregnant during treatment with quinagolide were found.[516] However, a review of 176 pregnancies in women treated with quinagolide reported 24 spontaneous abortions, 1 ectopic pregnancy, 1 stillbirth, and 9 fetal malformations.[517] Therefore, neither pergolide nor quinagolide can be recommended if pregnancy is desired.

Cabergoline has been shown to cross the placenta in animal studies, but such data are lacking in humans. Data on exposure of the fetus during the first several weeks of pregnancy have been reported in almost 800 cases and such use has not shown an increased percentage of spontaneous abortion, premature delivery, multiple pregnancy, or congenital abnormalities.[518] Follow-up studies of up to 12 years following exposure to cabergoline during gestation showed no physical or developmental abnormalities in the 83 children followed by Ono and colleagues,[519] a slight retardation in verbal fluency in 2 and difficulty in achieving complete continence in 1 by age 4 among the 88 children followed by Lebbe and colleagues,[520] and seizures in 2 and "pervasive developmental disorder", an autism spectrum disorder, in 2 of the 61 children followed by Stalldecker and colleagues.[521]

In conclusion, with respect to using a dopamine agonist to facilitate ovulation and fertility, bromocriptine has the largest safety database and has a proven safety record for pregnancy. Although the database for cabergoline use in pregnancy is much smaller, it does not appear that cabergoline exerts any deleterious effects on pregnant women and the incidence of malformations in their offspring is not greater than in the general population. The safety databases for pergolide and quinagolide are quite limited, but they raise concerns, and so these drugs should not be used when fertility is desired. The effects of transsphenoidal surgery during gestation are not known specifically, but would not be expected to be significantly different from the effects of other types of surgery,[522] unless hypopituitarism should ensue.

Effect of Pregnancy on Prolactinoma Size

Estrogens have a marked stimulatory effect on PRL synthesis and secretion and the hormonal milieu of pregnancy can stimulate lactotroph cell hyperplasia.[2,3] Those autopsy studies showing lactotroph cell hyperplasia during pregnancy have now been corroborated *in vivo*; MRI scans showing a

gradual increase in pituitary volume over the course of gestation, beginning by the second month and peaking the first week postpartum. In some cases, a final height of almost 12 mm is reached.[523]

The stimulatory effect of the hormonal milieu of pregnancy may also result in significant prolactinoma enlargement during gestation (Fig. 3.4). Tumor enlargement may also occur because the dopamine agonist that had caused the tumor to shrink has now been discontinued. Data have been compiled from many studies that analyzed the risk of symptomatic tumor enlargement in pregnant women with prolactinomas, divided according to tumor size (Table 3.2).[518] For women with microadenomas, only 18 of 658 pregnancies (2.7%) were complicated by symptoms of tumor enlargement (headaches and/or visual disturbances). Surgical intervention was not required in a single case and medical therapy with reinstitution of bromocriptine resolved the symptoms in the five in whom it was tried. In 49 of 214 pregnancies (22.9%) in women who had not undergone prior surgery or radiotherapy for their macroprolactinomas, there were similar symptoms of tumor enlargement. 148 women with macroadenomas were identified who had undergone surgery or radiation prior to pregnancy; their risk of tumor enlargement was lower (4.8%).

Recommendations for Management During Pregnancy

Because of its well-established safety record and the smaller amount of data with cabergoline, bromocriptine is favored by some clinicians for women wishing to become pregnant. However, there really are no data to show that cabergoline is not safe and it is also commonly used in this setting. A patient with a microadenoma or a small, intrasellar macroadenoma treated only with a DA agonist should be carefully followed throughout gestation. PRL levels do not always rise during pregnancy in women with prolactinomas, as they do in healthy women, and PRL levels may also not rise with tumor enlargement.[524] Therefore, periodic checking of PRL levels is of no benefit. Because of the low incidence of tumor enlargement, routine, periodic visual field testing is not cost effective. Visual field testing and scanning are performed only in patients who become symptomatic. In the patient with tumor enlargement who does not respond to reinstitution of a DA agonist, surgery or early delivery may be required.

In a woman with a larger macroadenoma that may have suprasellar extension, there is approximately a 23% risk of clinically significant tumor enlargement during pregnancy when only a DA agonist is used. There is no clear-cut answer as to the best therapeutic approach, so this must be a highly individualized decision that the patient has to make after a clear, documented discussion of the various therapeutic alternatives.

Table 3.2 Effect of Pregnancy on Prolactinomas

Tumor Type	Prior Therapy	Number Of Patients	Symptomatic Enlargement
Microadenomas	None	658	18 (2.7%)
Macroadenomas	None	214	49 (22.9%)
Macroadenomas	Yes	148	7 (4.8%)

Data from Molitch ME. Prolactinoma in pregnancy. *Best Prac Res Clin Endocrinol Metab* 25:885–896, 2011.

One approach is to perform a prepregnancy transsphenoidal surgical debulking of the tumor. This should greatly reduce the risk of serious tumor enlargement, but cases with massive tumor expansion during pregnancy after such surgery have been reported.[525] After surgical debulking, bromocriptine or cabergoline would be required to restore normal PRL levels and allow ovulation.

A second approach would be to treat with bromocriptine or cabergoline to allow ovulation and then stop the drugs once pregnancy has been achieved, as in a woman with a microadenoma. This is the approach that is generally used.

A third approach, that of giving bromocriptine continuously throughout gestation, has been advocated.[512] At this point, however, data regarding the effects of continuous bromocriptine therapy on the developing fetus are still quite meager, and such therapy cannot be recommended without reservation. Data documenting safety of giving cabergoline throughout pregnancy are even fewer.[526-528] Should pregnancy at an advanced stage be discovered in a woman taking bromocriptine or cabergoline, the data that exist are reassuring and would not justify therapeutic abortion.

For patients with macroadenomas treated with DA agonists alone or after surgery, careful follow-up with one to three monthly visual field testing is warranted. Repeat scanning (without gadolinium) is reserved for patients with symptoms of tumor enlargement, evidence of a developing visual field defect, or both. Repeat scanning after delivery to detect asymptomatic tumor enlargement may be useful as well.

Should symptomatic tumor enlargement occur with any of these approaches, reinstitution of a DA agonist is probably less harmful to the mother and child than surgery. There have been a number of cases reported where such reinstitution of bromocriptine has worked quite satisfactorily, causing rapid tumor size reduction with no adverse effects on the infant.[518] Similarly, one case has been reported with the successful reinstitution of cabergoline.[526] Any type of surgery during pregnancy results in a 1.5-fold increase in fetal loss in the first trimester and a fivefold increase in fetal loss in the second trimester, although there is no risk of congenital malformations from such surgery.[522,529] Thus, DA agonist reinstitution would appear to be preferable to surgical decompression. However, such medical therapy must be very closely monitored, and transsphenoidal surgery or delivery (if the pregnancy is far enough advanced) should be performed is there is no response to the DA agonist and vision progressively worsens.

There is no evidence that breastfeeding stimulates tumor growth.[530,531] For women who wish to breastfeed, DA agonists must be withheld until such time as the woman wishes to stop, unless pregnancy-induced tumor growth required treatment.

Interestingly, postpartum PRL levels are often lower than they were prepartum with some patients achieving normalization of PRL without any therapy; the mechanism for this not known.[532] However, in many patients it may be reasonable to observe patients for a few months to determine their PRL and ovulatory status following delivery and cessation of breastfeeding, rather than automatically putting them back on their dopamine agonists.

CHAPTER 4

The Synthesis and Metabolism of Steroid Hormones

Jerome F. Strauss III

Steroid hormones and the secosteroid, vitamin D, belong to an ancient family of signaling molecules with diverse functions, including central roles in the regulation of female and male reproductive processes. The human steroid hormones are derived from cholesterol, an abundant plasma lipid and a structural component of plasma membranes and other organelles. Seemingly subtle modifications of the four fused rings of the sterol skeleton and side chain result in molecules with different and diverse activities. This chapter reviews the general features of the synthesis and metabolism of steroid hormones, the ways in which these processes are controlled physiologically, the ways in which these processes can be modified by pharmacological intervention, and some genetic disorders that interfere with normal steroid synthesis and metabolism.

Steroid Hormone Structure and Nomenclature

Steroid hormones share a cyclopentanoperhydrophenanthrene backbone. Each carbon in this fused-ring structure is assigned a number identifier, and each ring, a letter (Fig. 4.1). The naturally occurring steroid hormones are named according to the saturated ring structures of the parent compound: *cholestanes*, of which cholesterol (5-cholesten-3β-ol) is a representative, have 27 carbons; *pregnanes* have 21 carbons (e.g., 4-pregnen-3-20-dione, also known by its trivial name, *progesterone*); *androstanes* have 19 carbons (e.g., 17β-hydroxy-4-androsten-3-one, or *testosterone*); and *estranes* have 18 carbons (e.g., 1,2,5[10]-estratriene-17β-ol, or *estradiol*). *Gonanes* contain 17 carbons (the cyclopentanoperhydrophenanthrene backbone), represented by synthetic progestins (e.g., desogestrel, norgestimate, gestodene). The backbone name is **not** synonymous with biological activity, which is determined mainly by which members of a family of nuclear transcription factors (steroid hormone receptors) the molecules activate. For example, cortisol and progesterone are members of the pregnane family, yet they have different biological activities and act through different receptors. Synthetic molecules that activate the progesterone receptor are derived from androgens containing 18 carbons (19-nortestosterone derivatives) and are therefore members of the estrane family. 27-Hydroxycholesterol, a member of the cholestane family, is a selective estrogen receptor modulator.[1]

The locations of substituents in the steroid backbone are indicated by the carbon number to which they are attached. Substituents at several positions have a significant effect on metabolism and biological activity of steroid hormones, including carbons 3, 7, 11, and 17. Atoms attached to asymmetric centers are, by convention, given the designation α if they project below the plane of the ring structure (in figures of structures, a dashed line or hatched triangle indicates the α configuration). The designation β (a solid line or filled triangle) is given to atoms that project above the plane. Hormone receptors and steroid binding proteins (e.g., sex hormone binding globulin, SHBG) distinguish between stereoisomers. In the case of estrogen receptors, 17β-estradiol is active, but 17α-estradiol is essentially inert. In the case of androgen receptors, testosterone with a 17β-hydroxyl configuration is active, but epitestosterone with a 17α-hydroxyl configuration has little activity.

Different enzymes catalyze the oxidation or reduction of α and β hydroxyl groups and reduce the Δ4 double bond in the steroid A ring to form 5α or 5β molecules. Such 5α-reduced steroids can be active (e.g., 5α-dihydrotestosterone, which activates androgen receptors), or inactive (e.g., 5α-dihydroprogesterone) with respect to classical steroid hormone receptor function. However, the notion that pregnane 5α-reduced compounds are inactive has been challenged by the recent revelation that 5α-reduced glucocorticoids may have anti-inflammatory activity acting through glucocortcoid receptors.[2] Although 5β-reduced steroids are not capable of activating classical steroid hormone receptors, these steroids and some 5α-reduced molecules, exert biological effects outside of the family of steroid hormone receptors, including modulation of neurotransmitter receptor function.

The naturally occurring steroid hormones are rarely referred to in the medical literature by their systematic names, which designate the parent structure and the number, location, and (if appropriate) orientation of substituents; instead, the trivial names are preferred.

Steroid hormones used in clinical practice are either: derived from biological sources (e.g., conjugated equine urinary estrogens); semi-synthetic, produced usually from a plant sterol starting material which can be chemically modified to yield a structure that is identical to the naturally occurring molecules; totally synthetic, which may result in the production of hormone isomers with different biological activity; or steroid drugs which are molecules not

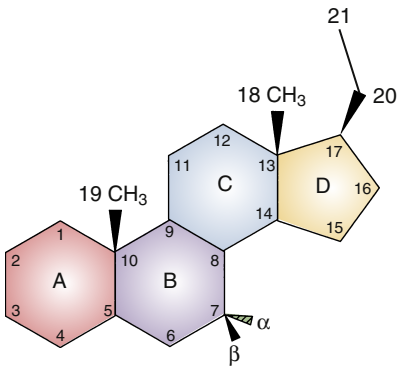

FIGURE 4.1 The steroid nucleus. Rings are identified with capital letters and carbon atoms are numbered. Substituents and hydrogens are shown projecting above *(β)* or below *(α)* the plane of the steroid nucleus.

found in humans and animals (e.g., medroxyprogesterone acetate and norgestrel). "Bioidentical" steroid hormones produced by total chemical synthesis may contain isomers that are not natural, which may result in biological activities that differ from the steroid hormones produced in humans. Because of this concern, it has been argued that the term "bioidentical" steroid hormones is misleading.

Organization of Steroidogenic Organs and Cells

The steroidogenic machinery is compartmentalized at the organ, cellular, and subcellular levels, which has important implications for the control of steroid hormone production.[3-6] Steroid synthesis involves a series of sequential modifications of cholesterol that result in the clipping of the side chain; alterations in olefinic bonds; and the addition of hydroxyl functions, proceeding invariably (although some have argued that shortcuts do exist) from cholesterol through the pregnane, androstane, and finally, estrane families.

Specific cell types can accomplish several of these sequential steps, but rarely can they generate an estrogen from cholesterol. Indeed, the requirement for cooperative efforts by two different tissues or cell types is a characteristic of estrogen biosynthesis. This joint effort enables the modulation of both androgen and estrogen production by factors that independently influence the cells involved in precursor synthesis, in addition to the cell type in which the final step, aromatization, occurs.[7] This cooperation is exemplified by estradiol synthesis in the ovarian follicle, where luteinizing hormone (LH) acts on the theca cells to stimulate production of androgen precursors and follicle-stimulating hormone (FSH) acts on granulosa cells to stimulate aromatization of these androgens into estrogens. Placental estrogen synthesis, likewise, requires precursors from another tissue, the fetal adrenal gland that is under the control of fetal pituitary adrenocorticotropic hormone (ACTH). The sulfated dehydroepiandrosterone secreted from the fetal zone of the adrenal cortex has negligible androgenic activity in the fetus and increased solubility in plasma, so it can be efficiently transported to the placenta, where cleavage of the sulfate group, followed by aromatization, takes place in the syncytiotrophoblast. Cooperative interaction among different cell types is also important in regulating the production of steroid hormones in the brain and hormone production in breast and endometrial cancers.

Another example of compartmentalization of the steroidogenic machinery at the organ level is the adrenal cortex, which has histologically and functionally distinct zones that determine the relative production rates of mineralocorticoids, glucocorticoids, and adrenal androgens.[4,8] The zona glomerulosa synthesizes mineralocorticoids; the zona fasciculata, glucocorticoids; and the zona reticularis and fetal zone of the fetal adrenal cortex produce androgens. One major functional distinction between the zona glomerulosa and the zonae fasciculata and reticularis is that aldosterone synthase is exclusively expressed in the zona glomerulosa, but 17α-hydroxylase is not. However, 17α-hydroxylase is abundant in the zonae fasciculata and reticularis. The zona reticularis expresses lower levels of type 2 3β-hydroxysteroid dehydrogenase (HSD3B2). Because the lyase of human 17α-hydroxylase does not efficiently act on progesterone, reduced conversion of pregnenolone to progesterone resulting from the low 3β-hydroxysteroid dehydrogenase activity facilitates the conversion of pregnenolone into dehydroepiandrosterone in the zona reticularis. Higher levels of cytochrome b_5 in the zona reticularis, which increase the lyase activity of human 17α-hydroxylase by an allosteric mechanism, further augments the capacity to produce dehydroepiandrosterone. The zona reticularis also has high levels of sulfotransferase. This constellation of enzymatic activities favors synthesis of dehydroepiandrosterone sulfate.

Acquisition, Storage, and Trafficking of Cholesterol

Steroidogenic cells have ultrastructural features that enhance their ability to obtain and store cholesterol for use in steroidogenesis (Fig. 4.2).[4,5] Unlike protein hormone–producing cells, steroid-producing cells do not store prefabricated hormone; they synthesize the hormones on demand from cholesterol that has been acquired from the plasma, synthesized de novo, or stored in membranes, or as sterol esters in lipid droplets. Because of cholesterol's limited solubility in water (it forms aggregates at 25 to 40 nM [the critical micelle concentration]), multiple proteins are required to move the steroid hormone precursor efficiently from one cellular compartment to another.

The plasma membrane has the highest content of free cholesterol, which is derived from plasma lipoproteins and de novo sterol synthesis. This sterol pool is not static, it exchanges with plasma free cholesterol and regularly cycles through the cell and back to the plasma membrane. During this cycling process, sterols can be diverted for use in steroid hormone synthesis or esterified and deposited in lipid droplets.

Numerous microvilli project from the plasma membrane on which lipoprotein-gathering receptors of the low-density lipoprotein (LDL) receptor family are located (e.g., LDL receptors; LDL receptor–related protein, very–low-density [VLDL] lipoprotein receptors). These receptors mediate lipoprotein uptake by an endocytic mechanism that delivers the lipoproteins to the lysosomes where the apolipoproteins are degraded. The lipoprotein cholesterol esters are then hydrolyzed by acid lipase (LIPA) to release free cholesterol.

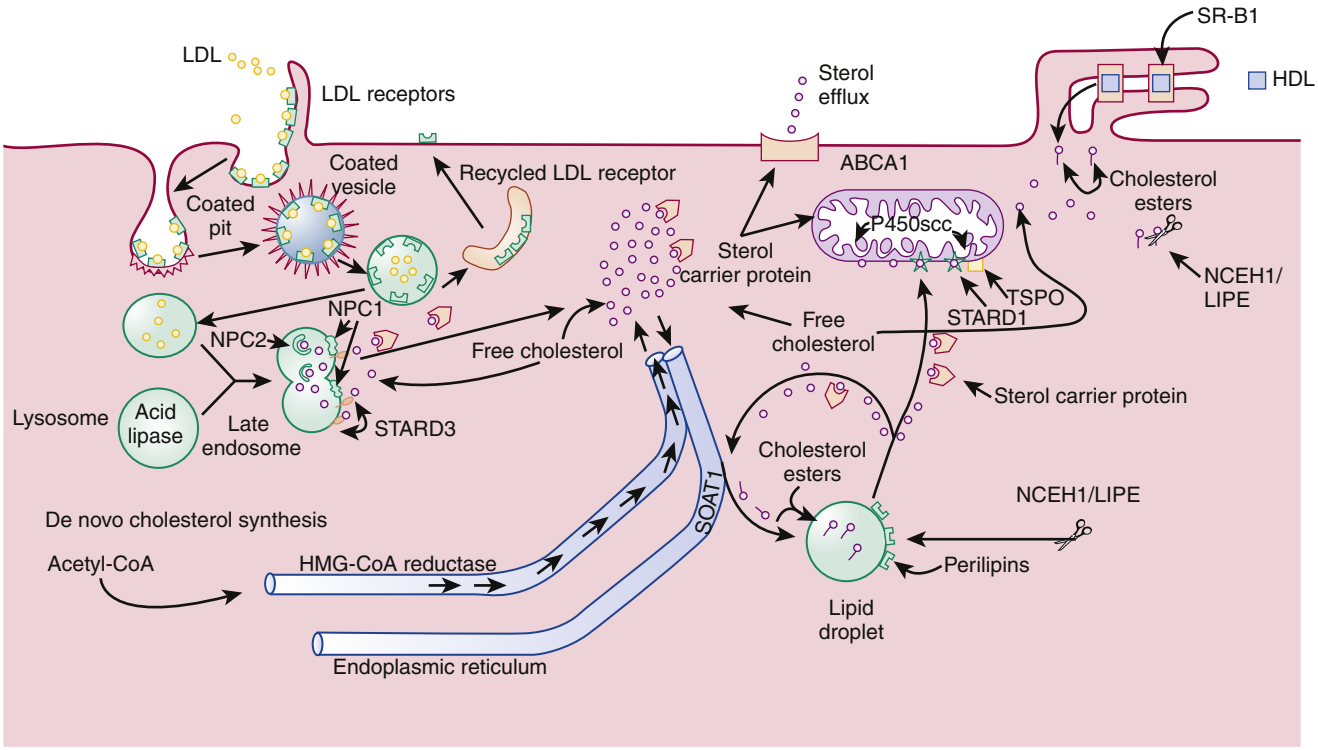

FIGURE 4.2 The acquisition, storage, and trafficking of cholesterol in steroidogenic cells. ABCA1, ATP-binding cassette transporter A1; FFA, free fatty acid; HDL, high-density lipoprotein; HMG-COA, 3-hydroxy-3-methyl-glutaryl-coenzyme A; LDL, low-density lipoprotein; LIPE, hormone-sensitive lipase; NCEH1, neutral pH cholesterol ester hydrolase; SR-B1 scavenger receptor type B; STARD1, steroidogenic acute regulatory protein; STARD3; (steroidogenic acute regulatory protein)-related lipid transfer domain 3; sterol carrier proteins include sterol carrier protein$_2$, STARD4, and STARD5; SOAT1, sterol-O-acyltransferase-1; TSPO, translocator protein.

Severe acid lipase deficiency (Wolman's disease) is associated with lysosomal accumulation of cholesterol esters and triglycerides, which can lead to damage of steroidogenic cells and compromised hormone production.[5] Free cholesterol is released from lysosomes through a system of sterol binding proteins encoded by genes *(NPC1, NPC2)* that when mutated cause the cholesterol storage disorder, Neiman-Pick Type C disease. NPC2, a soluble protein in the lysosome, delivers free cholesterol to NPC1, a membrane-associated cholesterol binding protein that controls sterol efflux. Other sterol binding proteins, including steroidogenic acute regulatory protein (STAR)-related lipid transfer (START) domain protein 3 (STARD3), also known as metastatic lymph node 64 protein (MLN64), may participate in this process.[5] Stimulation of steroidogenic cells by trophic hormones increases the number of LDL receptors on the cell surface, and also accelerates the rate of LDL internalization and degradation.

High-density lipoproteins (HDL) can also provide cholesterol for hormone synthesis.[3,9] Receptors for HDL (scavenger receptor type B, class 1 [abbreviated SR-B1]) are located in closely apposed microvilli that form "microvillar channels" in which HDL particles are lodged.[3] Endothelial lipases (hepatic lipase or endothelial cell–derived lipases) may facilitate uptake of the HDL-carried sterols by steroidogenic cells, including the selective uptake the HDL sterol esters. Like LDL receptor expression, SR-B1 expression is up-regulated in response to trophic stimulation, facilitating the usage of HDL-delivered substrate. Individuals with a SR-B1 missense mutation (Pro297Ser) that reduces uptake function, have increased HDL levels and attenuated adrenal steroidogenesis in response to ACTH stimulation.

The process by which cholesterol is accumulated by the "HDL pathway" differs from that of the "LDL pathway." HDL cholesterol esters are selectively internalized by SR-B1, leaving the apolipoproteins on the cell surface. The internalized HDL cholesterol esters are then cleaved, by a cytosolic, neutral pH optimum sterol esterase (either *hormone-stimulated lipase* [LIPE] or *neutral cholesterol ester hydrolase*, NCEH1), thereby releasing free cholesterol.[3,10,11]

De novo synthesis of cholesterol, a process that involves at least 17 enzymes, takes place primarily in the abundant smooth endoplasmic reticulum (SER).[5] Steroidogenic cells have up to tenfold more SER by volume than rough endoplasmic reticulum. In certain cells, the SER takes on unique forms, exemplified by the whorls found in testicular Leydig cells. Enzymes involved in steroid formation and metabolism are also embedded in the SER. Trophic hormones that stimulate steroidogenesis generally increase both cellular cholesterol synthesis and lipoprotein uptake. Of note, biosynthetic intermediates between lanosterol and cholesterol stimulate oocyte maturation in *in vitro* assays. These 4,4-dimethyl sterols, referred to as *meiosis-activating sterols*, contain 29 carbons and are found in the testis and follicular fluid in low micromolar concentrations. However, their physiological role in gamete maturation *in vivo* and their potential use in clinical settings remain subjects of debate.

The quantitative importance of circulating cholesterol carried by LDL, HDL, and other lipoproteins as steroid hormone precursor in adults, as opposed to de novo cholesterol

synthesis, is demonstrated by the fact that radiolabeled plasma cholesterol in humans is almost fully equilibrated with the steroidogenic pool of cholesterol. Additional evidence for an important role of circulating lipoprotein cholesterol in steroidogenesis comes from the study of hypobetalipoproteinemia, a disorder in which there is virtually no circulating LDL.[12,13] This rare metabolic disease is associated with reduced adrenocortical steroid production and diminished progesterone levels in the luteal phase and in pregnancy, although the lower levels of progesterone elaborated are still sufficient to achieve a term pregnancy.

Individuals with familial hypercholesterolemia due to inactivating mutations in the LDL receptor have only modest impairment of steroidogenic gland function, reflecting the capacity of alternative sterol acquisition mechanisms to compensate for LDL receptor deficiency. The commonly used cholesterol-lowering statins [which inhibit 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase), the rate-limiting enzyme in de novo cholesterol synthesis] do not impair adrenal, testicular, or luteal steroidogenesis in adult humans despite the lowering of plasma LDL levels.[14,15]

Smith-Lemli-Opitz syndrome, an autosomal recessive disease, offers interesting insight into the relationship of plasma cholesterol and de novo sterol synthesis for the supply of precursors for fetal steroidogenesis.[16] The disease is caused by inactivating mutations in an enzyme involved in the terminal steps of cholesterol synthesis, 3β-hydroxysteroid Δ^7-reductase (DHCR7). As a result, cholesterol levels are quite low and 7-dehydrocholesterol levels are elevated. Hypospadias or ambiguous genitalia is a frequent finding in affected male neonates, reflecting diminished fetal testicular testosterone synthesis. Estrogen production during pregnancy is also reduced, resulting from impaired fetal adrenal hormone production. Adrenal insufficiency has been reported in some affected individuals, although others compensate with modest elevations of ACTH secretion.[16,17] Interestingly, B-ring unsaturated equine-like steroids (1,3,5[10], 7-estratetrenes) are produced from the 7-dehydrocholesterol that accumulates, showing that the steroidogenic enzymes do not have an absolute requirement for cholesterol as a starting material.[18] Desmosterolosis, a rare autosomal recessive disease caused by mutations in the 3β-hydroxysterol Δ^{24} reductase, is also associated with ambiguous genitalia in affected males, presumably as a result of impaired fetal testicular testosterone synthesis.[16]

Cytoplasmic lipid droplets represent another major depot of substrate in steroidogenic cells: as much as 80% of the total cholesterol content of steroidogenic cells can be found esterified in these droplets. The sterol esters are synthesized in the endoplasmic reticulum from cholesterol acquired from lipoproteins or de novo synthesis by sterol O-acyltransferase 1 (SOAT1, previously named acyl-coenzyme A, cholesterol acyltransferase-1 or ACAT1), encoded by one of two related genes.[19] The esters generated by SOAT1 accumulate within the SER, and subsequently bud off as lipid droplets (Fig. 4.2). A targeted mutation in the *Soat1* gene in mice results in markedly reduced sterol ester storage in the adrenal cortex without impairment of basal or ACTH-stimulated corticosterone production by adrenal cells. These findings suggest that transit through the sterol ester pool is not part of an obligatory itinerary for steroidogenic cholesterol.

The limiting membranes of the lipid droplets contain a family of proteins, called perilipins.[20,21] These proteins protect the droplet contents from hydrolysis in the basal state. They also serve as scaffolds, anchoring lipases to the lipid droplet surface, as well as mediating physical and functional interactions between lipid droplets and other organelles, including mitochondria (Perilipin 5). Mobilization of cholesterol ester stores occurs when cells are stimulated by trophic hormones. An adenosine 3′,5′cyclic monophosphate (cAMP) mediated process leads to phosphorylation of perilipins by protein kinase A, and subsequent detachment of perilipins from the droplet surface, giving lipases access to the sterol esters.

The lipases that free cholesterol from lipid droplet sterol esters are hormone sensitive lipase (LIPE) and neutral cholesterol esterases (NCEH1) (Fig. 4.2).[10,11,22,23] Protein kinase A activates LIPE by phosphorylation of serine residues, promoting binding of the sterol esterase to lipid droplets. This enzyme's role in steroidogenesis was suggested by reduced production of corticosterone under ACTH stimulation associated with an accumulation of lipid droplets in the adrenal cortex of mice deficient in *Lipe*. Others described targeted mutation of both the *Lipe* and *Nceh1* genes resulting in adrenal enlargement and lipid accumulation, but no impairment in ACTH-stimulated corticosterone production. The different mouse models demonstrate a role for both hormone sensitive lipase and neutral cholesterol ester hydrolase activities in mobilization of sterol esters. The variable impact of enzyme deficiency on steroidogenesis in these murine models may be related to the time of study since lipid accumulation may have secondary deleterious effects on cell function beyond the disruption of sterol ester hydrolysis.

The size and number of lipid droplets change as the ester pool expands or contracts.[24] The quantity of sterol ester stored is determined by the availability of cholesterol to the cell through de novo synthesis, through accumulation of lipoprotein-carried cholesterol, and by the steroidogenic activity of the cell. Trophic stimulation promotes cholesterol ester hydrolysis and diverts cholesterol into the steroidogenic pool away from SOAT1, preventing re-esterification and resulting in a net depletion of cholesterol from the lipid droplets. Conversely, pharmacological blockade of steroid hormone synthesis (e.g., with the cholesterol side-chain cleavage inhibitor, aminoglutethimide) or defects in cholesterol use for steroidogenesis (e.g., congenital lipoid adrenal hyperplasia) increase sterol ester storage by increasing the amount of cholesterol available to SOAT1.

The exact intracellular itinerary of lipoprotein-derived cholesterol, free cholesterol from the plasma membrane, or free cholesterol released from lipid droplets, remains to be elucidated. In particular, much is still unknown about the ways in which sterol is presented to the mitochondria, where the first step in steroidogenesis takes place. It is likely that sterol distribution to and from organelles occurs through a dynamic vesicular–tubular late endosomal compartment, as well as through the assistance of lipid transfer proteins.[5] The lipid transfer proteins involved in this process may include ATP binding cassette transporter G1 (ABCG1), proteins with a structure resembling the *steroidogenic acute*

regulatory protein (STARD1), including STARD4, STARD5 (Fig. 4.2) and *sterol carrier protein-2* (SCP2).

The mitochondria of steroidogenic cells are frequently found in close association with cytoplasmic lipid droplets, which may facilitate movement of substrate from these depots to the mitochondria.[21,24] They have tubulovesicular cristae, in contrast to the lamellar cristae that are characteristic of mitochondria in other cells. The remodeling of cristae in the human syncytiotrophoblast is believed to facilitate steroidogenesis. The inner mitochondrial membranes contain the cholesterol side-chain cleavage enzyme, which catalyzes the first step in cholesterol metabolism into steroid hormones leading to the formation of pregnenolone. The hydrophobic cholesterol substrate must move from the mitochondrial outer membrane across the aqueous intermembranous space to reach the inner membrane. This translocation process is the major rate-limiting step in steroidogenesis. The capacity to produce large amounts of steroid hormone in rapid response to trophic stimulation requires the action of STARD1, the prototypic member of the START domain family, which greatly enhances the flux of substrate to the side-chain cleavage system (Fig. 4.2).[5,6] The mitochondrial cholesterol side-chain cleavage system is also juxtaposed to downstream enzymes in the steroidogenic pathway on the endoplasmic reticulum, allowing for efficient metabolism of pregnenolone.

Regulation of Cellular Cholesterol Balance

Cellular free (non-esterified) cholesterol balance is highly regulated by transcriptional and post-translational mechanisms. The expression of genes involved in cholesterol biosynthesis (e.g., the gene encoding 3-hydroxy-3-methylglutaryl coenzyme A reductase, *HMGCR*) and the uptake of plasma cholesterol *(LDLR)* are controlled by master transcription factors, the sterol regulatory element-binding proteins (SREBF1 and SREBF2).[25] The SREBPs are synthesized as inactive precursors that are bound to the endoplasmic reticulum. When cells are depleted of sterols, SREBP cleavage-activating protein (SCAP) transports the SREBPs from the endoplasmic reticulum to the Golgi apparatus where they are cleaved through the action of two different proteases, releasing an NH_2-terminal domain transcription factor which enters the nucleus, where it activates genes controlling lipid synthesis and uptake. Cholesterol loading inhibits the movement of SREBPs to the Golgi and consequently the proteolytic processing, resulting in reduced transcription of the cholesterol synthesis and uptake genes. A micro ribonucleic acid RNA, miR-33, derived from an intron located within the gene encoding SREBF2, post-transcriptionally modulates expression of genes involved in cellular cholesterol balance.

Metabolites of cholesterol, the side-chain oxygenated sterols including 22-, 24-, 25-, and 27-hydroxycholesterol, and 7-hydroxylated sterols, are endogenous regulators of cellular cholesterol metabolism through the liver X receptors (LXRalpha and LXRbeta, also known as NR1H3 and NR1H2, respectively).[26,27] In addition to LXRs, *steroidogenic factor 1* (SF-1, also known as NR5A1) and a related protein liver receptor homolog-1 (LRH-1, also known as NR5A2), play roles in regulating genes encoding cholesterol metabolizing enzymes including *SOAT1*, *LIPE*, and *STARD1*.

Post-translational mechanisms influencing sterol synthesis and uptake include cholesterol-induced ubiquitination of HMG-CoA reducatase, which tags the protein for degradation by proteasomes. Another post-translational mechanism by which cells control sterol balance is the degradation of LDL receptors by proprotein convertase subtilisin/kexin 9 (PCSK9), a secreted serine protease that binds to LDL receptors on the cell surface and interferes with their recycling so that they are directed to lysosomes for degradation.

Cells also control their sterol economy by reverse cholesterol transport (sterol efflux), mediated by members of the ATP-binding cassette subfamily A1 (ABCA1), which transfers cholesterol to plasma lipoproteins.

In the primate corpus luteum undergoing functional luteolysis, a fall in STARD1 expression results in diminished progesterone production.[28,29] To maintain free cholesterol balance, expression of lipoprotein receptors is reduced (reduced uptake), and expression of ABCA1 is increased (increased efflux), perhaps by hydroxysterol activation of LXR transcription factors. Excess cholesterol not available for steroidogenesis is esterified and deposited in cytoplasmic lipid droplets. These "homeostatic" adjustments reflect, in part, changes in gene transcription, post-transcriptional and post-translational processes.

Overview of Steroidogenesis

The cellular manufacture of steroid hormones involves the action of several classes of enzymes: the cytochromes P450, hemeprotein mixed-function oxidases (named because of their distinct absorption peak at 450 nm when reduced in the presence of carbon monoxide), the hydroxysteroid dehydrogenases and reductases.[6,30]

Cytochrome P450s catalyze the major alterations in the sterol framework, cleavage of the side chain, hydroxylations, and aromatization. These hemeproteins require molecular oxygen and a source of reducing equivalents (i.e., electrons) to complete a catalytic cycle. Each member of the steroidogenic cytochrome P450 family of genes is designated "CYP," followed by a unique identifying number that usually refers to the carbon atom at which the enzyme acts.

The hydroxysteroid dehydrogenases reduce ketone groups or oxidize hydroxyl functions, employing pyridine nucleotide cofactors, usually with a stereospecific substrate preference and reaction direction. In addition to being involved in hormone biosynthesis in steroidogenic cells, this family of enzymes works with the reductases, steroid sulfotransferases, and steroid sulfatase to regulate the level of bioactive hormone in target tissues. The hydroxysteroid dehydrogenases are key determinants of the cellular response to endogenous steroid hormones as well as steroidal drugs.

The reductases, using the pyridine nucleotide nicotinamide adenine dinucleotide phosphate (NADPH) as a cofactor, produce saturated ring A steroids from Δ^4-steroids (again, with stereospecificity). Table 4.1 lists the key steroidogenic enzymes by class and the respective gene designation. Figure 4.3 outlines the pathways of steroid hormone synthesis, indicating where specific enzymes act.

Table 4.1 Key Human Steroidogenic Proteins and Their Genes

Protein	Chromosomal Gene	Chromosomal Locus	Substrates*	Major Activities	Known Deficiency States
StAR STARD1	*STARD1*	8p11.2	Cholesterol flux within mitochondria	Sterol delivery to P450scc	Congenital lipoid adrenal hyperplasia
P450scc	*CYP11A1*	15q23-q24	Cholesterol Hydroxysterols	Cholesterol side chain cleavage	Side chain cleavage enzyme deficiency

Adiol, Δ^5,3β-androstanediol; 3α-Asdiol, 3α-androstanedione; 11-DOC, 11-deoxycorticosterone; Asdione, androstanedione; Asone, androsterone; COA, coenzyme A; CMO, corticosterone methyl oxidase; DHEA, dehydroepiandrosterone; DHT, dihydrotestosterone; HSD, hydroxysteroid dehydrogenase; Preg, pregnenolone; Prog, progesterone.

Key Proteins in the Biosynthesis and Catabolism of Steroid Hormones

Steroidogenic Acute Regulatory Protein (STARD1): the Principal Regulator of Gonadal and Adrenal Steroidogenesis

Translocation of cholesterol from the outer mitochondrial membranes to the relatively sterol-poor inner membranes is the critical step in steroidogenesis.[5,6] This translocation process occurs at modest rates in the absence of specific effectors. It is markedly enhanced by STARD1, a protein with a short biological half-life. The following evidence established STARD1 as the key mediator of substrate flux to the side-chain cleavage system:

1. Expression of STARD1 is directly correlated with steroidogenesis.
2. Co-expression of STARD1 and the cholesterol side-chain cleavage enzyme system in cells that are not normally steroidogenic results in substantial pregnenolone synthesis above that produced by cells with

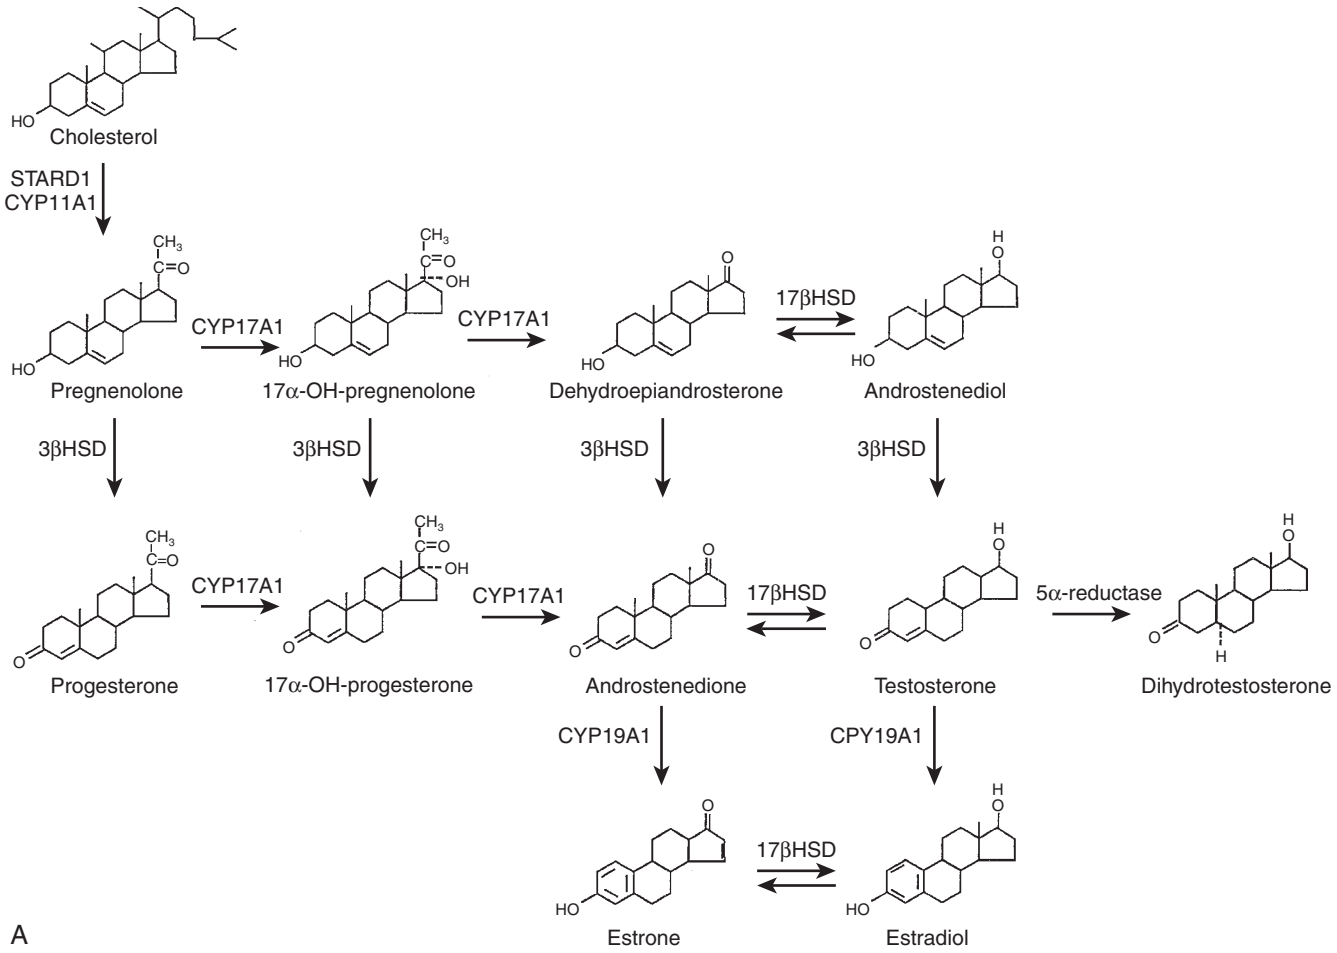

FIGURE 4.3 **A,** *Biosynthetic pathway for sex steroid hormones.*

the cholesterol side-chain cleavage enzyme system alone.

3. Mutations that inactivate STARD1 cause congenital lipoid adrenal hyperplasia, a rare autosomal recessive disorder in which the synthesis of all adrenal and gonadal steroid hormones is severely impaired before the cholesterol side-chain cleavage step.
4. Targeted deletion of the murine *StarD1* gene results in a phenotype in nullizygous mice that mimics human congenital lipoid adrenal hyperplasia.

Human STARD1 is synthesized as a 285–amino acid protein. The N-terminus of STARD1 is characteristic of proteins synthesized in the cytoplasm and then imported into mitochondria, with the first 26 amino acid residues predicted to form an amphipathic helix. Newly synthesized STARD1 preprotein (37 kDa) is rapidly imported into mitochondria and processed to the "mature" 30-kDa form. The preprotein has a very short half-life (minutes), but the mature form is longer-lived (hours).

STARD1 contains two consensus sequences for cyclic AMP (cAMP)-dependent protein kinase phosphorylation at Ser57 and Ser195. Ser195 of human STARD1 must be phosphorylated for maximal steroidogenic activity in model systems.

Tissues that express STARD1 at high levels carry out trophic hormone–regulated mitochondrial sterol hydroxylations through the intermediacy of cAMP. STARD1 messenger RNA (mRNA) and protein are not present in the human placenta, an observation that is consistent with the fact that pregnancies hosting a fetus affected with congenital lipoid adrenal hyperplasia go to term. Although estrogen production is impaired in these pregnancies as a result of diminished fetal adrenal androgen production, placental progesterone synthesis is not significantly affected, indicating that the trophoblast cholesterol side-chain cleavage reaction is independent of STARD1.

The abundance of STARD1 protein in steroidogenic cells is determined primarily by the rate of *STARD1* gene transcription, which is influenced by transcription factors involved in the control of other genes involved in cholesterol metabolism (e.g., SREBFs, NR5A1, NR5A2, LXRs), although STARD1 mRNA stability and translational mechanisms may also contribute. In differentiated cells, the *STARD1* gene is activated by the cAMP signal transduction cascade within 15 to 30 minutes. In differentiating cells (e.g., luteinizing granulosa cells), the induction of *STARD1* transcription takes hours and requires ongoing protein synthesis.

Originally, STARD1 was believed to stimulate cholesterol movement from the outer to the inner mitochondrial membrane as it was imported into the mitochondria. The importation process was proposed to create contact sites between the two membranes, allowing cholesterol to flow down a chemical gradient. However, a STARD1 protein lacking the

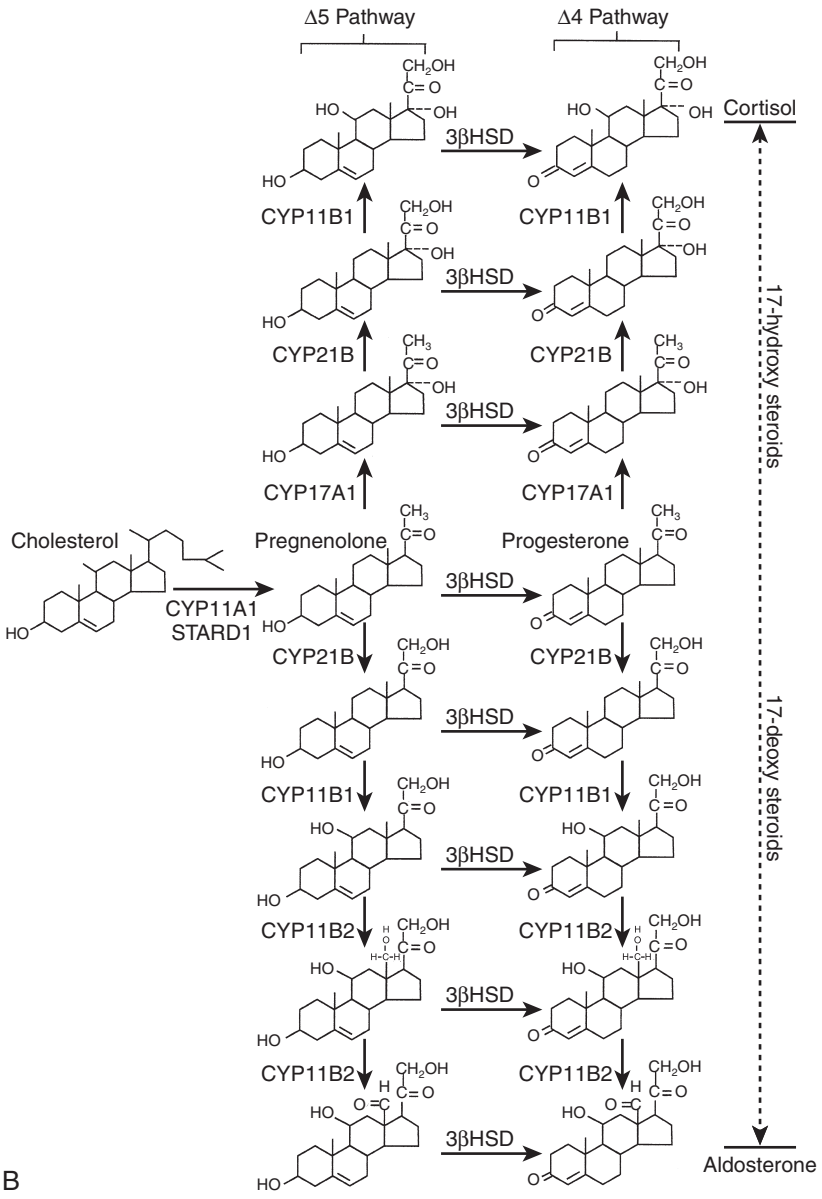

FIGURE 4.3, CONT'D B, Biosynthetic pathway for adrenal steroid hormones. Note that the 3β-hydroxysteroid dehydrogenase in the gonads and adrenal cortex is the type 2 enzyme (HSD3B2), whereas the type 1 enzyme is responsible for this activity in the placenta. Note also that the 17β-hydroxysteroid dehydrogenases involved in the reduction and oxidation of steroids are different enzymes, as described in the text. CYP, cytochrome P; HSD, hydroxysteroid dehydrogenase; STARD1, steroidogenic acute regulatory protein.

N-terminal 62 amino acids (N-62 STARD1), which contain the mitochondrial targeting sequence, was found to be as effective as STARD1 in stimulating steroidogenesis. Other STARD1 constructs engineered for prolonged tethering to the surface of the mitochondria were very active in stimulating pregnenolone production, suggesting that the residency time of the protein on the mitochondrial surface determines the duration of the steroidogenic stimulus. Recombinant human N-62 STARD1 in nanomolar concentrations enhanced pregnenolone production by isolated ovarian mitochondria in a dose- and time-dependent fashion, with significant increases in steroid production observed within minutes. Collectively, these findings strongly suggest that STARD1 acts on the outer mitochondrial membrane to promote cholesterol translocation. This perspective implies that import of the protein into the mitochondrial matrix, rather than being the *trigger* to steroid production, is actually the "off" mechanism because it removes STARD1 from its site of action (Fig. 4.3). Consequently, on-going production of STARD1 preprotein is required to sustain steroidogenesis.

The findings of the previously described experiments are most consistent with the idea that STARD1 enhances desorption of cholesterol from the sterol-rich outer mitochondrial membrane to the relatively sterol-poor inner membranes. The desorption process may involve a pH-dependent conformational change (molten globule transition). Even though STARD1 contains a hydrophobic pocket that binds cholesterol, sterol binding is not required for steroidogenic activity.

The molecule or structure on the mitochondrial outer membrane that STARD1 acts on has not yet been identified. It could be a lipid configuration or a protein. One protein candidate is the translocator protein (TSPO), also known as the peripheral-type benzodiazepine receptor (PBR), an outer mitochondrial membrane protein that also binds cholesterol.[5,6] Knock-down of TSPO expression

blocks steroidogenesis in cultured cells, even in the presence of STARD1, suggesting that TSPO is required for STARD1 action and that it may serve to activate a pore, comprised of other mitochondrial membrane proteins including the voltage-dependent anion channel (VDAC), through which cholesterol could flow to the inner mitochondrial membrane in the presence of STARD1. However, the nature of STARD1–TSPO-VDAC interactions remain to be elucidated.

As noted above, mutations in the *STARD1* gene cause congenital lipoid adrenal hyperplasia, a rare autosomal recessive disease. Exceptions occur in Japan and Korea, however, where the mutation accounts for at least 5% of all cases of congenital adrenal hyperplasia.[5,6,31] The pathophysiology of the disease entails a two-step process in which impaired use of cholesterol for steroidogenesis leads to accumulation of sterol esters in lipid droplets. These droplets ultimately compress cellular organelles, causing damage through the formation of lipid peroxides. This damage occurs prominently in the adrenal cortex and Leydig cells.

Mutations found in the *STARD1* gene, which is composed of seven exons, include frameshifts caused by deletions or insertions, splicing errors, and nonsense and missense mutations. All of these mutations lead to the absence of STARD1 protein or the production of functionally inactive protein. Several nonsense mutations were shown to result in C-terminus truncations of STARD1. One of these mutations, Gln258Stop, results in the deletion of the final 28 amino acids of the STARD1 protein and accounts for 80% of the known mutant alleles in the affected Japanese population. Known point mutations that produce amino acid substitutions occur in exons 5 to 7 of the gene, the exons that encode the C-terminus. Mutations that cause partial loss of STARD1 activity are associated with a milder disease phenotype.

Although affected XY subjects are pseudohermaphrodites (46,XY disorder of sexual development [DSD]) because of an inability to generate sufficient fetal testicular testosterone to masculinize the external genitalia, XX subjects have normal external genitalia, develop female secondary sexual characteristics, and experience menarche. They are, however, anovulatory and unable to produce large amounts of estradiol and progesterone in a cyclic fashion. The fact that some ovarian estradiol synthesis occurs reflects the existence of STARD1-independent substrate movement to the cholesterol side-chain cleavage system.

Other START Domain Proteins

A family of proteins exists sharing a domain that is similar to the C-terminus of STARD1, the *StAR-related lipid transfer (START) domain proteins*.[32] The absence of STARD1 from the human placenta, an organ that produces a significant amount of pregnenolone, documented the existence of STARD1-independent steroidogenesis, but raised the possibility that another protein, possibly STARD3, might subserve the function of STARD1 in the placenta. Other cytosolic START domain proteins (STARD4, STARD5) could be involved in the movement of cholesterol to the mitochondria as sterol carrier proteins, although their specific roles in sterol trafficking remain to be elucidated (Fig. 4.2).

The Cholesterol Side-Chain Cleavage Enzyme (P450scc Encoded by *CYP11A1*)

Cholesterol side-chain cleavage is catalyzed by cytochrome P450scc and its associated electron transport system, consisting of a flavoprotein reductase (ferredoxin or adrenodoxin reductase) and an iron sulfoprotein (ferredoxin or adrenodoxin), encoded by the *FDX1* gene, which shuttles electrons to cytochrome P450scc.[6,33,34] The side-chain cleavage reaction involves three catalytic cycles: the first two lead to the introduction of hydroxyl groups at positions C-22 and C-20, and the third results in scission of the side chain between these carbons (Fig. 4.4). Each catalytic cycle requires one molecule of NADPH and one molecule of oxygen so that the formation of one mole of the cleavage products, pregnenolone and isocroapraldehyde, uses three moles of NADPH and three moles of oxygen.

The slowest step of the reaction is the binding of cholesterol to the hydrophobic pocket of P450scc, where the heme resides. The sterol substrate remains bound to a single active site on cytochrome P450scc for all three cycles because of the tight binding of the reaction intermediates. The dissociation constant (K_d) for binding of cholesterol, a measure of the enzyme's affinity for its substrate, is approximately 5000 nM, whereas the K_d for the binding of the intermediate product 22-hydroxycholesterol is 4.9 nM; the K_d for 20,22-dihydroxycholesterol is 81 nM. However, the estimated K_d for pregnenolone, the end product, is 2900 nM, which permits its dissociation from the enzyme at the end of the reaction.

Reducing equivalents are shuttled to cytochrome P450scc by ferredoxin in cycles of reduction and oxidation, facilitated by differential affinities of the proteins, depending on their state of oxidation or reduction.[34] Ferredoxin forms a 1:1 complex with ferredoxin reductase, which catalyzes reduction of the iron-sulfur protein. The reduced ferredoxin then dissociates and forms a 1:1 complex with cytochrome P450scc and is subsequently oxidized when it donates its electrons to P450scc. Oxidized ferredoxin returns to ferredoxin reductase for electron recharging. This recharging is facilitated by the fact that ferredoxin reductase has a greater affinity for oxidized over reduced ferredoxin. The binding of cholesterol to cytochrome P450scc increases its affinity for reduced ferredoxin, which enhances the shuttle of electrons to substrate-loaded enzyme.

The rate of formation of pregnenolone is determined by:

1. Access of cholesterol to the inner mitochondrial membranes
2. The quantity of cholesterol side-chain cleavage enzyme, and secondarily, its flavoprotein and iron-sulfur protein electron transport chain
3. Catalytic activity of P450scc, which can be influenced by post-translational modification

Acute alterations in steroidogenesis generally result from changes in the delivery of cholesterol to P450scc, whereas long-term alterations involve changes in the quantity of enzyme proteins as well as cholesterol delivery.

The *CYP11A1* gene, located on chromosome 15q23-q24, consists of nine exons, an organization shared by the other mitochondrial steroidogenic P450 enzymes, 11β-hydroxylase and aldosterone synthase.

Mutations in the *CYP11A1* gene that result in significantly diminished cholesterol side-chain cleavage activity have been reported in association with adrenal insufficiency and XY sex reversal, phenotypes that are similar to those

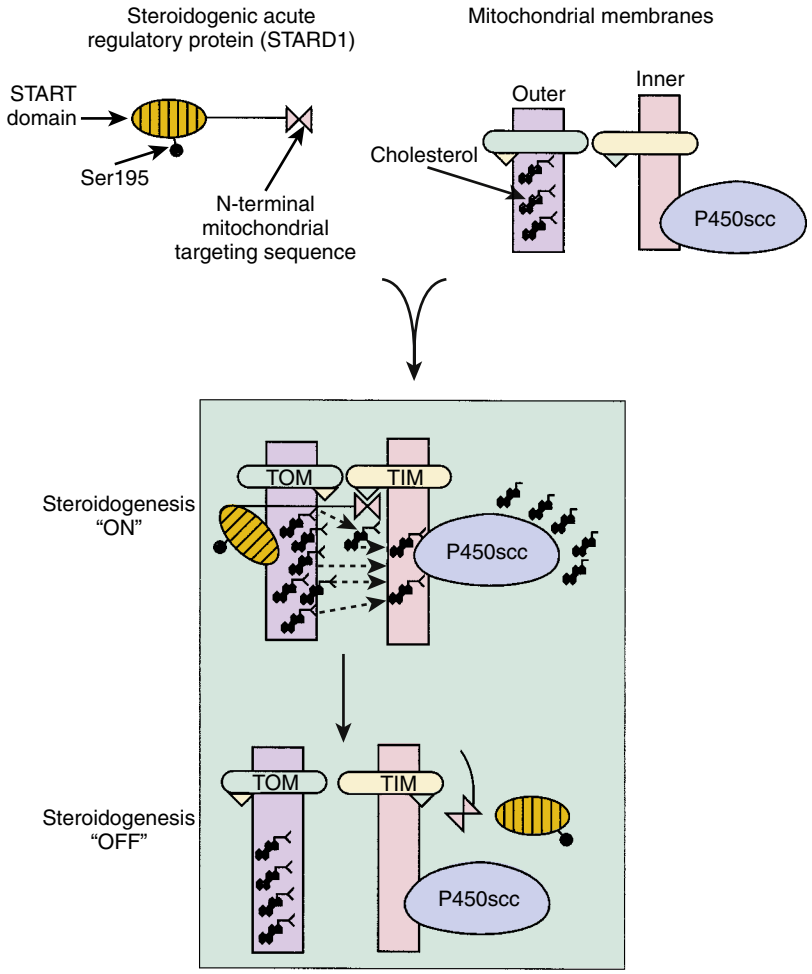

FIGURE 4.4 Structure of steroidogenic acute regulatory protein (STARD1) and model for its mechanism of action on intramitochondrial cholesterol translocation. TIM, inner mitochondrial membrane translocator; TOM, outer mitochondrial membrane protein translocator.

associated with inactivating mutations in the *STARD1* gene.[6,35-37] An interesting *CYP11A1* mutation was discovered in an XY subject, born prematurely with sex reversal and adrenal failure. The subject was homozygous for a single-nucleotide deletion leading to a premature termination codon at codon 288, predicted to delete the C-terminal 242 amino acids, including the heme-binding site, which should result in a nonfunctional protein.

The discovery of mutations causing severe P450scc deficiency in humans challenges the notion that absence of P450scc activity in the fetus and placenta is incompatible with pregnancy progressing beyond the usually limited period of luteal progesterone support. Therefore, compensatory mechanisms exist to maintain sufficient progestational activity to sustain pregnancy and fetal viability in women hosting a fetus with *CYP11A1* mutations. Another surprising and distinguishing feature of subjects with *CYP11A1* mutations is the absence of adrenal hypertorophy, as seen in *STARD1* mutations.

17α-Hydroxylase/17,20-Lyase (P450c17; CYP17A1)

P450c17 is an endoplasmic reticulum enzyme that catalyzes two reactions: hydroxylation of pregnenolone and progesterone at carbon 17, and conversion of pregnenolone into C19 steroids (in the case of the human enzyme, progesterone is also converted, but to a much lesser extent).[6] The 17α-hydroxylation reaction requires one pair of electrons and molecular oxygen. The lyase reaction requires a second electron pair and molecular oxygen. The reducing equivalents are transferred to the P450c17 heme iron from NADPH by NADPH cytochrome P450 reductase (POR). The hydroxylase and lyase reactions are both believed to proceed through a ferryl oxene mechanism, with the substrate bound to the enzyme in the catalytic pocket in the same orientation. P450c17 also catalyzes 16α-hydroxylation of progesterone and dehydroepiandrosterone.

The importance of POR in steroid metabolism catalyzed by endoplasmic reticulum cytochrome P450 enzymes has been illuminated by the phenotype of individuals with POR deficiency, which causes a form of congenital adrenal hyperplasia.[38,39] The autosomal recessive disorder results in a steroid profile suggestive of combined 21-hydroxylase and 17-hydroxylase/17-20 lyase deficiency, which presents as a range of phenotypes, including adrenal insufficiency, ambiguous genitalia, and Antley-Bixler skeletal malformation syndrome.

Several factors determine whether substrates only undergo 17α-hydroxylation or subsequent scission of the 17,20 bond, including:

1. The nature of the substrate
2. The amount of POR and flux of reducing equivalents
3. Allosteric effectors
4. Post-translational modification of P450c17 (Fig. 4.5)

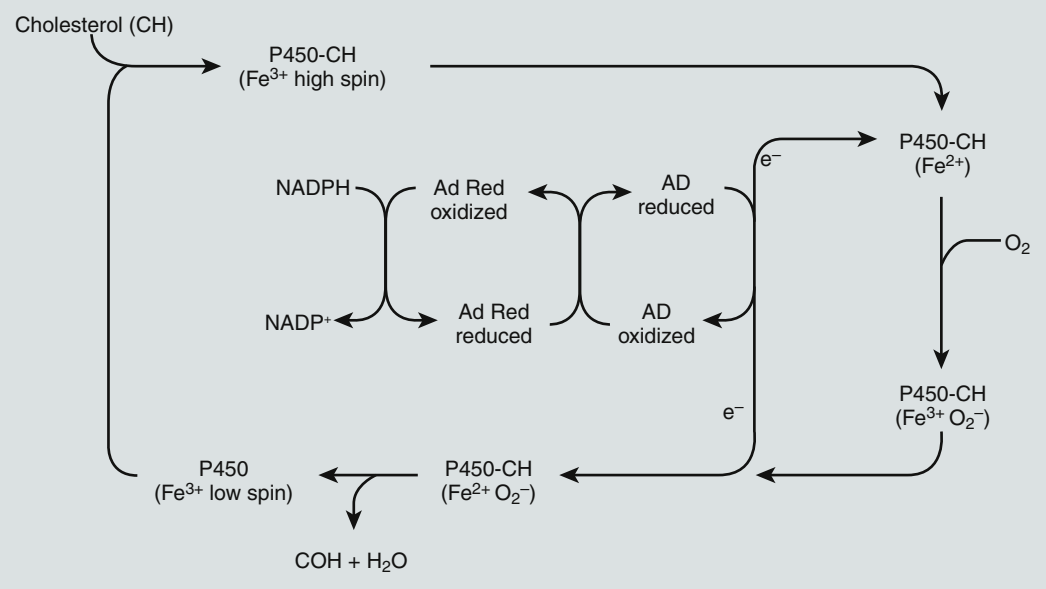

FIGURE 4.5 Catalytic cycle for P450scc. Cholesterol (CH) binds to P450scc. Reducing equivalents are shuttled to P450scc by adrenodoxin (AD), which receives electrons from adrenodoxin reductase (Ad Red), which oxidizes nicotinamide adenine dinucleotide phosphate (NADPH). P450scc goes through three sequential catalytic cycles with substrate and reaction intermediates remaining bound to the enzyme (not reflected in the scheme shown above) to convert 1 mole of cholesterol to 1 mole of pregnenolone and isocaproic acid, using 3 moles of NADPH and molecular oxygen. The P450scc heme iron undergoes oxidation and reduction, changing its electron spin resonance state. NADP, nicotinamide adenine dinucleotide.

Collectively, these factors determine the nature of the products produced by the enzyme, which, in the gonads and zona reticularis, favor androgens through augmentation of lyase activity. In contrast,17α-hydroxylation required for glucocorticoid and mineralocorticoid synthesis is favored in the zona fasciculata and glomerulosa.

Human P450c17 preferentially uses Δ^5 substrates for 17,20 bond cleavage. Cytochrome b_5 (CYB5A) promotes electron transfer for the lyase reaction acting as an allosteric effector, and not as an electron donor per se, because the apo b_5 protein is also effective.[40] Cytochrome b_5 also increases the use of 17α-hydroxyprogesterone as a substrate for androstenedione synthesis. The distribution and regulation of cytochrome b_5 expression in the adrenal cortex, being greatest in the adult zona reticularis, supports a role for this protein in the regulation of lyase activity. The product of a second cytochrome b_5 gene (type 2 cytochrome b_5, CYB5B), found in human testis and expressed in the adrenals, also increases lyase activity.

Phosphorylation of P450c17 at serine and threonine residues by a yet-to-be-identified protein kinase appears to be necessary for maximal 17,20-lyase activity.[41] The phosphorylated P450c17 protein is evidently a substrate for protein phosphatase 2A (PP2A), since inhibitors of PP2A enhance lyase activity in cultured adrenal tumor cells.

Adrenarche, the increased production of adrenal androgens in the absence of increased production of cortisol or levels of ACTH, may result from enhanced P450c17 lyase activity due to increased expression of cytochrome b_5 or the state of P450c17 phosphorylation. The availability of electrons to P450c17 has been proposed to influence the relative ratio of 17,20-lyase activity to 17α-hydroxylase activity. However, increasing the ratio of P450-oxidoreductase to P450c17 augments both the 17α hydroxylation and the lyase reactions, making this an unlikely mechanism by which lyase-to-hydroxylase activity is differentially regulated.

A P450c17-independent mechanism for conversion of pregnenolone into dehydroepiandrosterone in glial tumor cell homogenates promoted by $FeSO_4$ has been described. This conversion presumably results from the fragmentation of tertiary hydroperoxides, which are probably derived from pregnenolone molecules oxygenated at carbons 17 and 20.[42] The physiological significance of this pathway, if any, to the formation of C19 steroids in the brain or other tissues is unknown.

The *CYP17A1* gene, located on band 10q24.3, consists of eight exons. Mutations in this gene cause combined or isolated deficiency states for each activity of P450c17.[6,39] Individuals with combined deficiency have a marked diminution in the production of C19 and C18 steroids, low levels of cortisol that result in elevated ACTH secretion, and excess production of steroids proximal to the P40c17 reaction. Hypertension from sodium retention and hypokalemia are a consequence of the increased production of 11-deoxycorticosterone. The inability to produce sex steroid hormones prevents adrenarche, and puberty in females, and results in incomplete or absent development of male genitalia (46, XY DSD).

Four recurrent mutations have been described that cause combined 17α-hydroxylase and lyase deficiency in different populations: a 4-bp insertion resulting in a frame shift and altered C-terminal sequence (Holland); in-frame deletions of amino acid residues 487 through 489 (Southeast Asia); a deletion of phenylalanine in the N-terminus of the protein (Japan); and non-synonymous mutations (Tryp406Arg and Arg362Cys) (Brazil). Isolated 17,20-lyase deficiency is very rare.[6,39] The documented cases result from point mutations that permit pregnenolone or progesterone to be bound and undergo 17α-hydroxylation, but prohibit the efficient

receipt or usage of a second pair of electrons provided by POR to support the 17,20-lyase reaction.

Aromatase (P450aro, CYP19A1)

Aromatase, an endoplasmic reticulum enzyme, catalyzes three sequential hydroxylations of a C19 substrate by using three molecules of NADPH and three molecules of molecular oxygen to produce one molecule of C18 steroid with a phenolic A ring.[6,43] The first hydroxylation yields a C19 hydroxyl derivative, which is converted in a second hydroxylation to a gem diol that collapses to yield a C19 aldehyde. The final hydroxylation involves the formation of a 19-hydroxy-19-hydroperoxide intermediate that results in the elimination of the C19 methyl group as formic acid and concurrent aromatization. This sequence of reactions takes place at a single active site on the enzyme, with reducing equivalents transferred to P450aro by POR. The crystal structure of aromatase in complex with androstenedione revealed hydrogen bonding and tight packing of hydrophobic side chains that explain the enzyme's specificity for androgen substrates.

The aromatase protein is encoded by a single large gene, *CYP19A1*, on band 15q21.1. This gene gives rise to cell-specific transcripts from different promoters (Fig. 4.6).[6,44] The promoter driving ovarian aromatase expression lies adjacent to the exon encoding the translation start site (promoter IIa). In granulosa cells, FSH stimulates transcription of the genes encoding both aromatase and POR, which provides its reducing equivalents. A separate promoter lying approximately 100 kb upstream from the start of translation controls placental *CYP19A1* transcription. Expression of aromatase in adipose tissue, skin, and brain is driven from other promoters. Cytokines (including interleukin-11, interleukin-6, oncostatin-M, and leukemia-inhibiting factor) increase P450arom expression in adipose tissue via the I.4 promoter.

Several cases of aromatase deficiency have been described.[6,45-47] Pregnancies in which the fetus is affected with aromatase deficiency are characterized by low maternal urinary estrogen excretion, maternal virilization, and ambiguous genitalia or female pseudohermaphroditism (46, XX DSD) in affected genetic females. The maternal and fetal virilization in the absence of placental aromatase activity highlights the importance and efficiency of the placenta in converting maternal and fetal androgens into estrogens.

Among the mutations identified in the *CYP19A1* gene are an 87-bp insertion at the splice junction between exon 6 and intron 6, causing the addition of 29 in-frame amino acid residues, with the other mutations being mainly missense or nonsense mutations in exons 4, 9, and 10. The mutant protein with the 29 in-frame amino acid residues displayed less than 3% of normal aromatase activity. Expression of the mutant complementary DNA confirmed that the protein had only a trace of aromatase activity. Compound heterozygous mutations in coding sequences found in patients with aromatase deficiency have also been shown to have minimal activity. When aromatase activity has been measured in placenta from offspring with *CYP19A1* mutations, activities have been markedly reduced to 21% of normal values.

Mice deficient in aromatase have been created by targeting the *Cyp19a1* gene.[48] The aromatase-deficient (ArKO) mice show many of the features of human aromatase deficiency and the consequential lack of estrogens, including a profound bone phenotype with reductions in all indices of bone mineralization.

Families with autosomal dominant estrogen excess resulting from over-expression of aromatase have been reported.[49-52] The phenotypes include severe prepubertal gynecomastia in males and macromastia and premature puberty in females. The aromatase over-expression is caused in some families by heterozygous genomic rearrangements. In some cases an inversion results in a constituitively active cryptic promoter placed in control of the *CYP19A1* gene, driving excess aromatase production.

Inappropriate expression of aromatase in neoplastic and non-neoplastic tissue has also been found. In these pathological conditions, exemplified by breast cancer, there appears to be a shift in promoter use to favor the stronger gonadal (promoter IIa or I.3) over the weaker adipose tissue promoter (promoter I.4). This shift allows for activation of a cAMP-dependent signaling pathway, accounting for excessive aromatase expression and the resulting increase in estrogen synthesis.

11β-Hydroxylases (P450c11β and P450c11AS)

The human genome contains two genes located on band 8q24.3 that encode related mitochondrial enzymes involved in 11β-hydroxylation and aldosterone synthesis, respectively, P45011β, encoded by *CYP11B1*, and P450c11AS (also referred to as "P450aldo," "P450c18," or "P450cmo"), encoded by *CYP11B2*.[6] These two genes are located 40 kb apart; each containing nine exons. The encoded proteins differ in only 33 amino acid residues. Both enzymes display 11β-hydroxylase activity, but P450c11AS can also carry out the two oxygenation steps at carbon 18 required for the production of aldosterone. They require molecular oxygen as well as reducing equivalents for catalysis, the latter shuttled to the enzymes by the adrenodoxin reductase–adrenodoxin system.

CYP11B1, a gene whose transcription is stimulated by ACTH-triggered cAMP signaling pathways, is expressed in the zonae fasciculata and reticularis of the adrenal cortex. In contrast, *CYP11B2* expression is restricted to the zona glomerulosa. Transcription of this gene is stimulated by protein kinase C signaling pathways, which are turned on by angiotensin II.

Mutations in the *CYP11B1* gene cause 11β-hydroxylase deficiency, whereas mutations in *CYP11B2* cause 18-hydroxylase or corticosterone methyl oxidase I deficiency and 18-oxidase or corticosterone methyl oxidase II deficiency.[6,53,54] Unequal crossover of the adjacent *CYP11B1* and *CYP11B2* genes creates a third hybrid gene, in which the cAMP-regulated promoter of the *CYP11B1* gene drives expression of a chimeric protein with aldosterone synthase activity. This leads to a state of glucocorticoid-suppressible aldosteronism.

Accounting for 5% to 8% of cases of congenital adrenal hyperplasia in European ancestry populations and 15% in Middle Eastern populations, 11β-hydroxylase deficiency is characterized by high levels of 11-deoxycortisol and deoxycorticosterone, resulting in salt retention and hypertension. Affected females are virilized by the excess production of adrenal androgens driven by elevated ACTH levels. *CYP11B1* mutations causing 11β-hydroxylase deficiency

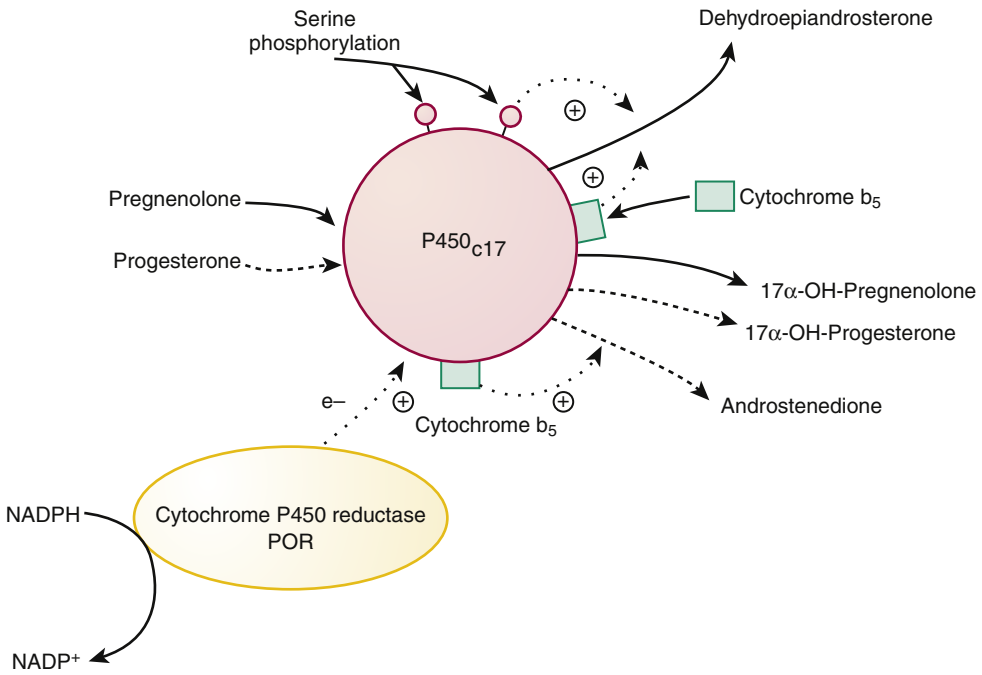

FIGURE 4.6 Factors modulating 17α-hydroxylase and 17,20-lyase activities of P450c17. Phosphorylation of serine/threonine residues and cytochrome b5 stimulate *(designated by plus symbol)* lyase activity, with pregnenolone being the preferred substrate for the lyase reaction. Dephosphorylation of the serine/threonine residues by protein phosphatase 2A reduces lyase activity. Flow of reducing equivalents (e^-, electrons) from cytochrome P450 reductase (POR) stimulates both 17α-hydroxylase and lyase activities. H6PDH, hexose-6-phosphate dehydrogenase; NADP, nicotinamide adenine dinucleotide; NADPH, nicotinamide adenine dinucleotide phosphate.

include those resulting in non-synonymous amino acid substitutions and a premature stop codon.

Corticosterone methyl oxidase I deficiency results from the complete absence of P450c11AS activity. Aldosterone synthesis is absent, but the production of corticosterone and cortisol is retained. An increased ratio of corticosterone to 18-hydroxycorticosterone in the presence of low aldosterone and elevated plasma renin activity is diagnostic. Corticosterone methyl oxidase II deficiency is caused by mutations that inactivate 18-methyl oxidase while retaining 18-hydroxylase activity. This causes elevated 18-hydroxycorticosterone and low aldosterone levels.

21-Hydroxylase (P450c21,CYP21A2)

P450c21 is an adrenal endoplasmic reticulum enzyme that catalyzes the 21-hydroxylation of progesterone and 17α-hydroxyprogesterone in the pathway of mineralocorticoid and glucocorticoid biosynthesis.[6,53,55,56] The Michaelis constant (K_m) for 17α-hydroxyprogesterone (1.2 μM) is lower than that for progesterone (2.8 μM), and the apparent maximum velocity (V_{max}) for the former substrate is twice that for progesterone. The enzyme requires 1 mole of molecular oxygen and reducing equivalents (generated from NADPH through POR) to accomplish the hydroxylation of carbon 21. Mutations inactivating POR cause a partial deficiency in 21-hydroxylase activity, as well as a partial deficiency in 17α-hydroxylase/17-20 lyase activity.[6,38] The primary regulator of *CYP21A2* expression in the zona fasciculata is ACTH by way of a cAMP-mediated signal transduction cascade.

The *CYP21A2* gene is adjacent to a pseudogene *(CYP21A1P)*, separated by the complement *C4B* gene. These genes are embedded in the human leukocyte antigen region on band 6p21.1. Frequent unequal crossovers and gene conversions make 21-hydroxylase deficiency one of the most common autosomal recessive metabolic diseases, occurring in 1:10,000 to 1:15,000 births.[55] Unequal crossover, with the complete loss of the *C4B* gene and a net deletion of *CYP21A2*, along with gene conversion events in which mutations in the pseudogene are introduced into the expressed gene, result in reduced 21-hydroxylase enzyme levels or impaired catalytic activity (Fig. 4.7). Large-scale deletions/gene conversions may extend into the adjacent gene encoding tenascin-X, which when mutated in both alleles, causes a form of Ehlers-Danlos syndrome.[56]

The signs and symptoms of congenital adrenal hyperplasia caused by 21-hydroxylase deficiency reflect deficits in cortisol (because of inability to convert 17α-hydroxyprogesterone into 11-deoxycortisol) and aldosterone (because of inability to convert progesterone into deoxycorticosterone). Another contributing factor is the accumulation of adrenal androgens that results from elevated ACTH levels, due to the absence of cortisol-negative feedback on the hypothalamic–corticotrophin axis.

The clinical phenotypes are, however, variable and dependent on the severity of the 21-hydroxylase deficiency.[6,55] The non–salt-wasting, salt-wasting, and non-classic forms are associated with certain mutations that affect the amount of residual 21-hydroxylase activity, with the salt-wasting form being characteristic of severe enzyme deficiency (deletions and large gene conversions). The simple virilizing (non–salt-wasting) form is associated with mutations that substantially reduce activity (e.g., the missense mutation resulting in a non-synonymous amino acid substitution Ile172Asp), and the non-classic (or *late-onset*) form is caused by mutations that do not severely impair the level of expression or activity of P450c21 (e.g., Val28Leu, Pro30Leu).

Hydroxysteroid Dehydrogenases and Reductases

Hydroxysteroid dehydrogenases (HSDs) or oxidoreductases catalyze the interconversion of alcohol and carbonyl functions in a position- and stereospecific manner on the steroid nucleus and side chain, using oxidized (+) or reduced (H) nicotinamide adenine dinucleotide, NAD(H), or nicotinamide adenine dinucleotide phosphate NADP(H)

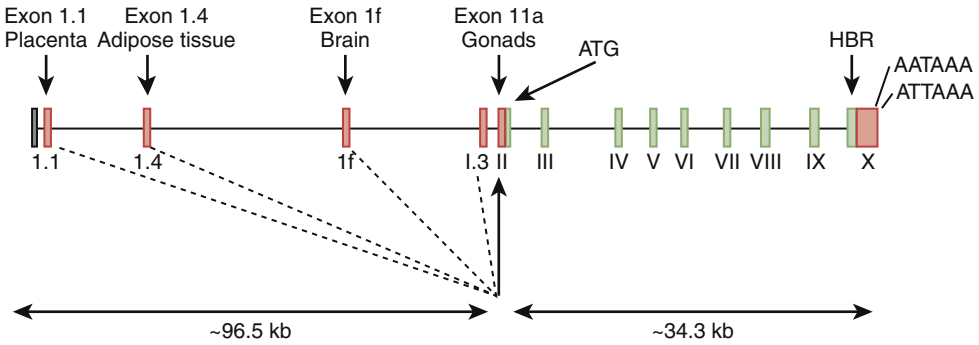

FIGURE 4.7 Structure of the human *CYP19A1* gene showing the protein coding exons indicated by Roman numerals and the location of the different 5′-UTR-coding exons and tissue-specific promoters. The P450arom heme-binding region (HBR) and polyadenylation signals in exon 10 are indicated. ATG, methionine codon. *(Modified from Kamat A, Hinshelwood MM, Murry BA, et al. Mechanisms in tissue-specific regulation of estrogen biosynthesis in humans.* Trends Endocrinol Metab *13:122, 2002.)*

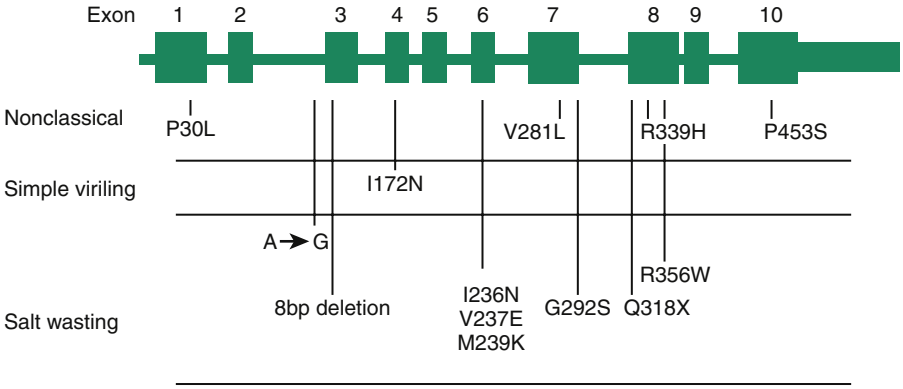

FIGURE 4.8 Structure of the *CYP21A2* gene and selected mutations causing phenotypes of 21-hydroxylase deficiency. *(Modified from White PC, Speiser PW. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency.* Endocr Rev *21:245, 2000.)*

as cofactors.[6,30,57] In some instances, HSDs display bifunctionality (e.g., they oxidize or reduce 17β and 20α oxy functions), such as HSD17B2. Although the HSDs can catalyze both the oxidation and reduction reactions *in vitro* under different conditions (e.g., substrate, pH and cofactor), *in vivo* they catalyze reactions in one direction and can be classified as dehydrogenases or reductases. The enzymes are members of the short chain dehydrogenase reductase or aldo-keto superfamilies (www.med.upenn.edu/akr/).

The importance of cofactor availability to HSDs is exemplified by inactivating mutations in the hexose-6-phosphate dehydrogenase *(H6PDH)* gene, which regenerates NADPH in the endoplasmic reticulum required for the HSD11B1 reaction. Individuals with these mutations have apparent cortisone reductase deficiency due to impaired HSD11B1 activity.[6,58]

Multiple isoforms of HSDs exist, and coupled with their tissue-specific expression, account for the ability of specific enzymes to act predominantly as reductases (ketone reduction) or dehydrogenases (alcohol oxidation). In steroidogenic tissues, HSDs catalyze the final steps in progestin, androgen, and estrogen biosynthesis. In steroid target tissues, HSDs can regulate the occupancy of steroid hormone receptors by converting active steroid hormones into inactive metabolites or relatively inactive steroids to molecules with greater binding activity.

This is best exemplified by the human type 2 11β-HSD (HSD11B2), which controls mineralocorticoid activity in the kidney by converting cortisol (which has high affinity for both the glucocorticoid and mineralocorticoid receptors) to cortisone (which does not bind to the mineralocorticoid receptor). Thus, the specificity of mineralocorticoid receptor activation is not determined by the receptor, but by activity of the HSD that removes the more abundant potential mineralocorticoid receptor ligand, leaving aldosterone as the controlling activator (Fig. 4.8).[59] Because of their tissue-specific roles in controlling the bioavailability of steroids, HSDs are interesting targets for pharmacological manipulation.[30]

3β-Hydroxysteroid Dehydrogenase/$\Delta^{5\text{-}4}$ Isomerases

The 3β-HSD/$\Delta^{5\text{-}4}$ isomerases are membrane-bound enzymes localized to the endoplasmic reticulum and mitochondria that use nicotinamide adenine dinucleotide (NAD+) as a cofactor. These enzymes catalyze dehydrogenation of the 3β-hydroxyl group and the subsequent isomerization of the Δ^5 olefinic bond to yield a Δ^4 ketone structure. They convert pregnenolone into progesterone, 3-17α-hydroxypregnenolone into 17α-hydroxyprogesterone, and dehydroepiandrosterone into androstenedione.[6,60]

The dehydrogenase and isomerase reactions are performed at a single bifunctional catalytic site that adopts different conformations for each activity. The 3β-hydroxysteroid dehydrogenase step is rate-limiting in the overall reaction sequence, and the NADH formed in this reaction is believed to alter the enzyme conformation to promote the isomerase reaction.

The human genome has two active 3β-HSD/$\Delta^{5\text{-}4}$ isomerase genes: one encodes a protein predominantly expressed in the placenta, liver, breast, and brain (HSD3B1), the other a protein expressed in the adrenal cortex and gonads (HSD3B2). These two genes, each consisting of four exons each, lie 100 kb

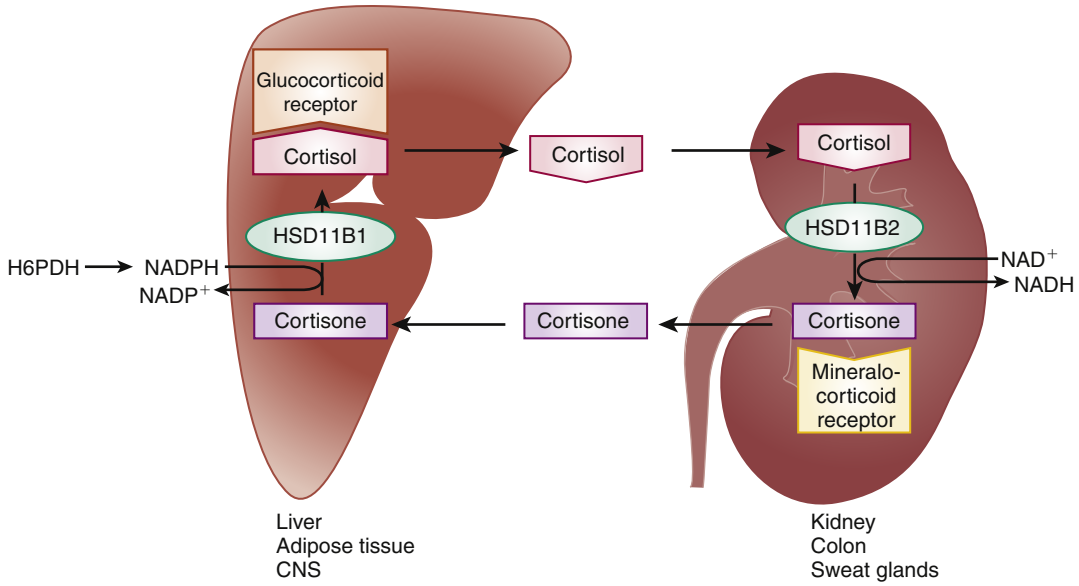

FIGURE 4.9 The roles of 11β-HSD types 1 (HSD11B1) and 2 (HSD11B2) in controlling levels of bioactive glucocorticoids. HSD11B1 reduces inactive cortisone into cortisol in liver and other tissues, whereas HSD11B2 oxidizes cortisol to cortisone. Cortisone cannot activate the mineralocorticoid receptor, thus allowing aldosterone (a steroid that is less abundant than cortisol) to specifically regulate the mineralocorticoid receptor. The supply of NADPH to HSD11B1 is a major determinant of the reaction and inactivating mutations in the H6PDH gene, which generates NADPH, cause cortisone reductase deficiency *(Modified from Seckl J, Walker B. 11β-Hydroxysteroid dehydrogenase type I-A tissue-specific amplifier of glucocorticoid action.* Endocrinology *142:1371, 2001.)*

apart on band 1p13.1. The human genome also contains five unprocessed pseudogenes closely related to *HSD3B1* and *HSD3B2* on band 1p13.1, with two of them lying between the expressed genes. The DNA sequences of the exons of the two active genes are very similar, and the encoded proteins differ in only 23 amino acid residues. HSD3B1, however, has a lower K_m for substrate than HSD3B2 (<1 μM vs 1–4 μM), which facilitates metabolism of lower concentrations of Δ^5 substrate. Electron microscope cytochemistry has localized HSD3B2 activity to the perimitochondrial endoplasmic reticulum and in subcellular fractions containing STARD1 and P450scc. In some cell types, HSD3Bs appear to be localized in the inner mitochondrial membrane. Thus, these enzymes are positioned to act on pregnenolone produced by the cholesterol side-chain cleavage system.

Because most steroidogenic cells have a large capacity to generate progesterone when presented with exogenous pregnenolone, the 3β-HSD/$\Delta^{5\text{-}4}$ isomerases are not believed to be rate-determining enzymes. However, mutations causing deficiency of HSD3B2 cause a form of congenital adrenal hyperplasia characterized by impaired adrenal and gonadal steroidogenesis with accumulation of Δ^5 steroids in the circulation. The presence of active HSD3B1 in extra-adrenal and extra-gonadal tissues results in the formation of some Δ^4 steroids (e.g., 17α-hydroxyprogesterone).[6]

In its severest form, HSD3B2 deficiency is associated with salt wasting because of insufficient mineralocorticoid production.[6,53,60] Kinetic analysis of mutant proteins associated with the salt-wasting and non–salt-wasting forms of the disease showed a four to fortyfold reduction in catalytic efficiency for the conversion of pregnenolone into progesterone. The salt-wasting form of the disease is associated with frameshift mutations resulting in protein truncation and a variety of missense mutations that affect affinity for the cofactor and protein stability. The greater instability of the mutant proteins found in subjects with salt-wasting disease compared with those proteins found in the non–salt-wasting form appears to account, in part, for the different clinical phenotypes.

A so-called attenuated, or late-onset, form of 3β-HSD deficiency, diagnosed by steroid measurements, has been described in the literature. However, no mutations have yet been discovered in the genes encoding *HSD3B1* and *HSD3B2* in subjects with this clinical diagnosis. Mutations in the distal promoter or epigenetic factors that might alter enzyme expression cannot be ruled out. The apparent reduced 3β-HSD activity could also be the result of alterations in the membrane environment that affect catalytic activity or post-translational modifications to the enzyme that diminish its function.

Mutations in *HSD3B1* have not been detected, although several sequence variants that are evidently without functional significance have been described. Because the HSD3B1 is the primary 3β-HSD/$\Delta^{5\text{-}4}$ isomerase in the placenta, it is possible that mutations that inactivate HSD3B1 would lead to miscarriage or preterm birth as a result of insufficient placental progesterone production.

11β-Hydroxysteroid Dehydrogenases: Key Regulators of the Activity of Glucocorticoids

The biological activity of cortisol in target tissues is controlled by the action of two different 11β-hydroxysteroid dehydrogenases that are members of the short-chain alcohol dehydrogenase family (Fig. 4.9). These enzymes catalyze the interconversion of active glucocorticoids and their inert 11-keto metabolites.[6,59] The type 2 enzyme (HSD11B2) is an endoplasmic reticulum protein with reversible oxidoreductase activity *in vitro*, but preferentially catalyzes the

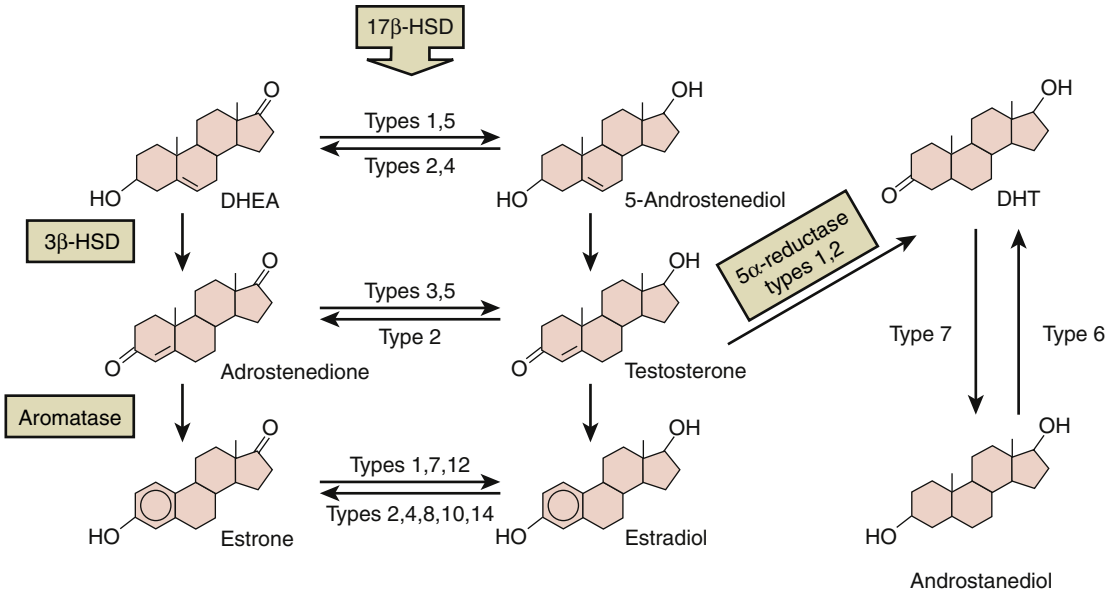

FIGURE 4.10 The family of 17*β*-HSDs and some of their roles in androgen and estrogen synthesis and metabolism. DHT, dihydrotestosterone. *(Modified from Luu-The V. Analysis and characteristics of multiple types of human 17β-hydroxysteroid dehydrogenase.* Steroid Biochem Mol Biol *76:143, 2001.)*

reduction of the 11-keto group, using NADPH as a cofactor *in vivo*. This enzyme is expressed in the liver, lung, adipose tissue, brain, vascular tissue, and gonads, where it regenerates cortisol from 11-ketosteroids. In the case of the placenta, the activity ensures transport of biologically active cortisol to the fetus in the first half of pregnancy.

Targeted deletion of the type 1 enzyme gene *(Hsd11b1)* in mice results in animals with lower blood glucose levels in response to overfeeding and stress, impaired activation of gluconeogenesis, and blunted sensitivity to natural glucocorticoids. This finding substantiates a role for HSD11B1 in the amplification of cortisol and corticosterone action. HSD11B1 also plays a key role in the pharmacology of glucocorticoids. Hepatic HSD11B1 converts cortisone and prednisone, inactive prohormones, into active cortisol and prednisolone.

As noted above, mutations in the *H6PDH* gene cause a syndrome characterized by high ratios of cortisone to cortisol, impaired cortisol negative feedback resulting in elevated ACTH secretion, and increased production of adrenal androgens leading to hyperandrogenism, sexual precocity and a polycystic ovary syndrome-like phenotype. Mice with targeted mutations in *H6pdh* share many of the phenotypes of mice with *Hsd11b1* mutations. Heterozygous mutations in the *HSD11B1* gene causing a mild form of cortisone reductase deficiency have recently been described.[61]

HSD11B2, also an endoplasmic reticulum enzyme, has a higher affinity for its substrate than HSD11B1 and catalyzes the oxidation of cortisol with NAD^+ as a cofactor. It shares only modest amino acid sequence identity (21%) with HSD11B1. HSD11B2 is highly expressed in the kidney, colon, salivary glands, and placenta, all tissues that respond to aldosterone, or in the case of the placenta, tissues that act to separate the maternal and fetal endocrine systems (which is important in the third trimester). By converting cortisol and corticosterone to 11-keto compounds, HSD11B2 protects the renal mineralocorticoid receptors,which cannot distinguish cortisol or corticosterone from aldosterone, from inappropriate activation by the glucocorticoids.

Mutations that inactivate HSD11B2 produce a syndrome of apparent mineralocorticoid excess in humans, which is mimicked in the mice deficient in the enzyme that display hypertension, hypokalemia, and renal structural abnormalities. Glycyrrhizic acid, a component of licorice, and its metabolite carbenoxolone, are competitive inhibitors of HSD11B2, but also cause reduced expression of the HSD11B2 mRNA when administered *in vivo*. As a result, a drug-induced syndrome of apparent mineralocorticoid excess is produced.[62,63]

17β-Hydroxysteroid Dehydrogenases: Multiple Enzymes with Specific Biosynthetic and Catabolic Roles

The adrenals, gonads, and placenta reduce 17-ketosteroids into 17β-hydroxysteroids (which have greater biological potency), whereas target tissues usually oxidize 17β-hydroxysteroids, inactivating them.[6,57,64-66] In humans, these metabolic processes are mediated by at least 7 of the 14 known mammalian 17β-HSDs, designated types 1 through 14, according to the chronological order in which they were identified (Fig. 4.10). They are all members of the short-chain dehydrogenase–reductase family, except the type 5 enzyme, which is an aldo-keto reductase. They have different cofactor and substrate specificities, including molecules that are not steroids, subcellular locations, and tissue-specific patterns of expression.

The structures of the genes encoding the 17β-HSDs differ, and their nucleotide sequence homology is low. They can be grouped into enzymes that catalyze NAD^+-dependent oxidation (types 2, 4, 6, 8, 9, 10, 11, and 14) and those that catalyze NADPH-dependent reduction (types 1, 3, 5, and 7). Because of the broad substrate specificities, the

primary roles of several of these enzymes are in basic metabolic pathways unrelated to steroid metabolism, and deficiencies of these enzymes cause metabolic disease.

The type 1 enzyme (HSD17B1) is referred to as the "estrogenic" 17β-HSD because it catalyzes the final step in estrogen biosynthesis by preferentially reducing the weak estrogen estrone to yield the potent estrogen 17β-estradiol. The enzyme is a cytosolic protein that uses either NADH or NADPH as a cofactor. It has 100-fold higher affinity for C18 steroids than for C19 steroids. It also converts 16α-hydroxyesterone into estriol and shows modest 20α-HSD activity.

The structural gene encoding HSD17B1 consists of six exons and is located on bands 17q11-12 in tandem with a highly homologous pseudogene. It is expressed in granulosa cells of the ovary and the placental syncytiotrophoblast. HSD17B1 is also expressed at higher levels in breast cancer cells relative to the HSD17B2, which converts estradiol into estrone. Amplification of *HSD17B1* in estrogen receptor-positive breast cancers is associated with lower survival compared to subjects without amplification. The crystal structure of HSD17B1 has been determined to a resolution of 2.2 Å with and without bound substrates, providing a molecular framework for the design of specific inhibitors which might be employed in chemotherapy of estrogen-responsive cancers.[66,67]

HSD17B2 is an endoplasmic reticulum enzyme that inactivates hormones; it preferentially oxidizes testosterone into androstenedione, and it oxidizes estradiol into estrone using NAD+ as its cofactor. HSD17B2 also has the ability to convert 20α-hydroxyprogesterone into progesterone.

The gene encoding HSD17B2, located on band 16q24, contains five exons. It is expressed in liver, secretory endometrium, and the fetal capillary endothelial cells of the placenta, as well as the endothelial cells of the larger vessels. This expression pattern is consistent with its role of inactivating testosterone and estradiol. HSD17B2 in the fetal capillary endothelium protects the fetal compartment from estradiol formed in the syncytiotrophoblast, and from any testosterone escaping aromatization. Its expression in the secretory endometrium permits the conversion of estradiol to estrone, whereas 20α-hydroxyprogesterone is converted back into progesterone, resulting in progestational dominance. In normal breast tissue, HSD17B2 expression predominates over HSD17B1 expression.

HSD17B3 is referred to as the "androgenic" 17β-HSD because it catalyzes the final step in androgen biosynthesis in the Leydig cells, reducing androstenedione to testosterone using NADPH as cofactor. It also can reduce estrone to estradiol. HSD17B3, an endoplasmic reticulum enzyme, is not expressed in the ovary, requiring androgen-producing cells of the ovary to employ another enzyme, probably HSD17B5, to synthesize testosterone. The *HSD17B3* gene, comprised of 11 exons, is located on band 9q22.

In the absence of HSD17B3 activity, the testes are unable to convert androstenedione into testosterone, resulting in male pseudohermaphroditism (46, XY DSD) associated with ten to fifteenfold elevations in the ratio of blood androstenedione to testosterone.[6,68] Females with mutations in the *HSD17B3* gene are asymptomatic, and produce normal amounts of estrogens and androgens. Molecular analysis of the *HSD17B3* gene in affected individuals revealed mutations that affect splicing, cause amino acid replacements in exons 9 and 10, and a small deletion leading to a frameshift. Many of the missense mutations result in proteins that are devoid of catalytic activity when expressed in eukaryotic cells.

HSD17B5, located on chromosome 10p15-14, is a member of the aldo-keto reductase family (AKR1C3). It has 3α-HSD and 20α-HSD activity in addition to 17β-HSD activity that produces testosterone from androstenedione. It is expressed in the adrenal cortex and may serve as the "androgenic" 17β-HSD of ovarian theca cells.[69,70] HSD17B5 is also expressed in prostate, mammary gland, and Leydig cells.

HSD17B6 (also known as 11-cis retinol dehydrogenase, RODH), encoded by a gene on chromosome 12q13.3 has 3α-HSD activity and catalyzes the conversion of androstanediol to dihydrotestosterone in the prostate. It is also a 3α-3β epimerase. Polymorphisms in the *HSD17B6* gene have been associated with polycystic ovary syndrome phenotypes in some, but not all, studies.

Human HSD17B7 is involved in cholesterol synthesis but also thought to produce active estrogens and inactivates androgens. It transforms estrone into estradiol, and has 3-keto reductase activity for dihydrotestosterone. The gene located on band 10p11.2 is expressed in the ovary, breast, placenta, testes, prostate, and liver cells.

3α- and 20α-Hydroxysteroid Dehydrogenase Activities

A number of HSDs catalyze reactions at both the 3 and 20 positions of steroid hormones (e.g., AKR1C1).[6,30] The enzymes that are 3α-reductases are encoded by tandemly duplicated genes on chromosome 10p14-p15, and are all members of the aldo-ketoreductase family. They are expressed in liver, prostate, breast, and uterus, but some are also expressed in the testis and adrenals. Recessive mutations in one of these genes, AKR1C2, was discovered in four 46,XY individuals with disordered sexual development, implicating this enzyme in a pathway of bioactive androgen biosynthesis through conversion of androsterone to androstanediol, followed by HSD17B6-mediated conversion of androstanediol to dihydrotestosterone.[71]

The enzymes with 20α-HSD activity that are members of the aldo-keto reductase family reduce progesterone to yield the inactive steroid, 20α-hydroxyprogesterone. They are cytosolic proteins with a molecular weight of approximately 34 kDa, exemplified by genes expressed in human keratinocytes and cells of the liver, prostate, testis, adrenal gland, brain, uterus, and mammary gland. These enzymes prefer NADPH to NADH as a cofactor.[6,30]

Enzymes with 3α-hydroxysteroid oxidative activity are members of the short-chain dehydrogenase/reductase family. As noted previously, enzymes of the short-chain dehydrogenase–reductase family have 20α-HSD activity, including HSD17B1 and HSD17B2. HSD17B2 preferentially oxidizes 20α-hydroxyprogesterone into progesterone.

$\Delta^{4\text{-}5}$ Reductases

The $\Delta^{4\text{-}5}$ reductases are membrane-associated enzymes that reduce the Δ5-4 double bond in steroid hormones by catalyzing direct hydride transfer from NADPH to the carbon 5 position of the steroid substrate.[6,72,73] They produce either 5α or 5β-dihydrosteroids.

5α-Reductases

Two different human 5α-reductases sharing 50% similarity in amino acid sequence and a molecular weight of approximately 29 kDa have been identified.[67,68] The genes for type 1 *(SRD5A1)* and 2 *(SRD5A2)* 5α-reductases each have five exons. The substrate-binding domain of the 5α-reductases is encoded by exon 1, and the cofactor-binding domain is encoded by exons 4 and 5. The type 2 5α-reductase gene, *SRD5A2*, is located on chromosome 2p23, whereas the type 1 5α-reductase gene, *SRA5A1*, is located on chromosome 5p15, with a pseudogene on Xq24-qter. A third enzyme containg a 5α-reductase domain, SRD5A3, has been identified but its role in steroid metabolism has not been established.

SRD5A2 is predominantly expressed in male genital structures, including genital skin and prostate, where it reduces testosterone to yield the more potent androgen, 5α-dihydrotestosterone. SRD5A1, which catalyzes a similar reaction on both C21 and C19 steroid hormones, is expressed in the liver, kidneys, skin, and brain. Although this enzyme can also make 5α-dihydrotestosterone, its tissue distribution suggests that its predominant function is to inactivate steroid hormones.

SRD5A2 has an acidic pH optimum and a K_m for testosterone in the nanomolar range, whereas SRD5A1 has a broad alkaline pH optimum and a lower affinity for its substrates in the micromolar range. SRD5A2 can also be distinguished from the type 1 enzyme by its selective inhibition by finasteride, with an inhibition constant (K_i) of 3 nM.

Inactivating mutations in *SRD5A2* cause male pseudohermaphrodism (46, XY DSD). The enzyme defect is characterized by abnormal testosterone-to-5α-dihydrotestosterone ratios. Affected males have varying degrees of abnormal development of the external genitalia, ranging from mild hypospadias to severe defects in which the external genitalia are essentially female. Wolffian ducts develop normally in response to adequate levels of testosterone.

Females carrying mutations in the *SRD5A2* gene have a normal phenotype and normal menstrual cycles. They have a low incidence of hirsutism and acne, and like males with the disease, have low ratios of 5α- to 5β-dihydrosteroid metabolites in the urine. The infrequency of acne in both affected males and females, the rarity of hirsutism in affected females, the absence of male pattern baldness, and the finding of an atrophic prostate in affected males indicates that SRD5A2 plays an important role in androgen metabolism in skin and in the androgen-dependent growth of the prostate.

Among the mutations reported are deletions that inactivate SRD5A2, and missense mutations that impair enzyme activity by affecting substrate or cofactor binding. A *SRD5A2* variant (Ala49Thr) that has increased catalytic activity has been associated with increased risk of prostate cancer.

Mutations have not been described in the human *SRD5A1* gene. However, targeted deletion of the murine counterpart results in a female phenotype of reduced fecundity and a parturition defect caused by failed cervical ripening. This defect can be reversed by administration of 5α-androstanediol.[74,75]

The only known human 5β-reductase (SRD5B1 or AKR1D1) is a member of the aldo-keto reductase superfamily.[76] This enzyme is involved in steroid hormone inactivation in the liver. Its reaction mechanism is similar to that described for 5α-reductase, except that an A/B *cis*-fused ring product is formed. The enzyme efficiently catalyzes the NADPH-dependent reduction of the Δ5-4 double bond in C27, C21, and C19 steroids to yield the 5β-dihydrosteroids, with a distinct preference for C27 steroids. In keeping with this observation, mutations in the *SRD5B1 (AKR1D1)* gene on chromosome7q32-q33 that encodes this enzyme result in abnormal bile acid synthesis, along with a marked reduction in the primary bile acids and 5β-reduced steroid metabolites.

Sulfotransferases

A family of enzymes introduce the sulfonate (SO_3^-) anion from an activated donor, *3′-phosphoadenosine-5′-phosphosulfate* (PAPS), to a steroid hydroxyl acceptor, inactivating the hormone.[6,77,78] The major enzymes carrying out this reaction include estrogen sulfotransferase (SULT1E1), encoded by a gene on chromosome 4q13.1, an enzyme that sulfonates the 3-hydroxyl function of phenolic steroids, and the hydroxysteroid sulfotransferases, encoded by the closely linked *SULT2A1* and *SULT2B1* genes on chromosome 19q13.4.

The SULT2A1 enzyme, also known as *dehydroepiandrosterone sulfotransferase*, has a broad substrate range including the 3α-, 3β-, and 17β-hydroxy functions of steroid hormones. SULT2A1 enzyme is expressed at high levels in the fetal zone of the adrenal cortex, as well as in the zona reticularis after adrenarche, and in the liver, gut, and testes. This enzyme is developmentally regulated in the adrenal cortex, with expression increasing between ages 5 and 13 years in association with adrenarche. The GATA-binding factor 6 (GATA6) transcription factor, which is known to increase transcription of other genes involved in androgen biosynthesis, also activates expression of the *SULT2A1* gene.

The *SULT2B1* gene gives rise to two protein isoforms through alternative splicing. The SULT2B1a isoform sulfonates pregnenolone, whereas the SULT2B1b isoform preferentially sulfonates cholesterol. They both sulfonate dihydrotestosterone. Unlike the *SULT2A1* gene that is expressed in a limited number of tissues, SULTB1 isoforms are present in a variety of hormone-producing and hormone-responsive tissues, including the placenta, ovary, uterus, and prostate.[79]

SULT1E1 is expressed in many tissues, including the adrenal gland, liver, kidneys, muscle, fat, and uterus. In the endometrium, progesterone increases its activity, contributing to the inactivation of estradiol in the secretory phase. The importance of estrogen sulfotransferase in modulating local levels of bioactive estrogens has been shown in mice with targeted deletions of the gene.[80] Male mice with estrogen sulfotransferase deficiency have Leydig cell hyperplasia and become infertile with age, due to elevated testicular levels of bioactive estrogen. Adipose tissue mass also increases. Hydroxylated metabolites of polychlorinated biphenyls are potent inhibitors of estrogen sulfotransferase, with IC50 values in the picomolar range.[81] The blockade of estradiol inactivation by these compounds may account for the reported "estrogenic" activity of polychlorinated biphenyls.

Mutations in the gene that encodes one of the enzymes that synthesizes the sulfate donor, PAPS, (PAPS synthase

type 2 [PAPSS2]), results in increased free DHEA levels, with the subsequent conversion of DHEA into biologically active androgens.[6]

Steroid Sulfatase

The sulfonate function on steroids is cleaved by steroid sulfatase, an enzyme encoded by the *STS* gene on chromosome Xp22.3.[6,79,82-84] This enzyme plays a key role in controlling the generation of biologically active steroids from the inactive sulfated molecules (e.g., estrone sulfate and dehydroepiandrosterone sulfate). The sulfated steroid substrates, which are hydrophilic and not membrane-permeable, are thought to be taken up by cells via specific transport proteins, including organic anion transport polypeptide B (OATP-B).

The syncytiotrophoblast is enriched in steroid sulfatase, which plays a key role in placental estrogen synthesis by liberating sulfonated androgen precursors produced in the fetal compartment prior to aromatization. The enzyme is also expressed in skin, where it metabolizes cholesterol sulfate and sulfated estrogens.

Sulfatase deficiency is associated with marked impairment of placental estrogen synthesis during pregnancy and ichthyosis developing after birth.[83,84] It occurs mostly in males because of the X chromosome location of the sulfatase gene, at a frequency of 1:2000 to 1:6000 live born males. The majority of subjects with steroid sulfatase deficiency have a deletion of the entire gene that results from recombination of repetitive elements that flank the locus. The large deletions of the *STS* gene occur in association with mutations in the adjacent Kallmann's syndrome gene *(KAL1)*. Partial deletions in the *STS* gene causing enzyme deficiency have also been described.

Characteristically, in pregnancies hosting an affected fetus, maternal plasma estriol and urinary estriol excretion are quite low, approximately 5% of the levels found in normal pregnancies. Excretion of estrone and estradiol are also reduced, at approximately 15% of normal. Maternal serum 16α-hydr oxydehydroepiandrosterone levels are elevated, and intravenous administration of dehydroepiandrosterone sulfate to the mother does not lead to an increase in estrogen excretion, whereas administration of dehydroepiandrosterone does.

Steroid sulfatase is expressed in estrogen target tissues, including endometrium, bone, and breast. Increased sulfatase expression may contribute to greater bioavailability of estradiol in certain tumors, including breast and endometrial cancers. Inhibitors of sulfatase have been developed and tested in clinical trials (Irosustat).[85]

UDP-Glucuronosyl Transferases

Glucuronidation, catalyzed by a family of uridine 5'-diphospho UDP-glucuronosyl transferases, is part of the metabolic clearance mechanism for steroid hormones by the liver and extrahepatic tissues.[86-89] There are 18 known UDP-glucuronosyl transferases that have been divided into three subfamilies: UGT1A , UGT2A, and UGT2B. UGT1A enzymes are encoded by a single gene that gives rise to alternatively spliced products capable of acting on estrogens. The UGT2 enzymes are products of separate genes *UGT2A* and *UGT2B*. *UGT2A* is expressed in olfactory epithelium, and *UGT2B* is expressed in the liver, kidney, breast, lung, and prostate. At least seven members of the UGT2B family have been identified with different steroid substrate specificities. Three UGT2B enzymes, UGT2B7, UGT2B15, and UGT2B17, appear to be responsible for glucuronidation of 5α-dihydrotestosterone, androsterone, and androstane-3α-17β-diol, Of these, UGT2B15 and UGT2B17 are expressed in the prostate where they are proposed to modulate steroid action.[90] Polymorphisms in genes encoding UDP-glucuronosyl transferases have been associated with estrogen levels, suggesting a role for these phase II biotransformation enzymes in regulating the bioactive steroid economy.

Other Steroid Hormone Metabolical Pathways

There are several metabolical fates of steroid hormones that have a significant role in the synthesis of bioactive hormones. A pathway for androgen production, referred to as a "backdoor pathway" is one example.[71] Among the other fates of steroid hormones are esterification to long-chain fatty acids, formation of catechol estrogens, and the 7α-hydroxylation of androgens. Equine steroidogenic tissues also have a novel pathway for biosynthesis of estrogens, resulting in a phenolic A ring and an unsaturated B ring.

An Alternative Pathway for Androgen Synthesis

Fetal androgen synthesis in marsupials involves a novel pathway that leads from 17α-hydroxyprogesterone to 5α-dihydrotestosterone without going through androstenedione or testosterone as intermediates (Fig. 4.11). This pathway, recently identified in humans, is initiated when either progesterone or 17α-hydroxyprogesterone is 5α-reduced. The resulting 5α-C_{21} steroids are reduced by 3α-HSDs (AKR1C2/4) yielding substrates for P450c17. Androsterone produced by P450c17 can ultimately be converted to 5α-dihydrotestosterone by HSD17B6.[71] This pathway also contributes to androgen excess in the context of 21-hydroxylase deficiency.

Catechol Estrogens

Catechol estrogens are generated by the actions of genes encoded by *CYP1A1* and *CYP1A2* (which catalyze 2-hydroxylation of estrogens), and *CYP1B1*, which is an estrogen 4-hydroxylase.[91-93] Although the catechol estrogens are short-lived *in vivo* and are postulated to have physiological functions as locally generated signaling molecules, they also yield potent genotoxic molecules implicated in carcinogenesis. The 4-hydroxyestrogens can be oxidized to quinone intermediates that react with purine bases of DNA, resulting in depurinating adducts that generate highly mutagenic apurinic sites (Fig. 4.12). Quinones derived from the 2-hydroxyestrogens produce stable DNA adducts and are presumed to be less genotoxic. Metabolism of catechol estrogens may also generate oxygen-free radicals.

Catechol estrogens are methylated by catechol-O-methyltransferase, resulting in a catecholamine-like substance. The methylated catechol estrogens have anti-angiogenic and antitumor activity through inhibition of hypoxia-inducible factor-1α (HIF-1α), a pro-angiogenic transcription factor. There is evidence that altered production of 2-methoxyestradiol may contribute to the pathogenesis of preeclampsia through its modulation of anti-angiogenic factor production by the placenta.[94,95]

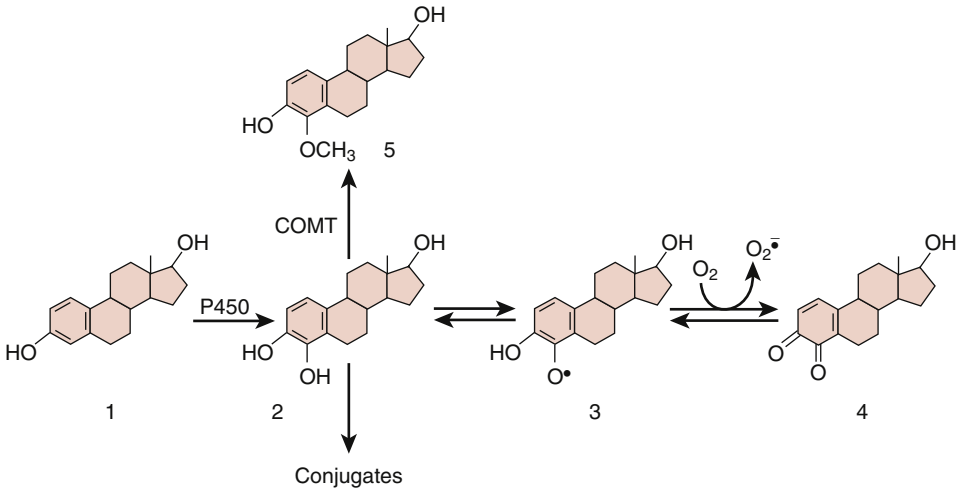

FIGURE 4.12 Metabolism of estradiol (1) by P450 enzymes, including P4501B1 to 4-hydroxyestradiol (2). Metabolic cycling between 4-hydroxyestradiol and estradiol 3,4-quinone (4) can be catalyzed by P4501A1 for the oxidation step and cytochrome P450 reductase for the reduction step. The semiquinone intermediate (3) is a free radical that can react with molecular oxygen to form superoxide radical and quinone. 4-Hydroxyestradiol can be converted to 4-methoxyestradiol (5) by catechol-O-methyltransferase (COMT). *(From Liehr JG. Catecholestrogens in the induction of tumors in the kidney of the Syrian hamster. In Goldstein DS, Eisenhofer G, McCarty R [eds].* Advances in pharmacology: catecholamines. bridging basic science with clinical medicine, *vol 42. San Diego, Academic Press, 1998, pp 824–828.)*

Steroid Fatty Acid Esters

Steroids esterified to long-chain fatty acids are present in blood bound to lipoproteins, or are found in tissue, particularly steroidogenic glands and fat.[96,97] These hydrophobic molecules may serve as a depot form of steroid, but they also have unique biochemical attributes. Estradiol 17-esters are produced in blood by the action of lecithin-cholesterol acyl transferase and in tissues by SOATs. The fatty acid esters of estradiol have pronounced antioxidant activity. Fatty acid esters of other steroids, including pregnenolone, testosterone, dehydroepiandrosterone, and glucocorticoids, have also been described.

Steroid 7α-Hydroxylation

Substituents on carbon 7 of the steroid nucleus can have a significant effect on activity. A cytochrome P450 encoded by the *CYP7B* gene catalyzes 7α-hydroxylation of steroid hormones and oxysterols. The 7α-hydroxylation of dehydroepiandrosterone produces a molecule with enhanced immunostimulatory activity, a property demonstrable in animal bioassays.[98]

B-Ring Unsaturated Steroids

The pregnant mare produces estradiol and estrone, but also B-ring unsaturated estrogens (equilin [with an 8,9 olefinic

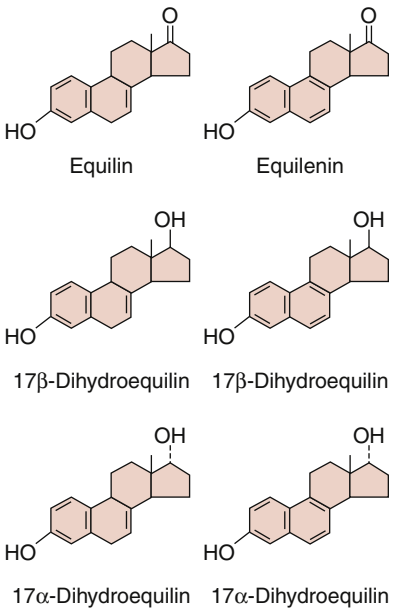

FIGURE 4.13 Structures of equine estrogens.

bond], equilenin [with a phenolic B ring], 17α-dihydroequilin, 17α-dihydroequilenin, 17β-dihydroequilin, and 17β-dihydroiequilenin) (Fig. 4.13).[99]

These B-ring unsaturated compounds are potent estrogens *in vivo*. Although 7-dehydrocholesterol can be converted into B-ring unsaturated estrogens (as occurs in Smith-Lemli-Opitz syndrome), the biosynthesis of these compounds in the pregnant mare occurs by a pathway not requiring the synthesis of squalene or cholesterol, and thus does not involve 7-dehydrocholesterol. Evidently, they are derived from a C25 sesterterpene pathway that coexists with the normal biosynthetic route of "standard" estrogens from a cholesterol precursor.

Vitamin D Synthesis and Metabolism

Mounting epidemiological evidence indicates that in addition to calcium and bone metabolism the secosteroid, vitamin D, plays important roles in immune function and reproduction, and that vitamin D deficiency is associated with reproductive disorders. The impact of vitamin D on reproduction is demonstrable in genetically engineered mice. Vitamin D receptor (Vdr) and 1α-hydroxylase *(Cyp27b1)* knockout female mice display reduced fecundity, impaired folliculogenesis, and anovulation. These reproductive abnormalities are evidently due to dysfunctional calcium homeostasis since high calcium diets partly restore fertility and increase the rate of conception in *Vdr* null mice.

Vitamin D_3 is produced in the innermost layers of the skin (stratum basale and stratum spinosum) through the action of ultraviolet light on 7-dehydrocholesterol (Fig. 4.14).[100,101] Vitamin D_3 travels to the liver where it is converted into 25-hydroxyvitamin D_3 by an endoplasmic reticulum P450, CYP2R1, a highly conserved and substrate-specific 25-hydroxylase. Mutations in the *CYP2R1* gene lead to deficient 25-hydroxylation of D_3. 25-Hydroxyvitamin D_3 in plasma is mainly bound to vitamin D binding protein (also called group specific protein). Megalin and cubilin, endocytic receptors, participate in the uptake of vitamin D binding protein and its 25-hydroxyvitamin D_3 cargo for further metabolism. The 25-hydroxyvitamin D_3 is converted into the biologically active 1,25-dihydroxyvitamin D_3 by the action of a mitochondrial enzyme, CYP27B1, in the kidney, but also in monocytes, maternal decidua and placental trophoblast cells. Inactivating mutations of the *CYP27B1* gene are associated with clinical and radiographic features of rickets, hypocalcemia, and low serum concentrations of 1,25-dihydroxyvitamin D_3. The *CYP27B1* gene and the formation 1,25-dihydroxyvitamin D_3 by the kidney are regulated by negative feedback by 1,25-dihydroxyvitamin D_3, stimulated by parathyroid hormone (PTH), whose levels reflect calcium status, and inhibited by fibroblast growth factor 23 (FGF23), which reflects phosphate homeostasis.

The 24R-hydroxylase, CYP24A1, acts on 25-hydroxyvitamin D_3 and 1,25-dihydroxyvitamin D_3. This enzyme is thought to play the key role in inactivation of 1,25-dihydroxyvitamin D_3, although some have argued that the 24-hydroxylated vitamin D molecules may have biological roles.

Regulation of Expression of the Steroidogenic Machinery

The regulation of expression of genes encoding proteins involved in steroidogenesis in the ovary, testes, and adrenal cortex shares a number of similarities with respect to the involvement of *cis* elements and transcription factors. SF-1, a nuclear receptor, also known as Ad4BP and by the nuclear receptor family designation NR5A1, is essential for development of steroidogenic glands. Most of the genes encoding key proteins involved in steroidogenesis (e.g., *SRB1*, *STARD1*, *CYP11A1*, *CYP11B2*, *CYP17A1*, *CYP19A1*, *CYP21A2*) contain one or more NR5A1 response elements in their proximal promoters. These elements are important for basal as well as stimulated expression of these genes, generally by a cAMP-mediated signal transduction pathway.

The importance of cAMP signaling in steroidogenic tissues is reflected in increased steroid production when specific phosphodiesterases are blocked, which elevates intracellular cAMP levels, or when mutations occur in the gene encoding the regulatory subunit of protein kinase A *(PRKAR1A)*, resulting in unrestrained protein kinase A activity.[6,102] There appear to be several mechanisms by which NR5A1 action is modified by cAMP action, including phosphorylation of the protein by kinases, providing a link between this transcription factor and molecules that transduce signals from plasma membrane receptors.[103]

The importance of NR5A1 to the regulation of steroidogenic tissues was documented by gene targeting. Mice deficient in NR5A1 lacked adrenal glands and gonads, and males were consequently sex-reversed. Haploinsufficiency of *Nr5α1* in the mouse resulted in an impaired adrenal steroidogenic response to stress, although basal steroidogenesis was not affected due to compensatory hypertrophy.[103] *NR5A1* haploinsufficiency has been reported in humans with primary adrenal failure and XY sex reversal.[104] It is now

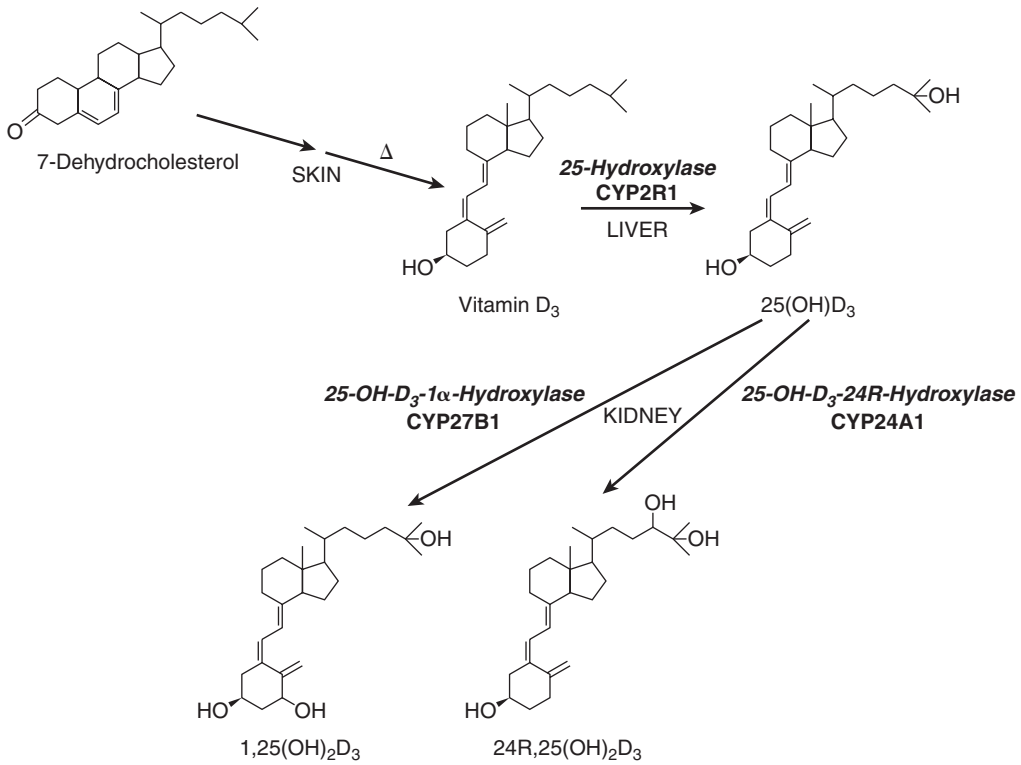

FIGURE 4.14 Metabolism of vitamin D3. 7-Dehydroxholesterol is converted to vitamin D3 in the skin triggered by ultraviolet light (Δ). Vitamin D3 is transported to the liver, mostly bound to protein, where it undergoes hydroxylation at the C25-position catalyzed by CYP2R1. 25-Hycroxyvitamin D3, the major form circulating vitamin D, undergoes hydroxylation in the kidney at either the C1 position, catalyzed by CYP27B1, or the C24 position, catalyzed by CYP24A1, resulting in 1a,25-dihydroxyvitamin D3, or 24R,25-dihydroxyvitamin D3. *(Modified from Henry, HL. Regulation of vitamin D metabolism.* Best Pract Res Clin Endocrinol Metab. *2011;25(4):531–541.)*

evident that variation in the NR5A1 gene is associated with a range of phenotypes such as 46,XY disorders of sex development, hypospadias, anorchia, male factor infertility, and primary ovarian insufficiency. Among the *NR5A1* mutations reported are missense mutations within the DNA-binding region, a nonsense mutation, a and a frameshift mutation predicted to disrupt RNA stability or protein function. Functional studies of the missense mutants (Cys33Ser, Arg84His) and of one nonsense mutant (Tyr138Stop) showed impaired activation of NR5A1–responsive target genes.[104]

Although NR5A1 is clearly an important regulator of embryological development of steroidogenic glands and control of transcription of proteins comprising the steroidogenic machinery, other transcription factors participate in the latter process. A related transcription factor, liver receptor homologue-1 (SF-2 or NR5A2) recognizes the same canonical DNA motif to which NR5A1 binds and may share functions with NR5A1 in certain tissues, including the adrenal cortex, testis, and ovary.[105] Both NR5A1 and NR5A2 have been crystallized and found to contain phospholipid-binding pockets, with phosphatidyl inositols being the presumed ligands. These observations suggest that phospholipids may be regulatory molecules controlling expression of genes involved in steroidogenesis.[106]

The tissue-specific regulation of genes expressed in multiple steroidogenic glands (e.g., *CYP17A1*) requires the action of other transcription factors working either independently or in concert with NR5A1 in a combinatorial fashion. In addition, the activity of NR5A1 is regulated by transcription factors that either bind to NR5A1 response elements and prevent activation of transcription (chicken ovalbumin upstream promoter-transcription factor [COUP-TF]) or bind to NR5A1 and block its ability to transactivate promoters (DAX-1, also known as NR0B1). Interestingly, expression of the latter gene is up-regulated by NR5A1, so there is a complex control mechanism in place for modulating these antagonistic molecules.

Other transcription factors that are known to be important for the expression of genes involved in steroidogenesis include GATA4 and GATA6, members of the GATA family of transcription factors originally identified as being central to hematopoiesis and endoderm development, and LXRalpha.[27,107,108]

It is notable that the human placenta is an outlier in many respects in terms of the regulation of steroidogenesis.[109] First, the placenta does not express certain genes that are pivotal to gonadal and adrenal steroid hormone synthesis, including *NR5A1*, *STARD1*, *HSD3B2*, and *CYP17A1*. Moreover, HSD3B1 replaces HSD3B2 in the placenta, and a START domain protein, STARD3 (which is not subject to acute regulation), may subserve STARD1's role in cholesterol movement to the placental side-chain cleavage system.

Unlike the gonads and adrenal cortex, the placenta's capacity to produce progestins is believed to be largely determined by levels of adrenodoxin reductase (which governs the availability of reducing equivalents) and P450scc. In addition, *CYP19A1* transcription in the placenta is driven by a different promoter than that used by the gonads. Thus, placental

steroidogenesis is controlled in a distinctly different way than gonadal and adrenal steroid production. The mechanism is more tonic, with steroidogenic capacity determined primarily by differentiation of trophoblast cells and growth of the placenta as opposed to tight regulation by trophic hormones.

Examples of Extraglandular Steroidogenesis

Although steroid hormone synthesis traditionally has been studied in the classic steroidogenic glands (ovaries, testes, adrenal cortex, and placenta), it is now evident that production of bioactive steroids, albeit at much lower levels, occurs at extraglandular sites, such as the brain, vascular tree, and adipose tissue.[110,111] Synthesis also occurs in pathological conditions affecting the endometrium (endometriosis and endometrial cancers), breast (breast cancer) and prostate (prostate cancer).[82,90,110,112]

Synthesis of Neurosteroids

The notion that steroid hormones could be synthesized in the central nervous system evolved from the discovery of appreciable levels of pregnenolone and dehydroepiandrosterone and their fatty acid esters in the brains of animals, even after gonadectomy or adrenalectomy.[113,114] It was subsequently shown that enzymes required for steroid hormone synthesis were expressed in the brain, spinal cord, and peripheral nervous system at the mRNA and protein levels. Included in this category are STARD1, P450scc, P450c17, P450arom, P450c11β, and P450c11AS, HSD17B1, and HSD17B2, as well as 3β-HSD, 5α-reductase, 3α-HSD, 11β-HSD activities.

The enzymes and their associated activities are distributed in different brain regions and cell types, including glia (astrocytes and oligodendrocytes) and neurons. They probably can act on circulating "prohormones" as well as participate in the de novo synthesis of steroids. The expression of the steroidogenic enzymes in the brain is developmentally regulated, although little is known about the mechanisms that control expression.

The known neurosteroids may act via the classic nuclear hormone receptors, but there is also good evidence that nonclassic signaling pathways are involved, including actions on gamma-aminobutyric acid $(GABA)_A$, N-methyl-D-aspartic acid (NMDA), alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), glycine, serotonin, Sigma type 1, nicotinic acetylcholine, and oxytocin receptors. The actions of neurosteroids on these receptors have been implicated in stress responses, anxiolysis, seizure disorders, memory, unipolar and postpartum depression, and protection against neuronal injury. The evidence supporting these notions has mostly been derived from *in vitro* studies and animal studies. However, pharmacological evidence from human studies based on synthetic neurosteroids (e.g., the short-acting anesthetic alphaxolone) substantiates the concepts derived from animal experimentation.

Steroid Hormone Metabolism in Skin

Skin is an important site of production of vitamin D precursors.[100,101] It also makes a contribution to testosterone production in women by metabolizing prohormones, such as dehydroepiandrosterone sulfate and androstenedione into testosterone.[115] The *HSD3B1*, *17BHSD3*, and *SRD5A1* and *SRD5A2* genes are expressed in skin, allowing for local formation of androgens that can activate the androgen receptors present in the stroma, sebocytes, and dermal papillae. Recent studies suggest that expression of STARD1 and aromatase in skin is correlated with skin androgen and estrogen levels.

Secretion, Production, and Metabolic Clearance Rates of Steroid Hormones

The concentration of a steroid in the circulation is determined by the rate at which it is secreted from glands, the rate of metabolism of precursor or prehormones into the steroid, and the rate at which it is extracted by tissues and metabolized. Steroid metabolism is influenced by sex, age, weight, and thyroid function. The *secretion rate* of a steroid refers to the total secretion of the compound from a gland per unit time.

Secretion rates have been assessed by sampling the venous effluent from a gland over time and subtracting out the arterial or peripheral venous hormone concentration. Although seemingly simple in concept, this procedure is quite challenging in practice. Much of the difficulty originates from the potential of the catheterization process to disturb gland function (e.g., endocrine changes resulting from the stress of the procedure) and the possibility of dilution or contamination from blood draining other glands. For example, the role of the postmenopausal ovary in androgen production has been challenged because of potential contamination of adrenal venous blood in ovarian venous samples.[116]

The *metabolic clearance rate* of a steroid is defined as the volume of blood that has been completely cleared of the hormone per unit time. The *whole-body metabolic clearance rate* is usually measured, reflecting the sum of clearance rates for each tissue or organ. Experimentally, this measurement is accomplished by infusion of an isotopically labeled steroid at a constant rate.[117] At equilibrium, the concentration of the infused steroid in peripheral venous blood is constant, and the rate of clearance from the blood equals the rate of entry. The metabolical clearance rate is calculated by dividing the infusion rate by the concentration of the steroid isotope in peripheral blood, giving the metabolical clearance rate in milliliters per day or liters per day.

Most of the circulating steroids are removed from blood by the liver. Hepatic blood flow in humans is approximately 1500 L/day, so metabolical clearance rates exceeding this level generally reflect extraction of steroids by other organs in addition to the liver. The lung, with its high rate of blood flow, is another potentially important site of C21 and C19 steroid metabolism.[118,119] In addition to the amount of sex hormone binding globulin (SHBG), and therefore the amount of bound steroid, obesity, irrespective of SHBG levels, increases the metabolical clearance rate. The uptake of steroids into the liver as well as other organs is highly influenced by their affinity for plasma steroid–binding proteins and albumin. Binding of steroid hormones SHBG and corticosteroid-binding globulin (CBG) reduces peripheral metabolism.[120,121] The binding of free steroids to albumin

Table 4.2 Blood Production Rates, Secretion Rates, Metabolical Clearance Rates, and Normal Serum Concentration of Sex Steroid Hormones

Steroid Hormone	Reproductive Phase	MCR (L/Day)	PR (mg/Day)	SR (mg/Day)	Reference Values
Men				*Testes*	
Androstenedione		2200	2.8	1.6	2.8-7.3 nmol/L
Testosterone		950	6.5	6.2	6.9-34.7 nmol/L
Estrone		2050	0.15	0.11	37-250 nmol/L
Estradiol		1600	0.06	0.05	<37-210 pmol/L
Estrone sulfate		167	0.08	Insignificant	600-2500 pmo/L
Women				*Ovary*	
Androstenedione		2000	3.2	2.8	3.1-12.2 nmol/L
Testosterone		500	0.19	0.06	0.7-2.8 nmol/L
Estrone	Follicular	2200	0.11	0.08	110-400 pmol/L
	Luteal	2200	0.26	0.15	310-660 pmol/L
	Postmenopausal	1610	0.04	Insignificant	22-230 pmol/L
Estradiol	Follicular	1200	0.09	0.08	<37-360 pmol/L
	Luteal	1200	0.25	0.24	699-1250 pmol/L
	Postmenopausal	910	0.006	Insignificant	<37-140 pmol/L
Estrone sulfate	Follicular	146	0.1	Insignificant	700-3600 pmol/L
	Luteal	146	0.18	Insignificant	1100-7300 pmol/L
Progesterone	Follicular	2100	2	1.7	0.3-3 nmol/L
	Luteal	2100	25	24	19-45 nmol/L

MCR, metabolic clearance rate; PR, production rate; SR, secretion rate.

is of relatively low affinity; consequently, metabolical clearance rates of albumin-bound unconjugated steroids are relatively high compared with those of hormones, such as testosterone and cortisol, which bind, respectively, to SHBG and CBG with high affinity.[122] Sulfoconjugated steroids are an exception because they bind tightly to albumin, and as a result, are cleared very slowly from the blood. Consequently, concentrations of sulfated steroids in blood are usually several-fold higher than their respective unconjugated forms. In contrast, steroid glucuronates are weakly bound to albumin and are rapidly cleared.

The *production rate* of a steroid hormone refers to entry into the blood of the compound from all possible sources, including secretion from glands and conversion of prohormones into the steroid of interest.[113] At steady state, the amount of hormone entering into the blood from all sources will be equal to the rate at which it is being cleared (metabolical clearance rate) multiplied by blood concentration (production rate = metabolic clearance rate × concentration). If there is little contribution of prohormone metabolism to the circulating pool of steroid, then the production rate will approximate the secretion rate.

The fraction of prohormone that is metabolized into the steroid of interest, known as the *rho (ϱ) value*, can be estimated by infusing an isotope of the prohormone at a constant rate until equilibrium is reached, then determining the blood concentrations of the unconjugated prohormone isotope and the isotopic product.[123] The amount of prohormone entering into the circulation can be calculated using the ϱ value and by the production rate.

Table 4.2 shows the secretion, production, and metabolical clearance rates of the major steroids, and Table 4.3 provides the ϱ values of selected sex steroid hormones. Note that there are some differences in these values between sexes and in the favored direction of interconversion, which reflects the integrated activities of the different 17β-hydroxysteroid dehydrogenases that selectively oxidize or reduce androgens and estrogens.

Table 4.3 Mean ϱ Values for Interconversion of Key Sex Steroid Hormones

Interconversion			ϱ Values: Female	ϱ Values: Male
Androstenedione	→	Testosterone	0.03	0.052
Testosterone	→	Androstenedione	0.122	0.076
Androstenedione	→	Estrone	0.007	0.0114
Testosterone	→	Estradiol	0.0014	0.0033
Estrone	→	Estradiol	0.041	0.05
Estradiol	→	Estrone	0.176	0.156

Plasma Steroid Hormone–Binding Proteins

Greater than 97% of the circulating fractions of testosterone, estradiol, cortisol, and progesterone are bound by plasma proteins of hepatic origin. SHBG and albumin bind testosterone and estradiol, whereas CBG and albumin bind cortisol and progesterone, and to a far lesser extent testosterone. High affinity binding of natural steroid hormones to SHBG requires a 17β-hydoxy group, and a 5α-hydrogen function. An olefinic bond in the A ring or an aromatic A ring reduces binding affinity. Consequently, testosterone has a greater affinity for SHBG than does estradiol; 65% and 78% of circulating testosterone is bound to SHBG in men and women, respectively, whereas only 30% and 58% of estradiol in men and women, respectively, is associated with SHBG. The remainder is mostly bound to albumin.

The protein-bound steroid hormone is generally considered a reservoir, restrained from free diffusion into cells, where it can act and can be metabolized. This notion is substantiated by the discovery of variants in the SHBG gene that include a missense mutation (Pro156Leu) that causes abnormal glycosylation and impaired secretion. Women with this

variant display symptoms of hyperandrogenemia, reflecting a greater proportion of bioavailable testosterone.[124]

Association studies and genome-wide linkage scans suggest that variation in plasma SHBG levels is influenced by polymorphisms in the *SHBG* gene, as well as several other genes at different loci in different ethnic groups.[125,126] Interestingly, the level of SHBG in plasma, as influenced by these polymorphisms, is associated with risk for developing type 2 diabetes mellitus with higher SHBG levels being protective. The molecular mechanisms underlying this association remain to be elucidated. [127]

Although SHBG is generally believed to reduce the entry of sex steroids into target tissues, it has been argued that the steroid bound to binding globulins may be selectively accumulated by some cell types by "receptors," and that target tissues also synthesize SHBG that acts locally to facilitate signal transduction by way of a cAMP mechanism.[128] However, there is no evidence for a specific SHBG receptor, suggesting that uptake of SHBG may be related to its binding to extracellular matrix elements of receptors for other proteins.

Because of the importance of plasma steroid–binding proteins in influencing the amount of bioavailable hormone, any genetic or physiological variation or pharmacologically induced change in the production of these proteins by the liver can have a significant effect on steroid hormone action and metabolism. The clinical evaluation of subjects with suspected disorders of hormone production or action may require an assessment of the level of binding protein or a measurement of the bioavailable or free fraction of hormone to clarify the basis for the clinical presentation. Conditions with increased SHBG levels are associated with increased free estradiol/testosterone ratios and those with reduced SHBG with decreased free estradiol to testosterone ratios. For example, suppression of SHBG levels associated with obesity, hyperinsulinemia and hyperglycemia contributes to the symptoms of hyperandrogenemia associated with polycystic ovary syndrome, which is frequently accompanied by these metabolical phenotypes. Table 4.4 summarizes changes in SHBG- and CBG-binding capacity under different physiological and pathophysiological conditions, as well as the influence of certain pharmacological agents.

The gene encoding vitamin D binding protein (GC) is polymorphic with alleles showing different population distributions that are associated with skin pigmentation. Binding protein levels are increased by estrogen and are unaffected by age or body mass index (BMI).

Table 4.4 Factors Influencing the Binding Capacity of Sex Hormone-Binding Globulin and Cortisol-Binding Globulin

	Binding Capacity	
Factors and Endocrine Status	*SHBG*	*CBG*
Exogenous estrogen	↑	↑
Pregnancy	↑	↑
Exogenous androgens	↓	↓
Anabolic steroids	↓	NC
Synthetic progestins (androgenic properties)	↓	NC
Thyroid hormone (hyperthyroidism)	↑	↓
Prolactin (hyperprolactinemia)	↓	NC
Growth hormone (acromegaly)	↓	NC
Old age (men)	↑	NC
Postmenopausal	↓	↓
Obesity	↓	NC
Hyperinsulinemia	↓	↓

CBG, Cortisol-binding globulin; NC, no change; SHBG, Sex hormone-binding globulin.

Inhibitors of Steroidogenic Enzymes

The inhibition of steroidogenic enzymes has been shown to be an effective strategy for terminating pregnancy and treating disorders of excessive hormone production (including Cushing's syndrome, steroid hormone–secreting malignancies, and hormone-dependent cancers of the prostate, endometrium, and breast). Inhibitors of aromatase are also used in the induction of ovulation. The inhibitors include steroid-based and non–steroid-based molecules that act as competitive inhibitors or mechanism-based enzyme poisons (Fig. 4-15).

Endocrine-disrupting chemicals, often believed to act through direct effects on steroid hormone receptors, are now known to interfere with steroidogenic enzymes and enzymes involved in steroid metabolism. These actions may alter endogenous steroid hormone production and catabolism and lead indirectly to altered responses of hormone-responsive target tissues.[129]

Inhibitors of P450scc

Aminoglutethimide, a drug originally introduced as an antiepileptic, is a non-steroidal competitive inhibitor of P450scc and P450arom.[130] The free amine of the drug (essential to the drug's inhibitory activity) interacts with the P450 heme to prevent reduction of Fe^{3+}, which is an obligatory step in the P450 catalytic mechanism. Ketoconazole and related compounds also inhibit P450scc as well as other P450bsteroidogenic enzymes.

P450c17 Inhibitors

Ketoconazole, an antifungal agent that blocks P450s involved in ergosterol biosynthesis, is an effective inhibitor of the 17,20-lyase activity and blocks androgen biosynthesis.[123] Other compounds that are used in experimental systems to block 17α-hydroxylase/17,20-lyase activity are too toxic for clinical application. Newer compounds, including the 17-heteroarylsteroids, abiraterone acetate, and VN/124-1 (TOK-001) ([3β]-17-[1H-benzimidazol-1-yl]androsta-5,16-dien-3-ol) are less toxic and are used in the treatment of "castration-resistant" prostate cancer.[131]

P450c11 Inhibitors

Metyrapone, an 11β-hydroxylase inhibitor, reduces cortisol production, with a concomitant increase in 11-deoxycortisol. It is used in diagnostic testing of the hypothalamic–pituitary–adrenal axis and has also been used to treat Cushing's syndrome, but its utility in this regard is limited by side effects.[132]

Aromatase Inhibitors

Two major classes of aromatase inhibitors have been developed, the nonsteroidal imidazole and triazole analogs

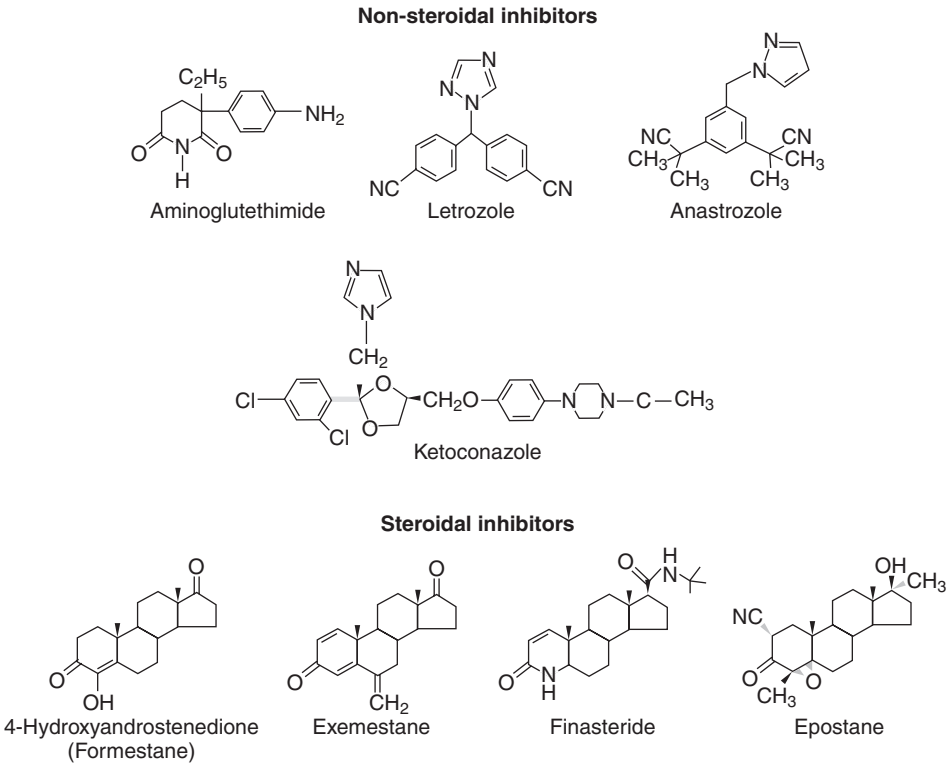

FIGURE 4.15 Structures of nonsteroidal and steroidal enzyme inhibitors.

based on ketoconazole, and the steroidal mechanism-based inactivators.[133] The first class of compounds is relatively nonspecific because they can inhibit other steroidogenic P450s. Two triazole compounds that are reversible competitive inhibitors of P450arom are in clinical use (letrozole [Femara] and anastrozole [Arimidex]). These drugs bind to the iron atom of the heme protein and exclude the substrate from the catalytic pocket.

The steroidal mechanism–based inhibitors include 4-hydroxyandrostenedione (formestane) and 6-methylandrosta-1,4-diene-3,17-dione (exemestane) (Fig. 4.15). They are fundamentally innocuous by themselves, but are activated by the catalytic mechanism of P450arom to produce electrophilic species, which then covalently modify the active site. Inactivation requires both NADPH and oxygen. Inhibition by these drugs is long-lasting because new aromatase must be synthesized to overcome the inactivation event. The mechanism-based inhibitors are selective because they only inactivate the target enzyme. In the case of 4-hydroxyandrostenedione, the ultimate electrophilic species responsible for enzyme inactivation is unknown.

5α-reductase Inhibitors

The 4-azasteroids represented by finasteride were developed as selective inhibitors of type 2 5α-reductase to prevent the formation of the potent androgen 5α-dihydrotestosterone.[134] These inhibitors contain a heterocyclic A ring with a nitrogen substitution at C4. The potent competitive inhibition of SRD5A2 (K_i = 3 nM) seen with finasteride was originally attributed to the ability of this compound to produce a mimetic of the enolate transition state. It is now evident that finasteride acts as a mechanism-based inactivator of 5α-reductase to form an isocitrate dehydrogenase (NADP+)–dihydrofinasteride bisubstrate analog with a K_i of 10^{-13} M (Fig. 4.16).

Other steroidal-based inhibitors include steroid acrylates, which contain a carboxylic acid substituent at C3. The carboxylate moiety again mimics the enolate transition state. Interestingly, these compounds are potent noncompetitive inhibitors because they form an abortive enzyme—NADP+–acrylate complex. Dual-enzyme 5α-reductase inhibitors (e.g., GI198745) that are under development can suppress dihydrotestosterone production by 99% 24 hours after oral administration.

3β–Hydroxysteroid Dehydrogenase/$\Delta^{5\text{-}4}$ Isomerase Inhibitors

Compounds originally developed to target 3β-HSD were derivatives of 2α-cyanoketone (2α-cyano-4,4,17α-trimethylandrost-5-en-17β-ol-3-one).[135] The subsequently developed compounds trilostane and epostane are relatively specific competitive inhibitors for blocking steroidogenesis in the adrenal cortex and placenta, respectively.[136]

HSD11B1 inhibitors

Inhibitors of HSD11B1, which prevent conversion of cortisone into cortisol, are being developed to treat type 2 diabetes, insulin resistance, dyslipidemia, and obesity.[137,138]

Other Enzyme Targets for Reducing Sex Steroid Production

Inhibition of HSD17B1, and steroid sulfatase is an approach to the reduction of bioavailable estradiol levels.[30,66,67,85] Tibolone, a drug used in Europe for hormone replacement

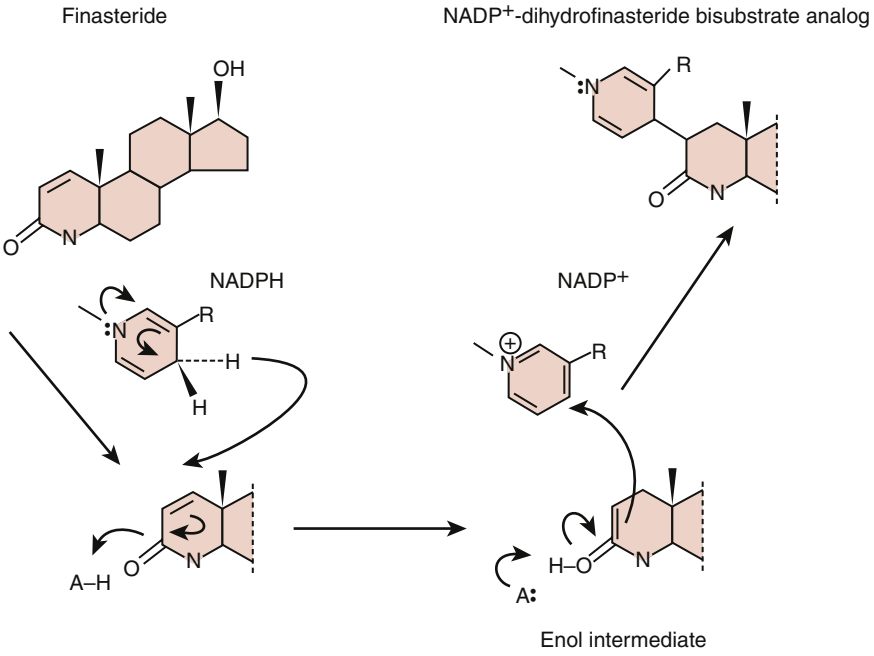

FIGURE 4.16 Inhibition of 5α-Reductase type 2 by finasteride. Finasteride is reduced by 5α-reductase via an enol intermediate, which then reacts with NADP+ to produce a NADP+–dihydrofinasteride bisubstrate analog, which is a potent enzyme inhibitor. NADP, nicotinamide adenine dinucleotide phosphate. *(Modified from Strauss JF III, Penning TM. Synthesis of the sex steroid hormones: molecular and structural biology with application to clinical practice. In Fauser BCJM, Rutherford AJ, Strauss JF III, et al [eds]. Molecular biology in reproductive medicine. New York, Parthenon, 1999, pp 201–232.)*

therapy, has the interesting property of inhibiting sulfatase activity in breast cancer cells, but not in bone cells, a tissue-selective pattern of action that could reduce estradiol bioavailability in breast, but not in bone.[139] As noted previously, hydroxylated metabolites of polychlorinated biphenyls are potent inhibitors of estrogen sulfotransferase and thus increase the bioavailability of estradiol.[81]

CHAPTER 5

Steroid Hormone Action

John M. Busillo
Turk Rhen
John A. Cidlowski

Steroid Hormone Receptors Act as Ligand-Dependent Transcription Factors or Repressors

Steroids are small, lipophilic hormones synthesized from a common precursor molecule, cholesterol, within the adrenal glands or the gonads (see Chapter 4). The adrenal cortex is the primary source of circulating mineralocorticoids and glucocorticoids, while the gonads are the main source of circulating active sex steroids called *estrogens*, *progestins*, and *androgens*. Despite their shared molecular origin and basic structural similarities, mineralocorticoids, glucocorticoids, estrogens, progestins, and androgens are distinct classes of steroid hormones that interact with specific, high affinity receptors to exert their biological effects. These hormones control diverse physiological and cellular processes and affect virtually every aspect of vertebrate biology, from sexual differentiation, growth, and reproduction to immunity, brain function, and behavior. Consequently, a clear and complete understanding of the basic mechanisms of steroid hormone action is of critical importance for reproductive health and general well-being. Also of significance are the unique mechanisms that lead to hormone-specific effects and function and to differences in hormone responsiveness between species.

This chapter reviews what is known about the mechanisms of steroid action. Briefly, the classic mode of action of steroid hormones is to enter cells, interact with cognate receptors, and stimulate or inhibit transcription of target genes (Fig. 5.1).[1] Hormone-dependent changes in receptor conformation ultimately influence transactivation and transrepression of gene expression by (1) disrupting interactions with molecular chaperones that keep the receptor in a ligand-independent state; (2) promoting the formation of receptor dimers; (3) promoting interactions with specific DNA sequences in the promoter of target genes; and (4) facilitating recruitment of coactivator or corepressor proteins that alter chromatin structure and contact the basal transcription machinery.

To fully understand the commonalities of steroid hormone action and appreciate the specificity of signaling by different classes of steroids, it is important to understand the evolution of receptors (mineralocorticoid [MR], glucocorticoid [GR], estrogen [ER], progestin [PR], and androgen [AR]) from a common ancestral protein. Next is a discussion of hormone-dependent activation and repression of gene expression and the physiological roles played by each of these receptors. This is followed by a discussion of general factors that influence steroid hormone action. Finally, the chapter examines more recent work, which has begun to elucidate alternative modes of action for steroid hormones and their receptors. Such mechanisms include interactions with other transcription factors and nongenomic effects mediated by second messenger signaling pathways.

Evolution of Steroid Hormone Receptor Structure and Function

Steroid receptors belong to a larger family of structurally and evolutionarily related proteins called *nuclear receptors*.[2-4] A bioinformatic analysis of the human genome identified 49 genes encoding for nuclear receptors, which appears to represent the total number of paralogs found in humans.[5] Paralogs are related genes found within a single genome that evolved by gene duplication. Through alternative splicing and alternative translation initiation, it is predicted that these 49 genes could result in 75 receptors in the human proteome.[5] Although a complete review of the nuclear receptor family of transcription factors is beyond the scope of this chapter, a brief discussion is in order.

All nuclear receptors, including steroid receptors, exhibit a modular structure composed of distinct domains (Fig. 5.2). In general, these receptors contain a variable amino-terminal region (A/B), a highly conserved DNA-binding region (C), a highly variable hinge region (D), and a moderately conserved hormone or ligand-binding domain (E). Some receptors also contain a carboxy-terminal F domain. The primary structure of each human steroid receptor is shown, along with its physiological ligand (Fig. 5.2). Specific residues within the DNA- (C) and ligand-binding (E) domains play an important part in receptor dimerization, which is critical because most nuclear receptors are only transcriptionally active as homo- or heterodimers. Finally, nuclear receptors have one or two regions called *activation function 1 and 2* (AF1 and AF2) that are required to transactivate gene expression. Whereas the activity of AF1 is usually ligand-independent and located in the A/B domain, AF2 is found in the ligand-binding domain and is predominantly regulated by hormone binding.

Some nuclear receptors have defined natural ligands, such as steroid hormones, thyroid hormones, retinoids, or vitamin D, but others have no identified ligand and are called *orphan receptors*. The finding that diverse compounds

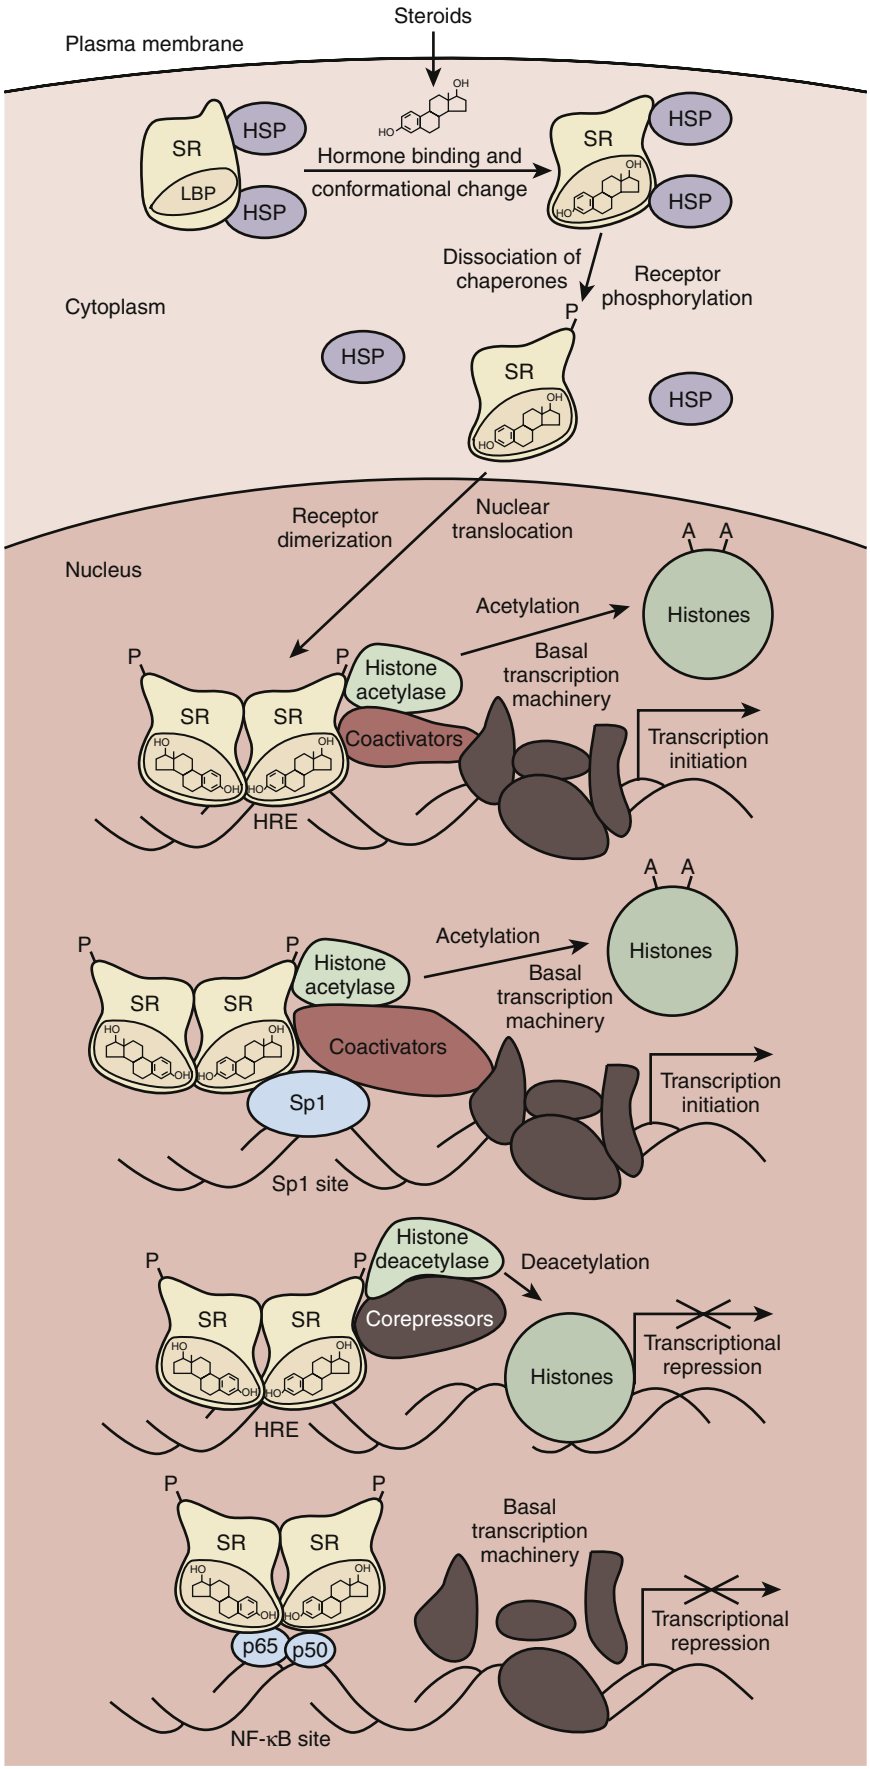

FIGURE 5.1 General mechanism of action for cytoplasmic steroid receptors as described in the text. The two subunits of nuclear factor kappa B are p50 and p65. A, acetyl group; HSP, heat shock protein; HRE, hormone response element; LBP, ligand-binding pocket; NF, nuclear factor; P, phosphate group; SR, steroid receptor.

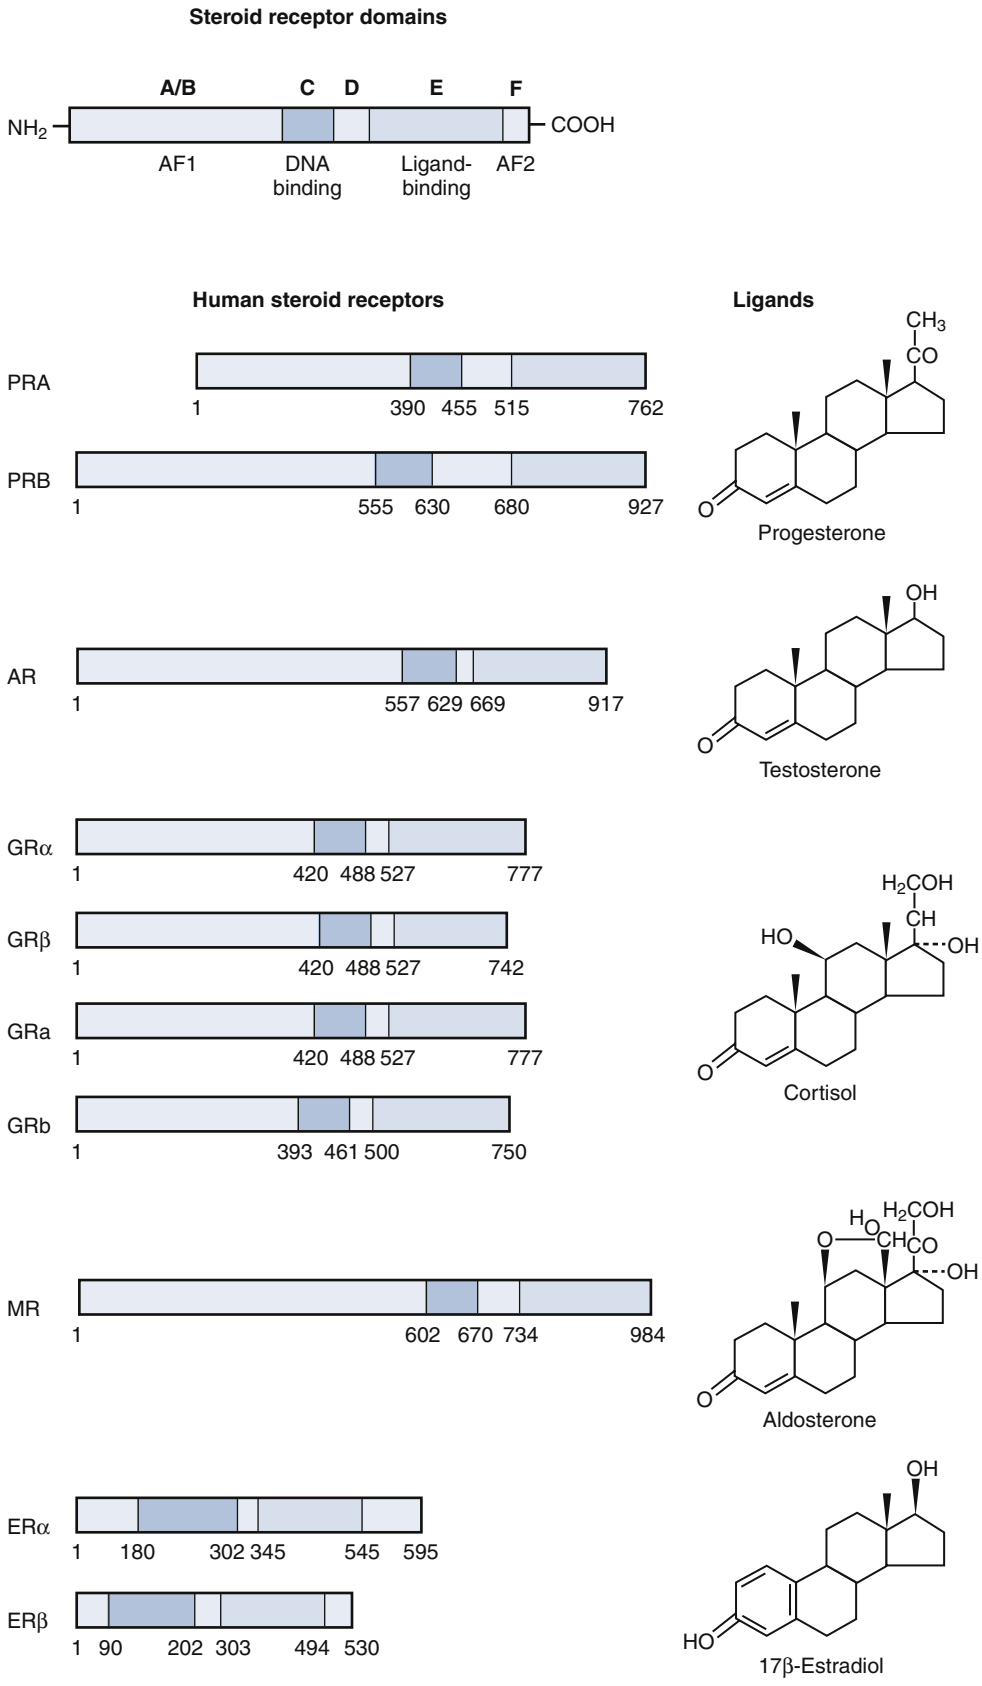

FIGURE 5.2 Schematic diagram of the primary structure of a generic steroid receptor and its functional domains. Region A/B contains transactivation function 1 domain (AF1). Region C contains the DNA-binding domain. Region D is the hinge region. Region E contains the ligand-binding domain. Region F contains the transactivation function 2 (AF2) domain. The primary structure of human steroid receptors, their isoforms, and their physiological ligands: AR, androgen receptor; ER, estrogen receptor; GR, glucocorticoid receptor; MR, mineralocorticoid receptor; PRA, progestin receptor isoform A; PRB progestin receptor receptor isoform B.

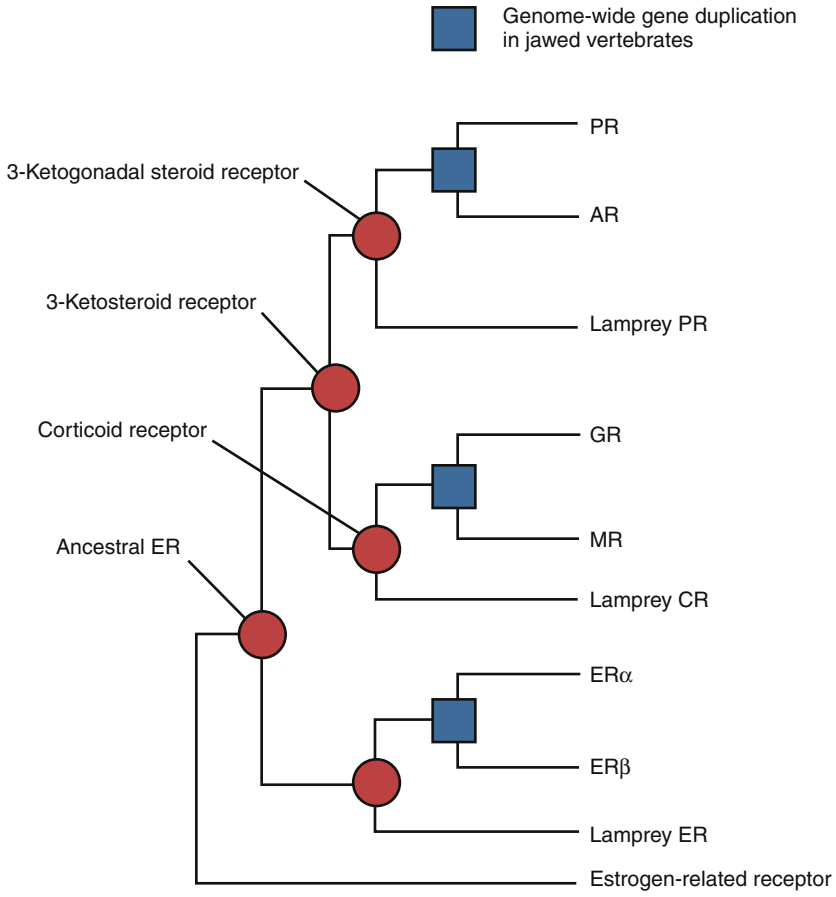

FIGURE 5.3 Phylogeny of the steroid receptor gene family. AR, androgen receptor; CR, corticoid receptor; ER, estrogen receptor; GR, glucocorticoid receptor; MR, mineralocorticoid receptor; PR progestin receptor.

act as ligands for nuclear receptors and that some receptors have no apparent ligand led to the hypothesis that ancestral nuclear receptors were constitutive transcription factors that independently evolved the ability to bind ligand.[6,7] However, a second hypothesis posits that ancestral receptors were ligand-dependent transcription factors that evolved specificity for different ligands by gene duplication, mutation, and functional divergence. There are several lines of evidence that favors the latter hypothesis for the evolution of ligand binding in the steroid receptor family. First, the primary, secondary, and tertiary structures of the ligand-binding domain of different steroid receptors are highly similar.[8-11] Second, detailed sequence, structural, and functional analyses strongly support the hypothesis that the ancestral steroid receptor bound estrogens and specificity for other steroids evolved by serial and parallel duplications of the ancestral gene, mutation of nucleotides coding for specific amino acids, and structural and functional divergence of the paralogs.[12-14] Finally, steroid hormone receptors are nuclear receptors unique to the chordate lineage, indicating that they originated when the first chordates evolved.

Gene Duplication of Ancestral Steroid Hormone Receptors

Phylogenetic analysis of the primary amino acid sequences of 73 steroid receptors from jawed vertebrates (e.g., fish, amphibians, reptiles, birds, and mammals) and a jawless fish (the sea lamprey) indicate that there were two serial duplications of an ancestral steroid receptor before the divergence of these lineages approximately 450 million years ago.[13] Maximum likelihood reconstructions of the ancestral amino acid sequence indicate that the first steroid receptor was probably an ER-like molecule (Fig. 5.3). After this gene was duplicated, one copy was constrained by natural selection and retained its function as an "estrogen receptor," whereas the other copy evolved specificity for 3-ketosteroid–like ligands (Fig. 5.3). Duplication of the latter gene then produced a corticoid receptor–like protein and a receptor for 3-ketogonadal steroid–like molecules (e.g., androgens, progestins, or both). Whereas these three steroid receptors (i.e., the ER, corticoid, and 3-ketogonadal steroid receptors) are present in the sea lamprey, six steroid receptors are present in fish and tetrapods, suggesting a genome-wide duplication in the last common ancestor of jawed vertebrates (indicated by blue boxes in Fig. 5.3).

This final duplication then led to the evolution of the true androgen and progesterone receptors from the ancestral 3-ketogonadal steroid receptor, glucocorticoid and mineralocorticoid receptors from the ancestral corticoid receptor, and ERα and ERβ from the ancestral estrogen receptor. The number of paralogs for other gene families, such as the homeobox *(Hox)* genes, supports the hypothesis that many genes were duplicated in parallel in the ancestor of jawed vertebrates.

Structural and Functional Divergence of Steroid Hormone Receptors

Experiments deleting large regions of different steroid receptors have clearly shown that domain C is responsible for

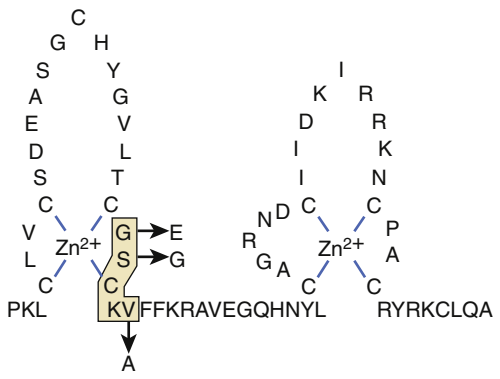

FIGURE 5.4 Amino acid sequence of the DNA-binding domain of human glucocorticoid receptor showing two zinc fingers and the P box, which is outlined. The three mutant residues that change glucocorticoid receptor binding specificity from glucocorticoid-responsive element and estrogen-responsive element are indicated by the *arrows*.

DNA binding and that domain E is responsible for ligand binding (Fig. 5.2). Furthermore, swapping the entire ligand-binding domain among different receptors show that this region determines specificity for particular classes of steroid hormone. Nevertheless, crystal structures of various steroid hormone receptors show that all ligand-binding domains fold into a highly homologous three-layered structure with a small ligand-binding pocket in the center. This pocket is composed of roughly 30 amino acids that are in close proximity or make direct contact with hormones when bound to their cognate receptors. In agreement with structural studies, experiments using site-directed mutagenesis indicate that specific, but minor, changes of amino acids within the ligand-binding pocket can lead to dramatic changes in the hormone-binding specificity of steroid receptors. For example, the human PR, GR, and MR contain a conserved cysteine residue that appears to be critical for contacting the C20 keto group found in progestins, glucocorticoids, and mineralocorticoids.[13,15] Mutation of the corresponding threonine to cysteine in the AR reduces its affinity for androgens and allows the receptor to transactivate gene expression in the presence of progesterone and corticoids.[16] Based on structure-function studies of this sort and phylogenetic analyses, Thornton[13] proposed a series of relatively minor amino acid changes that may account for broad changes in hormone specificity during the evolution of steroid receptors.

Similar studies of the DNA-binding domain have defined the molecular basis for interactions between steroid receptors and particular DNA sequences.[17,18] The DNA-binding domain of nuclear receptors contains two zinc fingers. The first finger interacts with the major groove of DNA, whereas the second is involved in receptor dimerization. Mutation of three residues within a five residue motif known as the Proximal box *(P box)* of the first zinc finger of the GR to the corresponding residues in ER changes the binding specificity from DNA sequences called *glucocorticoid-responsive* elements to *estrogen-responsive* elements and vice versa (Fig. 5.4). Although the DNA-binding domain is very highly conserved among nuclear receptors, these residues are variable among different receptors, which may in part account for receptor-specific regulation of distinct sets of genes. These examples illustrate that site-directed mutagenesis and fine-scale comparison of amino acid sequences among receptors, in the context of the tertiary structure of the DNA- and ligand-binding domains, can lead to testable hypotheses about the evolution of signaling and regulation of gene expression by different classes of steroids.[19]

Activation and Repression of Gene Expression

Given this background on the evolution of different steroid receptors, we now focus on the general function of these receptors and the activation and repression of gene expression by each class of steroid hormone. Steroid receptors have taken on more or less distinct physiological roles during evolution. ERα, ERβ, PR, and AR are primarily involved in sexual differentiation and reproduction. Estrogens and progestins are essential for normal female development and reproduction. Androgens are involved in various aspects of male reproductive physiology and development. Although androgens, estrogens, and progestins are sex-typical hormones, they are not sex-limited, and they play a physiological role in both sexes. In contrast, GR and MR principally regulate nonreproductive traits, although glucocorticoids have recently been implicated in general reproductive function.[20] Glucocorticoids are considered stress hormones that control the function of many tissues, whereas mineralocorticoids play a more restricted role in regulating electrolyte balance and a few other traits. Despite the general separation of these functions, each class of steroid can also modulate the action of other steroids. Cross-talk among steroid hormones is therefore an important subject that will be addressed subsequently.

Estrogen Receptor

The biological effects of estrogens were believed to be mediated by a single receptor (i.e., ERα) until the cloning of a second receptor (i.e., ERβ); both receptors, ERα and ERβ, are products of different genes.[21] Subsequently, it has been shown that these two receptors play distinctive roles in estrogen signaling and that the genes encoding ERα and ERβ are differentially expressed in different tissues (Table 5.1).[22,23] Although both ERα and ERβ are required for normal ovarian function, the phenotypes of ERα and ERβ knockout mice are dissimilar. The ERα knockout mouse is anovulatory and accumulates cystic follicles, whereas the ERβ knockout mouse contains histologically normal ovaries, but still display impaired ovulation. Based on the available evidence, it appears that ERα bears much of the load for mediating the effects of estrogen in other tissues of both sexes. For instance, only ERα is required for the effects of estrogen on growth and differentiation of the uterus and mammary gland development. In males, knocking out ERα results in infertility, whereas males lacking ERβ reproduce normally. Despite the fact that both ERα and ERβ bind natural estrogens with similar affinity (Table 5.2),[22] in vitro studies have identified that their unique amino terminal (A/B) domain is responsible for the observed functional differences between the receptors.

A number of estrogen-regulated genes have been identified in the uterus. Lactoferrin is strongly induced by

estrogen and is commonly used as a marker for the effects of estrogen in the uterus. However, the functional role that lactoferrin plays in the uterus is currently unknown.[24] Estrogens enhance insulin-like growth factor 1 (IGF-1) signaling by inducing the expression of IGF-1 and down-regulating IGF binding proteins 3 and 5, resulting in the proliferation of uterine epithelial cells. Estrogen also induces the expression of the glycoprotein mucin 1 (Muc-1), which plays a role in blastocyst attachment and provides a barrier against uterine infections.[25,26]

In addition to their normal role in regulating uterine function, estrogens are a risk factor for the initiation and progression of breast cancer. Moreover, ER antagonists slow or stop the growth of breast cancer by blocking estrogen-regulated gene expression. The carcinogenic effects of estrogen in breast tissue may, in part, be mediated by the induction of vascular endothelial growth factor (VEGF),[27] as tumor growth is generally dependent on angiogenesis and a steady blood supply. Interestingly, the breast cancer susceptibility gene *(BRCA1)*, can directly interact with ER and block the induction of VEGF. Mutations that inactivate *BRCA1* and confer increased risk for breast cancer, may be due to a loss of the ability to antagonize the actions of estrogen.

Somatic mutations and genetic polymorphisms in the human ER itself are also associated with various disease states. An adult male without functional ERα (i.e., the mutation produces a premature stop codon) had decreased bone mineral density, signs of increased bone turnover, and incomplete closure of bone epiphyses, indicating that estrogens (and ERα) play an important role in bone growth and homeostasis in humans.[28] This finding is in general accord with studies of male ERα knockout mice, which have decreased bone mineral density. While genetic polymorphisms within ER have been associated with increased risk of osteoporosis in humans, the underlying mechanisms responsible for these associations are not clear (reviewed in Gennari et al.[29]). A number of ER mutations have been detected in breast cancer.[30] For example, deletion of exon 5, which falls within the ligand-binding domain, generated a receptor that was constitutively active in the absence of estrogens. Deletion of exon 7, which also falls within the ligand-binding domain, produced a receptor that displayed dominant negative activity when co-expressed with wild-type ER. Additional mutations, including base pair insertions and deletions or that result from alternative splicing result in deletion of other exons and alter signaling through the ER. However, it is not currently known whether the mutations occurred before or after the development of malignancy.

Progesterone Receptor

Like estrogens, progestins have broad effects, including the establishment and maintenance of pregnancy, regulation of mammary gland development, control of ovulation, and regulation of female reproductive behavior. Interestingly, the PR has two isoforms, "PRA" and "PRB," which are derived from the same gene. PRA and PRB are identical except for an additional 164 amino acids at the amino-terminal end of PRB due to an alternative translation initiation site. Female mice with a targeted disruption of the PR gene (i.e., both A and B isoforms are inactive) are unresponsive to progesterone, strongly indicating that the pleiotropic effects of progestins are mediated by the PR.[31] In contrast to females, male mice that lack a functional PR appear normal and are able to reproduce as well as wild-type males. Analyses of PRA and PRB activity using transient transfection assays have shown that the two isoforms have distinct transcriptional activities within the same promoter and are each able

to recognize unique promoters. Whereas PRB is a transcriptional activator in most promoter contexts and cell types, PRA appears to have promoter and cell-specific effects on progestin target genes, as well as inhibiting PRB action in contexts where PRA alone is inactive.

Mice with targeted deletion of either PRA or PRB has led to an initial characterization of the specific roles of each PR isoform in different tissues *in vivo*.[32] PRA is required for uterine development and reproduction, whereas PRB is required for normal development of the mammary gland. However, transgenic mice carrying an extra copy of PRA have abnormal morphological development of mammary glands.[33] These results suggest that overexpression of PRA, or an increased ratio of PRA:PRB, can have important physiological consequences. Although the ratio of PRA:PRB changes during development and as a function of reproductive stage in different tissues,[34,35] it remains to be determined whether these changes influence progesterone signaling. A third potential PR isoform, "PRC," has also been cloned and appears to result from translation initiation at a downstream methionine.[36] Although PRC lacks the first zinc finger in the DNA-binding domain, it modulates the transcriptional activity of PRA and PRB on a reporter gene.

In accord with the finding that PRB is necessary for full differentiation and branching of the mammary ducts, progesterone has also been shown to regulate a number of genes that may be involved in breast cancer.[37] The PROGINS allele of PR, characterized by an Alu insertion in intron G, is linked to mutations in exons 4 and 5 that increase the stability and transcriptional activity of the receptor *in vitro*. Interestingly, there is epidemiological evidence that individuals carrying the PROGINS allele have reduced risk of breast cancer,[38] while it was found at a higher frequency in patients with ovarian cancer.[39] Subsequent work confirmed an association of this polymorphism with increased risk of ovarian cancer, but only in women who had not used oral contraceptives.[40]

In the uterus, progesterone up-regulates expression of regulators of cell cycle progression, growth factors and their receptors, while repressing cell cycle arrest proteins.[41] Localized suppression of the immune system in both nonpregnant females and during gestation of the semi-allogenic embryo is another essential role played by progesterone and PR. While it is not known which genes are involved in nonpregnant females, the down-regulation of regulated on activation, normal T cell expressed and secreted (RANTES) in the endometrial stromal cells may be involved during pregnancy.[42] The induction of osteopontin and the repression of the oxytocin receptor are two other key genes regulated by progesterone because of their role in uterine physiology and partuition.[43,44]

Androgen Receptor

Androgens produced by the testes during and after the sex-determining period coordinate the development and differentiation of many sexually dimorphic tissues by specifically activating the AR.[45] Only one isoform of the AR has been recognized to date. Testosterone produced by Leydig cells in embryonic testes directs the development of the male external genitalia, vas deferens, and related structures from the wolffian ducts. Evidence indicates that the early surge in testosterone also directs male-typical patterns of neural development and behavior that are expressed later in life. In the absence of androgens and in AR knockout mice, the wolffian ducts regress and female external genitalia develop.[46] Likewise, mutations in the human AR can lead to complete androgen insensitivity and development of female genitalia or partial androgen insensitivity and ambiguous genitalia. Given the readily observed phenotype, a large number of AR mutations have been described.[47,48] For example, mutations that substitutes a proline at residues 689 and 865 greatly reduces or eliminates dihydrotestosterone binding and abolishes androgen-dependent transactivation.[49,50] It is interesting to note that different mutations at a given residue can generate different phenotypes. Substitution of threonine for methionine at residue 807 produces partial androgen insensitivity and ambiguous genitalia by reducing but not completely blocking androgen binding to AR. In contrast, arginine or valine substitutions at the same site totally abrogate androgen binding and produce complete androgen insensitivity syndrome.[51]

Androgens are secreted at low levels in immature males, but are again produced at high levels later in development (i.e., at puberty and in sexually mature males). At this point, androgens govern the development of secondary sexual characteristics, activate male reproductive and aggressive behavior, and allow spermatogenesis. Meiosis in germ cells begins at puberty in males and is continuous thereafter. The rate of programmed cell death (or apoptosis) in germ cells during spermatogenesis has a large influence on sperm output and male fertility. Androgens play an important role as a survival factor because testosterone withdrawal from mature males increases germ cell apoptosis.[52] *Bax*, a well-known proapoptotic gene, could be involved in germ cell death as it is elevated upon testosterone withdrawal.[53] Evidence suggests that the Fas pathway may also play a role in germ cell apoptosis as both Fas ligand and Fas receptor are expressed at elevated levels in dying germ cells. Androgens regulate prostate development and differentiation in the embryo and the adult and are believed to be a risk factor for prostate cancer in humans. Treatment of prostate cells with dihydrotestoterone induces changes in cell morphology and regulates a large number of genes involved in small molecule transport, membrane signal transduction, intracellular signal transduction, and metabolism.[54]

Other important aspects of AR function relate to physiological differences in signaling by different androgens.[55] In particular, dihydrotestosterone is a more potent androgen than testosterone, leading to greater stabilization of the receptor and more efficient signaling. Local conversion of testosterone to dihydrotestosterone to enhance androgen action is discussed in another section of this chapter.

Glucocorticoid Receptor

Glucocorticoids are often referred to as *stress hormones* because they are synthesized and secreted in response to pain and emotional trauma, caloric restriction, agonistic social encounters, and general anxiety. Mice homozygous for a null mutation in the GR (i.e., GR knockouts) die around the time of birth, indicating that the GR and glucocorticoids are essential for life.[56] In humans, there are at least nine GR isoforms produced from a single gene. Whereas GRα and GRβ are produced by alternative splicing at the 3´ end of GR mRNA, GR-A, GR-B, GR-C1-3, and GR-D1-3

are produced by alternative translation initiation at the 5′ end of GR mRNA.[57] Glucocorticoids alter the physiology of numerous tissues throughout the body during periods of acute stress. For example, the inhibitory effects of stress on reproduction are mediated by glucocorticoids at all levels of the hypothalamic–pituitary–gonadal axis. These hormones also influence brain function and behavior. Glucocorticoids mobilize energy stores by inducing the degradation of proteins to free amino acids in muscle, lipolysis in adipose tissue, and gluconeogenesis in the liver. Glucocorticoids play a role in the immune and vascular systems, where they induce programmed cell death in lymphocytes and block inflammatory responses. Although these changes are adaptive in the short term, chronic stress accompanied by prolonged glucocorticoid secretion is pathological.

In addition to mediating stress responses, glucocorticoids play an essential part in normal physiology. For example, glucocorticoids regulate the expression of numerous genes involved in energy homeostasis. The expression of phosphoenolpyruvate carboxykinase *(PEPCK)*, is induced by glucocorticoids and is enhanced by the glucocorticoid-dependent increase in the transcriptional coactivator peroxisome proliferator-activated receptor gamma coactivator 1 (PGC-1) in the liver.[58,59] It has been reported that glucocorticoids also increase pyruvate dehydrogenase kinase 4 levels,[60] which phosphorylates and inactivates the pyruvate dehydrogenase complex (PDC). In turn, PDC inactivation promotes gluconeogenesis by conserving three-carbon substrates. Glucocorticoids regulate the expression of genes related to other physiological processes as well. For example, the well-known anti-inflammatory effects of glucocorticoids are mediated in part by induction of the gene for inhibitor of nuclear factor kappa B alpha (IκBα), which keeps the proinflammatory transcription factor nuclear factor kappa B (NF-κB) in an inactive state in the cytoplasm.

Mineralocorticoid Receptor

Aldosterone, the major circulating mineralocorticoid, specifically binds to and activates the MR. In contrast, cortisol (or corticosterone in rodents) binds to and activates both the MR and GR. To prevent inappropriate MR activation by glucocorticoids, 11β-hydroxysteroid dehydrogenase converts cortisol (or corticosterone) to inactive metabolites in cells containing MR (discussed in detail in Chapter 4). One critical function of aldosterone is to regulate electrolyte balance and blood pressure. Aldosterone's primary target tissue is the distal tubule of the kidney, where it promotes the retention of Na^+ and the elimination of K^+ during urine formation. Retention of Na^+ leads to absorption of water from the distal tubules, an increase in blood volume, and maintenance of blood pressure. Mineralocorticoid insufficiency causes death by Na^+ and water loss, a fall in blood volume, and circulatory shock. Accordingly, MR knockout mice also die of Na^+ and water loss.[61] On the other hand, mineralocorticoid excess contributes to hypertension and pathologies associated with high blood pressure. Additional targets of aldosterone include the heart, brain, smooth muscle, endothelial cells, and adipose tissue, although less is known regarding the cellular and molecular mechanisms of mineralocorticoids in these tissues.

Work has identified several mineralocorticoid-induced genes involved in Na^+ resorption in tight epithelia.[62,63] Aldosterone, for example, increases both the mRNA and protein of serum- and glucocorticoid-regulated kinase (Sgk), activating the phosphatidylinositol-3-OH kinase (PI3K) pathway, stabilizing the epithelial Na^+ channel (ENaC) in an open state as well as increasing the number of ENaCs in the apical membrane. It is also important to note that aldosterone induces the α subunit of ENaC and the α_1 subunit of the sodium/potassium ATPase pump (Na+/K+-ATPase) by the classic transcriptional mechanism attributed to steroid hormones, which is critical for generating the electrochemical gradient necessary for Na^+ resorption at the apical membrane. Aldosterone also induces the expression of the Na+/H+ transporter and numerous other genes that may play a role in electrolyte balance. The role of genes repressed by aldosterone, however, remains unclear.[63] Given this background on the function of different steroid receptors and a few genes regulated by these receptors, we will now focus on commonalities of steroid hormone action that were most likely present in the ancestral steroid receptor.

General Factors That Influence Steroid Hormone Action

Although numerous factors affect signaling by steroid hormones *in vivo*, this chapter focuses on some of the more important and well-characterized regulatory mechanisms. Foremost among the factors determining whether a cell responds to circulating steroid hormones is the intracellular availability of a given steroid and its receptor. Intracellular enzymes metabolize active steroids to inactive forms or vice versa, providing preemptory control over steroid hormone action (see Chapter 4). The number of receptors within a cell also determines its responsiveness to hormone, with regulation of receptor expression at all levels from transcription to protein degradation. When sufficient hormone and receptor are present in a cell, the ligand binds and activates the monomeric receptor (Fig. 5.1). The ligand-bound receptor undergoes a conformational change, dissociates from regulatory heat shock proteins, and is phosphorylated. Cytoplasmic receptors translocate to the nucleus, where they bind as homodimers to specific DNA sequences called *hormone-responsive elements*. The MR, GR, PR, and AR are predominantly cytoplasmic in the absence of ligand. In contrast, ERα and ERβ are localized in the nucleus in the absence of ligand and do not require nuclear translocation for their transcriptional activity. Within the nucleus, the ligand–receptor complex interacts with coactivator and corepressor proteins that remodel chromatin or contact the basal transcription machinery, thereby increasing or decreasing the probability of initiation of transcription. Although we discuss basic regulatory mechanisms at each step in the dynamic process just outlined, the reader is referred to primary research and review articles that treat each mechanism in greater detail.

Hormone Availability

Intracellular enzymes can activate or inactivate steroid hormones to produce tissue-specific or even cell-specific patterns of hormone responsiveness. Aromatase P450, which converts androgens to estrogens, is expressed in the gonads, brain, adipose tissue, skin, and placenta.[64] In most female mammals, the circulating levels of estrogen varies during the

menstrual or estrous cycle. At the nadir of the cycle, circulating estrogen levels are usually below the concentration necessary to activate ER. In contrast, estrogen levels at the peak of the cycle are generally high enough to activate the ER. Consequently, the synthesis and secretion of estrogens from the ovary into general circulation is the main mechanism controlling estrogen action in females. Whereas males have plasma levels of estrogens that are below the concentration necessary to activate ER, they still require estrogen for normal reproductive function and behavior, as demonstrated by ERα knockout mice.[65,66] Therefore, it would seem that the expression of male copulatory behavior in a variety of vertebrates depends on the local conversion of testosterone to 17β-estradiol by aromatase and subsequent activation of ER within the medial preoptic area of the brain.[67,68]

Similarly, localized expression of 5α-reductase, which converts testosterone to dihydrotestosterone, plays a crucial role in regulating androgen action.[69] This reaction is particularly important because dihydrotestosterone binds to the AR with higher affinity than does testosterone and is essential for full virilization of the external genitalia during male development. Interestingly, female knockout mice for type 1 5α-reductase show significant impairment of parturition, suggesting that androgens also play an important role in female reproductive physiology.[70] In general accord with this finding, female knockout mice for AR have smaller litter sizes than wild-type littermates.[46]

In yet another example of steroid-metabolizing enzymes regulating steroid hormone action, two isoforms of 11β-hydroxysteroid dehydrogenase (11β-HSD) oppose each other's action and regulate local levels of active and inactive glucocorticoids (see Chapter 4).[71] Whereas 11β-HSD type 1 is a reductase that converts weak glucocorticoids (i.e., cortisone and 11-deoxycorticosterone) into potent glucocorticoids (i.e., cortisol and corticosterone), 11β-HSD type 2 is a dehydrogenase that catalyzes the reverse reaction to inactivate the more potent glucocorticoids. Clinical and experimental evidence suggests that the relative activity of these enzymes in particular tissues may play an important role in normal glucocorticoid physiology and pathophysiology. These examples illustrate how local biosynthesis or inactivation of steroid hormones can facilitate or inhibit steroid hormone action in a tissue- or cell-specific manner.

Receptor Expression

All other factors being equal, the level of expression of steroid receptors is a major factor regulating steroid hormone action. Whereas certain cells or tissues are insensitive to steroid hormones because they lack the appropriate receptors, other cells and tissues express large numbers of receptors and are exquisitely sensitive to low concentrations of hormones. In addition, hormone responsiveness is often modulated by up- or down-regulation of steroid receptors. One of the best-characterized mechanisms of sensitization is induction of PR gene expression by estrogens. During the ovarian cycle in the rat, 17β-estradiol concentrations slowly rise as ovulation approaches, and 4 hours before ovulation, progesterone concentrations surge.[72] These changes in hormone levels lead to biochemical changes in neurons of the ventromedial hypothalamus that facilitate the display of female sexual behavior. The surge in 17β-estradiol activates the ER and increases transcription and subsequent translation of the PR gene, thereby sensitizing the ventromedial hypothalamus to the subsequent surge in progesterone.[72,73] Essentially the same pattern and mechanism of PR induction by estrogens occurs in stromal cells of the uterus, priming these cells for decidualization in response to progesterone and the implanting blastocyst.[74] Another uterine cell type, the luminal epithelium, displays the opposite pattern of PR expression during the reproductive cycle.[75] Uterine epithelial cells express PR constitutively and rapidly down-regulate PR in response to estrogens. However, the mechanism responsible for this decrease in PR protein is currently unknown. It is also unclear whether PR down-regulation leads to hormone desensitization in these cells.

Changes in mRNA stability provide a second mechanism for regulating the levels of receptor expression in tissues. The preovulatory surge in luteinizing hormone (LH) decreases levels of ERβ mRNA in granulosa cells of rat preovulatory follicles.[76] This decrease in ERβ mRNA is due to a decrease in the half-life of the message from approximately 18 to 5 hours, rather than a decrease in transcription of the ERβ gene. Moreover, the LH-induced decline in steady-state levels of ERβ mRNA is mimicked by forskolin, indicating that LH signaling occurs through the activation of adenylyl cyclase and the generation of cyclic AMP (cAMP). Interestingly, a similar effect was also seen with the protein kinase C (PKC) activator phorbol myristoyl acetate (PMA). The stability of ERα mRNA is also regulated in the Michigan Cancer Foundation-7 (MCF-7) breast cancer cell immortalized line. In these cells, 17β-estradiol decreases the half-life of ERα mRNA from 4 hours to 40 minutes by increasing the ribonuclease activity associated with polyribosomes.[77] In contrast, 17β-estradiol up-regulates ERα mRNA in the endometrium by selectively increasing message half-life from 9 to 24 hours.[78] These studies demonstrate hormone- and tissue-specific effects on the stability of steroid receptor mRNA.

Another well-established mechanism for steroid receptor regulation occurs at the protein level. Treatment with a given steroid generally results in a time-dependent decrease in the level of its cognate receptor in a process called *homologous down-regulation*. Accordingly, a decrease in receptor levels usually results in desensitization to subsequent treatment with the same steroid. Receptor degradation occurs by targeting of the receptor into the ubiquitin–proteasome pathway. The effects of proteasome inhibition on steroid hormone action clearly need further study because there are paradoxical effects on receptor levels and receptor function. Whereas GR accumulation by proteasome inhibition leads to increased transcriptional activity of the receptor, proteasome inhibition of ER and PR degradation results in a decrease in hormone-induced transcription.[79,80] In sum, regulation of steroid receptor expression occurs at multiple levels from gene transcription to mRNA stability to degradation of the mature protein (Fig. 5.5).

Hormone Binding and Changes in Receptor Conformation

Various lines of evidence show that ligand-induced changes in steroid receptor conformation play a central role in transduction of the hormonal signal into a transcriptional response. Early studies, for example, found that trypsin digestion produced different patterns of cleavage for inactive and active

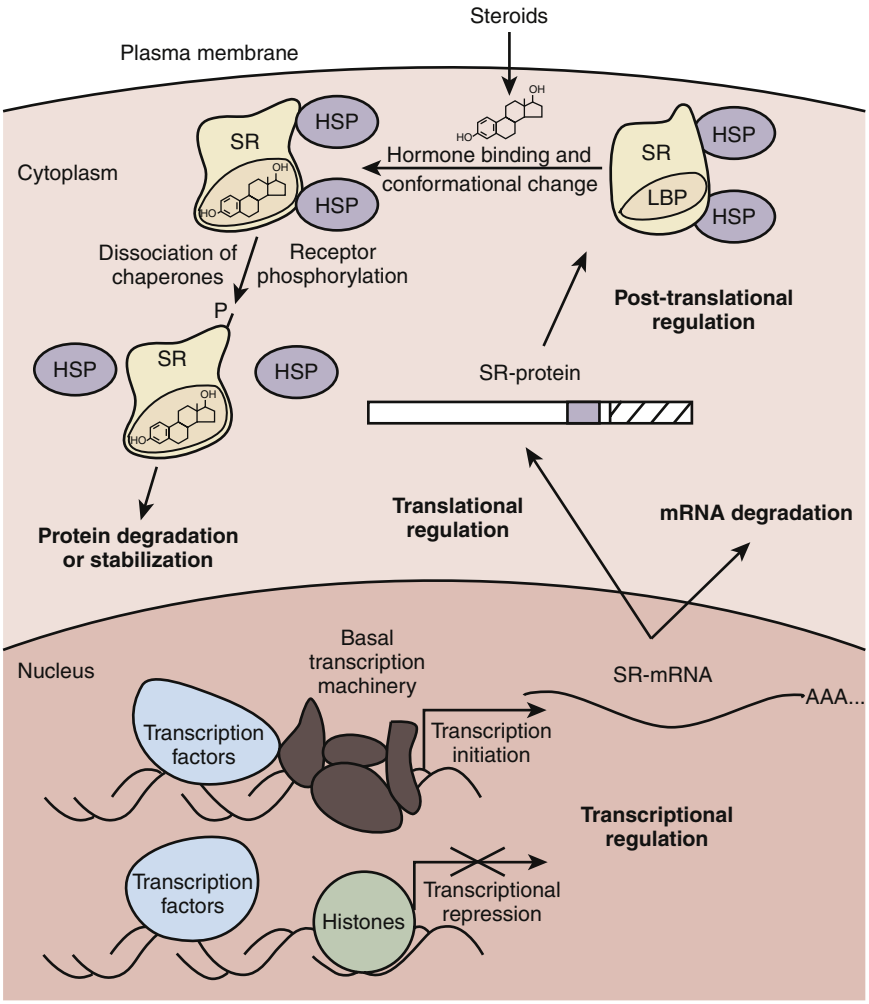

FIGURE 5.5 Schematic diagram showing levels of regulation of steroid receptor expression. AAA, polyadenylated mRNA tail; HSP, heat shock protein; LBP, ligand-binding pocket; mRNA, messenger RNA; SR, steroid receptor.

(i.e., ligand-bound) receptors, suggesting that binding of ligand to receptor caused conformational changes that either concealed or revealed trypsin cleavage sites. Other experiments found that protein to protein interactions between steroid receptors and heat shock proteins were disrupted by the addition of ligand. This result could also be explained by ligand-induced conformational changes that disturb putative contact sites between these proteins. Release of molecular chaperones is critical for receptor activation. Recent work verified inferences about receptor conformation by directly examining the crystal structure of the ligand-binding domain of the AR, ER, PR, and GR, either alone or in complex with ligand.[11,81-83] In particular, these studies showed that the ligand-binding domain is composed of 12 alpha helixes and 4 beta strands folded into a three-layered sandwich (Fig. 5.6). It was also shown that steroid hormones bind within a hydrophobic pocket in the core of the ligand-binding domain and that there are substantial structural differences between ligand-free and ligand-bound receptors.

One of these structural differences provides a basis for the ligand-induced increase in AF-2 activity. The C-terminal helix 12 moves like a trap door to close behind the ligand as it enters the hormone-binding pocket. The new position of helix 12, which contains AF-2, allows the receptor to interact with proteins called *coactivators* that are required for ligand-dependent transcription (Fig. 5.6). Although hormone antagonists bind the same site as agonists, they induce a different receptor conformation (Fig. 5.6). In general, antagonists have a bulky side chain that sticks out of the ligand-binding pocket and prevents movement of helix 12 into a position favorable for coactivator recruitment. Conformational changes are also important for a number of other aspects of steroid hormone action, including cooperativity for hormone binding and receptor dimerization. *Cooperativity* simply means that binding of hormone to a monomeric receptor facilitates binding of hormone to a second receptor, presumably through receptor dimerization.

Steroids have been found to have opposing effects in different tissues in postmenopausal women undergoing hormone replacement therapy (i.e., reduced risk of colorectal cancer and hip fractures, but increased risk of coronary heart disease, pulmonary embolism, stroke, and breast cancer).[84] The finding that combined estrogen and progestin therapy can have beneficial effects in some tissues and harmful effects in others highlights the importance of designing new ligands that dissociate these effects. Selective ER modulators (SERMs) are compounds that have been developed to retain the beneficial effects of estrogens while eliminating unwanted side effects. Raloxifene and tamoxifen are two of the best-characterized ligands in this regard, having been crystalized in complex with ERα.[85-87] Raloxifene acts as an estrogen agonist in bone by increasing bone mineral density and decreasing

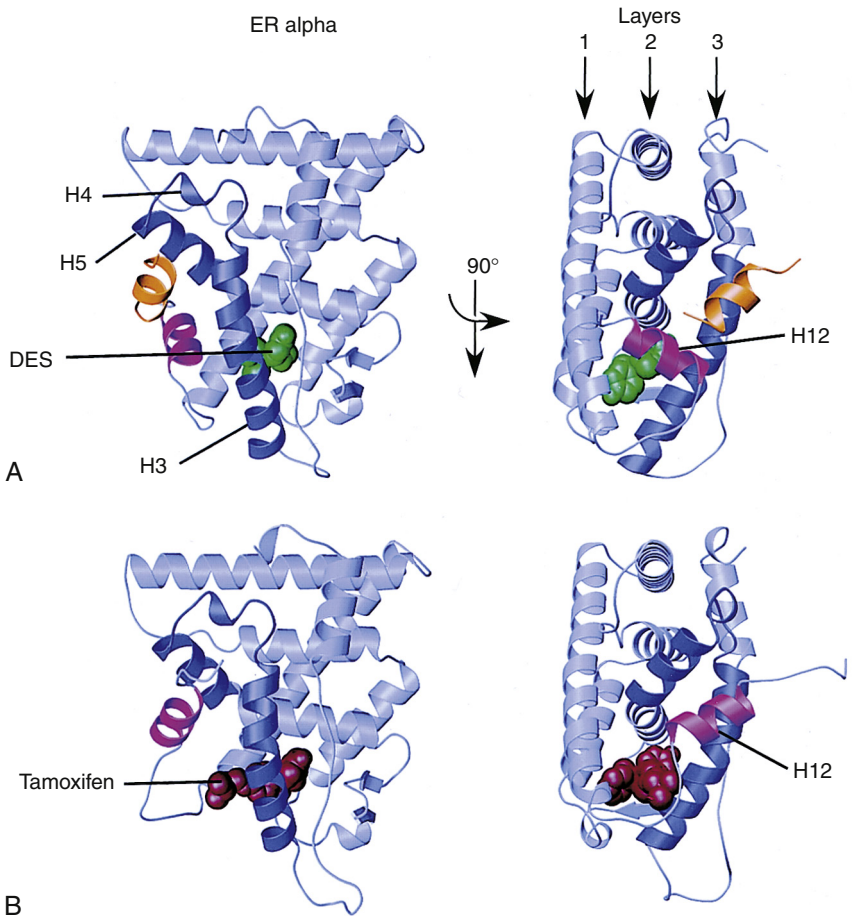

FIGURE 5.6 **A,** Structure of the ERα ligand-binding domain (LBD) bound to diethylstilbestrol (DES; *green*) and interacting with a peptide from the GR-interacting protein (GRIP1) nuclear receptor box II *(orange)*. **B,** Structure of the ERα LBD bound to tamoxifen *(red)*. Note that the position of helix 12 differs between the receptor bound to agonist (DES) and antagonist (tamoxifen). H, helix. *(From Shiau AK, Barstad PM, Loria L, et al. The structural basis of estrogen receptor/coactivator recognition and the antagonism of this interaction by tamoxifen. Cell 95:927–937, 1998, with permission from Elsevier).*

the risk of vertebral fractures in women with osteoporosis. In contrast, raloxifene acts as an estrogen antagonist in the breast and uterus. Tamoxifen, on the other hand, antagonizes estrogen action in the breast, but acts as an agonist in the uterus. Tamoxifen is therefore an effective treatment for breast cancer, but it increases the risk of endometrial cancer.

It has been hypothesized that differences in receptor conformation induced by different SERMs are responsible for the tissue-specific effects of these compounds. For example, raloxifene and tamoxifen may elicit different interactions between a particular ER subtype (i.e., ERα) and tissue-specific coactivators and corepressors. Alternatively, a given SERM could have opposing effects on different ER subtypes (i.e., ERα versus ERβ), which are differentially expressed in estrogen-responsive tissues. The compound tetrahydrocannabinol is just such a ligand, activating ERα by allowing interaction with the coactivator GR-interacting protein 1 (GRIP1) or transcriptional intermediary factor 2 (TIF2) and inhibiting ERβ by preventing interaction with the same coactivator.[83] Progress is also being made with selective progesterone receptor and AR modulators.[88,89] Although such compounds hold much promise, there is still a tremendous amount of research to be done. Ultimately, it will be essential to examine structural changes induced by a variety of ligands, ranging from pure and partial agonists to full antagonists as well as selective steroid modulators, to determine whether they work by similar or different mechanisms (i.e., by altering the position of helix 12 or changing cooperativity in hormone binding and receptor dimerization).

Recent structural studies have revealed that minor changes in DNA sequences itself can alter the structure of the GR DNA-binding domain, suggesting that DNA itself can act as an allosteric modulator of GR structure and function.[90] The structure of an entire steroid receptor, rather than that of isolated domains, is needed to fully understand how structural changes induced by ligand and DNA affects steroid hormone action.

Receptor Phosphorylation

Steroid receptors are proteins modified by phosphorylation at multiple sites. These modifications have distinct effects on the function of different receptors, often in a cell- or promoter-specific manner. Studies mapping phosphorylation sites have shown that steroid receptors are generally phosphorylated at specific serine residues adjacent to proline residues, although particular threonine and tyrosine residues can also be phosphorylated. Although some residues appear to be basally phosphorylated, others are modified in response to ligand binding or activation of other signaling pathways; these include cyclin-dependent kinases, mitogen-activated protein (MAP) kinases, and stress-activated kinases. For example, GR is basally phosphorylated in the synthesis (S) phase and hyperphosphorylated at the growth again/mitotic (G2/M) phase during the cell cycle, implicating cyclin-dependent kinases.[91] It is interesting to note that GR can be phosphorylated in response to glucocorticoid treatment during the S phase, but not the G2/M phase. This pattern of

GR phosphorylation is correlated with the ability of glucocorticoids to activate gene expression at different stages of the cell cycle. The phosphorylation status of the mouse GR has been shown to have a promoter-specific effect in transient transfection assays.[92] Mutation of phosphorylation sites reduced transcriptional activity on a minimal promoter containing simple glucocorticoid response elements, but not on the more complex mouse mammary tumor virus promoter.

Whereas the overall pattern of receptor phosphorylation is critical for receptor function, the contribution of site-specific phosphorylation of nuclear receptors is beginning to be appreciated. The ligand-dependent phosphorylation of serine 404 of GR expands the transcriptional profile of the receptor.[93] Additionally, phosphorylation of serine 134 of GR, which is ligand-independent, acts as a sensor of cellular stress and modulates glucocorticoid-mediated signaling.[94] Mutation of just one serine at position 118 of the ER reduced transcriptional activity by as much as 75%, but this effect was also cell- and promoter-specific.[95] This particular residue can be phosphorylated by MAP kinase *in vitro*. Additional studies have shown that *in vivo* activation of MAP kinase by growth factors leads to phosphorylation of serine 118 and potentiation of transcription via recruitment of a specific coactivator to AF1.[96] Phosphorylation of ER at other sites has been reported to alter receptor dimerization and DNA binding.[95] A phosphoserine at position 650 in the hinge region of the AR appears to be required for full transcriptional activity of this receptor.[97] Cross-talk between the PR and the neurotransmitter dopamine plays a physiological role in the control of sexual behavior in female mice: PR and sexual receptivity can be activated by dopamine in the absence of progesterone.[98] Like the ER, the PR can be phosphorylated in a ligand-independent manner at serine 294 by activation of MAP kinases.[99] Phosphorylation at this residue targets the PR for degradation by the proteasome, but paradoxically enhances transcriptional activity of the receptor.[100]

In summary, various kinases can phosphorylate steroid receptors via ligand-dependent and ligand-independent mechanisms. In turn, receptor phosphorylation can alter steroid hormone action. Given the general importance of these modifications, it is somewhat surprising that protein phosphatases have not been more widely studied for their effects on steroid hormone action.

Interaction with DNA

Steroid receptors enhance or repress gene transcription by forming homodimers that interact with specific DNA sequences in the promoter of target genes.[101] The core motif for hormone response elements consists of two six–base-pair sequences arranged as a palindrome with a three–base-pair spacer (i.e., the consensus estrogen-responsive element is AGGTCAnnnTGACCT, where *n* can be any nucleotide). One receptor in each homodimer contacts each half site. As described earlier, three amino acids in the DNA-binding domain are responsible for specific interactions between the ER and the consensus estrogen-responsive element versus the GR and the consensus glucocorticoid-responsive element (i.e., GGTACAnnnTGTTCT). However, hormone-specific patterns of gene regulation cannot be totally explained by this mechanism because the GR, MR, AR, and PR have similar consensus response elements, as determined by *in vitro* studies.

One explanation for specific regulation of gene expression by glucocorticoids, mineralocorticoids, androgens, and progestins is that natural hormone response elements diverge significantly from the glucocorticoid-response element consensus sequence described earlier. Although nucleotide variants generally lower the affinity of steroid receptors for the hormone response element, they increase binding specificity. In fact, a study of many different hormone response elements *in vitro* indicates that receptors discriminate among nucleotides in the spacer region and in the sequences flanking the six–base-pair motifs that directly interact with the receptor.[18] In other words, each steroid receptor responds in a unique way to different hormone response elements. Studies analyzing ERα and ERβ activity on different natural estrogen response elements support the hypothesis that steroid receptors interact with DNA in an allosteric manner,[102,103] which was later confirmed by crystallography of GR.[90] In turn, DNA-induced variation in receptor structure can influence the recruitment of coactivators to the receptor. Studies of hormone response elements from androgen-sensitive genes suggest another mechanism for steroid receptor specificity; the AR binds direct repeats of the six–base-pair motif, rather than the inverted palindrome typical of other steroid receptors.[104] Additional studies have shown that the distance of the hormone response element from the promoter influences transcriptional activity of steroid receptors.[105] In short, steroid receptor–DNA interactions contribute significantly to the specificity of steroid hormone action, as well as to variation in hormone responsiveness among genes.

Interaction with Coactivators and Corepressors

Within the last decade, it has become clear that the ability of steroid receptors to induce or inhibit gene transcription depends on interactions with proteins called *coactivators* and *corepressors*.[4,106] Steroid receptor recruitment of these proteins serves as a molecular switch regulating chromatin organization at target genes. Coactivators such as the Cyclic AMP Response Element Binding Protein (CREB)-binding protein and p300 have intrinsic histone acetylase activity. Covalent attachment of acetyl groups to specific lysine residues modifies nucleosome function and increases the access of basal transcription factors to promoters (Fig. 5.1). Conversely, low levels of histone acetylation are associated with tightly wound nucleosomes and gene repression (Fig. 5.1). Nuclear receptor corepressor (NCoR) is a protein that interacts with some but not all nuclear receptors to repress transcription. In the case of antagonist-bound ER and PR, NCoR is recruited along with proteins, such as histone deacetylase 3 (HDAC3), that have histone deacetylase activity.

The discovery of additional coregulatory proteins with enzymatic activity expands on the relatively simple model of transcriptional regulation by histone acetylation and deacetylation. These proteins have diverse functions, including methylation, demethylation, phosphorylation, dephosphorylation, poly(ADP-ribosylation), ubiquitination, and sumoylation of steroid receptors, coactivators, corepressors, and histones.[107,108] Overall, the transition between transcriptional repression and activation of a given gene by

steroids appears to result from highly dynamic and context-dependent interactions among these cofactors.

The kinetics of ER-dependent recruitment of coregulatory proteins to promoters has been examined in detail for two estrogen-responsive genes.[109-111] The general picture emerging from these studies is that different cofactors are brought to and released from the promoter in a specific order. Another important observation was that cofactor recruitment and release was cyclical, suggesting that recruitment of a particular cofactor is required for the subsequent recruitment of another cofactor and so on, until the final coregulatory complex is assembled. The final steps in this cycle are formation of the preinitiation complex and transcription by RNA polymerase. Repetition of this cycle suggests that steroid-dependent transcription within a cell would occur in waves and could be rapidly modulated by reversible covalent modifications of coregulatory proteins at each step during cofactor exchange.

Although some coactivators only enhance transcription on chromatin templates, others are able to augment steroid receptor transcriptional activity on naked DNA.[106] These proteins act as molecular bridges spanning the DNA-bound receptor and the basal transcription machinery, thereby stabilizing the preinitiation complex and facilitating transcription initiation. Steroid receptor coactivator 1 (SRC-1) and GRIP1 are two such proteins among a growing family of related nuclear receptor coactivators. These proteins contain multiple leucine-X-X-leucine-leucine (LXXLL, where *X* indicates any amino acid) motifs that are required for specific interactions with AF2 of different steroid receptors. For example, whereas the second LXXLL motif of GRIP1 interacts with the ER and is required to potentiate transcription, the third LXXLL motif of GRIP1 interacts with the GR to potentiate transcription.[11]

Although different coactivators may contribute to receptor-specific patterns of gene expression, there is a certain degree of functional overlap among members of the coactivator family. Recent studies have identified a host of other coactivator proteins (i.e., Vitamin D receptor interacting protein [DRIP], thyroid hormone receptor activating protein [TRAP], and Brahma-related gene 1 [Brg1]) that presumably add to the complexity and specificity of steroid hormone action.[106,112]

Interaction with Other Transcription Factors

Steroid receptors can interact with other transcription factors to facilitate or inhibit their activity. Interestingly, these effects are mediated by direct protein–protein interactions and do not require the DNA-binding domain of steroid receptors. A well-characterized example is the mutually antagonistic interaction between GR and NF-κB. These transcription factors are involved in the regulation of many proinflammatory genes, with glucocorticoids inhibiting gene expression and activators of NF-κB enhancing gene expression.[113] It appears that the GR hinders the transcriptional activity of NF-κB by multiple mechanisms, including direct and indirect interactions with NF-κB. There is some indication that GR–NF-κB interactions can prevent NF-κB from binding κB-responsive elements. In other cases, the GR does not block DNA binding, but interacts with the transactivation domain of the p65 subunit of NF-κB (Fig. 5.1). The GR thereby disrupts NF-κB interactions with the basal transcription machinery. Another hypothesis is that the GR competes for a limited number of coactivators that are required to form a bridge between NF-κB and the basal transcription machinery. Additional studies are required to clarify the relative importance of these mechanisms and whether they contribute to cell- or tissue-specific patterns of glucocorticoid antagonism of NF-κB signaling.

Interactions also occur between steroid receptors and the transcription factor AP-1 (Jun:Fos heterodimers). Whereas glucocorticoids and the GR generally antagonize AP-1 activity, estrogens and the ER can stimulate transcription via interactions with AP-1.[114,115] The mechanism responsible for the opposing effects of glucocorticoids and estrogens is currently unknown, but there is some evidence from transient transfection studies that antagonism between glucocorticoids and estrogens may be mediated by interactions at AP-1–responsive sites.[116] There are two distinct pathways for interaction between the ER and AP-1.[114] In the first, AP-1 stimulates transcription by recruiting CBP/p300 and p160 coactivators, such as GRIP1. The estrogen–ER complex then interacts with GRIP1 by the same AF1 and AF2 contacts as it does at estrogen-responsive elements. In a second pathway, estrogen antagonists bound to ER enhance the activity of AP-1 without physically interacting in the AP-1 complex. The antagonist–ER complex is believed to recruit corepressor proteins, such as NCoR, away from the AP-1 complex, thus relieving repression.

The ligand-bound ER can also interact with the C-terminal DNA-binding domain of the transcription factor Sp1. However, this interaction is independent of the DNA-binding domain of ER because DNA-binding–deficient forms of the ER can stimulate transcription via consensus GC-rich Sp1-binding sites. Taken together, these results indicate that protein–protein interactions are critical for cross-talk between ER and Sp1.[117] In yet another example of cross-talk, signal transducer and activator of transcription 5 (STAT5) and the GR synergistically activate the beta-casein gene.[118] Although steroid receptors interact with numerous transcription factors to enhance or inhibit gene expression in artificial systems, additional work is required to establish the physiological relevance of these mechanisms in whole organisms.

Nongenomic Actions of Steroids

Some effects of steroid hormones are entirely independent of their classic genomic action and are also independent of interactions with other transcription factors.[119] In general, these "nongenomic" effects occur rapidly and sometimes before those required for transcriptional activation. It is interesting to note that estrogen can have rapid, nongenomic effects, even though the ER is primarily nuclear in its localization. Roughly 2% of the cellular ER, however, is located at or near the plasma membrane and has been implicated in nongenomic signaling by estrogens.[120,121] Moreover, these early steroid effects cannot be blocked by inhibitors of transcription, such as actinomycin D, or inhibitors of translation, such as cycloheximide. Although rapid, nongenomic actions of steroids have been recognized for decades, the mechanisms responsible for these effects have only recently begun to be elucidated.[122] In this section, we will review a few examples of nongenomic actions for each class of steroid

hormone. This area of research is currently the most exciting and dynamic in the study of steroid hormone action.

Signaling Via Second Messenger Cascades

Skepticism surrounded many of the early studies of nongenomic effects because pharmacological doses of steroids were used. One of the first studies with physiologically relevant steroid levels showed that intravenous injection of 17β-estradiol produced a rapid increase in uterine cAMP in the presence of an inhibitor of transcription.[123] Subsequent work by others repeated these observations and extended them to show that estrogen-induced generation of cAMP could indirectly stimulate transcription via a cAMP response element.[124] Studies in breast cancer cells have shown that the G-protein–coupled receptor, GPR30, is required for activation of adenylate cyclase by estrogen antagonists.[125] Interestingly, estrogen antagonists could activate GPR30 in cells that lacked the classic ER. However, it is unclear whether the same mechanism is responsible for the rapid effects of estrogen agonists on cAMP levels in the uterus.

Estrogens have also been shown to activate phosphatidylinositol-3-OH kinase (PI3K) in an ER-dependent manner and to modulate cardiovascular function.[126] The ER binds in a ligand-dependent manner to the p85alpha regulatory subunit of PI3K, thereby increasing its activity. Activation of PI3K leads to the activation of protein kinase B (Akt), which directly phosphorylates and activates endothelial nitric oxide synthase (eNOS). Activated eNOS generates NO, causes vasodilation, and decreases vascular leukocyte accumulation. Estrogen-induced inhibition of leukocyte accumulation protects against ischemia–reperfusion injury. Inhibitors of PI3K and eNOS blocked the protective effect of estrogen. Much like the indirect activation of transcription via cAMP, estrogen can activate transcription indirectly by activating the PI3K/Akt pathway.[127] Hafezi-Moghadam and coworkers[128] showed a similar pattern of activation of eNOS by ligand-activated GR. Briefly, dexamethasone stimulated PI3-kinase and Akt, thereby activating eNOS. NO-dependent vasorelaxation led to decreased inflammation and reduced myocardial infarct size after ischemia–reperfusion injury in the mouse heart.

Glucocorticoids have rapid behavioral effects in a variety of vertebrates.[129] Sexual behavior is inhibited in less than 10 minutes by corticosterone in the roughskin newt. In contrast, glucocorticoids enhance lordosis within 5 minutes in female rats. Although the mechanisms involved have not been clearly defined, it appears that glucocorticoids influence neuronal signaling through the *N*-methyl-D-aspartic acid (NMDA) receptor. Corticosterone decreases female preference for male odors in mice. When coadministered with corticosterone, NMDA antagonists blocked this effect.[130] Preincubation of rat hippocampal neurons with glucocorticoids for just 10 minutes prolonged the NMDA-induced rise in intracellular Ca^{2+}.[131] Studies in rats have shown that extracellular aspartate and glutamate (excitatory neurotransmitters) levels increase in the hippocampus shortly after corticosterone administration.[132]

Mineralocorticoids also produce rapid, nongenomic effects that are not blocked by inhibitors of transcription or translation. For example, aldosterone administered at physiologically relevant concentrations (i.e., approximately 0.1 nM) activates the Na+/H+ transporter and increases intracellular pH in renal cells within 3 to 20 minutes.[133] In addition to this rapid effect on transporter activity, aldosterone induces transcription of the Na+/H+ transporter gene by the classic mode of steroid hormone action.[134] Nongenomic and genomic mechanisms of aldosterone action may therefore play important roles in acute and long-term electrolyte balance, respectively. Aldosterone also produces rapid effects on Na+/H+ transporter activity in other cell types, including human mononuclear leukocytes, endothelial cells, and vascular smooth muscle cells. Glucocorticoids were generally unable to activate the Na+/H+ transporter, indicating that the effect is specific for mineralocorticoids. A diacylglycerol-dependent mechanism involving PKC has been implicated in aldosterone activation of the Na+/H+ transporter in some, but not all studies.[135] Intracellular levels of inositol trisphosphate (IP_3) and calcium are rapidly elevated after mineralocorticoid treatment in colon cells. Whereas low calcium in the medium prevented the increase in intracellular calcium, depletion of intracellualar calcium stores by pretreatment with thapsigargin had no effect. Thus, calcium appears to enter from outside the cell in response to aldosterone, rather than being released from intracellular stores. Nevertheless, the MR does not appear to be required for rapid, nongenomic effects on calcium levels, thus implicating a non-classic receptor that has yet to be identified.[136]

Progesterone stimulates motility, Ca^{2+} influx, and the acrosome reaction in spermatozoa.[122,137] These effects are most likely nongenomic because they occur within a few seconds to minutes and because mature sperm have highly condensed chromatin that is transcriptionally inactive.[138] Given that progesterone is found in follicular fluid, in oviductal fluid, and in the extracellular matrix of oocytes around the time of fertilization, progesterone may play a physiological role in the acrosome reaction. In any case, progesterone induces a rapid Ca^{2+} influx in sperm that is blocked by Ca^{2+} chelators or La^{3+}. Thapsigargin, which elicits a rise in cytoplasmic Ca^{2+} by releasing intracellular stores, also triggers the acrosome reaction. Interestingly, PKC appears to be involved in mediating progesterone-induced increase in Ca^{2+}.[139] In conjunction with these changes, progesterone activates phospholipase C, causes rapid hydrolosis of phosphatidylinositol 4,5-biphosphate, and stimulates the synthesis and secretion of platelet-activating factor, which can itself induce the acrosome reaction. There is also evidence that progesterone may activate a distinct membrane receptor that interacts with and activates a gamma-aminobutyric acid GABA(A) receptor/chloride channel. In turn, this channel modulates the acrosome reaction.[137]

Androgens and estrogens rapidly activate the MAP kinase (i.e., sarcoma [Src]/Src homology 2 domain-containing [Shc]/extracellular signal-regulated kinase [ERK]) pathway and block programmed cell death (apoptosis) in a variety of cell types.[140] Androgen action on this signaling pathway is mediated by the classic AR and results from an interaction between the ligand-binding domain and Src homology domain 3 of the protein tyrosine kinase Src. Androgen activation of this pathway is dependent on a conformational change in Src and its subsequent interaction with Shc, which links receptor tyrosine kinases with intracellular signaling proteins. Further studies show that Shc is required for phosphorylation and activation of ERK1/2 in response

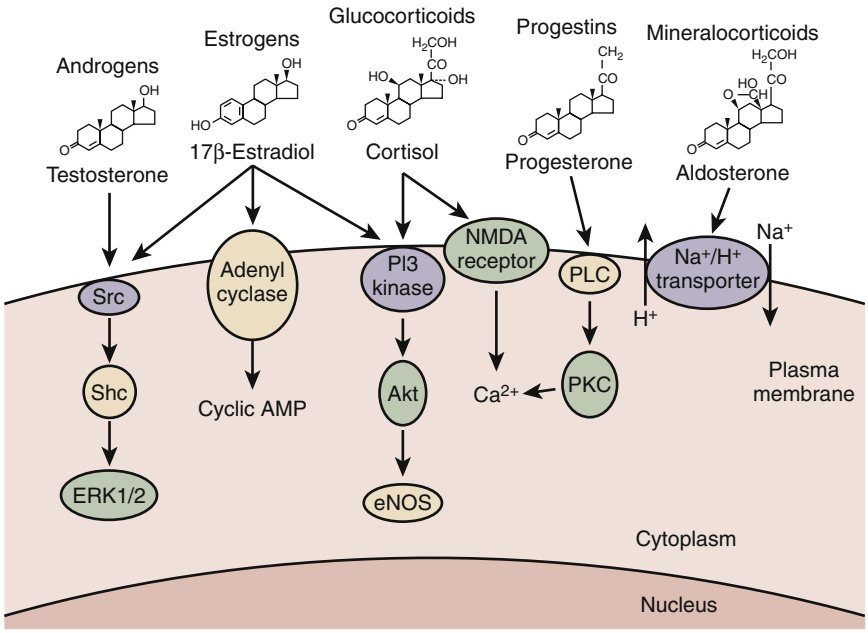

FIGURE 5.7 Schematic diagram showing representative non-genomic effects of steroids. to androgens. Although the events downstream of ERK 1/2 have not been elucidated, evidence is accumulating that the MAP kinase pathways play an important role in cell survival.[140] Estrogens activate the same MAP kinase pathway, but via interaction between ER and the SH2 domain of Src.[140] Based on these results, it was proposed that cross-talk between androgens and estrogens *in vivo* may be mediated in part by AR and ER interactions with Src. Another important finding from that study was that nongenomic and genomic effects mediated by the classic ER can be dissociated using synthetic ligands. Estren did not activate a reporter gene containing estrogen responsive element (ERE), but was able to protect against apoptosis. Conversely, pryazole activated a reporter gene containing EREs, but was unable to protect against apoptosis.

Summary

In conclusion, multiple interactions between steroid hormones and other signaling molecules increase the complexity of steroid hormone action. It has become widely accepted in recent years that physiologically relevant levels of steroids can activate second messenger pathways independently of their classic effects on gene expression (Fig. 5.7). In turn, these second messengers can significantly alter cell, organ, and whole animal physiology. It is important to note that steroid-dependent activation of non-classic pathways can also lead to changes in gene transcription.[124,127] Steroid hormones can therefore have strictly nongenomic effects, genomic effects that are indirectly mediated by second messenger pathways, and genomic effects mediated by steroid receptors that act as ligand-gated transcription factors. Inhibitory and synergistic cross-talk with other transcription factors is another important mode of action for steroid receptors. It has also been shown that steroid receptors can be activated by various factors (e.g., MAP kinases, dopamine) in a ligand-independent manner. As basic mechanisms of steroid hormone action are further elucidated, we will be able to address questions of critical importance for the treatment of disease and for maintenance of general health and well-being. For example, it will be critical to determine whether different mechanisms of steroid hormone action are independent of each other or whether inhibition or activation of one mechanism always affects other mechanisms. It is imperative to obtain such information if we hope to correct abnormal physiological and cellular processes without disrupting normal processes.

CHAPTER 6

Prostaglandins and Other Lipid Mediators in Reproductive Medicine

Colin D. Funk
Wen-Chao Song
Garret A. FitzGerald

The study of prostaglandins had its beginning in reproductive biology. In the 1930s, von Euler first characterized active substances present in semen that induced uterine contractility.[1] The active elements were named *prostaglandins*, based on the erroneous belief that they were produced by the prostate gland. We now know that the copious quantities of prostaglandins in semen are produced by the seminal vesicle gland and that prostaglandin biosynthesis is not limited to the accessory glands of the male reproductive system.

Discovery of the widespread occurrence of prostaglandins, their broad range of biological activities, chemical structures, and biosynthetic pathways, and determination of their relevance to the mechanism of action of nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin have engaged the interest of generations of reproductive endocrinologists. The general relevance of the field to diverse aspects of biology has prompted an era of intense and broad-based research that few other fields have experienced.[2] The Nobel Prize was awarded to Bergström, Samuelsson, and Vane in 1982 for elucidating the structure and biosynthesis of prostaglandins and for revealing the mechanism of action of NSAIDs.[3]

Today, prostaglandins and related lipid mediators are collectively referred to as *eicosanoids*. Eicosanoids (from *eicosi*, a Greek root meaning "20") are derived enzymatically from 20-carbon polyunsaturated fatty acids, principally arachidonic acid in mammalian species. They are produced by almost all cells in the body in response to hormonal stimulation or mechanical trauma. They evoke a wide array of biological actions in diverse tissues (including the reproductive system) at extremely low concentrations. Tissue specificity in eicosanoid action is afforded by selective expression of biosynthetic enzymes and membrane receptors (and perhaps also nuclear receptors) for eicosanoids. They are short-lived because they are susceptible to spontaneous or metabolical inactivation and act as paracrine or autocrine modulators of cellular function.

In this chapter, we first summarize the salient features of eicosanoid biosynthesis and pharmacology, and then we review the current understanding of their actions in the reproductive system. We also introduce at the end of the chapter other noneicosanoid lipid mediators that are now gaining recognition in reproductive medicine. For a more detailed and comprehensive review of the earlier literature on eicosanoids in reproduction, readers are urged to consult the corresponding chapter in a previous edition of this book.[4]

Biosynthesis of Eicosanoids

Nomenclature

The term *eicosanoid* refers to both prostaglandins and thromboxanes (products of the cyclooxygenase pathway, abbreviated as PG and TX, respectively) and leukotrienes (products of the 5-lipoxygenase pathway, abbreviated as LT). All PGs have a hairpin configuration and contain a cyclopentane ring with two side chains oriented in *trans* positions relative to the cyclopentenone ring. Each group of prostaglandins is allocated a letter (e.g., A, E, F), which denotes particular functional groups at carbons 9 and 11 of the ring structure.

The degree of unsaturation of the side chains is indicated by the subscript numeral after the letter; thus, PGE_1, PGE_2, and PGE_3 have one, two, and three double bonds, respectively. In the case of $PGF_{2\alpha}$, the subscript α denotes the stereochemistry of the 9-hydroxyl group in the cyclopentane ring.

A similar system is used for nomenclature of TXs that have oxygen-bridged six-member rings in place of the five-member ring seen in PGs. All LTs have three conjugated double bonds, and the subscript numeral (e.g., the 4 in LTA_4 and LTC_4) denotes the total number of double bonds in the molecule. LTA_4 is an unstable epoxide and serves as a parent molecule in the biosynthesis of LTB_4 (hydrolysis product), LTC_4, LTD_4, and LTE_4 (peptide derivatives).

Release of Arachidonic Acid From Phospholipid Stores

Eicosanoids are not stored, but rather are synthesized *de novo* when cells are activated by hormonal or mechanical

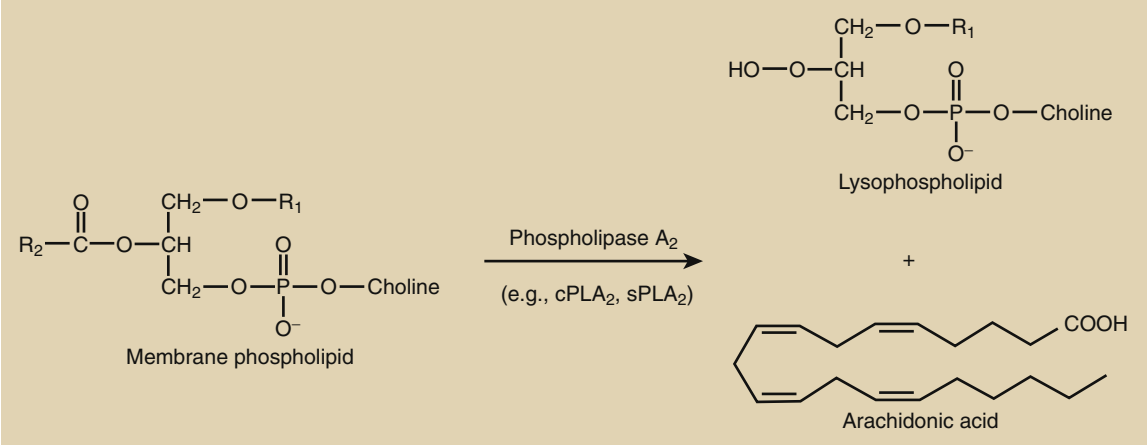

FIGURE 6.1 Release of free arachidonic acid from membrane phospholipid stores is the first step in eicosanoid biosynthesis. Arachidonic acid (R_2-COOH), located at the sn-2 position of phospholipids (phosphatidylcholine, phosphatidylethanolamine, and phospatidylinositol) is mainly cleaved by phospholipase A_2 enzymes when cells are activated. R_1 is often a C16 or C18 saturated or monounsaturated fatty acid in acyl linkage.

stimuli. The first obligatory (and often rate-limiting) step in eicosanoid biosynthesis is the release of arachidonic acid from membrane phospholipid stores (Fig. 6.1).[5,6] This process is exquisitely regulated by a host of enzymes, particularly several types of phospholipase A_2 (PLA_2),[7] and it appears to be coordinated with the induction of downstream eicosanoid biosynthetic enzymes.[6,8-10]

Recent studies suggest that at least three types of PLA_2 are involved in arachidonic acid release during different stages of cell activation.[6] Under basal conditions, the Ca^{2+}-independent PLA_2 ($iPLA_2$) is the dominant phospholipase involved in the liberation of arachidonic acid and other polyunsaturated fatty acids from membrane phospholipids.[6] The phospholipase $iPLA_2$ is primarily involved in membrane remodeling and usually does not cause significant eicosanoid production, because its activity in arachidonic acid release is balanced by acylase enzymes. However, the activity of $iPLA_2$ may become significant when acylase enzymes are down-regulated. For example, mice heterozygous for acyl-coenzyme A synthetase 4 deficiency accumulated high levels of uterine PGs, had abnormal uterus polycysts, and displayed reduced fertility.[11]

When cells are activated, such as by receptor ligation or calcium ionophore stimulation, intracellular calcium levels rise and the Ca^{2+}-dependent cytosolic PLA_2 ($cPLA_2$) becomes involved.[6] The activity of $cPLA_2$ far exceeds that of acylase enzymes, and as a result, there is rapid accumulation of free arachidonic acid to be acted on by either constitutive or inducible eicosanoid-synthesizing enzymes.

Under certain situations of sustained cellular activation, secreted PLA_2 ($sPLA_2$) family members may also participate, further increasing the supply of free arachidonic acid to meet the need of eicosanoid-synthesizing enzymes. Clearly, $cPLA_2$ plays a key role among these enzymes because cells lacking $cPLA_2$ are generally devoid of eicosanoid biosynthesis.[7]

Pathways of Eicosanoid Biosynthesis

After its release from membrane phospholipid stores, arachidonic acid is transformed enzymatically to various eicosanoids through multiple pathways (Fig. 6.2). One pathway is initiated by the enzyme PG H synthase (PGHS, also known as *cyclooxygenase* [COX])[12] and results in the production of PGs, TX (TxA_2), and prostacyclin (PGI_2). These cyclooxygenase-derived products are also referred to as *prostanoids*.

The initial cyclized fatty acid derivative formed in this reaction is PG G_2 (PGG_2). The peroxide moiety at the 15-carbon position of PGG_2 is subsequently reduced to an alcohol group to form PGH_2 as a result of the inherent peroxidase activity of PGHS (Fig. 6.2). Both PGG_2 and PGH_2 are unstable intermediates with very short half-lives.

The conversion of PGH_2 to individual PGs is relatively tissue-specific, depending on the local expression of specific PG-synthesizing enzymes.[12,13] For example, TxA_2 is synthesized in platelets and macrophages, whereas PGI_2 is the dominant COX product of macrovascular endothelial cells.[2,13]

The second major pathway of arachidonic acid metabolism is initiated by lipoxygenases. Like cyclooxygenase, lipoxygenases (LOX) are also dioxygenases that catalyze the insertion of molecular oxygen into arachidonic acid to form a hydroperoxy derivative.[14] The insertion of molecular oxygen can occur at several carbon positions (e.g., 5, 12, and 15) along the fatty acid chain. These determine the specificity of the enzymes, hence, the origin of names such as *5-lipoxygenase* and *12-lipoxygenase*.[14] The enzyme 5-lipoxygenase is of particular importance because its product, 5-hydroperoxy-eicosatetraenoic acid (5-HPETE), serves as a precursor for the LT family of eicosanoids, which are involved in host defense and immediate-type hypersensitivity reactions.[2,15]

Other important eicosanoids formed from lipoxygenase pathways include lipoxins, which are mostly produced by the interaction of neutrophils with other cells in the vascular compartment. They are believed to play a role in the resolution of inflammatory responses.[16]

Arachidonic acid can also be metabolized by an additional pathway, through the activity of cytochrome P450 enzymes.[17] Unlike the cyclooxygenases or lipoxygenases, cytochrome P450 enzymes catalyze the mono oxygenation (insertion of one atom of oxygen from O_2) of arachidonic

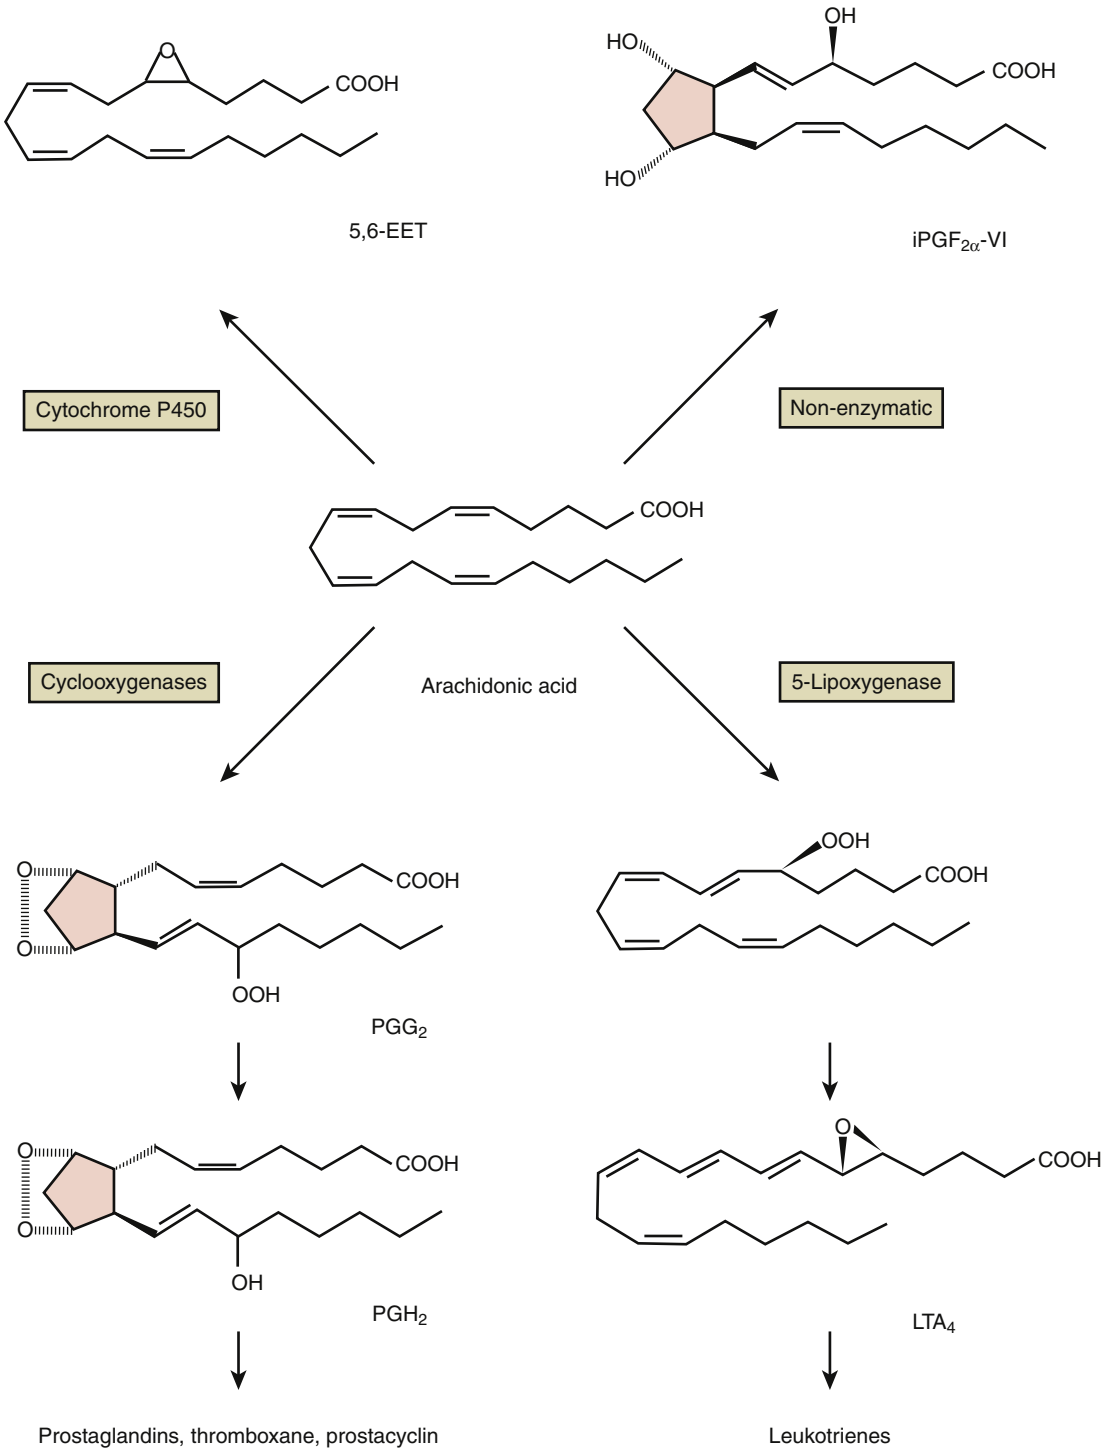

FIGURE 6.2 Major pathways of eicosanoid biosynthesis from arachidonic acid. Arachidonic acid is converted by two forms of cyclooxygenase (formally known as *prostaglandin H synthase*) to PGH_2 and then to prostaglandins, thromboxane, and prostacyclin; by lipoxygenases to leukotrienes (depicted) and other products, such as hydroxy-eicosatetraenoic acids (HETEs) (not shown); by cytochrome P450 enzymes to epoxy-eicosatrienoic acids (EETs; 5,6-EET is shown as an example). Arachidonic acid can also be converted nonenzymatically to isoprostanes through free radical–catalyzed peroxidation and cyclization (there are 64 potential isomers of isoprostanes[22,23]; the structure of isoprostane isomer VI of prostaglandin F2 alpha ($iPGF_{2\alpha}$-VI) is shown as an example). In contrast to the enzymatic pathways, formation of isoprostanes can occur on phospholipids, and release of free arachidonic acid is not a prerequisite.[24]

acid, with hydroxy or epoxy derivatives of arachidonic acid as their major products.[17] Cytochrome P450 products modulate nephron ion transit and renovascular tone.[17-19] Some cytochrome P450–derived epoxy metabolites of arachidonic acid are elevated in women with pregnancy-induced hypertension,[20] and others may have anti-inflammatory activities.[21]

Lastly, peroxidation of arachidonic acid and cyclization to PG-like compounds called *isoprostanes* can also occur nonenzymatically by free radical–catalyzed reactions.[22,23] In

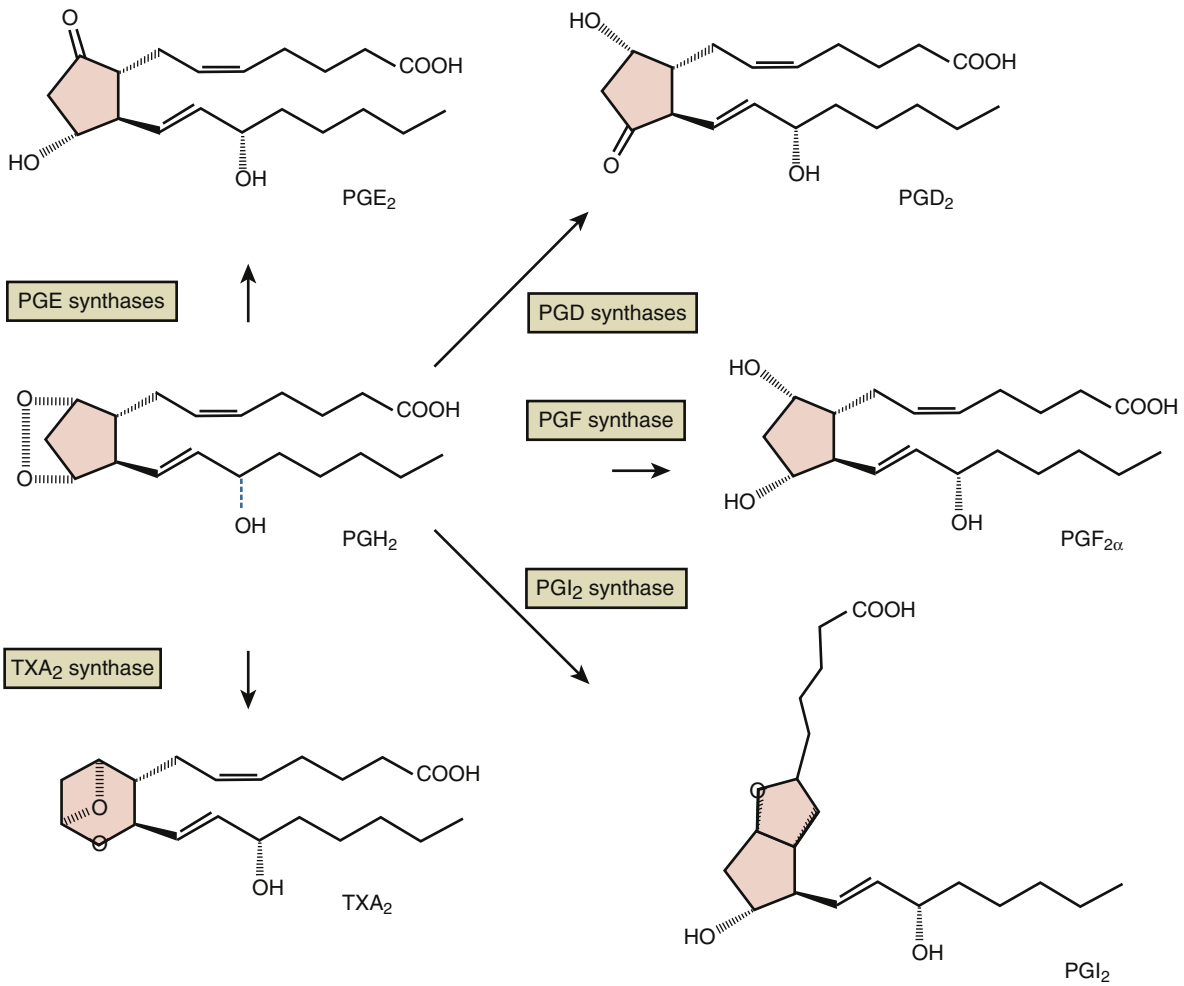

FIGURE 6.3 Biosynthesis and structures of prostanoids from prostaglandin (PG) H_2 (PGH_2). Formation of PGE_2 is catalyzed by PGE synthases, of which at least three have been identified.[8-10,30,31] Formation of PGD_2 is catalyzed by at least three different PGD_2 synthases.[192] Formation of $PGF_{2\alpha}$ is catalyzed by PGF synthase, a member of the aldo-keto reductase family of enzymes. Thromboxane A_2 (TxA_2) and PGI_2 are formed by TxA_2 synthase and PGI_2 synthase, respectively. Both enzymes are cytochrome P450 enzymes associated with microsomal membranes.

contrast to the enzyme-produced eicosanoids, isoprostanes can be formed *in situ* on phospholipids and then released by phospholipases.[24] Isoprostanes may serve as incidental ligands for eicosanoid receptors under certain conditions.[23,25]

More importantly in the clinical setting, urine and plasma isoprostane levels have proven to be reliable markers of lipid peroxidation and oxidant stress in vivo.[22,23] For example, elevated levels of urinary isoprostanes were detected in women with android obesity[26] and in individuals with alcohol-induced liver injury.[27] Both conditions are associated with increased oxidant stress and inflammation, as determined by other independent markers.

Major Products of the Cyclooxygenase Pathway: Prostaglandins, Thromboxanes, and Prostacyclin

Two COX enzymes that initiate the formation of prostaglandins (Fig. 6.2), encoded by separate genes, have been identified in vertebrates.[12,28] One COX enzyme (COX-1) is largely constitutively expressed, whereas the other (COX-2) is more often inducible by cytokines, growth factors, and hormones. This categorization as constitutive COX-1 and inducible COX-2 is useful, but is not always the case (e.g., COX-2 is constitutively expressed in some organs, such as the kidney glomerulus[29]).

The subsequent conversion of PGH_2 to individual prostanoids is relatively tissue-specific and is catalyzed by the corresponding isomerases and synthases (Fig. 6.3).[28] For example, TxA_2 synthase is expressed in platelets and macrophages, PGI_2 synthase is found in endothelial cells, and $PGF_{2\alpha}$ synthase is abundant in the uterus.[2]

There are at least two types of glutathione-dependent PGE_2 synthases.[8-10,30] One PGE_2 synthase, cPGES, is a constitutively expressed cytosolic enzyme functionally coupled to COX-1; the other is a microsomal and inducible enzyme, mPGES-1, which appears to be coupled to COX-2.[8-10,30] Another enzyme, mPGES-2, found in bovine endometrium and other sites, is less well characterized, and its role in PGE_2 synthesis is unclear.[31]

Major Products of the 5-Lipoxygenase Pathway: The Leukotrienes

Products of the 5-lipoxygenase pathway with well-defined biological activities are mainly produced by inflammatory

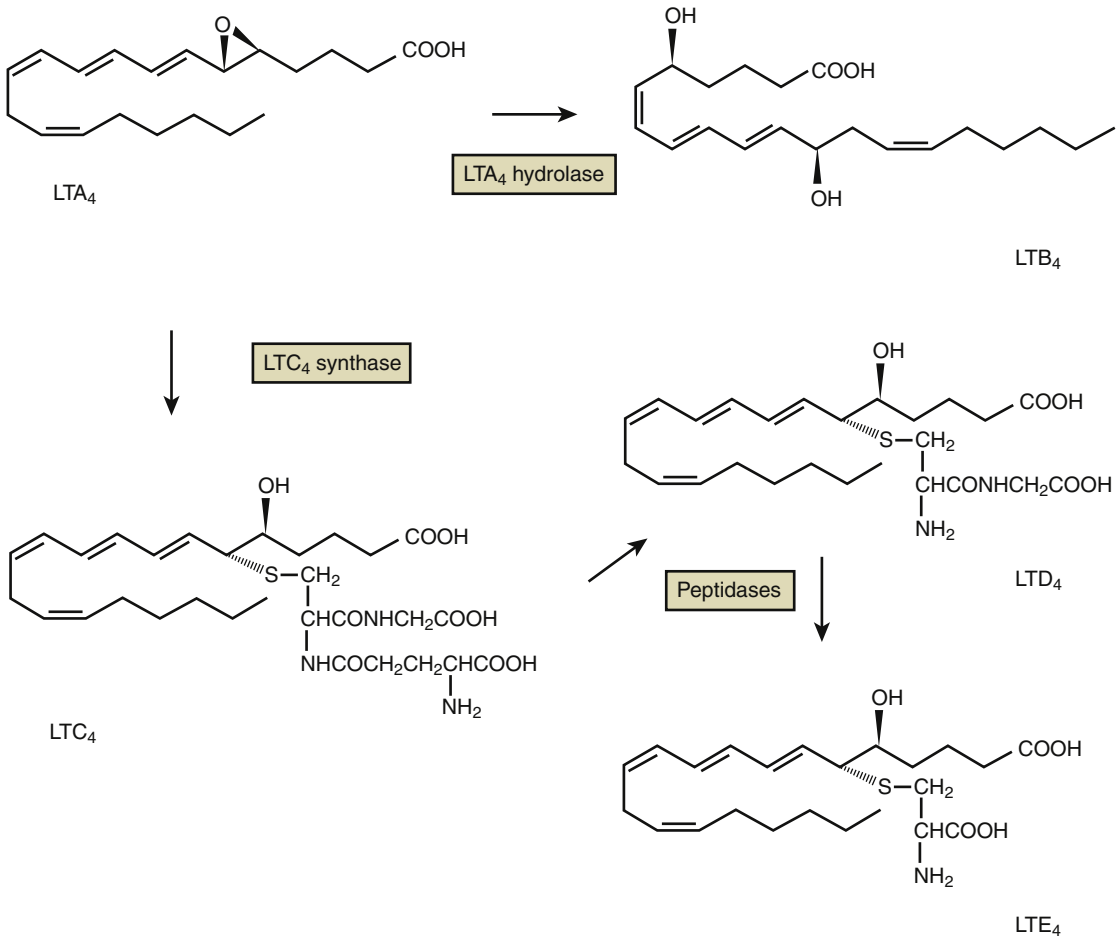

FIGURE 6.4 Structures and biosynthesis of leukotrienes (LTs) from LTA_4. LTA_4 is formed by 5-lipoxygenase and is prone to spontaneous hydrolysis. Hydrolytic attack by LTA_4 hydrolase produces LTB_4, a dihydroxy derivative of arachidonic acid with specific stereochemistry of the hydroxy groups. Conjugation of LTA_4 with glutathione is catalyzed by LTC_4 synthase. Sequential cleavage of the oligopeptide moiety in LTC_4 by extracellular peptidases yields LTD_4 and LTE_4.

cells.[2,32-34] The activation and biochemical cascade of the 5-lipoxygenase (5-LOX) pathway in leukocytes is particularly well understood, because it gives rise to the potent LT family of lipid mediators that have chemotactic or smooth muscle–contracting properties.[2]

Biosynthesis of LTs is initiated by the formation of 5-HPETE from arachidonic acid by 5-LOX in a Ca^{2+}-dependent process that involves translocation of both 5-LOX and $cPLA_2$ to the nuclear envelope.[2,35,36] The activity of 5-LOX also requires the cooperation of an accessory protein, 5-lipoxygenase–activating protein (FLAP), in intact cells.[37]

Some 5-HPETE molecules can escape from the active site of the 5-LOX enzyme and are ultimately reduced by cellular peroxidases to the corresponding 5-hydroxy derivative of arachidonic acid (5-HETE). Other 5-HPETE molecules may be further converted to the labile epoxide known as *leukotriene* A_4 (LTA_4) by a secondary dehydrase activity contained in 5-LOX (Fig. 6.4).[34] LTA_4 undergoes one of several potential transformation routes, depending on the cellular context.

Hydrolytic attack of LTA_4 by LTA_4 hydrolase produces LTB_4[38] a potent chemotactic agent for neutrophils. The conjugation of LTA_4 with glutathione is catalyzed by LTC_4 synthase, thereby forming LTC_4 at the nuclear envelope.[39] Sequential cleavage of the peptide moiety of LTC_4 by extracellular peptidases produces LTD_4 and LTE_4 (Fig. 6.4).

The three cysteinyl LTs, LTC_4, LTD_4, and LTE_4, are the major constituents of the *slow-reacting substance of anaphylaxis* released from antigen-sensitized guinea pig lungs that produced slow and sustained smooth muscle contraction of intestinal smooth muscle strips, observed more than 60 years ago.[32] LTA_4 can also serve as a precursor for the transcellular biosynthesis of lipoxins.[40] A number of biological activities, particularly in the resolution of the inflammatory response, have been proposed for lipoxins.[16]

Lipoxygenases with catalytic oxygenase specificity at different carbon positions of arachidonic acid, such as 12-LOX and 15-LOX, produce the corresponding HETEs as their main end products.[14] The physiological role of these enzymes and their specific products has proven to be elusive—although the murine 15-LOX homologue, which produces both 12-and 15-LOX products, has been implicated in atherogenesis.[41,42] Interestingly, the HPETE product of this enzyme is involved in the initiation and propagation of low-density lipoprotein oxidation, a process known to contribute to the accumulation of fat-laden macrophages in atherosclerotic lesions.[41,42] Products of the same enzyme may also regulate local interleukin-12 production by macrophages in atherosclerotic lesions.[43]

Transport and Metabolism of Eicosanoids

Although eicosanoids are lipid compounds, they do not permeate the cell membrane freely. A PG transporter (PGT), belonging to the organic anion transporter polypeptide family, has been identified and is found in a limited range of cells, where it is subject to humoral and physical stimuli.[44] PGT mediates the cellular uptake of most prostanoids, but not PGI_2.[44] Vascular expression of PGT appears to be responsible for clearing most classes of PGs when these compounds are infused into an animal and enter the pulmonary circulation.[44] On the other hand, multidrug-resistance protein 4 (MRP4) functions as a PG efflux transporter.[45] In the LT pathway, newly synthesized LTC_4 is transported outside of the cells by transporters such as multidrug-resistance protein 1 (MRP1).[46]

A hallmark of eicosanoids is the transient nature of their existence. Products such as PGI_2 and TxA_2 are chemically unstable and are degraded spontaneously through hydrolysis in aqueous solutions, particularly at neutral to acid pH. PGI_2 undergoes hydrolysis to form 6-keto $PGF_{1\alpha}$, a stable and inactive product, whose metabolite, 2,3-dinor-6-keto-$PGF_{1\alpha}$, has been used as a surrogate marker for systemic PGI_2 biosynthesis *in vivo*. Similarly, TxA_2 rapidly undergoes facile hydrolysis to form the inactive product TxB_2, which is subject to beta oxidation. Plasma or urinary TxB_2 metabolites have served as useful indices of TxA_2 formation *in vivo*.

The most important catabolical step for PGs is the conversion of the 15-hydroxy group to a 15-keto group by a NAD(+)-dependent 15-hydroxyprostaglandin dehydrogenase (15-OH-PGDH).[47] 15-OH-PGDH is a cytosolic protein with highest concentrations in the lungs, the placenta, the spleen, and the kidney cortex.[47] Both PGE_2 and $PGF_{2\alpha}$ are excellent substrates for 15-OH-PGDH.[47]

The second notable step in the degradation of PGs is reduction of the double bond at position 13 by $\Delta^{13,14}$-PG reductase, which is highly specific for 15-keto PGs; this enzyme has a tissue distribution similar to that of 15-OH-PGDH.[48] The metabolites then undergo both beta (i.e., carboxyl chain) and omega oxidation, resulting in urinary excretion of the final products.

Pharmacology of Eicosanoids

COX-1, COX-2, Traditional NSAIDs, and Selective COX-2 Inhibitors

The discovery of the COX-2 enzyme and its physiological and pharmacological characterization in the early 1990s hailed a new era in eicosanoid research.[49] COX-2 expression is readily inducible by cytokines, growth factors, and hormonal stimulation.[12] The two COX enzymes, within a given species, share 60% to 65% sequence identity in their primary structures.[12]

Both enzymes are membrane-anchored proteins, localizing primarily to the luminal surface of the endoplasmic reticulum and the nuclear envelope.[12] The crystal structures of COX-1 and COX-2 are remarkably similar, as are their catalytical mechanisms and kinetics. However, two subtle structural and biochemical differences have been noted between the two isozymes. First, the active site of COX-2 is larger and more accommodating than COX-1; this property

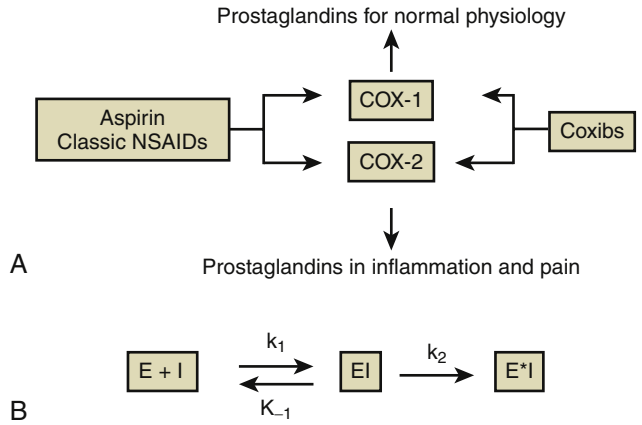

FIGURE 6.5 Mechanism of action of aspirin, traditional nonsteroidal anti-inflammatory drugs (NSAIDs), and coxibs. **A,** Aspirin and traditional NSAIDs inhibit both COX-1 and COX-2, whereas coxibs preferentially inhibit COX-2. **B,** All COX enzyme (E) inhibitors (I) exhibit one of three kinetic models of inhibition: (1) rapid, reversible binding to form EI (e.g., ibuprofen); (2) rapid, lower-affinity reversible binding, followed by time-dependent, higher-affinity, slowly reversible binding (e.g., flurbiprofen and coxibs); (3) rapid, reversible binding, followed by covalent modification (acetylation) of a serine residue in COX (aspirin). The mechanism for the time-dependent inhibition is not well understood, but may involve conformational change of the enzyme (E*I). Coxibs confer their selectivity for COX-2 by causing time-dependent inhibition of COX-2, but not COX-1 enzymes.

was exploited by the pharmaceutical industry for the purpose of developing selective COX-2–specific NSAIDs. Second, the gross kinetics (e.g., K_m, V_{max}) for COX-1 and COX-2 are similar, but COX-2 competes more efficiently with COX-1 in intact cells when the release of arachidonic acid is limiting.[6,28] Thus, when COX-1 and COX-2 are both present in the same cells, catalysis of arachidonic acid (provided exogenously or through activation of cellular lipases) is favored by COX-2.[6] COX-1 appears to function independently only when COX-2 is absent or inhibited.[6,28,50]

Researchers have proposed that this difference in sensitivity to arachidonic acid concentration is related to the sensitivity of their heme groups to lipid peroxide–catalyzed oxidation, and thus activation of the cyclooxygenase enzymes.[51] The concentration of lipid peroxide required to activate COX-1 is 10 times more than that required to activate COX-2 in the presence of low concentrations of arachidonic acid.[51]

Aspirin and traditional NSAIDs (e.g., indomethacin) function as nonselective inhibitors of both COX-1 and COX-2,[12] and their mechanisms of action have been extensively investigated, even before the discovery of COX-2. Long-term use of traditional NSAIDs in managing inflammatory disorders is associated with significant adverse effects, such as gastrointestinal bleeding (Fig. 6.5).[2,12,28,49] COX-2 was initially portrayed as the COX isoform responsible for producing PGs that contribute to the inflammatory process, which offered a rationale for developing selective inhibitors targeted at COX-2.

According to this "outdated" paradigm, COX-1 is responsible for synthesizing the "housekeeping" PGs required for maintaining normal physiological (e.g., mucosal protection in the stomach and normal kidney function). Thus, the adverse

Table 6.1 Summary of Eicosanoid Receptor Types and Properties

Receptor	Cognate Ligand	Property*	Intracellular Signaling
IP	PGI_2	Relaxing	↑ cAMP
TP	TXA_2	Contractile	↑ Ca^{2+}
FP	$PGF_{2\alpha}$	Contractile	↑ Ca^{2+}
DP1	PGD_2	Relaxing	↑ cAMP
DP2 (CRTH2)	PGD_2	Chemoattractant	↑ Ca^{2+}
EP1	PGE_2	Contractile	↑ Ca^{2+}
EP2	PGE_2	Relaxing	↑ cAMP
EP3	PGE_2	Inhibitory	↓ cAMP

*Smooth muscle activities.
cAMP, cyclic AMP; SMC, smooth muscle cells.

effects associated with traditional NSAID use would result from their inhibition of the COX-1 enzyme, whereas their anti-inflammatory efficacy would be attributable to coincidental inhibition of COX-2 (Fig. 6.5). This principle formed the basis for the development and marketing of the selective COX-2 inhibitors known as the coxibs (e.g., celecoxib, rofecoxib, and valdecoxib) for treating the arthritides[2,52]; however, a designation of COX-1 and COX-2 as "good" and "bad" enzymes turned out to be an oversimplification.

COX-1 and COX-2 genes and enzymes are present even in zebrafish[12,53] suggesting that both enzymes have fundamental physiological roles to play. Indeed, both COX-1 and COX-2 gene–disrupted mice display multiple developmental and physiological defects, including abnormalities in steps of reproduction.[54-57] Also, the administration of the selective COX-2 inhibitors to healthy human subjects suppressed systemic prostacyclin biosynthesis.[58] This finding further supports the notion that, in some settings, for example, endothelial cells subjected to hemodynamic shear, COX-2 is constitutively expressed and active, participating in normal physiological processes.

Eicosanoid Receptors

An explosion of knowledge regarding the expression, structure, signaling pathways, and physiological functions of eicosanoid receptors has taken place in the past 20 years.[59,60] The existence of membrane receptors for eicosanoids was supported by early pharmacological evidence[61] and was consistent with the notion that eicosanoids are locally released paracrine mediators acting on self and neighboring cells.

The first eicosanoid receptor to be cloned was the human TX receptor in 1991.[62] There are 13 distinct eicosanoid receptors cloned and characterized, 9 for cyclooxygenase-derived prostanoids and 4 for LTs (Table 6.1).[2,59,60] All 13 eicosanoid receptors characterized so far are rhodopsin-like, seven transmembrane domain–containing, G-protein–coupled receptors.[59,60] The nine G-protein–coupled prostanoid receptors, conserved in mammals from mouse to human, are the TX receptor (TP), the prostacyclin receptor (IP), the $PGF_{2\alpha}$ receptor (FP), two PGD receptors (DP1 and DP2), and four PGE_2 receptors (EP1, EP2, EP3, and EP4). These receptors are encoded by separate genes. In addition, there are several splice variants for the EP3, FP, and TP receptors, which differ only in their C-terminal tails (Fig. 6.6).[59,63-65]

The second PGD receptor, DP2 (also known as CRTH2),[66] induces intracellular calcium mobilization and is a chemoattractant receptor for type 2 T-helper cells.[66] DP2 is also found on human eosinophils where both PGD_2 and 15-deoxy-PGJ_2 (a degradation product of PGD_2) serve as activation ligands at nanomolar concentrations.[67,68]

The remaining eight prostanoid receptors fall into three categories according to their functional properties and the secondary messenger systems to which they couple. IP, DP1, EP2, and EP4 are smooth muscle–"relaxing" receptors that signal predominantly through a G_s-mediated increase in intracellular cyclic AMP (cAMP). The FP, TP, and EP1 receptors form the "contractile" subgroup and transduce their signals through a G_q-mediated increase of intracellular calcium. The EP3 receptor is regarded as an "inhibitory" receptor because it is coupled to G_i and causes inhibition of intracellular cAMP.

Several aspects of prostanoid receptor biology and pharmacology require comment. First, the existence of four subtypes of PGE_2 receptors is quite remarkable because all other prostanoids (except PGD_2) each have only a single receptor. Sequence-based phylogenetic tree analysis of the prostanoid receptors reveals that the four PGE_2 receptors were the first to evolve because homology among these subtypes is less than that among receptors of different classes of prostanoids.[59,60] Thus, the four PGE_2 receptors must have evolved to play distinctive physiological functions, and other prostanoid receptors are likely derived from functionally related PGE_2 receptor subtypes through gene duplication.[60]

Second, although there is high ligand selectivity for each of the prostanoid receptors, cross-activation by prostanoids other than the cognate ligand may occur; coupling to alternative downstream signaling pathways at different concentrations of the same ligand may also take place.[60,69] Third, the multiplicity in prostanoid receptor subtypes and signaling pathways, coupled with their differential tissue expression, explains why the same PG at different concentrations or in different tissues can sometimes produce opposing effects.

Among the four membrane LT receptors characterized to date, two are receptors for LTB_4 (BLT1 and BLT2) and two are for the cysteinyl LTs (CysLTl and CysLT2). The high-affinity ligand-binding BLT1 is primarily expressed on leukocytes,[70] whereas BLT2 has a wider tissue distribution and binds LTB_4 with lower affinity.[71] Both of these receptors signal through intracellular calcium mobilization, as well as through inhibition of adenylyl cyclase.

The existence of distinct cysteinyl LT receptors has been supported by pharmacological evidence.[72] CysLT1 has been the primary target for the development of anti-LT drugs for asthma symptom management. Molecular characterization of CysLTl confirmed it to be a G-protein–coupled receptor, with LTD_4 as its preferred endogenous ligand.[73] CysLTl is expressed on lung smooth muscle cells and tissue macrophages, and activation of the receptor results in an elevation of intracellular calcium.[73]

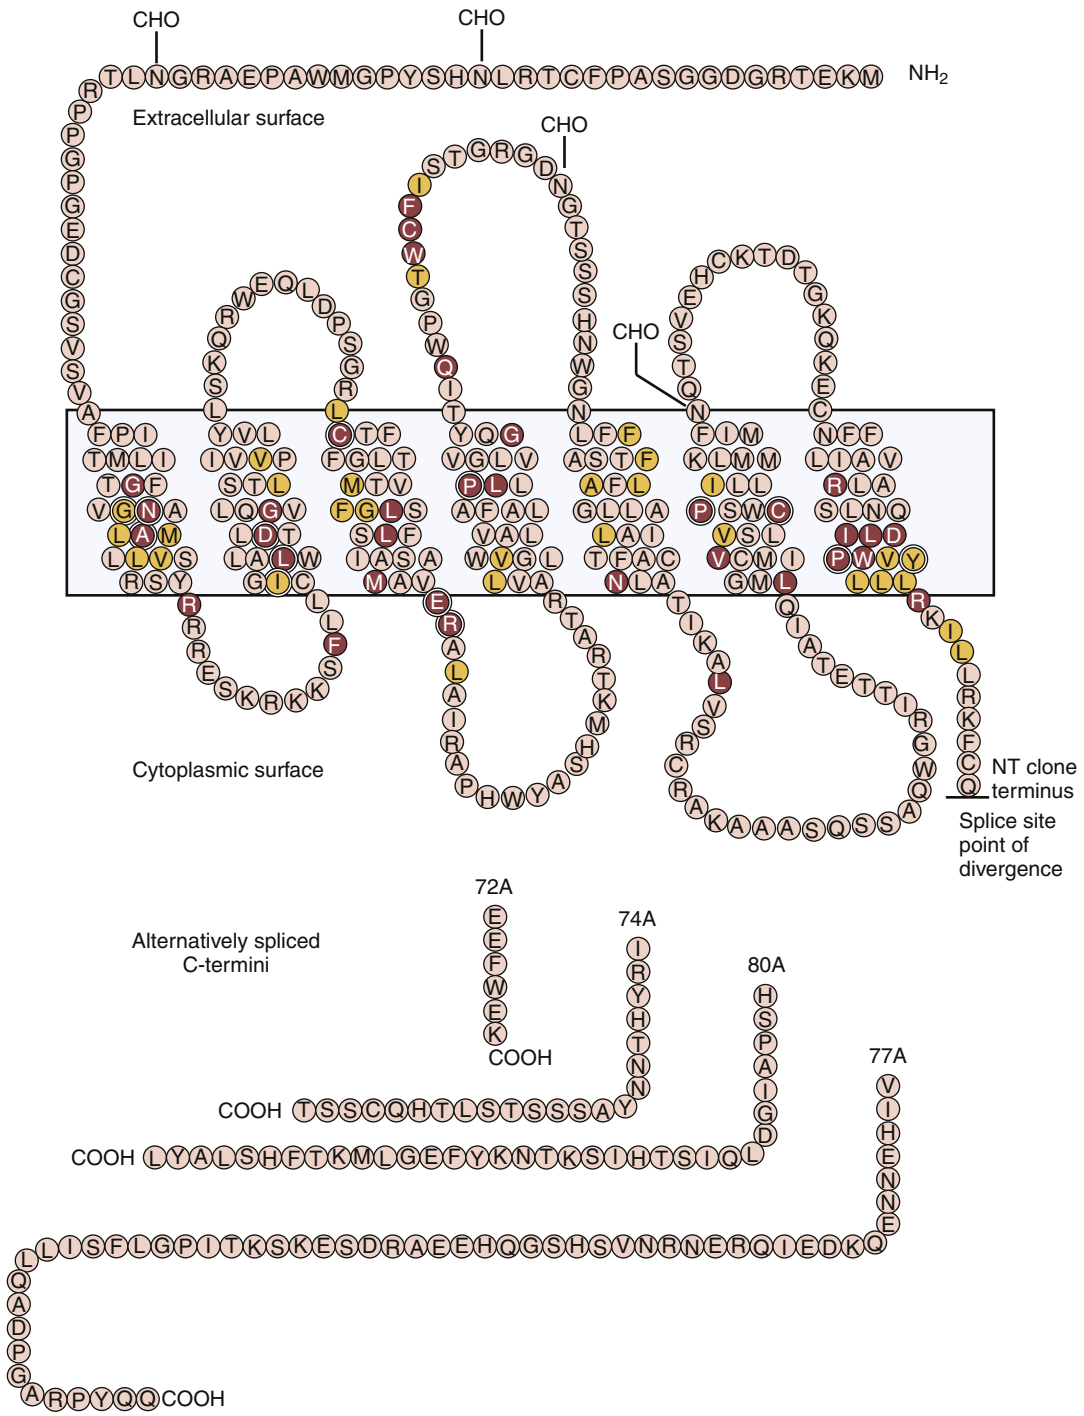

FIGURE 6.6 Schematic representation of five rabbit EP3 receptor splice variants differing only in their intracellular carboxyl termini. The carboxyl-variable tails range from 56–amino acid residues for clone 77A to none for the NT (no-tail) clone. Conserved residues in the EP3 receptor are also identified after EP3 receptor sequences from various species are aligned with those of other prostanoid receptors. Conserved residues are indicated by *yellow circles,* and invariant residues are indicated by *red circles.* Residues with *bulls-eye symbols* are conserved across the entire superfamily of G-protein–coupled receptors; those without this inset are unique to the prostanoid receptors. The amino acid sequences of each splice variant are represented by a one-letter amino acid code. *(From Breyer RM, Bagdassarian CK, Myers SA, et al. Prostanoid receptors: subtypes and signaling.* Annu Rev Pharmacol Toxicol *41:661–690, 2001, with permission.)*

CysLT2, originally defined by pharmacological methods in trachea and pulmonary vein preparations, is expressed in the spleen, Purkinje fibers of the heart, the adrenal gland and the microvasculature of certain organs.[74,75] Both LTD_4 and LTC_4 are equipotent agonists for this receptor, which also increases intracellular calcium when activated.[74] Other CysLT receptors may exist but still await definitive characterization.

Apart from activating plasma membrane receptors, there is considerable interest in the putative functions of eicosanoids as ligands for nuclear receptors, specifically members of the peroxisomal proliferator–activated receptor (PPAR)

Table 6.2 Physiological Roles and Therapeutics of Eicosanoids in Reproduction

Function	COX Enzyme	Eicosanoids	Receptor	Therapeutics
Ovulation	COX-2	PGE_2	EP2	
Luteolysis		$PGF_{2\alpha}$	FP	
Fertilization	COX-2			
Implantation	COX-2	PGI_2	PPAR

Erectile dysfunction				PGE_1

COX, cyclooxygenase; NSAIDs, nonsteroidal anti-inflammatory drugs.

family. However, unlike the well-accepted functions of the membrane receptors, the involvement and *in vivo* significance of nuclear receptors in eicosanoid signaling remains an evolving concept.[76] Several prostanoids in the PGA and PGD series have been shown to be ligands for PPARα or PPARδ in receptor activation and functional assays (e.g., promotion of fibroblast differentiation to adipocytes); dehydration products of these prostanoids (such as 15-deoxy-$\Delta^{12,14}$-PGJ_2) and products of lipoxygenase pathways, such as 8(S)-HETE and LTB_4, have similar activities.[77-80]

PGI_2 formed from COX-2 has been proposed to act as a natural ligand for PPARδ to mediate processes ranging from colorectal carcinogenesis,[81] to apoptosis,[82] to embryo implantation.[83] However, the relative importance of eicosanoids signaling through nuclear receptors under physiological conditions remains speculative compared to the well-established signaling via eicosanoid G protein receptor-coupling.

Eicosanoids and Reproduction

The role of eicosanoids in reproductive processes is one of the most intensely investigated of their biological functions. In fact, the uterine-contracting property of PGs led to their discovery. The activity of PGs in stimulating uterine contractility and inducing cervical ripening rendered them and their synthetic analogs attractive candidates for labor induction and as abortifacients.[84-86] For example, misoprostol, a PGE_1 analog, has been used, alone or in combination with mifepristone, for first-, second-, and third-trimester abortions.

Traditional NSAIDs, via their capacity to inhibit eicosanoid biosynthesis, block ovulation in several mammalian species,[87] and PGE_2 and $PGF_{2\alpha}$ are well known as effective luteolytic agents within the veterinary community.[88,89] PG biosynthesis is involved in maintaining ductus arteriosus (DA) patency during fetal life, and in anecdotal reports, NSAID use during pregnancy was associated with increased risk of premature DA closure and fetal demise.[90,91] Advances in eicosanoid pathway molecular biology have significantly improved our understanding of the role PGs play in reproduction. Much of this knowledge has emerged from studies using knockout mice. Table 6.2 summarizes the major reproductive steps where eicosanoids are known to play a physiological role or have been shown to have therapeutic relevance.

Gonadotropin Release

Prostaglandins modulate the secretion of luteinizing hormone (LH) and, to some extent, follicle-stimulating hormone (FSH).[92] This is believed to occur through modulation of hypothalamic LH-releasing hormone (LHRH), because PGE_2 stimulates the release of LHRH *in vivo*,[93] but does not directly affect the release of LH from the pituitary.[92-93] Furthermore, immortalized neurons contain transcripts of both COX-1 and COX-2.[94] PGE_2 may also regulate the LHRH pulse generator.[92,94-95]

However, studies of COX-deficient mice have shown that the hypothalamic content of LHRH in COX-1-deficient and COX-2-deficient mice is comparable to that of wild-type mice.[96] This observation suggests that neither COX-1 nor COX-2 plays an indispensable role in LHRH production in mice. The potential effect of COX enzyme deficiency on the pulsatility of LHRH release during the estrous cycle remains to be evaluated.

In contrast to hypothalamic LHRH, pituitary FSH content was significantly elevated in both COX-1– and COX-2–deficient mice.[96] There was also a tendency for increased pituitary LH content in the COX-deficient mice, although the increase was less pronounced.[96] The mechanism for the increase in pituitary FSH content in the COX-deficient mice is not clear. Nevertheless, serum gonadotropin and steroid levels in COX-1– and COX-2–deficient mice were unchanged compared with wild-type mice.[96]

Furthermore, COX-1– and COX-2–deficient mice exhibited estrous cycles and normal mating behavior. Therefore, COX enzymes may not be involved in the regulation of the neuroendocrine axis suggesting that the reproductive abnormalities observed in COX-deficient mice[54-57] must have resulted from defects in peripheral reproductive organs.

Ovulation

An essential role for PGs in ovarian function was established many years ago,[87] and the intricacies of their mechanism of action have been delineated (see Chapter 9). A series of elegant studies established that induction of COX-2 in the preovulatory follicles of the rat ovary was an obligatory downstream event in the LH surge–stimulated ovulation process.[97-100]

In contrast to the COX-1 enzyme, which was constitutively expressed in thecal cells and corpora lutea, LH-induced COX-2 enzyme was present in granulosa cells of the rat preovulatory follicles.[97-100] This observation was later extended to other mammalian species, including the cow and mare.[101] Interestingly, the time required for COX-2 induction in preovulatory follicles after the LH surge differed considerably in various species (2 to 4 hours in the rat, 18 hours in the cow, and 30 hours in the mare), yet induction of COX-2 expression always occurred approximately 10 hours before ovulation in each of these mammals.[101]

LH surge–induced COX-2 expression in the granulosa cells of macaques, a primate species, has also been established using reverse transcriptase–polymerase chain reaction and immunocytochemistry methods.[102] Furthermore, follicular administration of indomethacin in the rhesus monkey was demonstrated to significantly, although not completely, inhibit oocyte release from the ovary.[103]

Thus, in primate, rodent, and domesticated animal species, the induction of COX-2 seems to serve as an "alarm" signal for ovulation.[101,104] Ovulation, initiated by the LH surge that leads to a cascade of proteolytic events that culminate in follicle rupture and release of the ovum, has often been compared to an inflammatory response.[105] In this regard, it is fitting that COX-2, rather than COX-1, should be implicated in this process.

The predominant role of COX-2 in the ovulation process was ratified by studies using COX-1– and COX-2–deficient mice. Mice lacking the COX-2 enzyme had multiple reproductive failures, including ovulation defects, whereas COX-1–deficient mice had impaired parturition, but ovulated normally.[57,96] Biochemical studies showed that exogenous gonadotropins (pregnant mare serum gonadotropin [PMSG] and human chorionic gonadotropin [hCG]) stimulated a fourfold increase in ovarian PGE_2 levels in wild-type and COX-1–deficient mice 8 hours after hormonal challenge; COX-2–deficient mice showed no such increase.[96]

Examination at the cellular level showed that the primary defect responsible for failed ovulation in COX-2–deficient mice was impaired expansion of the cumulus oophorus. This impairment possibly originated from an alteration in the proteoglycan contents of the cumulus oophorus and follicular wall.[96] Whether COX-2 deficiency might also have affected the activation of proteolytic enzymes that participate in the breakdown of the follicular wall is not yet known. Indomethacin treatment, however, did cause oocyte retention but did not prevent follicular rupture in the rhesus monkey ovary.[103]

The critical role of COX-2 in ovulation has also been corroborated by pharmacological studies using coxibs as selective inhibitors of this enzyme in wild-type animals. Administration of celecoxib to mice[106] and NS-398 to rats[107] decreased, but did not abolish, ovulation in the treated animals. NS-398 also reduced PGE_2 synthesis in isolated LH-stimulated rat preovulatory follicles *in vitro*.

The degree of inhibition of PGE_2 synthesis by NS-398 in this assay was similar to that achieved by indomethacin, supporting the conclusion that COX-2 mediated the previously observed ovulation blockade by traditional NSAIDs.[87] Finally, delayed follicular rupture in humans by the selective COX-2 inhibitor rofecoxib was observed in a randomized double-blind study,[108] supporting a link between NSAID use and reversible female infertility originating from ovulation interference.[108]

Several lines of evidence suggest that PGE_2 is the principal COX-2 product that mediates the ovulation process.[109] First, ovarian PGE_2 production is increased in response to the LH surge. Second, application of exogenous PGE_2 to gonadotropin-primed, COX-2–deficient mice corrected the anovulatory phenotype.[96] Administration of $PGF_{2\alpha}$ in the same experiment also slightly improved the ovulation outcome, but this was most likely attributable to cross-activation of PGE receptors by $PGF_{2\alpha}$ because no ovulatory abnormality was detected in FP-deficient mice.[110]

Third, a moderate reduction in the ovulation rate has been detected in two independently generated EP2-deficient mouse lines,[111,112] but no apparent ovulation defect has been seen in other prostanoid receptor–mutant mice. EP2-deficient mice had severely compromised fertility, which was attributed partially to an ovulation defect and predominantly to fertilization failure.[111,112]

A role for EP2 in ovulation and fertilization is supported by its specific expression in the cumulus cells of the preovulatory follicles, where it is up-regulated in response to gonadotropin stimulation.[112] The impaired fertilization of EP2-deficient mouse eggs was shown to result from abortive cumulus expansion in the oviduct,[112] a phenomenon also observed in the preovulatory follicles of COX-2–deficient mice.[96] These studies suggested that EP2 may be essential for the late-stage events of ovulation by inducing ordered cumulus expansion after ovulation to ensure successful fertilization; however, it is relevant but not indispensable for follicular rupture and ova release.

Contrary to these initial findings, another follow-up study of adult COX-2–deficient and EP2-deficient mice concluded that the ovulatory process, *not* follicular growth, oocyte maturation, or fertilization, is primarily affected by these deficiencies.[113] This study also showed that severely compromised ovulation, seen in adult COX-2–deficient and EP2-deficient mice, was not manifested in immature (3-week-old) mice with those same deficiencies. This finding suggests that the process of ovulation may be more dependent on PGs in adult mice.[113]

If EP2 is the receptor subtype physiologically responsible for initiating PGE_2-induced ovulation in follicles, then the incomplete penetration of the ovulation phenotype in EP2-deficient mice could indicate compensatory responses from other EP receptor subtypes in this process. In addition to EP2, EP4 messenger RNA (mRNA) and protein are detected in mouse and monkey oocytes.[109] More recent data have implicated multiple EP receptors in regulating proteolysis in the primate periovulatory follicle.[114]

Corpus Luteum Function and Luteolysis

Ovarian PGE_2 levels were slightly suppressed in both COX-1–and COX-2–mutant mice 24 hours after hormonal stimulation.[96] This discovery suggested that, whereas COX-2–derived PGs are responsible for ovulation, both isozymes may contribute to PG production during formation of the corpora lutea. However, neither COX isoform is indispensable for granulosa cell development or corpora lutea formation, because ovarian morphology and steroid hormone production in COX-deficient mice were similar to those of

wild-type mice 24 to 30 hours after gonadotropin stimulation.[96] There was also no apparent difference in estrous cyclicity between wild-type, COX-1–deficient, and COX-2–deficient mice.[96]

The role of $PGF_{2\alpha}$ as a physiological luteolysin has been well established in many nonprimate mammalian species that depend on the presence of the uterus for corpus luteum regression. Indeed, this finding proved to be a major breakthrough in the livestock industry, where $PGF_{2\alpha}$ and its synthetic analogs are routinely used to regulate the breeding of domesticated animals.

Although FP is expressed in the corpora lutea of mice during a normal estrous cycle, no change was found in the estrous cycle or in the number of corpora lutea in homozygous FP-deficient mice.[110] On the other hand, FP-deficient pregnant mice showed a parturition defect due to lack of luteolysis before the onset of labor.[110] Thus, $PGF_{2\alpha}$ acts as a luteolysin in pregnant mice, but not in nonpregnant, normally cycling female mice.

The involvement of PGs in the luteolysis of primate species is not as well defined (see Chapter 9). Unlike in other mammals, the primate corpus luteum undergoes luteolysis in the absence of the uterus. There is, however, evidence to suggest that locally produced PGs in the ovary may act as mediators to promote luteolysis. For example, $PGF_{2\alpha}$ is produced by the human corpus luteum, and specific receptors for $PGF_{2\alpha}$ are located in human luteal tissue.[115] High doses of $PGF_{2\alpha}$ injected directly into human corpus luteum *in vivo* also caused premature regression of the corpus luteum and shortening of cycle length.[116]

On the other hand, results from PG synthesis–inhibitor experiments in the rhesus monkey have been equivocal.[117,118] Also, it is not known whether PG levels change significantly in the primate ovary or corpus luteum during the luteal phase.[119] Thus, although there is considerable evidence that PGs of ovarian or luteal origin may participate in the induction of corpus luteum regression in primates, further studies will be required to conclusively resolve this question.[119]

Fertilization, Implantation, and Decidualization

The role of PGs in oocyte maturation and fertilization is supported by the phenotype of COX-2–deficient mice (see Chapter 9).[57] In addition to an ovulation defect, the few ovulated eggs from COX-2–deficient female mice recovered after PMSG and hCG challenge were totally incapable of being fertilized.[57] In accordance with this observation, immunostaining detected COX-2 enzyme in wild-type mouse cumulus cells enclosing ovulated eggs.[57] Thus, local COX-2–derived PGE_2 in the cumulus cells may function as an autocrine factor to activate EP receptors and induce cumulus cell expansion necessary for successful fertilization.

COX-1, on the other hand, is not required for embryo implantation and uterine decidualization.[57] Because COX-2–deficient mice are defective in ovulation and fertilization, the implantation and decidualization processes in these animals could be investigated only by embryo transfer (from wild-type mice) and by a procedure involving intraluminal infusion of oil to induce artificial decidualization.[57,83,120]

Initial published studies showed that 50% of the transferred embryos were successfully implanted in the uteri of wild-type mice at day 5 after pseudopregnancy, but fewer than 2% of the embryos implanted in the uteri of COX-2–deficient mice were successfully transferred.[57] Likewise, induction of artificial decidualization in wild-type mice caused a sixteenfold increase in uterine wet weight, but did not produce any appreciable weight gain in COX-2–deficient mouse uteri.[57] The failure of implantation and decidualization in COX-2–deficient mice is not secondary to steroid hormone insufficiency from ovarian dysfunction, because supplementation of progesterone and estradiol did not rescue the phenotype.[57]

A specific role for COX-2 (but not COX-1) in these processes is also supported by the dynamic regulation of COX-2 expression in mouse uterus. Although COX-2 is normally expressed minimally in the uterus, it is robustly induced at 2 hours after artificial decidualization and its expression returns to basal levels within 8 hours. COX-1, in contrast, is constitutively expressed in the mouse uterus and barely changes its expression during decidualization.[57]

A critical role for COX-2 in implantation was disputed in a separate study conducted by Cheng and Stewart.[120] Their investigation into the role of COX-2 in embryo implantation and uterine decidualization concluded that COX-2 has a role in mediating the initial uterine decidual response, but is *not* essential for embryo implantation, sustained decidual growth, or embryo development throughout the remainder of pregnancy.[120]

PGI_2 may be the eicosanoid that mediates COX-2–dependent embryo implantation and uterine decidualization.[57,83] Researchers have proposed that the effect of PGI_2 in these processes is mediated by the nuclear receptor PPARδ. PGI_2 is the most abundant prostanoid formed at implantation and decidualization sites, and PGI_2 synthase transcriptsare also present and up-regulated at the implantation sites between day 5 and day 8 of pregnancy.[57,83]

The finding in earlier studies that two PGI_2 analogs (carbaprostacyclin [cPGI] and iloprost) activated PPARδ[121] and that IP-deficient mice had normal fertility[122] led to the hypothesis that endogenous PGI_2 mediates embryo implantation and decidualization through PPARδ.[57,83] The coordinated uterine expression of PPARδ and COX-2 during decidualization supports this contention. The hypothesis was also supported by the finding that PGI_2 agonists such as cPGI and iloprost (as well as a classic PPARδ-selective agonist, L-165,041) restored implantation and decidualization in COX-2–deficient mice.[57,83] Moreover, PPARδ was found to be essential for spontaneous and preimplantation PGI_2-stimulated embryo development and blastocyst hatching.[123] The implantation of cultured embryos was enhanced by PPARδ activation.

Nevertheless, many questions remain to be answered about the validity of this hypothesis. First, varied phenotypes of PPARδ-deficient mice have been reported.[124] Second, cPGI and iloprost have been shown to activate PPARδ,[57,83,121] but one cannot assume with certainty that endogenous PGI_2 will do the same. Indeed, cicaprost, another PGI_2 agonist for membrane IP, was not an activator of PPARδ,[121] suggesting that caution should be exercised when extrapolating data from PGI_2 analogs. Third, it is possible that implantation and decidualization could be mediated

by COX-2 and PPARδ as separate and redundant pathways. To further muddy the waters, more recent studies suggest that IP receptors play an important role in preimplantation embryo development and mediate the embryo's response to exogenous PGI_2.[125] A PPARδ agonist had no effect in IP receptor knockout mice, suggesting that the nuclear receptor pathway may be downstream of IP activation. Clearly, more research is needed on this topic. Even if the PGI_2-PPARδ hypothesis is accepted at face value, the mechanism and downstream events of this signaling pathway in the uterus remain to be established. No specific defect in the expression of implantation-related genes or steroid responsiveness has been found in the uterus of COX-2–deficient mice.[57] The direct causes of impaired implantation and decidualization failure in these animals are still unknown. Clearly, however, other eicosanoids are needed for the implanted embryos to develop to term. Thus, administration of cPGI was shown to improve implantation and decidualization in COX-2–deficient mice, but the subsequent growth of the implanted embryos in these mice was not comparable to that implanted in the wild-type mice.[57,83] Interestingly, coadministration of cPGI with PGE_2 markedly improved embryonic and decidual growth in COX-2–deficient mice.[83]

Menstruation and Dysmenorrhea

Abnormal PG biosynthesis is involved in the pathogenesis of human dysmenorrhea, a gynecological disorder that is defined as the occurrence of pain associated with menstruation (for a more detailed discussion of this topic, please see Chapter 27). Elevated levels of $PGF_{2\alpha}$ and PGE_2 occur in the endometrium and menstrual fluid of women who have dysmenorrhea, with an elevated ratio of $PGF_{2\alpha}$ to PGE_2.

A markedly increased capacity for PGI_2 synthesis has been detected in endometriosis tissue. This elevation is considered to cause hyperalgesia and to contribute significantly to dysmenorrhea in endometriosis.[126] Furthermore, intrauterine administration of $PGF_{2\alpha}$ induces uterine contractility and dysmenorrhea-like pain.[4]

Cumulative data of clinical trials have indicated that 80% of patients with significant primary dysmenorrhea experience adequate pain relief with the use of traditional NSAIDs.[127] Both celecoxib and valdecoxib, two COX-2–selective inhibitors, have also been used for the treatment of primary dysmenorrhea.[128,129] However, valdecoxib was removed from clinical use in 2005 because of an association with elevated risk of Stevens-Johnson syndrome and cardiovascular hazard, whereas celecoxib remains in use.

Parturition and NSAID Use in Preterm Labor

There has been a great deal of interest in the role that PGs play in term and preterm labor (see Chapters 12 and 28). Aspirin-like drugs were shown to delay parturition in humans more than 30 years ago,[130] and NSAIDs are also well known to be effective agents in attenuating the progression of term and preterm labor in various species.[131,132] PGE_2 and $PGF_{2\alpha}$, produced by both maternal and fetal tissues during pregnancy,[133] stimulate uterine contractions *in vitro* and *in vivo*; they also promote the coordinated inflammatory response that results in dilation and thinning of the cervix.[133] Studies with COX-1– and prostanoid receptor–deficient mice have provided additional insight into the role and mechanism of action of PGs in the process of parturition and preterm labor.

Although FP-deficient female mice grew and developed normally and became pregnant as expected, they did not deliver fetuses normally at term.[110] This complication was due entirely to impaired parturition. Fetuses could be rescued from FP-deficient mothers by cesarean operation before or at the expected term and survive normally. Uterine induction of the oxytocin receptor at term, an event believed to trigger parturition, did not occur in the FP-deficient mouse uterus.[110]

Additionally, FP-deficient mice did not experience a decline in maternal plasma progesterone level close to term; this decline usually occurs before parturition in mammals. It was quite revealing, however, that ovariectomy just before term completely normalized the parturition defect in FP-deficient mice.[110] Thus, ovariectomy of gravid FP-deficient mice decreased plasma progesterone levels, induced uterine oxytocin receptor expression, and initiated the onset of labor within 24 hours.[110] These observations suggest that $PGF_{2\alpha}$ induces labor through its luteolytic action in the ovary in rodents; its uterotonic action in the myometrium apparently is not essential for parturition.

A similar parturition defect was characterized in COX-1–deficient mice, and administration of $PGF_{2\alpha}$ was sufficient to correct this defect.[134] Thus, COX-1 is essential for the normal onset and progression of term labor and cannot be compensated for by unimpaired COX-2 activity. Remarkably, ovarian $PGF_{2\alpha}$ levels could be blocked by 85% in a COX-1 knockdown mouse model, and residual PG was still sufficient to promote timely luteolysis for initiation of labor.[135] There is still uncertainty regarding the contribution of fetal $PGF_{2\alpha}$ to this process. In one experiment involving reciprocal blastocyst transfers between wild-type and COX-1–deficient mice, maternal COX-1 expression was found to be both sufficient and necessary for the normal onset of labor.[134]

However, in another study, COX-1–deficient females carrying wild-type fetuses delivered their pups on schedule and with normal survival rates,[136] suggesting that maternally derived $PGF_{2\alpha}$ is dispensable. The idea that fetal $PGF_{2\alpha}$ contributes to parturition is also supported by another study by Cook and coworkers who found that increased mouse placental $PGF_{2\alpha}$ biosynthesis, catalyzed at least in part by up-regulated COX-2, is associated with uterine activation and the timing of birth.[137]

It is notable that studies of FP-deficient mice suggested that the primary target of $PGF_{2\alpha}$ action with regard to parturition is the corpus luteum, yet COX-1 mRNA levels in the ovary were quite low and relatively unchanged during pregnancy.[110] This contrasted with a fortyfold induction of COX-1 in the uterus in late gestation.[110] In addition, PGF synthase and a $PGF_{2\alpha}$-metabolizing enzyme, 15-OH-PGDH, were also time-dependently regulated in the pregnant mouse uterus, with a dramatic increase in PGFS and a decrease in 15-OH-PGDH toward late gestation.[138] Thus, primarily uterine-derived $PGF_{2\alpha}$ apparently activates ovarian FP and determines the timing of labor.

The lack of a parturition phenotype in PG receptor–deficient mice other than FP knockout mice suggests that PGs are less important in promoting cervical ripening and

myometrial contraction in the mouse. This hypothesis is supported by the finding that the luteolytic effect alone of $PGF_{2\alpha}$ made its function indispensable for murine parturition. This role contrasts greatly with what is believed to occur in human labor. Various PGs are produced in human myometrium with prostacyclin being the highest.[139] Recently, PGI_2 was paradoxically shown to prime pregnant human myometrium for an enhanced contractile response in parturition via induction of genes encoding for contractile proteins via the IP receptor.[140,141] Receptor sites for EP1, EP3, and FP are also present in human myometrial tissue,[142] as are the enzymes that generate PGs, including COX-2 and PGE synthase isoforms.[143]

Increased PG production is also associated with cervical ripening and a topically applied PG product, containing either dinoprostone or misoprostol, is the most popular means to soften and dilate the cervix in human labor induction.[144] Local administration of PGs to the cervix in pregnant women results in clinical, histological, and biochemical changes that are consistent with those observed during physiological cervical ripening. The mechanism of action of PGs in human cervical ripening is not known, but may include induction of major degrading enzymes and alterations in the expression of genes encoding proteins that modify proteoglycan function. The lack of a phenotype in COX and PG receptor knockout mice in cervical ripening and uterotonic responses may indicate a species difference, or it may suggest compensation in these tissues between the two COX enzymes.

Although COX-1 is involved in term labor, COX-2 induction is likely to be primarily responsible for PG-mediated preterm labor. COX-2, but not COX-1, is induced during inflammation-mediated preterm labor elicited by lipopolysaccharide (LPS) administration.[145] In a murine model, the COX-2–selective inhibitor SC-236 was found to be more effective than the COX-1–selective inhibitor SC-560 in stopping LPS-prompted preterm labor and increasing uterine PG synthesis.[145] Furthermore, COX-1–deficient mice, which showed delay in the onset of term labor, exhibited no delay in the onset of preterm labor after LPS treatment.[145]

Although it is likely that COX-2–derived $PGF_{2\alpha}$ acted as a luteolysin in the mouse model of LPS-induced preterm labor, it is not known whether the uterotonic effect of $PGF_{2\alpha}$ and other COX-2–derived PGs may also have played a role in this setting. The latter possibility may be particularly relevant to human preterm labor, because indomethacin, an inhibitor of both COX-1 and COX-2, has been used successfully in treating human preterm labor, both when given systemically and when delivered locally through the vaginal route.[146]

The clinical utility of indomethacin as a tocolytical agent, however, is tempered by concerns over fetal and neonatal complications, such as constriction of the ductus arteriosus.[146] The adverse effects associated with indomethacin use in preterm labor have been mainly linked to inhibition of COX-2 based on mouse studies using selective COX-1 and COX-2 inhibitors.[147] COX-1–selective inhibitors, should they be developed clinically, would be expected to produce fewer adverse effects than traditional NSAIDs when used as tocolytical agents.[147] Studies in animals and pregnant women comparing indomethacin and coxibs produced mixed results when fetal ductus blood flow was used as a measure of potential adverse effects. [148]

Ductus Arteriosus Remodeling

As mentioned earlier in the chapter, one of the complications of using NSAIDs such as indomethacin to treat preterm labor is the induction of premature closure of the fetal DA.[90,149] The DA is a large fetal vessel that shunts deoxygenated blood away from the pulmonary circulation to the descending aorta and to the umbilicoplacental circulation, where oxygenation takes place. In neonates, rapid remodeling of the DA leads to its closure after adaptation of spontaneous breathing in newborn infants. Although patency of the DA *in utero* is essential for proper fetal growth and development, failure of the DA to close after birth, called *persistent patent DA*, compromises postnatal health by causing circulatory complications such as pulmonary hypertension and congestive heart failure.[149]

Prostaglandins are intimately involved in DA function and its perinatal remodeling, and details of their mechanism of action are emerging. The finding that indomethacin administration induced premature DA closure in fetuses[90,149] suggested that fetal PGs are essential for maintaining DA patency. However, mice lacking both COX-1 and COX-2, unable to make any PGs, die postnatally with patent DA,[136,150] indicating that fetal-derived PGs are not necessary for maintaining DA patency *in utero*. Such PGs *do*, however, play an indispensable role in DA remodeling after birth.

How does one reconcile this phenotype with the results of pharmacological inhibition studies? Researchers have proposed that PGE_2 in the fetal circulation (supplied in part by the placenta) maintains dilation of the DA *in utero*, and that COX-2 in the DA produces constrictor PGs that are important for DA contraction after birth.[150] Thus, indomethacin-induced premature DA closure in fetuses may have reflected inhibition of dilatory PGE_2 synthesis in the placenta without sufficient inhibition of ductal COX-2 to attenuate DA contraction. Although COX-1 deficiency alone did not affect perinatal DA remodeling, it was found to exacerbate the phenotype of patent DA on the background of COX-2 deficiency.[150]

In other studies, mice deficient in the smooth muscle relaxant receptor EP4[151,152] or the PGE_2-metabolizing enzyme 15-OH-PGDH[153] also failed to survive postnatally due to patent DA. EP4 expression in DA and 15-OH-PGDH expression in the fetal lung increase dramatically just before birth, supporting the conclusion that these proteins play an important role in perinatal DA remodeling.

The phenotypes of EP4-deficient and 15-OH-PGDH–deficient mice, together with the results of pharmacological studies, support alternative models for the DA remodeling process.[152-154] Signals through EP4 have two essential roles in DA patency and remodeling, namely, vascular dilation and intimal cushion formation (ICF). The vascular smooth muscle–relaxing ability of PGE_2 acting via EP4 maintains patency during fetal life. When PGE_2 levels plummet at birth due to rapid and efficient metabolism by late gestation–induced 15-OH-PGDH activity, the vasodilatory role is curtailed and functional DA closure is triggered rapidly by an increase in oxygen tension. ICF occludes the vascular lumen and results in permanent closure after birth. ICF within the DA is a result of an increase in vascular smooth muscle cell migration and proliferation and the production

of hyaluronic acid (HA) under the endothelial layer, along with decreased elastin fiber assembly. PGE_2 via EP4 signaling during late gestation controls a gene, *HAS2*, that regulates HA synthesis and ICF.[154]

Pregnancy-Induced Hypertension and Preeclampsia

The possible involvement of PGs in pregnancy-induced hypertension (PIH) and preeclampsia and the potential therapeutic efficacy of low-dose aspirin in their prophylactic treatment have received considerable attention. PIH and preeclampsia occur in 10% of pregnancies and are recognized as important, prevalent sources of risk to both mother and fetus (see Chapter 28).

Although the exact cause of the disease is unknown, dysregulated production of PGI_2 and TxA_2 has been postulated as one of many potential etiological factors.[155] Decreased urinary PGI_2 metabolites are found to precede the development of PIH,[156] and increased TxA_2 metabolite excretion occurs in patients with severe preeclampsia.[157,158]

Such changes may predispose to vasoconstriction of small arteries, activation of platelets, and uteroplacental insufficiency—clinical outcomes that are associated with PIH and preeclampsia. In a murine model of enhanced TxA_2 activity, transgenic overexpression of TP in the vasculature resulted in intrauterine growth retardation that was rescued by timed suppression of TxA_2 synthesis with indomethacin.[159]

Many clinical trials have been conducted to evaluate the use of low-dose aspirin in the prevention of preeclampsia. Although some randomized studies indicated a beneficial effect for women at increased risk, most large-scale clinical trials did not establish a positive effect of low-dose aspirin use on reducing the incidence of preeclampsia or on improving perinatal outcomes in pregnant women at high risk for preeclampsia.[160-162]

In some studies, neither maternal serum TxB_2 concentrations at enrollment nor their subsequent reduction by low-dose aspirin intake were correlated with adverse pregnancy outcomes[163,164] but this may reflect poor study design as serum thromboxane does not adequately reflect augmented thromboxane biosynthesis. It is possible that aspirin trials failed because an increase in TX production is not the initial anomaly. Less controversial than the role of ASA in improving fetal outcomes in preeclampsia is the time-dependent hypotensive effect of low dose aspirin in a variety of hypertensive populations, including women with preeclampsia.

Eicosanoids in Male Reproduction

Although PGs are critically involved in multiple steps of female reproduction, as previously discussed, their physiological role in male reproduction is not well understood—although it appears to be less remarkable, based on gene knockout studies. No discernible male reproductive phenotype has been noted in any of the COX-deficient or prostanoid receptor–deficient mice.[54,55]

On the other hand, a number of studies have described androgen-dependent regulation and distinctive tissue distribution patterns of COX-1 and COX-2 enzymes, as well as PG-synthesizing enzymes, in the male reproductive tracts of rodents and humans.[165-168] Specific functions have also been documented for COX-2–derived PGD_2 and PGE_2 in mediating cytokine production in Leydig cells and in regulating apoptosis in the rat epididymis.[169,170] Although they are not definitive, such studies do suggest that PGs may be synthesized and functional in a regulated manner in the male reproductive organs, even though their physiological roles in these sites are dispensable.

In the future, a better understanding of the eicosanoid network in the male reproductive system may lead to new PG-based therapies or provide mechanistic insight about existing therapies. For example, highly specific expression of COX-2 has been found in the distal end of the rat vas deferens.[165] Because the distal vas comprises an extensive submucosal venous plexus connected to the penile corpora cavernosa, PGs from the vas may play a role in erection.[165] In this context, it is notable that intracavernosal injection of PGE_1 has been used clinically as an effective therapy for erectile dysfunction in man.[171,172] While PGs were originally isolated in large amounts in male seminal vesicles, their role at this site has remained enigmatic. The recent finding that ovarian PGs may act as sperm guidance factors via an insulin and Forkhead box class O (FOXO) transcription factor pathway[173] could indicate a synergistic role with male accessory gland-derived PGs.

Other LIPID Mediators: Lysophosphatidic Acid and Sphingosine-1-Phosphate

Besides eicosanoids, other lipid mediators have been implicated in reproductive function, in particular, lysophosphatidic acid (LPA) and sphingosine-1-phosphate (S1P). First, we briefly examine the features, synthesis, and signal transduction of LPA, and then we turn our attention to S1P.

The lipid mediator LPA is a lipid-signaling molecule as well as an intermediate in the *de novo* biosynthetic pathway of phospholipids, consisting of a glycerol backbone, a phosphate head group, and a long-chain fatty acid (usually oleic acid or palmitic acid), most commonly in acyl linkage (Fig. 6.1).[174] LPA generation is complex, proceeding by at least two pathways: conversion from lysophospholipids or via phosphatidic acid. Several phospholipase activities are necessary, including phospholipase A_1 (PLA_1)/PLA_2 plus lysophospholipase D (lysoPLD) and phospholipase D(PLD). Additional extracellular phospholipases, such as secretory PLA_2 (sPLA$_2$-IIA), membrane-associated PA-selective PLA_1 (mPA-PLA_1), and lecithin–cholesterol acyltransferase (LCAT), can also be involved.[175] LPA signaling is mediated primarily by six members of the G-protein–coupled receptor family, currently referred to as LPA_1, LPA_2, LPA_3, LPA_4, LPA_5, and LPA_6.[176]

The lipid mediator S1P is a bioactive sphingolipid derived from the abundant phospholipid sphingomyelin. Sphingomyelinases generate ceramide, which is cleaved by ceramidases to sphingosine, followed by phosphorylation by sphingosine kinases to S1P (Fig. 6.7).[177] S1P signals extracellularly via transmembrane receptors but also has intracellular targets.[178,179] There are five S1P receptors, also members of the GPCR family, referred to as $S1P_1$, $S1P_2$, $S1P_3$, $S1P_4$, and $S1P_5$.[180] The S1P stimulation of these receptors elicits a battery of downstream effects, including inhibition of cAMP and activation of mitogen-activated protein kinases, phospholipase C, and PI3 kinase to evoke a broad range of cellular activities.[180]

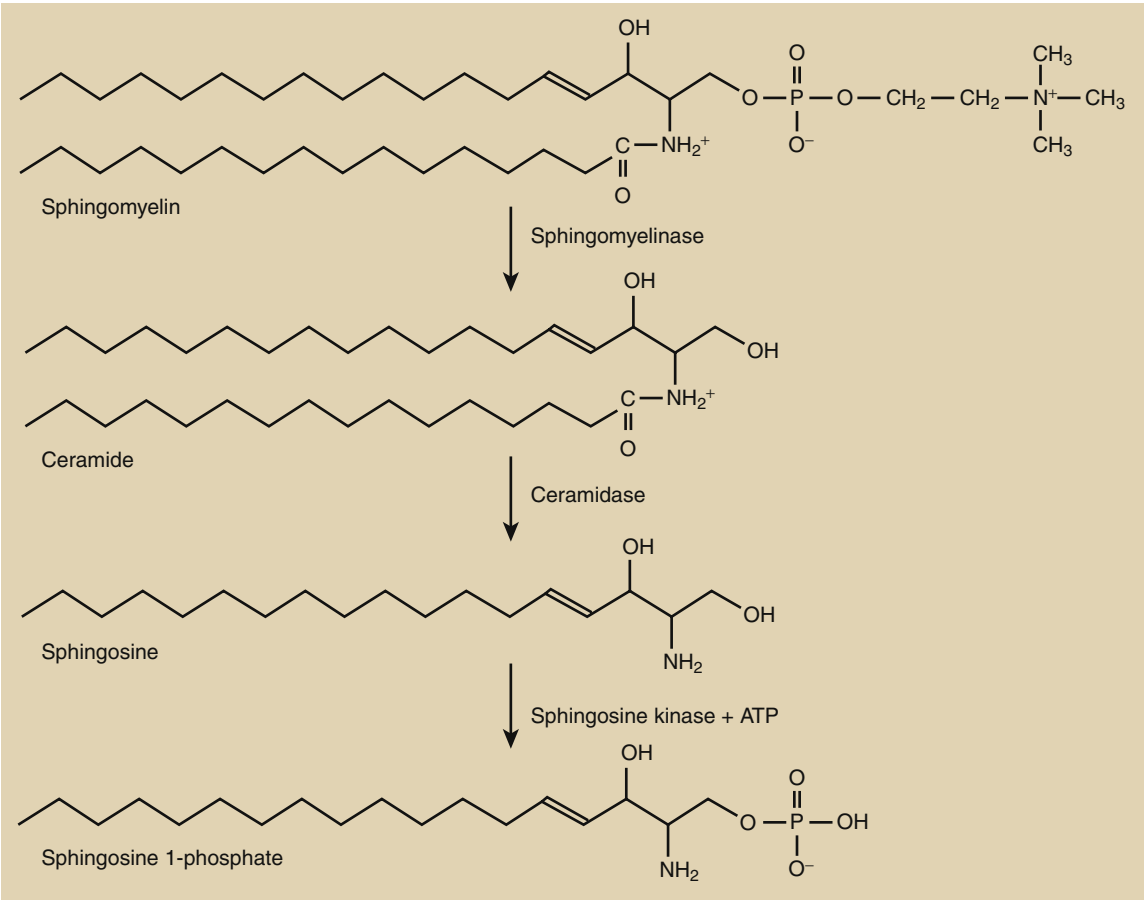

FIGURE 6.7 Structures and biosynthesis of a representative sphingosine-1-phosphate (S1P) lipid mediator from sphingomyelin. Sphingomyelinase removes the phosphorylcholine head group to yield ceramide. Ceramidase cleaves the amide bond removing one aliphatic chain to generate sphingosine. In the presence of ATP, sphingosine kinase will phosphorylate sphingosine to generate S1P.

LPA and S1P in Reproductive Function

The effect of LPA on the female reproductive system was recognized as early as 1980, when a series of LPA molecules with variable fatty acyl side chain lengths and degrees of saturation were shown to stimulate rat uterine smooth muscle contraction.[181] Most of the LPA receptor genes have been disrupted in mice, with some affecting reproductive function. LPA_3 (also known as *Edg7*) exhibits a female reproductive phenotype.[182,183] LPA_3 mRNA has been detected in oviduct, placenta, and uterus, but not in ovary and oocytes with expression highest early in pregnancy, at approximately embryonic day 3.5 (E3.5) in mice. LPA_3 is regulated positively by progesterone and negatively by estrogen.[182,183] LPA_3-deficient females produce small litters and show a prolongation of pregnancy by approximately 1.5 days (normal gestation, 19.5 days).[182] The mice show no obvious defects in ovulation, ovum transport, or blastocyst development. However, the defects were related to delayed implantation and altered crowding or positioning of embryos, which led to delayed embryonic development and death, accounting for the reduced litter size. The observed phenotypes were the result of maternal LPA_3 signaling and were not due to embryo LPA_3 signaling.[182] Strikingly, the phenotypes were similar to those seen with $cPLA_2$ female knockout mice and rodents treated with indomethacin.[184-186] Remarkably, LPA_3-deficient female uteri had markedly reduced COX-2 expression and PGE_2/PGI_2 levels at E3.5, thus linking LPA signaling to PG biosynthesis and fertility control.[182] Overall, this particular study raises speculation that therapeutic manipulation of LPA_3 signaling could influence the low implantation rate that is a major drawback during infertility treatments using assisted reproductive technologies.

LPA_1, LPA_2, and LPA_3 are differentially expressed in male testes with the latter two in the basal regions of seminiferous tubules, primarily in immature germ cells (spermatogonia and spermatocytes) and LPA_1 showing stage-specific expression in germ cells.[187] Triple knockout mice exhibit male reproductive defects including alterations in mating behavior and heterogeneic spermatogenic disruption resulting in sterility.[187] Many questions remain to be answered on the mechanisms for these effects.

Of the "newer" LPA receptors LPA_4, LPA_5, and LPA_6, there is no evidence for the involvement of these signaling pathways in reproductive function. LPA_4 has been detected in female ovaries, uterus, and placenta, but only one of three research groups reported a reduced litter size in mice deficient for LPA_4 but this was apparently attributable to other nonreproductive mechanisms.[188]

Clues to the roles of S1P in reproductive function have come from various sources. Based on expression studies of the five receptor subtypes that bind S1P, it is known that only three ($S1P_1$, $S1P_2$, and $S1P_3$) show widespread

distribution in mice, with evidence in gonadal tissues and in the uterus during decidualization (E4.5-7.5).[180,189] $S1P_1$ and $S1P_2$ colocalize with COX-2 at the maternal/fetal interface throughout pregnancy, suggesting a link between sphingolipid and PG signaling and indicating that S1P coordinates uterine mesometrial angiogenesis during implantation.[189]

Because $S1P_1$-deficient mice die in mid-embryogenesis as a result of complications of vasculogenesis, it has not been possible to decipher a role for this particular signaling pathway in reproductive function.[180] Both $S1P_2$- and $S1P_3$-null mice show no obvious phenotypes, with the exception of slightly smaller litter sizes.[176,180] However, when both rceptors are knocked out there is infertility.[176] The specific roles of each S1P receptor subtype in female reproductive function will still require more study.

A role for S1P in the preservation of female fertility is being recognized.[190] Programmed cell death (apoptosis) is an established paradigm in the mammalian female germline. Ceramide generated by membrane cleavage of sphingomyelin by sphingomyelinase or via *de novo* biosynthesis by ceramide synthase is translocated from cumulus cells to adjacent oocytes to induce germ cell apoptosis.[191] This is prevented by S1P, a ceramide metabolite within the same pathway or by acid sphingomyelinase (ASM) deficiency. The therapeutic management of infertility by S1P in premature menopause and in female patients with cancer appears promising, but awaits further study.[190]

Sphingolipids also seem to play a role in male germ cell apoptosis.[192,193] Ceramide induces an early apoptotic pathway event in male germ cells that is partially suppressed by S1P. However, although maintenance of normal sphingomyelin levels in testes and normal sperm motility are dependent on ASM, testicular ceramide production and the ability of germ cells to undergo apoptosis do not require ASM.

Summary

Prostaglandins and other lipid mediators are involved in many steps of the human reproductive process. Detailed understanding of their mechanisms of action in these steps has been greatly facilitated by the characterization of two COX enzymes, individual PG, LPA, and S1P receptors, and by the engineering of COX, PG, and LPA receptor gene–disrupted animal models. These studies have shown some distinct roles played by each of the two COX enzymes and by specific PG and LPA receptor pathways in mammalian reproduction.

Despite the tremendous progress made so far, much remains to be learned, particularly with regard to the molecular events downstream of PG, LPA, and S1P receptor activation in each of the reproductive steps where PGs, LPA, and S1P were found to be essential. Another challenge is to integrate the findings in animal models into the study of PGs, LPA, and S1P in human reproductive endocrinology. Continued interest and research in the field may lead to new PG-based and other lipid mediator therapies for reproductive disorders (such as endometriosis and preterm labor) and the reduction of adverse effects of NSAID use in women of reproductive age.

CHAPTER 7

Growth Factors and Reproduction

Caterina Clementi
Stephanie A. Pangas
Martin M. Matzuk

Beginning in early embryonic development, multiple growth factor pathways are essential for viability. In particular, transforming growth factor beta (TGFβ) family signaling pathways are important in growth and differentiation, as well as for regulation of embryonic stem cells (ESCs). For example, activins maintain human ESCs in their totipotent state, whereas bone morphogenetic proteins (BMPs) cause differentiation of human ESCs. Throughout reproduction, TGFβ family members function along with other growth factor signaling cascades (e.g., wingless-related (WNT), epidermal growth factor [EGF], steel-factor receptor [KIT], etc.) to permit the maintenance of the germline, development of the reproductive tracts, production of gametes, and creation of the next generation (Fig. 7.1). In this review, we will focus on major growth factor signaling in the mammalian reproductive tract beginning with the development of primordial germ cells (PGCs), and we will primarily concentrate on the roles of the TGFβ family.

Ovarian Development

Growth Factors in Primordial Germ Cell Formation and Migration

Future components of the mammalian ovary and testis develop long before a distinct bipotential organ can be discerned (Fig. 7.2). Growth factors are key for maintenance of the germline and their migration to the genital ridge. At the onset of gastrulation, PGC progenitors are induced in the epiblast in response to instructive signals from BMPs. This has been defined with great help through the development of mouse models[1-4] and is summarized in Table 7.1. BMP4 and BMP8B secreted from the extraembryonic ectoderm, and BMP2 secreted from the visceral endoderm, are required for the early discrimination of PGC precursors from somatic cells of the embryo. These BMPs signal in a dosage-dependent manner to the epiblast cells through a BMP receptor cascade, which involves phosphorylation of the BMP SMADs, SMAD1 and SMAD5, that along with their common SMAD partner, SMAD4, have been shown to function in this pathway. BMP2, BMP4, and BMP8B act on the pluripotent epiblast cells in the posterior of the embryo between embryonic day (E) 5.5 and E6.0 to induce their competency to become PGC precursors. At ~E6.25, six epiblast cells adjacent to the extraembryonic ectoderm express the BMP-regulated and PGC specification genes, PR domain containing 1 *(PRDM1*; also called *BLIMP1)* and *PRDM14*, and become committed to be true PGC precursors, the first such fate-committed cells of the embryo.[5] By E7.5, 40 founder PGCs are established.

Once PGC specification has occurred at E7.5, PGCs express markers of pluripotency including *POU5F1*, octomer-binding transcription factor 4 *(OCT4)*, SRY-box containing gene 2 *(SOX2)*, *NANOG*, developmental pluripotency-associated 3 *(DPPA3) (Stella)*, and *ALPL* (alkaline phosphatase). Between E7.5 and E8.5, the PGCs demonstrate major chromatin changes, increasing the levels of trimethylation of lysine 27 on histone H3 (H3K27me3) and erasing the dimethylation (H3K9me2) marks,[6] patterns that resemble the chromatin patterns of pluripotent stem cells. The H3K27me3 marks appear to repress the somatic cell gene expression program similar to ES cells. These changes cause PGC arrest at the G2 stage of the cell cycle, transiently causing the PGCs to become transcriptionally silent as they migrate from the base of the yolk sac along the hindgut to the genital ridge.[6]

An extracellular matrix gradient is important for PGC migration, and if too much matrix is deposited, PGCs show reduced migration. For example, suppression of TGFβ signaling by removing the TGFβ type 1 receptor, *Tgfbr1*, leads to enhanced migration due to reduction in the levels of TGFβ-induced collagen type 1 in the extracellular matrix.[7] Alternatively, *in vitro* migration assays demonstrate that KIT ligand, a growth factor that binds to KIT on PGCs, functions as an effective chemoattractant for PGC migration into the genital ridge. Consistent with the pleiotropic roles of the KIT ligand-KIT pathway, these proteins not only function in PGC migration but also aid in PGC survival and proliferation. The PI3K/AKT and SRC kinase pathways are also involved downstream of KIT in the functioning of the PGCs.[8]

Ovary Specification

PGCs proliferate during their migration to the genital ridge and after colonization. At this time, the gonad is not sexually differentiated and is termed "bi-potential" or "indifferent." BMP signaling within the bipotential gonad is necessary to develop a niche for migrating PGCs. Deletion of the BMP type 1 receptor, *Bmpr1a/Alk3*, in the genital ridge leads to death of somatic cells within the mesonephric mesenchyme and reduced levels of *Kitl* in the coelomic epithelium, ultimately decreasing the number, as well as

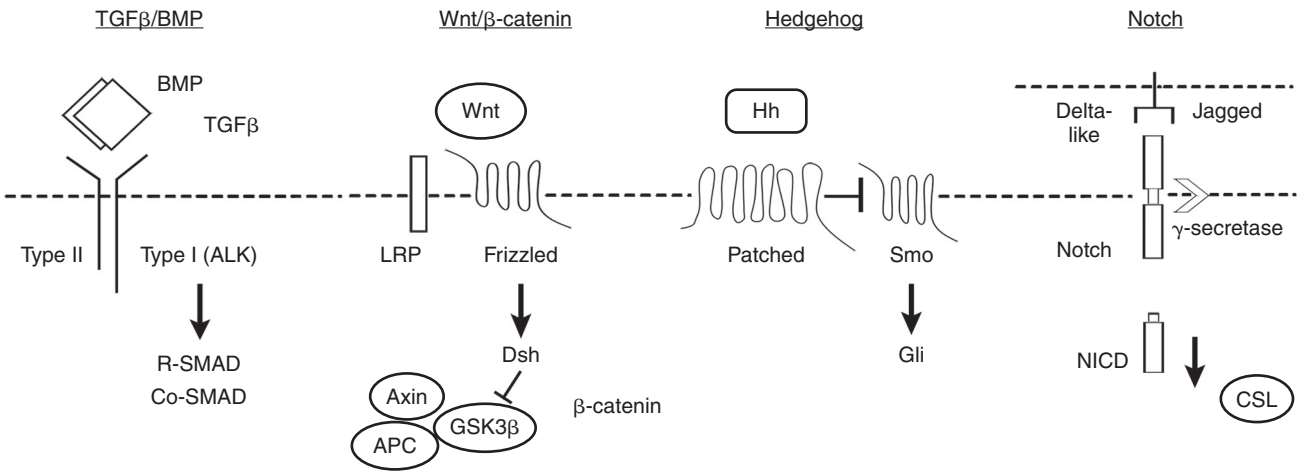

FIGURE 7.1 Canonical signaling for four major developmental pathways in ovarian and uterine function. **TGFβ /BMP:** TGFβ family members are secreted as dimeric proteins that bind to cell surface type 2 and type 1 serine threonine kinase receptors, which phosphorylate the intracellular SMAD transcription factors (R-SMAD). Once phosphorylated, the R-SMADs form a complex with a common SMAD (co-SMAD) and accumulate in the nucleus to regulate target genes. **WNT/β-catenin:** In the absence of WNT signaling, β-catenin is degraded by a complex including glycogen synthase kinase 3 (GSK3), axin and adenomatous polyposis coli (APC).[13] In its presence, WNT binds to a Frizzled receptor and coreceptor (low density lipoprotein receptor-related protein [LRP]) and β-catenin is stabilized by inactivation of the GSK3β complex by the phosphoprotein Disheveled (Dsh). β-catenin then accumulates in the cytosol and translocates to the nucleus as part of a transcriptional complex that includes T-cell factor/lymphoid enhancer binding factor (TCF/LEF) family members (not shown). **Hedgehog**: Hedgehog binds to the transmembrane receptor, Patched, resulting in the derepression of the Smoothened (Smo) receptor and activation of the glioma associated oncogene (GLI) transcription factors. **Notch:** The membrane-bound Notch receptor binds to its ligands, Delta-like and Jagged, localized on adjacent cell membranes. This actives the γ-secretase complex that cleaves the Notch intracellular domain (NICD). The NICD then translocates to the nucleus and interacts with the Epstein-Barr virus latency C promoter binding factor, suppressor of hairless/Lag1 (CSL) transcription factor family. Core components of each pathway are shown, without additional positive and negative regulatory inputs.

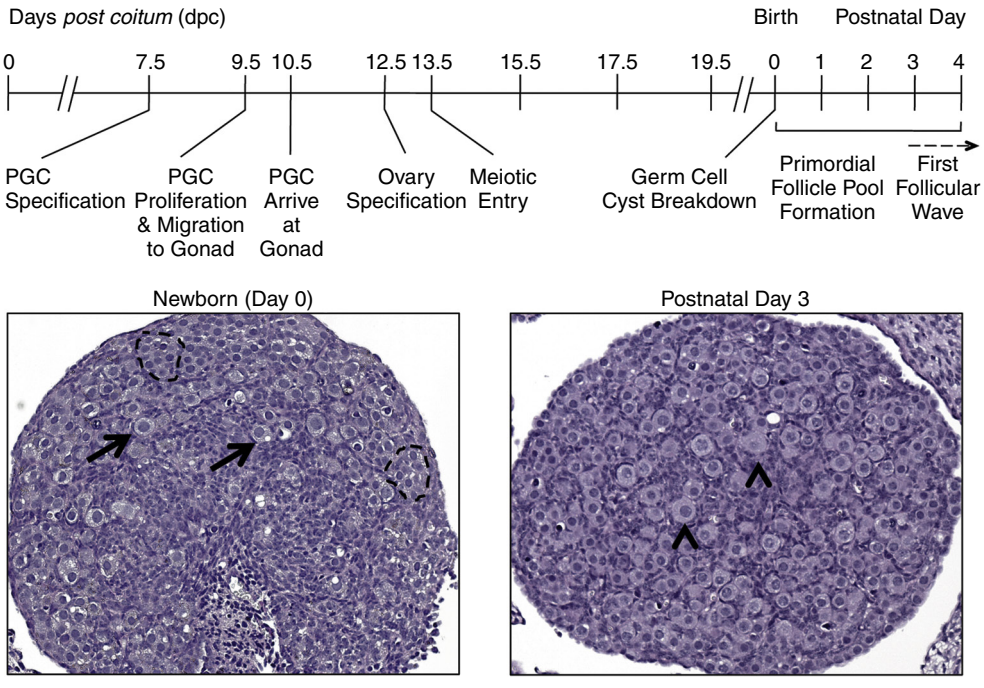

FIGURE 7.2 Timeline for female germline development from fertilization to birth in wild-type mice. Days post coitum (dpc) are shown in the top panel with key landmarks shown below. *Left lower panel,* histology of a newborn mouse ovary (postnatal day 0). Oocytes are organized into germ-cell-cysts *(dashed lines)* containing multiple oocytes, with a few forming primordial follicles *(arrows). Right lower panel,* Histology section of a postnatal day 3 mouse ovary. Most germ-cell-cysts have undergone breakdown to form primordial follicles, which in turn activate to form primary follicles *(arrowheads).*

migration, of the PGCs.[9] In mice, PGC proliferation ceases around E10.5-11.5, corresponding to 8 to 9 weeks of gestation in humans. *Bmp7* is required for germ cell proliferation, and *Bmp7* null mice have reduced numbers of germ cells after E11.5.[10] Activin may substitute for BMP7 in human embryos, since BMP7 is not expressed in the human ovary and BMP signaling alternatively promotes germ cell apoptosis.[11] Activin increases germ cell survival and proliferation in human ovaries prior to the entry of PGCs into meiosis.[12]

Differentiation of the bipotential gonad to form an ovary requires multiple signaling inputs, including that from the WNT-β-catenin pathway. Partial sex reversal is seen in XX

mice null for *Wnt4*, the WNT pathway activator protein *R-spondin 1 (Rspo1)*, or follistatin *(Fst)*, an antagonist of activin and BMP signaling. Loss of function *RSPO1* in XX patients results in complete female-to-male sex reversal while duplication of the chromosome region containing *WNT4* and *RSPO1* causes XY male-to-female sex reversal. Similarly, XY male-to-female sex reversal is observed in mice with a stable overexpression of β-catenin. β-catenin appears to be a central component to ovary specification, integrating signaling from the WNT and TGFβ family. Activation of WNT signaling allows stabilization and nuclear translocation of β-catenin, which interacts with a number of transcription factors of the TCF-LEF family to promote specific gene transcription.[13] Increased levels of β-catenin prevent the expression of SOX9, a transcription factor that promotes testes development by inducing Sertoli cell differentiation. β-catenin also increases expression of *Fst*, which shows a female-specific expression pattern at 11.5 dpc. *Wnt4*-null or *Fst*-null ovaries develop a coelomic vessel similar to that found in testes, and germ cells are lost by birth. *Wnt4*-null ovaries show an up-regulation of *Inhbb* (activin B) and *Fst*-null ovaries also express *Inhbb*. Genetic crosses between *Wnt4*-null or *Fst*-null mice to *Inhbb*-null mice prevents development of the coelomic vessel and rescues normal ovary development, indicating that *Inhbb* expression (via suppression by Wnt4) or activity (via antagonism through follistatin) must be limited to maintain ovary specification.[14-16] *Bmp2* is also expressed in a female-specific pattern after E11.5, though *Bmp2*-null mice die prior to this time period, and its function in the developing ovary has yet to be determined.

Male germ cells arrest in mitosis during embryogenesis and do not enter meiosis until after birth. In contrast, female germ cells enter meiosis shortly after ovary specification, which occurs around E13.5 in the mouse. Meiotic entry requires signaling inputs that are both intrinsic and extrinsic to the germ cells. Meiotic initiation at E13.5 in the mouse occurs in an anterior to posterior wave in the ovary from retinoic acid (RA) that is produced from the mesonephros. RA in the female ovary induces expression of *Stra8 (stimulated by retinoic acid gene 8)* in the germ cells. Germ cells from female mice null for *Stra8* do not enter into meiosis and do not express the meiotic markers *Dmc1* and *Spo11*. *Stra8* expression in the male is prevented by expression of *Cyp26b1*, which degrades RA. Loss of *Cyp26b1* in the testes results in a parallel increase in *Stra8* expression in germ cells as seen in normal ovary development and provides further support for the importance of RA signaling as a regulator of *Stra8* and meiotic onset. Additional genes are likely employed to maintain *Stra8* suppression in male germ cells prior to birth and their entry into meiosis, including *Nanos2*, an RNA-binding protein,[17] and *Nodal*, a member of the TGFβ family.[18]

Formation of the Ovarian Reserve

During embryonic development, oocytes within the ovary are found as clusters, or germ cell cysts (Fig. 7.2). These clusters form by both aggregation as well as clonal division.[19,20] Meiotic progression in oocytes ceases at the diplotene stage of prophase I when germ cells are enclosed by somatic cells into individual follicles called primordial follicles. Oocytes in primordial follicles remain arrested until released to complete meiosis I during ovulation and form the "ovarian reserve", which is thought to ultimately determine reproductive lifespan. Germ cell cyst breakdown occurs around birth in mice or during the second trimester in humans. In mice, the majority of germ cells within the cysts will die, with an estimated one-third remaining as primordial follicles.[21] Massive germ cell loss also occurs in humans, with an estimated 1 million oocytes surviving at birth from approximately 6 million in the fetal human ovary.

The mechanism for how oocytes become enclosed in primordial follicles has remained elusive, though multiple signaling inputs are likely required, particular those factors that mediate the interaction of oocytes with germ cells (Fig. 7.3). Signaling pathways that have been implicated in germ cell-cyst breakdown are kit ligand (KITL), nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF), Notch-Jagged, and anti-müllerian hormone (AMH).[22] Improper germ cell cyst breakdown can manifest as multiple oocytes within follicles (called *polyovular follicles*), though their biological effects on fertility are not certain. Mice with mutations in the TGFβ family, such as ovarian activin βA *(Inhba)* deficiency, inhibin alpha subunit overexpression, and knockout mice for oocyte-expressed *Bmp15*, often show increases in polyovular formation. In addition, polyovular follicle formation can be generated by exposure of neonatal mice to estrogen and estrogen-like compounds, which may suppress ovarian activin expression, thus disrupting the regulation of germ cell cyst breakdown.[23-25]

The origin of the somatic cells that surround each primordial follicle and eventually become granulosa cells of the follicle has been controversial. Sertoli cells and granulosa cells may arise from ingressing cells of the coelomic epithelium during gonad development, though the timing of their specification may be different.[26,27] In the testis, regulation of the transcription factor *Sox9* by the testis-determining factor, sex determining region on chromosome Y (SRY) is required for Sertoli cell differentiation. In the ovary, forkhead box 2 (FOXL2) acts to maintain granulosa cell differentiation, in

Table 7.1 Phenotypes for Mice with Mutations in PGC Pathway Components (Ordered Based on Temporal Function During Embryogenesis)

Gene Symbol	Phenotype; Findings
Bmp2	Embryonic lethal; reduced PGC
Bmp4	Embryonic lethal; no PGC
Bmp8b	Viable; male infertility; reduced PGC
Smad1	Embryonic lethal; reduced PGC
Smad5	Embryonic lethal; reduced PGC
Smad4	Embryonic lethal; absent PGC
Prdm1 (Blimp1)	Embryonic lethal; PGC specification defect
Prdm14	Infertility; PGC specification defect
Pou5f1 (Oct4)	Pluripotency marker
Nanog	Pluripotency marker
Sox2	Pluripotency marker
Kitl	Variable phenotypes depending on mutation; PGC migration defect
Kit	Variable phenotypes depending on mutation; PGC migration defect
Tgfbr1 (ALK5)	Embryonic lethal; enhanced PGC migration

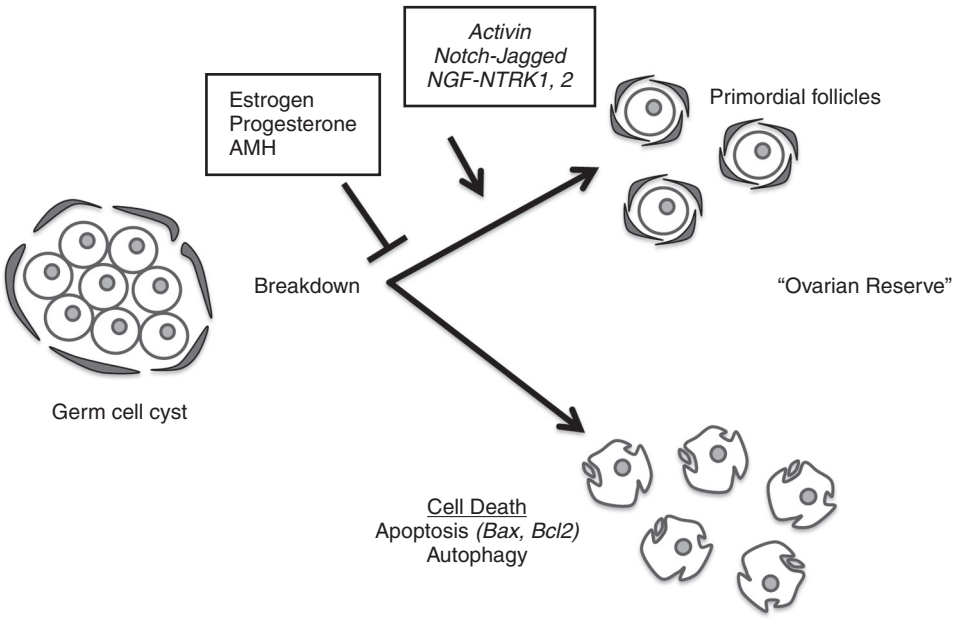

FIGURE 7.3 Key pathways in mice regulating germ cell cyst breakdown to form the ovarian reserve. Oocytes in germ-cell-cysts *(left)* undergo breakdown to either form primordial follicles *(upper pathway)* or die *(lower pathway)*. The number of resting primordial follicles makes up the "ovarian reserve." Key signal transduction pathways that regulate these processes are shown.

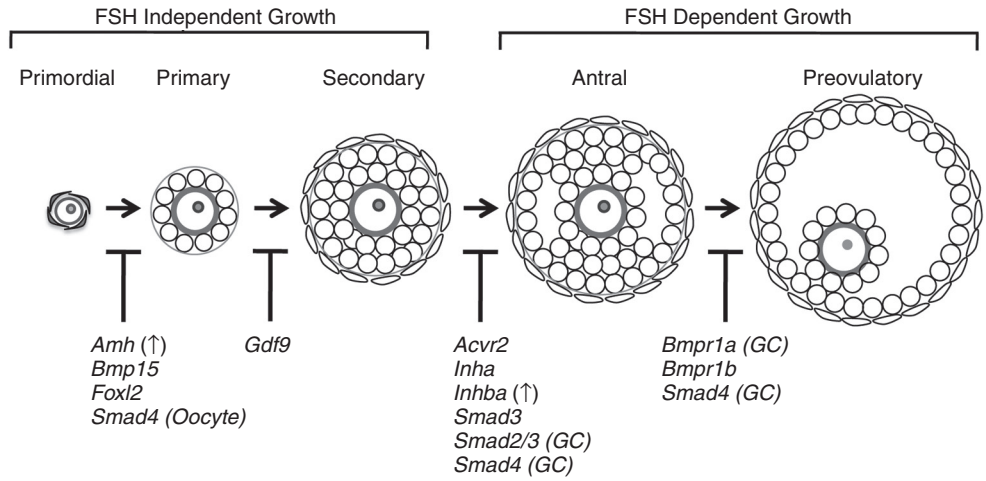

FIGURE 7.4 Schematic of follicle development. Resting follicles (primordial) are recruited into the growing pool and initially form "primary" follicles as granulosa cells form a cuboidal epithelium around the oocyte and proliferate. Multiple layers of GCs and acquisition of a thecal cell layer characterize "secondary follicles." An antrum then forms, and the follicle undergoes further differentiation to the preovulatory or "Graafian" stage under the influence of pituitary gonadotropins. Blocks in follicle development for various mouse knockout models are shown as discussed in the text and tables. Arrows in parentheses indicate a more rapid transition when the indicated genes are deleted.

part by suppressing expression of *Sox9*.[28] Mutations in the *FOXL2* genes are associated with several human diseases. The *FOXL2* gene is mutated in women with blepharophimosis ptosis epicanthus inversus syndrome (BPES), which in one form is associated with primary ovarian failure. Subsequently, it was shown that mice null for *Foxl2* were sterile with small ovaries and defects in primordial follicle assembly and growth (Fig. 7.4). FOXL2 interacts with different transcription factors, including SMAD2 and SMAD3, to control gene transcription in non-ovarian cell types, such as regulating *FSHB*, *FST*, and gonadotropin releasing hormone receptor synthesis in anterior pituitary cells.[29-31] In the developing mouse ovary, BMP2 and FOXL2 also cooperatively up-regulate *Fst* gene expression.[32] A somatic missense mutation in *FOXL2* is associated with almost all adult granulosa cell tumors,[33] a rare class of ovarian tumors. This mutation causes an amino acid substitution in the DNA-binding domain of FOXL2, though its functional consequence has not been fully clarified.

Ovarian Folliculogenesis

Ovarian Follicle Development

Once formed, quiescent primordial follicles supply all the oocytes during the reproductive lifespan of the female. This source of oocytes appears to be nonrenewable in mammals, although germ-like stem cells that can be differentiated into oocytes in culture have been reported.[34] Following their initial recruitment, a cohort of primordial follicles

Table 7.2 Mouse Models for Ligands in the TGFβ Family

Mutant Gene	Reproductive Phenotype	Fertility Status
Amh	Increased primordial follicle activation	Normal
Bmp6	Reduced ovulation	Subfertile
Bmp7	Reduced primordial germ cells	N.A.
Bmp15	Decreased ovulation and fertilization rates	Normal to subfertile
Gdf9	Follicular arrest at the primary follicle stage	Infertile
Fst	Loss of oocytes by birth	N.A.
Fst (Conditional)	Reduced growing follicles, ovulation and fertilization defects	Subfertile to infertile
Inha	Infertility, abnormal follicle growth, sex-cord stromal tumors	Infertile
Inhba (Conditional)	Increased polyovular follicles	Subfertile
Inhbb	Lactation defects	Infertile
Inhba Inhbb (Conditional)	Increased numbers of antral follicles and accumulation of corpora lutea	Infertile
Tgfb2	Increased oocytes at birth	N.A.*

*N.A., not available due to embryonic or perinatal lethality
The full version of this table, including references, can be found on the companion Expert Consult Web site at www.expertconsultbook.com.

undergoes a defined number of developmental follicular stages (Fig. 7.4).[35] The phosphoinositide-3-kinase (PI3K) regulates activation of oocytes within primordial follicles. Activation of PI3K signaling though deletion of the negative regulatory protein, *Pten*, or loss of an inhibitory transcription factor, *Foxo3*, results in global activation of primordial follicles and sterility in mice. The requirement of PI3K signaling in oocytes may be limited to the primordial follicle stage, because conditional deletion in mice of *Pten* from the primary stage onward has no affect on reproduction. Other oocyte-specific transcription factor cascades regulate early oocyte development, including *Nobox*, *Sohlh1*, *Sohlh2*, and *Figla*, which initiate an oocyte-specific gene expression pattern. Mutations in *NOBOX* and *FIGLA*, or their downstream targets, such as *GDF9* and *BMP15*, have been further implicated in the development of primary ovarian insufficiency in women.[36]

Following primordial follicle activation, pregranulosa cells undergo a squamous to cuboidal transition, forming the "primary follicles" (Fig. 7.4). Granulosa cell proliferation continues, and a second somatic cell layer composed of thecal cells recruited from the ovarian stroma, forms adjacent to the basement membrane surrounding the outermost layer of granulosa cells, resulting in a population of "secondary follicles." The oocyte-specific TGFβ family member, growth and differentiation factor 9 *(Gdf9)* is required at this stage, and mice null for *Gdf9* arrest at the primary to secondary stage and do not develop a thecal layer (Fig. 7.4); (Table 7.2). Thecal cells are required for steroidogenesis, as they produce androgens necessary for production of estrogen, and may provide additional growth factors and nutrients necessary for follicle growth.[37] The follicle arrest in *Gdf9*-null follicles is due to overproduction of inhibin α *(Inha)*—one of the subunits required to make the protein hormone inhibin, an antagonist of activin. Ovaries from *Inha-Gdf9* double knockout (DKO) mice develop multilayer follicles and form a morphologically distinct layer of cells that appear to be thecal cells. However, the thecal cells in *Inha-Gdf9* DKO ovaries never fully differentiate and are nonfunctional due to lack of expression of key genes, such as *17 alpha-hydroxylase (Cyp17)*, the luteinizing hormone (LH) receptor *(Lhcgr)*, and *Kit*.[38]

An additional TGFβ family member, anti-müllerian hormone (AMH) is also important as regulator of early follicle development, particularly for inhibition of primordial follicle activation (Table 7.2). AMH was discovered based on its function in sex determination and its ability to cause regression of the Müllerian duct during male reproductive tract development (see following section in this chapter, "Regression of the Müllerian Ducts"). In the ovary, AMH is expressed from granulosa cells of growing follicles until their development becomes dependent upon follicle-stimulating hormone at the later antral stages. Mice null for AMH initially have normal sized litters compared to wild-type mice, but demonstrate an accelerated loss of primordial follicles associated with an increasing number of growing follicles. This suggests that AMH negatively regulates primordial follicle activation.[39] In women, serum levels of AMH correlate with the number of antral follicles, and both decline with age. Thus, AMH has become a marker of ovarian reserve as well as reproductive disease in women. Its clinical utility is currently controversial but expanding in scope for use in monitoring ovarian reserve, response to *in vitro* fertilization protocols, granulosa cell tumor recurrence, and ovarian diseases such as primary ovarian insufficiency and polycystic ovary syndrome.[40,41]

Coordination of growth, and communication between cell types in the follicle is essential for follicle development to occur.[42] Multiple signaling pathways have critical inputs, including WNT-β-catenin, steroid hormone signaling, and kit ligand-kit signaling.[1,43] Preantral follicle growth is largely thought to be driven by intraovarian factors independent of input from FSH (Fig. 7.4). Mice null for the FSHβ subunit *(Fshb)* are infertile and do not form antral follicles. A similar block in follicle development is also seen in mice null for the activin binding receptor, *Acvr2a*, which have suppressed FSH production due to loss of activin signaling in the pituitary. Exogenous administration of gonadotropins in *Fshb*-null females results in ovulation, thus "rescuing" the phenotype[44], and demonstrates the switch from gonadotropin-independence to dependence at the final stages of follicle growth (Fig. 7.4).

Activin is a homodimer of β subunits derived from one of four genes in mammals, primarily *Inhba* or *Inhbb*, which generate activin A (βA:βA homodimers), activin B (βB:βB), or activin AB (βA:βB). Inhibin is an antagonist of activin and is formed by the dimerization of the *Inhba* or *Inhbb* gene products with a dissimilar alpha subunit, a product of the *Inha* gene (α:βA, inhibin A or α:βB forming inhibin B). Activin and inhibin were discovered based on their ability to stimulate (activin) or inhibit (inhibin) the secretion of FSH from the pituitary.[45] They are now known to be potent regulatory proteins with paracrine, autocrine, and endocrine functions in embryonic and adult tissue homeostasis, including the ovary. Inhibin antagonizes activin by competition for activin's binding receptors in conjunction with betaglycan,

Table 7.3 Phenotypes of Mice with Ovarian Deletion of the SMAD Transcription Factors

Gene	Cre	Cell-Specific Deletion	Reproductive Phenotype	Fertility Status
Smad1	Amhr2cre	Granulosa cell	None	Normal
Smad2	Amhr2cre	Granulosa cell	None	Normal
Smad3	Amhr2cre	Granulosa cell	None	Normal
Smad4	Amhr2cre	Granulosa cell	Reduced antral follicles and ovulation rates, cumulus cell defects, increased luteinization, increased progesterone	Subfertile, then 50% infertile by 6 months
Smad4	Gdf9-icre	Oocyte	Reduced litter sizes	Subfertile
Smad4	Zp3-cre	Oocyte	None	Normal
Smad5	Amhr2cre	Granulosa cell	None	Normal
Smad8	Knockout	Global	None	Normal
Smad2 Smad3	Amhr2cre	Granulosa cell	Reduced antral follicles and ovulation rates, cumulus cell defects	Subfertile, then infertile at 5 months
Smad1 Smad8	Amhr2cre	Granulosa cell	None	Normal
Smad5 Smad8	Amhr2cre	Granulosa cell	None	Normal
Smad1 Smad5	Amhr2cre	Granulosa cell	Granulosa cell tumors	Subfertile, then infertile at 4-6 months
Smad1 Smad5 Smad8	Amhr2cre	Granulosa cell	Granulosa cell tumors	Subfertile, then infertile at 4-6 months

The full version of this table, including references, can be found on the companion Expert Consult Web site at www.expertconsultbook.com.

a co-receptor.[46,47] Activin signaling can also be inhibited by follistatin, a high-affinity binding protein that prevents activin from binding to its receptors.

The activin subunits, *Inhba* and *Inhbb*, are expressed primarily in granulosa cells, though the receptors localize to thecal cells, granulosa cells, and oocytes.[48] Intraovarian activin promotes cell proliferation, and may modulate FSH action and steroidogenesis. *Inhba*-null mice and *Fst*-null die shortly after birth with craniofacial defects.[49-51] *Inhbb*-null female mice give birth to normal-sized litters, but offspring fail to thrive because the mothers have lactation defects.[52] Tissue-specific ("conditional") knockouts of *Inhba* and *Fst* have been generated in granulosa cells (Table 7.3). Stepwise removal of both activin subunit genes (*i.e.*, conditional deletion of *Inhba* concurrent with global loss of *Inhbb*) results in female sterility.[53] Activin-deficient mice have increased antral follicles and defective ovulation, suggesting that activin's role at the preantral stage is either limited or redundant with other factors. Strikingly, activin-deficient ovaries display an increasing number of corpora lutea with age and increases in two hormones of the reproductive axis, FSH and progesterone. Corpora lutea, the temporary endocrine structures that produce progesterone necessary for pregnancy to occur, fail to regress in activin-deficient ovaries, supporting a role for activin in the very terminal stage of follicle development. One key gene that is regulated by the TGFβ family, *Ctgf* (connective tissue growth factor), is down-regulated in activin-deficient ovaries.[53] Conditional deletion of *Ctgf* also results in impaired ovulation and increases in the number of corpora lutea as the activin-deficient ovary.[54]

Follistatin and inhibin are two antagonists of activin. Conditional deletion of follistatin in granulosa cells results in infertility in female mice (Table 7.2).[55] Deletion of the inhibin alpha subunit *(Inha)* also results in infertility and defects in follicle growth, but importantly causes the development of sex-cord stromal tumors (Table 7.2).[56,57] Activin-production from these tumors causes a cancer cachexia-like death in early adult *Inha*-null male and female mice.[58] Tumor development in *Inha*-null females can be slowed by removing *Acvr2a*, by deleting one of activin's downstream transcription factors (*Smad3*; discussed later in the chapter), or by overexpressing follistatin. These models support a growth-promoting role for activin in granulosa cells and sex-cord stromal tumor development.

SMAD2 and SMAD3 are the principle transcription factors that relay activin, TGFβ, and GDF9 signaling. Significant redundancy between these proteins likely exists during granulosa cell development, because single conditional knockouts of either *Smad2* or *Smad3* do not show reproductive defects (Table 7.3). However, *Smad2 Smad3* conditional DKO mice have reduced female fertility and fecundity, reduced numbers of antral-stage follicles, and contain follicles that have undergone premature luteinization. Furthermore, cumulus expansion—a process of extracellular matrix formation and loss of oocyte-cumulus cell connections that occurs during ovulation—is altered (discussed later in the chapter).[59] The phenotype of the *Smad2 Smad3* DKO is similar to that found for granulosa cell-specific *Smad4* conditional knockouts,[60] though the latter also showed increased atretic preantral follicles, suggesting that a SMAD4-dependent non-SMAD2-3 pathway may be important for preventing atresia in the preantral follicle stage.

BMPs are also expressed during preantral and antral stage follicle development from oocytes (*Bmp6* and *Bmp15*), granulosa cells *(Bmp2)*, and thecal cells (*Bmp4* and *Bmp7*). *Bmp6*-null mice have mild changes in their fecundity and BMP6 may regulate some aspects of ovulation.[61] BMP15 plays critical roles in sheep fecundity (discussed later in the chapter), and may interact with GDF9, as mice null for *Bmp15* containing one allele of *Gdf9* have reduced litter sizes compared to *Bmp15*-null mice.[62] Conditional deletion of two of the BMP type 1 receptors, *Bmpr1a* and *Bmpr1b*, in the ovary results in granulosa cell tumor development, as does deletion of the downstream BMP signaling SMADs, *Smad1* and *Smad5*. The histologic, hormone, and gene expression profile of the *Smad1 Smad5* DKO mice is similar to the juvenile form of human granulosa cell tumors.[63] *Smad1 Smad5* DKO mice die from metastatic disease, but do not develop the cancer cachexia-like syndrome of

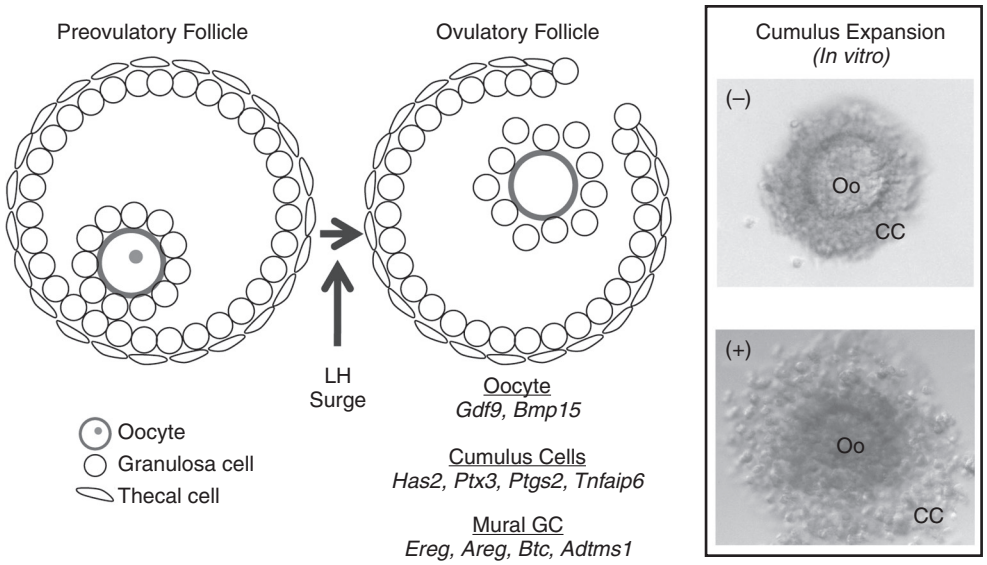

FIGURE 7.5 Ovulation and cumulus expansion in the mouse. Prior to the LH surge, preovulatory follicles contains an oocyte surrounded by cumulus cells and separated from the mural granulosa cells by a fluid filled cavity called an antrum. After a surge of luteinizing hormone (LH), the cumulus cells undergo expansion and become embedded in a hyaluronan-rich matrix, and the cumulus-oocyte complex is extruded from the follicle. An example of cumulus expansion *in vitro* using intact mouse cumulus-oocyte complexes and FSH treatment is shown in the right panels. Genes known to play critical roles in cumulus expansion are indicated underneath the cell types that express them. Oo, oocyte; CC, cumulus cells.

Inha-null mice, suggesting that activin is not overexpressed from the *Smad1 Smad5* DKO tumors. However, activated phosphorylated SMAD2 and SMAD3 is found in *Smad1 Smad5* DKO or *Inha* null tumors, as well as human juvenile granulosa cell tumors samples, suggesting that an active SMAD2/3 pathway plays a conserved role in development or progression of granulosa cell tumors.

Cumulus Expansion and Ovulation

Preantral follicle growth is followed by an antral follicle stage, which is defined by the presence of a fluid fill cavity, the antrum (Fig. 7.4). Under the influence of pituitary gonadotropins, antral follicles are selected to undergo final differentiation, ovulation, and subsequently, corpus luteum formation. Because of the presence of an antrum, preovulatory follicles contain two independent populations of granulosa cells: mural granulosa cells line the follicle wall and are closest to the theca and vasculature, while cumulus cells surround the oocyte and are linked initially with the oocyte for their functions (Fig. 7.5). The growth factor contributions of the mural and cumulus cell and their relevance to ovulation are most apparent at the time of the LH surge. The LH receptor *(Lhcgr)* is preferentially expressed only in mural granulosa cells, allowing them to respond to the LH surge, which initiates a cascade of events leading to oocyte meiotic resumption, cumulus expansion, follicle rupture, and terminal differentiation of the remaining granulosa and thecal cells to create the corpus luteum. Cumulus cell expansion, which is the production of a hyaluronan-rich extracellular matrix surrounding the oocyte, is initiated by the LH surge and is required for normal ovulation and fertilization. However, since the cumulus granulosa cells lack LHCGR and yet respond to the LH, this indicates an indirect effect of the LH surge on their fate.

How does the LH surge lead to induction of target genes in cumulus cells that are critical for cumulus expansion? Conti and colleagues have shown that the LH surge causes a rapid increase in epidermal growth factor (EGF)-like family members, amphiregulin (AREG), epiregulin (EREG), and betacellulin (BTC) specifically in mural granulosa cells of preovulatory follicles (Fig. 7.5).[64] These ligands are synthesized as membrane proteins and released from the cell surface into the antral fluid by proteolytic cleavage. These EGF-like proteins activate the EGF receptor (EGFR) on cumulus cells to exert the indirect effect of the LH surge to stimulate cumulus expansion and oocyte maturation. The effects of these EGF-like factors on cumulus expansion occurs through up-regulation of the genes encoding hyaluronan synthase 2 *(Has2)*, tumor necrosis factor-induced protein 6 *(Tnfaip6)*, pentraxin 3 *(Ptx3)*, and prostaglandin synthase 2 *(Ptgs2)*, whose products are essential for formation and stabilization of the extracellular matrix of the cumulus cells (discussed later in the chapter). Transcripts for *Areg*, *Ereg*, and *Btc* are also detected in cumulus oocyte complexes after the surge, suggesting an autocrine regulatory loop maintains high EGF-like growth factor expression in cumulus cells. These data are not specific to mice since amphiregulin is abundant in human follicular fluid from patients undergoing *in vitro* fertilization.[65,66]

Whereas EGF-like factors play an important role in cumulus expansion and oocyte maturation, oocyte-secreted growth factors are also essential for cumulus expansion. *In vitro*, expansion of isolated cumulus oocyte complexes can occur with the addition of EGF (as well as FSH and cyclic adenosine monophosphate [AMP] analogs). The oocyte is required for expansion since oocytectomized cumulus oocyte complexes fail to expand when only FSH or EGF is added to the culture medium.[42] Expansion of OOX complexes are rescued by co-culture with denuded oocytes or conditioned

medium from denuded oocytes, indicating the presence of oocyte growth factors are also involved in the expansion. As mentioned earlier, follicular development in *Gdf9* KO mice is arrested at the primary follicle stage. However, our group has shown that recombinant GDF9 up-regulates *Has2*, *Ptgs2*, *Ptger2*, *Tnfaip6*, and *Ptx3* in granulosa cell culture systems.[67,68] Injection of mouse oocytes with *Gdf9* si-RNA, but not *Bmp15* si-RNA, suppresses *Has2* and *Ptgs2* expression, and cumulus expansion when oocytectomized cumulus complexes are incubated with knockdown oocytes.[69]

The cumulus cell matrix contains an essential meshwork of hyaluranon and proteins. Hyaluronan chains from the structural backbone of the cumulus matrix, and these chains are stabilized through interactions with other matrix proteins. TNFAIP6 catalyzes the formation of covalent cross-links between hyaluronan and the heavy chain of serum-derived inter-α-trypsin inhibitor (IαI), and PTX3 stabilizes the cumulus matrix through interactions with IαI. PTGS2 synthesizes PGE2 and prostaglandin EP2 receptor (PTGER2), appears to function upstream of TNFAIP6. Although *Has2* ovary-specific knockouts have not been generated, the importance of the regulation of the other EGF/GDF9/BMP15 regulated gene products *in vivo* in cumulus expansion is obvious. Targeted disruption of *Ptgs2*, the prostaglandin E receptor 2 *(Ptger2)*, *Tnfaip2*, or *Ptx3* results in abnormal or absent cumulus expansion and extreme subfertility while *Tnfaip6*-null females are sterile. Knockdown of *Has2* in cultured cumulus oocyte complexes suppresses cumulus expansion. IαI biosynthesis in the liver requires alpha-1-microglobulin-bikunin light chain (encoded by *Ambp*) for proper assembly and secretion, and *Ambp*-null females have impaired cumulus expansion and subfertility. Thus, oocyte-secreted growth factors (GDF9 and BMP15) and EGF-like growth factors (AREG, EREG, and BTC) combine to induce an array of genes that are necessary for mammalian cumulus expansion and fertility.

Mutations in mice, sheep, and humans have been important in identifying key functions of GDF9, BMP15, and their downstream gene products in cumulus expansion. GDF9 signals through a heterodimeric complex of type 1 and a type 2 receptors to phosphorylate SMAD2/3 and complex with SMAD4 and conditional deletion of both *Smad2* and *Smad3* or *Smad4* in granulosa cells using *Amhr2-cre* disrupts cumulus expansion *in vivo* and suppresses fertility (as mentioned above).[59,60] Naturally occurring mutations in sheep *BMP15* and *GDF9* or the BMP type 1 receptor, *BMPR1B/ALK6*, modify ovulation rate in sheep (Table 7.4). In most cases, mutations in *BMP15* or *GDF9* increase ovulation rate when heterozygous, but homozygous null animals are sterile. Ovaries from homozygous mutant sheep appear similar to mouse *Gdf9-null* ovaries, with follicles arrested at the primary stage. Partial immuno-neutralization against GDF9, BMP15 or in combination in sheep will increase ovulation rate and the number of lambs, indicating that both GDF9 and BMP15 regulate this process.[70] Genetic variants have been identified in women with premature ovarian failure (*BMP15* or *GDF9*) or dizygotic twinning *(GDF9)*.

While there is convincing evidence that GDF9 is sufficient to function as a cumulus expansion-enabling factor (CEEF), there is, however, controversy as to whether GDF9 is the sole CEEF.[71] BMP15 has also been implicated in the regulation of cumulus expansion and upregulates expression of EGF-like growth factors in cumulus cells *in vitro*.[72] Although the fertility defects in *Bmp15*$^{-/-}$ mice are subtle and *Gdf9*$^{+/-}$ are phenotypically normal, *Gdf9*$^{+/-}$ *Bmp15*$^{-/-}$ double mutant mice on a 129SvEV inbred background are infertile with impaired cumulus expansion.[62] Furthermore, coculture of *Gdf9*$^{+/-}$ *Bmp15*$^{-/-}$ oocytes with OOX cumulus complexes fails to enable cumulus expansion in the presence of FSH and the cumulus cells have less activation of MAPK, suggesting BMP15 acts synergistically with GDF9 as a CEEF.[73] BMP15 is believed to signal through the type 1 activin receptor-like kinase, ALK6 (also known as BMPR1B) to activate SMAD1/5/8 pathways.[74] *Bmpr1b*$^{-/-}$ female mice are infertile secondary to defects in cumulus expansion, despite a paradoxical increase in *Ptgs2*.[75] Finally, BMP15 is found in the follicular fluid of patients undergoing *in vitro* fertilization (IVF) and is associated with increased fertilization and embryo development.[76] Although a direct link with BMP15 and cumulus expansion in human cumulus oocyte complexes was not made, other studies have associated higher levels of *HAS2* and *PTGS2* in human cumulus cells with higher quality embryos.[77,78] As both *BMP15* and *GDF9* are expressed in human cumulus oocyte complexes,[79] the relative contribution of each factor in human cumulus expansion and developmental potential remains to be determined. Studies in *Bmp15*$^{-/-}$ and *Gdf9*$^{+/-}$ *Bmp15*$^{-/-}$ mice, however, suggest both growth factors influence developmental competence of oocytes following fertilization.[73,80]

Nuclear receptor interacting protein 1 (NRIP1), also known as receptor interacting protein 140 (RIP140), functions as a coregulator of the nuclear receptor superfamily. *Nrip1*$^{-/-}$ female mice are also infertile secondary to anovulation; however, the unruptured follicles in these mice go on to form corpora lutea with trapped oocytes.[81] More detailed histological analysis of *Nrip*-null ovaries demonstrated defects in cumulus expansion,

Table 7.4 Mutations Affecting Ovulation Rate and Prolificacy Sheep BMP15 and GDF9

Gene	Mutation	Breeds	Protein Domain	Mutation Type
GDF9	FecG^{H}	Belclare, Cambridge	Mature	Substitution
	FecG^{E}	Santa Inês*	Mature	Substitution
BMP15	FecX^{B}	Belclare	Mature	Substitution
	FecX^{I}	Inverdale	Mature	Substitution
	FecX^{H}	Hanna	Mature	Premature stop
	FecX^{G}	Galway	Prepro	Substitution; premature stop
	FecX^{L}	Lacaune	Mature	Substitution
	FecX^{R}	Rasa Aragonesa		Premature stop
BMPR1B	FecB	Booroola,† Merlino, Hu, Han, Garole, Javenese Thin-tail	Kinase domain	Substitution

*Heterozygotes have normal ovulation rates, but rates increase in homozygous sheep.
†Heterozygotes and homozygotes have increased ovulation rates with the heterozygotes midway between homozygotes and non-carriers.

Table 7.5 Mouse Models with Defects in the Periovulatory Period

Mutant Gene	Reproductive Phenotype	Fertility Status
Luteinizing hormone β *(Lhb)*	Block in folliculogenesis; early antral stage	Infertile
Luteinizing hormone/choriogonadotropin receptor *(Lhcgr)*	Block in folliculogenesis; early antral stage	Infertile
Prostaglandin-endoperoxide synthase 2 *(Ptgs2)*	Defects in ovulation, cumulus expansion, and implantation	Mostly infertile
Prostaglandin E receptor 2, subtype EP2 *(Ptger2)*	Defects in cumulus expansion; decreased fertilization	Subfertile
Pentraxin 3 *(Ptx3)*	Defects in cumulus-oocyte complex integrity and ovulation	Subfertile
Tumor necrosis factor alpha induced protein 6 *(Tnfaip6)*	Impaired cumulus matrix formation resulting in failed cumulus-oocyte complex expansion	Infertile
CCAAT/enhancer-binding protein β *(Cebpb)*	Reduced ovulation; fail to form corpus luteum	Infertile
Nuclear receptor interacting protein (*Nrip1*; RIP40)	Ovulation defect; ovaries accumulate luteinized and unruptured follicles	Infertile
Progesterone receptor (*Pgr*; PR)	Anovulation; corpora lutea absent	Infertile
Alpha 1 microglobulin/bikunin *(Ambp)*	Defects in ovulation and cumulus-oocyte complex integrity	Subfertile
Amphiregulin *(Areg)*	Suppressed cumulus expansion, delayed meiotic reentry	Subfertile
Bone morphogenetic protein 15 *(Bmp15)*	Defects in cumulus expansion and ovulation	Subfertile
Bone morphogenetic protein receptor, type 1B *(Bmpr1b)*	Defects in estrous cyclicity, cumulus expansion, and endometrial gland development	Subfertile
Epiregulin ($Ereg^{wa2/wa2}$; hypomorph)	Suppressed cumulus expansion, defective meiotic resumption, ovulation defect	Subfertile
MAD homolog 4 *(Smad4)* (cKO)	Premature luteinization; decreased ovulation with trapped oocytes	Subfertile

The full version of this table, including references, can be found on the companion Expert Consult Web site at www.expertconsultbook.com.

suggesting NRIP1 also is an important mediator of this process, as well as ovulation. Gene expression profiling showed that following gonadotropin stimulation *Nrip*-null mice fail to induce many genes already discussed that are important for cumulus expansion, including EGF-like growth factors (*Areg*, *Ereg*, and *Btc*), *Has2*, *Ptgs2*, *Tnfaip6*, *Cspg2* (versican); whereas many genes involved in cell to cell adhesion are up-regulated (and might, therefore, impede expansion). *Nrip1* is most dramatically up-regulated in mural granulosa cells following PMSG administration (to mimic FSH), whereas *Cebpb* increases after PMSG plus hCG administration.[81-83] Because both FSH and LH activate cAMP/PKA/CREB pathways to influence gene expression, the increase in NRIP1 and C/EBPβ in the periovulatory period may function to modulate transcription of the many target genes with cAMP response elements.

The timing of luteinization is important for normal reproductive function and the fact that it occurs following ovulation supports a role for oocyte-derived inhibitors that prevent premature luteinization. As mentioned, oocyte-secreted factors (OSFs) oppose FSH signaling to define two distinct granulosa cell populations in the antral follicle. Specifically, OSFs signal through SMAD2/3 to oppose FSH induction of ovulatory *(Lhcgr)* and steroidogenic *(Cyp11a1)* markers in the cumulus cells close to the oocyte,[84] suggesting a TGFβ family member, such as GDF9, may be an important inhibitor of luteinization. Support for this is seen in mice with conditional deletion of the common SMAD, *Smad4*, in granulosa cells of preantral follicles.[60] Although *Smad4* cKO ovaries exhibit a number of follicular defects (discussed earlier in the chapter), including impaired cumulus expansion and ovulation, there were a number of small and large follicles with luteinizing cells surrounding oocytes, and these findings were accentuated after exogenous gonadotropin (PMSG) administration only in 3-week-old animals. Molecularly, in contrast to control mice, granulosa cells from PMSG-stimulated *Smad4* cKO mice had significantly higher levels of genes related to steroidogenesis and luteinization, including *Lhcgr*, *Cyp11a1*, *Hsd17b7*, *Star*, secreted frizzled protein *(Sfrp4)*, and the prostaglandin F2α receptor *(Ptgfr)*. While it is also possible that the loss of SMAD4 prevents granulosa cells from responding appropriately to BMP/TGFβ/activin signals from the surrounding stroma that might also inhibit luteinization, Eppig and colleagues provide convincing evidence that OSF-activation of SMAD signaling is key to preventing premature differentiation of granulosa cells.[84]

While we have tried to highlight critical mediators of ovulation, cumulus expansion, and luteinization, many additional factors are involved in these processes in the periovulatory follicle. Mutant mouse models illustrating the diverse number of factors that regulate these events are summarized in Table 7.5.

Formation of the Reproductive Tracts

In mammals, the sex of an organism is determined by two connected mechanisms: first, the chromosomal sex causes the indifferent gonad to acquire a specific gonadal sex (primary sex differentiation), which in turn, is responsible for determining the phenotypic sex (secondary sex differentiation). Individuals carrying a Y chromosome are considered genetically males; the *Sry* gene is located on the Y chromosome and has been shown to be essential for the gonad to differentiate into testes.[85-87] The production of male-specific hormones and growth factors by the testes causes the expression of characteristics typical of males.

Before sexual differentiation, mammalian embryos of both sexes have an indifferent gonad and two pairs of reproductive ducts: the wolffian (mesonephric) ducts and the müllerian (paramesonephric) ducts. The male and female reproductive tracts and the kidneys primarily develop from the intermediate mesoderm. In humans, the wolffian ducts first appear at Carnegie stage 10 (equivalent to E9 in mouse) as mesenchymal ridges that segregate from the intermediate mesoderm and undergo mesenchymal to epithelial transition to form two epithelial canalized ducts. The wolffian ducts give rise to the vas deferens and the seminiferous

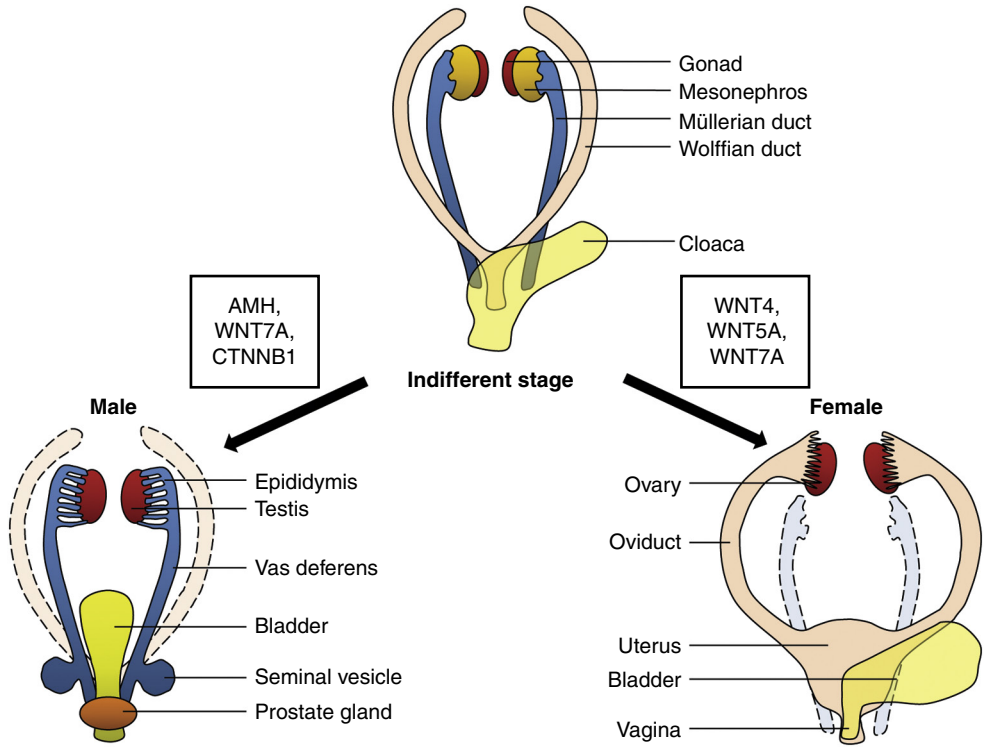

FIGURE 7.6 Sexual differentiation of the reproductive system. At the indifferent stage, male and female embryos have bipotential gonads, and both müllerian and wolffian ducts. Depending on the presence or absence of the Sry gene in males and females respectively, the gonads and ducts differentiate into male or female reproductive organs. The expression of *Wnt7a* in the müllerian duct induces the production of AMH receptor (AMHR2) and makes the müllerian duct responsive to AMH. When Sry is expressed, the indifferent gonad becomes testis, which produces AMH and induces the regression of the müllerian duct. The testis also allows the maintenance of the wolffian duct through the production of testosterone. When Sry is not expressed, the müllerian duct is maintained and develops into the female reproductive tract; this process requires the expression of different members of the Wnt signaling pathway. At the same time, since the indifferent gonad became ovary, testosterone is not produced and the wolffian duct is not maintained.

tubules of the male reproductive system. The anlages of the müllerian ducts form from an invagination of the coelomic epithelium through the mesonephros at Carnegie stage 16 (E11.5 in mouse) extend to contact the wollfian ducts, and finally elongate toward the cloaca (dependent on the presence of the wolffian ducts). At E15.5, the müllerian ducts differentiate into the oviducts, uterus, and upper vagina (Fig. 7.6).[88-90]

In the past 15 years, the use of knockout mice has identified the main regulators of reproductive tract formation (Table 7.6). For example, female and male mice homozygous null for the pair-box gene *Pax2* completely lack the genital tracts. Mice null for *Emx2* show initial formation of the wolffian ducts but subsequent degeneration at E11.5, while in *Emx2* null females, no müllerian ducts are observed at E13. Lastly, female mice lacking the *Lim1* transcription factor that survive past E10 completely lack müllerian duct derivatives.

Table 7.6 Main Genes Involved in the Development of the Reproductive Tracts

Gene	Phenotype
Pax2	Null mice show neonatal lethality; males and females lack kidneys, ureters, and genital tracts
Emx2	Null mice show neonatal lethality; females and males lack kidneys, ureters, gonads, and genital tracts
Lim1	Null mice show embryonic lethality; females lack müllerian duct

Regression of the Müllerian Ducts

In both female and male mice, the müllerian ducts form at E11.5, but they regress in males during the secondary sex differentiation between E13 and E14. Anti-müllerian hormone (AMH), a TGFβ superfamily member, has been shown to be responsible for the regression of the müllerian ducts in males.[91-94] AMH is secreted by Sertoli cells of the fetal testis while its receptor (AMHR2) is expressed in mice in the mesenchyme of the müllerian duct at ~E13.5. In females, because the gonad differentiates into ovaries and no AMH-producing Sertoli cells are formed, the müllerian ducts are not stimulated to regress and are therefore maintained. AMH is both necessary and sufficient for the regression of the müllerian ducts; male mice homozygous for a mutant allele of *Amh* or its type 2 receptor *(Amhr2)* have a normally developed male reproductive tract but also bear a uterus and oviducts (Table 7.7). These mice have functional sperm but most are infertile due to the hindering of the sperm transfer by the female reproductive organs. Moreover, when *Amh* is overexpressed in female mice, the derivatives

Table 7.7 Genes Involved in Müllerian Duct Regression and Development

Gene	Phenotype
Amh	Null males have a complete male reproductive tract and functional sperm, but also uterus and oviducts; females are fertile with enlarged ovaries. Female mice overexpressing Amh show blind vagina and no uterus or oviducts
Amhr2	Null males have a normal male reproductive tract, but also uterus and oviducts
Alk2, Alk3	Alk2 and Alk3 null mice show embryonic lethality; conditional ablation of Alk2 and Alk3 in the müllerian duct mesenchyme (Alk2-Alk3 double conditional knockout mice) causes duct retention in males
Smad1, Smad5, Smad8	Smad1 and Smad5 null mice show embryonic lethality; Smad8 null mice are viable and fertile. Deletion of Smad5, Smad1-Smad5 or Smad5-Smad8 in the müllerian duct mesenchyme causes partial müllerian duct retention. Smad1-Smad5-Smad8 triple conditional knockout mice show complete müllerian duct retention
Wnt7a	Null mice show partial perinatal lethality; null males fail to undergo müllerian duct regression. Females are infertile due to abnormal development of uterus and oviduct
Wnt4	Null mice show neonatal lethality; null females are masculinized: they have wolffian duct and lack müllerian duct
Wnt5a	Null mice show perinatal lethality; females show caudal truncation of the reproductive tract and defective uterine glandular development
Ctnnb1	Null mice show embryonic lethality; male mice with a conditional deletion of Ctnnb1 in the müllerian duct mesenchyme show müllerian duct retention

The full version of this table, including references, can be found on the companion Expert Consult Web site at www.expertconsultbook.com.

of the müllerian ducts are absent. Considering the importance of this protein for achieving correct sexual differentiation, it is not surprising to find that its expression is subject to tight regulation; some of the genes upstream of AMH and responsible for its regulation show how AMH is connected to the testis-determining pathway. SRY is required for the activation of SRY-box containing gene *(Sox9)* expression, and SOX9 and steroidogenic factor 1 (SF1) have been shown to cooperate in the regulation of *Amh* transcription.[95] In addition, it has been suggested that Wilms tumor homolog (WT1) synergizes with SF1 to activate the transcription of *Amh*, and dosage sensitive sex-adrenal hypoplasia congenital (DSS-AHC) critical region on the X chromosome gene 1 (DAX1) antagonizes this synergy.[96]

When expression of either of the type 1 receptors, *Acvr1 (Alk2)* or *Bmpr1a (Alk3)*, is conditionally ablated, the müllerian duct mesenchyme does not regress in male mice, a phenotype similar to *Amh* and *Amhr2* null mice; this indicates that the two receptors act redundantly to transduce the AMH signal.[97] In addition, the three BMP-specific SMADs (SMAD1, SMAD5, and SMAD8) can activate the regression of the müllerian ducts to varying degrees[97] and mice with loss of these genes in combination retain müllerian duct derivatives.

Several pieces of data have been produced in support of the hypothesis that AMH signaling interacts with the wingless-related mouse mammary tumor virus (MMTV) integration site (WNT) pathway to regulate the regression of the müllerian ducts (Table 7.7).[98] WNT signaling seems to play a role both upstream and downstream to AMH. In particular, WNT7A, which is also involved in the development of the müllerian ducts, is required in the duct epithelium for the expression of *Amhr2* in the surrounding mesenchyme of the müllerian duct. Thus, WNT7A makes the müllerian duct responsive to AMH, and, accordingly, the müllerian duct fails to regress in male mice carrying a null mutation in the *Wnt7a* gene. In the canonical WNT pathway, the binding of WNT ligands to the cognate receptors causes the nuclear accumulation of β-catenin (CTNNB1); β-catenin forms a complex with cofactors to promote the activation of downstream target genes.[13] When *Ctnnb1* is conditionally ablated in the mesenchyme of the müllerian ducts of male mice, there is no regression of the ducts. The lack of CTNNB1 in the mesenchyme does not compromise the expression of *Amhr2* in those cells, indicating that WNT7A signaling is not affected and that another WNT is responsible for CTNNB1 activation in the mesenchyme during duct regression. WNT4 is a good candidate since AMH has been shown to be necessary and sufficient for the expression of *Wnt4* in the duct mesenchyme of male mice during its regression. However, males without WNT4 in the mesenchyme of the müllerian ducts do not show any defect in duct regression. It is noteworthy that these results have been obtained by using a conditional knockout model *(Amhr2-Cre)* that may have a *cre* recombinase activity not sufficiently high to recombine the *Wnt4* floxed allele to an efficient extent.

Müllerian Duct Development

The female reproductive tract in mammals includes the oviducts (fallopian tubes), uterus, cervix, and the vagina.[99] Different mammalian species exhibit significant variations in the morphology of the reproductive tract that are primarily due to differences during the development of the müllerian duct, the embryonic structural precursor of the mature female reproductive tract. Besides these morphological differences, the processes that enable the continuation of the mammalian species all rely on the functionality of this group of organs: the fertilization of the oocytes by spermatozoa occurs in the oviducts; the implantation of the embryo and its development take place in the uterus (with the exception of the egg-laying mammals); and the fetus moves through the cervix and vagina to finally be delivered.[90]

The absence of SRY in females sets a permissive environment for the gonads to become ovaries (primary sex differentiation; see section above "Ovary differentiation"); because the ovaries do not produce testosterone or AMH, the wolffian ducts are not supported in their development and thus regress. At the same time, the absence of AMH allows the müllerian ducts to be maintained. WNT4 has been shown to be essential for the formation of the müllerian ducts, and both male and female mice null for WNT4 lack müllerian ducts.[100] *Wnt4* is expressed in the mesonephros at E9.5-11 but not in the mesonephric tubules or wolffian ducts. *Wnt4* is also observed in the mesenchyme of the indifferent gonad at E11; during primary sex differentiation, expression of *Wnt4* decreases in the male gonad but is

maintained in the female gonad. The müllerian ducts form at E12 from a region of the coelomic epithelium positive for *Wnt4* expression, and *Wnt4* is expressed in mesenchymal cells surrounding the müllerian ducts throughout fetal life.

Wnt4 null mice die shortly after birth due to kidney failure.[101] In the absence of WNT4, newborn female mice show masculinization of the gonad, absence of the müllerian duct, and a fully developed wolffian duct, indicative of a reversal of sexual phenotype.[100] Absence of the müllerian duct can be due to either a block in the formation or to a male-specific regression taking place in the sexually reverted females. To identify the cause of the müllerian duct absence, an analysis of *Wnt4* null mice at an earlier time point was performed, which revealed that WNT4 is responsible for the initial phases of the formation of the müllerian duct in both sexes. In the absence of WNT4, female mice also exhibit a failure in the suppression of Leydig cell development and gonadal steroidogenesis. The presence of these male-specific processes in females leads to the maintenance of the wolffian ducts.

WNT7A is another member of the WNT family that plays a central role in the development of the female reproductive tract.[102] *Wnt7a* is expressed along the length of the müllerian duct epithelium in males and females when the duct forms at E12.5. It continues to be expressed throughout life in the derivatives of the müllerian duct in females; in males, *Wnt7a* expression disappears when the müllerian duct regresses. Female and male mice homozygous for a mutant *Wnt7a* allele are sterile. The female sterility is caused by defective differentiation of the müllerian duct derivatives; there are no oviducts and the uterus is thinner than in controls due to a reduction of the epithelial and stromal compartments, a severe defect in uterine gland formation, and a hyperplastic myometrium. A closer investigation of the reproductive tract reveals that the oviducts and the uterus of mutant mice are affected by partial posteriorization: the oviducts show features typical of the uterus, and the uterus has characteristics of the vagina. Accordingly, the expression of *Hoxa10* and *Hoxa11*, which have been shown to be required for the correct anterior-posterior patterning of the reproductive tract, shows postnatal reduction.[103] Thus, after WNT4 initiates the process of ductal formation, WNT7A is required to regulate the morphogenesis of ductal derivatives.

WNT5A is a third member of the WNT family that is highly expressed in the uterus and plays a role in both its development and postnatal growth.[104] The female reproductive tract is immature at birth and undergoes a process of differentiation during the first 2 weeks of postnatal life. Interactions between the epithelial and mesenchymal compartments are of central importance in the regulation of uterine differentiation. In particular, the epithelium is developmentally plastic, and its differentiation is stimulated by signals generated in the stroma. *Wnt5a* is highly expressed in the uterine mesenchyme and regulates stromal-epithelial crosstalk during uterine growth. Mice null for *Wnt5a* die at birth with defects in anterior-posterior body axis development.[105] The posterior structures of the reproductive tract (cervix and vagina) are absent in newborn *Wnt5a* mutants, and the uterine horns show significant reduction in size. When reproductive tracts from newborn *Wnt5a* null mice are grafted into wild-type adults, the uterus fails to develop glands, suggesting that WNT7A and WNT5A play nonredundant roles in uterine gland formation.

Role of Growth Factors in Uterine Biology

Regulation of Uterine Receptivity

Successful reproduction ensures species survival. In mammals, the female zygote is released from the ovary during ovulation and is fertilized by sperm in the reproductive tract. Upon fertilization, the zygote starts a process of cellular division and differentiation that leads to the formation of an implantation competent structure, the blastocyst, made up of two distinct populations of cells: the inner cell mass and the trophoblast. To successfully continue and complete its development, the embryo needs to rely on a supporting structure that provides nourishment and protection for the whole gestational period. In mammals, this structure is the uterus, and, as a first step, the embryo needs to make physical contact with it and start a molecular cross-talk that eventually leads to its implantation. Depending on the species, different strategies of implantation are used: in rats and mice, the luminal epithelium of the uterus undergoes apoptosis to facilitate the invasion of the embryo through the uterine wall; in primates, the luminal epithelium remains intact and the embryo intrudes between the epithelial cells to finally reach the stromal compartment.[106,107] The implantation of the embryo occurs during a limited period of time called the "window of receptivity." A highly regulated synchrony between the development of the embryo and the receptive status of the uterus needs to be accomplished to achieve a successful implantation.

The sexual hormones estrogens (in particular 17β-estradiol, E2) and progestins (in particular progesterone, P4) are produced by the ovaries in cyclic waves and cause profound changes in the uterus during the different phases of the estrous (mice) or menstrual (humans) cycle (Fig. 7.7). P4 and E2 act on the uterus by binding and activating the nuclear receptors PR and ER, respectively. Once activated, the nuclear receptors translocate into the nucleus and promote the transcription of downstream target genes. The receptive status of the uterus changes cyclically and can be classified as prereceptive, receptive, or nonreceptive (refractory). During the prereceptive phase, the uterus is not able to accept the implantation of the embryo but prepares for its arrival. In both humans and mice, an increase in the serum levels of P4 is observed prior to implantation during a phase called "secretory phase;" P4 acts on the endometrium by stimulating its full differentiation and making it a favorable environment for a potentially implanted embryo. During this period, tubular glands and spiral arteries develop, and the endometrium becomes thick and spongy. To achieve the receptive stage, a temporary rise in the levels of E2 is needed. The window of receptivity lasts 24 to 36 hours in mice (day 4 and morning of day 5 of pregnancy) and about 4 days in women (days 20 to 23 of the menstrual cycle). If the implantation of the embryo does not take place, the endometrium is reabsorbed in mice or expelled (menstruation) in humans to complete the estrous/menstrual cycle. After its degeneration, the endometrium undergoes a "proliferative phase" and regenerates under the influence of E2, signaling the beginning of a new cycle.

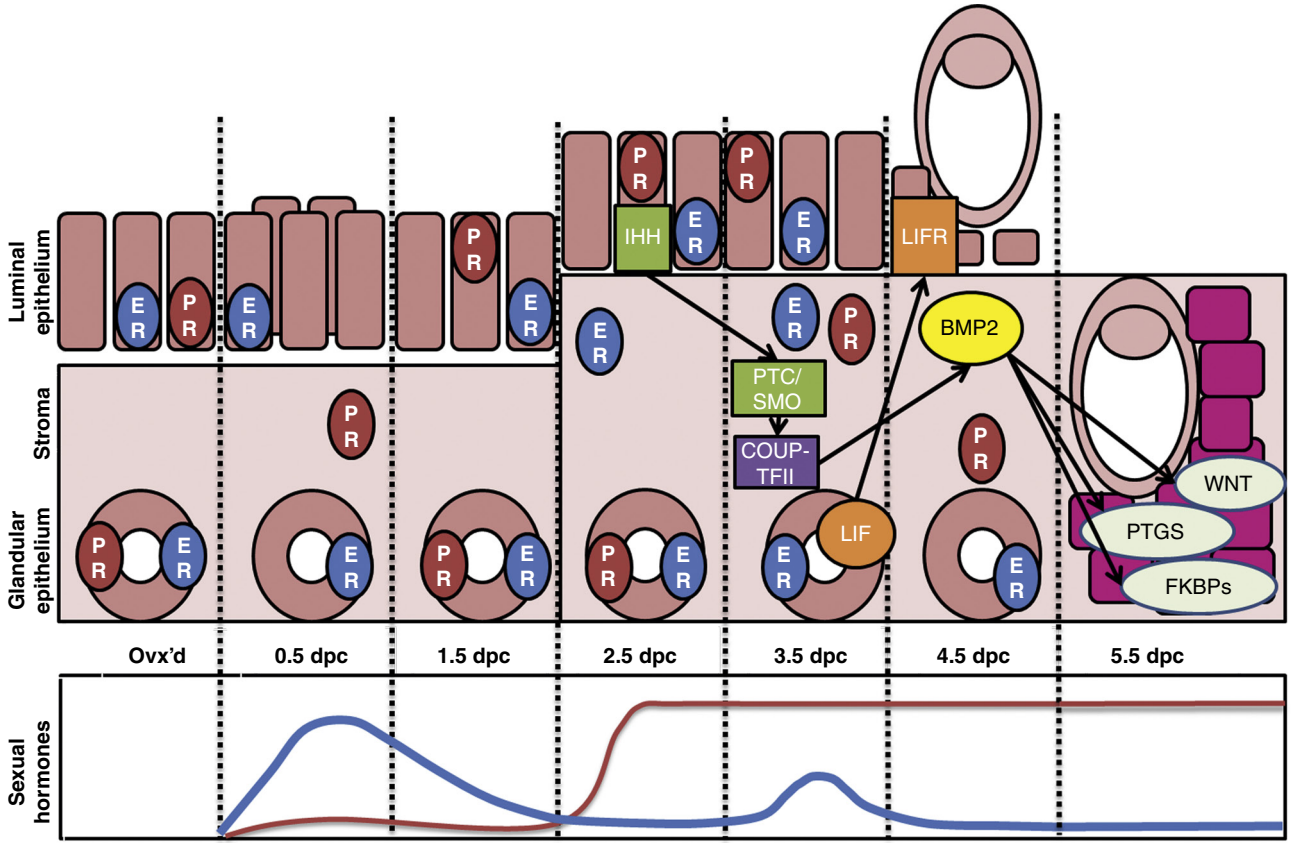

FIGURE 7.7 Molecular regulation of embryo implantation in the mouse. Estrogen and progesterone receptors are differentially expressed in the epithelial and luminal compartment of the uterus before the implantation and control the uterine receptivity through the regulation of several downstream factors. At 2.5 days post coitum (dpc), an increase in the levels of ovarian progesterone (P4) promotes the expression of indian hedgehog *(Ihh)* in the uterine epithelium. IHH acts on the adjacent stromal compartment where it causes the production of COUP-TFII at 3.5 dpc that, in turns, activates the expression of *Bmp2* at 4.5 dpc. A peak in the levels of estrogen (E2) at 3.5 dpc causes leukemia inhibitory factor *(Lif)* to be expressed in the glandular epithelium; LIF signals through its cognate receptor LIFR in the luminal epithelium and triggers the molecular and cellular changes that make the epithelium become receptive to the attachment of the embryo. When the embryo attaches at 4.5 dpc, the stromal cells are stimulated to proliferate and differentiate into decidual cells. BMP2 acts upstream to WNTs, PTGS2, and FKBPs to regulate the decidual reaction in stromal cells.

The molecular mechanisms that regulate the receptivity of the uterus and the implantation of the embryo have been investigated, and several mouse models have been produced to clarify the roles that different factors play during these processes. In this section, we will discuss the main signaling pathways shown to be involved in the regulation of the early stages of pregnancy in mammals.

Implantation of the Embryo

Estrogen and progesterone act on the uterus to trigger the changes that will make it receptive to the implantation of the embryo (Fig. 7.7). One mechanism that has been demonstrated to be required for achieving a receptive state is the inhibition of ER activity in the epithelium mediated by stromal PR. Therefore, to achieve the receptive state, estrogen and progesterone regulate the pre-implantation events by regulating the communication between stromal and epithelial compartments and many factors function in uterine receptivity. The secreted protein indian hedgehog *(IHH)* was identified as a gene differentially regulated by P4 in the luminal and glandular epithelium of the uterus during the peri-implantation period. IHH acts by binding the transmembrane receptor Patched1 (PTCH1) and by blocking its inhibitory action on another receptor, Smoothened (SMO) (Fig. 7.1); (Table 7.8).[108] The loss of inhibition of SMO activates the transcription of the glioma-associated oncogene homolog[48] (Gli) family of transcription factors and the orphan nuclear receptor Chicken Ovalbumin Upstream Transcription Factor II (COUP-TFII or nuclear receptor subfamily 2, group F, member 2, NR2F2). Because *Ihh* is expressed in the uterine epithelium and COUP-TFII is localized in the stromal compartment, this signaling pathway plays a central role in the regulation of the communication between epithelium and stroma of the uterus. In particular, IHH is required for the attachment of the embryo to the uterine epithelium, and mice lacking IHH in the uterus are sterile.[109] The ablation of *COUP-TFII* in the uterus phenocopies the defects observed in *Ihh* cKO mice and causes an increase in ER activity in the uterine epithelium. Thus, IHH and COUP-TFII play a central role as regulators of uterine receptivity by mediating the P4-dependent suppression of ER activity.

COUP-TFII also promotes the expression of another important factor involved in the regulation of the early pregnancy phases, BMP2.[110] *In situ* hybridization studies

Table 7.8 Genes Involved in the Regulation of Embryo Implantation

Gene	Phenotype
Ihh	Null mice die before or immediately after birth. Females with a conditional deletion of Ihh in the uterus show failure of blastocyst attachment. Decidualization is defective
NR2F2	Null mice show embryonic lethality. Females with a conditional deletion of COUP-TFII in the uterus are sterile; both embryo attachment and uterine decidualization are impaired
Bmp2	Null mice show embryonic lethality; females with a conditional deletion of Bmp2 in the uterus are sterile due to failure of uterine stromal cell decidualization
Wnt4	Null mice show neonatal lethality; female mice with a conditional deletion of Wnt4 in the uterus are severely subfertile due to impaired implantation

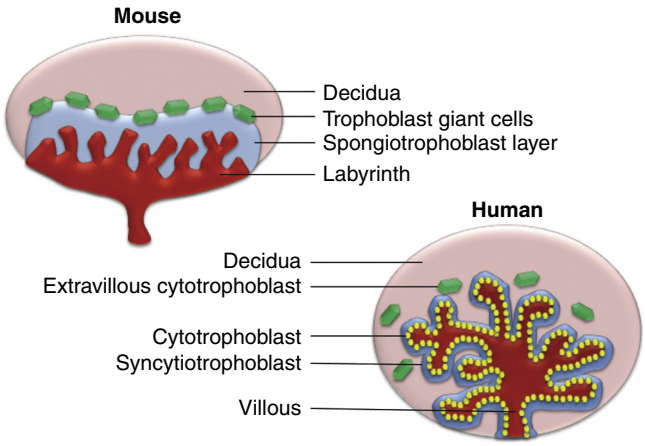

FIGURE 7.8 Schematic of the fetal-maternal interface in mouse and human. The placenta is composed of two main parts: the maternal decidua and the trophoblast of embryonic origin. During implantation, the extravillous cytotrophoblast in humans and the trophoblast giant cells in mouse, invade the uterine tissue and modify the maternal vasculature to obtain nutrients for the growing fetus as pregnancy progresses.

show that *Bmp2* is expressed in the uterine stroma at the moment of embryo implantation, and mice lacking BMP2 in the uterus are sterile.[111]

In wild-type mice, the attachment of the embryo to the uterine epithelium triggers a wave of intense proliferation and differentiation of the stromal compartment; this process is called decidualization and requires BMP2.[111] The role of BMP2 in the regulation of the decidualization has been investigated also in cells obtained from biopsies of human endometrium. Similar to the mouse, BMP2 is required in human endometrial stromal cells to induce their differentiation into decidual cells.[112] In agreement with a model in which IHH acts upstream to regulate the BMP pathway, mice lacking IHH or COUP-TFII, besides having an attachment defect, are also unable to decidualize. During decidualization, BMP2 activates several downstream targets. In particular, FK-506-binding protein 3 (FKBP3), FKBP4, and FKBP5 have been proposed to be induced by BMP2 and be required to modulate the activity of PR by acting as cochaperones of steroid hormone receptors. BMP2 is also necessary for inducing the expression of *Wnt4* and *Wnt6* during decidualization, and *Wnt4* cKO in the uterus are unable to support the invasion of the embryo through the endometrial wall and decidualize. When *Wnt4* is knocked down, differentiation of human endometrial cells is strongly reduced, demonstrating that the roles of WNT4 in decidualization is conserved in mice and humans. Moreover, besides its role in uterine development during embryonic life, WNT4 continues to be required for postnatal development of the uterus: *Wnt4* cKO mice show an abnormal stratification of the luminal epithelium and a reduced number of uterine glands.

Regulation of Trophoblast Proliferation, Invasion, and Migration

The trophectoderm is the outer layer of the blastocyst. The primary role of the trophoblastic cells is to differentiate to form the fetal part of the placenta, the organ that allows the fetus to connect to the maternal uterus, receive nutrients and hormones, eliminate waste, and exchange gas. Distinct epithelial cell types arise from trophoblast progenitor cells; in humans, 6 days after fertilization, two populations of trophoblast cells can be distinguished. The inner layer is composed of proliferating mononucleated cells called cytotrophoblasts. These cells can further differentiate by fusing together to form an outer, nonproliferating syncytiotrophoblast layer. The syncytiotrophoblast covers the villi (labyrinth in mice), providing a large surface for exchanging gas and nutrients. Additionally, this population of cells exhibits endocrine activity. The extravillous cytotrophoblasts (EVT, trophoblast giant cells in mice) arise from the villi and are responsible for actively invading the maternal decidua and rupturing the uterine capillaries to establish an interface between the maternal circulation and embryonic extracellular fluids (Fig. 7.8).[113-116]

Decidual cells, uterine natural killer cells,[117] and macrophages secrete a number of factors that regulate proliferation and invasion of the trophoblast at the fetal-maternal interface. The activity of the trophoblast is finely regulated by a balance of substances with distinct effects (Table 7.9). The factors that play a role in the regulation of the trophoblast activity can be divided in three main groups: (1) factors that promote proliferation of the EVT; (2) factors promoting the EVT migration/invasion; and (3) factors that inhibit proliferation, invasion, and migration of the trophoblast. The trophoblast is also an active source of factors; in particular, it secretes matrix metalloproteinases (MMPs), which destroy the extracellular matrix and facilitate the penetration into the endometrial environment. The invasion of the trophoblast relies on the precise control of the balance between MMPs and their inhibitors (TIMPs) on one hand and between urokinase-type plasminogen activator (uPA) and its inhibitors (PAI-I and PAI-II). uPA is a key protease for invasion, both independently and for its ability to activate other proteases. The interaction between uPA and its receptor (uPAR) at the cell surface has been shown to regulate local proteolysis and facilitate invasion and migration of the trophoblast. Moreover, human EVT shows a polarized

Table 7.9 Factors Produced at the Maternal-Fetal Interface; Their Effects on the Invasion, Proliferation, and Migration of the Trophoblast; and the Intracellular Molecular Pathways That They Regulate

Factor	Expression	Invasion	Proliferation	Migration	Downstream Pathway(s)
EGF	Placenta, deciduas	↑	↑	↑	MAPK, PI3K
CSF1	Trophoblast, placenta, deciduas	↔	↑	n.d.	MAPK, JAK/STAT
IGFII	Trophoblast	↑	↔	↑	$G_{i,}$ MAPK

expression of uPAR at the invasion front. The uPA-uPAR system in rodents is different because uPA knockout mice do not show fertility or placentation defects.[118]

Immunohistochemical and *in situ* analyses have shown that several growth factors and cytokines are expressed at the fetal-maternal interface. EGF receptor *(Egfr)* is expressed by human trophoblast cells, and its ligands (EGF, AREG, and transforming growth factor α, *TGFA*) are broadly expressed in both placental and uterine cells. EGF promotes the proliferation, invasion, and migration of EVT. Confirming the role of the EGF pathway during placentation, *Egfr* KO mice are embryonic lethal due to impaired placental growth (although this phenotype is observed only in some strains of mice). Using an invasive extravillous trophoblast cell line (HTR8/Svneo), it has been shown that EGF promotes the transcription of *Mmp9* and *Timp1* through the activation of phosphatidylinositol 3-kinase (PI3K) and mitogen-activated protein kinase (MAPK) pathways. Colony-stimulating factor 1 (CSF1) has an effect on trophoblast cell proliferation similar to EGF.

Trophoblast-derived insulin-like growth factor 2, IGF2, and decidua-derived insulin-like growth factor binding protein 1, IGFBP1, bind their distinct receptors on EVT and independently stimulate the migration and invasiveness of the trophoblast in an autocrine and paracrine way, respectively. The two factors have been shown to act through independent pathways: whereas IGF2 binds IGFR2 and causes the activation of MAPK and the inhibition of G proteins in EVT cells, IGFBP2 acts by binding the α5β1 integrin with its RGD domain and triggering the activation of FAK and stimulation of MAPK pathway. Another key signaling pathway regulating the invasion of the trophoblast is hepatocyte growth factor (HGF); HGF has been shown to promote the motility in tumors by activating signal transducer and activator of transcription 3 (STAT3). The effects of both HGF and STAT3 on trophoblast invasion have been described, although no evidence of a HGF-induced activation of STAT3 has been reported in trophoblast cells. HGF is secreted by the placenta and acts in a paracrine way by binding its receptor on trophoblast cells. HGF regulation of the invasion process has been shown both *in vitro*, where HGF stimulates the invasion of trophoblast cells in a dose-dependent way, and *in vivo*, since *Hgf* knockout mice have a lethal placental failure defect (reviewed in ref. 116 and 119). Interleukin 11 (IL11) is another decidual-expressed cytokine that activates STATs to mediate its signal. IL11 receptor α *(Il11ra1)* KO females are sterile due to defective decidualization, which eventually leads to uncontrollable trophoblast invasion. STAT3 is activated through its phosphorylation by LIF, causing an increased secretion of TIMP1 and TIMP2 and enhancing the invasiveness of human EVT cell culture.[120] STAT3 activity must be finely regulated to allow the trophoblast to establish a functional connection with the maternal blood vessels without proceeding too far and damaging the uterine environment. One mechanism that has been shown to be essential for controlling STAT3 activation is the negative regulation of LIF by suppression of cytokine signaling 3 (SOCS3). The importance of this signaling pathway in preventing the uncontrolled invasion of the trophoblast is demonstrated by the finding that *SOCS3* KO leads to embryonic lethality due to placental failure.

Several members of the TGFβ superfamily are produced by both the decidua and the trophoblast during pregnancy and have been shown to inhibit the invasion and the proliferation of EVT by acting in a paracrine and autocrine manner. TGFβ1, -2, and -3 cause a decrease in the secretion of MMP9 and uPA, and Nodal, acting through its type 1 receptor ALK7, has been shown to inhibit the activity of MMP2 and MMP9 and to promote the activity of TIMP1. Moreover, Nodal has been shown to inhibit proliferation and induce apoptosis in human trophoblast cells through a SMAD2/3-dependent mechanism.[121] Another factor that negatively regulates invasion, proliferation, and migration of EVT is the TGFβ-binding proteoglycan decorin (DCN). This factor colocalizes with TGFβ in decidual extracellular matrix, although its inhibitory action has been shown to be independent from TGFβ when the combined effects of the two factors were tested on propagated EVT cell lines.[122] DCN appears to act as a reservoir for inactive TGFβ, and the proteolytic action of EVT causes the release and activation of TGFβ to prevent the overinvasion of the decidua. The effects of TGFβ are also modulated by SMAD ubiquitination regulatory factor 2 (SMURF2), a homologous to the E6-AP carboxyl terminus (HECT) type E3 ubiquitin ligase that targets TGFβ receptors and SMADs for proteasome-mediated degradation; SMURF2 is highly expressed in human placental villi during the first trimester of pregnancy, and, when overexpressed in EVT cells in culture, it

enhances their migration and invasion by reducing the protein levels of TGFβ type 1 receptor.[123]

Growth Factor Pathways in Male Reproduction

In addition to the roles of growth factors in PGC formation and migration, development of the male reproductive tracts, and sex determination, growth factor pathways are also involved in the testis and epididymis. In particular, BMP7, BMP8a, and BMP8b are expressed in testicular germ cells, regulate Sertoli cell activity, function during spermatogenesis, and are important for male fertility. These BMPs, along with BMP4, also function in the epididymis and regulate sperm motility. Mouse mutations in the *Bmp7*, *Bmp8a*, and *Bmp8b* genes lead to defects in the head and tail of the epididymis, while heterozygous mutation in *Bmp4* leads specifically to epithelial degeneration in the body of the epididymis.

Activin and inhibin are not only involved in the regulation of ovarian granulosa cell tumor formation but also play key roles in testicular Sertoli cell tumor development. Absence of *Inha* leads to Sertoli cell tumor formation, while DKO of SMAD1 and SMAD5 or DKO of INHA and AMH (or AMHR2) result in Sertoli cell and Leydig cell tumor development. A key role of activins signaling through SMAD3 to regulate development of these testicular tumors is clear since *Inha Smad3* DKO males fail to develop these tumors (unlike in female granulosa cells where SMAD2 and SMAD3 play redundant functions).

Growth Factors in the Clinic

Whereas proteins (e.g., recombinant and purified FSH, LH, and hCG and GnRH analogs) and steroid hormones (e.g., estrogens, progestins, and androgens) have a major place in the clinical setting, there are fewer examples where growth factors have been used clinically. However, based on our discussions above, it is obvious that growth factors must play a key role in the assisted reproductive technology (ART) clinic. For example, when recombinant human colon stimulating factor 2 (GM-CSF; 2 ng/mL) was added to different culture media, it statistically increased from 30% to 76% the proportion of 2-4 cell human embryos that could develop to the blastocyst stage.[124] As ART clinics optimize conditions for *in vitro* mutation (IVM) of human oocytes, strategies that utilize recombinant growth factors that are normally synthesized in mural granulosa cells (e.g., EGF-like peptides) or in the oocyte (e.g., GDF9 and BMP15) will likely develop for these cultures.[125] Small molecules that regulate these processes may also come into play.

Since growth factors are also important for interaction of the hatched blastocyst and the uterine endometrium and establishment of pregnancy, growth factors may also play a role *in vivo* in this setting. In the mouse, recombinant human BMP2 could partially rescue the uterine decidual response in mice with a knockout of *Bmp2*, indicating that similar strategies could be developed for women who do not have appropriate uterine responses to the implanting embryo.[111] Immunotolerance of the maternal endometrium to the implanting conceptions is also necessary for a successful pregnancy and factors such as interleukin 1b and other pro-inflammatory cytokines could be used for modulating this process.[126] Diagnostically, measurement of growth factors in the follicular fluid (e.g., colony stimulating factor 3 [G-CSF]) may help to define oocyte competence before fertilization is attempted while endometrial mRNA analysis of IL15, IL18, and tumor necrosis factor superfamily member 12 (TWEAK) in the mid-luteal phase may help to define uterine receptivity for women with repeated ART failures.[127] These latter genes appear to correlate with the appropriate numbers of CD56-positive uterine natural killer (uNK) cells, which are necessary for proper spiral artery development post-implantation.

In a rare controlled multicenter study to test the efficacy of recombinant human leukemia inhibitory factor (LIF), women with two unexplained implantation failures in an ART setting were given subcutaneous LIF or placebo over 7 days.[128] However, pregnancy rates with LIF (17.6%) were statistically suppressed compared to placebo (34.0%), indicating that LIF in this setting is contraindicated.

Conclusions

In this chapter, we discuss how various growth factors act and interact to regulate multiple aspects of reproduction in mammals. The use of mouse models combined with high throughput methods of data production and analysis has led to the accumulation of a notable amount of useful information on how fertility is regulated; several growth factor signaling pathways, like TGFβ, WNTs, Hedgehog, EGF, IGF and Notch, have been shown to be of central importance in reproductive biology and their reciprocal regulation and cooperation is a complex problem under intense investigation. Considering the role that a number of these factors have been suggested to play in several reproductive diseases (i.e., polycystic ovarian syndrome [PCOS], premature ovarian failure [POF], ovarian cancer, preeclampsia, and endometriosis), the goal for the future is that the knowledge resulting from these efforts will provide the tools necessary to improve the diagnosis of infertility and to design new approaches for its treatment.

Acknowledgments

We thank Ms. Shirley Baker for assistance with manuscript preparation. Studies in the Pangas and Matzuk laboratories have been supported by the Eunice Kennedy Shriver National Institute of Child Health and Human Development (HD07495, HD32067, HD33438, HD36289, HD57880, and HD60496 to Dr. Matzuk), National Cancer Institute (CA60651 to Dr. Matzuk; CA138628 to Dr. Pangas), the Ovarian Cancer Research Fund, and the Mary Kay Ash Charitable Foundation. Additional funding was provided by a Burroughs Wellcome Career Award in the Biomedical Sciences to Dr. Pangas.

Table S7.1 Phenotypes for Mice with Mutations in PGC Pathway Components (Ordered Based on Temporal Function During Embryogenesis)

Gene Symbol	Phenotype; Findings	References
Bmp2	Embryonic lethal; reduced PGC	1,2
Bmp4	Embryonic lethal; no PGC	3,4
Bmp8b	Viable; male infertility; reduced PGC	5,6
Smad1	Embryonic lethal; reduced PGC	7-9
Smad5	Embryonic lethal; reduced PGC	10-12
Smad4	Embryonic lethal; absent PGC	13-15
Prdm1 (Blimp1)	Embryonic lethal; PGC specification defect	16
Prdm14	Infertility; PGC specification defect	17
Pou5f1 (Oct4)	Pluripotency marker	18,19
Nanog	Pluripotency marker	19-21
Sox2	Pluripotency marker	19,22
Kitl	Variable phenotypes depending on mutation; PGC migration defect	23
Kit	Variable phenotypes depending on mutation; PGC migration defect	23
Tgfbr1 (ALK5)	Embryonic lethal; enhanced PGC migration	24,25

Table S7.2 Mouse Models for Ligands in the TGFB Family

Mutant Gene	Reproductive Phenotype	Fertility Status	References
Amh	Increased primordial follicle activation	Normal	26
Bmp6	Reduced ovulation	Subfertile	27
Bmp7	Reduced primordial germ cells	N.A.	28
Bmp15	Decreased ovulation and fertilization rates	Normal to subfertile	29
Gdf9	Follicular arrest at the primary follicle stage	Infertile	30
Fst	Loss of oocytes by birth	N.A.	31
Fst (Conditional)	Reduced growing follicles, ovulation and fertilization defects	Subfertile to infertile	32
Inha (Conditional)	Increased polyovular follicles	Subfertile	33
Inhbb	Lactation defects	Infertile	34
Inhba Inhbb (Conditional)	Increased numbers of antral follicles and accumulation of corpora lutea	Infertile	33
Tgfb2	Increased oocytes at birth	N.A.*	35

*N.A., Not available due to embryonic or perinatal lethality.

Table S7.3 Phenotypes of Mice with Ovarian Deletion of the SMAD Transcription Factors

Gene	Cre	Cell-Specific Deletion	Reproductive Phenotype	Fertility Status	References
Smad1	Amhr2cre	Granulosa cell	None	Normal	36
Smad2	Amhr2cre	Granulosa cell	None	Normal	37
Smad3	Amhr2cre	Granulosa cell	None	Normal	37
Smad4	Amhr2cre	Granulosa cell	Reduced antral follicles and ovulation rates, cumulus cell defects, increased luteinization, increased progesterone	Subfertile, then 50% infertile by 6 months	38
Smad4	Gdf9-icre	Oocyte	Reduced litter sizes	Subfertile	39
Smad4	Zp3-cre	Oocyte		Normal	
Smad5	Amhr2cre	Granulosa cell	None	Normal	36
Smad8	Knockout	Global	None	Normal	36
Smad2 Smad3	Amhr2cre	Granulosa cell	Reduced antral follicles and ovulation rates, cumulus cell defects	Subfertile, then infertile at 5 months	37
Smad1 Smad8	Amhr2cre	Granulosa cell	None	Normal	Unpublished data, S. Pangas
Smad5 Smad	Amhr2cre	Granulosa cell	None	Normal	36
Smad1 Smad5	Amhr2cre	Granulosa cell	Granulosa cell tumors	Subfertile, then infertile at 4-6 months	36
Smad1 Smad5 Smad8	Amhr2cre	Granulosa cell	Granulosa cell tumors	Subfertile, then infertile at 4-6 months	36

Table S7.4 Mutations Affecting Ovulation Rate and Prolificacy Sheep BMP15 and GDF9

Gene	Mutation	Breeds	Protein Domain	Mutation Type	References
GDF9	$FecG^{H}$	Belclare, Cambridge	Mature	Substitution	40
	$FecG^{E}$	Santa Inês*	Mature	Substitution	41
BMP15	$FecX^{B}$	Belclare	Mature	Substitution	40
	$FecX^{I}$	Inverdale	Mature	Substitution	42
	$FecX^{H}$	Hanna	Mature	Premature stop	42
	$FecX^{G}$	Galway	Prepro	Substitution; premature stop	40
	$FecX^{L}$	Lacaune	Mature	Substitution	43
	$FecX^{R}$	Rasa Aragonesa		Premature stop	44
BMPR1B	FecB	Booroola†, Merlino, Hu, Han, Garole, Javenese Thin-tail	Kinase domain	Substitution	45

*Heterozygotes have normal ovulation rates, but rates increase in homozygous sheep.
†Heterozygotes and homozygotes have increased ovulation rates with the heterozygotes midway between homozygotes and non-carriers.

Table S7.5 Mouse Models with Defects in the Periovulatory Period

Mutant Gene	Reproductive Phenotype	Fertility Status	References
Luteinizing hormone b *(Lhb)*	Block in folliculogenesis; early antral stage	Infertile	46
Luteinizing hormone/choriogonadotropin receptor *(Lhcgr)*	Block in folliculogenesis; early antral stage	Infertile	47,48
Prostaglandin-endoperoxide synthase 2 *(Ptgs2)*	Defects in ovulation, cumulus expansion, and implantation	Mostly infertile	49,50
Prostaglandin E receptor 2, subtype EP2 *(Ptger2)*	Defects in cumulus expansion; decreased fertilization	Subfertile	51-53
Pentraxin 3 (Ptx3)	Defects in cumulus-oocyte complex integrity and ovulation	Subfertile	54,55
Tumor necrosis factor alpha induced protein 6 *(Tnfaip6)*	Impaired cumulus matrix formation resulting in failed cumulus-oocyte complex expansion	Infertile	56
CCAAT/enhancer-binding protein b *(Cebpb)*	Reduced ovulation; fail to form corpus luteum	Infertile	57
Nuclear receptor interacting protein (*Nrip1*; RIP40)	Ovulation defect; ovaries accumulate luteinized and unruptured follicles	Infertile	58
Progesterone receptor (*Pgr*; PR)	Anovulation; corpora lutea absent	Infertile	59
Alpha 1 microglobulin/bikunin *(Ambp)*	Defects in ovulation and cumulus-oocyte complex integrity	Subfertile	60,61
Amphiregulin *(Areg)*	Suppressed cumulus expansion, delayed meiotic reentry	Subfertile	62
Bone morphogenetic protein 15 *(Bmp15)*	Defects in cumulus expansion and ovulation	Subfertile	29
Bone morphogenetic protein receptor, type IB *(Bmpr1b)*	Defects in estrous cyclicity, cumulus expansion, and endometrial gland development	Subfertile	63
Epiregulin (*$Ereg^{wa2/wa2}$*; hypomorph)	Suppressed cumulus expansion, defective meiotic resumption, ovulation defect	Subfertile	62
MAD homolog 4 *(Smad4)* (cKO)	Premature luteinization; decreased ovulation with trapped oocytes	Subfertile	38

Table S7.6 Main Genes Involved in the Development of the Reproductive Tracts

Gene	Phenotype	References
Pax2	Null mice show neonatal lethality; males and females lack kidneys, ureters, and genital tracts	64
Emx2	Null mice show neonatal lethality; females and males lack kidneys, ureters, gonads, and genital tracts	65
Lim1	Null mice show embryonic lethality; females lack müllerian duct	66

Table S7.7 Genes Involved in Müllerian Duct Regression and Development

Gene	Phenotype	References
Amh	Null males have a complete male reproductive tract and functional sperm, but also uterus and oviducts; females are fertile with enlarged ovaries. Female mice overexpressing Amh show blind vagina and no uterus or oviducts	67,68
Amhr2	Null males have a normal male reproductive tract, but also uterus and oviducts	69,70
Alk2, Alk3	Alk2 and Alk3 null mice show embryonic lethality; conditional ablation of Alk2 and Alk3 in the müllerian duct mesenchyme (Alk2/Alk3 double conditional knockout mice) causes duct retention in males	71,72
Smad1, Smad5, Smad8	Smad1 and Smad5 null mice show embryonic lethality; Smad8 null mice are viable and fertile. Deletion of Smad5, Smad1/Smad5 or Smad5/Smad8 in the müllerian duct mesenchyme causes partial müllerian duct retention. Smad1/Smad5/Smad8 triple conditional knockout mice show complete müllerian duct retention	71
Wnt7a	Null mice show partial perinatal lethality; null males fail to undergo Mullerian duct regression. Females are infertile due to abnormal development of uterus and oviduct	73,74
Wnt4	Null mice show neonatal lethality; null females are masculinized: they have Wolffian duct and lack müllerian duct	75,76
Wnt5a	Null mice show perinatal lethality; females show caudal truncation of the reproductive tract and defective uterine glandular development	77,78
Ctnnb1	Null mice show embryonic lethality; male mice with a conditional deletion of Ctnnb1 in the müllerian duct mesenchyme show müllerian duct retention	79

Table S7.8 Genes Involved in the Regulation of Embryo Implantation

Gene	Phenotype	References
Ihh	Null mice die before or immediately after birth. Females with a conditional deletion of Ihh in the uterus show failure of blastocyst attachment. Decidualization is defective	80,81
NR2F2	Null mice show embryonic lethality. Females with a conditional deletion of COUP-TFII in the uterus are sterile; both embryo attachment and uterine decidualization are impaired	82
Bmp2	Null mice show embryonic lethality; females with a conditional deletion of Bmp2 in the uterus are sterile due to failure of uterine stromal cell decidualization	83
Wnt4	Null mice show neonatal lethality; female mice with a conditional deletion of Wnt4 in the uterus are severely subfertile due to impaired implantation	84

Table S7.9 Factors Produced at the Maternal-Fetal Interface; Their Effects on the Invasion, Proliferation, and Migration of the Trophoblast; and the Intracellular Molecular Pathways That They Regulate

Factor	Expression	Invasion	Proliferation	Migration	Downstream Pathway(S)	References

CHAPTER 8

Neuroendocrine Control of the Menstrual Cycle

Janet E. Hall

The Reproductive Axis

Normal reproductive function in women involves repetitive cycles of follicle development, ovulation and preparation of the endometrium for implantation should conception occur in that cycle. This pattern of regular ovulatory cycles is achieved through precise functional and temporal integration of stimulatory and inhibitory signals from the hypothalamus, the pituitary and the ovary (Fig. 8.1). The reproductive system functions in a classic endocrine mode initiated by pulsatile secretion of gonadotropin releasing hormone (GnRH) from the hypothalamus into the pituitary portal venous system. GnRH regulates the synthesis and subsequent release of follicle stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary into the circulation. FSH and LH stimulate ovarian follicular development, ovulation, and corpus luteum formation and the coordinated secretion of estradiol, progesterone, inhibin A, and inhibin B. A key component of this system is the modulatory effect of ovarian steroids and inhibins on gonadotropin secretion, acting either directly at the pituitary level or through alterations in the amplitude or frequency of GnRH secretion. Negative feedback restraint of FSH secretion is critical to the development of the single mature oocyte that characterizes human reproductive cycles. In addition to negative feedback controls, the menstrual cycle is unique among endocrine systems in its dependence on estrogen positive feedback to produce the preovulatory LH surge that is essential for ovulation.

Neuroendocrine Components of the Reproductive Axis

Gonadotropin Releasing Hormones

Luteinizing-releasing hormone (LHRH) was isolated, characterized, and synthesized in 1971.[1] The central role of this decapeptide in propagation of the species makes it fitting that Drs. Schally and Guillemin received the Nobel Prize in Physiology and Medicine in 1977 for its isolation.[1] It was expected that separate releasing hormones for LH and FSH would be discovered. However, subsequent studies provided evidence that both LH and FSH are secreted in response to LHRH, resulting in the common use of the term gonadotropin-releasing hormone (GnRH) for the decapeptide originally referred to as LHRH. It is now known that GnRH is located on chromosome 8p and works through its own receptor, which is encoded on chromosome 4.

GnRH neurons differentiate in the olfactory placode, cross the cribiform plate into the forebrain, and migrate to the medial basal hypothalamus where they establish connections with the pituitary portal system in the median eminence as part of the hypothalamic tuberinfundibular system.[2] The initial leg of this migratory journey occurs along the scaffold of olfactory, vomeronasal, and terminal nerves. Genetic studies in patients with abnormalities in GnRH secretion, with concomitant disruption of the olfactory system (Kallmann Syndrome; KS) or without anosmia (normosmic idiopathic hypogonadotropic hypogonadism; nIHH), in combination with functional studies in animal and cell systems have identified key components of the developmental regulation of GnRH neurons and provided critical insights into the growing complexity of this process.[2] Among the genes associated with KS or nIHH, *KAL1*, fibroblast growth factor 8 *(FGF8)* and its receptor fibroblast growth factor 1 *(FGFR1)*, prokineticin 2 *(PROK2)* and its receptor *(PROKR2)*, heparin sulfate 6-O-sulfotranferase 1 *(HS6ST1)*,[3] chromodomain helicase DNA binding protein 7 *(CHG7)*,[4] nasal embryonic LH-releasing hormone factor *(NELF)*, semaphorin-3A *(SEMA3A)*,[5] and *(WDR11)*[4] are all involved in different aspects of early migration and axonal guidance of GnRH neurons on the path to their eventual home in the hypothalamus (Table 8.1). In the human there are approximately 7000 GnRH expressing neurons in areas of the brain linked to gonadotropin regulation.[6] Unlike neurons secreting other hypothalamic releasing factors, GnRH neurons do not exist in a defined nucleus, but are scattered throughout the medial basal hypothalamus, with an additional population in the preoptic area.[7]

Mammals, including humans, simultaneously express more that one molecular form of GnRH (Table 8.2).[8] GnRH II is located on chromosome 20p13 and works through its own receptor which is encoded on chromosome 1. GnRH II is widely expressed both within and outside the brain. It likely plays a role in reproductive behavior in lower animal species. It is a potent stimulator of LH and FSH *in vitro* and *in vivo* in animal models, but its role in the human is unknown. GnRH III has been identified in human brain by immunohistochemistry and HPLC, has a similar hypothalamic distribution to that of GnRH, and may act through

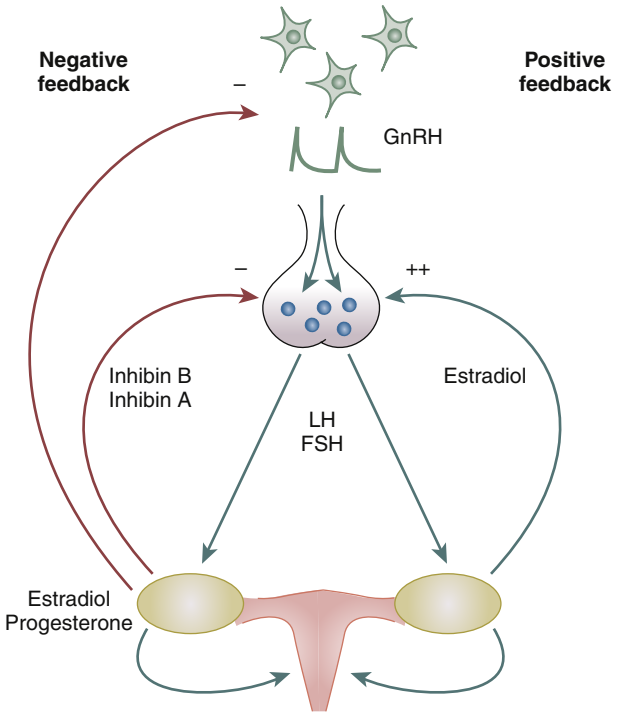

FIGURE 8.1 Neuroendocrine control of reproduction requires the pulsatile secretion of gonadotropin-releasing hormone (GnRH) released into the pituitary portal system to stimulate the synthesis and secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the gonadotropes. The gonadotropins, in turn, stimulate follicular development and secretion of gonadal steroids and peptides whose negative feedback effects on the hypothalamus and pituitary restrain gonadotropin secretion. At the midcycle, rising levels of estradiol are responsible for the positive feedback, which generates the preovulatory gonadotropin surge.

the GnRH receptor. Although there is some evidence in lower animal species that GnRH III may have preferential FSH releasing properties,[9] a GnRH III consensus sequence has not been found in the human genome[8] and thus, it is unlikely that GnRH III plays a role in human reproduction.

Pulsatile Secretion of GnRH

A prominent feature of the reproductive system is the absolute requirement for pulsatile secretion of GnRH into the pituitary portal system for normal gonadotropin secretion. The now classic studies of Knobil and colleagues in hypothalamic-lesioned monkeys receiving GnRH first showed that intermittent stimulation of the pituitary results in secretion of LH and FSH while constant GnRH stimulation is associated with suppression of gonadotropin levels.[10] Isolated GnRH neurons exhibit an intrinsic pulsatility,[11] but there is also a significant body of research indicating that external influences modify and coordinate the secretion of GnRH, influencing both the amplitude and frequency of pulsatile GnRH secretion.

Neuromodulators of GnRH Secretion

While a number of neurotransmitters are involved in the control of GnRH secretion in animal species, only a few have been shown to have an effect in the human.[12] Although there is evidence for a stimulatory role of the α-adrenergic system in a number of animal models, it is much less likely that it plays a role in control of the human menstrual cycle. The role of the dopaminergic system remains controversial, but studies that have documented an increase in LH pulse frequency in response to a dopamine antagonist in women with hypothalamic amenorrhea suggest dopamine may inhibit GnRH secretion in women.[13,14]

Kisspeptin

Knock out models suggest that there is considerable redundancy in the systems that ultimately control GnRH secretion; however, an emerging body of evidence indicates that the kisspeptin pathway is a key upstream modifier of GnRH secretion. As with the genes that are now known to control the developmental migration of GnRH neurons, a role for kisspeptin in reproduction was initially discovered by the combination of genetic studies in patients with IHH which identified mutations in the gene encoding the kisspeptin receptor (*KISS1R*, formerly known as G-protein coupled receptor 54 [*GPR54*]) and knock-out mouse models.[15] Kisspeptin is an extremely powerful stimulator of LH, an action that is blocked by a GnRH antagonist indicating that the effect on LH is through GnRH. The kisspeptin system is thought to play a dominant role in the onset of puberty and has also been implicated in estrogen negative feedback in the arcuate. This system has also been implicated in estrogen positive feedback in the anteroventral periventricular nucleus (AVPV) in rodents.[16,17] Its role in the midcycle surge in women is less clear as studies in women demonstrate a paucity of kisspeptin neurons in an analogous hypothalamic region[18] and evidence discussed below questions

the existence of a GnRH surge associated with the midcycle LH surge in women.

Neurokinin B

Neurokinin B (NKB), which is encoded by the tachychinin 3 gene *(TAC3)* and its receptor encoded by *TACR3* have also been implicated in the normal control of GnRH secretion through genetic studies in patients with KS or IHH. NKB stimulates LH secretion, acting upstream of the GnRH neuron.[19] *TAC3* and *KISS* are colocalized and there is mounting evidence that the effect of NKB on GnRH is exerted through kisspeptin.[20,21]

Endogenous Opioids/Dynorphin

There is substantial evidence for the involvement of endorphins in transducing the negative feedback effects of progesterone on pulsatile GnRH secretion.[22,23] Recent studies have identified dynorphin which binds to the kappa-opioid receptor as the key mediator of progesterone negative feedback.[24] In a variety of animal species and the human it has now been shown that kisspeptin, NKB, and dynorphin are coexpressed in cells in the median eminence that are now referred to as KNDy neurons. These neurons express estrogen, progesterone, and androgen receptors and are thought to mediate gonadal steroid feedback on GnRH secretion with increasing evidence that they are also involved in the specific generation of pulses of GnRH.[24] There is also evidence that gamma-amino butyric acid (GABA) may well be involved in mediating estrogen negative feedback on GnRH secretion.[12]

Gonadotropin Inhibitory Hormone

Gonadotropin inhibitory hormone (GnIH) is a hypothalamic neuropeptide that inhibits GnRH secretion. First discovered in the quail, there is now evidence that it is present in other avian species as well as in mammals, including the human.[25,26] GnIH is secreted into the pituitary portal system[27] and its receptor, G-protein coupled receptor 147 (GPR147) is present on both GnRH and gonadotrope cells, raising the distinct possibility that it functions at both the hypothalamic and pituitary level to regulate secretion of LH and FSH. Importantly, there is also evidence that GnIH increases food intake in sheep without reducing energy expenditure,[28] raising the possibility that GnIH may be a factor that mediates the inverse relationship between LH and body mass index in women.

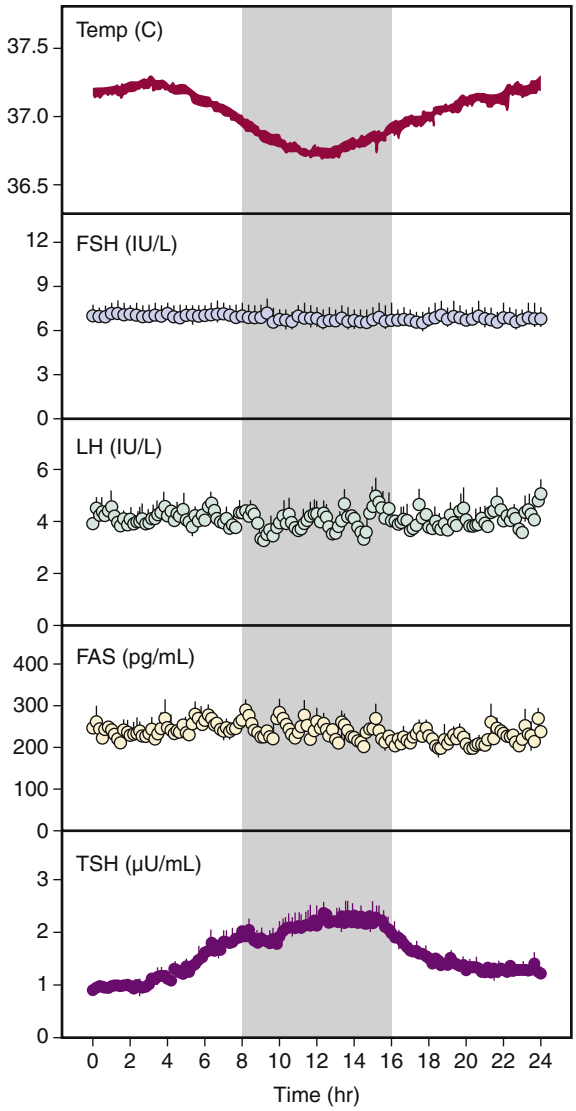

FIGURE 8.2 Mean + sem of temperature, FSH, LH, FAS, and TSH levels in early follicular phase women (n = 11) during a constant routine of light, position, wake, and nutritional intake over a 24 hour period indicate the constancy of gonadotropin levels across the day and night in the absence of sleep with maintenance of endogenous circadian rhythms of temperature and TSH. The shaded area represents the subjects' traditional sleep time during which they were kept awake. (*Adapted from Klingman KM, Marsh EE, Klerman EB, et al. Absence of circadian rhythms of gonadotropin secretion in women.* J Clin Endocrinol Metab *96:1456–1461, 2011.*)

Sleep and Circadian Effects on GnRH Secretion in Women

Endocrine systems are profoundly influenced by both sleep and endogenous circadian rhythms, which persist in the absence of sleep or other environmental cues. Diurnal (day and night) rhythms of LH and gonadal steroids have been well described in men and women. Studies in which sleep and other environmental cues were controlled have failed to demonstrate an endogenous circadian rhythm of LH or FSH in early follicular phase and postmenopausal women (Fig. 8.2), despite the presence of robust circadian rhythms of temperature, cortisol, and TSH.[29,30] In contrast, there is compelling evidence that sleep directly affects the pulsatile secretion of LH and presumably that of GnRH. Studies that have separated the effects of sleep from time of day demonstrate that during puberty in boys and girls, pulsatile LH secretion is increased during sleep.[31] Recent studies have further shown that in pubertal children, LH pulses are most commonly preceded by slow wave sleep (SWS).[32] These studies suggest that factors associated with SWS stimulate GnRH secretion or that there is an upstream regulator of both GnRH secretion and deep sleep in puberty. Paradoxically, with maturation of the reproductive system and the onset of ovulatory menstrual cycles, there is a notable slowing of pulsatile LH secretion at night in the early follicular phase of the cycle.[33,34] Sleep reversal studies in women[35] have demonstrated not only that the early follicular phase

night time slowing of LH pulses is due to sleep rather than time of day but also that, within sleep, brief periods of wakefulness are associated with the onset of LH pulses while SWS appears to be inhibitory to LH pulses (Fig. 8.3). It is tempting to speculate that prior progesterone exposure sensitizes the GnRH pulse generator to the inhibitory effects of sleep in the early follicular phase, possibly explaining the paradoxical effect of sleep on GnRH secretion in the early follicular phase compared with puberty.

Gonadotropin-Producing Cells of the Pituitary

LH and FSH are synthesized in gonadotropes, which comprise between 7% and 15% of the cells in the pituitary. Immunohistochemical studies in the rat indicate that approximately 70% of gonadotropes stain for both LH and FSH while the remainder stains for a LH or FSH with approximately equal numbers of cells staining for each. As the animals approach the day of the gonadotropin surge in proestrus, monohormonal cells begin to express both βLH and βFSH, while a population of cells that express growth hormone (GH) also express the gonaodtropin subunits.[36]

The process of biosynthesis and secretion of intact gonadotropins involves: (1) translation of βLH, βFSH, and the common gonadotropin α-subunit; (2) posttranslational modification and folding; (3) combination of the β− and α−subunits; and (4) hormone packaging and secretion. LH, FSH, and uncombined or free α-subunit (FAS) are all secreted in response to GnRH stimulation of the gonadotrope.

Multiple isoforms of LH and FSH, differing in their carbohydrate structure and charge, coexist in both pituitary and serum. More basic forms of both LH and FSH yield a greater *in vitro* potency, but a shorter half-life in the circulation while the opposite is true for less basic forms.[37] The greater number of sialic acid residues on FSH prolongs its half-life,[38] whereas the greater number of sulfonated N-acetyl-galactosamine (GalNAc) asparagine-linked oligosaccharides on LH is associated with more rapid clearance due to binding to a specific hepatic receptor.[39] Sulfonation and sialylation of LH and FSH vary across the menstrual cycle and in the absence of gonadal steroids; postmenopausal women have a greater preponderance of sialylated forms of both LH and FSH.[40] Consistent with these changes, the disappearance of LH following GnRH receptor blockade with a potent GnRH antagonist is significantly prolonged in postmenopausal women compared to women in the follicular phase and at the midcycle surge (MCS), while the disappearance of FAS is unaffected by the absence of gonadal function (Table 8.3).[41] The number of sulfonated and sialylated residues on LH and FSH is tightly linked to hormone clearance in women.[42]

There is also evidence that gonadotropin secretion is modulated by a factor or factors related to obesity. Serum levels of LH are inversely related to body mass index (BMI)

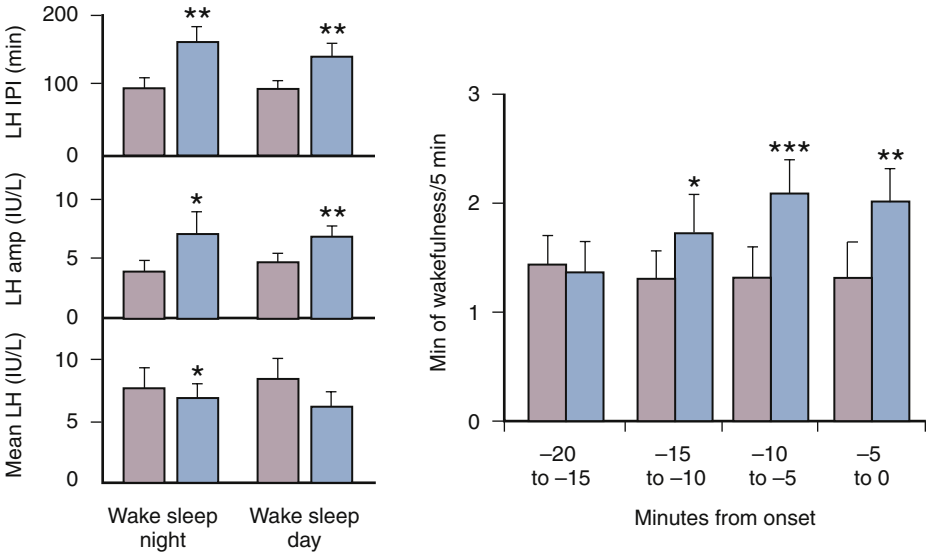

FIGURE 8.3 As indicated in the *left panel*, sleep is specifically associated with slowing of luteinizing hormone (LH) pulses. The LH interpulse interval (IPI) is longer and amplitude is higher in normal women during sleep *(blue bars)* compared with wake *(purple bars)*, whether sleep occurs at night or during the day. As indicated in the *right panel*, wakefulness is more likely in the 5 to 10 minutes before the onset of an LH pulse *(blue bars)* than in a similar time frame indexed to a random LH point that is not associated with an LH pulse *(purple bars)*. (*Adapted from Hall JE, Sullivan JP and Richardson GS. Brief wake episodes modulate sleep-inhibited luteinizing hormone secretion in the early follicular phase.* J Clin Endocrinol Metab *90:2050–2055, 2005.*)

in normal women and in women with polycystic ovary syndrome (PCOS).[43] Further studies have indicated that the inhibitory effect of obesity on LH secretion in PCOS is not mediated at the hypothalamus, but is associated with a decrease in both the pituitary response to GnRH and the half-life of endogenous, but not exogenous, LH.[44,45] The latter finding is consistent with the increase in sulfonated isoforms of LH and FSH as a function of increasing BMI in women with PCOS.[40]

Differential Control of LH and FSH Secretion

Although secreted from a common cell type within the gonadotrope, LH and FSH have markedly different functions in the control of ovarian physiology. These differences in function are reflected in their different patterns of secretion during normal reproductive cycles. The divergent control of LH and FSH is achieved through a combination of differential control of the synthesis and secretion of LH and FSH by the pattern of GnRH stimulation, the preferential control of FSH synthesis by the activin/follistatin system, and differential feedback by ovarian steroids and the inhibins on the two gonadotropins. Understanding the control of LH and FSH secretion is critical to our understanding of the dynamics of the menstrual cycle.

Gonadotropin Releasing Hormone

FSH is secreted along with LH in response to acute stimulation by GnRH, but the relative role of GnRH in the overall control of FSH synthesis is much less than for LH. Blockade of the GnRH receptor using a specific GnRH receptor antagonist results in 90% inhibition of LH secretion, but only 40% to 60% inhibition of FSH.[46]

Synthesis and secretion of LH and FSH are differentially controlled by the amplitude and frequency of GnRH stimulation.[47,48] LH secretion is highly responsive to increases in the dose of GnRH, while FSH is relatively insensitive to GnRH dose. A physiological frequency of GnRH results in synthesis and secretion of all three gonadotropin subunits. However, increases or decreases from the physiological frequency have differential effects on LH and FSH (Table 8.4). Slow frequencies of GnRH stimulation favor the synthesis and secretion of FSH *in vitro* and are associated with an increase in FSH *in vivo* in settings in which gonadal feedback is low.[49] In GnRH-deficient men and women, an increase in the frequency of GnRH stimulation results in an increase in mean levels of LH with no appreciable change in FSH (Fig. 8.4),[50,51] effects that have implications for the pathophysiology of PCOS in which the frequency of GnRH is consistently increased.[44] The direct effect of GnRH pulse frequency on GnRH receptor number[52] and the downstream effects of modulation of receptor number underlie the frequency modulation of LH and FSH secretion, at least in part.

While an increase in GnRH pulse frequency increases the synthesis and mean levels of LH, the LH pulse amplitude is inversely related to GnRH pulse frequency.[53,54] Thus, studies in GnRH-deficient men and women have shown that slower GnRH pulse frequencies are associated with higher LH amplitude in response to GnRH while faster frequencies are associated with a decrease in the amplitude

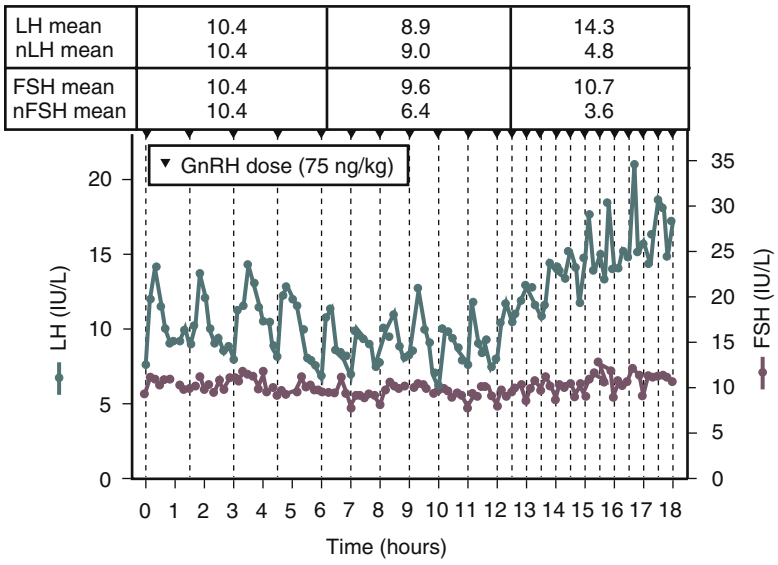

FIGURE 8.4 The differential effect of increasing gonadotropin-releasing hormone (GnRH) pulse frequency on luteinizing hormone (LH) and follicle-stimulating hormone (FSH) as demonstrated in a GnRH-deficient woman receiving IV pulsatile GnRH. After 7 days of administration of pulsatile GnRH at a dose of 75 ng/kg and a frequency of every 90 minutes, blood was sampled for 6 hours and the frequency was then increased to every 60 minutes for 6 hours and every 30 minutes for 6 hours with evidence of an increase in LH but not FSH. The mean LH and FSH are given for each frequency as indicated. The means of LH and FSH normalized for the overall amount of GnRH administered (nLH and nFSH), suggest that faster GnRH pulse frequencies are associated with early stages of pituitary desensitization. (*From Hall JE, Taylor AE, Hayes FJ, et al. Insights into hypothalamic-pituitary dysfunction in polycystic ovary syndrome.* J Endocrinol Invest *21:602–611, 1998.*)

response to GnRH. The decrease in LH amplitude seen with pulse frequencies that are faster than those encountered in physiological settings[50,51] may be the earliest sign of the pituitary desensitization that is well recognized in association with continuous infusions of GnRH or the use of a GnRH agonist.

Autocrine/Paracrine Regulation of Gonadotropins: Activin, Inhibin, and Follistatin

Activins, inhibins, and follistatins were first discovered as gonadal factors with preferential actions on FSH secretion from pituitary gonadotropes.[55] The inhibins, named for their inhibitory effect on FSH secretion in pituitary cell cultures, are heterodimers that are composed of one of two β-subunits, βA or βB, and a closely related α-subunit to form inhibin A or inhibin B. In contrast, the activins, which stimulate the synthesis and secretion of FSH, are composed of two β-subunits. Activin is secreted by gonadotropes and other pituitary cell populations and like other members of the TGF-β superfamily of growth and differentiation factors, activins exert most of their effects by autocrine or paracrine mechanisms. Activins sequentially interact with one of the two known type-II activin receptors, ActRII or ActRIIB and the type-1 receptor, activin receptor-like kinase 4 (ALK4). The expression of FSHβ is extremely sensitive to the stimulatory action of activins, which work in concert with and are permissive for the actions of GnRH through promotion of transcription of both FSHβ and the GnRH receptor.[56]

The inhibins act as specific antagonists of the FSH stimulatory actions of activin by binding to betaglyglycan and sequestering the type-II activin receptors. While inhibin is made in the pituitary, circulating inhibin derived from the ovary plays a far greater role in the negative control of FSH. In addition, bone morphogenic proteins, BMP-6 and BMP-7 are capable of modulating FSH synthesis in gonadotropes suggesting that other systems may also be involved in the control of FSH.[57]

Follistatin is a monomeric protein that is distinct from the activin and inhibin family and acts as a virtually irreversible binding protein by complexing with activin and masking the binding sites on activin for the type-I and type-II receptors.[55] The follistatin 288 isoform (FS288) has a high affinity for cell-surface proteoglycans and is presumed to act within the pituitary.[57] Follistatin is synthesized in many tissues in the body, including the pituitary where its synthesis in pituitary folliculostellate cells and gonadotropes is controlled by activin and GnRH and may be additionally modulated by gonadal steroids. Activin synthesis does not appear to vary during female reproductive cycles. However, specific changes in follistatin have been noted during the rat estrus cycle, suggesting that the effects of activin on FSH synthesis and secretion may be modulated through changes in follistatin.[57] Follistatin is increased by fast frequencies of GnRH stimulation and decreased with slower frequencies[58] compatible with the hypothesis that the activin and follistatin system mediates the effect of GnRH pulse frequency on FSH. Thus, while GnRH appears to be sufficient for control of LH synthesis and secretion, the activin-inhibin-follistatin system and perhaps BMPs play a significant role in conjunction with GnRH in regulating the synthesis and secretion of FSH.

Ovarian Feedback on the Hypothalamus and Pituitary

Negative Feedback

Estrogen

It is well known that low doses of estrogen inhibit gonadotropin secretion. Increased gonadotropin levels in patients with aromatase deficiency provide the most specific evidence of estrogen negative feedback on the control of both LH and FSH in men and women[59] although this is supported by the marked increase in LH and FSH levels in postmenopausal and ovariectomized women.[60] The loss of gonadal feedback in ovariectomized rats is associated with an increase in LH and FSH secretion; increased expression of LHβ, FSHβ, and α-mRNA; an increase in the number of cells expressing LHβ; an increase in cell size; and an increase in the amount of expression per cell. These changes are reversed by administration of low doses of estradiol,[61] which has also been shown to reverse the increases in gonadotropin secretion in the ovariectomized sheep and monkey.

There is considerable evidence that supports a primary hypothalamic site of estrogen negative feedback on pituitary gonadotropin secretion.[12,62] Studies, in which GnRH secretion has been measured, using a push-pull hypothalamic perifusion technique in the rat or cannulation of the pituitary portal circulation in the sheep and monkey, indicate that GnRH increases following ovariectomy and decreases with estrogen replacement. Estradiol administration is associated with a decrease in GnRH expression in rat hypothalamic tissue slices and in a GnRH neuronal cell line. Both indirect and direct mechanisms for estrogen regulation of hypothalamic GnRH neurons have been proposed. Studies in estrogen receptor (ER) knock-out animals support an important role of ERα in mediating estrogen negative feedback although both forms of the receptor are present in the hypothalamus.[62] Estrogen-receptive GABA neurons within the preoptic area may play a role in mediating the negative feedback effects of estrogen on GnRH secretion. There is also compelling evidence for a role of kisspeptin in estrogen negative feedback in rodents,[17,63] while β−endorphin is unlikely to be involved.[12]

In women, the mechanisms underlying estrogen negative feedback have generally been investigated in postmenopausal or ovariectomized women. The quantity of GnRH, estimated *in vivo* using submaximal GnRH antagonist administration, is higher in postmenopausal compared with premenopausal women,[64] consistent with the increase in GnRH mRNA that has been demonstrated in postmenopausal women studied at autopsy.[65] The quantity of GnRH returned to follicular phase levels with administration of low levels of estradiol, suggesting that the increase in GnRH in the absence of gonadal feedback can be attributed to loss of estrogen.[64] To further support a hypothalamic site of estrogen negative feedback in women, neuroimaging studies have now provided evidence of decreased metabolical activity in the medial basal hypothalamus in association with brief exposure to relatively low doses of estradiol.[66] Estradiol administration does not decrease GnRH pulse frequency in

the majority of studies in postmenopausal women and thus, the negative feedback effect of estradiol on the hypothalamus is likely to be mediated through changes in GnRH pulse amplitude.[60] These results in women are similar to those in which GnRH was measured directly in pituitary portal blood in ovariectomized sheep and monkeys and showed a decrease in GnRH pulse amplitude, but not frequency in response to estradiol administration.[67,68] Autopsy studies in women are consistent with a role for neurons expressing kisspeptin, NKB, substance P, dynorphin, and ERα in mediating the negative feedback of estrogen in the medial basal hypothalamus.[69,70]

While the studies detailed above demonstrate a significant hypothalamic effect of estrogen negative feedback, they do not exclude a pituitary site of action. In cultured pituitary cells, estradiol transiently reduces the LH response to GnRH[71] and administration of estradiol to hypothalamic-lesioned monkeys receiving pulsatile GnRH decreased LH secretion.[72] Both ERα and ERβ are present on gonadotropes[62] and characterization of the gonadotrope specific ERα (ESR1) knock-out mouse has now provided definitive evidence of a direct inhibitory effect of estradiol at the pituitary in the rodent.[73] Recent studies in postmenopausal women that isolated the pituitary from hypothalamic input have confirmed that physiological levels of estradiol have a direct pituitary effect on gonadotropin secretion that is greater for FSH than for LH.[74]

Progesterone

Progesterone has a profound effect on gonadotropin secretion that manifests at the hypothalamic level through slowing of pulsatile GnRH secretion.[75,76] This effect requires estrogen priming,[77] likely through upregulation of progesterone receptors in the hypothalamus.[78] In postmenopausal women receiving low doses of estradiol, addition of progesterone uniformly suppresses GnRH pulse frequency using either LH or FAS as markers of GnRH secretion[79-81] and administration of progesterone decreases the overall amount of GnRH secretion.[64] It is likely that progesterone exerts its effects on GnRH secretion through both direct and indirect mechanisms.[12,82] There is ample evidence that the β-endorphin system plays a critical role in mediating the effects of progesterone on GnRH pulse frequency and studies in sheep indicate that the inhibitory effect of progesterone on GnRH secretion is mediated by dynorphin.[24]

Inhibin/Activin/Follistatin

Evidence for a nonsteroidal gonadal factor with feedback effects on the pituitary dates to the early 1900s but it was not until the mid-1980s that inhibin was isolated and subsequently found to be part of a family of peptides that includes inhibin A, inhibin B, activin, and the functionally related protein, follistatin.[57] Inhibin B is present in the circulation in men while both inhibin A[83-85] and inhibin B[86-88] are detected in serum and follicular fluid in women during their reproductive years. Further studies have determined that inhibin B is produced by granulosa cells in the ovary[89] while inhibin A is produced by the luteinized granulosa cells of the corpus luteum.[89,90] Inhibin subunits are expressed in a variety of tissues including the adrenal. However, the only significant source of circulating dimeric inhibins is the gonads and there is compelling evidence that the principle mechanism of action of inhibin in suppressing pituitary FSH secretion is an endocrine action.

Activin acts as a local growth and differentiation factor in a variety of tissues, including the pituitary and ovary.[57] While activin has been measured in serum, circulating activin is irreversibly bound by the circulating isoform of follistatin, FS315.[91] As yet, no mechanisms have been identified within tissues that would alter neutralization by follistatin and therefore it is almost certain that within the pituitary activin acts in an autocrine and paracrine rather than endocrine fashion.

Gonadotropin Surge Attenuating Factor

Gonadotropin Surge Attenuating Factor (GnSAF), also known as gonadotropin surge inhibiting factor (GnSIF), is an ovarian factor that reduces GnRH-induced LH secretion.[92,93] Despite many years of investigation, the molecular structure of GnSAF[92,94,95] has not been completely characterized, hampering efforts to fully understand its regulation and physiological roles. Its name derives from the initially hypothesized role of this compound in preventing an early LH surge and thus, premature luteinization of the preovulatory follicle. However, there is now evidence in animal models and women that there is an inverse relationship between GnSAF bioactivity and follicle size, with highest concentrations in small growing follicles,[92] suggesting that it may well act earlier in the cycle than previously thought.

Positive Feedback

Estrogen

In addition to inhibition of gonadotropin secretion, estrogen exerts a stimulatory effect to generate the preovulatory LH surge. This positive feedback effect is seen in multiple animal species[62] and in women. There are two critical questions that form the basis of a mechanistic understanding of gonadotropin surge generation: the first is how estrogen can exert both inhibitory and stimulatory effects on LH secretion, and the second, is whether the site of estrogen positive feedback is at the pituitary, the hypothalamus, or both. The direction of estrogen feedback is dependent on both the degree of estrogen exposure and its duration with low levels of estradiol administration resulting in decreases in LH secretion within 12 to 24 hours, while positive feedback requires exposure to higher concentrations over a more prolonged duration.[96-98] There is ample evidence that high levels of estrogen augment the pituitary response to GnRH across species. Studies in animal models demonstrate an increase in the number of cells expressing the gonadotropin subunits, an increase in GnRH receptor number, an impact on the function of ion channels in the plasma membrane and regulation of both gene expression and second messenger systems within gonadotropes.[52,99,100] Studies in LβT2 pituitary cells indicate that activin may act in concert with estrogen to increase GnRH receptors on pituitary gonadotropes[56] while NPY secretion from the median eminence may contribute to pituitary sensitization through changes in the affinity of the GnRH receptor for its ligand.[101]

In the rat and sheep there is evidence that in addition to pituitary augmentation of the GnRH signal, estrogen positive feedback on gonadotropin secretion requires an increase in GnRH secretion[102] and in rodents, this increase

in GnRH secretion requires specific circadian signals.[103] In rodents, estrogen negative and positive feedback occur in distinct areas of the hypothalamus: the arcuate nucleus of the medial basal hypothalamus and the anteroventral periventricular nucleus (AVPV), respectively. While kisspeptin appears to be involved in both negative and positive estrogen feedback in the rodent, kisspeptin neurons in the arcuate nucleus coexpress NKB and dynorphin, whereas this is not the case in the AVPV.[24,63]

Generation of the preovulatory surge in nonhuman primates appears to be fundamentally different from that in the rodent—while there may be some alteration in GnRH input, this is not controlled in the preoptic area (the site of the AVPV), it is not tied to circadian signals, and the gonadotropin surge does not require an increase in GnRH.[104] As in nonhuman primates, an increase in GnRH secretion is not required for generation of a normal gonaodtropin surge in women.[105] In contrast to nonhuman primates, there is no evidence for augmentation of GnRH secretion or even an altered pattern of GnRH stimulation associated with generation of the surge in women.[106-108] Taken together, these data suggest that the gonadotropin surge in normal women requires ongoing pulsatile GnRH stimulation, but is otherwise mediated through the marked increase in pituitary sensitivity to GnRH (discussed later in the chapter in Midcycle Surge). Thus, while an increase in GnRH is required for generation of the gonadotropin surge in rodents and sheep, GnRH appears to play a permissive role in generation of the preovulatory LH surge in normal women as it does in the monkey.[102,104]

The Normal Menstrual Cycle

Clinical Characteristics

By convention, the first day of menses is designated Day 1 and marks the onset of the follicular phase of the menstrual cycle. The follicular phase encompasses the period of recruitment of multiple follicles and emergence and growth of the dominant follicle (Fig. 8.5). During the follicular phase, rising levels of estradiol are associated with endometrial proliferation. The luteal phase, which begins on the day after the LH surge, is characterized by formation of the corpus luteum, secretion of progesterone and a coordinated series of changes in the endometrium as it first prepares for implantation and then, with decline of the corpus luteum in the absence of pregnancy, loses its blood supply and sloughs.

The classic studies of Treloar and colleagues[109] indicate that median menstrual cycle length is 28 days, with a normal range between 25 and 35 days (Fig. 8.6). For the majority of reproductive life, there is little cycle-to-cycle variability although the intermenstrual interval declines between the ages of 36 and 40 years old. Both immediately following menarche and preceding menopause there is a significant degree of variability in the intermenstrual interval between and within individuals. Fluctuations in the length of the follicular phase are primarily responsible for the variations in cycle length both between women and as a function of normal aging in an individual woman. Luteal phase duration is more constant, lasting between 10 and 16 days in 95% of cycles. During the follicular phase, the progressive increase in diameter of the largest follicle as assessed by ultrasound is

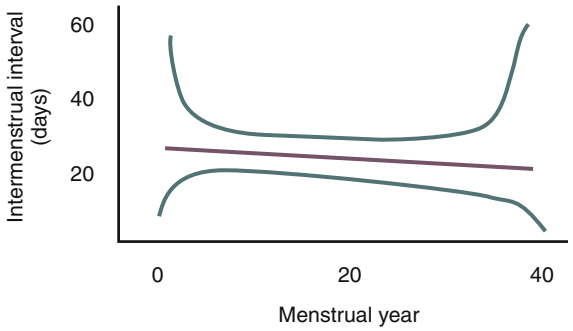

FIGURE 8.6 Median menstrual cycle lengths *(purple line)* from menarche (menstrual year 0) until menopause. The *green upper* and *lower* lines indicate the 95% confidence limits. FIGURE 8.5 The hormonal, follicular and endometrial dynamics of the normal menstrual cycle from the late luteal phase, through menses and the beginning of a new cycle of follicle development, ovulation and corpus luteum function, as indicated. With the support of the changing frequency of pulsatile gonadotropin-releasing hormone (GnRH) secretion, the integrated actions of follicle-stimulating hormone (FSH; *green*) and luteinizing hormone (LH; *light blue*) are responsible for: (1) follicular development with secretion of estradiol (E_2; *light green*), inhibin B *(pink)* and inhibin A *(blue);* (2) the preovulatory surge and ovulation; and (3) secretion of progesterone (Prog; *purple*), estradiol and inhibin A from the corpus luteum. Secretion of estradiol and progesterone result in proliferative and secretory changes in the endometrium (Endo), preparing it for implantation should conception occur. In the absence of conception, endometrial shedding follows the decline in hormone secretion secondary to demise of the corpus luteum.

highly predictable at approximately 2 mm per day until ovulation (Fig. 8.7). The accompanying increase in estradiol is associated with a progressive increase in the thickness of the endometrium while the luteal phase effects on the endometrium result in increased echogenicity (Fig. 8.7).

GnRH Dynamics and Pituitary Responsiveness

GnRH secretion can be measured directly in large animal species, and studies have indicated that under physiological circumstances, peripheral LH secretion occurs concomitantly with secretion of GnRH measured in pituitary portal blood.[110-112] LH has therefore been used as a marker of GnRH pulse frequency in the human, based on these studies and two additional lines of evidence. The first is that pulsatile secretion of LH is absent in patients with congenital isolated GnRH deficiency and can be restored with pulsatile administration of GnRH.[113] The second is that pulsatile secretion of LH in normal subjects is reversibly abolished by administration of a specific GnRH antagonist.[46] Thus, the occurrence of LH pulses can be taken as evidence for the occurrence of a preceding stimulatory GnRH pulse and LH pulse frequency can be used as a peripheral monitor of the frequency of pulsatile GnRH secretion. Although the glycoprotein free alpha subunit (FAS) is secreted from both the gonadotrope and thyrotrope under the control of GnRH and TRH, the pulsatile component of FAS secretion is entirely under the control of GnRH in euthyroid women.[106] Thus, FAS can also be used as a surrogate marker of GnRH pulse frequency. As its clearance is faster than that of intact LH, it is a preferable marker when GnRH pulse frequency is rapid or when the clearance of LH is prolonged. The amplitude of the LH or FAS response to GnRH depends on both the amplitude of the GnRH signal and on pituitary responsiveness to GnRH. Other techniques must therefore be used to assess the amplitude of GnRH secretion.

Results of frequent sampling studies (every 5 or 10 minutes for up to 48 hours) have demonstrated marked variations in the frequency and amplitude of LH pulses across the normal menstrual cycle (Fig. 8.8) and their precise regulation in relation to the preovulatory LH surge.[106,113-115]

Follicular Phase

In the early follicular phase (days 14 to 9 from the LH surge), the mean interpulse interval of GnRH is approximately 90 to 100 minutes.[33,115] The early follicular phase of established reproductive cycles is characterized by a marked slowing of GnRH pulse frequency during sleep (Figs. 8.3 & 8.8),[35] which may serve the function of maintaining FSH synthesis during this critical period of follicle recruitment.

In the midfollicular phase, GnRH pulse frequency increases and the interpulse interval shortens to approximately 60 minutes. LH pulse amplitude is markedly attenuated in the midfollicular phase, reflecting the negative feedback of estradiol secreted from developing follicles on the amplitude of GnRH pulses and possibly the increased frequency of GnRH stimulation and its effect on gonadotrope responsiveness.[50,51]

The circhoral frequency of GnRH secretion is maintained through the late follicular phase as LH pulse amplitude begins to increase due to the stimulatory effects of rising levels of estradiol on gonadotrope responsiveness to GnRH.

Midcycle Surge

In response to the exponential increase in estradiol secretion in the late follicular phase, LH levels increase tenfold over

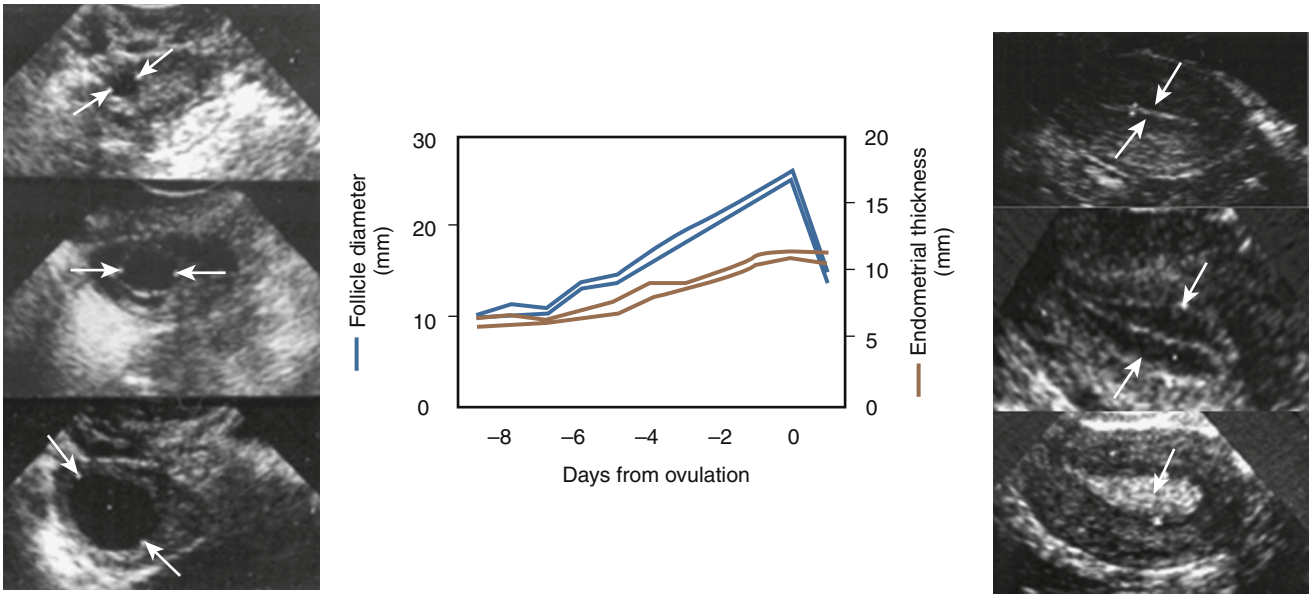

FIGURE 8.7 Follicular development is associated with a progressive increase in the diameter of the dominant follicle *(arrows)*, as seen on ultrasound *(left panels, top to bottom)* and an increase in endometrial thickness during the follicular phase *(right top and middle panels)*. Follicle diameter *(blue lines)* and endometrial thickness *(brown lines)* derived from studies in 42 women with normal menstrual cycles are presented in relation to the day of ovulation, which is indicated as 0. The appearance of the endometrium *(single arrow)* is markedly different in the luteal phase, showing increased echogenicity *(right bottom panel)*. (*From Adams JM, Hall JE. Increase in the size of the dominant follicle and endometrial thickness as measured by ultrasound during the follicular phase in 42 normal women. Personal Communication, 2003.*)

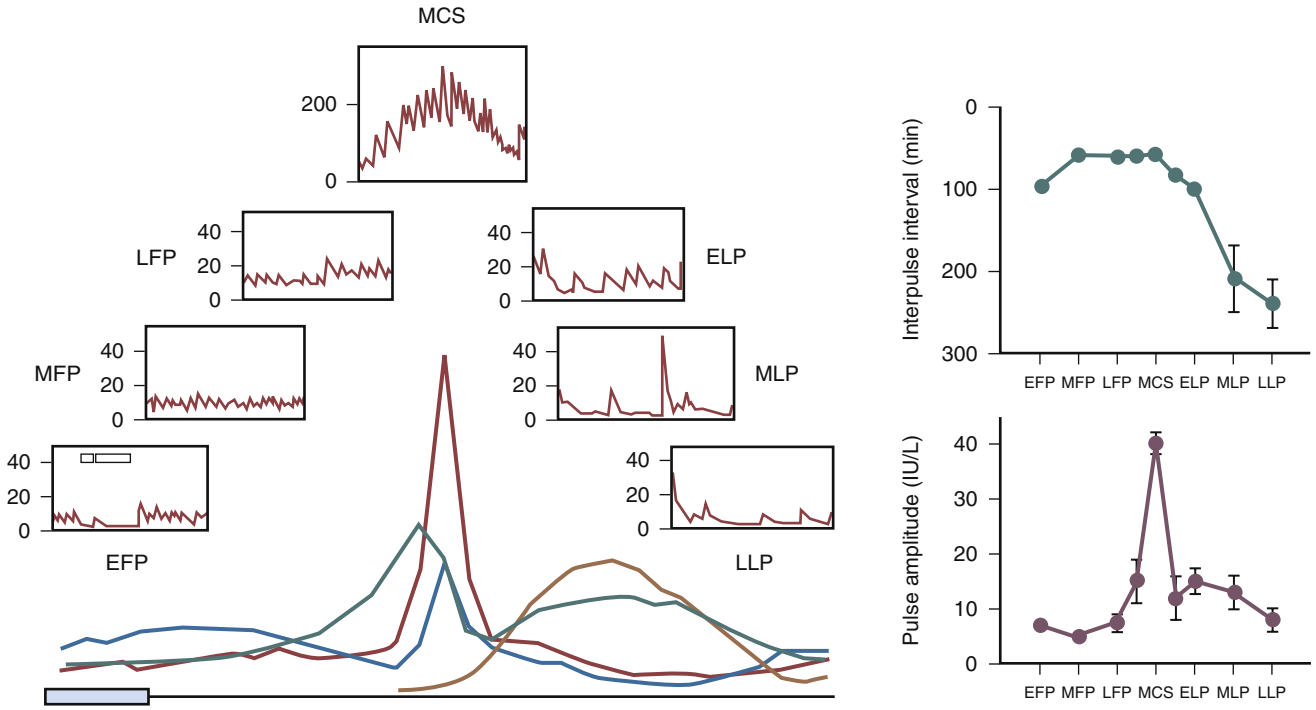

FIGURE 8.8 Dynamics of pulsatile luteinizing hormone (LH) secretion in relation to LH *(red)*, FSH *(teal)*, estradiol *(green)*, and progesterone *(brown)* in the early follicular phase (EFP), midfollicular phase (MFP), and late follicular phase (LFP), during the midcycle surge (MCS) and in the early luteal phase (ELP), midluteal phase (MLP), and late luteal phase (LLP) in normal women *(left panel)*. Menses is indicated by the *red rectangle*. The dynamic changes in the interpulse interval and amplitude of pulsatile LH secretion in relation to the phases of the menstrual cycle are indicated in the *right panel*. (*Adapted from Hall JE, Martin KA, Taylor AE. Body weight and gonadotropin secretion in normal women and women with reproductive abnormalities. In Hansel W, Bray, GA, Ryan DH.* Nutrition and Reproduction *[8]:378–393. 1998, Baton Rouge, Louisiana State University Press, Pennington Center Nutrition Series and Hall JE. Neuroendocrine physiology of the early and late menopause.* Endocrinol Metab Clin North Am *33:637–659, 2004.*)

a period of 2 to 3 days while FSH levels increase fourfold (Fig. 8.8). This midcycle surge of LH is absolutely required for final maturation of the oocyte and initiation of follicular rupture, which generally occurs 36 hours after the surge. The gonadotropin surge is therefore a critical component of normal reproductive cycles. However, the mechanisms responsible for this dramatic increase in gonadotropin secretion are incompletely understood and appear to be species specific. The classic studies of Yen and colleagues demonstrated that the responses of LH and FSH to exogenous GnRH administration are markedly influenced by the stage of the menstrual cycle with an exaggerated increase in secretion of both gonadotropins at the time of the midcycle surge.[116]

The pattern of estrogen exposure is critical to positive feedback. Exogenous administration of estradiol to normal women in the early follicular phase[96,97] or to postmenopausal women[74] induces an increase in both basal and GnRH-stimulated LH secretion that is dependent on both the dose and duration of estrogen exposure. There is further evidence that the surge occurs in response to the increase in estradiol rather than the drop in estradiol that frequently accompanies the onset of the surge.[97] In other words, the surge results from estrogen positive feedback rather than removal of estrogen negative feedback.

Other evidence indicates that a small increase in progesterone augments this surge. Secretion of progesterone is typically associated with the luteal phase, however, the earliest increase in progesterone is evident in normal women prior to the LH surge. Blockade of progesterone receptors by RU486 delays the surge by up to 3 days despite continued growth of the dominant follicle and rising levels of estradiol.[117] In studies in normal women in whom a graduated estrogen infusion was initiated in the early follicular phase, it has now been demonstrated that progesterone does not influence the height of the surge, but decreases the variability in its timing relative to the onset of the infusion.[97] Although an LH surge can be generated in response to recreation of normal preovulatory estradiol and progesterone levels, the amplitude of the surge is less that in normal women. This suggests that there may also be other ovarian factors required for generation of a surge of normal amplitude. One possibility is inhibin A which increases dramatically before the LH surge in normal cycles[85,118] and has been shown to increase GnRH receptor number and LH secretion in an ovine pituitary cell culture system.[119]

A key question is whether estrogen positive feedback in women is mediated at the hypothalamus, the pituitary or both. There is increasing evidence that the mechanisms underlying this critical process may be species specific. As reviewed above, there is compelling evidence from a variety of animal and *in vitro* studies that estradiol acts directly at the pituitary to increase gonadotrope sensitivity to GnRH.[52,99,100] In lower animal species, there is also evidence that hypothalamic mechanisms play a critical role in generating the preovulatory surge although studies in sheep indicate that the amplitude of the GnRH surge exceeds

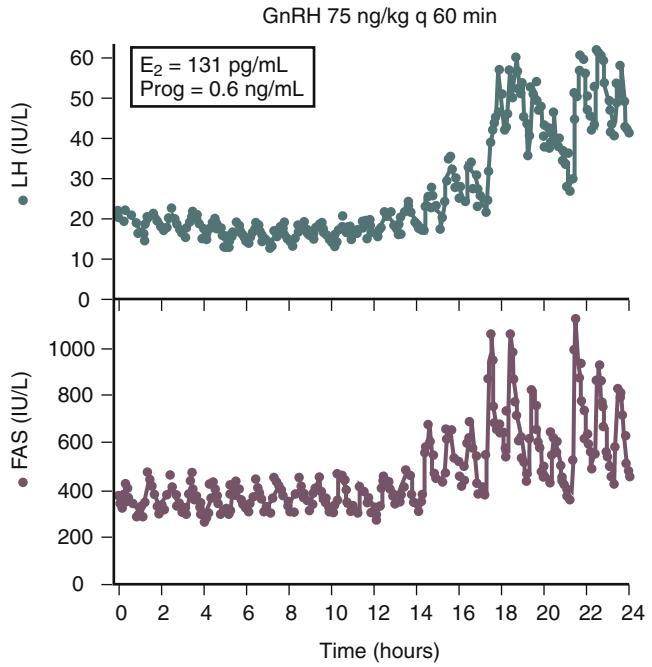

FIGURE 8.9 Luteinizing hormone (LH) and free α-subunit (FAS) sampled every 5 minutes in a gonadotropin-releasing hormone (GnRH)-deficient woman receiving pulsatile GnRH intravenously, demonstrating the abrupt increase in LH and FAS pulse amplitude and mean levels associated with estrogen positive feedback in the absence of any change in the dose or frequency of GnRH. E_2, estradiol; Prog, progesterone.

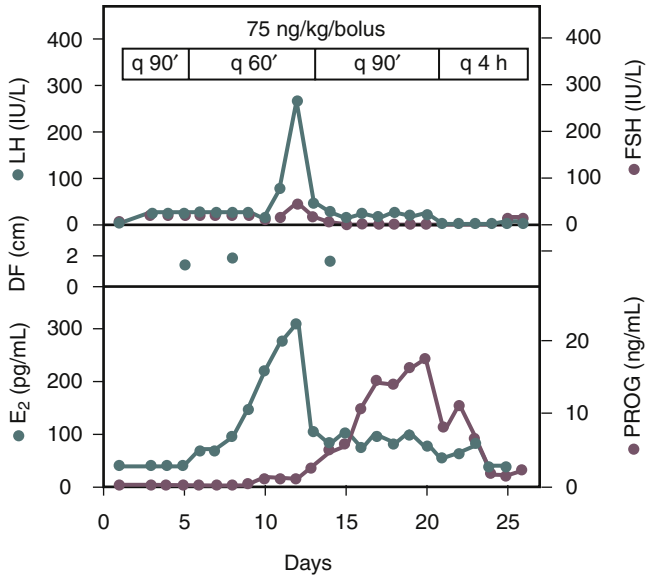

FIGURE 8.10 Administration of intravenous pulsatile gonadotropin-releasing hormone (GnRH) to a GnRH-deficient woman at a physiological frequency with follicular development, ovulation, and normal luteal phase function. Note that the luteinizing hormone (LH) surge is generated in association with an increase in follicle size and estradiol (E_2), but in the absence of an increase in the dose or frequency of pulsatile GnRH administration. FSH, follicle-stimulating hormone; DF, dominant follicle. (*Adapted from Hall JE, Martin KA, Whitney HA, et al. Potential for fertility with replacement of hypothalamic gonadotropin-releasing hormone in long term female survivors of cranial tumors.* J Clin Endocrinol Metab *79:1166–1172, 1994.*)

that needed to generate the LH surge.[102] Studies in GnRH-deficient women receiving exogenous GnRH replacement provide the most compelling evidence for the importance of pituitary sensitization to GnRH in generation of the midcycle surge in women. When GnRH is administered at a dose and frequency that mimic the GnRH pulse frequency in the normal menstrual cycle with development of a single dominant follicle, an abrupt increase in LH and FAS pulse amplitude is observed in the absence of any change in the dose or frequency of GnRH (Fig. 8.9) and a normal LH surge is achieved (Fig. 8.10).[120] These studies indicate that positive feedback can be achieved in women through pituitary mechanisms alone in the absence of any alteration in hypothalamic input.

Further studies indicate that gonadotropin surges are achieved with no increase in GnRH secretion in normal women. At the onset of both spontaneous and steroid-induced LH surges in normal women, complete GnRH receptor blockade results in termination of the surge,[107,121,122] indicating that ongoing GnRH secretion is essential for generation of the gonadotropin surge. However, neither the frequency nor the overall amount of GnRH is increased in association with the onset of the gonadotropin surge. Studies in normal women in which blood samples were drawn every 5 minutes for up to 36 hours at midcycle indicate a striking increase in LH and FAS pulse amplitude from the late follicular phase to the early portions and midportions of the surge with no change in pulse frequency during this same time period (Fig. 8.8).[106] To address the question of whether generation of the surge in women is associated with an increase in the amplitude of GnRH secreted with each bolus, submaximal GnRH receptor blockade was used to provide a semiquantitative estimate of the overall amount of endogenous GnRH secreted.[107] Results of these studies provided no evidence for an increase in the overall amount of GnRH secreted and, in fact, suggested that the amount of GnRH at the surge is less than in the early and late follicular phase. Consistent with this finding, further studies have shown that in GnRH-deficient women, the replacement dose of GnRH can be reduced by two-thirds in the late follicular phase from that required for development of a single dominant follicle without compromising the timing or height of the midcycle surge or the subsequent luteal phase (Fig. 8.11).[108]

Taken together, these studies indicate that GnRH is absolutely required for generation of the midcycle surge in normal women; however, there is no evidence for an increase in either the amplitude or frequency of GnRH secretion. Consistent with this conclusion, neuroimaging studies in postmenopausal women, in whom a gonadotropin surge was induced by administration of a graded estradiol infusion, show a marked increase in metabolic activity at the pituitary, but not the hypothalamus, in association with estrogen positive feedback on LH.[66]

The termination of the LH surge is associated with a dramatic decrease in pulse amplitude accompanied by a decrease in pulse frequency to approximately every 70 minutes (Fig. 8.8).[106] The decline in pulse frequency that accompanies the termination of the surge is due, at least in part, to the hypothalamic effects of progesterone on the GnRH pulse generator.

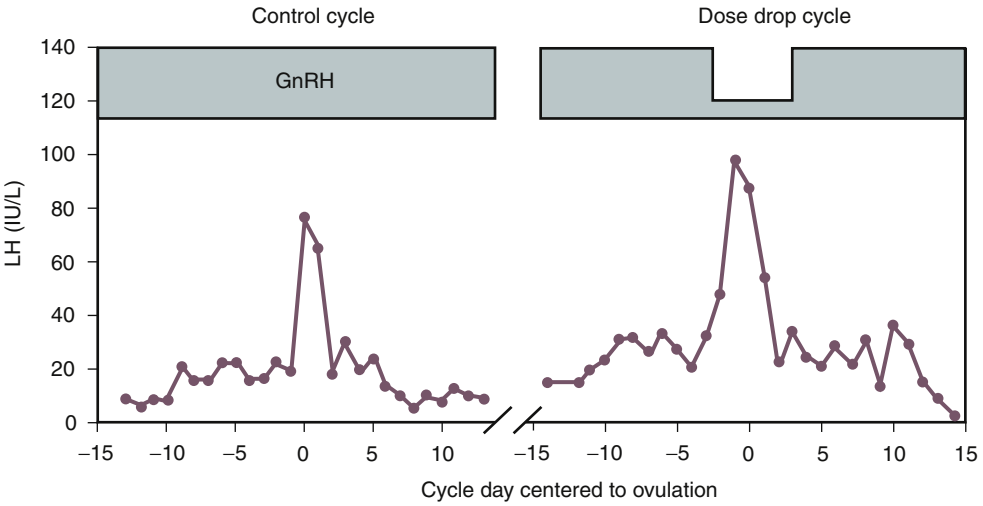

FIGURE 8.11 A normal surge of luteinizing hormone (LH) can be recreated in gonadotropin-releasing hormone (GnRH)-deficient women when the dose of exogenous GnRH *(green bars)* is reduced from 75 ng/kg to 25 ng/kg before the onset of the LH surge. (*From Martin KA, Welt CK, Taylor AE, et al. Is GnRH reduced at the midcycle surge in the human? Evidence from a GnRH-deficient model.* Neuroendocrinology *67:363–369, 1998.*)

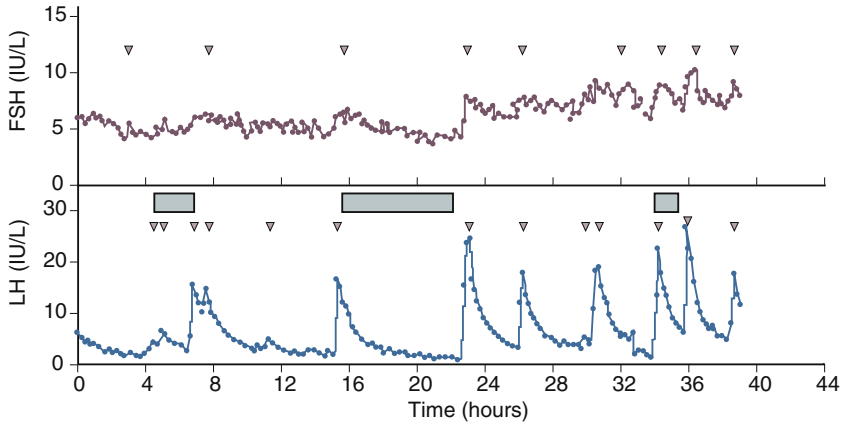

FIGURE 8.12 Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in a subject who underwent blood sampling every 10 min over a 2 day period during the luteal-follicular transition. This study was conducted beginning 12 days after the subject's preovulatory LH surge and 3 days before menses. Note the rise in FSH that is clearly evident before menses and is associated with an increase in the frequency of pulsatile LH secretion. The horizontal bars indicate sleep and the inverted triangles indicate statistically identified pulses. (*Adapted from Hall JE, Schoenfeld DA, Martin KA, et al. Hypothalamic gonadotropin-releasing hormone secretion and follicle-stimulating hormone dynamics during the luteal-follicular transition.* J Clin Endocrinol Metab *74:600–607, 1992.*)

Luteal Phase

Slowing of pulsatile GnRH secretion begins during the termination of the midcycle surge and continues through the early luteal, midluteal, and late luteal phases (Fig. 8.8). In the late luteal phase, interpulse intervals as long as 4 to 8 hours are observed. This slowing of the GnRH pulse generator is due to the effect of progesterone,[123] but is not expressed without the additional presence of estradiol.[77]

In the luteal phase, LH pulse amplitudes are significantly higher than in the follicular phase. The known inverse relationship between LH responsiveness to GnRH and GnRH pulse frequency[53,54] suggests that this increase in LH pulse amplitude is secondary to progesterone-induced slowing of GnRH pulse frequency. However, there is additional evidence from studies in GnRH-deficient women, in whom it is possible to control the dose of GnRH administered, that progesterone may act directly at the pituitary to increase LH responsiveness to GnRH.[124]

Luteal-Follicular Transition

The luteal follicular transition is characterized by declining function of the corpus luteum and declining levels of progesterone, estradiol, and inhibin A. Release from negative feedback permits FSH to rise, an increase that begins before menses and is critical for recruitment of a new cohort of follicles into the developing pool (Fig. 8.5). Maintenance of midluteal phase levels of estradiol prevents this increase in FSH.[125,126] Thus, it has been proposed that release from estrogen negative feedback is the key factor in the luteal-follicular rise in FSH and that other factors such as the decline in inhibin A secretion from the corpus luteum may not play a role. However, studies using tamoxifen to block the estrogen receptor in normal cycles suggest that inhibin A also plays a role in restraining FSH secretion during the normal luteal phase.[127]

LH pulse frequency increases before the onset of menses (Fig. 8.12). LH pulse frequency is inversely related to progesterone levels[114] and administration of midluteal phase levels of progesterone in conjunction with estradiol prevents the normal luteal-follicular increase in GnRH pulse frequency in normal women.[77] There is convincing evidence that the increase in GnRH pulse frequency that occurs between the luteal and follicular phases facilitates the luteal-follicular increase in FSH secretion. In normal women, the increase in FSH is significantly correlated with LH pulse frequency, while the inverse relationship between FSH and estradiol was not significant.[114] In GnRH-deficient women receiving pulsatile GnRH at a physiological frequency to recreate normal cycle dynamics, there is a partial increase in FSH associated with release from the negative feedback effects of estradiol and

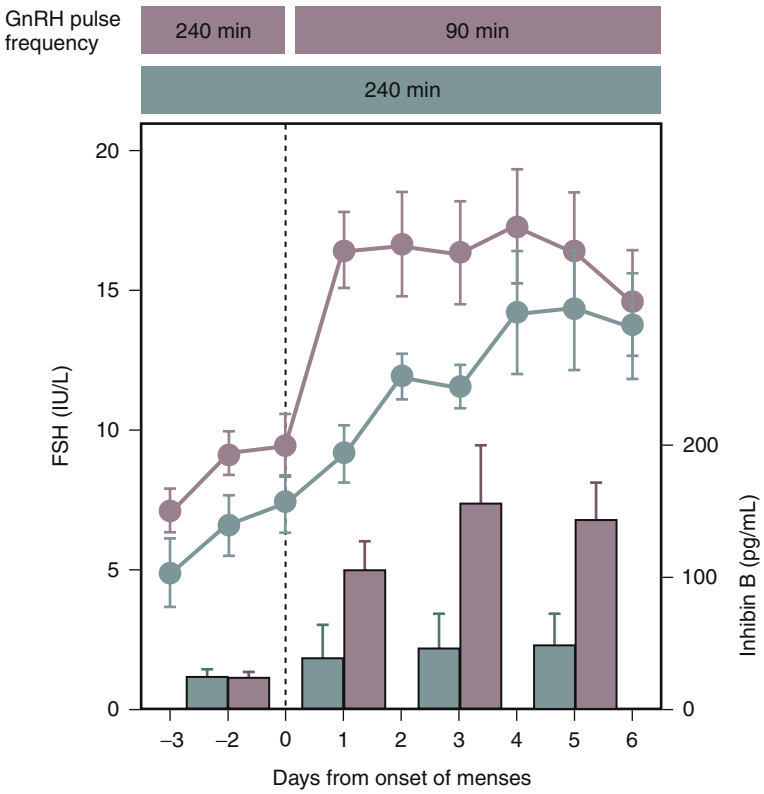

FIGURE 8.13 The increased frequency of pulsatile gonadotropin-releasing hormone GnRH during the luteal follicular transition facilitates the secretion of follicle-stimulating (FSH) as indicated in this study in GnRH-deficient women. The normal rise in FSH in relation to menses is attenuated when the frequency of intravenous GnRH (75 ng/kg) remains at the luteal phase frequency of every 240 minutes *(green circles)* compared to the usual increase to every 90 minutes at the time of menses *(purple circles)*. The bars indicate that the follicular phase increase in inhibin B is also attenuated in association with a persistently slow frequency of GnRH replacement *(green bars)* compared to the usual increase in frequency to every 90 minutes *(purple bars)* secondary to the inadequate rise in FSH. (*From Welt CK, Martin KA, Taylor AE, et al. Frequency modulation of follicle-stimulating hormone [FSH] during the luteal-follicular transition: evidence for FSH control of inhibin B in normal women.* J Clin Endocrinol Metab *82:2645–2652, 1997.*)

possibly inhibin A.[128] However, an increase in GnRH pulse frequency from the luteal phase frequency of every 4 hours to the follicular phase frequency of every 90 minutes is essential to recreate the normal intercycle rise in FSH (Fig. 8.13).

Thus, the slow frequency of GnRH secretion in the luteal phase is hypothesized to increase FSH synthesis either directly or through a decrease in follistatin and a concomitant increase in activin signaling. However, FSH secretion is inhibited by estradiol and possibly inhibin A. With the demise of the corpus luteum, estradiol and inhibin A levels fall as do those of progesterone. FSH is allowed to increase with release from negative feedback and is further stimulated by the increase in GnRH pulse frequency to its early follicular phase frequency.

There is now evidence that the progressive increase in GnRH pulse frequency from the early to the midfollicular phase represents a gradual loss of the restraining effects of low levels of progesterone on the GnRH pulse generator.[129] As the early follicular phase is characterized by sleep-related inhibition of pulsatile LH secretion, it is intriguing to speculate that a similar prolonged effect of progesterone is also involved in sensitizing the hypothalamus to the inhibitory effects of sleep during this cycle phase. The possibility that sleep-related slowing of GnRH pulse frequency in the early follicular phase may play an important role in maintaining synthesis of FSH at this critical time is suggested by the association of menstrual cycle abnormalities with altered sleep wake cycles in women exposed to transmeridian travel or rotating shifts.[130,131]

Secretion of Inhibin A and Inhibin B

The pattern of inhibin A secretion is characterized by a periovulatory increase and maximal levels in the luteal phase (Fig. 8.5).[83,84,118] In contrast, inhibin B is at its nadir in the luteal phase, begins to rise during the luteal-follicular transition to attain its highest levels in the early follicular and midfollicular phases, and declines in the late follicular phase followed by a brief periovulatory increase (Fig. 8.5).[85,87] The differential patterns of inhibin B and inhibin A in serum across the menstrual cycle suggest different sources and differential control of these two inhibin forms in normal reproductive cycles. Interestingly, their relationship to the secretion of the gonadotropins and estradiol does not easily confirm the anticipated endocrine role for either inhibin A or inhibin B in the control FSH. Inhibin B and FSH levels are positively rather than negatively related during the luteal-follicular transition, while the potential negative feedback effects of inhibin A on FSH might just as easily be accounted for by estradiol whose levels change in parallel to those of inhibin A.

Sources of Inhibin A and Inhibin B

The peak in inhibin A in the luteal phase and its decline with luteolysis are consistent with production by the corpus luteum, as expected from the high levels of βA inhibin subunit expression in the corpus luteum.[89] During folliculogenesis, peak levels of inhibin A are attained in the preovulatory period and inhibin A is correlated with the size of the dominant follicle in normal cycles[84,85] as is estradiol. Inhibin A is primarily the product of granulosa cells; however, there is some evidence for theca cell production in the mature follicle.[89] Studies of βA inhibin subunit expression[89] and measurement of dimeric inhibin A in follicular fluid,[132] are consistent in indicating maximal follicular phase levels in the preovulatory follicle. However, it is now appreciated that inhibin A is synthesized and secreted at earlier stages of follicular development than previously suggested by serum levels.[133]

In contrast to inhibin A, the pattern of inhibin B in serum suggests that it is primarily secreted from small antral follicles. A correlation of inhibin B levels with the size of the dominant follicle is remarkably absent in women undergoing spontaneous ovulatory cycles,[85] suggesting that inhibin B is not regulated in relation to dominant follicle growth. These data are consistent with studies showing that inhibin B levels in follicular fluid do not change as a function of follicle size or maturity.[132] They are also consistent with earlier studies demonstrating that expression of βB inhibin subunit mRNA is highest in early antral follicles, with lower levels in the dominant follicle and no evidence of βB-subunit expression in the corpus luteum.[89] The latter studies have also shown that inhibin B synthesis is confined to the granulosa cells and is absent in theca cells.

Regulation of Inhibin A and Inhibin B by Gonadotropins

A significant body of data has now demonstrated an increase in inhibin B secretion in conjunction with early follicular development stimulated by physiological levels of FSH. This was initially suggested by the relationship of the rise in FSH during the luteal-follicular transition to the concomitant increase in inhibin B (Fig. 8.5). In GnRH-deficient women, replacement of pulsatile GnRH at the slower luteal phase frequency of every 4 hours compared with the early follicular phase frequency of every 90 minutes was associated not only with failure of FSH to rise normally during the luteal-follicular transition, but also with the absence of both follicular growth and any increase in secretion of inhibin B (Fig. 8.13).[128] This study demonstrated the remarkable sensitivity of serum inhibin B levels to changes in FSH stimulation within the physiological range during the earliest stages of follicular development.

In studies designed to examine the time course of the response to specific and physiological gonadotropin stimulation, recombinant human LH (rhLH) or FSH (rhFSH) was administered to women following downregulation of endogenous GnRH secretion using a potent GnRH agonist.[133] Consistent with failure to observe LH receptors in small antral follicles, rhLH alone had no effect on follicle growth or hormone secretion when administered daily for up to 7 days. However, daily subcutaneous administration of rhFSH resulted in normal early follicular phase levels of FSH and an increase in inhibin B secretion that preceded that of estradiol and inhibin A (Fig. 8.14). One interpretation of these studies is that FSH directly stimulates inhibin B secretion from granulosa cells. However, administration of FSH at this stage of development also results in the recruitment of a cohort of follicles into the growing pool and a dramatic stimulation of granulosa cell number.

To determine whether the increase in inhibin B observed *in vivo* in the early stages of folliculogenesis results from direct stimulation of granulosa cell secretion or from an increase in granulosa cell number, studies were conducted using pre-antral and small antral follicles obtained from

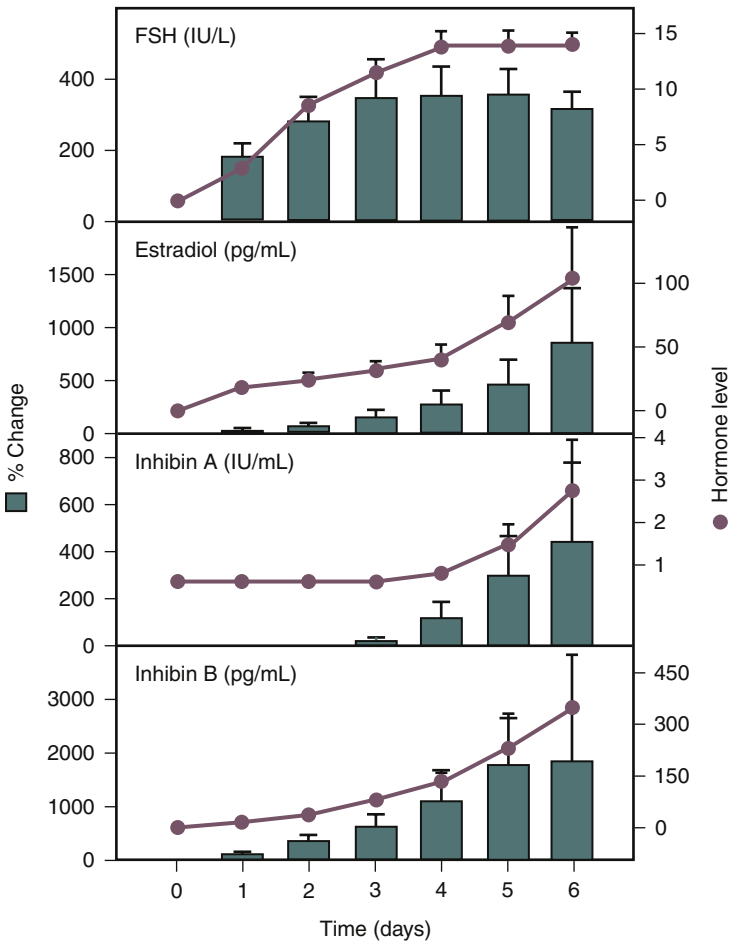

FIGURE 8.14 Hormone response to recombinant human follicle-stimulating hormone (FSH; 150 IU daily) for 6 days in normal women after GnRH agonist downregulation of endogenous gonadotropin secretion. (*From Welt CK, Smith ZA, Pauler DK, et al. Differential regulation of inhibin A and inhibin B by luteinizing hormone, follicle-stimulating hormone, and stage of follicle development.* J Clin Endocrinol Metab *86:2531–2537, 2001.*)

ovaries at the time of oophorectomy for nonovarian indications.[134] Results of these studies indicated that inhibin B is constitutively secreted from pre-antral follicles and that FSH stimulates secretion of inhibin A, but not inhibin B. Taken together, these studies demonstrate that inhibin B is constitutively secreted from granulosa cells and that the increase in inhibin B observed *in vivo* in response to FSH results from an increased number of granulosa cells rather than direct stimulation of secretion by FSH. At later stages of follicular development, both LH and FSH stimulate secretion of inhibin A and estradiol from the dominant follicle, but have no effect on inhibin B.[133]

Evidence for an Endocrine Role for Inhibin A or Inhibin B

Although an endocrine role of either inhibin A or inhibin B cannot be implied from their relationship to FSH during the normal menstrual cycle, several lines of evidence support such a role in the negative feedback regulation of FSH. Inhibin was initially discovered based on its ability to inhibit FSH secretion in pituitary cell cultures.[135] In addition, FSH levels decrease in response to administration of pharmacological doses of inhibin A administered in the follicular and luteal phases in the rhesus monkey.[136,137]

The most compelling line of evidence that inhibin regulates FSH secretion under normal physiological circumstances in women is the failure of physiological levels of gonadal steroids to restore FSH levels to normal in postmenopausal women. The model of reproductive aging has been used by a number of investigators to refine this evidence. FSH levels increase with age, before increases in LH or decreases in estradiol[138-140] and a number of studies have demonstrated an inverse relationships between increasing FSH and decreasing inhibin B[140-143] in association with reproductive aging.

Reproductive aging is associated with a decline in fertility that begins in the third decade, but accelerates rapidly after age 35. A gradual decrease in the pool of ovarian follicles which first accelerates around the same age would appear to underlie this decline in fertility.[144] It is also at age 35 that an increase in follicular-phase FSH is first seen. In women 35 or older with regular ovulatory cycles and follicular phase FSH levels within the normal range, there is a small, but significant increase in FSH in the early follicular phase only, decreased inhibin B levels across the entire follicular phase and estradiol levels that do not differ in the early follicular phase, but increase in the midfollicular and late follicular phases.[85] In the luteal phase, inhibin B, inhibin A, and progesterone are lower in the older cycling women while estradiol levels are preserved. Thus, the very earliest decrease in inhibin B occurs at a time that is marked by the beginning of the more rapid follicular depletion that heralds the menopause, suggesting that lower inhibin B levels reflect a decrease in available follicle number with aging. This change in inhibin B is associated with higher levels of FSH in the absence of alterations in estradiol, providing evidence for an endocrine role of inhibin B in the control of FSH secretion in reproductive-aged women. Studies conducted at later stages in the process of reproductive aging have uniformly confirmed increased FSH in conjunction with normal to higher levels of estradiol and lower inhibin B and further support the negative feedback role of inhibin B in control of FSH. While a decrease in inhibin A may occur slightly later in reproductive aging, it precedes the decline in estradiol levels.[145]

While studies of reproductive aging provide evidence of a negative feedback role of inhibin B on FSH secretion in normal women, these studies have not clarified the role of inhibin A or inhibin B relative to that of estradiol in the dynamic control of FSH during normal reproductive cycles. A key question is whether inhibin A and inhibin B contribute to the midfollicular decrease in FSH that is critical to the monofollicular development that characterizes reproductive cycles in normal women. The tools to determine the role of inhibin directly by either administration or blockade are not available. However, it is possible to investigate the estrogen component of FSH negative feedback and thereby infer the physiological role of inhibin. Studies in which estradiol levels were maintained by estradiol administration during the luteal-follicular transition have been interpreted to suggest that inhibin A is not involved in the negative feedback control of FSH in the luteal phase.[125,126] An alternative approach is to block estrogen negative feedback. The use of tamoxifen to block the estrogen receptor permitted evaluation of the relative role of estradiol and the inhibins in negative feedback on FSH.[127] Results suggest that the low levels of estradiol in the early follicular phase do contribute to negative feedback on FSH, as attested to by a prompt increase in early follicular phase FSH levels. An increase in FSH in response to estrogen receptor blockade was not seen in GnRH-deficient women receiving pulsatile GnRH replacement,[127] suggesting that the negative feedback of estradiol on FSH secretion in normal women is mediated entirely at the hypothalamic level in the early follicular phase.

Taken together, these studies suggest that estradiol plays a critical role in FSH negative feedback in the luteal phase and during the luteal-follicular transition. However, the failure of luteal phase FSH to increase to menopausal levels in the presence of estrogen receptor blockade suggests additional FSH restraint by inhibin A.

The control of FSH is dependent not only on inhibin and estradiol, but also on the activin/follistatin system. During the menstrual cycle, total activin A levels are highest at the midcycle and during the luteal follicular transition of the normal menstrual cycle.[146] However, there is no change in activin A in follicular fluid as a function of follicular development,[132] no change in free activin across the menstrual cycle,[147] and no difference in activin B between the follicular and luteal phases.[148] Taken together, these data suggest that activin does not play an endocrine role in the control of FSH secretion.

Racial Differences in Menstrual Cycle Dynamics

Racial disparities between African-American women and Caucasian women in the incidence of breast cancer, leiomyomas and osteoporosis raise the possibility of a greater lifetime exposure to estrogen in African-American women. Recent studies have now indicated that estradiol levels are significantly higher in weight-matched regularly cycling, ovulatory African-American women compared to their Caucasian counterparts with estradiol levels that are 18% higher in the late follicular phase, and 40% higher in the midluteal and late luteal phases.[149] In these studies, higher estradiol in the face of similar androstenedione levels suggests that

ovarian aromatase activity is higher in African-American women. Importantly, this apparent increase in aromatase activity in African-American women is not accounted for by differences in FSH levels.

Recent evidence also suggests that fertility and the results of fertility treatment are also highly influenced by race.[150,151] While the etiology of these differences is undoubtedly multifactorial, racial differences in reproductive hormones suggest that differences in fertility and fertility outcome should not be attributed to psychosocial influences without further investigation.

CHAPTER 9

The Ovarian Life Cycle

Jerome F. Strauss III
Carmen J. Williams

The ovary is a dynamic organ that undergoes some of the most dramatic changes in structure and function of any adult human tissue. The follicles are the major endocrine and reproductive compartments of the ovary, and their health and numbers determine both reproductive potential and reproductive life span (Fig. 9.1). The multiple cellular components of follicles interact in a highly integrated manner to secrete sex steroids and protein hormones, and control oocyte development. The follicle-derived hormones program secretion of gonadotropins that promote follicular development and entrain an ovulatory surge of luteinizing hormone (LH) when follicular maturation is completed, as well as prepare and sustain the reproductive tract for conception, implantation, and early pregnancy. The oocyte is a large and rare cell that is both totipotent and highly specialized in that it is capable of undergoing meiosis and fertilization, with the resulting formation of a new human being. Remarkably, some of these attributes can be suspended for years, only becoming operative when a lengthy process of maturation has been completed. Although many follicles initiate development, only a few (some 400 to 500 follicles or less than 1% of the endowment) make the complete journey to ovulation. The factors that govern the seemingly profligate expenditure of follicles during ovarian development and reproductive life remain largely unknown.

Primordial Germ Cells

The primordial germ cell lineage is established early in development, originating in the proximal region of the epiblast, close to the extraembryonic endoderm. A small number of cells emerge under the influence of inductive signals delivered by members of the transforming growth factor-β (TGF-β) superfamily, including bone morphogenetic protein (BMP)-2, BMP-4, and BMP-8B (see Chapter 7).[1-5] Studies conducted using genetically manipulated mice demonstrated that loss of any of these signals prevents the appearance of all or most of the primordial germ cells.

Primordial germ cell precursors must express SMAD1, SMAD5, and SMAD8, which are phosphoprotein downstream mediators of BMP signaling. Absence of these SMAD proteins results in a marked reduction in the founder cells of the germ cell lineage.[6,7] The *Bmp–Smad* gene dosage is critical, and distortion of the ratios impairs germ cell development. Mice homozygous for null mutations of the *Bmp2*, *Bmp4*, *Prdm1* (previously known as *Blimp1*), and *Prdm14* genes do not generate primordial germ cells.[1,8-10]

Primordial germ cells are identifiable as early as the end of the third week of human gestation by their large size and clear cytoplasm, which contains fewer organelles than the endoderm cells.[11,12] In mice, the expression of the interferon-induced transmembrane proteins *Ifitm1*, *Ifitm3* (previously known as *Fragilis*), and *Prdm1* signals their emergence, with the expression of *Prdm14* and *Dppa3* (previously known as *Stella*), marking the founder primordial germ cells.[8,9,13,14] PRDM1 coordinates the repression of genes normally expressed in somatic cells, and both PRDM1 and PRDM14 have roles in maintaining primordial germ cell pluripotency.[10,15] In addition to these protein regulators, microRNAs, which are short RNA sequences that regulate gene expression by transcriptional and post-transcriptional gene silencing, also control primordial germ cell specification. LIN28, a protein that represses the *Let7* microRNA processing pathway, is expressed in founder primordial germ cells, and prevents *Let7*-mediated destruction of *Prdm1*.[16] Other markers of primordial germ cells include tissue-nonspecific alkaline phosphatase[17] and POU5F1 (previously known as OCT4), a transcription factor present in embryonic stem cells and primordial germ cells.[18,19]

Once specified, primordial germ cells enter a period of migration and proliferation (Fig. 9.2). In the human, they migrate from the yolk sac epithelium to the hindgut by approximately 4 weeks post-fertilization, and then migrate through the dorsal mesentery, finally reaching the genital ridge by approximately 6 weeks post-fertilization. The cells change during this migration from a "resting" morphology, taking on an irregular shape, with protrusions and pseudopodia required for active amoeboid movement.[20,21]

Primordial germ cell proliferation is characterized by incomplete cytokinesis, resulting in clusters of cells known as "oocyte nests" that form a network as a result of cytoplasmic continuity via intracellular bridges.[22-25] Primordial germ cells that migrate to aberrant locations undergo apoptosis, so migration along the proper route is essential for successful proliferation.

Genes involved in primordial germ cell proliferation in mice include *Tiar1*, which encodes the RNA-binding protein TIAR23, and *Fancl* (Fanconi anemia, complementation group L), the gene responsible for the mouse "germ cell–deficient" mutation.[26,27] *Fancl* encodes a subunit of the Fanconi anemia nuclear protein complex that functions in DNA damage repair.[28] In addition, leukemia inhibitory

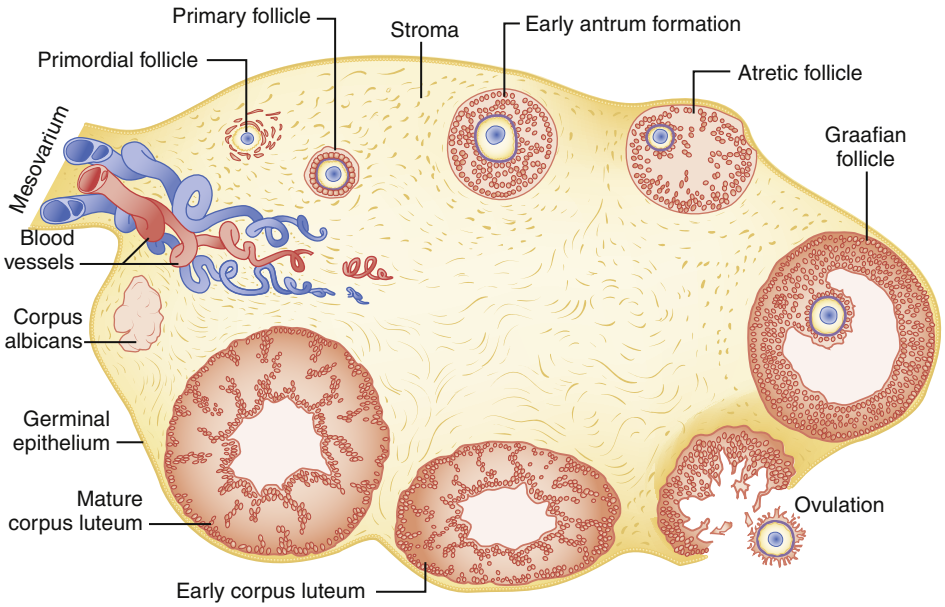

FIGURE 9.1 The follicular cycle of the human ovary. *(Modified from Ham AW, Leeson TS.* Histology, *4th ed. Philadelphia,* JB Lippincott, *1961.)*

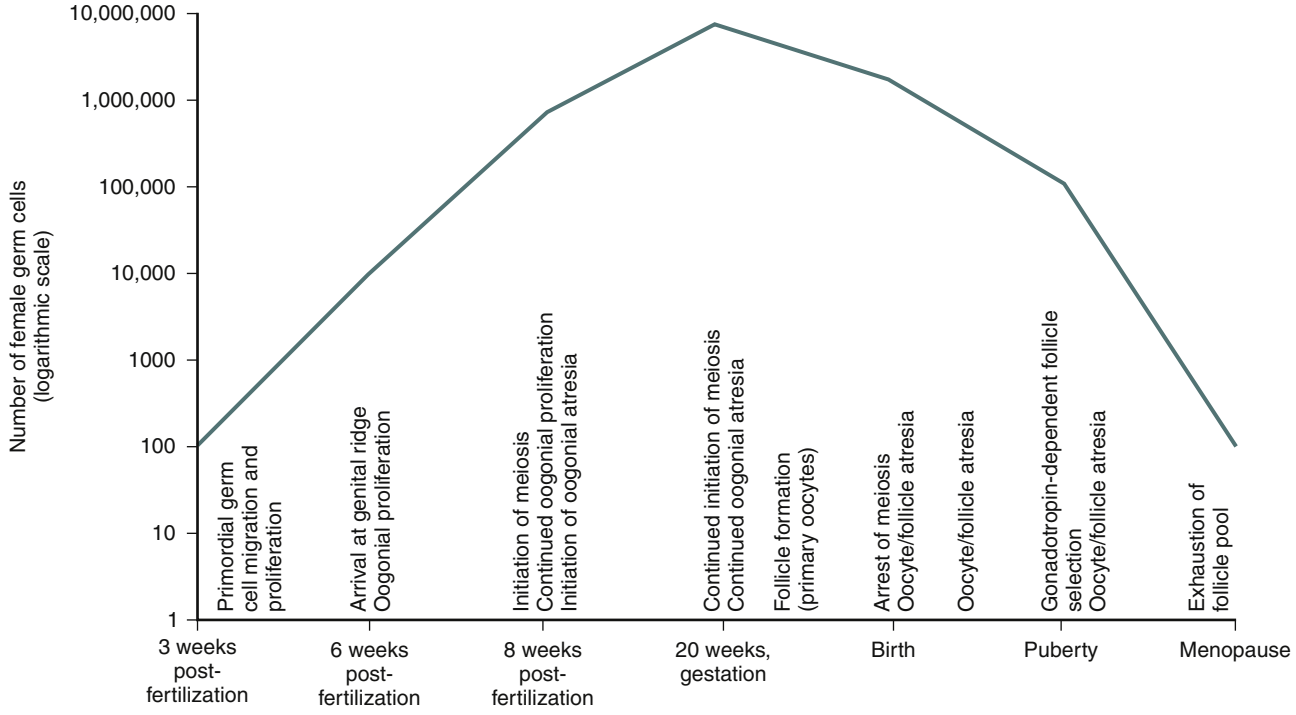

FIGURE 9.2 Changes in oocyte numbers during fetal and postnatal life. The total number of oocytes is a reflection of the balance between active proliferation and oocyte/follicle atresia.

factor (LIF) and related cytokines appear to be responsible, in part, for primordial germ cell proliferation.[29]

The transcription factor LHX1 maintains proper positioning of primordial germ cells in the hindgut.[30] The two interferon-induced transmembrane proteins expressed in primordial germ cells cause repulsive (IFITM1) and homing (IFITM3) activities involved in the migration process.[14,31] The cell adhesion protein integrin β1 must be expressed on the primordial germ cell surface for successful migration to the genital ridge.[32]

Two ligand/receptor signaling pathways, Kit ligand/Kit receptor tyrosine kinase and Cxcl12/Cxcr4, are required for primordial germ cell migration.[33-36] *Wnt5a*, which encodes a secreted morphogen, also provides a migration cue for primordial germ cells.[37] The genital ridge is absent or does not develop normally in mice homozygous for null mutations in the transcription factors *Wt1*, *Nr5a1*, *Lhx1*, *Lhx9*, and *Emx2* (Table 9.1).[38] In addition, nullizygous mice have other abnormalities because some of these genes regulate renal or adrenal development.

Table 9.1 Genes Involved in the Development of the Ovary

Gene Name	Other Aliases	Protein Type	Role
Wt1		Transcription factor	Genital ridge formation
Nr5a1	Sf1	Transcription factor	Genital ridge formation
Lhx1	Lim1	Transcription factor	Genital ridge formation
Lhx9		Transcription factor	Genital ridge formation
Emx2		Transcription factor	Genital ridge formation
Bmp2		Extracellular growth factor	Primordial germ cell specification
Bmp4		Extracellular growth factor	Primordial germ cell specification
Bmp8B		Extracellular growth factor	Primordial germ cell specification
Smad1		Transcription regulator	Primordial germ cell specification
Smad5		Transcription regulator	Primordial germ cell specification
Prdm1	Blimp1	Transcription repressor	Primordial germ cell development
Prdm14		Transcription regulator, epigenetic reprogramming	Primordial germ cell development
Cxcl12		Chemokine ligand	Primordial germ cell migration
Cxcr4		Chemokine receptor	Primordial germ cell migration
Ifitm1	Fragilis2	Transmembrane protein	Primordial germ cell migration
Ifitm3	Fragilis	Transmembrane protein	Primordial germ cell migration
Dazl	Dazla	Translation regulator	Primordial germ cell development
Tial1	Tiar	RNA-binding protein	Primordial germ cell development
Nanog		Transcription factor	Primordial germ cell proliferation, survival
Dnd1	Ter	RNA-binding protein	Primordial germ cell proliferation, survival, affect miRNA pathway
Apobec3		RNA-binding protein	Primordial germ cell proliferation, survival, affect miRNA pathway
Fancl	Pog	Ubiquitin ligase involved in DNA damage repair	Primordial germ cell proliferation
Itgb1		Cell adhesion	Primordial germ cell migration
Kitl	Steel, SCF	Transmembrane growth factor	Primordial germ cell migration, follicle formation and growth
Kit	W, c-kit	Tyrosine kinase receptor	Primordial germ cell migration, follicle formation and growth
Figla		Transcription factor	Primordial follicle formation, follicle growth
Foxo3		Transcription factor	Follicle growth
Nobox		Transcription factor	Follicle growth
Gdf9		Growth factor	Follicle growth
Bmp15		Growth factor	Follicle growth
Zfx		Transcription factor	Oocyte proliferation/survival
Atm		Cell cycle kinase	Meiosis
Wnt4		Secreted ligand	Oocyte-somatic cell contacts, meiosis entry, steroidogenic enzyme expression

The microRNA cluster, *Mir290-295*, is highly expressed in primordial germ cells, and female mice null for *Mir290-295* have premature ovarian failure due to primordial germ cell migration defects.[39,40] The downstream targets of these microRNAs have not been identified, and could include some of the protein regulators mentioned above.

Ovarian Morphogenesis

Germ cells play an indispensable role in the induction of gonadal development. In the absence of two functional X chromosomes, as in Turner syndrome (45, X, or other X chromosome structural abnormalities), primordial germ cells can proliferate and migrate to reach the developing gonad, but the germ cells fail to survive because pregranulosa cells are not maintained. As a result, streak gonads containing only stromal cells are present by the time of birth in classical cases, although some germ cells remain in individuals who are mosaics.[41]

Germ cells that arrive at the genital ridge are referred to as *oogonia*. By 6 to 7 weeks of intrauterine life, the oogonia population has expanded by mitosis to reach some 10,000 cells, and it reaches approximately 600,000 cells by 8 weeks of intrauterine life (Fig. 9.2). However, from this juncture, the oogonial endowment is influenced by three concurrent processes: mitosis, meiosis, and oogonial atresia. As a result of the combined impact of these processes, the number of germ cells peaks at 6 to 7 million by 20 weeks of gestation, and then declines.

Between weeks 8 and 13 of fetal life, some of the oogonia enter prophase of the first meiotic division. Entry into meiosis is triggered at least in part by retinoic acid that is produced locally in the fetal ovary and also by the mesonephros.[42] If correctly executed, meiosis appears to provide temporary protection from oogonial atresia. Oogonia that persist beyond the seventh month of gestation without entering meiosis undergo programmed cell death.[43]

Primordial follicle formation begins at around 20 weeks of gestation, and is accompanied by oocyte nest breakdown as the intercellular bridges are lost and pre-granulosa cells surround the primary oocytes. At midgestation, when the ovarian germ cell endowment is at its apex, two thirds of the total germ cells are intrameiotic primary oocytes; the remaining one third are oogonia. One reason for the subsequent decline in germ cell numbers is the declining rate of oogonial mitosis, a process that ends by approximately 7 months of intrauterine life. The reduction in germ cells is also the result of an increasing rate of oogonial atresia, which peaks at about month 5 of gestation, followed by follicular atresia, which begins around the sixth month of gestation.[44] Apoptosis is believed to be triggered by either a deficiency in survival factors, such as Kit ligand, LIF, or basic fibroblast

growth factor, or by death-inducing factors, such as Fas ligand, TGF-β, and activin.

Primordial follicles in the human ovary (30 to 60 μm in diameter) are composed of a late diplotene primary oocyte (9 to 25 μm in diameter) surrounded by a single layer of flattened granulosa cells (Fig. 9.3).[45] Follicles at this stage of development are not believed to be influenced by gonadotropins. Primary follicles (>60 μm in diameter) are characterized by a primary oocyte surrounded by a single layer of cuboidal granulosa cells. Secondary follicles (<120 μm) consist of a primary oocyte surrounded by several layers of cuboidal granulosa cells (<600 cells), as shown in Figure 9.3.

Inactivating mutations in the oocyte-specific transcription factor, folliculogenesis specific basic helix-loop-helix *(Figla)*, prevent the formation of primordial follicles. Mice homozygous for a null mutation in the X-linked zinc finger gene, *Zfx*, have a reduced number of oocytes, resulting in a diminished reproductive life span. Mutations in the *Atm* gene, the murine homologue of the human ataxia-telangiectasia gene, disrupt gametogenesis at the leptotene stage of meiosis, and consequently result in sterility. Deletion of the *Wnt4* gene alters the expression of steroidogenic enzymes in the ovary, resulting in increased testosterone synthesis and wolffian duct masculinization, and also affects germ cell entry into meiosis.[46,47] *WNT4* mutations are also associated with müllerian defects (Mayer-Rokitansky-Kuster-Hauser Syndrome) and hyperandrogenism in women. A more extensive list of mouse genes involved in ovary development and follicle formation is provided in Table 9.1.

Relentless and irreversible attrition from midgestation onward progressively diminishes the gonadal germ cell complement, leaving approximately 700,000 primordial follicles in the ovaries at birth.[48] This number decreases further to approximately 300,000 by the onset of puberty; of these follicles, only 400 to 500 will ovulate in the course of a reproductive life span (Fig. 9.2). Although there is good evidence that embryonic stem cells can give rise to oocyte-like cells and follicle-like structures in culture, the notion that germ cells and follicles can arise *in vivo* in the mammalian ovary during postnatal life from an oogonial stem cell population and contribute to the ovarian reserve remains controversial.[49,50]

Compared with the fetal testis, the human fetal ovary is generally believed to be steroidogenically quiescent, although cholesterol side-chain cleavage activity and 17α-hydroxylase/17, 20-desmolase activities are detectable. Even though follicles are present in the fetal and infant ovary, their steroidogenic capacity only becomes evident at puberty.

Epigenetic Programming and Germ Cell Development

Dramatic alterations in epigenetic programming of primordial germ cells are initiated soon after their specification, and continue after entry into the developing gonad. Nearly complete DNA demethylation occurs across the entire genome, including the inactive X-chromosome, which allows transcriptional activity to resume from the X-chromosome.[51] This global demethylation process is in part passive, i.e., simply a consequence of DNA replication in the absence of DNA methyltransferase activity, so maintenance methylation cannot be accomplished. An enzyme-mediated active demethylation process also occurs in combination with activation of the DNA base excision repair pathway, which is required to resolve the proper DNA sequences.[52] Post-translational modifications to DNA-associated histone proteins are either transiently or permanently lost, due to a combination of histone replacement by nonmodified histone proteins and repression of histone modifying enzymes such as histone methyltransferases.[53] These modifications are temporally associated with pronounced alterations in nuclear architecture, including chromatin decondensation and an increase in nuclear size.[54] Together, these epigenetic changes serve to almost fully erase the inherited somatic differentiation program, resetting the cells to a "naive" epigenetic state.

A critical step in mammalian germ cell development, the modification of genomic imprinting, occurs with these

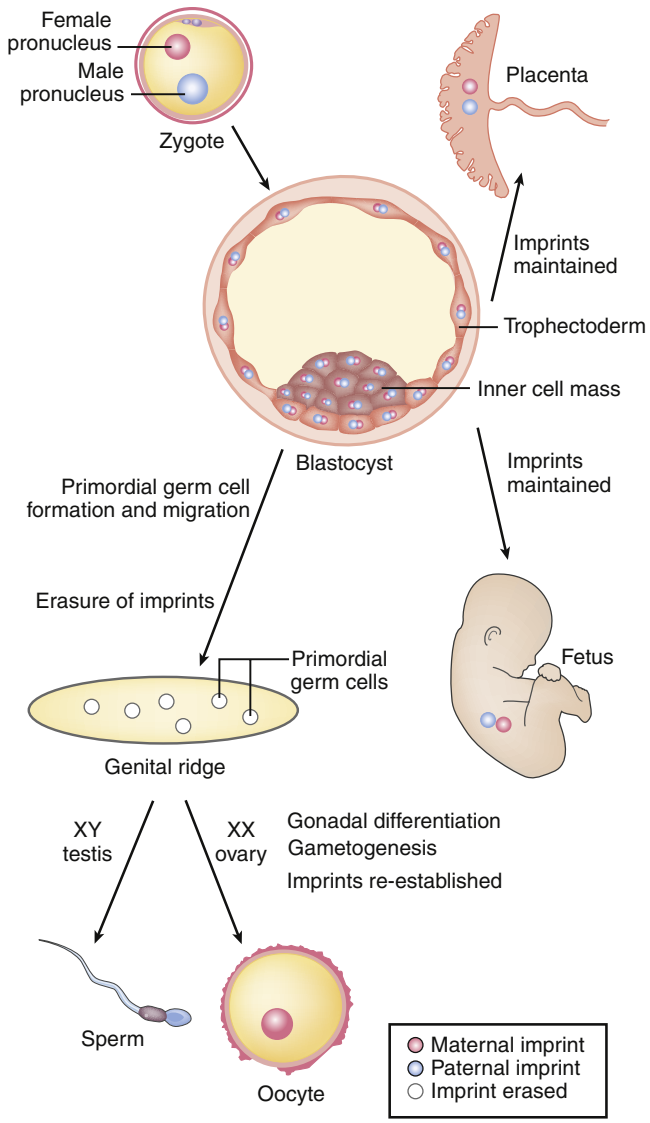

FIGURE 9.4 Erasure and reestablishment of genetic imprints during development. *(Adapted from Surani MA. Reprogramming of genome function through epigenetic inheritance.* Nature *414:122–128, 2001.)*

epigenetic reprogramming events. In mammals, there is an absolute requirement for the inheritance of a chromosomal complement from both the mother and the father.[55-57] The basis for this requirement is that specific genes must be expressed from *one* allele, not both, for successful development.[58-60] This task is accomplished by a tightly orchestrated set of modifications of the maternal and paternal chromatin that include methylation of CpG sequences of specific "imprinted" genes, depending on the parent of origin; the result is differential transcriptional regulation.[60-67] Complete erasure of these imprints occurs during the primordial germ cell epigenetic reprogramming process and is required in preparation for switching the inherited maternal and paternal imprinted patterns to reflect the sex of the progeny.[64] In the case of oogonia, both maternal and paternal imprints are erased, and maternal imprints are later established during oogenesis in the fetal ovary and during oocyte growth (Fig. 9.4).[63,66,67]

The Follicle and Its Surroundings

The Oocyte

Oocyte-Specific Genes

The growing oocyte expresses a number of genes that are essential for successful follicular development, fertilization, and preimplantation development. Mouse knockout studies have identified several oocyte–specific transcription factors essential for folliculogenesis. *Figla*, *Sohlh1* (spermatogenesis- and oogenesis-specific basic helix-loop-helix 1), and *Lxh8* (LIM homeobox 8) appear to be required for the formation of primordial follicles from naked primordial oocytes, whereas *Nobox* (newborn ovary homeobox) is involved in the transition of primordial to primary follicles. *Dazl* (deleted in azoospermia-like), *Cpeb1* (cytoplasmic polyadenylation element binding protein 1), and *Ybx2* (previously known as *Msy2*) are DNA or RNA-binding proteins involved in regulating mRNA translation within the oocyte.[68-70]

Oocyte growth is accompanied by formation of the *zona pellucida*, an extracellular matrix surrounding the oocyte.[68-72] The zona pellucida protects the developing germ cell in the follicle, the ovulated egg in the oviduct, and the cleavage-stage embryo. It also serves as the initial site of contact with sperm, and after fertilization, it becomes a barrier that discourages polyspermy. Three genes have been characterized that encode ZP1 (ZPA), ZP2 (ZPB), and ZP3 (ZPC), which are the main sulphated glycoproteins of the zona. A polymer of ZP2 and ZP3 proteins forms filaments that are interconnected by ZP1, a minor component of the zona pellucida. FIGLA regulates the coordinated expression of these genes during the oocyte growth phase. Humans and rats have a fourth ZP-1 like subunit (ZP4), which is not expressed in mice.[73]

In the mouse, ZP3 was believed for many years to be the primary sperm receptor, with ZP2 being a secondary receptor. However, recent compelling evidence indicates that this "ligand-receptor" model of sperm–ZP3 interaction may not be correct, and suggests that, instead, sperm specifically recognize and bind, not to ZP3 alone, but to the three-dimensional matrix formed by all three zona proteins.[74,75] Indeed, in the human, it is evident that components beyond ZP3 are required for sperm binding to the zona. After fertilization, a cortical granule metalloprotease named ovastacin is released from the egg and cleaves ZP2, which prevents additional sperm from binding the ZP and results in the ZP to block polyspermy.[76]

Mice lacking ZP1 form structurally abnormal zonae and have reduced fecundity. In mice lacking ZP2, a thin zona forms that is not retained in preovulatory follicles. The antral-stage follicle number is substantially reduced, few eggs are ovulated, and no two-cell–stage embryos can be found in mated animals. Moreover, blastocysts derived from *in vitro* fertilized oocytes from females lacking ZP2 do not undergo normal development. Mice lacking ZP3 form no zona pellucida despite the expression of the other zona proteins. Few eggs are ovulated, and the females are sterile. As in the ZP2 mutant, *in vitro* fertilized eggs from ZP3-deficient mice do not develop beyond the blastocyst stage.

Several oocyte-specific "maternal effect" genes have been identified in mouse models that are expressed in

the oocyte, but are only required during preimplantation embryo development. Four maternal effect genes encode proteins that form a "subcortical maternal complex" in oocytes, including *Nlrp5* (NACHT, leucine-rich repeat and PYD-containing 5; also known as *MATER*), *Filia*, *Ooep* (oocyte-expressed protein; also known as *Floped*), and *Tle6* (transducin-like enhancer of split 6).[77,78] Although *Nlrp5* and *Filia* transcripts are degraded during meiotic maturation, the proteins remain until the blastocyst stage. NLRP5 protein is required for development of embryos beyond the two-cell stage, possibly because it regulates mitochondrial function.[79,80] FILIA is required in oocytes and early embryos to regulate spindle function; embryos of *Filia*-null female mice develop poorly because of a high incidence of aneuploidy.[81] *Ooep*-null females have oocytes that lack cytoplasmic lattices, structures that store maternally contributed components required for embryo development. [82] *Nlrp2*, a gene related to *Nlrp5*, is expressed in both oocytes and granulosa cells during folliculogenesis; the maternal protein is required in early embryos for successful development.[83]

Zar1 (zygote arrest 1) encodes a cytoplasmic protein required for the transition from fertilized egg to cleaving embryo by an unknown mechanism.[84] *Gclm* (glutamate-cysteine ligase, modifier subunit) encodes a protein that regulates synthesis of glutathione, which is critical for controlling cellular redox status. Mouse embryos deficient in maternal GCLM have deficits in their ability to develop to the blastocyst stage.[85] *Npm2* (nucleoplasmin 2) encodes a nuclear protein generated before oocyte maturation that affects heterochromatin organization and histone deacetylation. In the absence of *NPM2*, ovulation and fertilization occur normally, but there is a complete failure of preimplantation embryo development. *Dppa3*, in addition to its role in primordial germ cell specification, is a maternal effect gene required for normal preimplantation embryo development.

Oocyte-Derived Factors and the Control of Follicular Growth and Maturation

The concept that the oocyte plays an important role in follicular function and is far more than a passive inhabitant of the follicle emerged from two observations: (1) that follicular survival depends on the presence of viable germ cells and (2) that removal of the oocyte from an antral follicle is followed by luteinization, indicating that the oocyte produces factors that restrain the terminal differentiation of granulosa cells.[86,87] Additional support for this concept was derived from experiments in which midsized oocytes from mouse secondary follicles were transferred by a grafting procedure into primordial follicles. This transfer resulted in a doubling of the rate of development of the primordial follicular cells in the presence of the secondary follicle oocyte.[88]

The effects of the oocyte on follicular growth are mediated in part by closely related members of the TGF-β superfamily that are selectively or specifically produced by the oocyte. These factors, growth differentiation factor (GDF)-9 and BMP-15, influence granulosa and theca cell function (Fig. 9.5) (see Chapter 7). The importance of GDF-9 and BMP-15 has been established through genetic manipulation of mice and the discovery of spontaneous

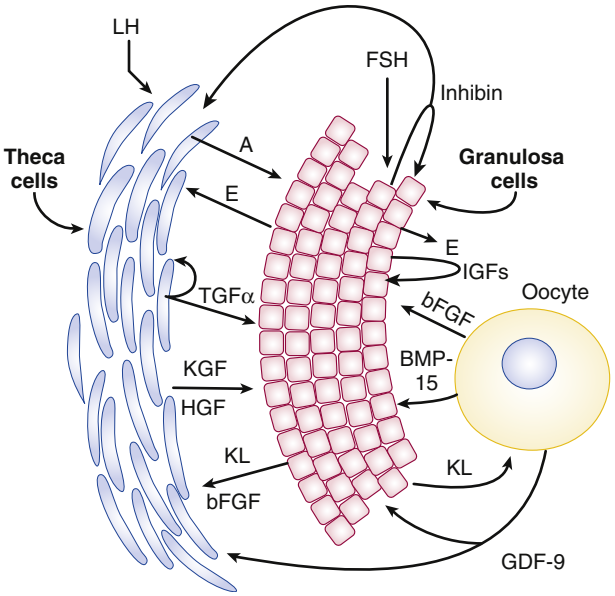

FIGURE 9.5 Paracrine and autocrine interactions between theca cells, granulosa cells, and the oocyte. mutations in the genes encoding GDF-9 and BMP-15, which affects follicular dynamics in sheep.[70,89-91]

Growth Differentiation Factor-9

Growth differentiation factor-9, encoded by a gene on chromosome 5q31.1, is highly expressed by oocytes and, to a lesser extent, by primate granulosa cells. The follicles of GDF-9–deficient mice arrest in growth at the primary stage, yet the oocytes continue to grow at a faster rate than wild-type oocytes, progressing to advanced stages of differentiation seen in the antral follicles of normal mice. However, there are ultrastructural abnormalities in the interconnections between granulosa cells and oocytes; the oocytes ultimately die, leaving a ribbon of zona pellucida behind. The theca also does not form around the follicles, implicating GDF-9 in the organization or proliferation of this follicular component. Studies in the rat also indicate that GDF-9 stimulates the growth of primary follicles, consistent with the block to progression at the primary stage in GDF-9–deficient mice.[70,92]

GDF-9 has a variety of actions on granulosa cells and theca cells that are species-specific, acting at least in part through interaction with the ALK5 (TGF-βRI) and BMP receptor type 2 (BMPRII) receptor complex.[93] In rodents, GDF-9 stimulates granulosa cell differentiation, including induction of LH receptors and steroidogenesis. In cumulus cells, GDF-9 promotes expression of hyaluronan synthase 2, pentraxin 3 and tumor necrosis factor inducible gene 6 (TSG-6), the latter being proteins that are incorporated into the proteoglycan extracellular matrix of the cumulus

oophorus complex. It also suppresses urokinase expression while stimulating COX-2 and prostaglandin synthesis and progesterone formation.[70,94,95] LH receptor expression is suppressed by GDF-9, which would discourage luteinization of the cumulus cells. These actions of GDF-9 promote unique phenotypes in the granulosa cells surrounding the oocyte, which are exposed to the highest GDF-9 concentrations. GDF-9 inhibits human theca cell steroidogenesis *in vitro*.[96] It also stimulates theca cell proliferation, a finding consonant with the apparent role of GDF-9 in the murine ovary in controlling thecal development.

Bone Morphogenetic Protein-15

Bone morphogenetic protein-15, also known as GDF-9b, encoded by a gene on the X chromosome, is another member of the TGF-β superfamily produced by oocytes.[97] It is related structurally to GDF-9 and shares a similar pattern of expression. Targeted deletion of the murine *Bmp15* gene causes a modest ovarian phenotype in nullizygous animals of subfertility with diminished ovulation and fertilization rates. However, mice nullizygous for *Bmp15* and heterozygous for a *Gdf9* mutation have severely impaired fertility, with abnormalities in folliculogenesis and cumulus cell function. Spontaneous point mutations in the ovine *Bmp15* gene (e.g., Inverdale and Hanna sheep) result in phenotypes that differ from those in *Bmp15* knockout mice.[70] In the heterozygous state, the number of follicles ovulating is increased, and thus there is an increase in fecundity. However, primary ovarian failure, with a phenotype resembling the murine *Gdf9* knockout, is observed in ewes homozygous for the mutations. *In vitro*, BMP-15 stimulates granulosa cell mitosis. Thus, its absence *in vivo* would be predicted to impair follicular growth, which is consistent with the ovarian abnormalities in homozygous mutant sheep.

BMP-15 binds to a receptor complex consisting of BMPR1B (activin receptor-like kinase 6, or ALK6) and BMPRII. A point mutation in BMPR1B in Booroola sheep is associated with an additive increase in ovulation rate, based on the copy number of mutant alleles. Targeted deletion of the *Bmpr2* gene in mice does not affect follicular development, but it does yield an infertility phenotype as a result of defects in cumulus cell expansion that prevent *in vivo* fertilization.

Both BMP-15 and kit ligand participate in a negative feedback loop: BMP-15 stimulates kit ligand expression by granulosa cells, whereas kit ligand inhibits BMP-15 expression in oocytes. In the presence of an oocyte, both BMP-15 and kit ligand stimulate granulosa cell mitosis. The observations that only the oocyte expresses kit, the kit ligand receptor, and that kit ligand suppresses expression of BMP-15, a granulosa cell mitogen, suggest that the oocyte must be involved in producing another granulosa cell mitogen.

GDF-9 and BMP-15 are both synthesized as proproteins that form dimers and are then proteolytically processed to yield the bioactive molecules. There is evidence that GDF-9 and BMP-15 can form heterodimers and that processing of the heterodimers is impaired.[98] Notably, the Inverdale mutation that inactivates BMP-15 dramatically impairs the proteolytic processing of both the mutant BMP-15 and wild-type GDF-9 in coexpressing cells. This observation suggests that the phenotype of the Inverdale sheep may be the result, at least in part, of GDF-9 deficiency due to interference by mutant BMP-15 with wild-type GDF-9 processing. Similarly, cells coexpressing mutant human forms of BMP-15 and GDF-9 associated with premature ovarian failure have decreased production of the mature proteins, likely because of impaired post-translational processing.[99]

Granulosa Cells

The granulosa cells are believed to originate from ovarian surface epithelium.[100] The cohort of granulosa cells that surrounds each oocyte has an oligoclonal origin, with three to five parent cells giving rise to the full complement of granulosa cells in a mature follicle.[101] Granulosa cells receive no direct blood supply, and because a basal lamina separates them from the vascularized theca interna, there is a relative blood–follicle barrier that restricts the entry of leukocytes and high–molecular-weight substances (such as low-density lipoproteins). The absence of a blood supply also necessitates intimate intercellular contact between neighboring granulosa cells and the oocyte.

Intercellular Communication Between Granulosa Cells and the Oocyte

Granulosa cells are interconnected by an extensive network of gap junctions, which are important for metabolic exchange and transport of small molecules between neighboring cells. The number of gap junctions per granulosa cell increases as follicles develop, coupling them into a functional syncytium. Moreover, granulosa cells extend cytoplasmic processes through the zona pellucida to form gap junctions with the plasma membrane of the oocyte. Cyclic GMP (cGMP), produced by granulosa cells, is one of the factors passed into the oocyte via gap junctions to maintain oocytes in a state of maturational arrest.

Gap junctions are composed of hexameric arrays of proteins called *connexins*. Connexin-37 and connexin-43 are two of the important follicular connexins, and they form gap junctions with different permeability properties. Connexin-37 is reported to be the predominant connexin in the oocyte, whereas connexin-43 predominates in the granulosa cells. However, at least the first layer of granulosa cells surrounding the oocyte also expresses connexin-37. Communication between granulosa cells and the oocyte occurs through homotypic connexin-37 gap junctions, whereas gap junctional communication between granulosa cells is via homotypic connexin-43 complexes.[102] Follicle stimulating hormone (FSH) induces connexin-43 expression in granulosa cells, whereas the ovulatory surge of LH suppresses connexin-43 mRNA expression and causes mitogen-activated kinase-mediated phosphorylation of connexin-43 protein that results in gap junction closure.

The importance of connexins to follicular function was shown in the ovarian phenotype of connexin-37 and connexin-43 knockout mice.[103,104] In connexin-37–deficient mice, created by targeting the *Gja4* gene, follicle growth is arrested at the preantral stage; oocyte growth, although it commences, is also subsequently arrested before meiotic competence is achieved, resulting in loss of oocytes and formation of luteinized structures. Connexin-43–deficient

mice, created by targeting the *Gja1* gene, have an ovarian phenotype characterized by diminished germ cell number and impaired growth of follicles beyond the primary stage.

Granulosa Cells and the Convergence of Multiple Signaling Pathways

Granulosa cells express receptors for and respond to a large number of factors that are either generated locally within the follicle or that enter the follicular compartment from the blood. These include oocyte-derived factors, autocrine factors produced by the granulosa cells themselves, products of theca cells, and circulating factors. The repertoire of signaling molecules that have been shown to affect primate as well as other animal granulosa cells *in vitro* and *in vivo* beyond FSH and LH is extensive, encompassing hypothalamic factors (e.g., gonadotropin releasing hormone [GnRH]), other pituitary hormones (e.g., growth hormone and prolactin), a large array of growth factors (e.g., epidermal growth factor [EGF] family members, TGFβ family members, and insulin-like growth factors), hormones controlling metabolism (e.g., insulin) and vascular tone (e.g., endothelins), cytokines (e.g., TNF-α) and adipokines (e.g., adiponectin). Some of these factors have a critical role as documented from the phenotypes associated with mutations in humans or spontaneous or induced gene mutations in animals as previously described for GDF-9 and BMP-15. However, functional genomics has not revealed a critical physiological or pathophysiological role for many of these factors in granulosa cells and follicles.

Granulosa Cell Endocrine Activity

The primary steroid hormone produced by the preovulatory granulosa cells is estradiol. The synthesis of this hormone requires a collaborative relationship with adjacent theca cells, which produce the immediate precursors for the aromatization reaction. The control of this process is under the direction of LH, acting on thecal elements, and FSH, acting on the granulosa compartment through multiple signaling pathways including protein kinase A and Akt (Fig. 9.6). The two cell–two gonadotropin model is a formidable example of the integrated function of the different cellular components of the follicle.

Studies of isolated granulosa cells have shown that FSH, but not LH, stimulates estrogen production when the cells are provided with an aromatizable substrate.[105] In contrast, isolated human theca cells do not produce substantial amounts of estrogens, but instead secrete dehydroepiandrosterone, androstenedione, and smaller amounts of testosterone when adenylate cyclase activity is stimulated. The aromatase activity of granulosa cells is estimated to be at least 700 times greater in the granulosa cells of large preovulatory follicles than in theca cells, arguing strongly for the cellular compartmentalization of estrogen synthesis outlined in the two-cell–two-gonadotropin model.

Inhibin, a member of the TGF-β protein superfamily, is produced by granulosa cells. It is a heterodimeric 32-kDa glycoprotein composed of two subunits, α (18 kDa) and β (12 kDa), linked by disulfide bonds. There is a single common α subunit, but there are different β subunits, denoted β_A and β_B. The $\alpha\beta_A$ and $\alpha\beta_B$ heterodimers are named inhibin A and B, respectively. In the ovary, the primary source of inhibin is granulosa cells. The main endocrine role for

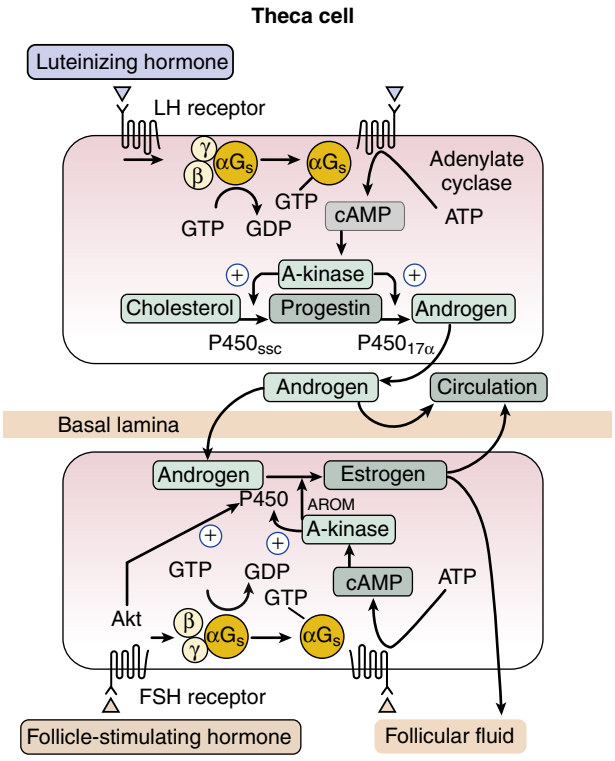

FIGURE 9.6 The two-cell–two-gonadotropin system for estradiol synthesis in the follicle. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are shown to stimulate adenylate cyclase via G-protein–coupled receptors. The cyclic AMP (cAMP) generated from ATP activates protein kinase A to stimulate expression of the respective steroidogenic enzymes in theca and granulosa cells. In addition, in granulosa cells, FSH binding to the FSH receptor leads to activation of AKT, also known as protein kinase B, probably via a phosphatidyl inositol second message, which augments aromatase expression. GDP, guanosine diphosphate; GTP, guanosine triphosphate. *(Modified from Erickson CF, Shimasaki S. The physiology of folliculogenesis: the role of novel growth factors.* Fertil Steril *76:943–949, 2001, with permission.)*

inhibin, for which it was discovered and named, is to suppress pituitary FSH production.[106,107] *In vitro*, inhibin augments LH- and IGF-stimulated androgen production by theca cells, and elevated inhibin production by granulosa cells in polycystic ovary syndrome may contribute to the hyperandrogenemia that is associated with this condition.

Although both isoforms of inhibin seem to have similar biological properties, their synthesis is regulated differently during the follicular and luteal phases. Inhibin B is secreted mainly during the early follicular phase, with levels decreasing in the midfollicular phase and becoming undetectable after the LH surge. Concentrations of inhibin A are low during the first half of the follicular phase, but increase during the midfollicular phase and peak during the luteal phase.

The secretion of inhibin A is regulated by gonadotropins, but production of inhibin B evidently is not. This differential regulation of inhibin A and B production was exemplified in measurements made on follicles of different sizes that showed that inhibin A was present in follicles down to a size of 6 mm, with levels increasing with increased follicular

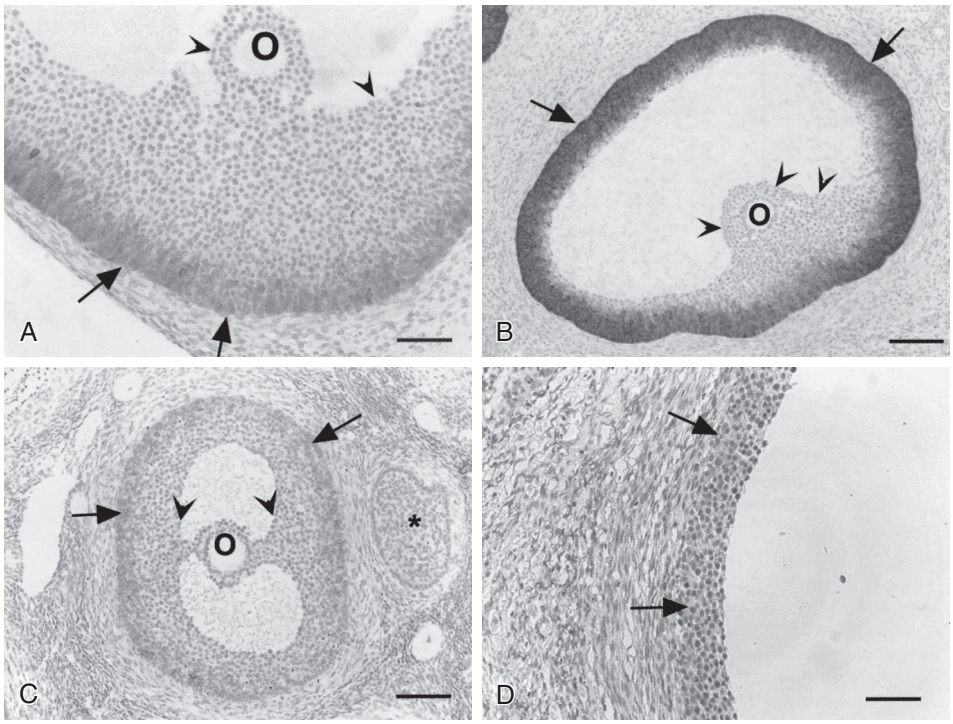

FIGURE 9.7 Heterogeneity of granulosa cell function in the developing follicle. size. In contrast, inhibin B levels showed no relationship to follicle size or maturation state.

Granulosa Cell Phenotypic Heterogeneity

Granulosa cells display different phenotypes within the follicle, depending on their location.[108-111] The mural granulosa cells, antral granulosa cells, and cumulus granulosa cells each have distinguishing features that are likely determined by their proximity to the oocyte and theca cells and by the paracrine substances that they produce. The mural granulosa cells in the antral follicle express the greatest steroidogenic activity (Fig. 9.7). In addition, mural granulosa cells in the preovulatory follicle have the highest level of LH receptors. The granulosa cells closest to the antral cavity have a lower expression of steroidogenic enzymes, whereas those in the middle region have greater mitotic activity than the antral and mural granulosa cells.

The cumulus cells, which are released with the oocyte at ovulation, do not express aromatase, and their LH receptor content and level of LH responsiveness are substantially lower than those of their mural counterparts. In mice, they have distinguishing gene expression patterns that include expression of *Slc38a3*, which encodes a sodium coupled neutral amino acid transporter, and higher expression of the anti-müllerian hormone gene, *Amh*. These cells proliferate after the LH surge and are active in producing an extracellular matrix consisting of hyaluronan, proteoglycans, and proteoglycan-binding proteins when stimulated by the prostaglandins generated in response to the ovulatory stimulus. The elaboration of this matrix leads to the preovulatory expansion of the cumulus–oocyte complex, which appears to be essential for ovulation (Fig. 9.8). Differential patterns of expression of prostaglandin E (EP) receptors allow granulosa cell subpopulations to respond uniquely to PGE2 during ovulation. Cummulus cells appear to respond via EP2

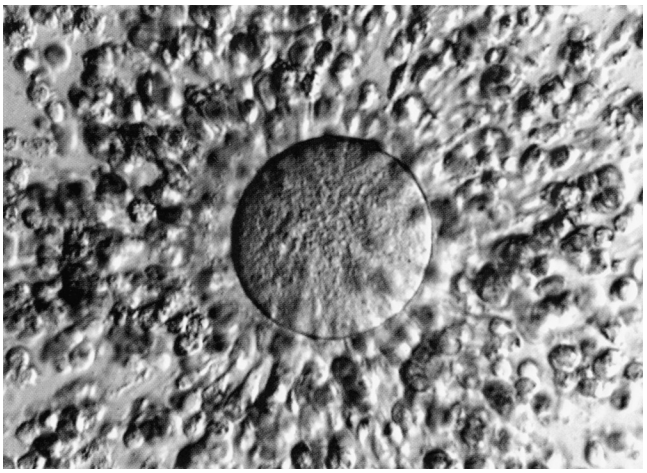

FIGURE 9.8 Appearance of a mature ovulated human oocyte. This metaphase II–arrested oocyte is surrounded by a highly expanded cumulus cell layer. The zona pellucida is visible only as a blurred region immediately around the oocyte (100×). *(Adapted from Veeck LL. An Atlas of Human Gametes and Conceptuses. New York, Parthenon Publishing, 1999.)*

and EP3, whereas rupture of a specific region of the follicle is through EP1 in granulosa cells near the apex. A growing body of literature suggests that cumulus cell viability (e.g., apoptosis) and expression of certain proteins and mRNAs correlates with oocyte competence and success in assisted reproduction.[112]

Luteinized granulosa cells of the ovulated follicle undergo terminal differentiation to give rise to the large luteal cell population of the corpus luteum. These cells have an increased capacity to synthesize progesterone, resulting from up-regulation of the machinery required to acquire cholesterol from the circulating lipoproteins, which now

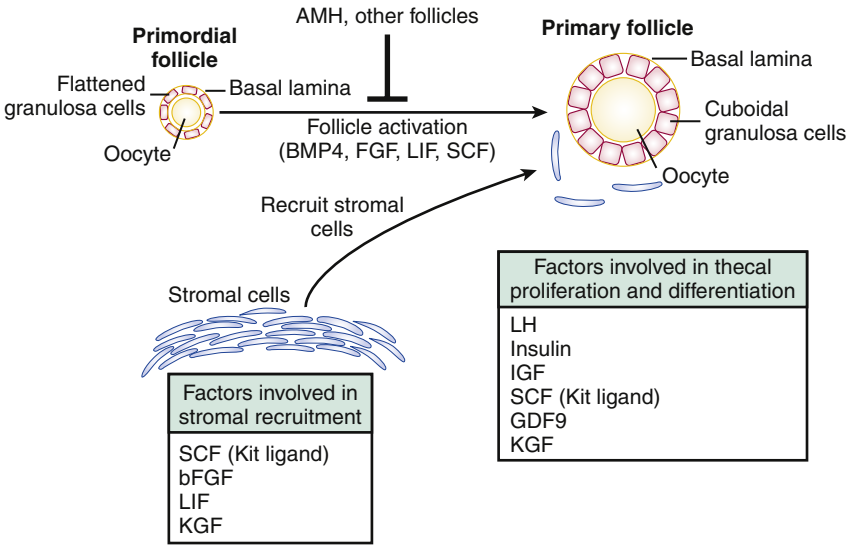

FIGURE 9.9 Recruitment to and differentiation of theca cells in the developing follicle. have access to the granulosa-lutein cells as a result of neovascularization of the developing corpus luteum. The granulosa-lutein cells also retain the capacity to synthesize estrogens from androgen precursors produced by theca lutein cells.

Theca Cells

The theca and interstitial cells are believed to arise from fibroblast-like mesenchymal cells in the stromal compartment. They first appear around follicles that have two or more layers of granulosa cells (Fig. 9.9).[113]

The Kit and Kit ligand system is thought to play a prominent role in early development of the androgen producing cells of the ovary and testis.[114] Production of GDF-9 by the oocyte is required for development of the theca layer. In the absence of GDF-9, theca cells are recruited to surround the follicle but do not undergo proper functional differentiation. Theca cells also express Kit, the receptor for Kit ligand, and researchers have postulated that Kit ligand produced by granulosa cells is important in organizing the theca layer around the developing follicle.

Theca cells engage in a bidirectional dialogue with granulosa cells through the production of keratinocyte-derived growth factor (KGF) and hepatocyte growth factor (HGF). KGF and HGF, like FSH, stimulate granulosa cells to produce Kit ligand, whereas Kit ligand acts on the theca cells to promote expression of KGF and HGF in a positive feedback loop (Fig. 9.5). Kit ligand, KGF, and HGF achieve their highest concentrations in large antral follicles. As the oocyte expresses Kit receptor, this feed-forward loop also affects oocyte function. Moreover, theca-derived insulin-like factor-3 (INSL3) acts on the oocyte to promote maturation.

Theca cells of the ovulated follicle are incorporated into the corpus luteum, where they represent the population of small luteal cells (theca lutein cells), expressing the steroidogenic machinery to produce androgen precursors that are transformed by the larger luteal cells derived from the granulosa cells of the luteinizing follicle, which express aromatase activity.

Hypertrophied theca interna cell remnants of atretic follicles are found in the ovary. These cells are thought to be targets of noradrenergic innervation that control steroidogenic activity. Hilar interstitial cells are large lutein-like cells with structural and functional characteristics indistinguishable from those of differentiated Leydig cells. Like Leydig cells, they contain the hexagonal Reinke crystals. Hilar cells are intimately associated with nonmyelinated sympathetic nerve fibers. The endocrine activity of these cells is assumed to be correlated with their prominence at the time of puberty, during pregnancy, and around the menopause.

Ovarian Stroma

The ovarian stroma contains fibroblastic cells that express some steroidogenic enzymes. The stroma may also harbor precursors of androgen-producing cells (Fig. 9.10).[115] Ovarian stroma cells express androgen receptors, and may proliferate under the influence of androgens, contributing to the increased stromal density characteristic of hyperandrogenemia of ovarian origin (e.g., polycystic ovary syndrome and androgen-producing ovarian tumors).

The stromal cells serve as insulators in the ovary, separating follicles and corpora lutea from adjacent structures

physically, as well as biochemically. Stromal cells produce growth factors and growth factor–binding proteins, the latter perhaps being key to the proposed insulator role. Ovarian stromal cells express substantial levels of gremlin, a protein that binds and inactivates BMPs; follistatin, which binds and inactivates activin; insulin-like growth factor (IGF)-binding proteins, and secreted frizzled-related proteins, which bind members of the WNT signaling family.

Ovarian Surface Epithelium

The ovarian surface epithelium, a flat to cuboidal epithelial layer of mesodermally derived cells, is also known as the *ovarian mesothelium* and by the misnomer of "germinal epithelium" because of the erroneous belief that it gave rise to germ cells.[116,117] During development, the ovarian surface epithelium may be one source of granulosa cells in addition to the rete ovarii, which has a common origin with the surface epithelium. In the adult ovary, the surface epithelium is characterized by expression of the mucin gene, *MUC1*, and the presence of cilia and apical microvilli. The cells sit on a basement membrane that covers a dense connective tissue layer.

The ovarian surface epithelium plays a role in the transport of material to and from the peritoneal cavity and in the repair of surface defects resulting from ovulation. During the ovulatory process, epithelial cells overlying the follicle undergo apoptotic cell death, followed by activation of a subsequent repair process. This process includes cell proliferation, which begins right after ovulation, and the resynthesis of extracellular matrix components. Proinflammatory cytokines may initiate these events.

Invaginations of surface epithelium into the ovary result in the formation of inclusion cysts. The ovarian surface epithelium in these inclusion cysts may undergo metaplasia and neoplasia. Although some researchers have suggested that these inclusion cysts form from invaginations around the site of ovulation, they have been reported to be prominent in polycystic ovary syndrome (PCOS), a condition characterized by oligo-ovulation or anovulation. Others have proposed that cysts containing müllerian ductal epithelium that are not present in normal ovaries are the cause of epithelial cancers of the ovary, and represent a common link to fallopian tube and peritoneal cancers.[118]

Ovarian Leukocytes and Macrophages

Macrophages, lymphocytes, and polymorphonuclear granulocytes are present in the ovary at various stages of its life cycle.[119] These cells have roles in normal ovarian function as well as in ovarian pathology, where for example, lymphocyte infiltration, particularly in the theca interna, is a characteristic feature of autoimmune ovarian failure.

Macrophages are a major cellular component of the interstitium, usually found near the perifollicular capillaries. Few other white blood cells are observed in the ovary in the early phases of follicular development, but a substantial infiltration of white blood cells occurs in the periovulatory period and in association with follicular atresia.[120] Mast cells increase progressively in number during the latter portion of the follicular phase, and their release of histamine may contribute to ovarian hyperemia at ovulation.[121,122]

After ovulation, eosinophils and T lymphocytes migrate into the corpus luteum, recruited by the expression of chemoattractants.[123,124] The infiltration and subsequent activation of these cells occurs before there is evidence of either functional or structural luteal regression. Activated T cells produce lymphokines that attract and activate macrophages. The dark stellate K cells that are scattered among the luteal cells are thought to be macrophages. They influence luteal cell function through discrete cell–cell contacts and the production of growth factors and cytokines.[125-127] Regulatory T cells, a population of lymphocytes which maintain antigen-specific T cell tolerance, may be of particular importance.[127] An abundance of these cells in the midcycle corpus luteum have been hypothesized to promote an anti-inflammatory or "tolerant" state. Luteolysis is associated with a loss of regulatory T cells, which would engender a pro-inflammatory state. The importance of invasion of T lymphocyte subtypes and macrophages into the corpus luteum in the process of luteolysis is highlighted by the fact that pregnancy delays this invasion.

Ovarian Innervation

The ovary has both extrinsic and intrinsic innervation. The extrinsic nerves, which are mainly sympathetic and sensory fibers with a small parasympathetic component, enter the ovary via the hilar perivascular plexus.[128-130] The main function of this extrinsic innervation is to regulate ovarian blood flow. However, it may also affect pain in pathological states like ovarian endometriomas and the endocrine function of ovarian cells. Excessive activation of thecal adrenergic receptors possibly plays a role in the pathogenesis of ovarian hyperandrogenism. Consistent with this notion, histochemical evaluation of ovarian tissue obtained from patients with PCOS suggested enhanced innervation of the theca–interstitial cell compartment.[131]

The human ovary is also endowed with intrinsic innervation. Some of the neurons are catecholaminergic, as identified by the expression of tyrosine hydroxylase, the rate-limiting enzyme in catecholamine synthesis. Most of these neurons express neurotrophin receptors.

The neurotrophins are a family of nerve survival and differentiation factors. These molecules act on the TRK proto-oncogene family of high-affinity receptors and the low-affinity p75 nerve growth factor (NGF) receptor.[132] NGF supports early follicular development. NGF-deficient mice, and mice lacking the NGF receptor, NTRK1, exhibit a substantial reduction in primordial follicle formation, and the ovaries have an increased number of oocytes that are not incorporated into a follicular structure.[133] The absence of NTRK2, the receptor for neurotrophin-4 (NTF4) and brain-derived neurotrophic factor (BDNF), is also associated with reduced primordial follicle formation. The studies of knockout mice indicate that NTRK1 and NTRK2 receptors are required for assembly of primordial follicles and early follicular development and that the action of NGF is in part through the induction of FSH receptors in developing follicles.

Mouse oocytes express the BDNF receptor TRK-B. BDNF, which is produced by granulosa cells in response to LH and NT-4/5, but not NT-3, stimulates mouse oocyte maturation, including extrusion of the first polar body,

and promotes early embryonic development *in vitro*.[134] Collectively, these findings suggest that the intraovarian neurotrophin system may be important for early follicular development and later oocyte maturation.

Neurotrophins and their receptors are also expressed in the human fetal ovary, with the TRK-B receptor being localized to germ cells and p75 NGF receptor in the stroma.[135] BDNF, NT-4/5, and NT-3 are detectable in human follicular fluid aspirated from women undergoing controlled ovarian hyperstimulation.

Ovarian Stem Cells

Embryonic stem cells are pluripotent and have been shown to give rise to oocyte-like structures *in vitro*, raising the possibility of an ovarian stem cell population that could generate germ cells in adult life.[49,50] Although this is a controversial notion, rare oogonial stem cells have been isolated from mouse and human ovaries through immunotagging with antibody to the N-terminus of DDX4, which is evidently expressed on the cell surface, and fluorescence-activated cell sorting.[136] The isolated cells divide in culture and form oocyte-like structures based on their morphology and expression of oocyte-specific markers, including DDX4 and LHX8. These oocyte-like cells from mouse ovary develop *in vitro* and *in vivo* into oocytes that are capable of fertilization and embryonic development. Oogonial stem cells isolated from human ovarian cortex show similar characteristics. Oogonial stem cells transfected with a green fluorescent protein (GFP)-tagged lineage marker and injected into the ovaries of adult mice, form GFP-expressing oocytes 5 to 6 months after injection. Some recovered GFP-tagged oocytes were successfully fertilized and subsequently developed in some instances to blastocyst stage. Oogonial stem cells isolated from adult human ovarian cortical strips and labeled with GFP were injected into human cortical strips that were transplanted into immunodeficient mice or re-aggregated with dissociated cells from cortical strips. Oocyte-like cells with meiotic markers and surrounded by somatic cells were found within grafts at 7 to 14 days after transplantation. Although the characterization of these oocyte-like cells was incomplete, these studies do provide evidence of a rare pluripotent stem cell population in the ovary. However, these cells do not appear to support follicular generation in numbers to prevent natural ovarian aging. Whether these stem cells make a quantitatively significant contribution to the ovarian follicular complement in normal women or women with ovarian dysfunction who have different follicular pool sizes (primary ovarian insufficiency or polycystic ovary syndrome) remains to be determined.[50]

The Follicular Life Cycle

Gougeon proposed that the various follicular classes, defined largely by size and the number of granulosa cells, represent sequential stages of development on the way to maturity (Fig. 9.11).[137] Based on this schema, approximately 1 year may elapse in the maturation of a primordial follicle to a dominant follicle. During much of this remarkably long period (approximately 300 days), follicles are believed to grow in a gonadotropin-independent manner. Gonadotropins influence the last 50 days of the maturation process.

Initiation of Follicular Growth

Follicular growth, which begins when primordial follicles emerge from their quiescent state, occurs continuously from the fifth to sixth month of intrauterine life until menopause. Although some researchers have suggested that the first formed follicles are the first ovulated, transition into the growth phase is more likely to be a random event

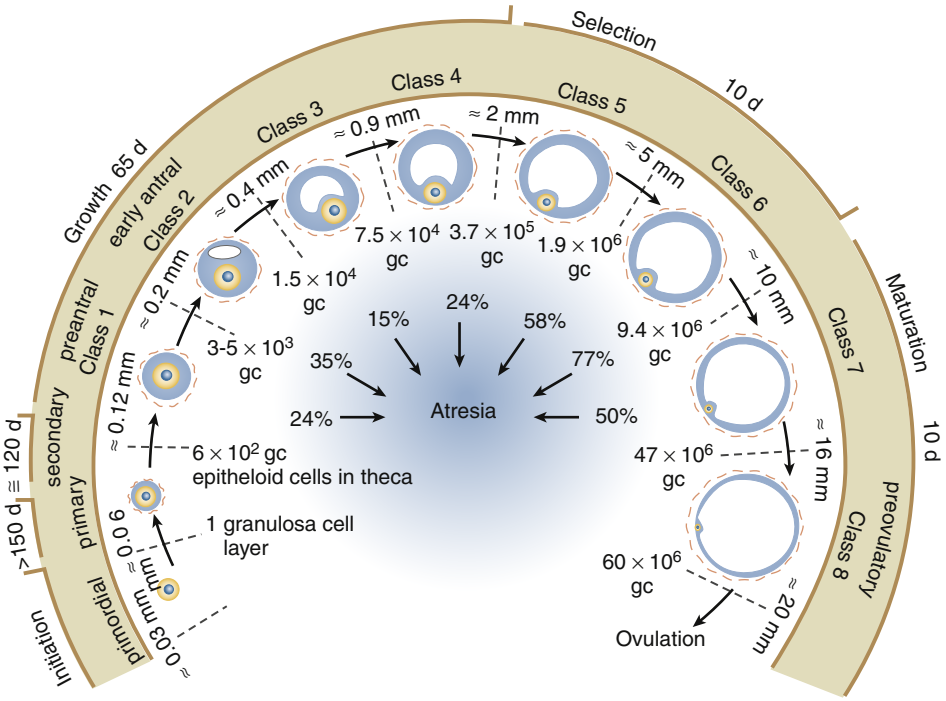

FIGURE 9.11 Stages of follicular development in the adult human ovary and extent of atresia in the eight classes of growing follicles. The classes are defined by the granulosa cell (gc) numbers and the corresponding estimated follicular diameter (mm). d, days. *(From Gougeon A. Dynamics of follicular growth in the human: a model from preliminary results.* Hum Reprod *1:81–87, 1986.)*

independent of the sequence in which follicles formed during development.

The initiation of follicular growth is characterized by morphological changes, including a change in granulosa cell shape from flattened to cuboidal, proliferation of granulosa cells, enlargement of the oocyte, and formation of the zona pellucida (Fig. 9.12). The transformation of flattened granulosa cells to a cuboidal shape has functional correlates, including the expression of certain mRNAs (e.g., follistatin mRNA). Granulosa cell proliferation and the change to a cuboidal shape precede increases in oocyte diameter. In the human, the first substantial increase in oocyte diameter occurs when there are 15 granulosa cells in the largest follicle cross-section. Oocyte growth is accompanied by elaboration of the zona pellucida, first evident as islands of periodic acid-Schiff–positive material. Subsequent increases in oocyte and follicular diameters are positively correlated until well into the secondary follicle stage, when oocytes reach a mean diameter of 80 μm. This stage corresponds to a follicular diameter of 110 to 120 μm and a granulosa cell endowment of approximately 600 cells. The germinal vesicle attains a mean maximal diameter of 26 to 27 μm at this follicular size.

The early theca interna is acquired at the end of the primary follicle stage. The theca externa forms as the follicle expands and compresses the surrounding stroma (Fig. 9.3).

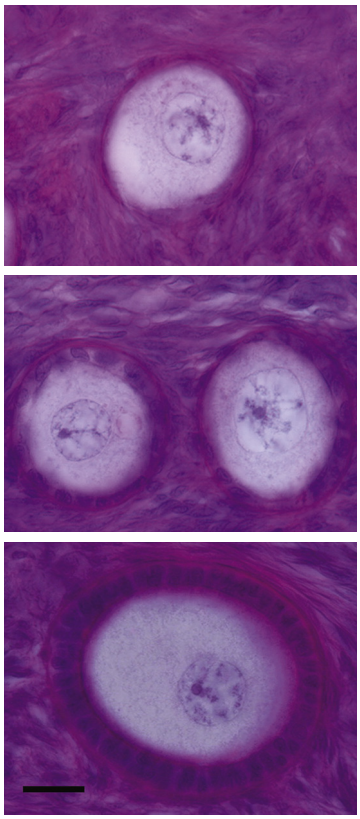

FIGURE 9.12 Changes in the structure of primordial follicles with initiation of growth. The change in morphology of the cumulus cells from flat to cuboidal represents the earliest morphological feature of this process. *(From Westergaard CG, Byskov AG, Andersen CY. Morphometric characteristics of the primordial to primary follicle transition in the human ovary in relation to age.* Hum Reprod *22[8]:2225–2231, 2007.)*

The migration of pretheca cells to the outer surface of the follicle is triggered by secreted signals from granulosa cells including Kit ligand and insulin-like growth factor-I.[138] Signals secreted from the oocyte including fibroblast growth factor (FGF2), platelet derived growth factor (PDGF), GDF-9, and BMP-15 also promote theca cell migration and proliferation (Fig. 9.5).[139]

As a secondary follicle is being formed, the granulosa cells develop FSH, estrogen, and androgen receptors and become coupled by gap junctions. The formation of the thecal layer is associated with the development of a follicular blood supply from arterioles that terminate in a wreath-like network of capillaries adjacent to the basement membrane. Concomitantly, the theca cells acquire LH receptors and the capacity to synthesize steroid hormones. The secondary follicles constitute the pool of preantral follicles from which FSH-dependent recruitment of follicles takes place.

Oocyte Growth

A significant component of the secondary follicle growth phase is dedicated to oocyte differentiation and growth. The growing oocyte is a metabolically active cell, synthesizing mRNAs and proteins that support growth and development through the early preimplantation embryo stages. The oocyte is supported in its growth by bidirectional transport of nutrients, growth factors, and other molecules across the gap junctions that directly connect the transzonal projections of the surrounding granulosa cells to the oocyte.[140]

Morphological alterations in the oocyte that occur during the growth phase include complete elaboration of the zona pellucida by the active production, assembly, and secretion of its component proteins. The quantity of several cytoplasmic organelles increases, particularly the mitochondria, which are estimated to number approximately 500,000 in a fully grown human oocyte.[141] In contrast, the centrioles that were present in oogonia are lost during the oocyte growth phase.[142] The distribution of the organelles changes, with clustering of the mitochondria, endoplasmic reticulum, and Golgi complex in the region immediately surrounding the germinal vesicle.[143]

During the growth phase, oocytes become competent to undergo meiotic maturation, or acquire "meiotic competence." The molecular basis for the acquisition of meiotic competence is not completely understood. However, it occurs only after the oocyte has reached a critical size. Meiotically competent oocytes do have certain attributes, including increased levels of the cell cycle proteins CDK1, cyclin B, and CDC25.[144,145] A threshold amount of these proteins is most likely a prerequisite for resumption of the cell cycle. Importantly, proper meiotic chromosome segregation depends on successful folliculogenesis and oocyte growth, processes that have substantial energy requirements. These requirements are met by transport of ATP and energy substrates from granulosa cells via gap junctions and also by oxidative phosphorylation of pyruvate within the oocyte proper. Mouse oocytes lacking PDH1A, an enzymatic subunit of pyruvate dehydrogenase, have decreased levels of ATP and nicotinamide adenine dinucleotide phosphate (NADPH) because they cannot perform oxidative phosphorylation of pyruvate. These oocytes grow and are ovulated, but do not successfully complete meiotic

maturation.[146] Similar processes may be compromised in the ovaries of older women, resulting in nondisjunction errors and aneuploidy in the embryo.[147,148]

Although it is not completed until late in preimplantation embryo development, reestablishment of genomic imprints begins to occur during oocyte growth, at least partially due to the activity of DNA methyltransferases.[149-152] Failure of the imprinting process in either oocytes or male germ cells results in aberrant expression of genes from the maternal or paternal alleles. These alterations in gene expression are associated with several inherited human diseases, including Beckwith-Wiedemann, Prader-Willi, and Angelman syndromes.[153,154] A global loss of maternal imprinting in the oocyte results in the formation of a complete hydatidiform mole.[155]

In addition to developing meiotic competence, oocytes in the growth phase begin to acquire the ability to support preimplantation embryo development and development to term, known as "developmental competence." Functional aspects of developmental competence are poorly defined, but include the ability of the oocyte cytoplasm to remodel sperm DNA and an enhanced ability to generate calcium oscillations.[156,157] Generation of a pool of maternal mRNAs that are highly stable but translationally repressed until maturation or fertilization is an important aspect of developmental competence.

At the completion of oocyte growth, transcription is actively silenced and protein translation slows substantially. Transcriptional silencing requires patent gap junctional communication with cumulus granulosa cells and is accompanied by changes in large-scale chromatin structure that are essential to confer growing oocytes with meiotic and developmental competence.[158,159] Maintenance of these chromatin changes requires the activity of histone deacetylases.[160] After transcriptional silencing, preovulatory oocytes rely on maternally derived proteins and mRNA stores to support the resumption of meiosis and the first cleavage divisions after fertilization.

Factors Initiating Follicular Growth

Intraovarian factors are believed to play key roles in regulating the early phases of follicular growth either as activators or inhibitors. Activators of follicular growth and development include LIF, basic fibroblast growth factor (FGF), and Kit ligand. Kit ligand, which is produced by granulosa cells and acts on Kit, a receptor on the oocyte and theca cells, is required for initiation of follicular growth and growth of the oocyte. An antibody to Kit that blocks interaction with Kit ligand interferes with the primordial stage of follicle development when injected into newborn mice. Conversely, recombinant Kit ligand accelerates the transition from primordial to primary follicles in neonatal rat ovaries. Anti-müllerian hormone (AMH), activin A, and the chemokine SDF-1/CXCL12, acting through its receptor, CXCR4, inhibit follicular growth.

The oocyte-derived proteins GDF-9 and BMP-15 are important for granulosa cell proliferation in a species-specific manner, as shown by the ovarian phenotypes of the *Gdf9* knockout mouse and sheep with homozygous mutations in the *Gdf9* and *Bmp15* genes. With GDF-9 deficiency, granulosa cells cease proliferating after approximately two doublings. The oocytes continue to grow, however, resulting in large oocytes that ultimately degenerate and are surrounded by a single layer of granulosa cells.[70,161]

Two signal transduction cascades have been identified to play critical roles in the activation of primordial follicles: the phosphatidylinositol-3-kinase (PI3 kinase)/Akt pathway and the mTOR (mammalian target of rapamycin) pathway. When disrupted, both pathways result in aberrant activation of follicular growth in mice and the ultimate depletion of primordial follicles.

PI3 kinase catalyzes the formation of the formation of phospholipid, 3,4,5 phosphoinositol phosphate (PIP3), which activates protein kinase PDK1, which in turn phosphorylates the kinase AKT, which phosphorylates the forkhead O3 transcription factor, FOXO3. Kit ligand, produced by granulosa cells, acts on Kit expressed on the oocyte and appears to activate this cascade, which ultimately leads to phosphorylation and inactivation (exclusion from the nucleus) of FOXO3, resulting in the inhibition of genes required for the initiation of follicular growth. Mice with null mutations for *Foxo3* do not restrain primordial follicle activation, which results in global follicle activation soon after birth and subsequent premature primordial follicle depletion and sterility.[162] The regulatory components involved in FOXO3 phosphorylation include PDK1 and PTEN (phosphatase and tensin homologue deleted on chromosome 10). Oocyte-specific deletion of *Pdk1* causes infertility secondary to depletion of primordial follicles. PTEN, is a PIP3 phosphatase and, therefore a negative regulator of phosphatidylinositol 3-kinase. Deletion of PTEN in the oocyte, which removes a restraint on activation of PDK1 and Akt results in activation of primordial follicular growth and early depletion of follicles because of FOXO3 phosphorylation.

mTOR is a member of the phosphatidylinositol-3-kinase family. mTOR complex 1 (mTORC1), one of two mTOR complexes with distinct functions, regulates transcription, translation and metabolism through downstream targets.[70] It is negatively regulated by a complex formed by two unrelated proteins, TSC1/TSC2, that work through the intermediacy of a small GTP hydrolase, RHEB, which activates mTORC1 that in turn activates translation by phosphorylating ribosomal S6 kinase and 4E-binding protein 1. When *Tsc1* and *Tsc2* function is ablated in mouse oocytes, the primordial follicle pool is established, but premature follicular activation depletes this pool resulting in infertility. The follicular activation in mice lacking TSC1 can be suppressed by the administration of the mTOR inhibitor, rapamycin. Although these observations provide strong evidence for the importance of the mTOR signaling pathway in follicular growth control, the upstream factor that initiates the signal transduction cascade has not been elucidated.

In addition to the PI3 kinase and mTOR pathways, several transcription factors are known to play roles in the transition from primordial to primary follicles based on functional genomic studies in mice, including NOBOX (newborn ovary homeobox), SOHLH1 (spermatogenesis and oogenesis helix-loop-helix 1), and SOHLH2. Mice bearing mutations in *Nobox*, *Sohlh1*, or *Sohlh2* have defects in the primordial to primary follicle transition and are infertile.[70]

Evidence suggesting that FSH is not required for initiation of follicular growth includes the fact that the process occurs in hypophysectomized animals. In humans and mice with inactivating mutations in the FSHβ subunit or FSH receptor gene, follicular development can occur to the secondary and early antral stages, but more slowly and with markedly reduced frequency than when normal levels of FSH activity are present. However, the importance of pituitary-derived factors (not necessarily FSH) in follicular growth and survival in the primate fetus was illustrated by the observation that hypophysectomy of the fetal Rhesus monkey results in oocyte depletion. Moreover, studies on rodent ovaries suggest that preantral follicles are gonadotropin-responsive. In human ovarian xenografts transplanted to immunodeficient and hypogonadal mice, FSH was shown to be required for growth of follicles beyond the two-granulosa–layer stage.[163] Thus, follicle growth before the antral stage, although possible in the absence of gonadotropins, may be facilitated by FSH.

Formation of Antral Follicles

There is little doubt that the transition from the secondary-follicle to the antral-follicle stage is promoted by FSH. Antral follicles are rarely observed in animals or humans with FSH deficiency (unless exogenous FSH is administered) or ovaries lacking FSH receptors. The antrum and its fluid facilitate the process of release of the cumulus–oocyte complex at ovulation and serve as a vehicle for nutrient exchange and waste removal in the avascular compartment.[164] The antrum also serves as a unique environment in which the cumulus–oocyte complex completes growth and maturation.

The development of the antrum requires the influx of water, which occurs primarily through a transcellular process. This may be mediated by the water channels formed by aquaporins 7, 8, and 9.[165] Because net transfer of water via the aquaporins requires an osmotic gradient, granulosa cells are believed to actively transport ions to create this gradient. Alternately, the hydrolysis of glycosaminoglycans in the antrum could increase the osmolarity of follicular fluid and support the influx of water.

Between 5 and 6 days before ovulation, the follicle undergoes rapid expansion—as a result of granulosa cell proliferation and the accumulation of antral fluid—and moves to the ovarian surface. The accelerated expansion of the follicle destined to ovulate can cause midcycle pelvic pain (mittelschmerz). The expression of the cell cycle gene, cyclin D2, is important for this expansion, because cyclin D2 null mice show impaired granulosa cell proliferation and consequently have an ovulation defect. On completion of this growth phase, the follicle, now referred to as a Graafian follicle, is prepared for ovulation.

Follicular Recruitment, Selection, and Dominance

The term "recruitment" has been used to describe the process by which the follicle departs from the resting pool to initiate growth. However, some authors also use this term to describe the engagement of a cohort of antral follicles into further growth. It has been suggested that the first situation be called *initial recruitment* and the latter, *cyclic recruitment*.[166] Cyclic recruitment, although obligatory, does not guarantee ovulation because growing follicles are vulnerable to atresia and thus may fall out from the growth trajectory. *Selection* refers to the process by which the maturing follicular cohort is reduced to a number appropriate for the species-specific ovulatory quota. This process entails negative selection against the subordinate follicles as well as positive selection of the follicles that will determine dominance.

Although traditional thinking holds that a single cohort (wave) of follicles develop during the menstrual cycle, ultrasound studies suggest that multiple waves occur. The "wave theory," supported by serial transvaginal ultrasound monitoring of normal ovulatory women and some earlier histological studies follicular recruitment, holds that two or more cohorts of 4 to 14 follicles ≥4 to 5 mm in diameter are recruited during the ovarian cycle, and that the dominant follicle that emerges in the final wave of the inter-ovulatory interval is destined to ovulate.[167]

In the early follicular phase, no gross morphological differences exist between the selected follicle and other healthy members of the cohort. However, the leading follicle can be distinguished from other members of the cohort by its size and the high mitotic index of its granulosa cells. Only the leading follicle has detectable levels of FSH in its follicular fluid. The leading follicle also contains significant levels of estradiol, a hallmark of the chosen follicle. Selection does not guarantee progression to ovulation, but given its temporal proximity to this event, ovulation usually does occur.

FSH is required for the transition of secondary preantral follicles to the antral stage. It also is a survival factor for antral follicles, and its withdrawal triggers programmed cell death in the absence of local factors that sensitize the follicle to FSH action or amplify its effects.[168,169] Follicular maturation initiated at the start of a new menstrual cycle is driven by an increase in FSH levels in the late luteal phase as progesterone, estradiol, and inhibin A levels fall. Preantral follicles apparently require a threshold FSH concentration to sustain growth, and this threshold level is reached during the late luteal phase. Remarkably, the threshold can be crossed with as little as a 10% to 30% increment in FSH, indicating that granulosa cells have a highly sensitive, but still mysterious, detection system with which they interpret circulating FSH levels. FSH can induce follicular growth to the preovulatory size of at least 17 mm in the virtual absence of LH. Although estradiol production is impaired under these circumstances, inhibin production is induced-reflecting the normal response of granulosa cells to FSH.

Granulosa cell division is promoted by FSH, possibly by an indirect mechanism. This action is mediated by growth factors produced by either somatic cells or the oocyte. For example, in rodents, estrogens produced in response to FSH are an important mitogen for granulosa cells. FSH also increases the number of gap junctions as well as the amount of junctional membrane between granulosa cells. An early sign that a dominant follicle has been selected is that its granulosa cells proliferate at a greater rate than the cells in the nondominant follicles. The differential mitotic rates can be detected in the late follicular phase.

One of the major actions of FSH is the induction of aromatase in granulosa cells (Fig. 9.6). Thus, little or no estrogen can be produced by FSH-unprimed granulosa cells,

even if they are supplied with aromatizable androgen precursors. FSH also induces expression of cytochrome P450 reductase, which transfers electrons to aromatase, and by type 1 17β-hydroxysteroid dehydrogenase (17BHSD1), the "estrogenic" 17β-hydroxysteroid dehydrogenase that reduces estrone to estradiol.

Follicle-stimulating hormone induces LH receptors in the granulosa cells of the preovulatory follicle. *LHR* mRNA is detectable in antral follicles (3–10 mm in diameter) and reaches maximal levels in granulosa cells in preovulatory follicles. In contrast, *FSHR* mRNA levels decline in granulosa cells as follicular diameter increases. Consequently, in the late stages of follicular maturation, LH can subserve FSH's function in propelling follicular maturation.[170] This attribute may allow the dominant follicle to complete its maturation cycle in the face of declining FSH levels; in addition, the dominant follicle is prepared to respond to the ovulatory LH surge.

The importance of FSH in follicular development has been documented by the discovery of mutations that inactivate the FSH β subunit and the FSH receptor in humans, and by targeted deletions of these genes in mice.[171,172] Women who are homozygous for FSH receptor mutations have the features of hypergonadotropic hypogonadism, with absent or poor development of secondary sexual characteristics and high FSH and LH levels. The ovarian phenotypes of humans with these mutations and those of FSH receptor and FSH β subunit knockout mice are similar. In the absence of functional FSH β subunit or FSH receptor, the ovaries are small and follicular development generally goes no further than the preantral stage. The genotype–phenotype correlation in humans with FSH receptor mutations is mirrored by the mouse knockout model; mice heterozygous for a FSH receptor gene mutation have accelerated loss of oocytes resulting in premature reproductive senescence.

Mutations in the transmembrane helices of the FSH receptor and the extracellular domain cause spontaneous ovarian hyperstimulation syndrome.[173] Mutations in the transmembrane helices result in ligand promiscuity, allowing the receptor to respond to endogenous human chorionic gonadotropin (hCG) and thyroid stimulating hormone (TSH), whereas mutations in the extracellular domain display increased specificity and sensitivity to hCG, but not to TSH.

Dominance refers to the status of the follicle destined to ovulate, and its role in regulating the size of the ovulatory quota. The follicle destined to ovulate attains dominance 5 to 7 days after the demise of the corpus luteum of the previous cycle.[174] This conclusion is supported by the observation that the levels of estradiol in the ovarian vein are remarkably different between ovaries by day 5 to 7 of the cycle, attesting to the emergence of the dominant follicle. This follicle continues to thrive under circumstances that it has made inhospitable for competing follicles in both ovaries.

The control of the temporal sequence of events leading up to follicular dominance has been elucidated by ablation studies in infrahuman primates, and also in women in which the dominant follicle or corpus luteum was destroyed or removed. Destruction of the largest follicle on day 8 to 12 in the primate ovary delays the next preovulatory surge of pituitary gonadotropins. Conversely, luteectomy in the midluteal phase (days 16 to 19) advances the gonadotropin surge. In women, the interval from ablation of the dominant follicle or corpus luteum to the next ovulation is 14 days. These findings are consistent with the notion that the cyclic structures of the dominant ovary (i.e., the ovary containing the dominant follicle or corpus luteum) are the timekeepers of the menstrual cycle. The 28-day menstrual cycle is thus the result of the intrinsic life span of the dominant follicle (follicular phase) and corpus luteum (luteal phase), not timing dictated by the brain or pituitary. These elegant experiments were conducted prior to the use of ultrasound monitoring of follicular growth, so it is not possible to reconcile these observations with sequential ultrasound studies of follicular dynamics in cycling women (i.e., follicular waves).

Studies on primate ovaries indicate that the selection of the follicle destined to ovulate has already occurred as early as day 8 of the cycle.[175] No other member of the follicular cohort is competent to serve as a surrogate for a destroyed follicle, and a timely mid-cycle gonadotropin surge is not achieved. In the case of the corpus luteum, the next round of follicular growth occurs only after its interference is removed—either naturally (luteolysis) or artificially (luteectomy). Studies on hormone-replaced luteectomized primates suggest that progesterone is the principal agent responsible for the inhibition of follicular growth in the luteal phase.[176] However, inhibin A secreted by the corpus luteum may also play a role in the suppression of FSH and thus follicular maturation. Also central to the process of follicular development is its vasculature. Inhibition of the action of vascular endothelial growth factor (VEGF) blocks follicular maturation secondary to an attenuation of follicular vascular density or reduced vascular permeability, which may limit access of critical growth factors or hormones necessary for follicular growth.[177]

Endocrine Characteristics of Follicles on the Way to Dominance

Follicles with a diameter of less than 8 mm have a relatively low intrafollicular estrogen-to-androgen ratio, but from the midfollicular phase onward, this ratio is reversed (Fig. 9.13). The "chosen" follicle is able to synthesize estradiol in sufficient quantities to result in appreciable passage of this hormone into the general circulation, and asymmetry in ovarian estrogen secretion as early as day 5 to 7 of the cycle.[178,179] In the late follicular phase, the intrafollicular concentrations of estradiol are directly correlated with follicular size and achieve concentrations of approximately 1 μg/mL at a time when circulating estradiol levels reach their peak.[179-182] After the ovulatory surge of LH, intrafollicular concentrations of estradiol decline and there is a parallel decrease in the concentration of androstenedione. Concurrently, progesterone and 17α-hydroxyprogesterone concentrations increase, reflecting early granulosa cell luteinization.

Inhibin A concentrations in follicular fluid increase with follicular maturation, whereas inhibin B, activin A, and free follistatin do not show variations with follicular size. Thus, as follicles mature, there is a switch from an environment dominated by activin to one dominated by inhibin A. The increase in inhibin A levels is correlated with increased expression of inhibin A α and β subunit mRNAs in granulosa cells.[181]

The IGFs are members of a family of low–molecular-weight, single-chain polypeptide growth factors named for

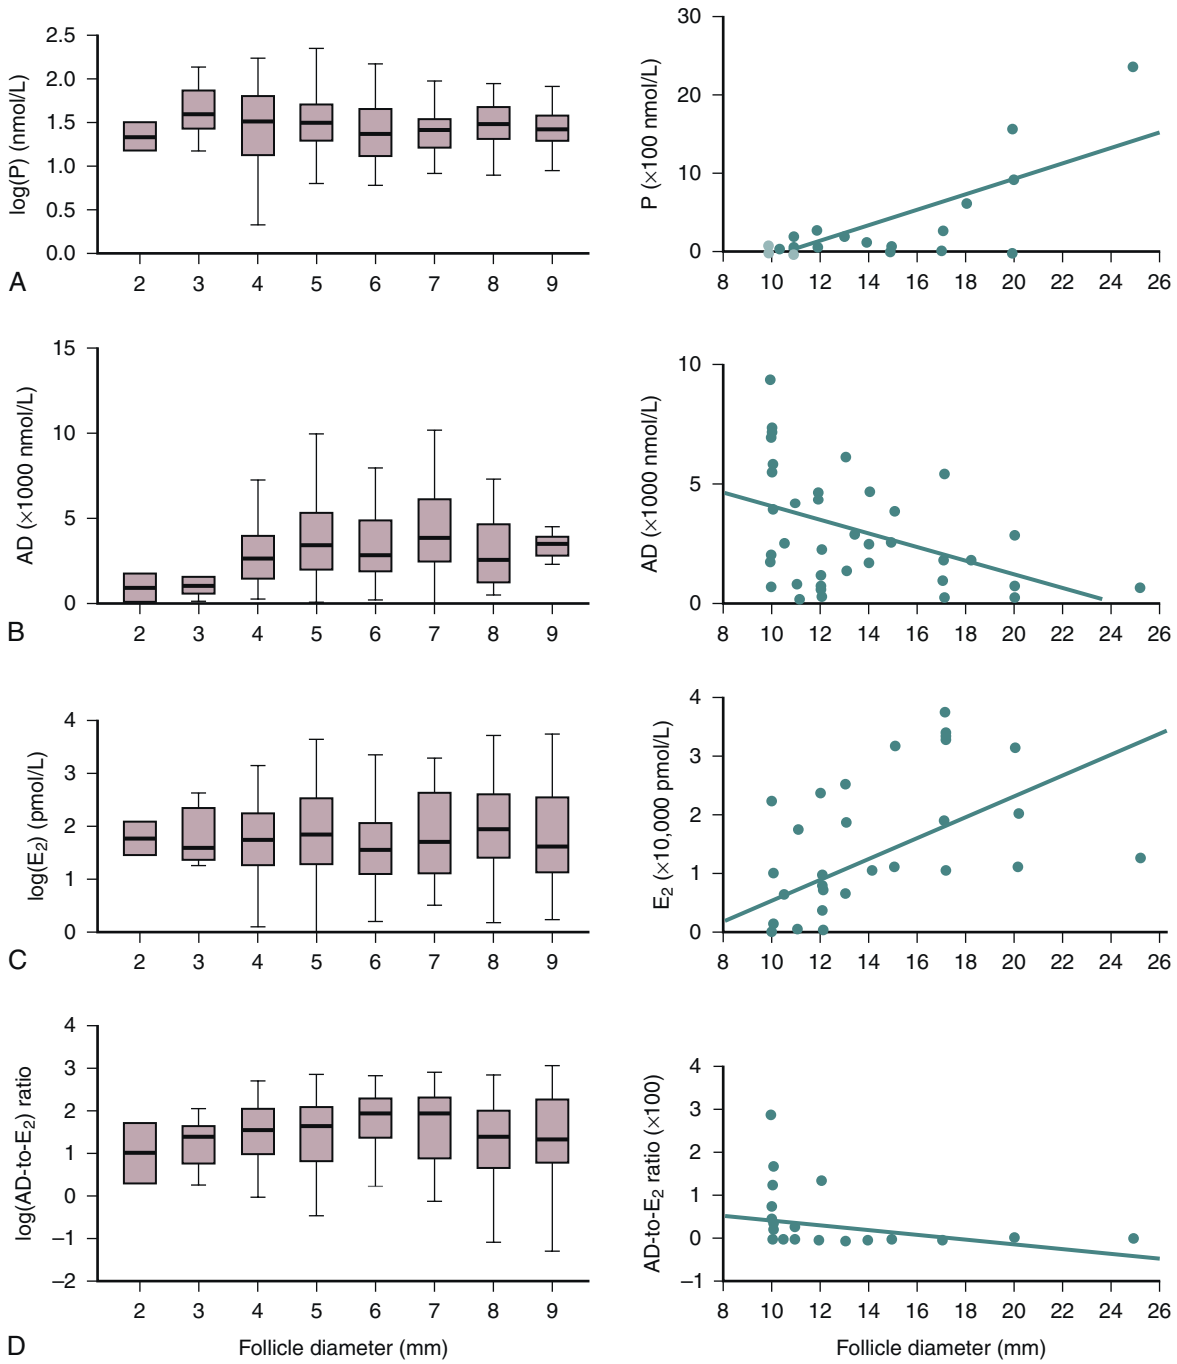

FIGURE 9.13 Follicular fluid steroid levels and follicular diameter. AD, androstenedione; E_2, estradiol; P, progesterone. *(From Van Dessel HJ, Schipper I, Pache TD, et al. Normal human follicle development: an evaluation of correlations with oestadiol, androstenedione, and progesterone levels in individual follicles.* Clin Endocrinol *44:191–198, 1996, with permission.)*

their structural and functional similarity to insulin (Fig. 9.14). Both IGF-1 and IGF-2 are present in human follicular fluid.[183,184] Follicular fluid IGF-1 is most likely derived predominantly from plasma. IGF-2, however, is produced by the theca and perifollicular vessels of all follicles, and the granulosa and theca cells of small antral follicles, and is abundantly expressed by preovulatory granulosa cells. In mice lacking IGF-1, follicular maturation is arrested; in addition, the animals are infertile, and granulosa cell proliferation in the basal state and in response to estrogen is impaired.[185] In women with Laron dwarfism, a disease characterized by IGF-1 deficiency, ovulation induction with human menopausal gonadotropins after administration of a GnRH analog resulted in development of mature follicles and fertilizable oocytes. This finding indicates that, in the human, IGF-1 is not essential for normal follicular development. IGF-2, however, would be present in this situation. Infusion of IGF-1 at levels that raise blood concentrations twofold above normal have no effect on ovarian function in Rhesus monkeys.[186] Thus, the locally produced IGFs appear to be sufficient to promote normal ovarian activity, and elevated IGF levels do not disrupt ovarian function.

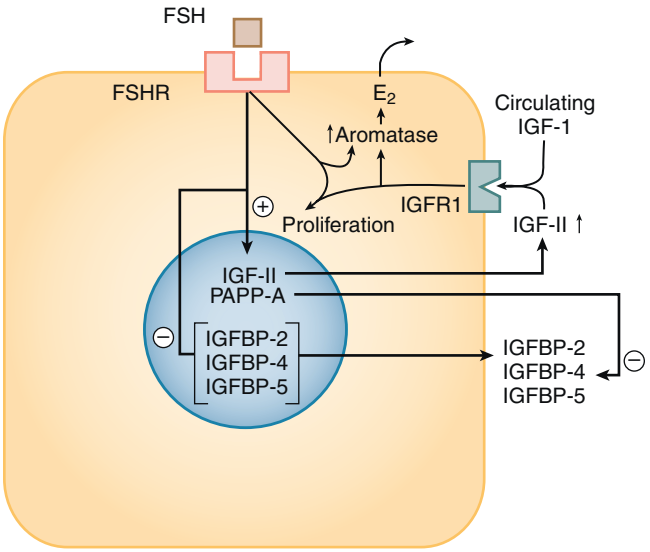

FIGURE 9.14 Intraovarian role of insulin-like growth factors (IGFs) and IGF-binding proteins (IGFBPs) in regulating granulosa cell function. E_2, estradiol; FSH, follicle-stimulating hormone; FSHR, follicle-stimulating hormone receptor; IGFR1, IGF receptor type 1; PAPP-A, pregnancy-associated plasma protein A.

In situ hybridization studies showed that IGF-1 receptors, which are activated by both IGF-1 and IGF-2, are present in the granulosa cells of dominant follicles. IGF-2 receptors, which probably are not involved in signaling, are found in theca and granulosa cells. IGF-1 and IGF-2 stimulate DNA synthesis, granulosa cell proliferation, and steroidogenesis by cultured human granulosa and granulosa–lutein cells. However, these *in vitro* experiments were conducted in restricted culture medium, so the addition of general trophic factors might be expected to increase cellular function.

The action of IGFs is modulated by the local elaboration of binding proteins. Of the seven IGF-binding proteins (IGFBPs) that have been described to date, at least five are expressed in the human ovary. The IGFBPs bind IGFs and neutralize their activity, and they also may have direct actions on ovarian cells. IGFBP-1, -2, -3, -4, and -5 have been identified either in follicular fluid or by analysis of mRNA from granulosa cells. Of these binding proteins, IGFBP-4 is of particular interest because it is a potent antagonist of FSH-stimulated estradiol production by human granulosa cells. IGFBP-4 also is present in atretic follicles, implicating this protein in the pathway leading to follicular atresia.

Secretion of IGFBPs is inhibited by gonadotropins and IGFs, resulting in enhanced IGF bioavailability and gonadotropin action. The proteolytic cleavage of IGFBPs is another mechanism controlling IGF bioavailability. IGFBP-4 protease expression is restricted to healthy follicles and corpora lutea.[187] The metalloproteinase activity of pregnancy-associated plasma protein A (PAPP-A), a large dimeric glycoprotein, degrades IGFBP-4 into inactive fragments. Granulosa cells from small follicles secrete low levels of PAPP-A, whereas granulosa cells from dominant follicles secrete high levels of this protein. The significance of this proteolytic mechanism is underscored by the fact that mice lacking PAPP-A have a reduced number of ovulated oocytes in a stimulated ovulation protocol, which is associated with lower serum estradiol levels, lower serum progesterone levels, and reduced expression of ovarian steroidogenic enzyme genes.

Insight into the importance of estrogens in ovarian function in women comes from the study of subjects in whom estrogen synthesis is impaired. Limited studies have been performed on women with 17α-hydroxylase/17,20 lyase (CYP17) deficiency who are incapable of producing thecal androgens to support granulosa cell estradiol synthesis. Promotion of follicular growth to the preovulatory stage in an estrogen-impoverished environment is possible in these individuals with exogenous gonadotropins after pituitary desensitization. The same is true in severely hypogonadotropic women given exogenous FSH. Follicles grow, but in the absence of exogenous LH, estradiol synthesis is minimal. Moreover, the development of follicular cysts with low estrogen levels is common in women with steroidogenic acute regulatory protein (STARD1), 17α-hydroxylase/17,20 lyase, and aromatase deficiency.[188] Hence, the high levels of estrogen associated with normal follicular maturation are not required for the growth of follicles to the size equivalent to the preovulatory stage.

Whether oocytes that are recovered from estrogen-deprived follicles are endowed with the properties that can lead to successful embryonic development after fertilization is less certain based on limited experience in humans with defects in ovarian estrogen biosynthesis. Animal studies with aromatase inhibitors suggest that estrogens are important for oocyte function.[189] Rhesus monkeys treated during follicular maturation with doses of an aromatase inhibitor that substantially reduces circulating estradiol levels showed no effects on follicular growth. However, a greater proportion of the oocytes recovered from follicles of the aromatase-treated animals were in prophase I, and there was retarded completion of maturation to MII. Whether this is a direct reflection of estradiol deficiency, a consequence of the suicide aromatase inhibitor (1,4,6-androstatrien-3,17-dione), or the result of compensatory changes in endocrine status due to the decline in estradiol is not known. However, clinical experience with competitive aromatase inhibitors like letrozole indicates that aromatase inhibition during follicular growth does not have a major negative impact on oocyte maturation.

The human ovary expresses the receptors that allow a variety of cells to respond to estradiol, but the physiological roles of estrogen in follicular health, maturation, and luteal function remain to be elucidated. Although estrogen receptor α and β1 and β2 are expressed, with the latter two receptor types being more prominent in luteinized granulosa cells, the extremely high levels of estradiol reached in the antrum of the preovulatory follicle (approximately 1 μg/mL) raise questions as to the function of the classical estrogen receptor system, which would be fully saturated by ligand. Moreover, follicle growth per se does not require high levels of estradiol as noted above.

Androgens have a number of effects on the primate ovary.[190-192] Administration of testosterone or 5α-dihydrotestosterone to Rhesus monkeys promotes accumulation of primary follicles as well as follicle survival, suggesting a folliculotropic action. In this model, androgen receptors are abundant in the granulosa cells of healthy preantral and antral follicles, with lesser expression in the theca

and stroma. Moreover, androgen receptors were positively correlated with a marker of cell proliferation (Ki-67) and negatively correlated with apoptosis. These observations contrast with the view that androgens are atretogenic, a concept that emerged primarily from studies on the rodent ovary in which androgens block granulosa cell proliferation *in vitro* in some systems and promote follicular atresia.[193]

Evidence that androgens have a detrimental effect on human follicular function includes the observation that follicular fluid enriched in 5α-dihydrotestosterone and poor in estradiol is characteristic of atresia. However, this steroid profile may be a consequence rather than a cause of atresia. Favoring a causal relationship are reports that high follicular concentrations of 5α-reduced androgens, such as 5α-dihydrotestosterone, act as competitive inhibitors of granulosa cell aromatase activity.[194] In this regard, follicles from patients with PCOS have greater 5α-reductase activity than follicles from normal ovaries. Thus, androgens may exert both positive and negative effects on follicular growth and function in a stage-dependent manner through androgen receptors as well as by nonreceptor-mediated mechanisms.

Ovulation

As mid-cycle approaches, the rise in estrogen emanating from the dominant follicle initiates an LH surge and, to a lesser extent, an FSH surge. This triggers the resumption of meiosis, ovulation, and luteinization (Fig. 9.15).[195]

In a normal menstrual cycle, the FSH-induced appearance of LH receptors on preovulatory granulosa cells allows LH to take over FSH's functions in the terminal stages of follicular maturation. These receptors also enable the granulosa cells to become competent to respond to the LH surge that initiates the resumption of meiosis, ovulation, and subsequent luteinization of the granulosa and theca cells. These events are triggered only when a threshold concentration of LH is achieved and not before that time. Notably, granulosa cells respond to FSH with activation of adenylate cyclase, but genes or events that constitute the program for ovulation and luteinization are not induced. The necessity for some LH to stimulate thecal androgen production and synergize with FSH for follicular maturation, together with the potential for high levels of LH to promote premature luteinization and possibly atresia of follicles that have not reached the Graafian stage, has led to the notion of an "LH window" for follicular maturation. This concept has pharmacological and clinical relevance with respect to ovulation induction.[196] Levels of LH that are capable of stimulating maturation of the dominant follicle retard the growth of smaller follicles and suppress aromatase activity.[170] This effect has led to the theoretical possibility of minimizing multifollicular development by using LH or hCG to drive terminal stages of follicular maturation.[197,198]

The threshold for activation of the ovulation–luteinization program may be sensed by granulosa and theca cells as a result of the intensity of the signal (i.e., the magnitude of the increase in cAMP); it may also be sensed by the activation of adjunctive signal transduction cascades that supplement the increase in cAMP. LH receptor activation of cAMP and IP3 signaling are dependent on LH dose, with a 10- to 100-fold higher level of LH needed to activate phospholipase C. These pathways influence expression of noncoding

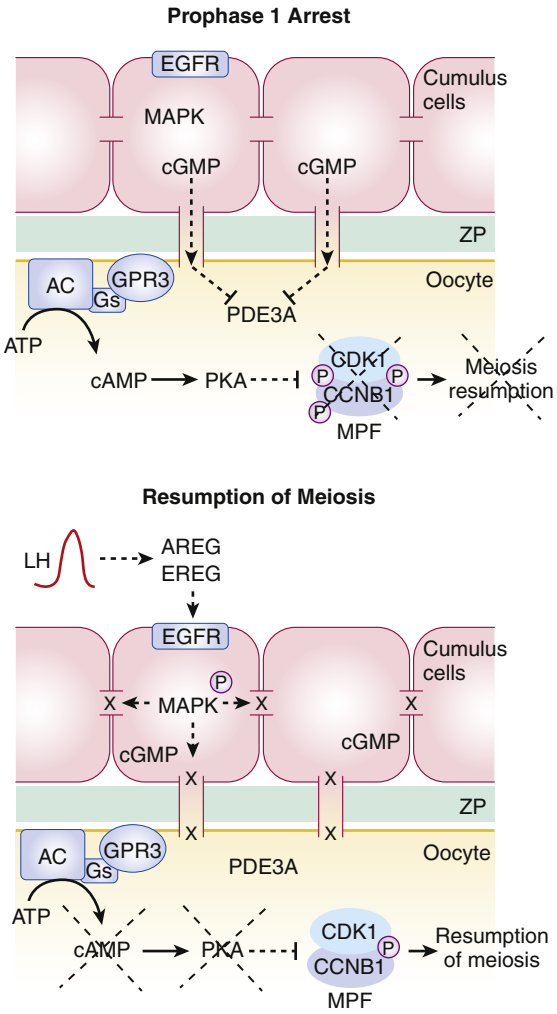

FIGURE 9.15 Meiotic arrest and resumption are controlled by cyclic nucleotides through regulation of maturation promoting factor. A. Prophase I arrest. The constitutively active Gαs-coupled receptor GPR3 stimulates adenylyl cyclase to produce cAMP. cAMP levels in the oocyte remain high because cGMP generated in granulosa and cumulus cells is transported into the oocyte via gap junctions and inhibits the activity of the cAMP phosphodiesterase, PDE3A. cAMP activates PKA, which indirectly prevents dephosphorylation and activation of MPF. B. Resumption of meiosis. The pituitary LH surge promotes expression of EGF-like factors, AREG and EREG, predominantly in the mural granulosa cells. These factors act through EGF receptors on cumulus cells to activate the MAPK pathway, resulting in closure of gap junctions. Additional unknown signaling pathways downstream of the LH surge cause a large drop in cumulus cell production of cGMP. Together with gap junction closure, this results in a dramatic decrease in oocyte cGMP and relief of inhibition of PDE3A. PDE3A then degrades cAMP, reducing PKA activity, indirectly resulting in dephosphorylation of CDK1 inhibitory sites and activation of MPF. MPF phosphorylates targets including lamins, histones, and other cellular components leading to resumption of meiosis.

RNAs, which appear to play a key role in coordinating gene expression patterns in the development of the ovulatory follicle and the response to the ovulatory LH surge.

LH initiates the sequence of events resulting in ovulation in part through the intermediacy of mitogen-activated protein kinases (MAPK). Studies in mouse double mutants for *Mapk1* and *Mapk3* revealed a phenotype of sterility

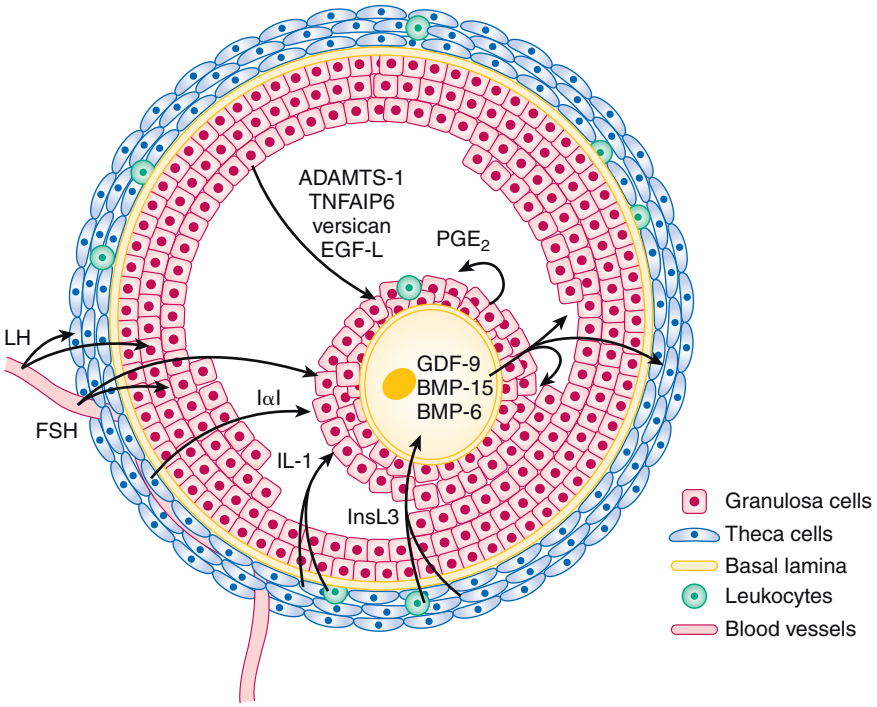

FIGURE 9.16 Mediators of ovulation. Theca cells or leukocytes within the theca layer secrete IL-1, a cytokine that stimulates expansion of the cumulus cells, and InsL3, a peptide that can trigger a reduction in oocyte cAMP levels. The mural granulosa cells secrete EGF family members that promote the cumulus cell responses leading to expansion. The mural granulosa cells also secrete proteins like versican and ADAMTS-1, which are incorporated into the cumulus cell matrix. Inter-α-trypsin inhibitor enters from the blood stream and is also incorporated into the matrix. Induction of prostaglandin synthesis enzymes leading to the formation of prostaglandin E2 by the cumulus cells creates an autocrine loop that drives cumulus expansion through promotion of expression of hyaluronan synthase 2, which leads to deposition of hyaluronan in the matrix, and tumor necrosis factor α-induced protein 6 (TNFAIP6), which catalyzes the covalent crosslinks between hyaluronan and inter-α-trypsin inhibitor. Pentraxin 3 also interacts with inter-α-trypsin inhibitor to stabilize the matrix. Oocyte-derived factors including GDF-9, BMP-6 and BMP-15 modulate granulosa cell responses.

associated with defects in cumulus expansion, ovulation, luteinization, and meiotic maturation.[70] Moreover, granulosa cells continued to proliferate and aromatase expression was maintained, indicating that the differentiation process triggered in granulosa cells by the LH surge involves the MAPK signaling pathway.

LH receptor knockout mice have a relatively normal theca layer around developing follicles.[199] However, follicular maturation is arrested at the early antral stage, and there are no signs of ovulation or luteinization. This phenotype is similar to that found in women with homozygous inactivating mutations in the LH receptor gene *(LHCGR)*. The clinical phenotype of affected women includes normal primary and secondary sexual characteristics, amenorrhea, and elevated circulating FSH and LH. The ovaries contain follicles in stages of development from primordial to antral, with well-developed theca layers, but no preovulatory follicles or corpora lutea. This phenotype supports the notion that LH is required for normal estrogen production by follicles, for ovulation, and for luteinization, but not for the formation of the theca layer.

Activating mutations of the human LH receptor are also informative regarding the role of LH in ovarian function.[199a] Women with these mutations have no obvious reproductive phenotype, in contrast to the precocious puberty found in men. One might have anticipated a hyperandrogenemic state in females, mimicking polycystic ovary syndrome with thecal hyperplasia. However, follicular compartments evidently develop in a coordinated fashion such that thecal responses to LH receptor activation do not occur prematurely. Moreover, levels of cAMP or other second-messenger molecules required for luteinization must be different from those generated by the constitutively active mutant receptor because premature luteinization of follicles does not occur.

The preovulatory LH surge precedes follicular rupture by as much as 38 hours. Before rupture, a number of critical changes take place in the granulosa cells and oocytes, including the suppression of transcription of genes that control granulosa cell proliferation; the loss of gap junction function, which uncouples the electrophysiological syncytium of the granulosa cells and the oocyte; and the induction of genes essential for ovulation in granulosa cells, including the genes encoding the epidermal growth factor–like factors amphiregulin, epiregulin, and betacellulin (Fig. 9.16). In mice, the latter growth factors activate EGF receptors, resulting in the induction of the gene encoding cyclooxygenase-2 (COX-2; *Ptgs2*) in granulosa cells and, consequently, prostaglandin E_2 synthesis. These act in concert with the EGF-like factors to trigger the cumulus cells to elaborate a hyaluronan-rich matrix that causes expansion of the cumulus. As described later, mice deficient in *Ptgs2* and the prostaglandin receptor EP2 *(Ptger2)* have ovulation defects that are related to an abnormality in cumulus expansion.[195,200]

Alterations in the extracellular matrix that promote expansion of the cumulus, a critical process for ovulation,

are mediated by genes encoding hyaluron synthase 2 *(Has2)*, required for production of the hyaluron backbone; the hyaluron-binding proteoglycan versican *(Cpg2)*; TSG-6 *(Tnfaip6)*; and pentraxin 3 *(Ptx3)*.[195,200] The matrix supporting cumulus expansion is composed of a meshlike network of hyaluronan chains that bind TSG-6, which transfers to hyaluronan the heavy chains of serum-derived inter-α-trypsin inhibitor, a complex macromolecule consisting of two heavy chains that are covalently bound to chondroitin sulfate and bikunin, a trypsin inhibitor. Pentraxin 3, a protein that forms pentamers, is another component that organizes the hyaluronan matrix. Mice deficient in TSG-6 and bikunin, one of the components of inter-α-trypsin inhibitor, have an ovulation defect associated with failed cumulus expansion.

A conical stigma eventually rises on the surface of the protruding follicle in preparation for rupture. The rupture of the stigma is accompanied by gentle (rather than explosive) expulsion of the egg and follicular fluid, which suggests that the fluid is not under high pressure.

In primates, ovulation is believed to alternate between ovaries due to the local actions of progesterone produced by the corpus luteum on follicular dynamics. However, this belief has not been supported by definitive evidence. Although some studies suggest that ovulation occurs with equal frequency in the right and left ovaries, others suggest that right-sided ovulation is more frequent.[201-203]

Requirements for Progesterone

An early action of LH in the ovulatory process, which occurs within hours of the surge, is the induction of progesterone receptors in granulosa cells.[204] hCG up-regulates progesterone receptor expression in cultured human granulosa cells in a protein kinase A-dependent fashion. The functional importance of progesterone receptor up-regulation is documented by the fact that progesterone receptor antagonists and drugs that inhibit progesterone synthesis prevent ovulation in laboratory animals and the Rhesus monkey. Moreover, administration of the progesterone receptor antagonist, ulipristal, in the immediate pre-ovulatory period delays follicular rupture in women.

Ovulation does not occur in mice with targeted deletions of the progesterone receptor gene, more specifically, the A form of the receptor. Consistent with a critical role for progesterone in ovulation, mice lacking the transcription factor liver receptor homolog 1 (NR5A2), which is thought to play a role in induction of the steroidogenic machinery required for progesterone synthesis, do not ovulate. Mice lacking a functional *PPARγ* gene, another gene regulated by the progesterone receptor, also show ovulatory defects. Finally, the nuclear receptor interacting protein RIP140 (NRIP1), which was originally described as a transcriptional repressor, is important for ovulation in the mouse. Mice lacking this nuclear protein are anovulatory, and many LH-induced genes are reduced in the mutant ovaries. The mutant mice show defects in cumulus cell function and the expression of genes controlling expansion of the cumulus–oocyte complex.

These observations indicate that progesterone regulates the expression of ovulation genes by a classic mechanism. However, the A form of the progesterone receptor is generally a repressor of transcription, raising the possibility that an important part of progesterone's action in the preovulatory period includes suppression of gene expression. A number of candidate genes that appear to be dependent on periovulatory progesterone have been identified, including a metalloproteinase and cathepsin L. COX-2 expression in progesterone receptor–deficient mice is normal, suggesting that prostanoids are not part of the progesterone-regulated ovulation program.

Requirements for Prostaglandins

The LH surge stimulates prostaglandin biosynthesis by ovarian follicles as a result of induction of the COX-2 enzyme in the preovulatory granulosa cells. COX-1 is not expressed by granulosa cells, and levels of this enzyme in the Graafian follicle do not change in response to an ovulatory stimulus.[205]

The requirement for prostaglandins in the process of ovulation has been revealed through pharmacological studies and gene targeting in mice.[206] Inhibitors of prostaglandin synthesis, administered systemically or locally into the antrum, inhibit ovulation in laboratory animals and Rhesus monkeys and lead to luteinized, but unruptured follicles. Evidence for a role for prostaglandins in human ovulation derives from studies in which rofecoxib, the orally administered selective COX-2 inhibitor, delayed the time of ultrasonographic signs of follicular rupture by more than 48 hours after the LH peak. Signs of rupture were evident within 36 hours in a placebo-treated group.[207,208]

Mice with targeted mutations in the *Ptgs2* gene have defects in ovulation that can be overcome by administration of exogenous prostaglandin E_2, which is believed to be the key prostaglandin involved in ovulation. One of the abnormalities in *Ptgs2* knockout mice is a failure of the cumulus to expand. Mice deficient in the EP2 receptor for prostaglandin E_2 also have an ovulation defect and a postovulatory abnormality in cumulus expansion. These observations implicate prostaglandin E_2 in the process of ovulation and cumulus expansion. Progesterone receptors are induced in the follicles of COX-2–deficient mice, providing further evidence that the roles of progesterone and prostaglandins in ovulation are distinct.

Requirement for EGF-like Factors

Luteinizing hormone stimulation induces the rapid, transient and sequential expression of the EGF-like growth factors amphiregulin, epiregulin, betacellulin, and neuregulin 1. These are synthesized as granulosa cell integral membrane proteins that are released by proteolytic cleavage of the extracellular domain. Upon release they bind to EGF tyrosine kinase receptors (ERBB2 and ERBB3). Incubation of rodent follicles *in vitro* with these growth factors recapitulates the morphological and biochemical events triggered by LH, including the necessary process of cumulus expansion and oocyte maturation. Mice with mutations in *Are* (amphiregulin) or *Ereg* (epiregulin) have an ovarian phenotype consistent with an *in vivo* role of these proteins in that they show reduced cumulus expansion in response to exogenous gonadotropins. Thus, the EGF-like growth factors are essential mediators of the follicular response to LH leading to ovulation.[209,210]

Mechanisms of Follicular Rupture

Several hypotheses have been advanced to explain the process of follicular rupture. An increase in hydrostatic pressure

is evidently not involved, because direct measurements have demonstrated that intrafollicular pressure is low in periovulatory follicles.[211,212] An increase in colloid osmotic pressure has been described, in part due to changes in concentrations of granulosa cell–derived proteoglycans. However, a cause-and-effect relationship between the altered composition of antral fluid and the enlargement and rupture of the follicle remains to be established.

Stigma formation and rupture also reflect the actions of enzymes working locally on the follicle wall. Instillation of protease inhibitors into the antral fluid inhibits ovulation. Among the candidate proteases proposed to be involved in ovulation are the plasminogen activators and members of the matrix metalloproteinase (MMP) family. Plasminogen activator has been localized in increasing concentrations in the walls of rat ovarian follicles just before ovulation.[195,213] But studies in knockout mice deficient in urokinase, tissue plasminogen activator, and plasminogen indicate that plasmin is not necessary for follicular rupture or, for that matter, for the activation of other proteases that might participate in ovulation.[213]

Mice deficient in MMP-3 (stromelysin-1), MMP-7 (matrilysin), MMP-9, and MMP-11 (stromelysin-3) reproduce normally, suggesting that, individually, these enzymes do not have an obligatory role in ovulation. The involvement of other members of the MMP family (e.g., MT1-MMP, ADAM-17) cannot yet be determined from existing knockout mice, because the mutant animals die either *in utero* or shortly after birth.

Members of the A disintegrin and metalloproteinase and thrombospondin motifs (ADAMTS) family appear to play a key role in ovulation. ADAMTS1 is induced in granulosa cells of the preovulatory follicle, but not in progesterone receptor knockout mice. Consequently, this gene has been implicated as a progesterone-regulated factor involved in ovulation.[195,200,213] Targeted deletion of the *Adamts1* gene in mice results in defects in follicular growth, ovulation, and consequently, female infertility, possibly as a result of abnormal cumulus expansion or release of active growth factors. ADAMTS4 may have a related role. Cathepsin L is another progesterone-regulated gene that degrades type I and type IV collagens, elastin, and fibronectin, all components of the follicle wall, and consequently, it could play a role in ovulation.

Rhesus monkey dominant follicle MMP1, MMP10, and MMP19, ADAMTS4, ADAMTS9, and ADAMTS15, cathepsin L, and urokinase-type plasminogen activator mRNA levels were up-regulated 12 hours after administration of an ovulatory dose of hCG. Moreover, a metalloproteinase inhibitor (GM6001) injected into the preovulatory follicle at the time of hCG administration prevented stigmata formation.

Oocyte Maturation

It has been known for decades that a follicle-derived oocyte maturation inhibitor was likely to be responsible for the maintenance of meiotic arrest because removal of an oocyte from its intrafollicular environment results in the spontaneous resumption of meiosis in culture. Thus, meiotic inhibition requires the intermediacy of the surrounding granulosa cells. Although the full biochemical nature of the oocyte maturation inhibitor remains a mystery, experiments in mouse models have identified many of the downstream mediators responsible for controlling meiotic arrest.

As in somatic cells, the oocyte cell cycle is controlled by alterations in the levels and activities of proteins now known as *cyclins* and *cyclin-dependent kinases*.[214,215] One of these proteins, maturation-promoting factor (MPF), was defined in bioassays as an activity that induced resumption of meiosis when microinjected into oocytes. MPF later was found to be a heterodimer of two proteins: cyclin B and cyclin-dependent kinase-1, or CDK1.[216-218] MPF is present in fully grown oocytes, but prior to the ovulatory LH surge its activity is restrained by the actions of two cyclic nucleotides, cyclic AMP (cAMP) and cyclic GMP (cGMP) (Fig. 9.15).

In prophase I-arrested oocytes, cGMP generated in the granulosa cells continuously enters the oocyte via gap junctions. Once in the oocyte, cGMP inhibits cAMP phosphodiesterase 3A (PDE3A), preventing breakdown of oocyte-derived cAMP.[219,220] The majority of oocyte cAMP is generated because of the presence of a constitutively active receptor, GPR3, at the plasma membrane. GPR3 couples to the stimulatory G protein Gs, which activates adenylyl cyclase and results in constant production of cAMP. Oocytes from *Gpr3* knockout mice fail to generate cAMP and therefore resume meiosis independently of an increase in LH.[221] A similar receptor expressed in rat oocytes, GPR12, may have this role. The steady state oocyte cAMP level is a balance of cAMP generated at the plasma membrane by adenylyl cyclase and cAMP degradation by cytoplasmic PDE3A activity.[222-224]

Oocyte-derived cAMP maintains meiotic arrest by stimulating activity of the cAMP-dependent protein kinase (PKA).[225,226] PKA phosphorylates at least three different proteins, WEE1B, MYT1, and CDC25B, resulting in inhibition of MPF activity and prevention of meiosis resumption.[227,228] As long as oocyte PDE3A activity is blocked by cGMP derived from granulosa cells, the amount of cAMP generated by the constitutively active Gs-linked receptor is sufficient to stimulate PKA activity and thereby maintain MPF in an inactive state. The requirement for cGMP to enter the oocyte from granulosa cells explains the spontaneous resumption of meiosis that occurs when the oocyte is removed from the follicle.

Resumption of Meiosis

The mid-cycle LH surge is responsible for initiating a series of events in the mature antral follicle that collectively result in activation of MPF and resumption of the meiotic cell cycle. Nuclear maturation is first visible morphologically when the germinal vesicle breaks down as a result of disruption of the nuclear lamins. With exposure to the cytoplasm, the chromatin condenses and moves toward the cortical region, and the meiosis I spindle forms. Progression through the remainder of meiosis I, with extrusion of the first polar body containing half of the oocyte's chromosome complement, soon follows (Fig. 9.17 and Table 9.2). The meiotic cell cycle proceeds immediately to metaphase of meiosis II and then becomes arrested at this stage; the oocyte is now referred to as a *secondary oocyte* or *metaphase II–arrested egg* (Fig. 9.17). Arrest in metaphase II occurs before physical release of the egg from the follicle during ovulation.

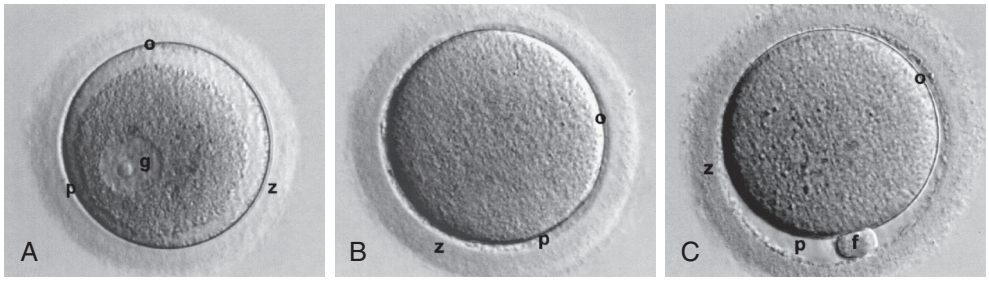

FIGURE 9.17 Appearance of human oocytes during meiotic maturation. **A,** Immature, germinal vesicle–intact stage. The chromatin is arrested in prophase of meiosis I; meiotic maturation has not begun. **B,** Germinal vesicle breakdown stage. Meiosis I has resumed, with breakdown of the germinal vesicle; the chromatin is progressing through the remainder of meiosis I. **C,** Mature oocyte. The first polar body has been emitted, and the remaining chromatin is arrested in metaphase of meiosis II. f, first polar body; g, germinal vesicle; o, oolemma (oocyte plasma membrane); p, perivitelline space; z, zona pellucida (200×). *(Adapted from Veeck LL. An Atlas of Human Gametes and Conceptuses. New York: Parthenon Publishing, 1999.)*

Table 9.2 The Acquisition of Meiotic and Developmental Competence in the Oocyte

	Primordial Oocytes	Primary	Preantral	Antral	Fully Grown Oocytes	MII-Arrested Eggs
Growth	Resting	Early growth	Mid growth	Late growth	Complete	Complete
Transcription	Limited	Active	Active	Active	Limited	Limited
GVBD	Incompetent	Incompetent	Competent	Competent	Competent	Complete
MII	Incompetent	Incompetent	Incompetent	Competent	Competent	Complete
Embryogenesis	Incompetent	Incompetent	Incompetent	Limited	Limited	Competent

GVBD, germinal vesicle breakdown; MII, metaphase.

Completion of meiosis, with extrusion of the second polar body, does not occur until fertilization.

Modulation of the levels of cGMP and cAMP within both the follicle cells and the oocyte are critical factors regulating meiosis. Midcycle LH surge-mediated stimulation of Gs-coupled LH receptors on follicular cells results in the activation of Gs and generation of cAMP by follicle cell transmembrane adenylyl cyclases. This cAMP subsequently activates transcription factors such as cAMP-response element binding protein 1 (CREB1) and cAMP-response element modulator (CREM) that induce or repress the transcription of specific genes important in modulating follicular cell function during oocyte maturation and ovulation.

Key events downstream of follicle cell LH receptor activation are decreased generation of cGMP in the cumulus cells and closure of gap junctions between the oocyte and cumulus cells, which together result in a precipitous drop in oocyte cGMP levels.[219] In response, oocyte PDE3A becomes active and breaks down cAMP, resulting in a loss of the PKA activity required to restrain MPF from inducing meiotic maturation. The LH-induced gap junction closure is mediated in part by synthesis and release from mural granulosa cells of the epidermal growth factor receptor (EGFR) ligands amphiregulin and epiregulin.[229] These ligands cause an increase in EGFR kinase activity that is required for gap junction closure. Follicle cells may also secrete other paracrine factors that promote oocyte maturation. For example, theca cells secrete insulin-like 3, which activates the inhibitory G protein (Gi)-coupled receptor, LGR8, found at the oocyte plasma membrane, diminishing oocyte cAMP production.[230]

There is clear evidence in lower species that steroid hormones are responsible for inducing oocyte maturation. Although steroids have been proposed to induce meiotic maturation in mammals, inhibition of follicular steroid production or action does not prevent resumption of meiosis in response to LH, so steroids cannot be obligatory for this process.

In addition to triggering alterations in oocyte MPF activity, the LH surge also induces translation of stored maternal mRNAs that are sequestered from the translational apparatus until meiotic maturation begins. One of these newly translated mRNAs encodes the serine-threonine kinase MOS, which is a component of a biological activity known as *cytostatic factor*, defined by its ability to induce metaphase arrest when microinjected into an actively dividing cell.[231] MOS indirectly activates a mitogen-activated protein (MAP) kinase that is responsible, at least in part, for the arrest of the oocyte cell cycle at metaphase of meiosis II.[232-234] Mice deficient in MOS are subfertile because their oocytes do not arrest at metaphase II.[235] Instead, the oocytes continue to divide without being fertilized (parthenogenetic activation) and as a result, the mice develop teratomas. With sufficient MOS production, eggs remain arrested in metaphase II until fertilization. The fertilizing sperm induces calcium oscillations that cause cyclin destruction and degradation of MOS protein, resulting in resumption of meiosis II and extrusion of the second polar body.

A family of C29 4,4-dimethylsterol intermediates in the biosynthetic pathway from lanosterol to cholesterol has been found to induce oocytes to resume meiosis.[236] One of these sterols, 4,4-dimethyl-5α-cholest-8,14,24-triene-3β-ol, was extracted from human follicular fluid and named follicular fluid meiosis–activating substance (FF-MAS). A related compound, 4,4-dimethyl-5α-cholest-8,24-diene-3β-ol, was isolated from bull testis and called T-MAS. These compounds are synthesized from lanosterol by P450 14α-demethylase, which is encoded by the *CYP51* gene.

FF-MAS and T-MAS are present in micromolar concentrations in preovulatory follicle follicular fluid: 1.6 μM for FF-MAS and about half that for T-MAS.

The accumulation of FF-MAS and T-MAS in mature follicles may be the result of increased synthesis as well as inhibition of cholesterol synthesis at steps beyond the formation of FF-MAS and T-MAS. Gonadotropins have been reported to cause a several-fold increase in *Cyp51* gene expression in rodent ovaries, which could contribute to enhanced MAS formation.[237] Additionally, progestins at concentrations found in follicular fluid in the preovulatory period block cholesterol synthesis at late steps, which would result in an accumulation of FF-MAS and T-MAS.

When perfused into rodent ovaries, FF-MAS can induce maturation of cumulus cell–deprived oocytes or oocyte maturation. However, experiments using various inhibitors of sterol synthesis—including drugs that block 14α-demethylase and those that inhibit enzymes that metabolize MAS—have yielded conflicting results. Inhibitors of 14α-demethylase block gonadotropin-stimulated, but not spontaneous meiosis in rodents, whereas drugs that block MAS metabolism generally result in germinal vesicle breakdown of cumulus-enclosed oocytes. Consequently, the physiological roles of FF-MAS and T-MAS in oocyte maturation, if any, remain uncertain. The pharmacological value of FF-MAS and T-MAS also is uncertain. Some, but not all, studies on *in vitro* oocyte maturation suggest effects of these compounds on maturation by stimulating progression to metaphase II or increasing the survival of oocytes without affecting maturation.

Cytoplasmic Maturation

A process of "cytoplasmic maturation," less obvious than the morphological changes of nuclear maturation, also occurs subsequent to the LH surge and is critical for successful egg activation and preimplantation embryo development should the egg be fertilized. At the ultrastructural level, there are changes in the distribution of the organelles, with movement of the endoplasmic reticulum, mitochondria, and cortical granules toward the oocyte cortex.[237a] The organelle movement is mediated by both microtubules and microfilaments, and depends on the presence of a fibrous structure in the oocyte cytoplasm known as "cytoplasmic lattices."[238,239] The Golgi complex breaks down, explaining the extensive decline in the ability of the mature egg to synthesize new proteins. With movement of chromatin to the cortical region, the oocyte becomes highly asymmetric. The actin cytoskeleton is altered, with a thickening of cortical actin overlying the metaphase II spindle. This region of the plasma membrane is devoid of microvilli—unlike the rest of the oocyte plasma membrane, which is enriched with microvilli. This loss of microvilli may reduce the chance of sperm entering the region of the metaphase II spindle, potentially interfering with the normal progression of meiosis.

The transition metal zinc is an essential element that serves both structural and catalytic roles within numerous cellular proteins such as zinc-finger transcription factors and metalloenzymes. Extensive zinc accumulation occurs during meiotic maturation, with an overall increase in oocyte zinc content of about 50%.[240] Reduction of available zinc in prophase I-arrested, germinal vesicle intact oocytes causes resumption of meiosis by perturbing the function of the zinc-binding protein FBXO43 (previously known as EMI2), and also causes abnormalities in cortical reorganization leading to diminished cell polarity.[241,242] The mechanisms mediating zinc uptake and storage in the oocyte are not yet defined, but likely involve plasma membrane zinc transporters and sequestration in subcellular compartments.

At the molecular level, cytoplasmic maturation is accompanied by the recruitment of specific dormant maternal mRNAs that are translated into protein. In rodents, examples of these recruited mRNAs are *Mos*, tissue plasminogen activator *(Plat)*, and the inositol 1,4,5-triphosphate receptor, type 1 *(Itpr1)*. As mentioned above, translation of *Mos* is critical for blocking cell cycle progression beyond metaphase II. Studies in the mouse suggest that the maturation-associated increase in IP3R-I protein is important for successful egg activation by increasing the ability of the egg to exhibit calcium oscillations.[243] The role of tissue plasminogen activator has yet to be clarified.

The molecular mechanism by which maternal mRNAs are recruited is cytoplasmic polyadenylation. Specific nucleotide sequences in the 3′ untranslated region of these mRNAs, known as *cytoplasmic polyadenylation elements*, direct the binding of poly(A) polymerase to those mRNAs and the addition of poly(A) tracts. Among the proteins that regulate this process are cytoplasmic polyadenylation binding element protein 1 (CPEB1) and deleted in azoospermia-like (DAZL).[244,245] Polyadenylation leads to the association of specific maternal mRNAs with polysomes, translation of the mRNAs, and consequently to increases in the levels of the encoded proteins.

Post-translational modification of cytoplasmic proteins also occurs during oocyte maturation. For example, microtubules undergo alterations in acetylation during the transition from metaphase I to metaphase II.[246] Microtubule acetylation is essential for proper organelle positioning and movement, possibly by affecting interactions between tubulin and cytoplasmic lattices.[239] In addition, phosphorylation and dephosphorylation of cytoplasmic proteins, particularly those involved in regulating the cell cycle, are required for successful cytoplasmic maturation.

Atresia

Atresia occurs at all stages of follicular development, spontaneously or in response to environmental factors or drugs.[247,248] Spontaneous atresia is primarily a reflection of the absence of essential trophic factors at critical times in follicular formation or maturation (e.g., FSH, IGFs, and other growth factors).[249,250] In fetal ovaries, apoptotic cell death is primarily responsible for elimination of germ cells. In adult quiescent follicles, the oocyte and granulosa cells are both involved in apoptotic death, whereas in growing follicles it is the granulosa cells that first undergo changes leading to atresia.[251] In growing follicles undergoing atresia, apoptotic granulosa cells begin to accumulate, whereas apoptosis is not evident in the oocyte or theca.[253]

The importance of apoptosis in the control of follicular dynamics is illustrated in the phenotypes of mutant mice. Mice lacking acid sphingomyelinase, an enzyme that produces the proapoptotic signaling molecule, ceramide, have

an enlarged oocyte reserve and are resistant to oocyte depletion by anticancer drugs and radiation. Fas-deficient mice (*lpr/lpr* mice) have increased numbers of secondary follicles, reduced numbers of large antral follicles, and defective oocyte and granulosa cell death in response to FAS ligand. The pattern of expression of FAS antigen in the human ovary, with abundant staining in oocytes of atretic primordial and primary follicles and granulosa cells of atretic antral follicles, is consistent with a role for Fas in atresia.[169] In mice lacking the proapoptotic protein, BAX, oocyte reserve is augmented due to reduced postnatal apoptosis and defective granulosa cell apoptosis.[252] Conversely, mice lacking the antiapoptotic protein, BCL-2, have a diminished oocyte reserve. The same is true for mice lacking *Bcl-w* or mice engineered with a hypomorphic *Bcl-x* allele. Mice lacking the death effector enzymes caspase-2, caspase-9, and caspase-11 have enlarged oocyte reserves as a result of attenuated fetal germ cell apoptosis. Caspase-12–deficient mice are resistant to anticancer drug–induced germ cell death and caspase-3–deficient mice display aberrant atresia as a result of defective granulosa cell apoptosis. In addition, TNF-α and TNF-α-related apoptosis inducing ligand (TRAIL) are implicated in apoptosis of granulosa cells in follicles undergoing atresia (Fig 9.18).

The kinases, PI3K and AKT, have emerged as central anti-apoptotic signaling molecules. They exert their influence through phosphorylation of the forkhead transcription factors FOXO1 and FOXO3, which when phosphorylated are excluded from the nucleus. When dephosphorylated, these factors activate transcription of pro-apoptotic genes including FAS ligand and pro-apoptic proteins of the BCL2 family, ultimately leading to activation of caspases (caspases 8, 9, and 3).[253]

Spontaneous Twinning and Spontaneous Ovarian Hyperstimulation Syndrome

Spontaneous dizygotic twinning, a result of multiple follicular maturation, is associated with elevated FSH levels, is more prevalent in older women, and is also a genetic trait.[254] The highest rate of spontaneous dizygotic twinning has been recorded in the Yoruba people of Nigeria, with an incidence fourfold greater than in white individuals.[255] The genes governing this trait, which presumably control either FSH levels or follicle sensitivity to FSH, have not yet been identified. Putative mutations and variants in several obvious candidate genes—including the inhibin α subunit, and the BMPRIB receptor—have been excluded from being major contributors to familial dizygotic twinning. However, a potential functional variant in the 5′-untranslated region of the FSH receptor gene that segregated with the dizygotic twinning has been reported. Rare genetic variants/mutations in the *GDF9* gene have been reported in mothers of dizygotic twins, but a causal link has not been established. There is no evidence that mutation in *BMP15* or its cognate receptors are associated with dizygotic twinning in women.[254, 256-258] However, this finding has yet to be confirmed, and more recent studies suggest complex inheritance patterns for dizygotic twinning, at least in Caucasian populations.[259]

Spontaneous ovarian hyperstimulation syndrome is exceedingly rare. It is associated with mutations in the FSH receptor gene that result in a nonsynonymous amino acid

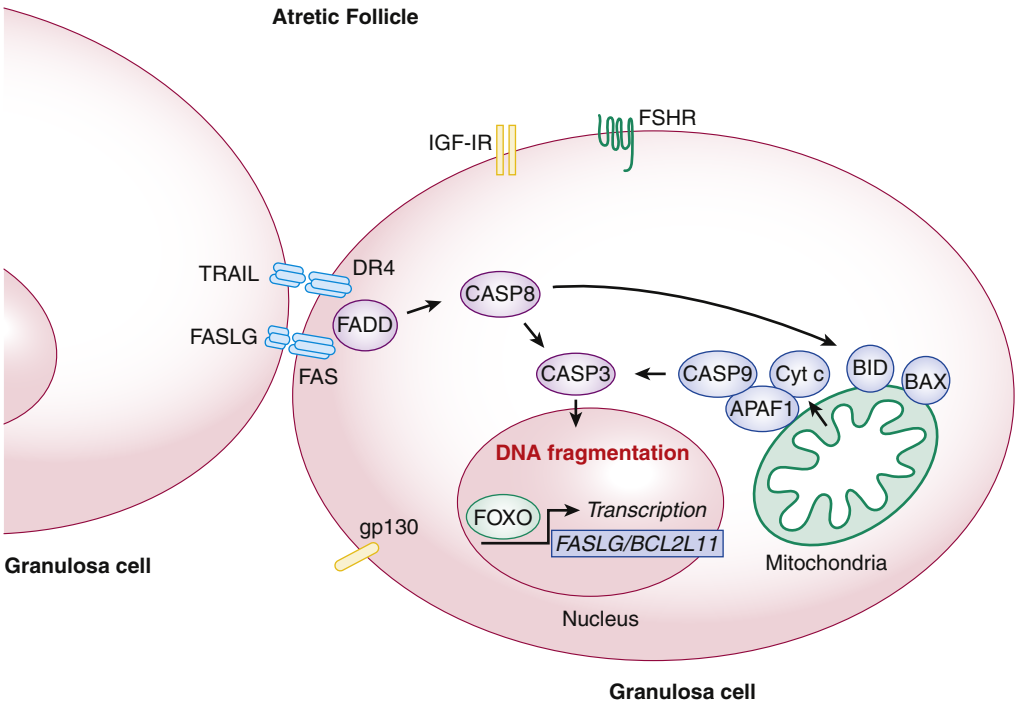

FIGURE 9.18 Factors involved in granulosa cell apoptosis. When cell survival signals such as FSH or insulin-like growth factos (IGF) decline, forkhead transcription factors (FOXO) are dephosphorylated and enter the nucleus where they stimulate production of pro-apoptotic genes including Fas ligand (FASLG) and BCL2LII. Death ligand receptors (FASLG-FAS and TRAIL-DR4) expression on the plasma membrane is increased. This triggers a cascade leading to activation of caspases (CASP) including via the release of cytochrome C from mitochondria, resulting in nuclear DNA fragmentation. *(Modified from Matsuda et al.* J Reprod Develop *58: 44–50, 2012.)*

substitutions (e.g., D576N) that broaden its ligand specificity to include hCG and TSH. Five mutations have been identified, all located in the seven transmembrane domains of the receptor.[260]

Corpus Luteum Formation, Function, and Demise

Initial Stages of Corpus Luteum Formation

After ovulation, the ruptured follicle is reorganized into the corpus luteum. The process of luteinization and formation of a corpus luteum is associated with significant alterations in gene expression, encompassing hundreds of different genes in the granulosa cells alone.[261] A prominent feature of this reorganization is the establishment of a rich vascular network. The hemorrhage into the ovulatory cavity associated with follicular rupture is accompanied by proliferation and penetration of capillaries and fibroblasts from the surrounding stroma. The resulting neovascularization of the developing corpus luteum makes it possible for large blood-borne molecules, such as LDL, which provides cholesterol substrate for progesterone production, to reach the granulosa and theca–lutein cells, and for secretory products to be efficiently transported into the circulation. The development of the corpus luteum blood supply thus parallels progesterone production. By the time the corpus luteum is fully formed, endothelial cells make up approximately 50% of the cellular content.

The vascularization of the corpus luteum is directed by angiogenic factors, including VEGF and basic FGF, which are triggered by LH.[262-264] There is a sixfold rise in VEGF in monkey follicular fluid within 6 hours of an ovulatory stimulus, with sustained elevations in VEGF concentrations lasting up to 36 hours. The granulosa cells appear to be a primary source of VEGF. Because there are no significant changes in VEGF mRNA during this time, the rise in VEGF protein appears to be a consequence of a post-transcriptional mechanism.

Evidence for an important role for VEGF in the development of the corpus luteum vascular network includes the finding that soluble VEGF receptor (FLT-1) administered to gonadotropin-treated rats almost completely suppresses luteal angiogenesis. The Notch ligand, delta-like ligand 4, which negatively regulates VEGF-mediated vessel sprouting and branching, plays a role in the development of the corpus luteum vasculature since *in vivo* neutralization of this factor results in enhanced angiogenesis and vascular density.

Moreover, as noted previously, VEGF appears to play an important role in follicular development before the LH surge because inhibition of VEGF by neutralizing antibodies or truncated FLT-1 interrupts preovulatory follicle development. The angiopoietins and the TIE-2 receptor expressed on endothelial cells also appear to contribute to the development and maintenance of the luteal vascular network, based on their spatial and temporal patterns of expression.

The mural granulosa cells undergo significant morphological changes in response to the LH surge, collectively referred to as *luteinization*. The mitotic potential of these cells is lost, as reflected in changes in the genes involved in granulosa cell proliferation: cyclin D2 expression is terminated, whereas cell cycle inhibitors *p21cip* and *p21kip* are increased.[265] The expression of genes encoding proteins involved in progestin synthesis (including *STARD1*, and *3BHSD2*) is dramatically increased as well.

The human steroidogenic cells of the corpus luteum are heterogeneous in size and function.[266-268] Luteinized granulosa and theca cells are both present. These two different cell types have different functional characteristics, as defined by immunohistochemistry and studies of their steroidogenic activity after purification. The granulosa–lutein cells display greater basal production of progesterone and are the presumed sites of luteal estrogen synthesis because they express aromatase. The theca–lutein cells have 17α-hydroxylase/17,20 lyase activity. These cells presumably produce the androgen precursors that are aromatized by granulosa–lutein cells, and they are probably the main sites of luteal 17α-hydroxyprogesterone production. Thus, a two-cell system for estrogen synthesis exists in the corpus luteum as it does in the follicle.

With respect to progesterone production, there are differences in the characteristics of cells of different sizes within the corpus luteum and their *in vitro* responses to trophic stimulation. These variations have been shown by studies on dispersed cell preparations purified on density gradients.

Relaxin, a hormone that may play a role in facilitating decidualization of the endometrium, suppression of myometrial contractile activity, and the maternal adaptation to pregnancy is produced by the large luteal cells of the corpus luteum from one of the two genes encoding this hormone (*RLN2* gene).[269] Immunohistochemical studies show progressive accumulation from the early to late luteal phases, with corpora lutea in the late luteal phase containing the most intensely stained cells. The highest circulating levels of relaxin are achieved in the first trimester, and levels then decrease by approximately 20% and remain constant throughout pregnancy.

The Role of Luteinizing Hormone

In addition to inducing ovulation and luteinization, LH has a central role in the maintenance of corpus luteum function. Long-term withdrawal of LH support in a variety of experimental circumstances almost invariably results in luteal regression. Withdrawal of LH during the monkey luteal phase, either by passive immunization or by termination of gonadotropin-releasing hormone (GnRH) infusions in animals dependent on GnRH to drive gonadotropin secretion, leads to a pronounced decline in progesterone and other steroid hormone levels.[270] Administration of a GnRH antagonist to women in the luteal phase also causes a marked fall in peripheral progesterone levels within 6 hours of treatment (Fig. 9.19). In the monkey model, luteal progesterone production is restored when LH levels recover if the LH deprivation has not been prolonged. The trophic role of LH in controlling luteal progesterone secretion is evident during the human mid- and late luteal phases, when LH secretion is characterized by distinct pulses and a corresponding pulsatile pattern of progesterone secretion is observed.[271]

It is notable that the monkey corpus luteum can be deprived of LH support for several days but can recover its endocrine function when LH is restored, remembering its temporal history and surviving for the usual 14-day duration.[270] This intrinsic memory suggests that the process

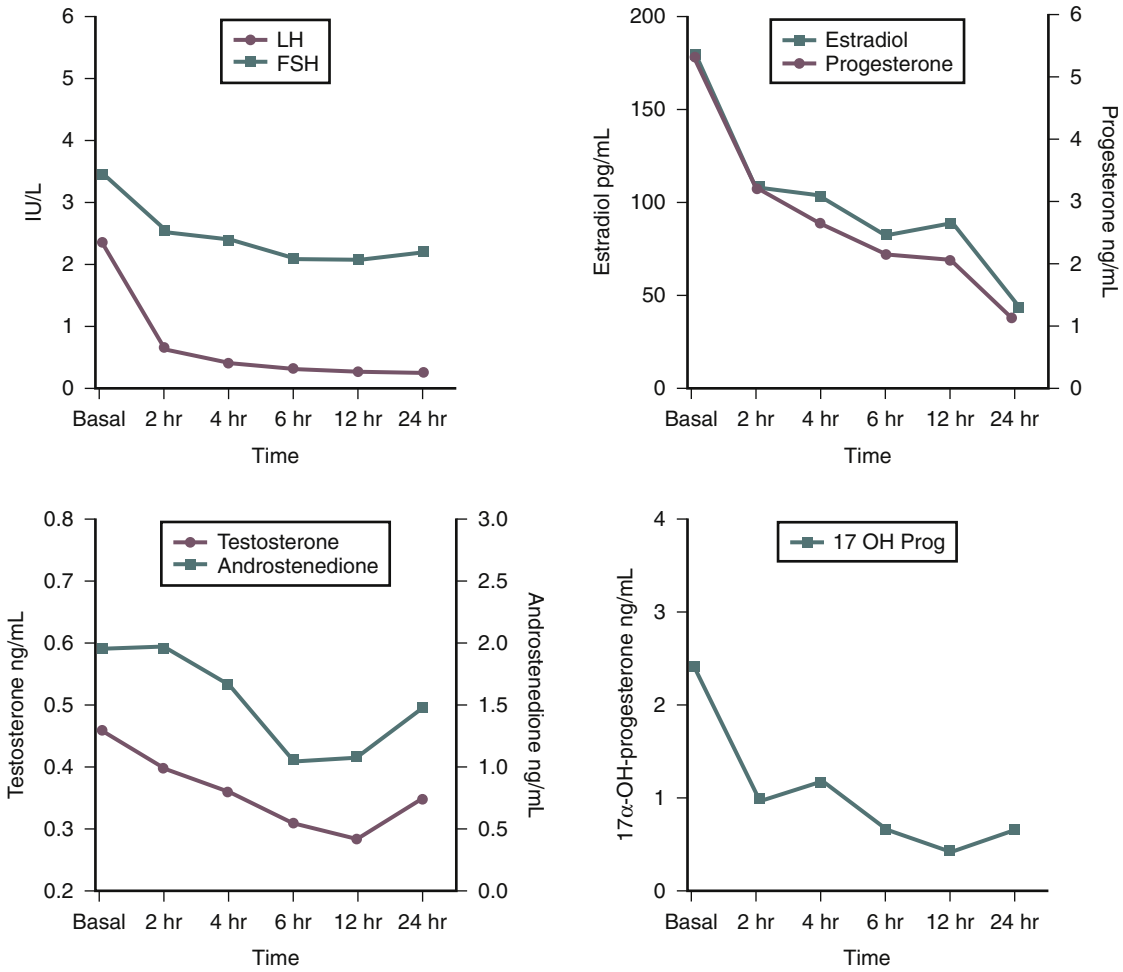

FIGURE 9.19 Effects of the gonadotropin-releasing hormone receptor antagonist cetrorelix (2 mg subcutaneously) on function of the midluteal phase corpus luteum. Plasma gonadotropin and steroid concentrations in a woman receiving cetrorelix in the midluteal phase. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

of luteinization triggers a preprogrammed life cycle that will play out in the absence of conception. The molecular and cellular mechanisms of this clock remain to be elucidated. One hypothesis is that the timekeeping is the result of sequential events that include steroid modulation of infiltration of leukocytes and immune cells that eventually suppress luteal function through the elaboration of cytokines.

Levels of LH/CG receptors in corpus luteum membranes rise progressively during the human luteal phase and then decline, but remain detectable by binding assays, even in the late luteal phase. This receptor is evidently fully engaged immediately after the endogenous LH surge, because injection of 10,000 IU hCG within the first few days after ovulation does not elicit a substantial increase in progesterone production.[272] However, by the mid- and late luteal phases, the corpora lutea show substantial steroidogenic responses to exogenous hCG. LH and hCG receptor mRNA expression tends to follow the same pattern as LH and hCG binding, with an increase in transcript abundance from the early to midluteal phases and a decline at the time of menses.[273,274] However, LH and hCG receptor transcripts are maintained should pregnancy occur.[275] In the Rhesus monkey, LH receptor mRNA expression is maintained in the late luteal phase and only declines after menstruation.[276-279]

Progesterone as a Luteotropin

The human corpus luteum produces 25 to 50 mg of progesterone daily. The luteal cells also appear to respond to this steroid, so it has both an endocrine and an intracrine role in reproduction. In the Rhesus monkey, the progesterone receptor antagonists mifepristone and HRP2000 inhibit hCG-stimulated progesterone and relaxin secretion by human granulosa–lutein cells.[280] Moreover, the reduction in the expression of STARD1 in the Rhesus monkey corpus luteum following administration of a GnRH-antagonist can be prevented by treatment with the progestin, R5020. Thus, the actions of LH and hCG on STARD1 expression may be, in part, indirect and attributable to the action of progesterone.[281]

Progesterone receptors, both the A and B forms, are present in the Rhesus monkey and human corpus luteum, with progesterone receptor mRNA increasing from the early to the midluteal phase. The ratio of progesterone receptor B to progesterone receptor A increases from the early to the late luteal phase. The above-noted actions of progesterone receptor antagonists on lutein cell steroidogenesis are

presumably a reflection of altered transcription regulated by these nuclear receptors.

Luteolysis

The functional life span of the corpus luteum in a nonfertile cycle is normally 14 ± 2 days. Unless pregnancy occurs, the corpus luteum is transformed into an avascular scar referred to as the *corpus albicans*. Regression of the corpus luteum, known as *luteolysis*, encompasses functional changes (i.e., endocrine changes, most prominently a decline in progesterone production) as well as structural changes (i.e., apoptosis and tissue involution).

Withdrawal of LH and a decline in LH receptors do not account for luteolysis in primates. However, there is a postreceptor loss of LH and hCG signaling efficiency that is reflected by the reduced response of the primate corpus luteum to hCG stimulation.[277-279] This reduced signaling efficiency in the late luteal phase leads to a decline in progesterone production associated with a fall in expression of the *STARD1* gene, in terms of both mRNA and protein.[272]

The decline in *STARD1* gene expression precedes a fall in expression of other steroidogenic enzymes. Administration of a large dose of hCG in the late luteal phase restores *STARD1* mRNA and protein levels to those found in the midluteal phase and causes a dramatic increase in plasma progesterone levels.[272] Infusion of exponentially increasing doses of LH or hCG also prolongs the life of the monkey corpus luteum.[278] These observations suggest that one important feature of functional luteolysis in the human is a decline in *STARD1* expression. High levels of hCG can prevent this decline, maintaining progesterone-producing capacity.

Microarray studies of the Rhesus monkey corpus luteum in which luteal regression was induced by a variety of methods (i.e., GnRH antagonist, prostaglandin F2α[PGF2α]) and compared to corpora lutea undergoing natural luteolysis revealed no consistent expression signature, although mRNA abundance for genes involved in cholesterol uptake and synthesis tended to be reduced.[282]

Structural regression of the corpus luteum is brought about by two processes: apoptosis and autophagolysis. Early corpora lutea show no evidence of DNA fragmentation, whereas midluteal and late luteal corpora display DNA fragmentation; the frequency of apoptotic cells is increased in the regressing corpus luteum compared with the midluteal phase. In contrast, the corpora lutea of early pregnancy show no detectable apoptotic DNA fragmentation.

The factors that control cell survival and death in the human corpus luteum remain a subject of debate.[279-289] BCL2, a cell survival factor, has been localized in granulosa–lutein cells, theca–lutein cells, endothelial cells, and blood vessels. Some researchers find no evidence of changes in BCL2 levels during the normal luteal phase or after hCG administration; however, others describe substantial changes with a decline in the late luteal phase. The proapoptotic protein BAX has been reported to remain unchanged throughout the luteal phase—and to increase from low levels in the midluteal phase to high levels in regressing corpora lutea, while being undetectable in corpora lutea of pregnancy. As described later in this section, expression of FAS and FAS ligand increases at the time of luteal regression. The existing data indicate that apoptosis is an important feature of human luteal regression, and some reports describe reciprocal changes in the expression of cell survival (BCL2) and proapoptotic (BAX and FAS) genes; however, morphological studies strongly suggest that autophagy contributes to luteal regression. These two processes may, of course, coexist in the regressing corpus luteum.

What triggers the diminished sensitivity of the primate corpus luteum to LH and subsequent luteal regression in a nonfertile cycle? Although PGF2α is a recognized luteolysin in animals, its role in regulating primate corpus luteum regression is less certain.[283] *In vitro*, PGF2α reduces gonadotropin-stimulated progesterone secretion by luteinized granulosa cells. PGF2α also suppresses *STARD1* gene expression in cultured human luteal cells. *In vivo*, infusion of PGF2α transiently reduces progesterone levels during the luteal phase in humans, and intraluteal injection of PGF2α causes a fall in progesterone production and tissue involution. Human corpora lutea in the late luteal phase express higher levels of the receptor for PGF2α and have higher PGF2α contents than in the early luteal phase. Moreover, the inhibitory effects of PGF2α on hCG-stimulated progesterone production are most notable in the late luteal phase. Collectively, these observations speak for a potential role for PGF2α in the initiation of human luteolysis, perhaps in the inhibition of luteal progesterone production. However, this is probably not the only mediator of primate corpus luteum regression.

Unlike domestic species, in which PGF2α of uterine origin is involved in triggering luteal regression, hysterectomy in the human has no effect on luteal life span.[283] Thus, if prostanoids are involved in human luteal regression, they are not of uterine origin. The corpus luteum itself may be the source. In the monkey, estrogen promotes luteolysis and also raises PGF2α levels in ovarian blood. The luteolytic action of estrogens is reportedly blocked by indomethacin; however, other researchers have suggested that the luteolytic action of estradiol in the primate is mediated by effects on gonadotropin secretion.

There is good evidence that cytokines of the TNF-α superfamily and interferon γ play roles in human luteolysis.[283] The temporal and spatial expression of FAS and FAS ligand mRNA and protein is strongly correlated with luteolysis in animal and human corpora lutea. The FAS-FAS ligand system can trigger apoptotic cell death. During the late luteal phase, the expression of FAS protein increases, diminishing only as the structure transitions into a corpus albicans.

Tumor necrosis factor-α inhibits steroidogenesis by human luteal cells *in vitro*.[283,284,286] TNF-α, derived from macrophages and leukocytes and also possibly endothelial cells, increases in the late luteal phase corpus luteum.[286] TNF-α–producing macrophages and leukocytes accumulate in the late luteal phase in regressing corpora lutea, probably due in part to up-regulation of monocyte chemoattractant protein-l (MCP-1) derived from endothelial cells.[283,287] Other proinflammatory cytokines produced by leukocytes could also contribute to the inhibition of steroid production. Interferon γ inhibits gonadotropin-stimulated progesterone production by human luteal cells *in vitro* and also induces cell death. It is another product of macrophages and leukocytes that could contribute to functional and structural luteolysis. As noted in the earlier discussion of ovarian leukocytes and lymphocytes, abundant regulatory T lymphocytes may be critical to sustaining luteal function and an anti-inflammatory state,

and a decline in this population of lymphocytes is thought to promote an inflammatory environment in which cytokines suppress luteal cell steroidogenesis.[127]

The vascular component of the corpus luteum may contribute to luteal regression through production of factors directly or indirectly involved in the luteolytic mechanism, including TNF-α, endothelin-1, and MCP-1.[283] Effects of luteolytic substances on endothelial cell function, including endothelial cell survival, can affect luteal perfusion. The endothelial cells may also be targets of PGF2α, and their role in the luteolytic process, best exemplified by studies in domestic species, has yet to be comprehensively evaluated in the human corpus luteum.

Reactive oxygen species produced by leukocytes infiltrating the corpus luteum are another potentially important factor in luteolysis.[283,289] Immunosuppressive levels of dexamethasone block luteolysis in a rat model. Both human and rat luteal cells respond to H_2O_2 with a rapid reduction in progesterone secretion and gonadotropin responsiveness. The action of H_2O_2 appears to be mediated by OH^-, which inhibits protein synthesis, depletes ATP, and induces DNA damage. The LH receptor also is uncoupled from adenylate cyclase by H_2O_2, and there is impaired mitochondrial use of cholesterol for steroidogenesis.

Rescue of the Corpus Luteum in the Cycle of Conception

In a cycle of conception, the human corpus luteum is rescued from luteolysis by the appearance of trophoblast-derived hCG.[290] In the corpus luteum of late pregnancy, hCG suppresses apoptosis, with a lesser effect on autophagy, allowing structural maintenance of the gland and sustaining expression of the *STARD1* gene.[198] The progressively rising concentrations of this luteotropin, first detectable in peripheral blood 8 days after ovulation, both stimulates steroidogenesis and prevents structural involution of the gland, which is the major source of progesterone for the first 10 weeks of gestation. The corpus luteum doubles in volume during the first 6 weeks of gestation as a result of hypertrophy of the luteinized granulosa and theca cells and accumulation of connective tissue and nonsteroidogenic cells, particularly endothelial cells.[279] Experimentally, a protocol of ever-increasing doses of hCG rescues both the human and monkey corpus luteum. Recent observations suggest that hCG stimulates luteal 11β-hydroxysteroid dehydrogenase type 1 expression, resulting in increased intraluteal generation of cortisol, which is proposed to act through the lutein cell glucocorticoid receptor to promote corpus luteum survival in the cycle of conception.[291]

The corpus luteum is essential for the first few weeks of pregnancy, and luteectomy results in miscarriage if performed before 7 weeks of gestation. Its secretory function, however, is not sustained at high levels throughout gestation, despite the presence of hCG. This characteristic has been documented by monitoring levels of 17α-hydroxyprogesterone, a steroid that is not produced by the placenta, and therefore largely reflects corpus luteum function. Levels of 17α-hydroxyprogesterone rise to peak concentrations at 6 weeks of pregnancy and then decline. Part of the decline in steroidogenic activity is due to the fact that the early hypertrophy of the corpus luteum is later followed by shrinkage. The biochemical changes underlying the functional and structural changes in the corpus luteum of pregnancy have not been elucidated.

The corpus luteum of pregnancy also secretes protein hormones, including inhibin A and relaxin. Relaxin may function to promote the decidualization of the endometrium and suppress uterine smooth muscle contractile activity, as well as the maternal adaptation to the pregnant state.

Luteoma of Pregnancy and Hyperreactio Luteinalis

Luteomas of pregnancy, rare benign tumors, which usually occur bilaterally from pockets, luteinized cells that develop under the influence of hCG. They appear to be more frequent in women with polycystic ovary syndrome. Androgen production by these tumors can range from modest to significant, causing maternal symptoms of hyperandrogenism and virilization of female fetuses. Progesterone and estrogen production has also been described. These tumors spontaneously regress after pregnancy.

Hyperreactio luteinalis, enlargement of the ovaries caused by theca-lutein cysts, usually in the third trimester, results from high levels of hCG associated with multiple gestations, molar pregnancies or choriocarcinoma. Approximately 30% of cases are associated with maternal symptoms of hyperandrogenism but the fetus appears to be protected through placental aromatization.

Ovarian Aging

With age, there is a decline in both the quantity and quality of the pool of follicles and oocytes.[292] Linear extrapolation of follicular depletion in women with regular menses predicts that, by 50 years of age, each ovary would contain 2500 to 4000 primordial follicles. Because the menopausal ovary is largely devoid of follicles, it has been thought that follicular depletion accelerates in the last decade of reproductive life. Recent re-analysis of the existing data suggests that the loss of follicles is best described by a simple power function with progressive increasing rates of follicle loss (Fig. 9.20). Below a critical number of some thousand follicles, which is reached at a mean age of 45 to 46 years, menstrual irregularity occurs. Thus, if oogonial stem cells truly exist in the human ovary, their capacity to contribute new follicular units is also exhausted. The median age of natural menopause in Caucasian women is 50. In some studies, unilateral oophorectomy and nulliparity are associated with an earlier occurrence of menopause and increasing parity with later menopause. One percent of women experience menopause below the age of 40, and 0.1% below the age of 30. Menopause occurring before the age of 40 is defined as premature ovarian failure.

The postmenopausal ovary, weighing less than 10 grams, is a lusterless structure with a wrinkled surface.[293,294] Morphologically, the main changes in the aging ovary are a decrease in volume and increasing fibrosis of the stroma, with accumulation of connective and scar tissue. A few primordial follicles and follicles undergoing maturation and atresia may be found up to 5 years after the last menses. A reduced vascular network, with smaller vessel lumens and thickening or sclerosis of the vessel walls, is characteristic, leading to diminished ovarian stromal blood flow, as assessed by Doppler ultrasonography.

With aging, the ovarian surface epithelium changes. Papillae and crypts are seen less frequently, and the surface epithelial cells become flatter, with fewer and shorter microvilli. Increased numbers of apoptotic and necrotic cells are observed.

Mechanisms of Natural Ovarian Aging

Ovarian aging reflects the combined interaction of genetic factors that determine the follicular complement, the additive effects of insults secondary to normal cellular metabolism, and environmental factors that affect follicular viability.[295-298] The importance of genetic factors is highlighted by the positive correlation in age of menopause between mothers and daughters, sisters, and monozygotic twins. Studies of sister pairs suggested that approximately 85% of the variation in age of menopause could be attributed to genetics, and as described below, candidate loci for age at natural menopause have been identified. Pre-menopausal hysterectomy has been associated with a twofold risk of ovarian failure. It is not yet known whether the surgery, and possible vascular compromise to the ovaries is the cause, or

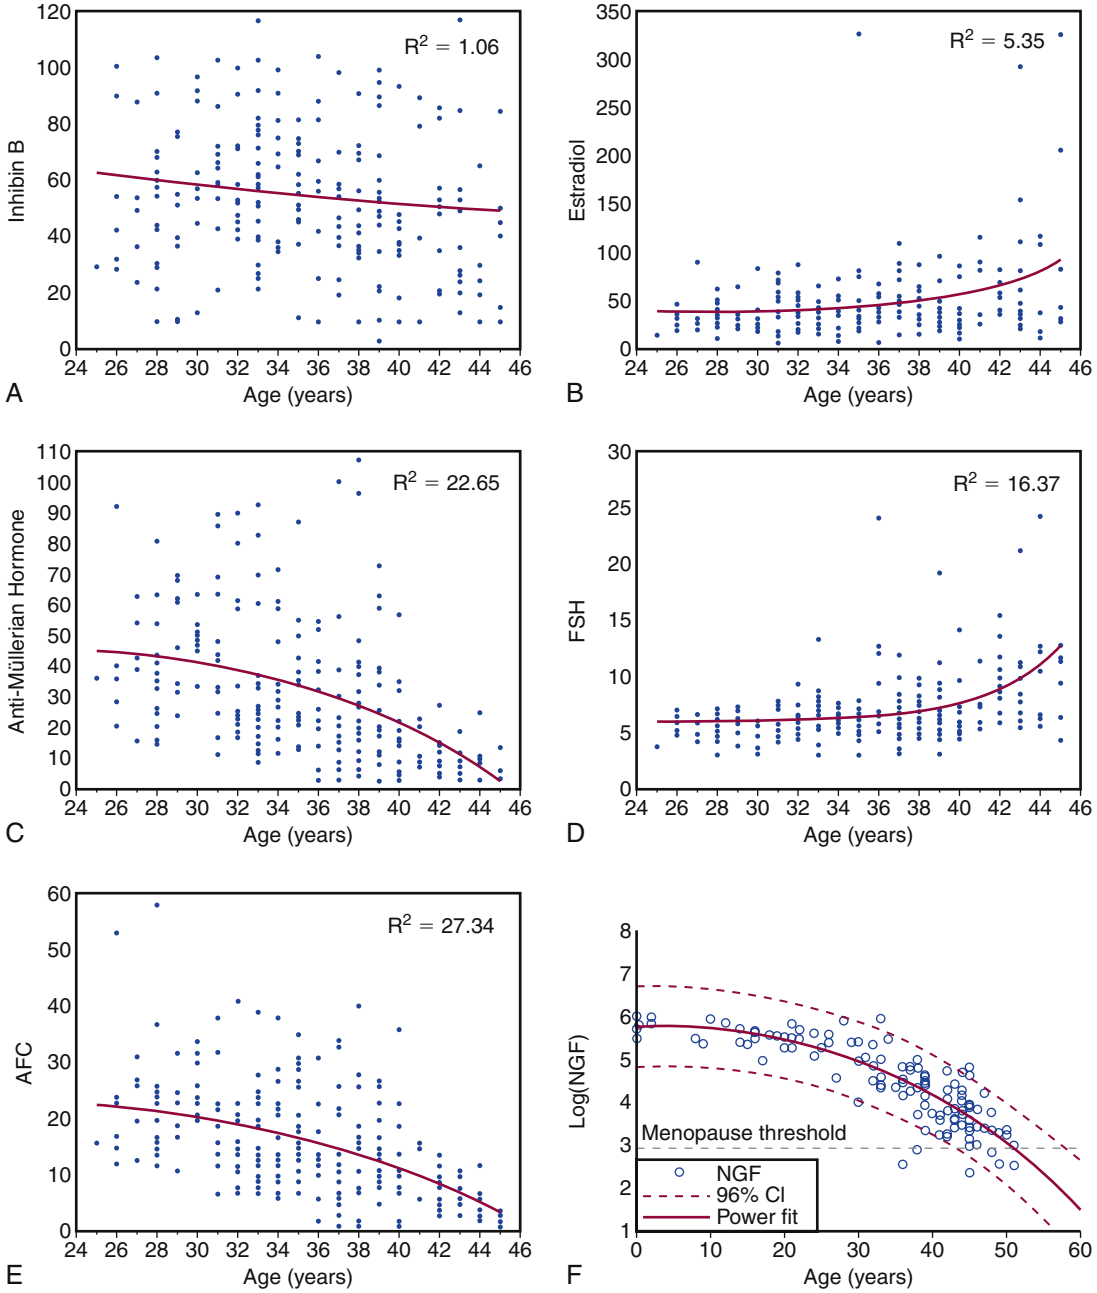

FIGURE 9.20 The power model relationships between ovarian reserve markers and age, with follicle counts of histological ovarian specimens. All but one of the serum markers has a relationship with age that mirrors the histological data (**F**). Serum markers and antral follicle counts (AFCs) show a gradual acceleration of oocyte loss with age, and FSH and estradiol (E2) levels exhibit an upturn with age, but this upturn occurs later than the downturn in follicle number in histological specimens. Inhibin B does not parallel the histological curve. *(Modified from Rosen et al.* Fertility & Sterility *97: 238–243, 2012.)*

whether the association is due to the pathology leading to the hysterectomy.

Oocyte aging is associated with increased meiotic nondisjunction.[296] The explanation for this phenomenon is not yet known, although oocytes apparently become more error-prone with respect to meiosis with age, probably because of a decline in chromosome cohesion. A two-hit model has been offered, which holds that there is a reduced frequency and pattern of recombination in a proportion of oocytes from the beginning; a second hit associated with an increased frequency of nondisjunction results from age-related damage due to oxidative stress and impaired microcirculation around the selected follicles. Hypo-oxygenation of the preovulatory follicle, assessed by the dissolved oxygen content of follicular fluid and hypoxia-responsive genes (e.g., VEGF), is associated with a high frequency of oocyte cytoplasmic defects, impaired postfertilization cleavage, and chromosome segregation defects. Centromeres have been reported to undergo a putative premature division at meiosis I in oocytes collected from older women. Moreover, examination of oocytes from older women at meiosis II showed a diffuse spindle and lack of bipolarity, with chromosomes irregularly and loosely attached to the spindle. These observations suggest that irregularities in the meiotic apparatus, including loss of key proteins in the spindle assembly checkpoint and chromosome cohesive ties, predispose aging oocytes to nondisjunction.[296]

Spontaneous deletions in the mitochondrial genome accumulate in muscle during aging, accelerating between the ages of 30 and 40 years. These deletions have been associated with a number of diseases and pathological processes, possibly arising as a consequence of damage resulting from the oxidative activity of mitochondria that is not adequately defended by cellular antioxidant mechanisms. Luteinized granulosa cells collected from women older than 38 years have a greater frequency of mitochondrial DNA deletions than those from women younger than 38 years of age.

Accumulation of these deletions in the oocyte mitochondria is another potential cause of ovarian aging. Indeed, the common delta mtDNA4977 deletion is found in 33% to 50.5% of oocytes, but in a smaller number of embryos (8% to 32.5%). This finding suggests that oocytes harboring these mitochondrial DNA deletions have an impaired ability to support embryonic development. Moreover, oocytes from older women have been found to be more likely to contain mitochondrial DNA deletions than those of younger women in some studies. Oxidative stress is hypothesized to be a cause of these DNA deletions, as well as induction of apoptosis. However, oxidative stress markers assessed in follicular fluid (e.g., conjugated dienes, lipid hydroperoxides, thiobarbituric acid–reactive substances) have not been correlated with the reproductive potential of oocytes in the setting of an *in vitro* fertilization/embryo transfer program. Shortened telomeres have also been found in women who experience early menopause.

Cigarette smoking represents an environmental factor that is associated with increased ovarian aging.[292,297] Smoking reduces the size of the ovarian follicular pool and advances the age of menopause by 2 years. It is also associated with reduced spontaneous fertility, poorer outcomes in assisted reproduction, and an increased incidence of trisomy 21. Follicular fluid cotinine levels, measures of a woman's exposure to cigarette smoke, are positively correlated with lipid peroxidation and negatively correlated with antioxidant activity.[299] Because inhibitors of oxidative stress mimic the ability of FSH to prevent follicular apoptosis, the shift in peroxidant and antioxidant activities in the follicular fluid of smoke-exposed women suggests a mechanism underlying smoking-associated ovarian aging. Smoking also may lead to the accumulation of mitochondrial DNA deletions as a result of oxidative stress. In an animal model, polycyclic aryl hydrocarbons, a component of cigarette smoke, up-regulated expression of the proapoptotic gene *Bax* in the ovary, resulting in follicular atresia.[300] Double-stranded genomic DNA breaks, as caused by chemotherapeutic agents may also contribute, which is consistent with genetic evidence for DNA repair pathways having a major role in controlling age of menopause.[301]

Genes Influencing the Age at Natural Menopause

Recent genome-wide association studies have revealed genetic loci associated with age of natural menopause as well as early menopause/ovarian insufficiency. Initial reports described loci on 20p12.3, 19q13.42, 13q34, 5q35.2, and 6p24.2. A subsequent meta-analysis of 22 genome-wide association studies confirmed some of these and added additional candidate loci with a statistical significance meeting genome-wide threshholds. Among the candidate genes identified to date are those involved in DNA replication and damage repair, hormone production and action, and immune function (Table 9.3). These include *EXO1*, *HELQ*, *UIMC1*, *FAM175A*, *FANCI*, *TLK1*, *POLG*, *MCM8*, and *PRIM1* in the realm of DNA repair, and *IL11*, *NLRP11*, and *PRRC2A* in the domain of immune function. Some of these candidates were previously identified in earlier genome-wide association studies *(MCM8)* or implicated in primary ovarian insufficiency, early menopause, or ovarian development (e.g., *FANC1*, *POLG*). The signaling pathways encompassed in a network analysis of the candidate genes included

inflammation (NF-κB) and mitochondrial dysfunction, both of which participate in cell death.[302-308]Although these findings represent a significant advance in our understanding of heritable factors determining reproductive lifespan, the functional genetic variants that contribute to the age of menopause in the candidate genes noted above, their mechanism of action, and their interactions with environmental factors and gonadotoxic agents, that affect ovarian reserve, remain to be determined.

Genes Implicated in Primary Ovarian Insufficiency

Primary ovarian insufficiency, also known as premature ovarian failure, is a complex, multifactorial disorder defined as cessation of ovarian function below the age of 40 in association with hypergonadotropic (elevated FSH levels) hypogonadism (diminished estrogen levels). It can be familial, with variable expression of the ovarian phenotype, syndromic (e.g., Turner Syndrome, autoimmune polyglandular syndrome 1, galactosemia), nonsyndromic, as well as iatrogenic. Approximately 25% of cases of primary ovarian insufficiency are iatrogenic, attributable to gonadotoxic therapies, and 50% are idiopathic.

Genes on the X Chromosome

Normal ovarian development requires the activity of autosomal genes and the presence of two functional X chromosomes. In a study of a cohort of more than 500 Chinese women with premature ovarian insufficiency, 12.1% were found to have X chromosome structural abnormalities, X-autosome translocations and X aneuploidy.[309] Although the requirement for two X chromosomes for ovarian development has long been recognized, the essential X-linked genes and their functions are largely unknown. Cytogenetic studies showed that terminal deletions from Xp11 to Xp22.1 are associated with primary amenorrhea, and deletions from Xq13 to Xq27 usually coincide with primary amenorrhea or primary ovarian insufficiency.[310] The latter stretch of the X chromosome is considered to be the critical region for normal ovarian function. Based on the study of interstitial deletions and breakpoints, this critical region has been subdivided into two domains encompassing Xq13-21 and Xq23-Xq27.[311] Deletions in these critical regions were thought to cause primary ovarian insufficiency because of haploinsufficiency of critical genes. However, with the exception of reports of rare mutations, definitive evidence for a key role for genes in or near disrupted loci is lacking. One example of an implicated X chromosome gene is *POF1B*, located at Xq21, which encodes a nonmuscle actin binding protein. Ovarian insufficiency was observed in members of a family homozygous for a point mutation in the actin-binding region of POF1B. In the absence of strong documentation of disrupted function of specific genes in the critical region, thinking has turned to the possibility that these structural abnormalities interfere with ovarian function as a result of aberrations in chromosome dynamics, or positional or epigenetic effects on flanking genes, including autosomal genes in translocations.[310-313]

A "premutation" in the fragile X syndrome gene *(FMR1)* on Xq27.3, which encodes an RNA-binding protein, FMRP, that controls mRNA stability, is associated with nonsyndromic primary ovarian insufficiency. The underlying mechanism of ovarian dysfunction resulting from the premutation has yet to be determined, although recent findings suggest that the premutation RNA causes a reduction in the number of growing follicles acting through Akt and mTOR.[314,315] The *FMR1* premutation is an expansion of a cytosine-guanine-guanine (CGG) repeat in the 5′-untranslated region from 56 to 200 copies, which reduces translation of the FMR1 mRNA. Approximately 20% of women carrying the premutation have primary ovarian insufficiency. Interestingly, when there are greater than 200 copies of the CGG repeat, FMR1 expression is silenced as a result of methylation of the CpG islands, causing fragile X syndrome, but not primary ovarian insufficiency. Population studies suggest that the number of premutation CGG repeats is not linearly correlated with the extent of ovarian dysfunction, and carriers of 80 to 100 CGG repeats are at higher risk of primary ovarian insufficiency. Other genes and environmental factors such as smoking are thought to influence the ovarian phenotype in premutation carriers. Microdeletions in the *AFF2 (FMR2)* gene on Xq28, approximately 600 kb distal to *FMR1*, have been associated with primary ovarian insufficiency, although the frequency of these mutations in women with ovarian insufficiency and the pathophysiological mechanism underlying this association are not known.[316] Some researchers have suggested that analysis of *FMR1* alleles could identify women with reduced ovarian reserve, but this approach is not recommended as a primary screening tool.[317]

Genes lying on the short arm of the X chromosome that may have a role in human ovarian function include *BMP15*, which lies on Xp11.2. It is a candidate gene for ovarian insufficiency, based on its involvement in follicular arrest in the sheep. A number of rare variants in *BMP15*, possibly mutations, causing nonconservative amino acid substitutions, have been identified in women with primary ovarian insufficiency or dizygotic twinning. Many of these variants affect the dimerization and post-translational processing of BMP-15 into the bioactive mature protein.[318-321] The affected individuals have been heterozygous for the variants/mutations and it is postulated that these variants might disrupt BMP-15 or GDF-9 signaling by affecting dimerization. However, some of these variants have been identified in normal individuals, so there is uncertainty about the pathophysiological roles of these variants or mutations. The zinc finger gene *ZFX*, on Xp22.1, which is important in ovarian development in the mouse because heterozygous and homozygous mutations are associated with a reduced germ cell number, is another candidate gene for ovarian failure, but little is known with respect to human ovarian biology.[322]

Autosomal Genes

A number of autosomal genes are associated with mostly rare forms of abnormal ovarian—differentiation or ovarian insufficiency due to either failure of normal follicular development, increased loss/destruction of follicles, or inability of follicles to respond to tropic hormones.

Mutations in the *GALT* gene encoding galactose-1-phosphate uridyltransferase, which cause galactosemia, are associated with syndromic primary ovarian insufficiency in almost all women homozygous for inactivating mutations. The loss of germ cells is thought to be due to the toxic effects of accumulated galactose metabolites or deficiency

of galactose-containing glycoproteins or glycolipids, and this occurs despite dietary control.[323]

Primary ovarian insufficiency is associated with the ataxia-telangiectasia resulting from mutations in the *ATM* gene, which functions in DNA repair and cell cycle control. Mutations in *TRIM37* cause mulibrey (muscle-liver-brain-eye) nanism, a peroxisomal disorder characterized by severe intrauterine growth restriction, cardiomyopathy, hepatomegaly, and premature ovarian failure.[324]

Forkhead transcription factor gene *FOXL2* mutations cause a syndromic form of premature ovarian insufficiency, blepharophimosis–ptosis–epicanthus inversus syndrome (BPES) type 1.[325a,326] This phenotype reflects the involvement of FOXL2 in granulosa cell function, including expression of genes involved in ovarian steroidogenesis, apoptosis, detoxification of reactive oxygen species, and cell proliferation. In mice lacking FOXL2, the ovaries are small and disorganized, with abnormal primordial and primary follicle formation, reflecting a granulosa cell abnormality. Oocytes are not initially affected but after birth, there is massive early germ cell atresia. Interestingly, a unique somatic mutation in the *FOXL2* gene is found in more than 95% of adult granulosa-cell tumors, the most common type of malignant ovarian sex cord-stromal tumor.

Mutations in the mitochondrial DNA polymerase gamma *(POLG)* are a rare autosomal dominant cause of sydromic ovarian insufficiency associated with progressive external ophthalmoplegia disorder or Parkinson's disease.[327,328] The *POLG* gene was also identified as a candidate for controlling natural age at menopause.

Mutations in the autoimmune regulator gene *(AIRE)* cause autoimmune polyendocrinopathy syndrome 1, which is associated with ovarian insufficiency due to immune cell-mediated depletion of ovarian follicles.[329-331]

Other rare syndromic forms of primary ovarian insufficiency include Demirhan syndrome, characterized by abnormal skeletal development caused by mutations in *BMPR1B*, encoding the GDF5 receptor; pseudohypoparathyroidism type 1a, caused by mutations in adenylate cyclase imprinted gene *GNAS1*, which occurs when a mutant allele is inherited from the mother leading to generalized hormone resistance; and ovarian leukodystrophy caused by mutations in the *EIF2B* gene.[332]

Genitourinary malformations, including sex reversal and streak gonads, are characteristic of syndromes associated with heterozygous mutations in the *WT1* and *NR5A1* genes.[333,334] Girls homozygous for a mutation in the *PSMC3IP* gene that affects the protein's ability to serve as a coactivator of estrogen receptor-mediated transcription have XX gonadal dysgenesis.[335] This observation provides a possible link between estrogen action in the ovary and follicular function/survival.

Mutations in the follicle-stimulating hormone receptor gene *(FSHR)* represent an infrequent cause of primary ovarian insufficiency with a unique gonadal phenotype. Women with these mutations have absent or poor secondary sexual development, elevated FSH and LH levels, with primordial follicles as well as early growing follicles present in their ovaries. Although some authors have reported that common polymorphisms in the *FSHR* gene are associated with reduced responsiveness to exogenous gonadotropins in stimulated cycles, this association has not been validated in studies on larger cohorts.

Mutations, again extremely rare, in genes known to be essential for ovarian development and folluculogenesis in mice or other animals also cause primary ovarian insufficiency in humans. The genes identified to date include the homeobox gene *NOBOX* and the basic helix-loop-helix transcription factor gene *FIGLA*.[325,332] *GDF9* mutations have been described as a cause of non-syndromic mutations in humans.[336-338] Conversely, mothers of dizygotic twins have an increased frequency of *GDF9* variants and missense mutations in *GDF9* have been found in Chinese women with polycystic ovarian syndrome.[339,340] However, a relationship between *GDF9* variants and twinning and polycystic ovary syndrome has not been replicated, nor has causality between these *GDF9* genetic variants and the phenotypes of twinning and polycystic ovary syndrome been established.

Polymorphisms in the gene encoding the inhibin α subunit (*INHA* 769G>A, A257T) have also been reported by some to be associated with premature ovarian failure, but others dispute this claim.[341,342] It is notable that the genome-wide association studies for natural age at menopause did not detect signals in most of the genes noted above.

Assessment of Ovarian Reserve

A variety of tests of ovarian reserve have been proposed including those that assess basal ovarian function (e.g., antral follicle counts, AMH levels) and those that assess response to a stimulus/challenge (e.g., clomiphene challenge test, GnRH agonist stimulation test) (Fig. 9.20). There is good evidence that some of these tests can predict ovarian response and treatment outcome in the context of assisted reproduction.[292,343-345] Although different measures are employed in some of these tests, the benefit of combining tests that have a strong correlation with ovarian response and clinical outcome is debated.

Fluid-filled follicles ranging in size from 2 to 10 mm (antral follicles) can be detected by transvaginal ultrasonography. The number of these follicles (defined as either those of 2 to 5 mm in size or 2 to 10 mm in size) parallels the number of primordial follicles and early growing follicles that are too small to visualize with current technology. The antral follicle count is highly correlated with chronological age and ovarian response to controlled ovarian stimulation including oocyte yield. However, ultrasonography cannot distinguish normal from atretic follicles.

Elevated day 3 FSH and estradiol levels are predictive of reduced ovarian reserve.[346] Generally accepted criteria for normal ovarian reserve include a cycle day 3 FSH level of less than 10 mIU/mL and an estradiol level of less than 80 pg/mL. However, there are wide variations FSH, with considerable overlap among values measured in older and younger women. Moreover, elevated FSH levels reflect primarily the egg quantity that can be expected in stimulated cycles. This is not directly linked to egg quality, which is primarily affected by aging, although egg quantity and egg quality are frequently linked in older women.[347-350]

Granulosa cell products inhibin B and AMH have been used as biomarkers of ovarian reserve. Inhibin B levels do not show a gradual decline with aging, and the decline when detected appears to be a better late marker of reduced follicle number. Consequently, basal inhibin B levels are not

recommended as a predictor of poor ovarian response to ovarian hyperstimulation.[292]

AMH is produced by granulosa cells of small follicles, and does not show major fluctuations during the cycle. Moreover, because AMH production appears to be independent of gonadotropin secretion, its levels show low intercycle and intracycle variability. Thus, AMH levels can be informative when sampled at random times during the cycle.[292]

Levels of AMH decline with aging, and are highly correlated with the number of antral follicles observed by ultrasonography. Of all of the potential biomarkers of ovarian reserve, AMH is the earliest to change with age, which has led some to propose that AMH levels can predict the time of natural menopause or reproductive potential.[351] In addition, AMH levels have consistently been found to be elevated in women with polycystic ovary syndrome, even in adolescents displaying phenotypes predictive of the disorder. Consequently, AMH has emerged as a valuable marker for ovarian aging, and can be used to predict both hyper- and hypo-responsiveness to controlled ovarian stimulation and ovarian function after gonadotoxic therapies in cancer survivors as AMH levels correlate with extent of gonadal insult.[352,353] Unfortunately, standardized assays for AMH with established normative values are not yet available to clinicians.[354]

Several challenge tests have been developed in an attempt to improve assessment of ovarian reserve and predict response to controlled ovarian stimulation and pregnancy rates. These provocative tests are not recommended for use in routine screening because their accuracy has not been demonstrated to be superior to basal assessments, particularly antral follicle counts and measurement of AMH levels.

The clomiphene citrate challenge test is a provocative assessment of ovarian reserve in which a cycle day 3 FSH level is determined, followed by administration of clomiphene citrate (100 mg/day) on days 5 to 9. A second FSH determination is obtained on cycle day 10. The test indicates reduced ovarian reserve if either initial or final FSH values are elevated. Although this is more cumbersome than "basal function" tests, it can reveal reduced ovarian reserve not detected using basal (day 3) FSH levels.[292]

Another provocative test based on the evaluation of FSH-sensitive follicles 24 hours after administration of a GnRH agonist (GnRH agonist stimulation test) has been evaluated in a small number of studies. This test can be predictive of poor ovarian response and pregnancy in the context of IVF.[292]

A third provocative test, also studied in a limited number of centers, is the response to a single dose of FSH with measurement of estradiol and inhibin B. Some reports suggest a high correlation with the size of the FSH-sensitive follicle cohort and antral follicle counts.[292]

Endocrine Activity of the Postmenopausal Ovary

Although devoid of follicles, the menopausal ovary is not a completely defunct endocrine organ in that it has a variable capacity to produce androgens.[355-357] The postmenopausal ovary is believed to be a source of testosterone, although there may be considerable variation among individuals with respect to androgen production (Fig. 9.21). This may be a reflection of variable numbers or activity of hilar cells. The circulating level of testosterone in postmenopausal women is only slightly lower than that observed in premenopausal women. Serum testosterone decreases approximately 50% after oophorectomy, and there is a significant level of testosterone in the ovarian vein compared with the peripheral blood in postmenopausal women.[358]

The postmenopausal ovary probably contributes no more than 20% of the daily production of androstenedione, with the adrenal being the predominant source. This proposal is supported by the following observations: (1) Serum androstenedione is minimally reduced after oophorectomy; (2) blood androstenedione has a diurnal rhythm (suggesting a substantial adrenal contribution); (3) serum androstenedione is markedly reduced after treatment with dexamethasone; (4) levels of androstenedione increase after the systemic administration of adrenocorticotropic hormone (ACTH), but not of hCG; and (5) the difference between androstenedione levels in the ovarian veins of menopausal women and levels in peripheral blood is of a lesser magnitude than that found in premenopausal women.

Some authors have concluded that the postmenopausal ovary is not a major site of androgen biosynthesis. Cauley and coworkers[359] examined hormone levels in postmenopausal women with and without ovaries and observed no statistically significant differences in circulating levels of testosterone and androstenedione between the two groups. Couzinet and colleagues[360] reported that plasma androgen levels were very low in all postmenopausal women with adrenal insufficiency and were similar between oophorectomized and nonoophorectomized postmenopausal women with normal adrenal function. These investigators also showed that dexamethasone dramatically suppressed plasma androgen production, whereas hCG treatment had no effect on plasma sex steroid levels, findings that are consistent with an adrenal source of androgens.

Estrogens in postmenopausal women arise almost exclusively from extraglandular aromatization of androstenedione.[361] Oophorectomy results in no substantial reduction

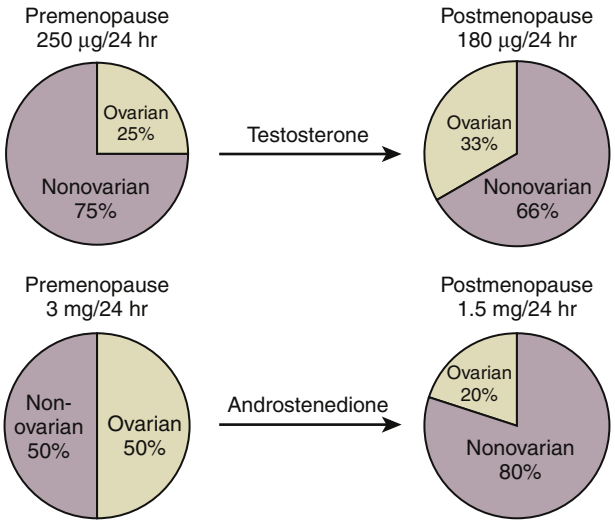

FIGURE 9.21 Sources of androgens in pre- and postmenopausal women.

in urinary estrogen excretion by postmenopausal women. However, adrenalectomy after oophorectomy virtually eliminates measurable estrogens from the urine. Longcope and colleagues[362] found a significant estradiol concentration gradient across the postmenopausal ovary in less than 20% of the women they studied. From *in vitro* studies, researchers concluded that the postmenopausal ovarian stroma is unable to aromatize androgens.[363]

Incubation of postmenopausal ovarian stromal slices with pregnenolone yielded progesterone, dehydroepiandrosterone, and testosterone. Incubation of strips of ovarian hilar tissue from postmenopausal women showed a steroidogenic pattern similar to that of the postmenopausal ovarian stroma. However, the overall amount of steroid produced was substantially greater compared with stroma. These findings imply that the hilar cells have greater importance than the stromal cells in the overall steroidogenic potential of the postmenopausal ovary. Consistent with this view, immunohistochemical studies of most postmenopausal ovaries show that stromal cells are rarely positive for expression of P450scc, 3β-hydroxysteroid dehydrogenase, and P450c17, three steroidogenic enzymes necessary for biosynthesis of androgens. Expression of steroidogenic enzymes involved in androgen biosynthesis is greatest in women with endometrial cancer or endometrial hyperplasia.[364]

There is some evidence that ovarian androgen production in postmenopausal women is gonadotropin-dependent. Administration of hCG to postmenopausal women results in a small increase in the circulating levels of testosterone.[365] Daily injection of hCG causes hyperplasia of the ovarian hilar cells and histochemical evidence suggesting active steroidogenesis.[366] The administration of hCG, but not ACTH, resulted in increased production of androgen, but not estrogen, by the ovaries.[367] Treatment of postmenopausal women with a long-acting GnRH agonist caused a decrease in circulating levels of testosterone, as well as a 22% decline in the levels of estradiol. The fall in serum estradiol levels was presumed to be the consequence of the reduction in serum testosterone levels. Taken together, these observations suggest that ovarian androgen biosynthesis is at least partially gonadotropin-dependent.

As suggested from the summaries of these studies, the main site of steroidogenesis may be the hilar cells. Binding sites for both LH and FSH were identified in the cortical stroma and in hilar cells.[368] Addition of hCG to hilar cells results in increased cAMP formation and steroid biosynthesis, indicating preserved responsiveness to gonadotropins.

Stromal hyperplasia can occur in the postmenopausal ovary, with the ovary enlarging with hyperplastic stromal nodules consisting of lipid-rich, luteinized cells that resemble theca interna. The ovaries with stromal hyperplasia produce large amounts of androstenedione, resulting in hirsutism and virilization.[369] Hilar cells can give rise to functional neoplasms (i.e., hilar cell tumors).[370,371] These tumors usually produce excess amounts of androgens, leading to virilization, but signs and symptoms of estrogen excess can also be evident when there is significant peripheral aromatization.

CHAPTER 10

The Structure, Function, and Evaluation of the Female Reproductive Tract

Bruce A. Lessey
Steven L. Young

The fallopian tubes, endometrium and myometrium, and uterine cervix function in concert to receive gametes, facilitate fertilization, support embryo growth, and ultimately orchestrate the timely expulsion of the mature fetus. The preparation of a receptive reproductive tract is programmed by ovarian steroid hormones acting directly on their cognate receptors and indirectly through the intermediacy of various steroid-regulated growth factors and cytokines. This chapter describes the structural and biochemical changes in the human reproductive tract during the normal menstrual cycle and pregnancy, the clinical evaluation of reproductive tract function, and the pathophysiology of some relevant disorders (see also Chapters 26 and 27).

The components of a receptive endometrium include the luminal epithelium, which undergoes apical surface specialization expressing cell adhesion molecules that permit adherence of the blastocyst; glandular epithelial cells, which secrete substances that support blastocyst development; decidual cells and large granular lymphocytes that modulate trophoblast function and endometrial angiogenesis through the secretion of growth factors, growth factor-binding proteins, angiogenic factors, and cytokines; a stromal extracellular matrix that facilitates trophoblast invasion. The combined actions of the locally acting molecules and extracellular matrix promote trophoblast proliferation and penetration of the endometrium, while controlling excessive penetration.

Innate and adaptive immune systems under the regulation of steroid hormones collectively defend the reproductive tract environment, but are also regulated to allow the fetal semiallograft to be accepted by the maternal host. The vascular system nourishes the endometrium in the initial receptive phase and is subsequently remodelled by invading trophoblasts to establish the placental blood supply. The coordinated contractile activity of the myometrium promotes sperm migration in a cycle of conception as well as facilitating embryo transport prior to attachment. During pregnancy, the myometrium experiences hormone-directed hyperplasia and contractile quiescence that accommodate fetal growth. In the absence of conception, the endometrium is shed through a controlled inflammatory-like reaction involving matrix metalloproteinases (MMPs), the production of vasoactive substances, and uterine contractions that, respectively, promote remodelling, hemostasis, and the expulsion of the shed endometrial lining. Compartmentalized and specialized endometrial cells at the menstrual interface provide remarkable regenerative capacity, assuring that a new intact luminal surface is prepared for the next round of oocyte release and potential fertilization.

Structure and Morphology

Morphogenesis of the Female Reproductive Tract

The female reproductive tract is derived from the urogenital ridge, which, during week 6 of gestation, gives rise to paired mesodermal (paramesonephic) tubes (the müllerian ducts) formed from longitudinal invaginations of the coelomic epithelium.[1-3] These form the fallopian tubes, with the caudal ends fusing by week 10 of gestation to produce the primordial uterus and upper portion of the vagina. A thin septum remaining after fusion eventually resorbs, yielding single cavities of the uterus and vagina. The primordial uterus is initially lined by a simple cuboidal epithelium that subsequently becomes columnar and pseudostratified. Beneath this epithelium lies a condensed mesenchyme that yields the endometrial stroma and the surrounding myometrium. Glandular epithelium buds from the luminal epithelium, invaginating into the stroma. By week 22 of gestation, the uterus has taken on the structure of the adult organ. Glandular secretory activity, glycogen accumulation, and stromal edema are evident by week 32 under the influence of placentally-derived steroid hormones. After delivery, with the precipitous fall in placental estrogens and progesterone, the endometrium regresses to an atrophic state, containing a few small-calibre glands and a poorly vascularized stroma.

The Role of the Wnt Family and Homeobox Genes

The embryonic events described above are driven, in large measure by the expression of secreted ligands of

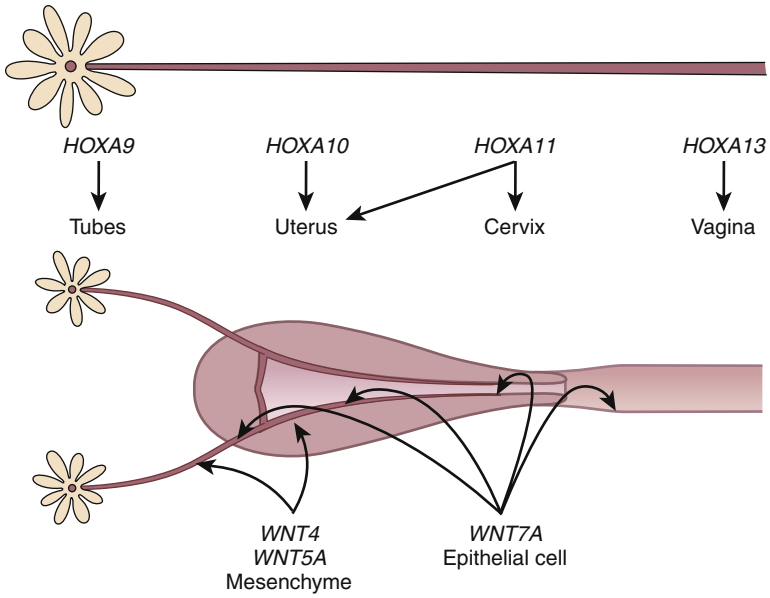

FIGURE 10.1 Expression patterns of *HOX* and *WNT* genes in the female reproductive tract during development. *(Adapted from Taylor HS. The role of HOX genes on the development and function of the female reproductive tract.* Semin Reprod Med *18:81–89, 2000.)*

the wingless-type MMTV integration site (Wnt) family (WNT4, WNTa, WNT7a) and transcriptional regulators of the homeobox (HOX) gene family (Fig. 10.1).[4-6] This morphogenetic program can only be played out in the absence of anti-müllerian-hormone (AMH), a member of the transforming growth factor β family made by the sertoli cells of the fetal testes. In the absence of testosterone, the müllerian ducts elongate and develop into the fallopian tubes, uterus, cervix, and upper part of the vagina. The elongation phase of the müllerian ducts requires a number of factors. Given their common embryonic origin, early development in the mouse of the kidneys, ureters, and reproductive tract are tightly linked and involve other specific genes including *Pax2*, *Lim1*, *Emx2*, as well as the members of the Wnt and abdominal-B HOXA families of genes.[7] *Lim1* encodes a transcription factor that along with PAX2 is essential for urogenital tract development. *Lim1* null mice lack uteri and oviducts.[8] *Pax2* null mice lack kidneys, ureters, and genital tracts.[9] Caudal elongation of the paramesonephric duct is absent. EMX2 is another transcription factor of the homeodomain gene family that appears to be essential for urogenital tract development.[10] EMX2 is highly expressed in the adult uterus and its expression is correlated with cell proliferation and appears to be inhibited by the homeobox gene, *HOXA10*. There is decreased expression of PAX2 and LIM1, and mesenchymal segmental polarity gene product, WNT4, is also absent in mice lacking EMX2, suggesting the essential role for this transcription factor.

The study of mice with targeted inactivation of *Wnt* genes revealed the importance of these signalling molecules in the development of the reproductive tract.[4] The müllerian ducts are absent in female mice lacking *Wnt4*, a gene expressed in the mesenchyme.[5] Moreover, female mice lacking *WNT4* are partially sex-reversed due to the retention of the wolffian ducts. Cases of *WNT4* null mutations associated with müllerian duct regression and a phenotype, including hyperandrogenemia, resembling that of the *WNT4* knockout mouse have been reported in women.[11] *WNT9b* is expressed in the wolffian duct epithelium and is necessary for müllerian duct extension.[12] Deficiency of *Wnt5a*, a gene expressed in the genital tubercle and genital tract mesenchyme, results in mice with stunted genital tubercles and the absence of external genitalia.[4] *WNT7a* expression is found in the luminal epithelium of the müllerian duct[13] and involved in paracrine signalling to the endometrial mesenchyme. Although *WNT7A* mutations have not been found in women with müllerian anomalies,[14] in mice lacking *WNTta*, the oviduct is not clearly demarcated from the upper uterine horn, and the uterus develops cellular characteristics that are similar to the vagina (including a stratified epithelium without uterine glands), and the uterine smooth muscle is disorganized.[8-9] Postnatal expression of *HOXA10* and *HOXA11* in the uterus is also lost. Mesenchymal beta-catenin appears to be the essential down-stream effector of the WNT7A pathway, and mediates its effects on the oviduct and proper development of the uterus.[15] The Wnt family of genes, including receptors and downstream signalling molecules, are also expressed in a regulated fashion in the adult reproductive tract, indicating that they have additional roles beyond those involved in early morphogenetic events including the regulation of steroid hormone action in adult tissues (discussed later in the chapter).[4-6,16-19]

The *HOX* genes encode an evolutionarily conserved family of transcription factors that contain a signature 60 amino acid deoxynucleic acid (DNA)-binding homeodomain.[6] They play critical roles in organizing cells along the anterior-posterior axis and directing them to select a particular pathway of development. Mammalian *HOX* genes are arranged in four different clusters, designated A through D, with each cluster organized in a linear arrangement that parallels the order of expression along the anterior–posterior body axis. The expression of *HOXA* genes in the human and mouse reproductive tract is conserved, with HOXA9 being expressed in the fallopian tubes, *HOXA10* and *HOXA11* in the uterus, *HOXA11* in the cervix, and *HOXA13* in the upper vagina.[6] Although there is a consistent regional distribution of HOX gene expression along the reproductive tract, there is evidence for some functional redundancy among

the adjacent genes. Like the *WNT* genes, the *HOXA* genes are also expressed in the adult uterus and their expression is under steroid hormone (estrogen and progesterone) regulation. *HOXA10* and *HOXA11* have both been implicated in the process of implantation.[20]

The importance of the homeobox gene family in reproductive tract function has been demonstrated through targeted deletions in specific *HOXA* genes. Another significant discovery was that hand–foot–genital syndrome and Guttmacher syndrome, autosomal dominant conditions that affect bones in the hands and feet and cause reproductive tract abnormalities (including bicornuate uterus), are caused by mutations in the *HOXA13* gene.[21,22] However, to date, mutations in *HOXA7* to *HOXA13* and HOX gene cofactor pre B-cell leukemia homeobox1 (PBX1) have yet to be found in subjects with congenital absence of the uterus and vagina. Mice with targeted deletions in the *HOXA10* and *HOXA11* genes have subtle abnormalities in uterine morphology, including transformation of the upper uterine segment into an oviduct-like histology (*HOXA10* mutants); reduced endometrial stromal development and expression of leukemia inhibitory factor (LIF) are seen in *HOXA11* mutants.[20,23] Notably, both *HOXA10* and *HOXA11* nullizygous females are infertile due to a uterine factor, implicating these genes in the implantation process in the adult. Mice lacking H6 homeobox 3 *(Hmx3)*, another homeobox domain gene product, are also infertile due to an implantation defect associated with perturbations in *WNT* and *LIF* gene expression.[24]

Müllerian anomalies represent a complex and rare collection of developmental defects occurring in 5% of the general population. Depending on the stage of development at which they occur, these defects in the reproductive tract can be mild (including a uterine septum) or severe with complete absence of the cervix, uterus, and fallopian tubes. These can be associated with infertility, endometriosis, and miscarriage but also can require surgical correction and are often discovered at the time of puberty, if not before.[25] Given the close developmental interaction between the müllerian and urinary system, it is not surprising that combined renal and müllerian duct agenesis occur.[26] The patterns and genetics of müllerian anomalies provide further insight into the embryology of the reproductive tract morphogenesis.

Mayer-Rokitansky-Küster-Hauser syndrome (MRKH) is the congenital aplasia or severe hypoplasia of the adult derivatives of the müllerian ducts, including the fallopian tubes, uterus, cervix, and upper vagina. Although müllerian hypoplasia can be a feature of many other specific genetic syndromes,[27] in MRKH, müllerian hypoplasia is the most prominent anomaly. MRKH has an incidence of at least 1 in 4500 women and is commonly subclassified into type I, isolated müllerian hypoplasia and type II, also known as müllerian Renal Cervico-thoracic Somite (MURCS association), involving renal, skeletal, and hearing defects, as well as occasional cardiac and digital anomalies.[11] The more common renal anomalies include unilateral agenesis, ectopia of kidneys and horseshoe kidney; the more common skeletal anomalies include fused vertebrae (commonly cervical) and scoliosis. Fusion of at least two cervical segments, short neck, low hairline, and restriction of neck motion, known as Klippel Feil syndrome, is seen.[11] The genetic basis of these syndromes is largely unknown, but a few gene defects have been associated. Copy number variants (CNVs), due to microdeletions and microduplications are relatively common,[28] especially at 16p11.2 and 17q12. In addition, CNVs involving the short stature homeobox *(SHOX)* gene at Xp22 were detected in some MRKH case series,[29] but not others.[30] Studies of candidate genes, suggested by mouse and human mutation phenotypes have been unrewarding, with failure to associate defects in AMH receptors, Wilms Tumor 1 *(WT1)*, *PAX2*, galactose-1-phosphate uridyl transferase *(GALT)*, cystic fibrosis transmembrane conductance regulator *(CFTR)*, or the *HOXA* cluster genes with MRKH syndrome.

More recently, a third distinct entity, MRKH associated with hyperandrogenism, has been reported and a clear association with four different defects in the *WNT4* gene have been confirmed.[31-34] Studies of the mutated WNT4 proteins in cell culture and WNT4 deficiency in mice suggest that the hyperandrogenism is a result of failure of WNT4-mediated repression (via beta catenin stabilization) of both *CYP17A1* and *HSD3B2* or only *CYP17A1*. The failure of müllerian duct formation appears to result from the requirement for WNT4/beta-catenin signaling in müllerian development. Multiple case series of MRKH without hyperandrogenism have failed to find any association with *WNT4* mutations, further strengthening the hypothesis that MRKH with hyperandrogenism is a clinically and genetically distinct disorder.[29,35-38]

A clinical approach to MRKH patients should include evaluation of pelvic anatomy imaging, renal anatomy imaging, measurement of plasma follicle stimulating hormone (FSH), estradiol, and testosterone. Depending on the associated symptoms and signs, adjunctive tests may include an electrocardiogram (ECG), audiogram, skeletal x-ray and pelvic laparoscopy. Dilator treatment or neovagina creation may also be necessary to allow sexual intercourse. Since surrogacy in a MRKH patient would allow her to have a genetically related child, genetic testing or pre-implantation genetic screening may be indicated.

The morphogenesis of the female reproductive tract does not require the action of estrogen. The oviducts, uterus, cervix, and vagina form in mice with inactivating mutations of both nuclear estrogen receptors (ERα and ERβ).[39] Despite this independence from maternal or fetal estrogens, normal differentiation of the female reproductive tract can, paradoxically, be disrupted by exogenous estrogens.[40] Diethylstilbestrol (DES), a synthetic estrogen that causes uterine and cervical anomalies in exposed females (discussed later in this chapter), and polychlorinated biphenyls suppress expression of *WNT7a* and alters the pattern of expression of *HOXA9* and *HOXA10* in the murine reproductive tract through ERα.[39-41] This suggests that alterations in *HOXA* and *WNT* gene expression are the likely molecular mechanism underlying the anatomical defects observed in human females exposed to DES in utero. Postnatal progesterone may also inhibit normal endometrial gland development, as shown in the neonatal ewe.[42] Using this model, it appears that aglandular endometrium involves disruption of the WNT system,[43] and illustrates that, while normal development may be independent of steroid hormones, exposure at the wrong time can alter the normal developmental pathways.

Steroid Hormone Regulation of Female Reproductive Tract Growth and Differentiation

Steroid Hormone Action in the Reproductive Tract

Many, but not all, of the reproductive tract responses to steroid hormones are mediated by nuclear receptors. These nuclear transcription factors undergo striking spatial and temporal changes in expression during the primate menstrual cycle.[44-47] The uterine response to steroid hormones is determined by the amount of bioavailable hormone, which is influenced by hormone production rates as well as local steroid metabolism; the repertoire of steroid receptors, coactivators, and corepressors expressed; and the action of growth factors and cytokines that modulate the action of steroid hormone receptors. The discovery of multiple forms of steroid hormone receptors with different transcriptional activities and cell and tissue-specific patterns of expression revealed new levels of complexity in the control of reproductive tract function. The patterns of expression of coactivators and corepressors add another level of intricacy, which is now being explored.[48,49] The presence of membrane bound receptors with specific recognition of steroid receptors helps coordinate the paracrine, autocrine, and juxtacrine cellular mechanisms and provides an explanation for rapid effects of steroid hormones as well as the relationship between steroid hormones and growth factor responses.[50,51] Rapid effects of estradiol are mediated by at least two distinct receptors, a membrane associated form of ERα and a recently described integral membrane receptor known as both G protein coupled estrogen receptor (GPER) and G protein coupled receptor 30 (GPR30).[50] GPR30 has been characterized as an estrogen receptor and subsequent development of a GPR30-specific agonist, G-1, and antagonist, G-15, have revealed important functions of this non-classical estrogen receptor in multiple physiological and pathophysiological processes.[52,53] In the endometrium, this receptor is present in the endometrial epithelium during the late proliferative phase and transitions to the stroma and decidua in the latter stages of the menstrual cycle and pregnancy.[54] Given the down-regulation of classical ERα in response to progesterone at this time, this receptor may provide alternative opportunities for estrogen to act and maintain progesterone receptor and other essential estrogen actions. Together, both steroid hormones provide a diversity of responses that modulate an exquisite complexity required for establishment of a successful pregnancy.

Estradiol is the primary trophic hormone for the uterus. The uterine growth response is mediated by ERα, whose concentrations are highest during the proliferative phase of the cycle and decline after ovulation (Fig. 10.2).[55] These changes correlate with the proliferative activity of the endometrium. Immunohistochemical studies demonstrate estrogen receptors in the nuclei of epithelial, stromal, and myometrial cells during the proliferative phase, with the epithelial cell staining being most prominent.[45,46] After progesterone levels rise in the luteal phase, estrogen receptor staining is restricted to the deep basal glands and vascular smooth muscle. *In situ* hybridization studies to distinguish patterns of expression of ERα and ERβ reveal that

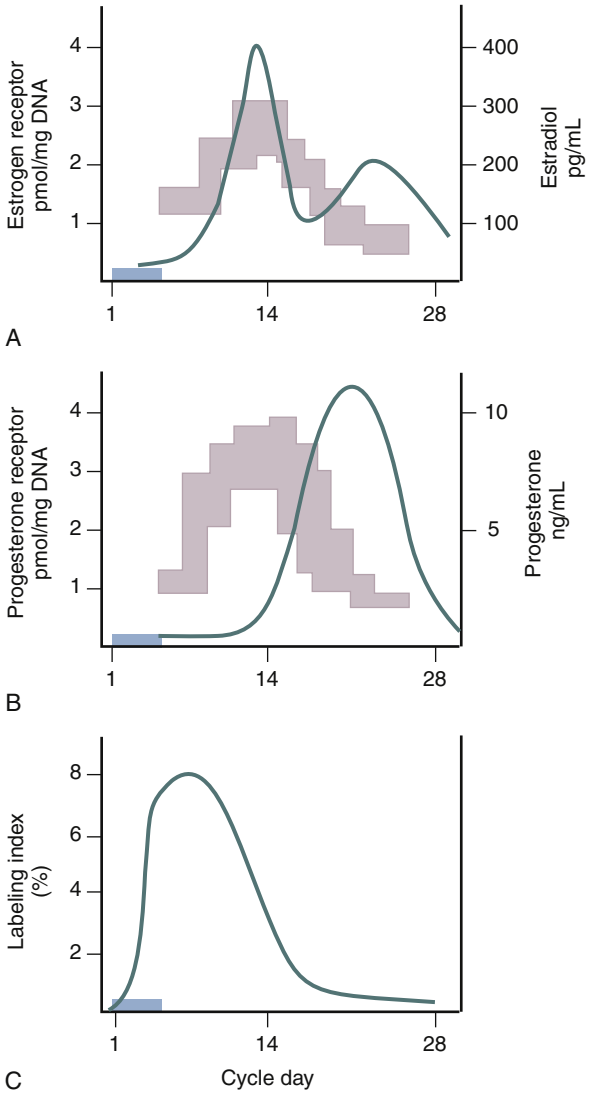

FIGURE 10.2 Estrogen and progesterone receptors in endometrial cells during the normal menstrual cycle. The concentrations of estrogen receptor (shaded area, **A**) and progesterone receptor (shaded area, **B**), mean values of plasma estradiol and progesterone (green lines, **A** and **B**), and endometrial proliferation as assessed by incorporation of [^{3}H]thymidine *in vitro* (labeling index, **C**). The black bar indicates menses. *(Modified from Frolich M, Brand EC, van Hall EV. Serum levels of unconjugated aetiocholanolone, androstenedione, testosterone, dehydroepiandrosterone, aldosterone, progesterone, and oestrogens during the normal menstrual cycle.* Acta Endocrinol [Copenh] *81:548–562, 1976.)*

transcripts for both receptor forms are expressed in the epithelial, stromal, and smooth muscle cells at all stages of the cycle.[56] However, ERα expression is more abundant in the endometrium. In the proliferative phase, ERα messenger ribonucleic acid (mRNA) is detectable in epithelial cells and stroma, while ERβ mRNA is predominantly in the glandular epithelium and is the only estrogen receptor found in vascular endothelium of the endometrium.[57] Expression of both transcripts falls in the secretory phase, with the decline in ERα expression being least in the basalis—consistent with the previously noted results of immunocytochemical studies. This fall in ERα at the time of implantation may be physiologically important and is a common finding across many

species.[46,47,58] Failure to down-regulate estrogen receptors indicates an imbalance in regulatory mechanisms of steroid hormone interactions, and is associated with endometrial dysfunction, endometriosis, and infertility [59] Endometriosis (discussed in detail later in the chapter) is also associated with increased local endometrial estrogen production (P450 aromatase over-expression)[60] and resistance to the down-regulatory effects of progesterone.[61]

A variant of ERβ, ERβcx/β2, formed by alternative splicing of the eighth exon of the "classical" ERβ (ERb1) transcript has been described with distinct ligand and coactivator affinity.[62] These isoforms have different selectivity for ligands and affinities coactivators. The patterns of ERβ1 and ERβ2 protein expression in the endometrium differ: ERβ1 expression appears to be more intense than ERβ2; ERβ1 protein levels are unchanged throughout the menstrual cycle while ERβ2 levels decline in the glands of the functionalis layer but not the basalis layer in the midsecretory phase. The physiological significance of these ERβ isoforms in the endometrium remains to be determined.

Studies on mice with targeted deletions in the ERα and ERβ genes have provided clues as to the roles of the two molecules in mediating uterine responses to estrogen.[39] ERα is responsible for the main uterotrophic actions of estradiol, as the uteri of mice lacking this receptor are hypoplastic and do not show the classical cell proliferation, increase in uterine wet weight, and edema in response to estradiol.[63] In mice lacking ERβ there is an exaggerated response to estradiol, including increased accumulation of uterine secretions and uterine dilatation.[64] This suggests that ERβ may function to attenuate the transcriptional activity of ERα in the uterus.[65] Severe uterine hypoplasia is observed in mice lacking both ERα and ERβ.[39] Progesterone receptors, which are up-regulated by estrogen, are reduced in the uteri of estrogen receptor knockout mice, but this reduction does not prevent the induction of progesterone-regulated genes. A role of ERβ has been suggested in endometriosis where ERβ is overexpressed. A high ERβ/ERα ratio may promote a reduction in estrogen-induced progesterone receptor, as a cause of progesterone resistance seen in this condition.[66]

Other members of the estrogen receptor family include estrogen receptor related alpha (ERRalpha) and beta (ERRbeta), orphan receptors with homology to the classical ERα. ERRalpha and its coactivator peroxisome proliferator-activated receptor gamma coactivator-1 alpha were found to show dramatically increased expression in the decidua, and stimulates metabolical pathways for energy generation perhaps in preparation for implantation.[67] ERRbeta is seen throughout the endometrium, including uterine natural killer cells, and a precise role for this receptor has yet to be determined in the endometrium.[68]

Is there a threshold dose of estrogen required to elicit a uterine growth response? Key and Pike proposed a threshold estrogen level of approximately 50 to 100 pg/mL at which point endometrial proliferation is triggered, and above which there is no further stimulation of endometrial proliferation. This estimation was made on the basis of comparing endometrial proliferation assessed through *ex vivo* thymidine incorporation into endometrial explants from different stages of the menstrual cycle with corresponding estradiol levels at the different days of sampling.[69] This hypothesis finds relevance in postmenopausal estrogen therapy where effects on bone, cardiovascular, and endometrial function are different and have different risk/benefit profiles.[70]

Progesterone antagonizes actions of estrogen in the endometrium and promotes glandular and stromal differentiation via progesterone receptors. The antagonism of the uterotrophic actions of estradiol involves several events, including alterations in estrogen receptor expression, inhibition of estrogen-induced translocation of the cell-cycle regulators, and induction of enzymes that catabolize estradiol.[71-73] These effects are mediated by specific cognate nuclear receptors that are induced by estrogen.

Three forms of the progesterone receptor (PR), designated PR-A, PR-B, and PR-C, have been identified.[74] These isoforms are derived from a single gene through the use of alternative promoters and alternate translation start sites. The PR-A form lacks a 164-amino acid N-terminal sequence present in the PR-B form. The PR-C form, the smallest of the progesterone receptors, also appears to be derived from an alternative translation start site. The A and B forms of the progesterone receptor have different functions, and the differential expression of these two isoforms determines tissue responses. The B form of the receptor is a strong transcriptional activator of several progesterone-responsive genes that do not respond to the A form. Further, PR-B contains a motif that interacts with the Src homology 3 (SH3) domain of the intracytoplasmic signaling component, Src; rapid activation of Src provides a mechanism for mitogen activated protein (MAP) kinase signaling.[75] When PR-B was tagged with a simian virus 40 (SV40) nuclear localization signal causing it to be translocated into the nucleus, it no longer was able to interact with Src or to activate MAP kinase signalling pathways.[76] In addition, the extended size of PR-B provides a binding site for the melanoma antigen A11 (MAGE-11),[77] a cycle-regulated endometrial coactivator protein;[78] MAGE-11 is required for isoform-specific PR-B up-regulation of FK506 binding protein 5 (FKBP5) immunophilin, which functions to stabilize the PR-B receptor complex.

The PR-A receptor functions as a transcriptional repressor of the PR-B and other steroid receptors, including the estrogen receptor. The C form, of which relatively little is known, binds progesterone but has no evident transcriptional activity. The C form may act as a repressor or modulator of progesterone receptor A and B activity through heterodimerization, or it may serve as a progesterone-binding "sink." Differential subcellular localization of PR-B outside the nucleus and PR-A inside the nucleus may also dictate isoform-specific activities of these too isoforms.[79,80]

Interestingly, a class of membrane receptors, with high affinity, low-capacity binding to P, but completely structurally distinct from the classical PRs has been described. This family of non-classical, membrane progesterone receptors, termed mPRα (PAQR VII), mPRβ (PAQR VIII), and mPRγ (PAQR V) was first described in fish and subsequently in mammals and amphibians.[81] Each mammalian mPR has been shown to specifically bind progesterone and can activate G-protein coupled signaling pathways.[82] Expression of each has been shown in human endometrium and myometrium, as well as placenta, but their role in progesterone regulation of uterine function remains unknown.[83]

Classical endometrial progesterone receptors peak at the time of ovulation, localized to both epithelial and stromal

cells, then decline. The rise is a reflection of the ability of estradiol to induce progesterone receptor expression while the decline after ovulation is caused by progesterone down-regulation of its own receptor.[44,46,84] By 4 days after ovulation, progesterone receptor staining of the epithelial cells declines markedly in the epithelial compartment and remains weak or absent during the remainder of the secretory phase. In contrast, staining of stromal cells remains moderate to strong. The PR-A form predominates in the stroma, while the PR-B is more abundant than the A form in epithelial phase of the secretory phase of the cycle.[85] Progesterone receptors have not been detected in vascular endothelial cells or vascular smooth muscle, but they are abundant in perivascular stroma. Consequently, the effects of progesterone or its withdrawal on the vasculature are likely indirect or perhaps via membrane PRs (discussed earlier in the chapter).

The significance of the different ratios of the two major progesterone receptor forms, with respect to regulation of gene expression in the human uterus, is increasingly being studied.[86-88] Clues are being provided from the study of mice with targeted deletion of the receptor isoforms. The uteri of mice lacking both the A and B form of the progesterone receptor are hyperplastic and contain inflammatory infiltrates.[72,73] Hyperplasia reflects the lack of antagonism to the uterotrophic actions of estradiol. Selective targeting of the A form of the progesterone receptor revealed that it is essential for progesterone-mediated actions on implantation and the decidual response. However, the examination of genes associated with the window of uterine receptivity that are known to be regulated by progesterone indicated that the A form controls expression of only a subset, while others appear to be under the control PR-B. Ablation of PR-A in mice uncovered an unexpected role for the B form of the receptor in inducing epithelial proliferation. Administration of estradiol to PR-A receptor–deficient mice resulted in uterine hyperplasia, but the combination of estradiol and progesterone resulted in even greater hyperplasia. It thus appears that progesterone receptor A antagonizes the uterotrophic responses mediated by both ERα and progesterone receptor B. With regards to implantation and decidualization, however, when PR-A null mice are examined, they are similar in their defects to mice that lack both PR-A and -B subunits, while PR-B knock out mice (PRBKO) were fertile.[89] Clinically, reductions in PR-B have been associated with proliferative states such as endometriosis,[90] supporting this paradigm of counter-regulatory mechanisms involving PR isoforms.

There is additional evidence for a dichotomous action of progesterone on uterine cell proliferation. DNA synthesis assessed by [^{3}H] thymidine incorporation into cells of the endometrium of the rhesus monkey *in vivo* or into explants of human endometrium *in vitro* is greatest in the epithelial cells of the functionalis and low in the deep zona basalis during the proliferative phase.[91] Labeling indices fall dramatically in the luteal phase with the exception of the basalis, where thymidine incorporation increases as progesterone levels rise. Using the double fluorescent labelling for ERα and the nuclear marker Ki-67, Okulicz demonstrated that the presence of ERα related directly with cell proliferation.[92] After ovulation, loss of ERα in the upper zona functionalis correlated with lack of cell proliferation, while in the zona basalis, where ERα persisted, proliferation was increased, even in the presence of high serum progesterone levels. This phenomenon of natural progesterone resistance is probably important for the rapid proliferation and healing that occurs after menses, providing a head start for the reestablishment of the endometrium following loss of the upper functionalis layer.

In addition to steroid hormone receptors, coactivators and chaperone proteins have an important impact on the uterine response to estrogens and progestagens.[48] The uterine expression of p160 coactivators, steroid receptor coactivator-1 (SRC1), steroid receptor coactivator-2 (SRC2), and steroid receptor coactivator-3 (SRC3) has been examined by immunocytochemistry. SRC3 levels increased in the glandular epithelium in the late secretory phase, whereas SRC1 and SRC2 expression did not change. However, in endometrial biopsies from women with polycystic ovary syndrome, SRC2 and 3, along with ERα, were elevated in stroma and glandular epithelium, demonstrating that an abnormal endocrine milieu can alter coactivator levels, which could, in turn, result in endometrial dysfunction.

Many of the effects of estrogen on epithelial proliferation and progesterone receptor expression are indirect, involving activation of estrogen receptors in the stroma, which produces paracrine substances that act on the epithelium to promote DNA synthesis.[93] Moreover, there are reciprocal paracrine interactions between the epithelium and the stroma. For example, under the influence of progesterone, the epithelium produces substances that affect response of the underlying stroma to estrogen.[94] Conversely, the stroma responds to progesterone by exerting an inhibitory effect on estrogen-induced epithelial cell DNA synthesis.[95]

The indirect actions of estradiol on epithelial proliferation have been demonstrated in elegant reconstitution and grafting experiments employing stroma and epithelium from wild-type and estrogen receptor knockout mice. Epithelial cell proliferation does not occur when stroma from ERα knockout (ERKO) mouse uterus is paired with epithelium from wild-type uterus.[93,94] Conversely, epithelial cell DNA synthesis in response to estrogen occurs when wild-type stroma is paired with epithelium from ERKO mice. Studies on human endometrial cells in culture are consistent with the mouse studies.[96] Estradiol increases epithelial cell proliferation when cocultured with stroma, but it does not increase proliferation in epithelial cells cultured in the absence of stromal cells.

What is the estrogen-stimulated signal from the stroma that promotes epithelial cell proliferation? Candidates include growth factors under the transcriptional control of the estradiol receptor, including insulin-like growth factor-1 (IGF-I), transforming growth factor alpha (TGF-α), and epidermal growth factor (EGF).[97] Alternatively, estradiol might suppress production of stromal factors that restrain epithelial cell proliferation. Among the growth factors, there has been particular interest in EGF and IGF-I. Studies using mouse models, including transplantation of uteri and vaginae from EGF receptor knockout mice, indicate that this receptor is required for the maximal fibromuscular stroma growth but not the epithelial cell proliferative response to estrogen.[98]

IGF-1 and IGF-2 both stimulate the proliferation of human endometrial stromal cells via the type 1 IGF receptor.

IGF-1 expression is greatest in the late proliferative and early secretory phase, whereas IGF-2 is most abundant in the mid-secretory endometrium and decidua of the first trimester of pregnancy. A family of binding proteins (IGFBPs) sequester IGFs, and modulate their activities in target tissues. One of the binding proteins, IGFBP-1, is a major secretory product of decidualized stromal cells, and it has been hypothesized to play a role in controlling trophoblast invasion.[99]

Estrogen is the primary regulator of IGF-1 expression in the uterus, which occurs predominantly in the stroma.[100,101] Estrogen also increases expression of IGF-1 receptors, which are primarily found on epithelial cells. The mitogenic response of the mouse uterus to estrogen is absent in mice with targeted deletion of the IGF-1 gene. Moreover, mice over expressing IGFBP-1, which results in reduced IGF-1 bioavailability, have a blunted DNA synthesis response to estrogen treatment.[102] Collectively, these observations suggest that IGF-1 produced in the uterine stroma in response to estrogen acts on the epithelial cells to stimulate DNA synthesis. However, tissue grafting experiments showed that a IGF-1 knockout mouse uterus responds to estrogen when placed into a wild-type animal, whereas a wild-type uterus placed into a IGF-1 knockout mouse showed minimal growth, indicating that systemic IGF-1 is sufficient to support estrogen-driven uterine growth.[103] These findings substantiate the importance of IGF-1 in the uterine growth response to estrogen. Although uterine growth can occur in the absence of a paracrine IGF-1 system, these studies do not preclude a role for locally generated IGF-1 as a redundant signalling mechanism or the role of other locally produced growth factors.

Progesterone Signaling

Progesterone is a vital steroid hormone that is involved in secretory preparation of the endometrium for implantation, decidualization, and suppression of myometrial contractility during pregnancy. As seen in a later section, progesterone possesses anti-inflammatory characteristics and promotes immunotolerance during implantation and pregnancy. It is also associated directly, or indirectly, with most of the secretory proteins made by the endometrium that support embryo development and implantation.

Progesterone signaling in the endometrium is a complex process involving differential actions of progesterone on each of the cellular compartments, including the epithelium, stroma, and resident bone-marrow derived immune cells, as well as the resulting paracrine communication between cells of adjacent compartments.[104,105] The complexity of these interactions is further extended by the dynamic changes in expression of the receptors for progesterone.

As discussed earlier in the chapter and in Chapter 5, both ERα and PR concentrations increase in response to circulating estradiol in the proliferative phase of the menstrual cycle. After ovulation, estrogen action may be unnecessary for normal secretory endometrial development,[106,107] and may inhibit implantation.[108] Estrogen receptors normally disappear in the endometrial epithelium at the time of implantation in most mammals studied to date, including humans.[46,109]

In mice, specific and selective deletion of ERα and PR as well as recombination studies of stroma and epithelium have yielded insight into the relative roles of these steroid receptors in each compartment. It has become increasingly clear that progesterone has both direct and important indirect roles in both stroma and epithelial function.[93,110,111] The relevance of these findings to human tissue remains to be fully understood.

During the early proliferative phase, when progesterone concentrations are low, cytoplasmic PR is shielded from degradation by heat shock proteins and by interactions with coactivator proteins (SRC1 and 2) and chaperone proteins such as FKBP4 and FKBP5. In mice with a SRC2 conditional knock *(Ncoa2 $^{-/-}$)* the females are infertile, similar to FKBP4 null mice, with each displaying implantation and decidualization failure.[112,113] In women, both FKBP4 and FKPB5 expression normally increases in the secretory phase, possibly regulated by HOXA10. Interestingly, blunted increases in FKBP4 are seen in endometrium from women with infertility and endometriosis,[114] regulated in part by changes in microRNA that regulate degradation of mRNA coding for FKBP4 and other progesterone-regulated genes.[115-117] Recent evidence links SRC1 to the progression of endometriosis as well. A proteolytic fragment of SRC1, cleaved by tumor necrosis factor-alpha (TNFα)–induced MMP-9, prevents TNFα-induced apoptosis of the endometrial epithelium and promotes epithelial-mesenchymal transformation, part of the pathophysiology of endometriosis.[118]

Much of our understanding of implantation and the role of progesterone is based on studies in the mouse. The action of progesterone begins with epithelial PR binding to progesterone followed by the induction of a key target gene, Indian Hedgehog (IHH).[111] Epithelial IHH is secreted and communicates with the endometrial stroma, through the receptor Patched-1 (PTCH1) resulting in increased stromal transcription factor, chicken ovalbumin upstream promoter transcription factor II (COUP-TFII), with down-stream effectors including bone morphogenic protein-2 (BMP2) and WNT4. Similar to mice lacking FKBP4, COUP-TFII-deficient mice are infertile and have excessive estrogen action and failure of ERα down-regulation. As mentioned earlier in this chapter, WNT4 is required for müllerian development and in adults is required for decidualization. WNT4 is also thought to be responsible for shuttling Forkhead box protein 1 (FOXO1), a transcription factor essential for decidualization, from the nucleus to the cytoplasm, preventing its apoptotic actions. These signaling pathways are shown in Figure 10.3.

Some of the stromal genes expressed in response to progesterone action include *HOXA10*, heparin-binding EGF-like growth factor *(Hbegf)*, cyclooxygenase 2 (Cox-2, encoded by *Ptgs2*) and mitogen inducible gene 6 *(Mig-6)*. Mig-6 is a negative regulator of EGF receptor and transgenic knockout mice for this protein have endometrial hyperplasia, suggesting this progesterone-regulated gene is an important brake for cell proliferation in the endometrium. The homeobox gene, HOXA10 is essential for uterine development, but in the adult has been shown to regulate FKPB4[119] and is therefore also essential for progesterone action and implantation. HOXA10 also directly upregulates epithelial receptivity genes such as the αvβ3 integrin.[120] Transgenic mice lacking PR, HOXA10, Cox-2, or LIF in transgenic mice all have decidualization defects and infertility.[121]

The uterus is a target for androgens, as well as estrogens and progestins.[122] Androgen receptors (AR) are expressed

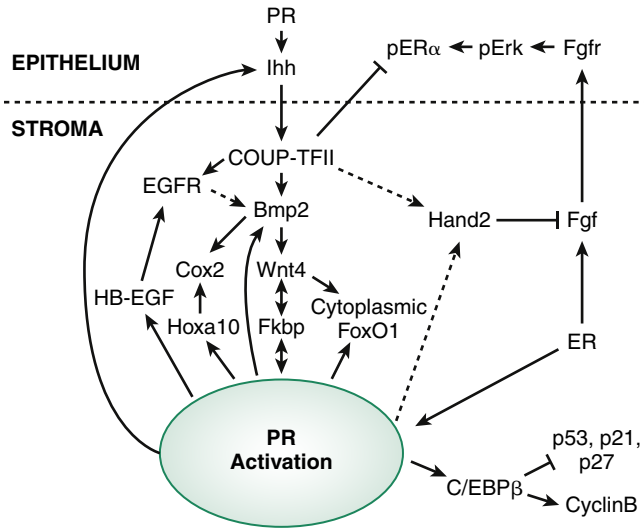

FIGURE 10.3 Progesterone signaling in the endometrium involves communication between the epithelium and the stroma, with complex interactions of the Indian Hedgehog and WNT pathways. One of the down-stream effects of progesterone is the down-regulation of estrogen signaling in both endometrial epithelial and stromal cells. *(Adapted from Large MJ, Demayo FJ. The regulation of embryo implantation and endometrial decidualization by progesterone receptor signaling.* Molecular and Cellular Endocrinology *358:155–165, 2012.)*

in the endometrium and myometrium, most prominently in the stromal cells during the proliferative phase and in the epithelial cells of the secretory phase. MAGE-11, was originally described as an AR coactivator,[123] reaches peak expression in the secretory phase and colocalizes with AR.[78] Interestingly, 5α-reductase types 1 and 2, which convert testosterone to dihydrotestosterone, are expressed in epithelial cells throughout the cycle.[124] Estradiol treatment increases androgen receptor expression in the stroma of the Rhesus monkey uterus, and estradiol in combination with either testosterone or progesterone augments epithelial and myometrial androgen receptor levels. Consistent with these observations, androgen receptor expression is elevated in the endometrium of women with polycystic ovary syndrome; this finding may explain, in part, the implantation defects and early pregnancy loss reported to be associated with this syndrome.[125] Androgens and AR may also have essential roles for reproductive tract function in females and this topic is becoming an active area of research.[126]

There is increasing interest in functional, non-traditional estrogen and progesterone receptors with roles in reproductive tract biology.[127-129] Rapid actions of estrogen have been known since the discovery of the estrogen receptor, though a thorough understanding of its mechanisms of actions has only recently been understood. Estradiol can act within minutes to stimulate second messenger generation and phosphorylation of kinases. One mediator for rapid estrogen signaing is the orphan G protein-coupled receptor, GPR30. This plasma membrane protein is thought to serve as an alternative steroid receptor to ERα. Evidence suggests that this protein mediates activation of EGF and down-stream kinase activity,[130,131] likely involving release of the growth factor EGF and MAP kinase activation.[132] Progestins may also use this pathway, adding further complexity to our understanding of estrogen/progesterone interactions.[133] It is not clear whether GPR30 is on the outer plasma membrane or within the endoplasmic reticulum.[50] During the menstrual cycle, endometrial GPR30 is maximal during the late proliferative phase, similar to traditional ERα —and like ERα, is increased in women with endometriosis.[54]

Membrane forms of PR have also been identified, including mPRα, mPRβ, and mPRγ.[134] Membrane PR have been shown to rapidly activate MAP kinase and inhibit cyclic adenosine monophosphate (cAMP).[135] Both mPRα and mPRβ have been localized to the myometrium of humans and function to inhibit cAMP with a possible role of facilitating uterine contractions at term.[136]

Steroid Hormone Metabolism in the Reproductive Tract

The level of bioactive steroid hormone in the uterus is determined in part by the activities of uterine enzymes that form active molecules from prohormones and catabolize active hormones (Fig. 10.4).[137] The enzymes that carry out transformations of steroid hormones are subject to regulation during the menstrual cycle. Estradiol taken up from the plasma can be converted into estrone by the action of 17β-hydroxysteroid dehydrogenases (17β-HSD), or converted to sulfated conjugates by estrogen sulfotransferase.[138] Three different forms of 17β-HSD capable of oxidizing estradiol to estrone have been detected in primate endometrium: the type 2, type 4, and type 8 enzymes.[139] Type 2 and type 8 enzymes are associated with microsomes; type 4 enzyme is in peroxisomes. Type 2 and type 4 enzymes use the oxidized form of nicotinamide adenine dinucleotide as a cofactor and are predominantly localized to glandular epithelium in the secretory phase. The endometrial type 2 enzyme shows the greatest change in expression during the cycle, peaking in the secretory phase. The type 8 enzyme appears to be constitutively expressed. Progesterone enhances the conversion of estradiol to estrone in endometrial cells by inducing expression of the type 2 17β-HSD and, to a much lesser degree, the type 4 enzyme. Progesterone also increases endometrial estradiol sulfation by increasing estrogen sulfotransferase activity. Thus, progesterone activates enzymatic pathways that inactivate estradiol. However, there are regional differences in the balance of systems removing and restoring estradiol in the uterus. For example, estrogen sulfatase is detected only in the glandular epithelium of the basalis, where it may function to increase the level of estradiol from estradiol sulfate.[140] The human uterus does not normally have the capacity to produce significant amounts of estrogen locally (either de novo or from circulating prohormones), but endometrial cancers, endometriotic lesions, and, to a lesser extent, eutopic endometrium of women with endometriosis aberrantly express components of the steroidogenic machinery ($P450_{arom}$) that endows the tissue with the capacity to synthesize estrogens from circulating adrenal or ovarian androgens or by *de novo* synthesis. Endometriosis lesions have been found to express StAR, the cholesterol side-chain cleavage enzyme, P450c17, aromatase, and type 1 17β-HSD in stromal cells (see Chapter 4). Estradiol produced in these lesions can enhance production of prostaglandin E2, which in turn stimulates transcription of the aromatase gene, resulting in a feed-forward mechanism for increasing local estrogen

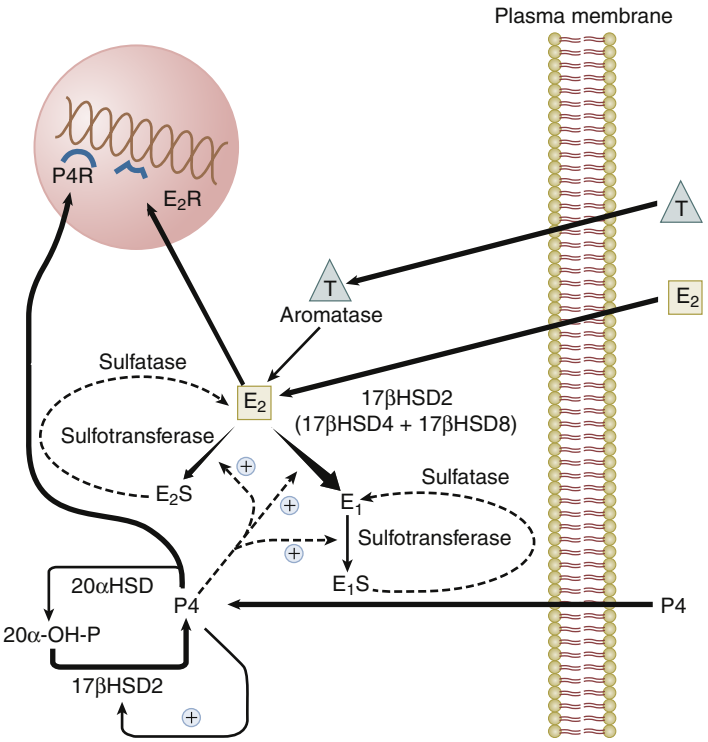

FIGURE 10.4 Steroid metabolism and action in the endometrium. P4 prevents the E_2-stimulated translocation of cyclin Di and Cdk4 into the nucleus while activating Cdk2, a cyclin A kinase, which inhibits the mitrogen effects of E_2.

levels. In addition, endometriotic lesions do not express the progesterone-regulated type 2 17β-HSD that converts estradiol to estrone, which effectively increases the bioavailability of estradiol. Eutopic endometrium from both endometriosis and polycystic ovary syndrome (PCOS) patients exhibit progesterone resistance as measured by decreased type 2 17β-HSD[141,142]; with the lack of deactivation of estradiol leading to increased estrogen action. Elevated estrogen may explain the increased proliferation seen in the endometrium of women with endometriosis[143] and contribute to the decrease in endometrial receptivity defects noted in these conditions.[59]

Aberrant expression of aromatase in endometriosis is thought to be due, in part, to the presence of steroidogenic factor 1 (SF-1), an orphan nuclear transcription factor that is not usually present in normal endometrium.[144] It has been proposed that SF-1 in endometriosis stromal cells displaces an inhibitory transcription factor, COUP-TFII (which is abundant in normal endometrial stromal cells) from SF-1 binding sites on the aromatase promoter, propelling assembly of the general transcription machinery and aromatase expression. In addition, by supplanting COUP-TFII, a mediator of progesterone action, may contribute to the progesterone resistance observed in this disease.[61] Other steroidogenic proteins found in endometriosis lesions, including StAR, P450scc, and P450cl7 are encoded by SF-1 (NR5A1)-regulated genes; a similar mechanism may underlie their expression in endometriosis.[145] The lack of type 2 17β-HSD in endometriosis has been attributed to abnormal expression of progesterone receptor isoforms with the A form, which generally suppresses transactivation, predominating over PR-B in endometriosis.[90,146] Studies also suggest aberrant expression of ERα[59] and ERβ,[147,148] as other features of endometriosis that promotes proliferation and cell survival.[66,149,150]

Progesterone is catabolized in the uterus to inactive 20α-hydroxyprogesterone by 20α-HSDs. The type 2 17β-HSD, which is increased in the secretory phase, is also a 20α-hydroxysteroid oxidase that converts 20α-hydroxyprogesterone back into progesterone.[137] The induction of the type 2 17β-HSD by progesterone in the secretory phase therefore not only contributes to the catabolism of estradiol, but also to the maintenance of endometrial progesterone levels.

The Adult Female Reproductive Tract and Dynamic Changes During the Menstrual Cycle

The Fallopian Tubes

The fallopian tubes facilitate gamete transport and serve as the venue for fertilization and early embryo transport. These functions are accomplished by the tubal epithelium and underlying smooth muscle. Although *in vitro* fertilization-embryo transfer has clearly demonstrated that the fallopian tubes are not essential for animal and human conception, an understanding of tubal physiology was essential to the development of the modern practice of assisted reproduction. Moreover, further elucidation of the oviductal environment could improve the outcome of assisted reproduction.

The oviduct has four anatomical regions spanning from the distal to the proximal end: the *fimbria* and *infundibulum*, the *ampulla*, the *isthmus*, and the *intramural segment*. The structures of the endosalpinx and myosalpinx in these segments are distinctive and correlated with their functional roles in gamete transport and the fertilization process.[151] In addition, the junctions between the ampulla and isthmus and the uterus and tube are important physiological sphincters that regulate the residence time of eggs and early embryos in the oviduct.

Gamete Transport

At the time of ovulation, the fimbriae become tumescent and congested, exhibiting pulsatile and sweeping movements.[152] The fimbriae and infundibulum have the highest density of ciliated cells in the oviduct, which beat in a centripetal direction in the peri-ovulatory period. The concerted movements of the fimbriae and ciliary strokes facilitate the pick-up of the ovulated egg and its entrance into the ampulla, which has a thin muscular layer and a mucosa that is thrown up in numerous folds, providing a large surface area for transport and exchange. Transport is arrested when the egg reaches the ampullary-isthmus junction, the site where fertilization occurs. Transport through the isthmus, which, in contrast to the ampulla, has only a few primary mucosal folds but a thicker myosalpinx, takes several days.[153]

The intramural segment of the tube, surrounded by abundant smooth muscle, serves as a second physiological sphincter. Activity of this sphincter appears to be regulated by adrenergic innervation, steroid hormones, and prostanoids. Gamete and embryo transport process is facilitated by contraction and relaxation of the myosalpinx. Light microscopic studies distinguish longitudinal and circular smooth muscle layers in the tube, but the ampulla appears to have a different organization, consisting of a continuous network of randomly anastomosed smooth muscle bundles that are repeatedly intertwined, branching into different orientations.[154] It has been proposed that this single network of muscular fibers generates random contractile waves that cause "stirring" of the tubal contents, a process that may facilitate fertilization and early embryo development by enhancing access of growth factors and nutrients and exchange of metabolites. Local production of prostaglandins F2α and E2 (which stimulate contraction) and prostacyclin (which causes relaxation) probably play an important role in regulating the contraction and relaxation pattern of both the longitudinal and circular muscle of the tubes.[155] Human chorionic gonadotropin (hCG) released by the early embryo can induce Cox-2 mRNA expression in tubal epithelium, which promotes increased prostacyclin production that would favour the opening of tubal sphincters.

Studies of laboratory and domestic species have shown that sperm reaching the oviduct are stored in the caudal part of the isthmic region through surface-associated sperm lectins that bind to oviductal epithelial cell glyco-conjugates.[156] These interactions appear to increase the viability of sperm and to suppress capacitation and sperm motility evidently by modifying intracellular calcium concentrations in the spermatozoa. Near the time that the egg enters into the ampulla of the tube, sperm initiate the capacitation process and are released from the oviduct epithelium in a hyperactivated state. Although there is a substantial body of literature documenting sperm binding to the oviduct in animals, there is no conclusive evidence that this occurs in humans. However, human sperm viability *in vitro* is promoted by coculture with oviductal epithelial cells despite the lack of tight binding.

The Tubal Epithelium and Tubal Fluid

The human tubal epithelium is composed of ciliated and secretory cells that undergo cyclic alterations in response to changes in ovarian steroid hormone levels.[157] In both the fimbriae and ampulla, epithelial cells attain their greatest height, extent of ciliation, and beat frequency in the late follicular phase. At the end of the luteal phase some cellular atrophy and loss of cilia is observed, particularly in the fimbriae, with hypertrophy and reciliation occurring in the subsequent follicular phase. In contrast, if pregnancy is achieved there is further atrophy and loss of cilia. These observations indicate that estrogen dominance promotes ciliogenesis while progesterone dominance leads to atrophy and deciliation. Female infertility, presumed to be of tubal origin, is a variable feature of primary ciliary dyskinesia and Kartagener syndrome, indicating that ciliary function in the female reproductive tract is important, but not absolutely essential, for *in vivo* fertilization.[158,159]

Gamete transport, fertilization, and early embryo development occur in a fluid environment created by the tubal epithelium. The production of oviductal fluid by selective transudation and secretion changes during the cycle in primates.[160,161] Tubal fluid accumulates at a rate of 1 to 3 mL every 24 hours, with a significant increase in accumulation around the time of ovulation. The primary cells responsible for fluid secretion in the oviduct are thought to be the non-ciliated cells, which maintain a transmural potential electrical potential through flux of chloride ions. The mechanisms of tubal fluid secretion and its regulation by steroid hormones, neurotransmitters, and inflammatory mediators are incompletely understood. Knowledge of tubal fluid composition has informed the development of culture media for *in vitro* fertilization and early embryo development.[161-164] Tubal fluid is enriched in bicarbonate compared with plasma, which facilitates sperm capacitation by activating a sperm soluble adenylyl cyclase; bicarbonate also promotes separation of the corona radiata of the egg. The high bicarbonate content of tubal fluid is maintained by carbonic anhydrase activity in tubal epithelial cells.

There are cyclic variations in the nutrient content of tubal fluid, which can influence human embryo development *in vitro*.[164] Such variation is exemplified by a sixfold decline in glucose, from 3.1 to 0.5 mM, from the follicular phase to the time of ovulation, and an increase in lactate from 4.9 to 10.5 mM during the same time. The levels of pyruvate in tubal fluid (0.14 to 0.17 mM), an important initial embryo energy substrate, do not change during cycle. Arginine, alanine, and glutamine are the most abundant amino acids in the tubal fluid; these and most other amino acids, except asparagine, are generally present in highest concentrations during the secretory phase. Taurine and hypotaurine are also major constituents that have been implicated in improved viability of gametes and preimplantation embryos.

Albumin is the major protein in tubal fluid that also contains secretory proteins from the epithelium. A high-molecular-weight mucin-like glycoprotein called *oviductin* (also known as oviduct-specific glycoprotein) is expressed exclusively by the oviduct epithelium under the regulation of estrogen.[165] Oviductin has chitinase-like domains that may facilitate its binding to oligosaccharides on the zona pellucida. This coating of oviductin may prevent ectopic pregnancy by forming a barrier between the embryo and the tubal epithelium. Oviducts also express a variety of growth factors and cytokines that could influence embryo growth and development.

The metabolical and secretory activity of animal and human tubal epithelial cells has been employed in human assisted reproduction. Several co-culture protocols have resulted in increased implantation and pregnancy rates, indicating a beneficial effect of a "tube-like" microenvironment. However, it is not known if any beneficial effects of co-culture are specific to oviductal epithelium as opposed to being a general salutary effect of a somatic cell layer.

Tubal Pregnancy

The fallopian tube is functionally important for transport of gametes and embryos, but ill-suited as a site of embryo implantation.[166] A period of receptivity for implantation seen in the endometrium is not observed in tubal epithelium.[167] Understanding ectopic implantation of human embryos provides further insight into the mechanisms governing endometrial implantation.[168]

The high incidence of ectopic pregnancy, about 1% to 2% of all pregnancies,[166] is often taken to suggest that the embryo's requirements for implantation depend less on the tissue into which it implants than its own intrinsic potential for attachment and invasion. However, the tight temporal control of endometrial implantation suggests a strong influence of the tissue comprising the implantation site. These apparently contradicting data may be reconciled by a more detailed understanding of ectopic pregnancies. While tubal epithelium is not normally receptive to implantation,[167] changes in tubal epithelium might lead to an altered molecular dialog or endocrine milieu that contributes to ectopic implantation.[169-173]

Tubal ectopic pregnancies, which comprise over 90% of all ectopics, are strongly associated with tubal infection and surgery. The most common single cause is thought to be a history of chlamydial infection. Chlamydial infection of murine fallopian tubes initiates an inflammatory cascade dependent on Toll-like receptor 2 (TLR2) and modulated by Toll-like receptor 4 (TLR4), leading to generation of inflammatory cytokines, including TNFα, interleukin (IL) -1beta, and IL-6, which lead to damage of fallopian tube epithelium, in part via MMP-9.[174] Interestingly, IFN-γ, unlike IFN-alpha or beta protects against tubal inflammation and destruction after murine chlamydial infection.[175,176] The factors mediating chlamydial damage in human fallopian tubes is less well understood, but expression and regulation of TLR2, TNF-alpha, IL-1beta, IL-1R, IFN-γ, and MMP-9 have been clearly documented in human tubal epithelium and MMP-9 immunoreactivity is absent in tubal epithelium of women with ectopic pregnancy.[177]

Recently, the role of estrogen signaling tubal transport of embryos was reported.[178] Since inflammatory actions of TLR2 and TLR4 are mediated via NF-kB activation and since NF-kB is noted to inhibit steroid hormone action in many cell types, the authors suggested that lack of estrogen action in the fallopian tube might lead to embryonic stasis and subsequent implantation into damaged epithelium. Thus, the role of tubal inflammation and damage in ectopic implantation provides a window to look at mechanisms governing normal embryo implantation.

The Endometrium

In discussions of structure and function, the primate endometrium is commonly described as consisting of two major layers, the *functionalis* and *basalis* (Fig. 10.5). The functionalis is a transient layer consisting of a compact zone that includes the stroma subjacent to the luminal epithelium and an intermediate spongy zone containing more

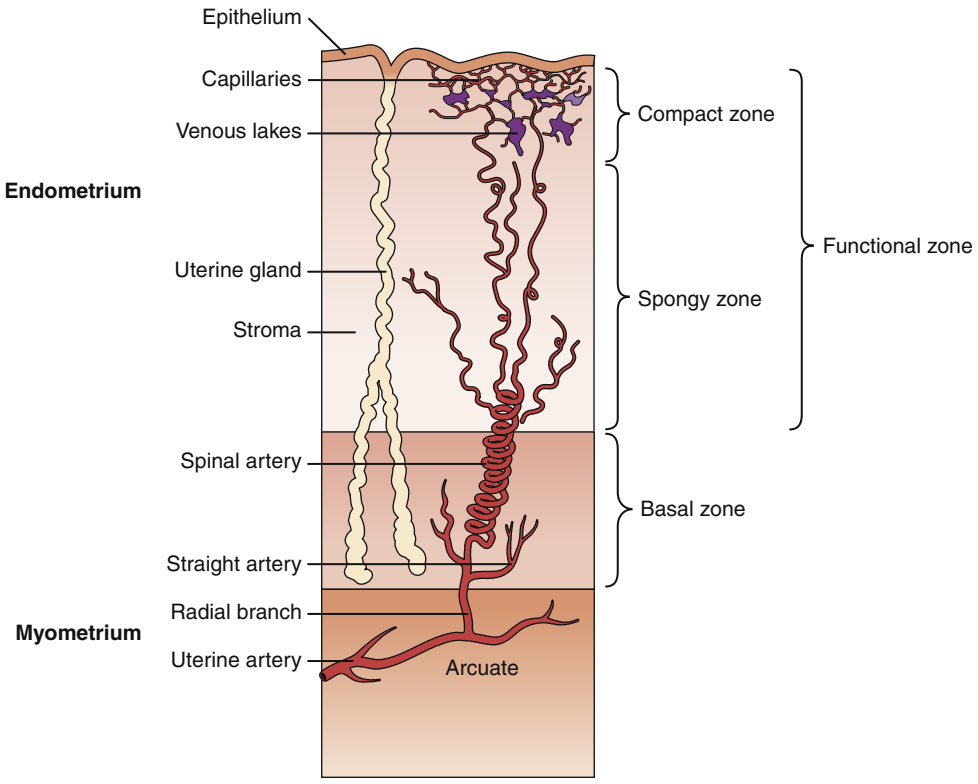

FIGURE 10.5 Histological organization of secretory-phase human endometrium. *(Modified from Weiss L, Creep RO [eds]. Histology, 4th ed. New York: McGraw-Hill, 1977, p 911.)*

densely packed tortuous glands, giving it a lacy histological appearance. The basalis, or basal layer, lies beneath the spongy zone and adjacent to the myometrium. It contains the gland fundi and supporting vasculature, and can generate the entire endometrium after the menstrual shedding of the *functionalis*. These endometrial layers are histologically definable during the secretory phase. However, in terms of function, the endometrium is best considered as a polarized gradient of cells with different phenotypes. The upper layers undergo a striking progression of histological change during the menstrual cycle, whereas the basal region shows only modest alterations. Patterns of cell proliferation, programmed cell death, and gene expression also show gradients across the layers, as described in the next sections. The majority of epithelial cell proliferation occurs in the upper regions of the functionalis during the proliferative phase of the cycle. Proliferatve activity in glands in the basalis is modest during the proliferative phase, with increased proliferative activity during the early to midsecretory phase,[179-181] maintaining both ER and PR at a time when these receptors are normally depleted in the upper functionalis epithelium.[46]

The Early Proliferative Phase

During the early proliferative phase, the endometrium is usually less than 2 mm in thickness. Proliferation of cells in the basal zones and epithelial cells persisting in the lower uterine and cornual segments result in the restoration of the luminal epithelium by day 5 of the menstrual cycle. At that time, mitotic activity is evident in both the glandular epithelium and stroma. Remarkably, this recurrent "wound healing" process does not normally produce scarring. Endometrial stem cells capable of yielding progenitors of both the stromal and epithelial components of the endometrium presumably contribute to the regenerative process.[182]

Rapid rejuvenation of the endometrium depends on many of the same factors that were involved in the ontogeny of the reproductive tract. WNT7A, is expressed solely by the luminal epithelium and is a diffusible factor that triggers cell proliferation through complex pathways.[18,19] Acting on the underlying stroma, soluble WNT7A binds to the receptor Frizzled (FZL) that phosphorylates the intracytoplasmic protein Dischevelled (DSH); (Fig. 10.6A). This protein inactivates glycogen synthase kinase beta (GSKβ) turning off the breakdown of beta catenin by ubiguitinization. Accumulation of beta catenin signals cell proliferation activities

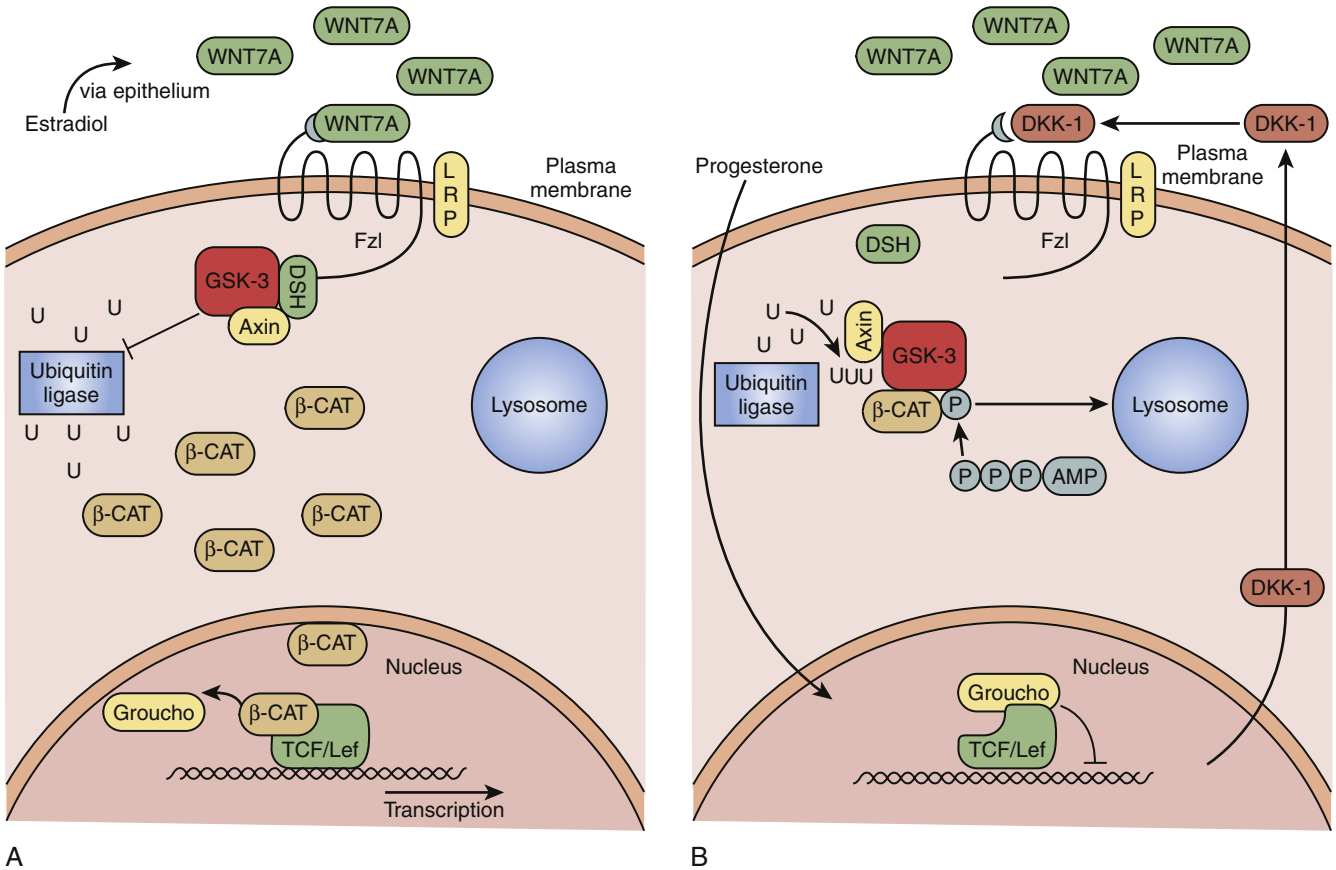

FIGURE 10.6 Wnt signaling pathways in proliferative and secretory phase of the menstrual cycle. WNT7A is a soluble factor thought to arise from the luminal epithelium. **A,** Under conditions of estrogen action, WNT7A binds to the receptor, Frizzled (FZL) initiating signaling through the intracytoplasmic protein dissheveled (DSH). Dissheveled binds axin and glycogen syntase kinase beta (GSK), allowing beta catenin (β-CAT) to accumulate and stimulate gene transcription leading to cell proliferation. **B,** When progesterone levels increase, cellular dickkopf-1 accumulate and inactivate Fzl through an accessory receptor, LRP. Without WNT7A, GSK facilitates the ubititinization of β-CAT, which makes it unavailable as a transcription factor.

associated with endometrial growth acting as a transcription factor in the nucleus. The diffusion gradient of WNT7A downward into the growing endometrium is an attractive model for self-regulatory mechanisms to determine the growth of the endometrium.

Counter-regulatory mechanisms to disable WNT7A/FZL/DSH pathways include the action of progesterone, which stimulates secretion of a protein called Dickkopf-1 (DKK-1); (Fig. 10.6B).[18,19] Dickkopf-1 binds to a coreceptor, LRP6 blocking the FZL receptor turning off the action of WNT7A by preventing beta catenin accumulation. Defects in DKK-1 production have been described in endometriosis and reflect progesterone resistance and might explain the proliferative phenotype of the endometrium in this condition.[114,183]

The glands during the early proliferative phase are narrow, straight, and tubular, lined with low columnar cells that have round nuclei located near the cell base (Fig. 10.7). At the ultrastructural level, the epithelial cell cytoplasm contains numerous polyribosomes, but the endoplasmic reticulum and Golgi complexes of these cells are not well developed.

The Late Proliferative Phase

The endometrium thickens in the late proliferative phase as a result of glandular hyperplasia and an increase in stromal extracellular matrix. The glands are widely separated near the endometrial surface and more crowded and tortuous deeper into the endometrium. The glandular epithelial cells increase in height and become pseudostratified as the time of ovulation approaches (Fig. 10.7).

The effect of steroid hormones on the proliferation and secretion within the endometrium is highly dependent on the zones (basalis vs. functionalis layers). Studies from the rhesus macaque endometrium using specific labelling techniques show proliferation during the "proliferative" phase is confined to the functionalis layer.[184] By the midsecretory phase, this proliferation has shifted to the basalis layer, presumably due to maintenance of epithelial and stromal estrogen receptors.[92,185]

The Early Secretory Phase

Ovulation marks the beginning of the secretory phase of the endometrial cycle, although it should be noted that the endometrial luminal and glandular epithelial cells also

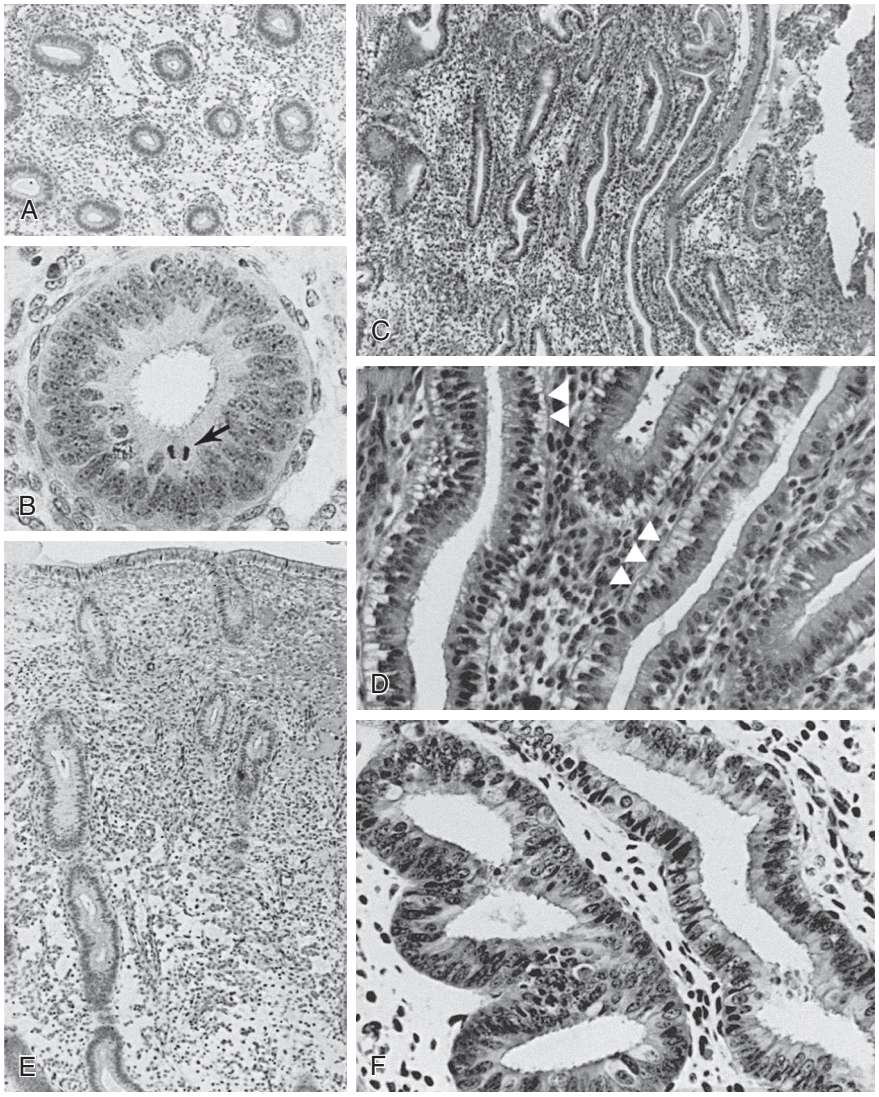

FIGURE 10.7 Histology of the endometrium during the menstrual cycle. **A** and **B,** Proliferative endometrium. Mitoses are present *(arrow)*. Nuclei in the glandular epithelium are pseudostratified. **C** and **D,** Secretory endometrium, day 18. Subnuclear glycogen vacuoles are uniformly present in glandular epithelium *(arrowheads)*. **E** and **F,** Midsecretory endometrium. Glandular secretory activity is present, and the stroma is edematous. The stromal cells in the more superficial layers as well as around vessels have become pseudodecidualized and exhibit a flattened, polygonal configuration with distinct cell borders.

display secretory activity during the proliferative phase. Mitotic activity in epithelial and stromal cells is restricted to the first 3 days after ovulation and is rarely observed later in the cycle. The nuclei of glandular epithelial cells and stromal cells develop heterochromatin in the early secretory phase (Fig. 10.6). The glandular epithelial cells begin to accumulate glycogen-rich vacuoles at their base, displacing the nuclei to the mid regions of the columnar cells. Evidence for modest secretory activity is seen in histological preparations as a light eosinophilic collection in the gland lumina. Ultrastructural studies of endometrial epithelia reveal abundant endoplasmic reticulum, and unusually large mitochondria with prominent cristae. A reticular network of argyrophilic fibers containing fibrillar collagens (collagen fiber type I and type III) is established in the stroma by the early secretory phase. Stromal edema contributes to the thickening of the endometrium at this time.

The Midsecretory Phase

A characteristic feature of this phase of the cycle is the development of the spiral arteries. These vessels become increasingly coiled as they lengthen more rapidly than the endometrium thickens. The endometrial glands are tortuous in the midsecretory and late secretory phases. Their secretory activity reaches a maximum about 6 days after ovulation, as reflected by loss of vacuoles from the epithelial cell cytoplasm (Fig. 10.7).

An ordered spherical stack of interdigitating tubules, the nucleolar channel system, appears transiently in the nucleoli of approximately 5% to 10% of the secretory phase epithelial cells between day 16 and 24 (Fig. 10.8).[186] The nuclear channel system is thought to form from an invagination of the inner nuclear membrane, providing a direct connection to the perinuclear space for transport of mRNA to the cytoplasm. Nopp140, a highly phosphorylated protein that associates with small nucleolar ribonucleoprotein particles that are required for RNA processing, appears to induce formation of this intranuclear endoplasmic reticulum.[187] The nucleolar channel system forms in response to progesterone and is an ultrastructural hallmark of the secretory phase during the expected time of implantation.

Stromal cells around blood vessels enlarge and acquire an eosinophilic cytoplasm and a pericellular extracellular matrix in the mid to late secretory phase. These changes, referred to as *predecidualization* to distinguish them from the further transformation of the stroma that occurs in a fertile cycle, subsequently spreads accentuating the demarcation between the subepithelial compact zone and the spongy zone. Unlike many laboratory animal species, an embryonic signal is not required for initiation of decidualization in the human uterus.

The fact that the predecidual changes occur first near blood vessels suggests that humoral or local factors provoke them. Among the local factors may be interactions with decidual granular lymphocytes, also referred to as uterine *natural killer* (NK) cells. NK cells encircle arterioles and closely associate with stromal cells through contacts that are remarkably similar to gap junctions.[188] At the ultrastructural level, the predecidual stromal cells display well-developed Golgi complexes and parallel lamellae of endoplasmic reticulum. Their surrounding matrix consists of laminin, fibronectin, heparan sulfate, and type IV collagen.[189,190] The profile of gene expression decidualizing human stroma cells *in vitro* has been mapped by microarray analysis and includes induction of 121 genes, down-regulation of 110 genes, and 50 genes showing a biphasic response.[191]

The stromal cells of the midsecretory and late secretory phase also express a repertoire of proteins that promote hemostasis—including tissue factor, a membrane-associated protein that initiates coagulation when it contacts blood, and plasminogen activator inhibitor type 1 (PAI-1), also known as Serpin E1, which restrains fibrinolysis.[192,193] The pattern of gene expression prevents focal hemorrhage that might result from trophoblast invasion during implantation.

The Premenstrual Phase

The main histological features of the premenstrual phase are degradation of the stromal reticular network, which is catalyzed by matrix metalloproteinases; infiltration of the stroma by polymorphonuclear and mononuclear leukocytes; and "secretory exhaustion" of the endometrial glands, whose epithelial cells now has basal nuclei. Morphological changes in the nuclei of granular lymphocytes, including pyknosis and karryorhexis suggesting apoptosis, have been proposed to be some of the first events presaging menses; these changes occur prior to the breakdown of extracellular matrix and leukocyte infiltration.[194] In the glandular epithelium, the nucleolar channel system and giant mitochondria characteristic of the early and midsecretory phases have vanished. The endometrium shrinks preceding menstruation,

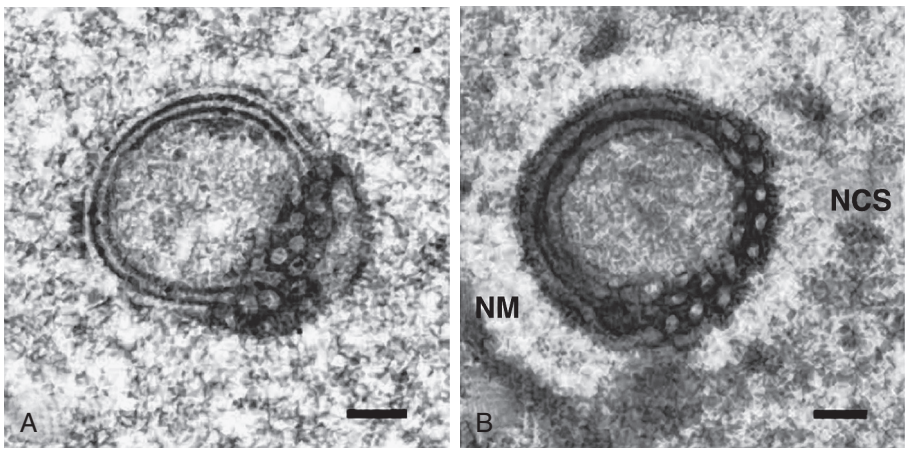

FIGURE 10.8 Images of the nucleolar channel system (NCS) at the electron microscope level. **A,** A nucleolar channel-like structure in COS cells transfected with a Nopp140 construct. **B,** A nucleolar channel system induced by progesterone in endometrial cells. Intranuclear endoplasmic reticulum induced by Nopp140 mimics the nucleolar channel system of human endometrium.* Cell Sci *114:4253–4264, 2001.)*

partly as a result of diminished secretory activity and the catabolism of extracellular matrix.

Menstruation

Menstruation, caused by progesterone and estrogen withdrawal, marks a failure to achieve pregnancy and the need to shed the specialized uterine lining that results from spontaneous decidualization. The uniqueness of this process is highlighted by the fact that, although circulating progesterone and estrogen levels decline with corpus luteum regression in non-fertile cycles in all mammals, menstruation only occurs in human females and some Old World primates. In menstruating species, moreover, tissues that respond to estrogen and progesterone such as the fallopian tubes, vagina and breast do not shed as ovarian steroid levels decline. The molecular mechanisms triggered by progesterone withdrawal include activation of the NF-κB transcriptional pathway (a major target of cytokines) and the resulting expression of genes, like endometrial bleeding—associated factor (EBAF; AKA Lefty), an anti—TGF-β cytokine that interferes with the action of other members of the TGF-β family that promote endometrial integrity. This orchestrated blockade of the actions of TGF-β appears to initiate many of the subsequent events of menstruation, including the elaboration of MMPs.[195]

Menstruation is a complex process of changes initiated by progesterone withdrawal.[196] The functional zone of the human endometrium is supplied by spiral arterioles that, in contradistinction to the radial and basal arteries that feed them, are highly sensitive to steroid hormones. In the classic studies of Markee,[197] the structure of autologous endometrial transplants into the anterior eye chamber was observed during menses, suggesting that an ischemic phase caused by vasoconstriction of the arterioles and spiral arteries precedes the onset of menstrual bleeding by 4 to 24 hours. It has been proposed that bleeding occurs after the arterioles and arteries relax, leading to hypoxia or reperfusion injury.

These findings of Markee form the basis for the vasoconstriction model of menstruation. However, the notion that menstruation is a consequence of generalized vasoconstriction and hypoxia/anoxia in the functionalis is not supported by studies of endometrial perfusion that have failed to reveal any significant reduction in endometrial blood flow in the perimenstrual phase and during menstruation.[198] In addition, an analysis of expression and localization of hypoxia-inducible factor (HIF), a heterodimeric transcription factor induced by hypoxia and thus a biochemical marker of reduced oxygen availability, was unrevealing. No up-regulation of the two HIF component subunits, HIF-lα and HIF-lβ, was observed, and no nuclear localization of HIF subunits took place in the peri-menstrual human endometrium.[199] These studies do not, however, exclude the possibility of localized regions of vasoconstriction and hypoxia.

An alternative hypothesis to the vasoconstriction model is that menstruation is an inflammatory response engendered by the withdrawal of progesterone. The inflammation hypothesis is supported by two features: the prominent accumulation of leukocytes in the endometrium in the premenstrual phase,[188] and the release of matrix-degrading enzymes characteristic of an inflammatory response.[200-203] The hypothesis of progesterone withdrawal—induced inflammation is supported by the uterine inflammation observed in mice lacking progesterone receptors. Apoptotic cell death, which can be triggered by inflammatory mediators, occurs in the late secretory phase first in stromal cells and then gradually spreading throughout the functionalis.[204-206] Rescue from apoptosis has been shown to occur *in vivo* with the administration of progesterone or exogenous hCG.[207]

Changes in proteins involved in apoptosis appear to contribute to the regional programmed death in the endometrium. The anti-apoptotic protein, B cell CLL/lymphoma 2 (Bcl-2), is prominently expressed in the glandular epithelium during the proliferative phase; expression declines in the secretory phase to reach low levels in the late secretory phase when apoptosis occurs.[206] Studies report an inverse pattern of expression of survivin, a recently discovered inhibitor of apoptosis. Survivin binds to and blocks the effector cell death proteases, caspase-3 and -7. The activities of caspase-3, -8, and -9, are higher in the secretory phase. Low rates of survivin expression in glandular epithelium are found in the proliferative phase, rising to peak expression in the late secretory phase. The protein was localized to the nuclei of cells in the functionalis and the cytoplasm in cells in the basalis. This differential distribution may indicate that survivin is not capable of suppressing apoptotic death in the functionalis in the late secretory phase but performs this role in the basalis, consistent with the observed patterns of apoptotic cell death. Elevated levels of survivin in endometriotic lesions correlates with reduced apoptotic death of cells in these lesions.[208]

Although the vasoconstriction and inflammation hypotheses of menstruation might appear to be distinct, there are several overlapping biochemical features of hypoxia and inflammation, including the release of pro-inflammatory cytokines and apoptotic cell death that tend to blur the distinctions between these models. The vascular changes in the endometrium in the perimenstrual phase, resulting either from ischemia-hypoxia or inflammatory reaction, lead to extravasation of blood. Autophagy and heterophagy are evident, as is apoptotic cell death. The superficial endometrial layers become distended by the formation of hematomas; fissures subsequently develop, leading to the detachment of tissue fragments and the ultimate shedding of the functionalis. The resulting menstrual effluent contains the fragments of tissue mixed with blood, liquefied by the fibrinolytic activity of the endometrium. Clots of varying size may be present if blood flow is excessive.

The inflammatory components of menstruation may be essential for the rapid restoration of tissue integrity that occurs following endometrial sloughing.[196] The withdrawal of progesterone, as a well-known anti-inflammatory mediator of the secretory phase, likely participates in the onset of inflammatory changes including induction of MMPs, urokinase-type plasminogen activator (uPA) and tissue-type plasminogen activator (tPA), and PAI-1 expression.[196,209,210] At menstruation and with progesterone withdrawal, Cox-2 is dramatically elevated via NF-κB with induction of prostaglandins and lipoxygenases (LOX).[211] One lipoxygenase, LOX15, is expressed with progesterone withdrawal. Since LOX15 is responsible for production of the anti-inflammatory eicosanoid lipoxin A4 (LXA4), expression may help curtail inflammatory responses.[212] Surprisingly, LXA4 was also recently shown to be a potent estrogen receptor agonist[213]

and could function to facilitate repair of the endometrium, particularly during menstruation, when circulating estrogen levels are low, but ERα (at least in the zona basalis) remains elevated.[185]

The duration of menses in ovulatory cycles is variable, generally lasting 4 to 6 days and usually similar from cycle to cycle in any individual ovulatory woman. The duration of flow is considered to be abnormal if it is less than 2 days or more than 7 days. The amount of blood lost in a normal menses ranges from 25 to 60 mL, being greater when coagulation and platelet disorders are present. Loss of more than 60 mL per month is associated with iron deficiency anemia.

Menstruation and the subsequent regeneration of the functionalis layer are notable for the lack of development of synechiae. The majority of cases of uterine synechiae causing Asherman's syndrome occur following pregnancy-related curettage, especially when curettage is performed during the first 4 weeks of the post-partum period when the uterus is particularly vulnerable.[214] Asherman's syndrome is usually associated with infection as well.

Stem Cells and Telomerase in Endometrial Renewal

Menstruation and cyclic repair of the endometrial lining requires both stem cells and an adaptation involving telomerase that imbues the endometrium with near immortality, compared to other tissues in the body. In 2004, the endometrium of women who had undergone bone marrow transplantation was examined and found to contain endometrial epithelial and stroma cells that had clearly been derived from the donor's bone marrow.[215] This was a remarkable finding for two reasons. First, this experiment suggested the possibility that bone marrow derived stem cells traffic and engraft to the endometrium and secondly, that these undifferentiated bone marrow stem cells undergo both mesenchymal and epithelial transformation adopting a phenotype indistinguishable from their host organ. This original observation was later confirmed in the mouse, using male bone marrow donors and female recipients, proving that these were not endometrial stem cells that reside in the bone marrow, but rather bone marrow derived pluripotent stem cells.

Endometrial derived pluripotent cells, whether native to the endometrium or derived from the bone marrow, appear to have unusual properties that may revolutionize how we think about stem cell research. These cells have been manipulated in the mouse model to differentiate into neuronal cell types with the potential to produce dopamine, and pancreatic beta cells that produce insulin.[216,217] Mesenchymal stem-like cells which express cluster of differentiation (CD)40b and CD146 have also been identified by Gargett and colleagues that can be differentiated into adipocytes, osteocytes, chondrocytes, myocytes and endothelium.[218] Based on these early reports, the ready access of stem cells of endometrial origin could obviate the need to perform bone marrow biopsy offering the promise of self-renewing source of autologous stem cells for grafting of a wide variety of cell types with applications for human diseases including Parkinson's or Type I diabetes, as well as treatment for Asherman's syndrome with the possibility of endometrial renewal.[219-221]

Early methods for identifying endometrial stem cells began with the study of retention of cells labelled with 5-bromo-2-deoxyuridine (BrdU).[222,223] These rare, highly proliferative and undifferentiated quiescent populations of cells maintain properties of clonicity, colony forming unit activity, and ability to reconstitute their tissue of origin.[224] The ability to identify the side population (SP) cells have been used to show that in the endometrium, these SP cells are maintained at a constant level (~1%) throughout the lifetime of a woman's reproductive life.[224,225] It was recently suggested that bone marrow derived cells do not contribute to this population of SP cells in the endometrium, suggesting they are a resident to the endometrium and therefore may be an endogenous source of self-renewing stem cells in the endometrium.[226]

The endometrium, unlike other tissues in the body, has the remarkable characteristic of longevity. Despite up to 450 cycles of menstruation and regeneration, the endometrium of the typical woman continues to renew itself with remarkable fidelity. Age is related to telomere length, which in other tissues determines the lifespan of a cell.[227] Endometrium expresses the enzyme telomerase, at levels similar to certain cancers.[228] Levels of telomerase are cycle dependent, with higher levels in the proliferative phase reaching their nadir during the midsecretory phase.[229,230] Interestingly, this enzyme is found in the epithelial but not the stromal compartment.[231] Based on recent reports, telomerase may be indirectly regulated by estrogen through WNT pathways involving beta-catenin expression.[232] In women and baboons with endometriosis associated with progesterone resistance, telomerase levels are increased, suggesting a possible link to this disease and the pathophysiology related to its chronicity and tendency to recur.[233]

Vascular Remodeling and Angiogenesis

Angiogenesis, the formation of new blood vessels from preexisting vessels, rarely occurs in the normal adult except in the female reproductive tract and ovary. Here, the cyclic processes of endometrial shedding and regeneration and corpus luteum formation entail remarkable changes in vessel growth and remodeling. The angiogenic process involves multiple steps and is tightly regulated by activators and inhibitors.[234-236] There are four phases of the endometrial cycle when important events relating to angiogenesis occur: (1) at menstruation, when there is repair of ruptured blood vessels; (2) during the proliferative phase, when there is rapid growth of endometrial tissue; (3) during the secretory phase, with the development of the spiral arterioles that feed a subepithelial capillary plexus; (4) in the premenstrual phase, when there is evidence for vascular regression. If angiogenic remodeling is abnormal, endometrial dysfunction can result, including menorrhagia.

Angiogenesis during the proliferative phase is by vessel elongation.[237] In the secretory phase, intussusception appears to account for the increase in vessel branching; this proliferation of endothelial cells inside of vessels ultimately produces a wide lumen that can be divided by trans-capillary pillars, or alternatively lead to capillary fusion or splitting. Although most prominent in the late menstrual and early and late proliferative phase, endothelial cell proliferation is continuous during the menstrual cycle. Thus, vessel growth

continues during the secretory phase despite the fact that the surrounding endometrial tissue has ceased to grow, resulting in the coiling of spiral arterioles.

Endometrial angiogenesis and vessel remodeling are directed by a network of signalling molecules and receptors that include members of the vascular endothelial growth factor family, fibroblast growth factors, angiopoeitins, angiogenin, and the ephrins and their cognate receptors—which can also exist as secreted ligand-binding domains that function as inhibitors as a result of alternative splicing.[234-236, 238] Although the temporal and spatial patterns of expression of several other angiogenic factors and their receptors have been defined in the endometrium, the specific roles of each of these factors in the endometrial angiogenesis–vessel remodeling cycle remain to be elucidated.

Of the members of the vascular endothelial growth factor family that includes VEGF-A, VEGF-B, VEGF-C, and VEGF-D, VEGF-A is most important for endometrial angiogenesis.[237-239] VEGF-A acts on two different receptors: VEGF receptor-2 (VEGFR2), which may play the dominant role in signaling endothelial cell proliferation; and another tyrosine kinase receptor, VEGFR1 (also known as FLT-1), which may play the dominant role in mediating VEGF effects on vascular permeability.[240-243] Both receptors are present on endothelial cells. VEGFR2, also known as kinase domain receptor (KDR), has been detected in stromal and epithelial cells of the premenstrual endometrium; this presence suggests actions on non-vascular compartments.

The premenstrual phase is characterized by a dramatic up-regulation of VEGFR2 receptor in stromal cells of the superficial layers of the endometrium in response to progesterone withdrawal. The action of VEGF on VEGFR2 may participate in the increased expression of MMP-1 in the stromal in the premenstrual phase.

VEGF-A expression is detectable in glandular epithelial and stromal cells in the proliferative phase, stimulated by estrogen through the actions of hypoxia induced factor -1 α (HIF-1α).[244,245] HIF-1α is also induced by prostaglandin E2, which is maximally produced at the time of menstruation.[246] VEGF released from neutrophils in intimate contact with the endothelial cells is thought to stimulate endometrial vessel growth. It is also present in uterine NK cells. During the secretory phase, VEGF-A can be identified in surface epithelial cells, which presumably secrete it into the uterine cavity. The release of VEGF from subepithelial NK cells has been suggested to play a role in directing the development of the subepithelial capillary network in the secretory phase.

VEGF-A has four common isoforms, It has four common splice variants (VEGF121, VEGF165, VEGF189, and VEGF 206). After ovulation, there is a remarkable shift in VEGF-A isoforms expressed in the uterus with the appearance of VEGF-A189 in the perivascular stromal cells; the VEGF-A189 isoform can be processed by proteolytic cleavage by plasminogen activator.[100] VEGF-A189 increases vascular permeability acting on VEGFR1 while its processed form binds to the VEGFR2 receptor, which mediates the mitogenic action on endothelial cells.

The highest VEGF-A levels are found in the menstrual phase, probably a response to pro-inflammatory cytokines. The surge might also be attributed to focal hypoxia, which is a potent stimulus to VEGF-A gene transcription. Expression of VEGFR1 and VEGFR2 is also greatest in the menstrual phase. The elevated levels of VEGF and cognate receptor expression at this time are presumed to be important for vessel repair and the preparation for angiogenesis in the proliferative phase. Notably, the functional activity of VEGFR2 (as assessed by receptor phosphorylation), a signature indicating ligand activation, is relatively low in the early menstrual phase when levels of soluble VEGFR1 (sFLT-1), which sequesters VEGF, are highest. VEGFR2 receptor phosphorylation increases substantially in the late menstrual phase, remaining modestly elevated in the early and late proliferative phase when sFLT-1 levels decline.[247]

The fibroblast growth factor (FGF) family of proteins may also participate in endometrial angiogenesis through interactions with the VEGF system. FGFs up-regulate VEGFR2 and VEGF-A expression, and, in a feed-forward loop, VEGF-A promotes the release of FGFs from the extracellular matrix. Basic FGF is a potent stimulus for αvβ3 integrin expression. This integrin is present at the site of active angiogenesis and fundamental to endothelial invasion and vessel elongation during angiogenesis.[248]

The angiopoietins (Ang) regulate vessel stability. Ang-1, expressed in vascular smooth muscle cells, binds to a cognate receptor, Tie-2, on endothelial cells, resulting in vessel stabilization. Ang-2 is a physiological antagonist of Ang-1. It also binds to the same Tie-2 receptor. Vessels atrophy when Ang-2 acts in the absence of VEGF-A, whereas angiogenesis is promoted in the presence of VEGF-A. *In situ* hybridization studies indicate that Ang-1 expression is most abundant in the glands and stroma of the early and midproliferative phase and reduced in the late proliferative phase.[249] Ang-2 expression is detected in the glands and stroma throughout the cycle, with highest expression in the early proliferative and mid to late secretory phases. In endometrium from women with menorrhagia, Ang-1 expression is consistently down-regulated; as a result, the ratio of Ang-1 to Ang-2 is reduced, which contributes to vessel instability.[249]

Angiogenin is a heparin-binding molecule that is expressed by endometrial epithelial and stromal cells at their greatest levels in the mid to late secretory phases and in the decidua of early pregnancy. Angiogenin is thought to contribute to the proliferation of vascular smooth muscle cells around the spiral arterioles. Like VEGF-A, expression of angiogenin is stimulated by hypoxia. It is also increased by progesterone.

Ephrins, a family of molecules and their cognate tyrosine kinase receptors, are believed to guide endothelial cells to specific targets. Ephrins have been detected in endometrial endothelial and stromal cells, but the functional roles of these molecules and their receptors in the uterus remains to be clarified.

The physiological consequences of angiogenesis are reflected in changes in endometrial blood flow. By measuring the clearance of radioactive xenon gas, highest endometrial perfusion was reported between day 10 and 12, and day 21 and 26 of the cycle.[86] Microvascular perfusion has been assessed by laser Doppler fluximetry with transvaginal placement of a fiber optic probe into the uterine cavity.[250] With use of this technique, endometrial perfusion was found to be highest during the proliferative phase and the early secretory phase, not too dissimilar from the finding based on xenon clearance. Uterine blood flow is greatest in the fundus, and higher flow rates are associated with better

outcomes in assisted reproduction. Notably, diminished uterine blood flow has not been found in the perimenstrual period, but these methods cannot easily identify localized areas of vasoconstriction.

Extracellular Matrix Remodeling

The biochemical basis for the dramatic structural changes in the endometrium in the perimenstrual period includes the action of specific matrix-degrading proteases, the MMPs.[195,200-203] Studies on human endometrial explants in culture demonstrated that degradation of the extracellular matrix occurs in the absence of progesterone and estrogen, which suppress expression MMPs. Moreover, this degradative process can be blocked by MMP inhibitors, but not by inhibitors of lysosomal cysteine proteinases—directly implicating MMPs in the catabolism of the endometrial extracellular matrix.

Enzymes of the fibrinolytic system, urokinase and tissue plasminogen activator, are increased in the endometrium as progesterone is withdrawn in the perimenstrual period. Moreover, PAI-l expression is reduced, allowing the plasminogen activators to activate plasmin and proteolytically cleave and activate the latent MMP proenzymes.[251]

MMPs represent a large family of proteinases that play a major role in remodeling of the extracellular matrix (Fig. 10.9). *In situ* hybridization and immunocytochemistry have been used to map the expression of MMPs and the endogenous inhibitors, tissue inhibitors of the matrix metalloproteinases (TIMPs), in the primate endometrium. Cell-specific and menstrual cycle-specific patterns were revealed, with the most profound changes occurring during the perimenstrual period.[201,252] After ovulation, the expression of interstitial collagenase (MMP-1), stromelysin-1 (MMP-3), and stromelysin-2 (MMP-10) in the endometrial stroma is essentially restricted to the perimenstrual and menstrual phase.

Other MMPs are detected during the proliferative and secretory phases but are significantly increased in expression perimenstrually. These include the type IV collagen-degrading enzymes, MMP-2 and MMP-9. The membrane-bound MMP, MMP-14 (which activates MMP-2), is detected during menstruation in stromal inflammatory cells and epithelial cells. TIMP-1, which is detectable in the endometrium throughout the cycle, is increased in the stroma, epithelium, and arterioles at menstruation.

The importance of progesterone withdrawal in regulating endometrial MMPs and the different temporal patterns of expression have been well-documented in *in vivo* and *in vitro* systems.[91] In a primate model in which hormone levels were manipulated by steroid implants, progesterone withdrawal resulted in up-regulation of MMP-1, -2, -3, -7, -10, -11, and -14. It is important to note that the expression of MMPs in the endometrium is heterogeneous.[195,252]

At the start of menstruation, MMP-1 is found in patches of stromal cells in the superficial zone; these patches are colocalized with areas of reduced stromal and epithelial expression of estrogen and progesterone receptors and focal disruption of the extracellular argyrophilic fibrillar network—reflecting the degradative activity of MMP-1. As the process of menstruation proceeds, MMP-1 expression spreads to include the entire functionalis. MMP-2 and MMP-3 expression is also limited to the stromal cells in the functionalis. During menses, MMP-1, -2, -3, and -9 localize primarily in and around arteriolar walls. The heterogeneity of MMP expression suggests that MMP gene transcription is under the control of local rather than systemic (steroidal) factors. In other words, steroids are indirectly influencing MMP expression.

Progesterone, particularly in the presence of estradiol, can suppress expression of certain MMPs (i.e., MMP-1, -2, -7, -9, and -11) in endometrial explant culture.[203] This action is most likely explained by changes in autocrine/paracrine signals—particularly pro-inflammatory cytokines or members of the transforming growth factor family which, respectively, are potent inducers and suppressors of MMP gene transcription. In culture systems, IL-lα has been implicated as the mediator of MMP-1, MMP-3, and MMP-7 expression in response to withdrawal of progesterone. Neutralizing antibodies to TGF-β prevent the action of progesterone in blocking MMP-3 and MMP-7 expression.

Endometrial bleeding factor (EBAF) is the orthologue of the murine gene named Lefty and another likely candidate for a progesterone-regulated cytokine controlling MMP expression.[253-255] Lefty was originally identified in human endometrium as a gene up-regulated in the late

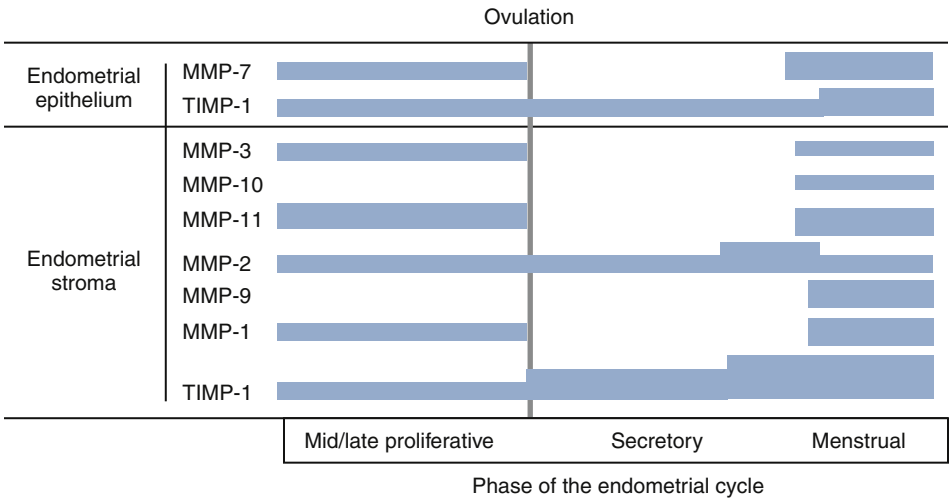

FIGURE 10.9 Schematic of matrix metalloproteinase (MMP) expression in the human endometrium during the menstrual cycle. *(Modified from Rodgers WH, Matrisian LM, Ciudice LC, el al. Patterns of matrix metalloproteinase expression in cycling endometrium imply differential functions and regulation by steroid hormones.* J Clin Invest *94:946–953, 1994.)*

secretory and menstrual phases of the normal cycle, being absent in the proliferative, early, and midsecretory endometrium. EBAF expression, which is predominantly found in the endometrial stroma and to a much lesser extent in the glandular epithelium, is suppressed by progesterone. Interestingly, endometrium from women with a history of abnormal bleeding and endometriosis expressed Lefty at unusual times including the proliferative, early, and midsecretory phases.[256] Such expression patterns may help explain the abnormal bleeding before menses, often associated with the presence of endometriosis.[257]

Unlike other members of the TGF-β family that promote the formation and stability of the extracellular matrix, EBAF down-regulates the elaboration of collagen in association with reduced expression of connective tissue growth factor while up-regulating expression of collagenolytic and elastinolytic enzymes.[258] These actions of EBAF are the result of antagonism of the SMAD (a portmanteau of two other protein names, Drosophila MAD, mothers against decapentaplegic, and C. elegans SMA, for small body size) signaling pathway that is activated by the other TGF-β growth factors. Thus, the decline in progesterone and estradiol in the late luteal phase initiates alterations in the endometrium that include up-regulation of proinflammatory cytokines (some of which may be contributed by immune cells that accumulate in the endometrium) and a natural TGF-β antagonist. The collective result is focal and then widespread expression of matrix degrading enzymes that result in the remodeling of stroma and blood vessels in the functionalis. EBAB/Lefty also has been shown to inhibit the expression of key decidual proteins, IGFBP-1 and PRL, through regulation of transcription factors FOXO1 and ETS1, thus causing infertility when prematurely expressed.[259]

Lysosomal involvement in the process of menstruation has been proposed because of three observations: (1) an increase in the abundance of lysosomes in the endometrium during the late secretory phase, (2) the cytochemical demonstration of acid phosphatase in the perimenstrual endometrium, and (3) the high specific activity of certain lysosomal hydrolases in endometrial tissue in the menstrual phase.[260] However, inhibitors of these enzymes, leupeptin and E-64, do not prevent the progesterone withdrawal—induced breakdown of extracellular matrix in endometrial explants as do the inhibitors of MMP activity. These observations suggest that lysosomal proteinases are not major contributors to the remodeling of the perimenstrual endometrium.

Vasoactive Substances

The *endothelins* are a family of potent vasoconstrictors produced by endothelial cells that act on two types of receptors present on vascular smooth muscle. Endothelin-1, produced by endometrial epithelial or stromal cells, may act on spiral artery smooth muscle cells to promote vasoconstriction. Enkephalinase, a membrane-bound metalloendopeptidase, degrades endothelin-1 and other vasoactive peptides, and is present in highest levels in the midsecretory endometrium.[116] Expression of the gene encoding enkephalinase is up-regulated by progesterone. The decline in progesterone levels at the end of the luteal phase results in a subsequent fall in enkephalinase, which prolongs the biological life of endothelin-1. Vasopressin may also function as a vasoconstrictor in the endometrium during the menstrual phase of the cycle.[261]

The production of prostaglandins, particularly $PGF_{2\alpha}$ and other eicosanoids in the endometrium, is enhanced by lysosomal phospholipases that liberate the arachidonic acid that accumulates in endometrium during the secretory phase; in turn, arachidonic acid is metabolized into prostanoids (see Chapter 6).[262] The premenstrual decrease in progesterone is also followed by an induction of the prostaglandin synthase, Cox-2, and decline in 15- hydroxyprostaglandin dehydrogenase activity which inactivates $PGF_{2\alpha}$. This induction of the prostaglandin synthase and the decline in 15-hydroxyprostaglandin dehydrogenase leads to increased production and bioavailability of $PGF_{2\alpha}$, which triggers myometrial contractions that compress the endometrial vasculature and promote hemostasis (Fig. 10.10).[263]

Hemostatic and Fibrinolytic Mechanisms

The relative activities of the hemostatic and fibrinolytic systems in the endometrium are shifted in the perimenstrual period such that clotting activity is reduced and fibrinolytic activity is increased. Consequently, menstrual fluid does not normally clot, even on prolonged storage. Decidualized stromal cells express tissue factor (TF), the primary trigger of thrombin formation and hemostasis, under the influence of progesterone.[192] TF is expressed in the endometrial stromal cells along with another hemostatic factor, plasminogen activator inhibitor-1 (PAI-1) under the influence of progestins, which suppresses MMP production.[264] Tissue factor production by the decidualized stromal cells declines with withdrawal of progesterone, along with the increase in MMP production.

The endometrial fibinolytic system includes urokinase-type plasminogen activator and tissue-type plasminogen activator, which cleave plasminogen to yield the fibrinolytic enzyme, plasmin.[192,265,266] This system is hormone regulated and can be modulated by drugs. Progesterone reduces expression of urokinase and increases that of PAI-1 in cultured endometrial cells. Removal of progesterone or the addition of the anti-progestin, RU486, reverses these

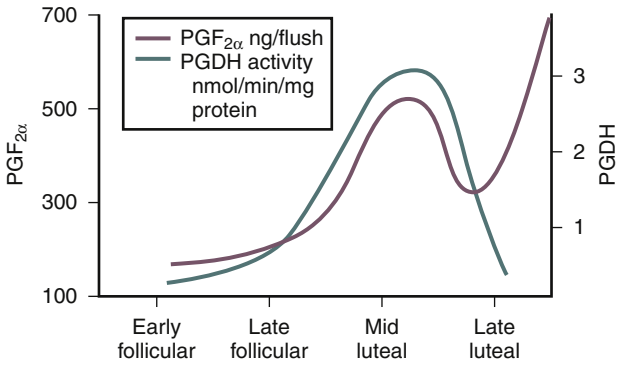

FIGURE 10.10 Changes in $PCF_{2\alpha}$ levels and endometrial 15-hydroxy prostaglandin dehydrogenase (PGDH) activity. *(From Casey ML, Hemsell DL, MacDonald PC, et al. NAD+ dependent 15-hydroxy prostaglandin dehydrogenase activity in human endometrium. Prostaglandins 19:115, 1980; Demers LM, Halbert DR, Jones DF, Fontana J. Prostaglandin F levels in endometrial jet wash specimens during the normal human menstrual cycle 10:1065, 1975.)*

responses.[266] Tranexamic acid, an antifibrinolytic agent, is a synthetic derivative of the amino acid lysine, that reversibly blocks lysine binding sites on plasminogen, and inhibits plasminogen activation to plasmin. This drug, administered orally or intravenously, can be used to control dysfunctional menstrual bleeding or bleeding associated with fibroids.

The Uterus in the Cycle of Conception and Pregnancy

In the event of oocyte fertilization, hCG from the implanting embryo rescues the corpus luteum from apoptosis and regression, maintaining serum progesterone secretion and endometrial integrity. This integrated mechanism demonstrating the importance of synchrony, creates a window of endometrial and ovarian receptivity that is essential for the success of the pregnancy.[267] Women who are delayed in establishing embryo implantation, beyond the normal window of implantation (7 to 10 days after ovulation), are at increased risk for miscarriage.

The examination of hysterectomy specimens revealed that the first consistent structural changes in the endometrium of early pregnancy are recrudescence or accentuation of glandular secretory activity, edema, and the predecidual reaction.[268] The increased prominence of the vasculature is considered to be a manifestation of increased blood flow, which together with VEGF production (a vascular permeability factor) may account for the associated edema. Endometrial biopsies in a cycle of conception suggest that stromal edema and vascular congestion are the earliest persistent morphological features of the endometrium of pregnancy.[269]

Within the first weeks of gestation, the endometrium undergoes characteristic changes in which epithelial cells of the endometrial glands become distended with a clear cytoplasm (Fig. 10.11). Many of the epithelial cells develop enlarged and hyper-chromatic nuclei. The enlarged nuclei are polyploid. Parallel channels of endoplasmic reticulum and large mitochondria are abundant in the epithelial cells, and the Golgi complexes have numerous stacked saccules. These changes are commonly referred to as the *Arias-Stella*

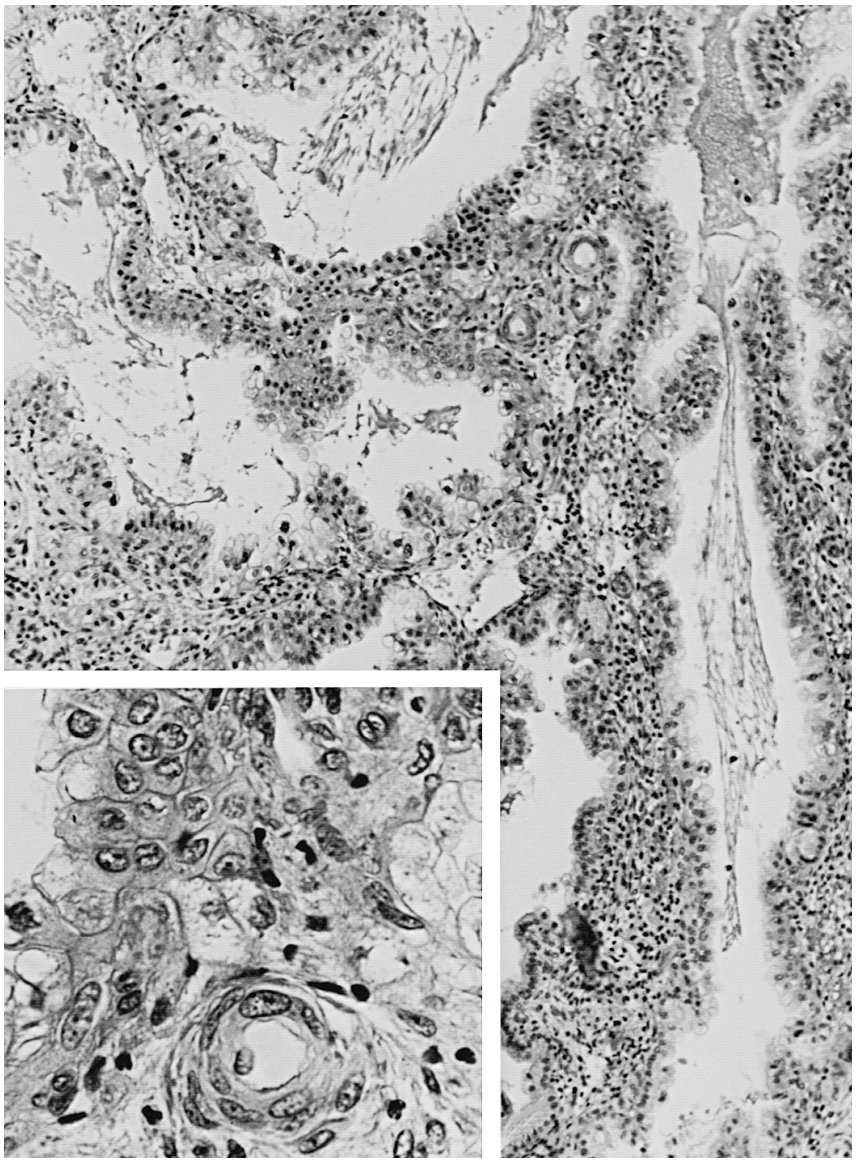

FIGURE 10.11 Arias-Stella reaction. Hypersecretory glands with enlarged hyperchromatic nuclei are present. The glands have scalloped borders. *Inset:* High-power view.

reaction.[270,271] The ultrastructural characteristics of the endometrium are consistent with a hypersecretory state, providing the earliest nutrition and maternal communication with the nascent embryo. As blood flow to the placenta requires vascular remodelling that occurs later, this uterine milk from the endometrial glands provides direct and essential sustenance for the early fetus.[272]

The Arias-Stella reaction has an irregular distribution in the uterus and is present in about 50% of the uteri of women with ectopic pregnancies. It could reflect changes in steroid hormone levels as well as the direct action of hCG on the endometrium, a subject discussed later in this chapter. The endometrium exhibits significant changes in cellular composition that are reflected in the marked alterations in the synthesis and secretion of endometrial proteins. As gestation advances, endometrial glands atrophy and are scarce at term.

The decidua develops with continued exposure of the uterus to progesterone, secreted first by the corpus luteum and later by the placenta. Based on *in vitro* studies, other factors (including hCG and relaxin) may act synergistically with progesterone to promote decidualization. Because exogenous cyclic adenosine monophosphate (cAMP) in the presence of progesterone represents a sufficient *in vitro* stimulus to induce stromal cell differentiation into decidual cells, relaxin and hCG likely exert their effects through this second messenger. Extrapolating from studies on the mouse, including findings on knock-out animals that have been found to be defective in decidualization, it is possible that amphiregulin, HOXA10, HOXA11, IL-11, LIF, Cox-2, and prostaglandins all have a role in the decidual response in humans.[273-275]

The decidualized stroma represents a tissue that is both permissive and simultaneously a restrictive barrier of trophoblast invasion and placentation; its remodeling is crucial to the morphogenesis of the placenta and the establishment of the uteroplacental circulation. Moreover, the decidualized stroma represents the arena where the fetal semiallograft is exposed to maternal immunologically competent cells. While creating a hospitable environment for trophoblast invasion, the decidua also sets limits on this process to prevent excessive penetration and tissue destruction beyond its bounds.

The plump, polygonal decidual cells are arranged in a cobblestone configuration. The ultrastructural features of the decidual cells—including prominent Golgi complexes, dilated rough endoplasmic reticulum, and dense membrane-bound secretory granules—are characteristic of secretory cells. The histologically distinct cell borders around decidual cells reflect the accumulation of a pericellular matrix (Fig. 10.12).[189,190] Abundant decidual cell prolyl hydroxylase, an enzyme involved in collagen synthesis, indicates the important role of these cells in extracellular matrix production. There is also an abundance of amorphous components, including high-molecular-weight proteins with voluminous saccharide moieties (e.g., heparin sulfate proteoglycan). Fibrillar collagens are partially broken down and reorganized. Type V collagen epitopes are unmasked; collagen type VI, "stiff" short collagen fibers that bridge other fibrillar collagens, disappears from most of the stroma and persists only in association with vessels and the basement membrane of the glands.

The deposition of a basement membrane-type matrix containing laminin and type II collagens around the decidual

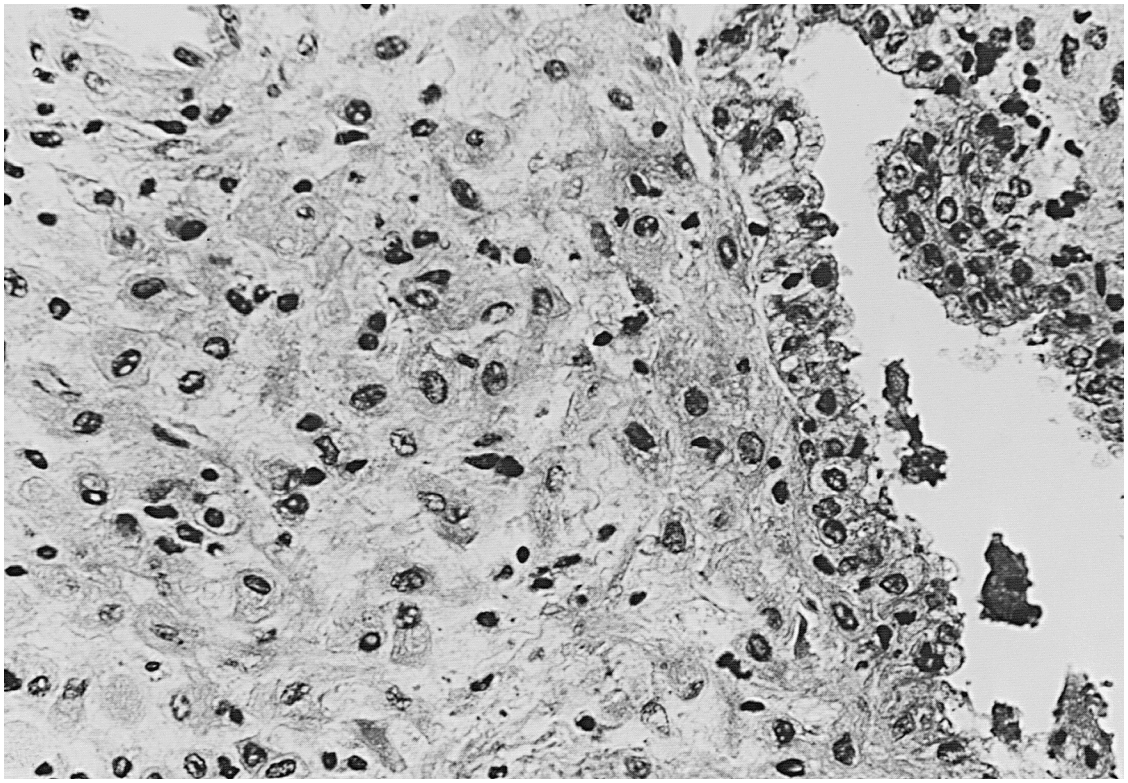

FIGURE 10.12 Decidua of pregnancy. Decidualized stromal cells are plump and have distinct cell borders. Glands are atrophic.

cells contributes to the formation of a "looser stroma" that serves as a substrate for the invading trophoblast cells. For example, entactin, a component of this basement membrane-like matrix, promotes trophoblast cell adhesion and migration. The decidual matrix is also a rich source of cytokines, protease inhibitors, protease precursors, and other factors that modulate cell behavior. These are derived, at least in part, from the decidual cells whose secretory products also include IGFBP-1 and TGF-β, which may restrain the invasion of trophoblast cells.[276,277] Forkhead box 0A1 (FOXO1A) has been shown to regulate many of the genes induced during decidualization including IGFPB-1 and prolactin.[278] Ghrelin is an endogenous ligand for the growth hormone (GH) secretagogue receptor and has also been shown to be involved in decidualization of human endometrium as well.[279,280] Ghrelin in combination with sex steroids estradiol and progesterone and cAMP increase both prolactin and IGFBP-1, while ghrelin alone antagonizes the actions of cAMP.[281] Reduced Ghrelin has been associated with infertility.[282]

The Endometrium in Advancing Age

Based on donor oocyte pregnancies achieved in post-menopausal women whose reproductive tract was programmed with exogenous steroid hormones, uterine aging in the absence of acquired pathology evidently does not preclude successful implantation and carriage of a pregnancy to term. The relentless ability of the endometrium to restore itself may hint at its longevity. A rich source of the enzyme telomerase,[230] the endometrium may have the ability to delay the normal aging process. However, there are structural changes that take place in the uterus with advancing age, pregnancy, and the cessation of ovarian function. Whether or not these changes affect the "reproductive potential" of the uterus or contribute to the increased incidence of pregnancy complications associated with advanced maternal age (e.g., increased incidence of stillbirth and intrapartum complications) are not known.

The basal endometrium interdigitates with the myometrium with advancing age, resulting in a degree of superficial adenomyosis that is a normal finding in the uterus in the fifth decade of life. The infiltrating endometrium does not undergo normal cyclic changes. This may be a consequence of a uterus hosting a past pregnancy.[283]

After menopause, in the absence of hormone replacement, endometrial atrophy is apparent and mitotic activity ceases. Epithelial cells shrink in size, and the stroma becomes fibrotic. A compact eosinophilic material is found in the lumina of the endometrial glands, occasionally engorging them and giving rise to the histological pattern referred to as *cystic atrophy*.

The Uterine Cervix

The cervix is a remarkable specialized structure at the base of the uterus that functions as a biological "gate", controlling the access of sperm and microorganisms into the uterine cavity.[284] During pregnancy, it helps retain the fetus and extra-embryonic tissues and fluids in the uterus, safely until the time of parturition. The endocervix is lined by layer of tall columnar ciliated and non-ciliated secretory cells. A rich extracellular matrix consisting of fibrillar collagens and elastin with embedded fibroblasts and a small percentage of smooth muscle cells (approximately 10%) lies beneath the endocervical epithelium. There are no true glands in the endocervix, but rather an intricate system of crypts or grooves. These endocervical cells stop at a sharply demarcated junction with the stratified squamous epithelium that covers the portio vaginalis at the external os.

The secretory cells of the endocervix elaborate mucus with an average production of 20 to 60 mg daily in a woman of reproductive age. At midcycle, this production rate increases tenfold to twentyfold. The mucus is a complex mixture of water, electrolytes, and mucins, which are large glycoproteins that are heavily laden with O-linked oligosaccharides. Human cervical mucus is approximately 92% to 94% water, but the water content rises to 98% at the time of ovulation. Inorganic salts make up approximately 1% of the mucus by weight.

Mucins represent 45% of the protein content of cervical mucus.[285,286] The mucin core proteins typically contain tandem repeat domains enriched in serine, threonine, and proline residues. These molecules have a role in protecting the upper reproductive tract from bacterial colonization by trapping microorganisms; they also protect the epithelial cell surface, and, as a result of their hydration, form a gel that keeps the cervical canal open.

The cervix expresses a number of mucin genes, including *MUCl*, *M17C4*, *M17C5AC*, *M17C5B*, *MUC6*, and *MUC8*. The periovulatory mucins form a hydrogel, a large mesh that facilitates penetration by motile sperm. The abundance of the mRNA encoding the major cervical gel-forming mucin, MUC5B, is greatest right before ovulation; the amount of MUC5B protein per unit protein in the cervical mucus reaches a peak at ovulation. Cervical expression of MUC5B mRNAs declines markedly after ovulation.

The composition of mucus determines its rheological properties, including consistency, flow elasticity, Spinnbarkeit (the capacity of liquids to be drawn into threads), thixotropy and tack, as well as its ability to form a fern-ing pattern when dried as a result of crystallization of salts (sodium chloride and potassium chloride) in the presence of protein. In the preovulatory phase the mucus is profuse, thin, clear acellular with an alkaline pH. Semi-quantitative scoring schemes that assess quantity, rheological properties like Spinnbarkeit, ferning, and the appearance of the cervix and cervical os, have been used to assess the estrogen status of women. Progestin-only contraceptives, including long-acting injectables and progestins delivered in implants, result in a viscous cervical mucus that impedes sperm penetration. These effects on cervical mucus and sperm penetration can be seen 3 days after insertion of a levonorgestrel-releasing implant.[287]

The Myometrium

The myometrium is organized into strata: an external hood-like layer covering the fundus, a dense network of fibers beneath it, and an innermost layer surrounding the internal os and tubal ostia. Magnetic resonance imaging (MRI) of the uterus of women of reproductive age reveals two distinct myometrial zones: the junctional zone underlying the endometrium (which has low signal intensity) and the outer myometrium (which has relatively high signal intensity).[288]

The junctional zone corresponds to the hypoechogenic layer of the myometrium, the subendometrial halo observed in ultrasound images. The lower T2-weighted signal intensity of the junctional zone is due to the lower water content (mostly a consequence of contractile activity of this zone that decreases its blood volume), less extracellular matrix, and more tightly packed smooth muscle cells. This zonal anatomy is apparently dependent upon sex hormones because it is not evident prior to menarche or in postmenopausal women who are not receiving hormone replacement therapy. MRI images reveal that the junctional zone is altered in early pregnancy, evidently as a consequence of embryo-derived factors.

The functions of the junctional zone of the myometrium appear to be linked to events in the menstrual cycle and the establishment of early pregnancy; those of the outer myometrium are related to pregnancy and parturition. The junctional zone has several unique features that distinguish it biochemically and functionally from the outer myometrium. Although steroid hormone receptors are expressed throughout the myometrium, the junctional zone exhibits cyclic changes in expression of estrogen and progesterone receptors that parallel those of the endometrium. This differs from the "outer" myometrium, which does not show marked cyclic changes in receptor expression.

During the menstrual cycle, subendometrial peristalsis has been observed by ultrasonography and ultra-fast MRI.[289-292] The frequency, intensity, and direction of the subendometrial contractions vary during the menstrual cycle. They average two to three cycles per minute and flow from cervix to fundus at midcycle; diminish in the luteal phase; and increase again during menstruation, but in a fundal-to-cervical direction. Changes in steroid hormone levels, expression of hormone receptors, and prostanoids govern the peristaltic activity. Some authors have suggested that the contractile activity of the junctional zone alters uterine shape from an elongated configuration in the follicular phase to a piriform configuration in the luteal phase, changes that make the uterine cavity more spherical after ovulation.[293]

In some pathological states, including endometriosis or adenomyosis, dystonic uterine contractions have been observed.[294-296] Whether or not these aberrant contraction patterns contribute to infertility and other symptoms of endometriosis remains to be determined. It is tempting to speculate that disruptions in the normal fundal-to-cervical contractions during menstruation might worsen the sensation of uterine cramping associated with endometriosis, and perhaps even contribute to the retrograde menstruation thought to underlie the pathogenesis of this disorder.

The myometrial compartment changes dramatically during pregnancy, primarily as a result of muscle hypertrophy, the elaboration of extracellular matrix, and an increase in lymphatics and blood vessels. The wet weight of the human uterus increases tenfold during pregnancy, and its carrying capacity increases from 300 mL to 4.5 L, largely owing to hypertrophy and hyperplasia of the myometrium. The myometrial hyperplasia is steroid hormone-dependent and probably mediated by growth factors, particularly the IGFs.[102] The primate myometrium expresses all components of the IGF signaling system, including IGF-1, IGF-2, and the type 1 growth factor receptor, as well as IGF-binding proteins (IGFBPs 2, 3, 4, and 5). Progesterone enhances expression of IGF-1 mRNA stimulated by estrogen. The stimulation of IGF-1 expression is accompanied by an increased number of Ki67– positive myometrial cells, indicating myometrial cell proliferation.

Immunology of the Reproductive Tract

The uterus is an immunologically privileged organ: it can accommodate the fetus and extra-embryonic tissues as a semi-allograft, yet it also is endowed with mucosal immunity, defenses against ascending foreign organisms, and a system to efficiently clear the endometrial detritus that results from menstruation (see Chapter 14). The human reproductive tract has components of both the innate and adaptive branches of the immune system. Uterine epithelial cells express members of the Toll-like receptor family (TLR 2-6, 9, and 10) which detect pathogen products and trigger a cellular response to these "foreign" molecules including peptidoglycans from Gram positive bacteria (TLR2), lipopolysaccharide from Gram negative bacteria (TLR4), and unmethylated CpG islands found in bacterial DNA (TLR9). The endometrium also produces host defense molecules, defensins, as well as cytokines and chemokines. Uterine lymphoid and myeloid cells play roles in tissue defense, immune modulation, angiogenesis, and tissue remodeling.[188,297-300] These cells are present in the fallopian tubes, uterus, and cervix, with the fallopian tubes and uterus containing a higher proportion of leukocytes than the cervix and vagina.[301]

Both innate and adaptive immune responses by the endometrium are regulated by steroid hormones. Progesterone has potent immunomodulatory effects[302]; it induces a local Th2-type cytokine response in the uterus, which includes an increase in IL-4, IL-5, and IL-15 and down-regulation of the IL-13 receptor α2, which is a negative regulator of the anti-inflammatory cytokine, IL-13 and powerful inhibitor of the Th2 response.[303] The Th2 response is believed to counter pro-inflammatory processes in the endometrium that could lead to rejection of the embryo. Steroid hormone-directed alterations in endometrial chemokine production influence the trafficking of blood leukocytes in the reproductive tract. Further, actions of progesterone are important in the overall immune suppressive phenotype adopted by the receptive endometrium.[304] Such actions of progesterone are dependent on the PR isoform (A and B) involved.[305]

During the secretory phase there is a profound recruitment of leukocytes into the endometrium starting in the perivascular locations around spiral arterioles and glandular epithelium.[306-309] Progesterone-induced alteration in endometrial cytokine/chemokine production contributes to this recruitment.[310] Cytokines IL-1, IL-11, IL-15, LIF, TGF-β regulate trafficking of leukocytes to the endometrium.[311] IL-15 recruits NK cells into the endometrium[312] as evidenced by the IL-15 null mice that lack uNK cells. Locally acting prostaglandins including PGE along with VEGF modulate vascular permeability.[309,313] Cyclooxygenase-2 (Cox-2), a rate limiting enzyme that regulates the biosynthesis of PGE2, is critical to implantation in animal models,[314,315] with PGE2 required for initiation and maintenance of decidualization.[316,317] Blockade of Cox-2 prevents decidualization in mice[315] indicating that Cox-2 plays a critical role in endometrial function at the time of implantation.[318,319] Reduced Cox-2 is associated with implantation

failure[320] and unexplained recurrent pregnancy loss,[321] and increased Cox-2 expression is found in endometriosis,[322,323] and may be associated with other immune changes seen in this disease, including increased Th1 or Th17 responses.[324] The development of an immunotolerant maternal immune response is essential for the acquisition of endometrial receptivity and the success of pregnancy.[325-327] Factors that support a more suppressed immune environment, including the recruitment of T regulatory cells (Tregs) and a shunting away from a pro-inflammatory, Th1/Th17 responses are likely critical to establishment of normal pregnancy and lack of these immune changes may underlie infertility and pregnancy loss associated with various inflammatory conditions such as endometriosis (discussed below).

Leukocytes and Lymphocytes

There are striking menstrual cycle–dependent changes in the immune cell population of the endometrium. Neutrophils, the most abundant leukocytes of the immune system, are rare in the normal endometrium until the peri-menstrual phase, when they accumulate and account for 6% to 15% of the total cell number. Eosinophils are also rarely found in the normal endometrium until the perimenstrual phase, when they also accumulate—usually in aggregates—and show evidence of activation, as revealed by the extracellular location of eosinophil cationic proteins. Macrophages are present in the endometrium throughout the cycle, increasing in number from the proliferative to the menstrual phases. Immediately prior to menstruation, the number of macrophages in the functional layer of the endometrium is equivalent to that of neutrophils.

Mast cells expressing tryptase (a characteristic of mucosal mast cells) and chymase (a characteristic of connective tissue mast cells) are found in the human endometrium. In the functionalis, mast cells are positive only for tryptase while those in the basalis express both enzymes. Degranulation of these cells may initiate activation of matrix metalloproteinases as a result of tryptase and chymase action on proMMP-1 and proMMP-3.

The endometrial lymphoid system has a distinctive composition and activity. There is good reason to believe that endometrial T cells are activated *in situ*, as judged by their expression of antigens that are characteristic of the activated state; these antigens include the major histocompatibility complex (MHC) class II molecules (also known as HLA) includes HLA-DR, HLA-DP, and HLA-DQ, and very late antigen 1. CD3+ T cells represent only 1% to 2% of the lymphomyeloid cells detectable in the human endometrium. They are present throughout the cycle in aggregates in the basalis, as well as singly throughout the stroma and in intraepithelial sites. The number of these cells increases prior to menstruation. The ratio of $CD4^+$ T helper lymphocytes to $CD8^+$ cytotoxic T cells in the endometrium is inverted compared with peripheral blood. The latter are cytolytic during the proliferative phase, but this activity diminishes in the secretory phase. This decline might reflect the influence of the tissue environment programmed by steroid hormone progesterone, or possibly an alteration in the leukocyte population through deletion or recruitment of $CD8^+$ cells with a different phenotype. Few B cells and plasma cells are present in the human endometrium.

Leukocytes make up between 15% to 30% of the cellular mass of the endometrium.[328] They communicate with the endometrial epithelium and trophoblast through complex networks of cytokines[329] and likely are involved in further leukocyte recruitment to the endometrium.[311] Reductions in this cytokine milieu is associated with pregnancy failure.[330]

In the human, progesterone is essential for establishment of pregnancy,[331] directing the coordinated biochemical modifications in the endometrium that regulate the controlled invasion of the fetal allograft, including the establishment of immunological tolerance.[332-334] The actions of progesterone on immunity are mediated in part through retinoic acid (RA), TGF-β,[335-337] and peroxisome proliferator-activated receptor γ (PPAR- γ), which exert a profound influence on CD4+ leukocyte differentiation. The actions of P (and RA and PPAR- γ) are disrupted in certain gynecological disorders including endometriosis, leading to alterations in the endometrial phenotype and contributing to infertility and early pregnancy loss.[109,338] Normal eutopic endometrium contains leukocytes in both stromal and intraepithelial locations.[306,308] Recent evidence suggests that maternal immune responses are critical for the acquisition of endometrial receptivity,[325-327] and that immune cells can directly regulate endometrial epithelial receptivity and associated gene expression.[339] Macrophages have been shown to regulate uterine epithelial gene expression in the mouse as well as human,[329,340] suggesting a mechanism for observed differences in eutopic endometrial gene expression in endometriosis. Conversely, inflammatory cytokines in peritoneal fluid or peripheral circulation of women with endometriosis could alter the differentiation pathways of monocytes toward a more hostile phenotype.[341]

T-Regulatory and Th-17 Cells and Endometrial Receptivity

As discussed in Chapter 14, the immune system is divided into "innate" immunity including monocytes, macrophages, dendritic cells (DC), neutrophils, basophils and mast cells, and natural killer cells from the lymphoid lineage. The adaptive immune system includes the T and B cells, which require innate immunity participation for establishment of an immunological memory.[342] Bone marrow (BM)-derived cells are known to traffic to endometrium, via steroid-regulated chemokine production.[215,343] Under the right circumstances, DC and Treg cells increase at the implantation site, along with uNK cells that interact with the invading placental cells to both direct and limit trophoblast invasion.[344] BM-derived decidual cells ultimately determine pregnancy outcomes.[338,345-353] Monocyte-derived leukocytes and uterine natural killer (uNK) cells comprise up to 20% to 40% of all endometrial cells in the secretory phase and are critical to the establishment of endometrial receptivity,[307,344,354] while the loss of function of these cells may account for infertility and recurrent pregnancy loss seen in women with endometriosis.[326,334,338,355-357]

Adaptation of the innate immune system is required for pregnancy and survival of the semi-allograft.[334,338] This immunotolerance is mediated in part by T-regs.[355,358] Treg cells as suppressors of inflammatory immune responses, keeps the immune system under control.[359] In the mouse

model, Treg cells proliferate and are activated in the uterus in response to paternal antigens and non-specific hormonally regulated factors.[338,360] In contrast, the subtype of inflammatory T cell called Th17 cells, is associated with multiple autoimmune and inflammatory conditions including colitis, multiple sclerosis, and rheumatoid arthritis.[361] IL-9 induces Th17 cell differentiation[362] attenuation of IL-9 decreases Th17 cells and reduces IL-6 producing macrophages,[363] contributing to Th17 differentiation. A balance in T-cell differentiation may ultimately define whether the endometrium becomes receptive to the fertilized oocyte and whether a pregnancy will be successful.

Uterine Natural Killer Cells

The uterine NK cell, also known as the granular lymphocyte, is a unique member of the lymphoid lineage found in the endometrium.[297] These are round cells that characteristically have bi-lobed or indented nuclei and a pale cytoplasm containing acidophilic granules. They are a specialized subset of NK cells based on their expression of cell surface antigens ($CD3^-$, $CD16^+$, and $NCAM/CD56^{bright}$). This pattern is different from blood NK cells, which have a phenotype of $CD56^{dim}$ and $CD16^+$.

Uterine NK cells are among the most abundant lymphomyeloid cells in the perimenstrual endometrium. Very few are present in the proliferative phase endometrium; they accumulate during the secretory phase, at which time they comprise 15% to 25% of the cells in the endometrial stroma. It has been postulated that the dynamic changes in uterine NK cell number during the cycle are determined by changes in endometrial prolactin production, which is then controlled by ovarian steroid hormones. This notion is based on the known roles of prolactin as an immunomodulator and the correlation between endometrial prolactin levels and NK cells.[364,365]

The NK cells persist in the decidua during the first trimester, when they represent 70% of the decidual leukocyte population. Their close association with stromal cells has led to the suggestion that they have an important role in initiating and maintaining decidualization. In a non-fertile cycle, the NK cells that amass during the secretory phase undergo programmed cell death.

When activated by interleukin (IL)–2 *in vitro*, the NK cells become competent to kill malignant cells (and some normal ones) through the release of cytotoxic proteins like perforin. From the late proliferative phase on, the NK cells express cytotoxic activity and are thought to play a role in protecting the endometrium against infection. The cells have also been proposed to modulate trophoblast invasion during implantation and placentation because of their abundance in the decidua during the first trimester.

Although *in vitro* studies document the killing activity of cytokine-activated NK cells, there is little evidence for destruction of trophoblast cells *in vivo*. Thus, any restraining activity that NK cells exert on invading trophoblast cells appears to be through a non-cytotoxic mechanism that may involve secreted cytokines, including colony-stimulating factor-1 (CSF-1), IL-1, LIF, and INF-γ. The apparent *in vitro* and *in vivo* resistance of trophoblast cells to death may be explained by the fact that trophoblast cells express a non-classical and nonpolymorphic major histocompatibility complex (MHC) class I antigen, HLA-G; NK killing activity is also suppressed by endometrial stromal cells.

In the transgenic mouse line TgE26, which lacks NK cells, abnormal implantation sites are found. Fetal demise follows, in association with changes in uterine arterioles suggestive of arteriosclerosis and hypertension.[365] These histopathological changes are reminiscent of pre-eclampsia in humans. In contrast, mice lacking IL-15, and consequently, circulating and decidual NK cells, are fertile but show a thickening in uterine vessels. These findings collectively implicate NK cells in vessel remodeling, a role consistent with their expression of angiogenic factors.

Factors Regulating Uterine Immune Cell Dynamics

Changes in lymphomyeloid cell populations in the endometrium, particularly their accumulation in the premenstrual phase, appear to be the result of recruitment from the peripheral circulation and intra-endometrial proliferation. The accumulation of migratory cells is directed by chemoattractant cytokines, chemokines, and the expression of intercellular adhesion molecules that attach leukocytes to the endothelium in preparation for extravasation and trafficking through the endometrium.[366] Expression of these molecules changes during the menstrual cycle, under the influence of steroid hormones as well as extrinsic inflammation, such as that seen in endometriosis.[367]

The expression of several chemokines has been documented in the human endometrium, including fractalkine (CX3CL1), Regulated on Activation, Normal T Expressed and Secreted (RANTES) (CCL5), IL-8, MCP-1 (CCL2), MCP-2 (CCL8), and eotaxin (CCL11). These chemokines bind to receptors on leukocytes, promoting the appearance of molecules that mediate adhesion to the endothelium, extravasation and chemotaxis along the concentration gradient of the chemokine, thus targeting specific leukocyte types to specific endometrial compartments. A repertoire of cell adhesion molecules expressed in the endometrium, including intercellular adhesion molecule-1 (ICAM-1), ICAM-2, VCAM-1, E-selectin, and PECAM, specifies the recruitment and location of leukocyte and platelet accumulation. ICAM-1 is present in the functionalis in the menstrual phase; ICAM- 2 is restricted to the vascular endothelium and does not appear to change during the cycle, vascular cell adhesion molecule-1 (VCAM-1) and E-selectin appear in the upper layer of the functionalis in the secretory phase, and the platelet endothelial cell adhesion molecule platelet endothelial adhesion molecule (PECAM) is abundant in the stroma during the menstrual phase.

Evidence for leukocyte proliferation in the endometrium includes the expression of Ki67 and incorporation of BrdU (both proliferation markers) by NK cells with a marked increase in the secretory phase. The uterine NK cell proliferation may be driven by progesterone-regulated stromal factors as $CD56^+$ cells proliferate *in vitro* in the presence of progesterone-treated endometrial tissue.

LIF is associated with a shift in Th1 to Th2 shift that is required for normal pregnancy and is defective in recurrent abortions in mice.[368] Maternal T cells increased LIF expression in response to paternal antigens and trophoblast, and reduced response was associated with poor reproductive

outcomes.[369] Progesterone is an anti-inflammatory immunomodulator in pregnancy and through induction of LIF and other cytokines that support trophoblast invasion.[304]

LIF and another biomarker of endometrial receptivity, αvβ3 integrin, are coexpressed in mouse and human endometrium[370,371] and like αvβ3 integrin, disturbances in LIF expression are associated with multiple reproductive pathologies.[275,372,373] While recent reports have linked these two important biomarkers,[374,375] their coregulation has only recently been demonstrated.[376]

Aberrant expression of both αvβ3 integrin and LIF is associated with decreased pregnancy success in *in vitro* fertilization (IVF).[377-379] Injection of peritoneal fluid from women with endometriosis reduced both LIF and αvβ3 integrin expression in the mouse uterus,[370] suggesting an inflammatory factor is responsible. Both LIF and αvβ3 integrin are positively regulated by paracrine actions of P (HB-EGF) and negatively regulated by inflammatory immune cells in the eutopic endometrium associated with endometriosis[370,380] and inflammatory tubal disease.[381] LIF has anti-inflammatory actions regulating cytokine action,[382] protecting against septic shock in the mouse model,[383,384] while αvβ3 integrin has been shown to interact with decay accelerating factor (DAF) and osteopontin (OPN),[109,385] that together block complement activation as part of innate immunity.[386] T cells from women with recurrent pregnancy loss secrete less LIF than normal women and defective LIF is associated with decreased Th2 cells and recurrent pregnancy loss.[368,387]

The Complement System

The human fallopian tube, endometrium, and cervical mucosa express components of the complement system.[388-391] The activation of the third (C3) and fourth (C4) component of complement induces chemotaxis of inflammatory cells, enhances phagocytosis, and mediates cell lysis. This system of natural immunity must be tightly regulated so that it can target foreign organisms and cells while avoiding untoward tissue damage. This is especially important during early pregnancy when the process of implantation might be disrupted. Complement activation is regulated by decay-accelerating factor (DAF, also known as CD55), which inactivates the C3 convertase enzymes that activate C3; and by membrane cofactor protein (MCP, also known as CD46), which serves as a cofactor for factor I-mediated degradation of activated C3 and C4.

A third protein, present only in rodents and named complement regulator decay accelerating factor (Crry), has DAF and MCP-like activities. Crry controls deposition of activated C3 and C4 on the surface of autologous cells. Fetal demise due to complement deposition and placental inflammation was observed in mice lacking Crry, reflecting unchecked activation of the complement system.[392] Complement activation appears to be an essential event in pregnancy loss associated with anti-phospholipid syndrome and can be prevented by administration of heparin.[393-395] These observations suggest that control of the complement system is essential for fetomaternal tolerance against attack by the innate immune system.

In the endometrium, complement component C3, factor B, and DAF are present in the glandular epithelium, and their expression is up-regulated in the secretory phase. MCP is expressed in the glandular epithelium throughout the menstrual cycle. Complement receptor type 1 is present in the stroma during the secretory phase; complement receptor type 2 is not detectable, and complement receptor type 3 is associated with infiltrating leukocytes in the luteal phase. The cyclic changes in C3, factor B, and DAF expression suggest progesterone regulation. In model human endometrial epithelial cell culture systems, however, steroid hormones did not alter decay accelerating factor expression, but heparin-binding epidermal-like growth factor (HB-EGF) did increase it.[151] Thus, the steroid hormone effects on expression of some of the complement system proteins may be indirect, perhaps acting through the stromal compartment.

Members of the integrin family are now thought to be involved in the regulation of C3, as part of the protective proteins that prevent the cascade of complement activation. DAF or Factor H may interact with these cell surface receptors (including the αvβ3 integrin and perhaps CD44) through binding to osteopontin (OPN) to limit C3 activation by digesting bound C3b. The αvβ3 integrin, OPN, and DAF all appear synchronously at the time of implantation in human endometrium and may serve as a primary safeguard against complement activation at the time of embryonic attachment, thus avoiding destruction of the early pregnancy by the host's defenses.

Anti-Microbial Peptides

Epithelial cells of the female reproductive tract elaborate antimicrobial peptides that presumably guard against ascending infection.[396,397] These peptides coat the epithelial surface and enter into the cervical mucus. Among the antimicrobial peptides expressed other than complement are lactoferrin, lysozyme, secretory leukocyte protease inhibitor (SLP1), and defensins. The α-defensins are elaborated by leukocytes and epithelial cells, and the β-defensins are elaborated by epithelial cells. Defensin-5, and α-defensin, are expressed in the upper half of the stratified squamous epithelium of the vagina and ectocervix, and in columnar epithelial cells of the fallopian tube and endometrium. β-defensin-1 and β-defensin-2 and secretory leukocyte protease inhibitor are produced by endometrial glandular epithelial cells. β-defensin-2 expression is increased by pro-inflammatory cytokines, and defensin-5 is also evidently up-regulated by inflammation. Defensin-5 and secretory leukocyte protease inhibitor levels in the endometrium also fluctuate during the endometrial cycle, being highest in the secretory phase.

Uterine Receptivity and Embryo Implantation

The timing of conception is exquisitely synchronized to ovarian events. With ovulation, progesterone from the nascent corpus luteum transforms the proliferative phase endometrium into a secretory structure and readies it for the newly fertilized ovum (Fig. 10.13A and B) (See Chapter 7).[114,388,398] In the appropriate endocrine milieu, the growing embryo will interact with the surface epithelium and invade into the underlying stroma, initiating gestation (Fig. 10.13C). Implantation can be divided into distinct

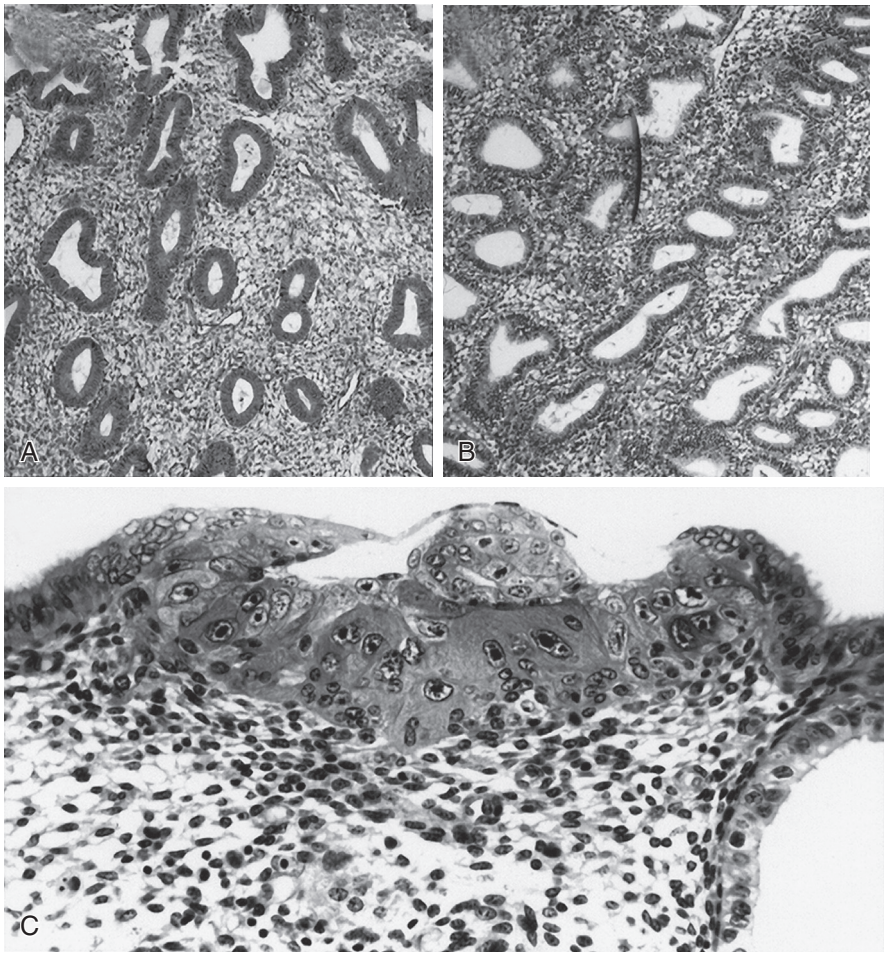

FIGURE 10.13 Proliferative (**A,** pre-receptive) and midsecretory (**B,** receptive) endometrium is regulated by ovarian steroids, resulting in successful implantation of the human embryo **(C).** *(Generously provided by Dr. Allen Enders, from the Carnegie Collection of early human implantation sites. Used with permission from Human Reproduction.)*

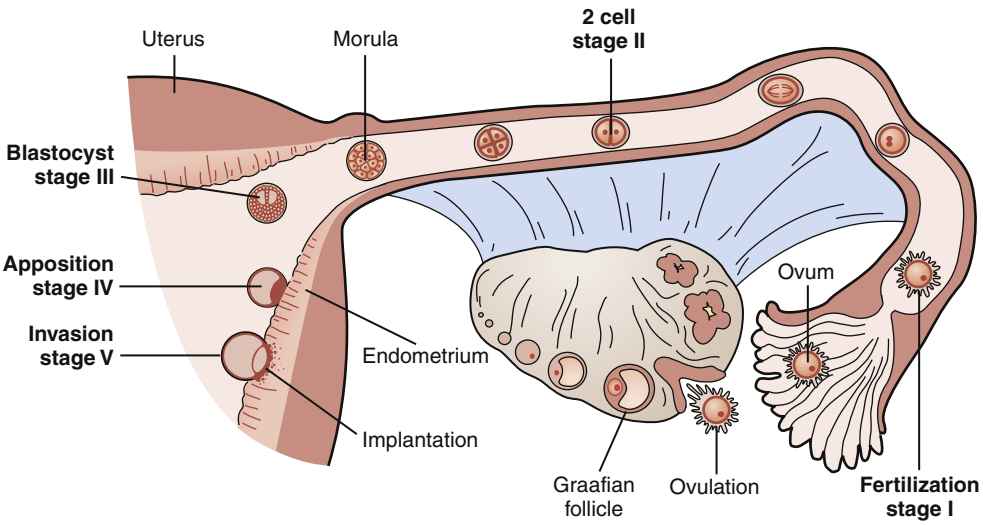

FIGURE 10.14 Stages of implantation beginning with ovulation, fertilization, then transport to the waiting endometrium. Implantation depends on synchronous development between the endometrium and the embryo.

and separate stages, timed precisely to the steroid-mediated changes ongoing in the endometrium (Fig. 10.14).[332] Following ovulation, the ovum enters the fallopian tube where fertilization occurs. The early cell divisions ensue and the embryo enters the uterine cavity at the morula stage, approximately 2 to 3 days after being fertilized. Implantation begins several days later, around the sixth to seventh day after fertilization. The initial attachment reaction (apposition) may be the rate-limiting step, and failure to adhere may preclude the subsequent stages of implantation.

Studies in experimental and domestic animals have demonstrated the synchronous development of the embryo and

endometrium that is required for normal implantation and development to occur.[399-403] In laboratory animals, there is a discrete "window" of time for implantation, which in some species lasts for only a matter of hours.[403] The concept of a "window" for implantation has also been demonstratred in the human female,[267,401,404,405] with a molecular basis that continues to be elucidated.[332,406-410]

Uterine receptivity is defined as the period of endometrial maturation during which the trophectoderm of the blastocyst can attach to the endometrial epithelial cells and subsequently proceed to invade the endometrial stroma and vasculature. The transition from the non-receptive to the receptive state is determined by the expression of membrane-bound, soluble, and secretory factors that support trophoblast attachment and subsequent migration. Factors expressed during this temporal window have been exploited as biomarkers of the receptive state.

The timing of implantation has been examined with increasing scrutiny over the past 50 years. In the 1950s, luteal phase hysterectomy samples in pregnant subjects suggested that embryos did not attach until day 20 of a 28-day cycle.[268] Using fertilized donor oocytes transferred into hormonally prepared recipients, Bergh and Navot later suggested that implantation occurred between cycle days 20 and 24.[411] More recently, by examining the time of pregnancy in 221 normal cycling women who were attempting pregnancy, Wilcox and coworkers showed implantation normally occurred between 7 and 10 days after ovulation (days 21 to 24).[267] In these studies, delayed implantation was associated with a higher miscarriage rate, possibly due to a shift in the time of implantation and the concomitant loss of synchrony between endometrium and embryo (Fig. 10.15). This explanation may provide insights into some cases of otherwise unexplained infertility and recurrent pregnancy loss.

Implantation can be viewed as a highly complex and orchestrated interaction between the maternal endometrium and the newly formed embryo.[332,412] As depicted in Figure 10.16, multiple soluble and membrane-bound factors have been elucidated that facilitate embryo growth, differentiation, attachment, invasion, and avoidance of immunological rejection. Maternal factors appear to simultaneously permit intrusion while limiting the degree of embryonic invasion into maternal tissue. Many of the embryonic signals or receptors have complementary ligands or coreceptors on the maternal surface. Mimicking of maternal antigens by the invading embryo is a strategy that is also used by the embryo to penetrate the endometrium, without triggering host defenses.[413] Some of the proteins involved in this process based on our current understanding of their roles are depicted in Figure 10.16.

Secreted Proteins of the Endometrium

The endometrium produces a large number of secreted proteins, collectively referred to as the endometrial secretome that serve autocrine, paracrine, and juxtacrine roles for the developing endometrium and embryo.[403,412] The uterine glandular epithelium also secretes glycogen which is thought to serve as a histiotrophic nutrition source for the embryo prior to 10 weeks gestation.[272] In addition to macromolecules, the endometrium also is likely to selectively secrete many small molecules, since it is well endowed with many members of the adenosine triphosphate–binding cassette transporter protein family, which are involved in the

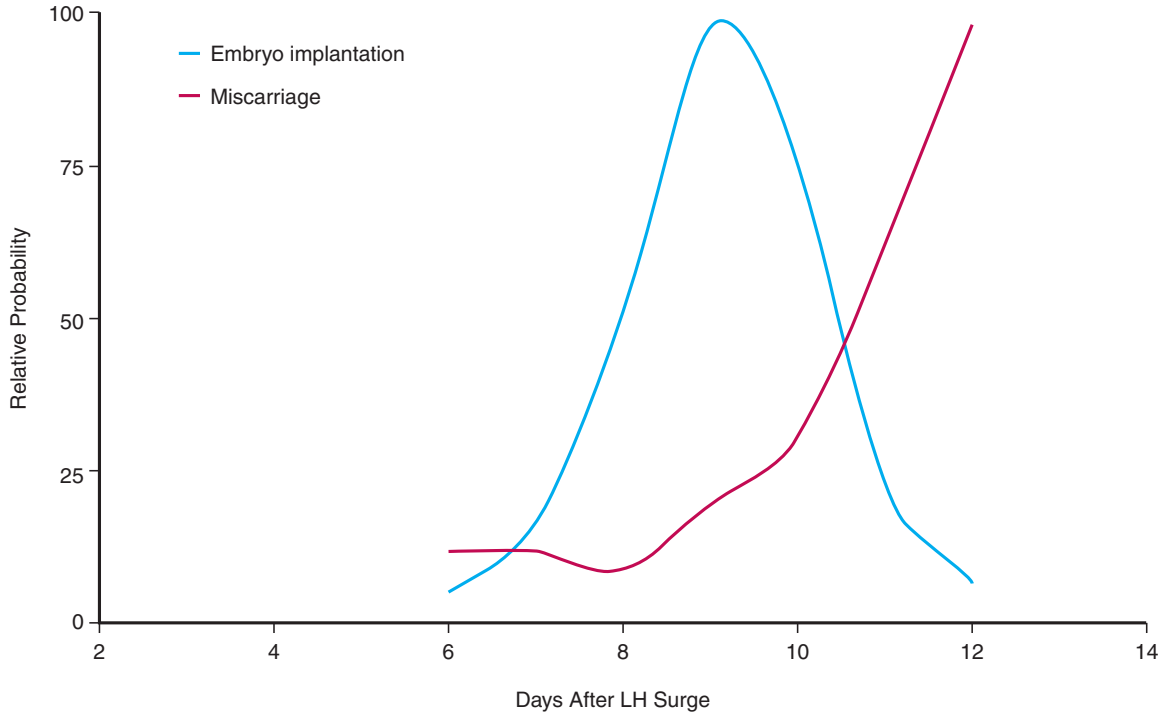

FIGURE 10.15 The timing of implantation in a population of fertile women. Most successful pregnancies implant between 7 to 10 days following a urinary luteinizing hormone (LH) surge *(blue line),* but the probability of miscarriage increases when implantation occurs outside of this 4 day window *(red line). (Adapted from Wilcox A, Barid DD, Winberg CR. Time of implantation of the conceptus and loss of pregnancy.* N Engl J Med *240:1796–1799, 1999).*

regulated secretion of a variety of small molecules, including drugs, lipids, and conjugated molecules.[414]

Endometrial secretions are found in the lumen of the uterine cavity and some are found in the general circulation (Fig. 10.16). A remarkable increase in secretory activity is associated with the luteal phase and early pregnancy, primarily in the glandular epithelial cells and later the decidua. Most of these secreted proteins are thought to be expressed because of the action, either directly or indirectly, of progesterone and many are implicated in regulation of embryo implantation and/or early embryo survival.[398,415,416] Therefore, an understanding of the mechanisms of progesterone action allows significant insight into endometrial function.

Glycodelin

Glycodelin, one of the most abundant products of the secretory phase endometrial glands and decidua, is known by several names: progesterone-associated endometrial protein, α-uterine protein, pregnancy-associated endometrial α2 globulin, endometrial protein 15, chorionic α2 macroglobulin, and placental protein 14 (an erroneous designation because glycodelin is an endometrial/decidual protein).[416,417] The mature form of glycodelin contains 162 amino acid residues and is 17.5% carbohydrate by weight. It has extensive structural homology with the β-lactoglobulins and, to a lesser extent, with retinol-binding proteins.

Glycodelin exists as isoforms depending on its glycosylation pattern. Glycodelin A is the major progesterone-regulated protein secreted into the uterine lumen. However, its functions with respect to the endometrium, implantation, and pregnancy are still largely unknown. Glycodelin A is a potent inhibitor of sperm-egg binding, and researchers have postulated that it may play a role as an immunomodulator because of its ability to suppress NK cells.[418,419] The absence of glycodelin A during the time of fertilization and its appearance during the time of implantation and placentation are consistent with these proposed functions.[420]

Glycodelin levels in uterine flushings are tightly correlated with the histological date of the endometrium (Fig. 10.17). It is not detectable in significant amounts in uterine flushings during the follicular and early luteal phase. Six days after ovulation, however, the levels rise rapidly to reach a concentration 100 times higher than plasma levels. In peripheral serum, glycodelin appears 5 days after ovulation, reaching peak concentrations in non-fertile cycles at about the time of menstruation; levels reach a nadir during the midfollicular phase of the subsequent cycle. In a cycle of conception, glycodelin levels increase rapidly after implantation, reaching a maximum at 8 to 10 weeks of gestation and subsequently declining in a pattern that mimics the changes in hCG.

The discordant pattern of glycodelin and progesterone in serum may reflect the slower turnover of the protein. Levels of glycodelin in serum fail to rise in women using combination-type oral contraceptives and in some patients with luteal-phase defects.[421] There is good—but not perfect—correlation between the progestational activity of steroids and their ability to stimulate endometrial glycodelin synthesis. Relaxin has also been implicated as a stimulus for glycodelin expression.[420,422] Specific histone deacetylase inhibitors have been shown to potentiate the action of progesterone on both endometrial epithelium and stroma.[423] The histone deacetylase inhibitor trichostatin (TSA) has

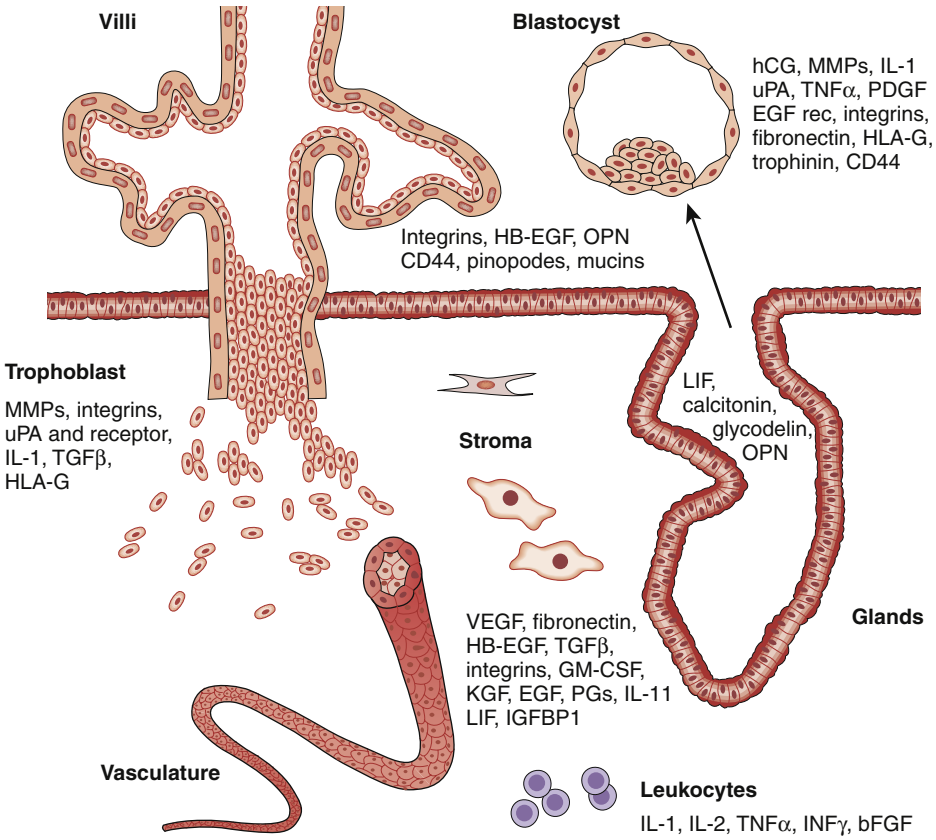

FIGURE 10.16 Schematic showing some of the factors and their cells of origin during normal implantation in women.

been shown to induce glycodelin in Ishikawa cells. Using an *in vitro* model of implantation, Uchida and coworkers showed that induction of glycodelin by a histone deacetylase inhibitor enhanced placental cell (JAR) spheroid attachment to Ishikawa cells.[424] This and other studies suggest a role for glycodelin in both the differentiation and function of the receptive endometrium.

Glycodelin has been shown to be decreased in the endometrium of women with infertility, including those with luteal phase defect[421] and polycystic ovary syndrome (PCOS).[425] In women exposed to the levonorgestrel containing IUD or the Yuzpe emergency contraception regimen, glycodelin expression was unaffected or increased.[426,427]

Insulin-Like Growth Factor Binding Protein-1

IGFBP-1, also known as *placental protein 12* or PP12, is a major secretory product of decidual cells.[428] It is one of several proteins that bind IGF-1 and IGF-2, affecting the ability of these growth factors to interact with the IGF receptors. Consequently, the binding proteins can have significant roles in modulating IGF effects. The protein undergoes post-translational modification by phosphorylation, which increases its affinity for IGF-1 and therefore its ability to neutralize IGF-1 action.

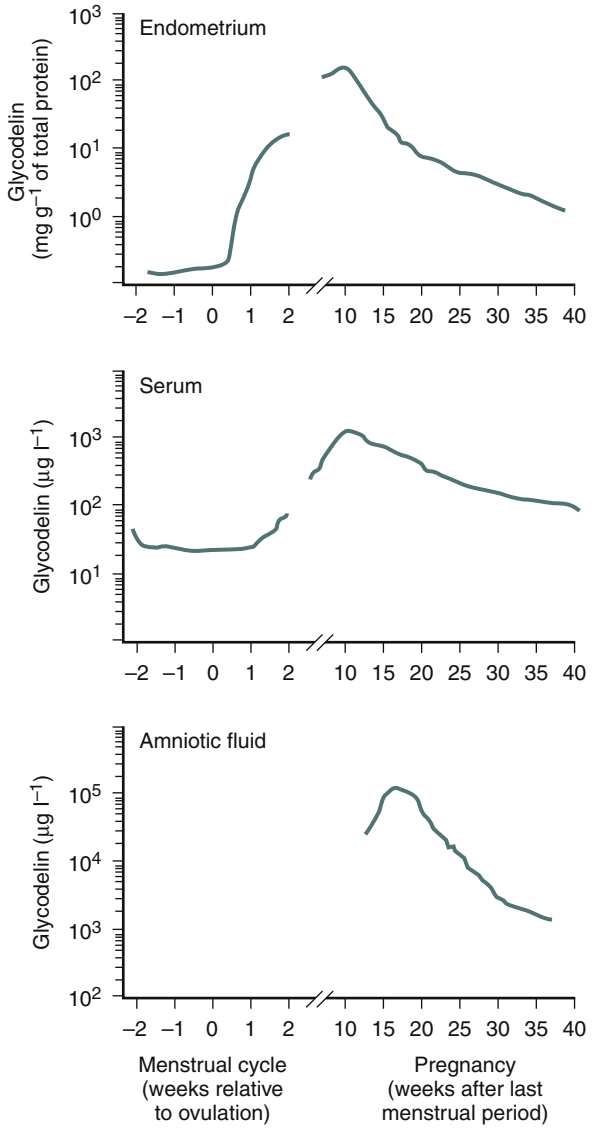

FIGURE 10.17 Glycodelin levels in endometrium, serum, and amniotic fluid. *(Reprinted with permission from Seppala M, Koistinen H, Koistinen R. Glycodelins.* Trends Endocrinol Metab *72:111–117, 2001.)*

IGFBP-1 derived from the decidua has been proposed to control the invasion and proliferation of trophoblast cells during implantation and placentation by sequestering IGFs. In a transgenic mouse model, over expression of IGFBP-1 in the decidua resulted in abnormal placental morphology due to defects in trophoblast invasion and differentiation.[429] Because IGFBP-1 contains the Arg-Gly-Asp (RGD) motif recognized by cell surface integrins that bind fibronectin, its actions may be more complex than simple IGF sequestration when it is presented to cells that express the RGD-binding integrins.[430]

Stromal cell IGFBP-1 mRNA levels are regulated by progesterone as well as by IGFs, insulin, relaxin and other growth factors as well as hypoxia.[431-433] Both IGF and insulin decrease decidual IGFBP-1 release while relaxin increases its release in a dose-dependent manner. HOXA10 may have a mild impact on IGFBP-1 expression, but in the presence of the forkhead–winged-helix transcription factor, FOX01, IGFBP-1 is markedly stimulated.[434] FOXO1, prolactin, and IGFBP1 are all induced during decidualization, and likely are involved in the progesterone-mediated stromal differentiation and prevention of apoptosis in preparation for nidation.

Intrauterine microdialysis studies revealed that IGFBP-1 is released into the uterine lumen in the late secretory phase (10 days after ovulation or later)[435] and increased secretion in response to hCG.[435] IGFBP-1 is increased between midsecretory to 6 weeks of pregnancy, as demonstrated by DNA microarray analysis on endometrium from ectopic pregnancy.[436] IGFBP-1 levels then decline in the second trimester only to rise again in late pregnancy, also accumulating in amniotic fluid. Pregnancy termination with the anti-progestin RU486 causes a marked decline in IGFBP-1 levels before a decrease in hCG levels, confirming the progesterone dependence of IGFBP-1 production by decidual cells.

Defects in IGFBP-1 have been noted in certain conditions associated with infertility and pregnancy loss, including polycystic ovary syndrome (PCOS) and endometriosis.[425,437] Such observations may reflect an altered endocrine milieu, higher insulin levels, or a relative progesterone resistance in these conditions (described later in the chapter). *In vitro*, insulin inhibits the normal process of endometrial stromal differentiation (decidualization). In addition, hyperinsulinemia down-regulates hepatic IGFBP-1, resulting in elevated free IGF-I in the circulation. Thus, the elevated androgens and estrogen seen in PCOS along with decreased progesterone in the absence of ovulation, likely contribute to endometrial dysfunction, infertility, increased miscarriage rate, endometrial hyperplasia, and endometrial cancer common in women with PCOS.

Osteopontin

Osteopontin (OPN) is a member of the SIBLING family of proteins.[438,439] Each of the proteins in this large family contain the three amino acid sequence arg-gly-asp (RGD) and have binding sites specific for two major cell surface receptors, αvβ3 and CD44.[438] Osteopontin is a 70-kDa

glycosylated phosphoprotein secreted by the glandular epithelium and is expressed during the midsecretory phase, localized to the luminal endometrial epithelium.[440] Osteopontin is regulated by progesterone.[440,441] The secretion of osteopontin and subsequent binding to the luminal surface suggests direct interaction is occurring between integrins and this molecule and a role as a "sandwich" ligand that serves as a bridge between surface receptors on the endometrial and embryonal surfaces. An additional role for osteopontin and these receptors is the prevention of complement fixation as part of a protective mechanism involving the innate immune system.[442]

Prolactin

Prolactin is produced by both the endometrium and the myometrium.[443,444] Serum levels of prolactin do not change across the menstrual cycle but rise markedly during the first trimester of pregnancy in parallel with the decidual response, reaching peak concentrations at 15 to 20 weeks of gestation. Prolactin, like IGFBP-1, is a downstream biomarker of decidualization of human endometrial stromal cells. Regulators of decidualization include ovarian steroids, cAMP or forskolin, IL-11. Recent studies suggest upstream mediators of decidualization may regulate prolactin expression, including various proteins expressed during the secretory phase including gherelin, IGFBP related protein-1, leptin, and oncostatin-M.[280,445-448] The proliferation of endometrial cells is inhibited during deciudalization perhaps through stromal factors, such as IL-6 and oncostatin-M.[445,449] Prolactins role in the decidualization process remains unclear. Prolactin receptor (PRL-R) is expressed on the endometrial stroma, and while PRL-R knockout mice had defects in decidualization, the phenotype including reduced expression of LIF, amphiregulin, HB-EGF, Cox-1, Cox-2, PPARδ, HOXA10, cyclin-D3, VEGF, and its receptors, Flk-1 and neuropilin-1, could all be rescued by exogenous progesterone. This suggests that ovarian PRL-R stimulation by prolactin inducing progesterone secretion is the critical event rather than any direct effect of prolactin acting directly on the decidualizing stroma.[450] A role for uterine prolactin controlling the NK cells has recently been suggested.[451] Prolactin produced by the decidua during pregnancy accumulates in the amniotic fluid, where it has been postulated to have effects on osmoregulation and fetal lung development.

Global Gene Expression Patterns During the Window of Implantation

The dramatic changes in growth, secretions, cell growth, and then cell death have been studied at the molecular level using DNA microarray. Demonstration of the key patterns of gene expression between the pre-receptive (early secretory) phase and receptive (midsecretory) phase were first defined in 2002; 370 genes (3.1%) displayed decreases ranging from 2 to greater than 100-fold while 323 genes (2.7%) displayed increases ranging from 2 to greater than 45-fold.[452] A survey of the gene expression patterns has recently been completed in normal fertile women.[453] The patterns of up- and down-regulated genes appear to define well the four stages of endometrial development and suggest that the functional characteristics of each phase is defined by the proteins that are expressed during each phase. Cell cycle proteins are the predominant feature of proliferating endometrium while secretory profile of gene expression characterizes the early secretory phase. In preparation for implantation, patterns of gene expression reflect changes in extracellular matrix, cell-cell communication and adhesion, negative effectors of proliferation, synthesis of amino acids, cell ion homeostatis, and modifications to the innate immune system. Finally, there are dramatic changes in gene expression toward cell death, enzymatic digestive processes and endocytoisis/phagocytosis, hemostasis, and anti-microbial responses in response to the shedding of the endometrium during menstruation.

The molecular phenotype of the human endometrium in the midsecretory phase has been characterized using DNA microarray analysis of RNA extracted from endometrial biopsies obtained from fertile women, using chips that contain the entire human genome.[452-455] A relatively small percentage of genes (less than 6%) represented on the chips were significantly increased or reduced in expression (at least two-fold) during the receptive phase. Microarray analyses have confirmed the up-regulation of transcripts previously known to be increased during the window of implantation (including osteopontin, DAF, glycodelin, and IGFBP-1) and the down-regulation of others (including MMP-7 and cyclin B). However, several previously unappreciated genes changed in expression, most notably members of the WNT signaling pathway (Fig. 10.6A and B). Such changes included the increased expression of the Wnt pathway inhibitor Dickkopf-1 (DKK1) and a striking decline in the soluble form of FrpHE (SFRP4), another Wnt pathway inhibitor.

The microarray analysis also revealed significant alterations in expression of genes encoding water and ion transporters, including up-regulation of claudin-4, *Clostridium perfringens* enterotoxin receptor. Expression of genes encoding proteins responsible for prostaglandin synthesis and action were also found to be altered, including up-regulation of phospholipase A2 and prostaglandin E2 receptor (EP1). The functional significance of these genes, as well as the alterations in others, remains to be determined. Moreover, the interpretation of the findings is complicated by the fact that alterations in specific endometrial cellular compartments could not be ascertained for the majority of the genes of interest. The data sets do, however, provide a first approximation of the molecular signature of the human endometrium during the putative time of implantation in a small group of fertile women. This information could be used to develop a diagnostic "chip" profile for establishing normal uterine function.

Now that the changes in the endometrial transcriptome across the menstrual cycle have been roughly defined, investigators can view each segment of the menstrual cycle, divided by histological stage, as a unique fingerprint detailing the role of steroid hormones and the availability of their cognate receptors in the endometrium.[453] Genes that are expressed during the proliferative phase in response to estrogen play roles in cell adhesion, cell to cell signaling, cell cycle regulation, and cell division. After ovulation in the early secretory phase in response to both ovarian estrogen and progesterone, gene expression shifts globally to include metabolic enzymes, transporter proteins, inhibitors of WNT signalling with a marked up-regulation of lipid metabolism,

phospholipase activity and prostaglandin metabolism. There is increased EGF signalling noted during this stage. The midsecretory is distinct from the other stages due to the down-regulation of ERα and PR in the epithelial compartment, reflected in the patterns of gene expression. Devoid of estrogen action and progesterone acting primarily in the stroma, there is a shift toward cell adhesion, communication and motility, reflecting an increase in intracellular signalling, anti-apoptosis and immune responses, including DAF, defensin, complement component 4, and glycodelin along with leukocyte differentiation and immunotolerance.

During the late secretory phase, in lieu of pregnancy, progesterone withdrawal leads to preparation for eventual menstruation with increased expression of matrix metalloproteinases, EBAF (Lefty; an anti-TGF-β cytokine) and signalling through the IL-2 receptor. Evidence of leukocyte infiltration with gene expression patterns reflecting leukocyte integrins. Genes encoding proteins for the humoral immune response are further up-regulated at this time, while the most down-regulated genes denote a closing of the window of receptivity, with loss of LIF, DKK-1, IGF-1, and complement proteins.

Gene Expression Differences in Women with Endometriosis and Infertility

One of the best studied gynecological conditions affecting women is endometriosis. Global comparisons of the endometrium from women with or without endometriosis has been reported, providing insights into the critical elements for implantation.[114,183] Comparing midsecretory endometrium from each group, the overall consensus is that of progesterone insensitivity in eutopic endometrium of women with endometriosis. In women with mild disease, changes in gene expression were modest, with an increase in the expression of 91 genes (0.7%) and a decrease in 115 genes (0.9%). Genes such as collagen α2 type I and bile salt export pumps are examples of genes that were over expressed. Another finding, down-regulation of an enzyme necessary for L-selectin ligands (N-acetylglucosamine-6-O-sulfotransferase) may be significant because L-selectins have been postulated to be receptors on the embryo necessary for adhesion to uterine epithelium. Glycodelin, a major progesterone-induced secretory product (see previous discussion in this chapter), was also reduced. These differences may provide a profile for endometrial dysfunction in this and other diagnoses that have been associated with implantation defects. Interestingly, when mild endometriosis was compared to moderate/severe endometriosis, there was a shift in progesterone resistance toward the early secretory phase, suggesting that stage of endometriosis matters when considering the effects on the eutopic endometrium.[114] Multiple studies have also examined the difference between eutopic and ectopic endometrium in women with endometriosis.[456-460]

MicroRNAs (miRNAs) are small non-protein coding ribonucleic acid sequences that regulate specific post-transcriptional mRNA targeting them for degradation. Genes coding for miRNA represent 1% to 4% of the genes in higher organisms and are highly processed sequences that are derived from larger RNA transcripts. These small precursor miRNAs of 70- to 90-nucleotides are transported to the cytoplasm where they undergo cleavage by the RNAse III enzyme, Dicer, to generate a double stranded miRNA duplex, eventually forming a single stranded miRNA that binds to complementary sequences on target mRNA and preventing their transcription.[461-463] This extraordinarily complex regulatory mechanism of transcription has now been studied in the human endometrium.[117,464-466] In endometriosis, complex networks of genes appear to be altered on the basis of specific changes in miRNAs,[116,117,466-469] providing a new dimension to the study of endometrial receptivity.[470]

The Role of Growth Factors, Cytokines and Gondadotropins in Establishing a Receptive State

Growth factors and cytokines play an essential role in the dramatic morphological changes that occur in the endometrium during the menstrual cycle and pregnancy. Among the growth factors whose expression has been demonstrated in the human endometrium and decidua are EGF and EGF-like molecules, including TGF-α and HB-EGF; acidic and basic fibroblast growth factor (FGF); IGF-1 and IGF-2; IL-1, IL-11 and IL-6; LIF; macrophage colony-stimulating factor (M-CSF, also known as CSF-1); granulocyte-macrophage colony-stimulating factor (GM-CSF); members of the TGF-β superfamily; platelet-derived growth factor (PDGF); tumor necrosis factor-α (TNF-α); and endothelins 1, 2, and 3. Many of these factors have been proposed to play a crucial role in endometrial function and during pregnancy.[332,428,471-486] The endometrium and decidua and embryo/trophoblast have also been shown to express receptors for many of these factors, including the EGF/TGF-α, IGF-1 and IGF-2, IL-1, CSF-1, GM-CSF, PDGF, and VEGF. With such a wide array of growth factors, it has become difficult to determine with clarity the role of each factor in endometrial growth and differentiation, or their importance in processes involving maternal embryonic interaction and placental development.[487]

Several growth factors have been shown to exert regulatory effects on the expression of extracellular matrix proteins, their cellular receptors (integrins, selectins, cadherins), and enzymes (MMPs) that also influence cell growth, differentiation, and remodeling.[488-490]

Leukemia Inhibitory Factor (LIF) and IL-11

IL-6, LIF, an IL-11 are glycoproteins that belong to the same family of cytokines whose receptors utilize gp130 as a common signalling molecule.[275,491,492] LIF named for its capacity to inhibit the proliferation of a mouse leukemic cell line, is expressed constitutively in the ampullary region of the fallopian tube and in a cyclic fashion in both epithelial and stromal cells of the endometrium, with epithelial expression being greater.[372,493-499] The functional LIF receptor, a complex consisting of LIF receptor β (which binds LIF) and gp130 (which mediates signal transduction) is present throughout the menstrual cycle in the luminal epithelium. LIF receptors are expressed by all trophoblast types, particularly the villous syncytiotrophoblast and cytotrophoblasts and to a lesser extent the extravillous trophoblast cells.

Sentinel observations in the mouse have clearly demonstrated that LIF of endometrial origin is crucial for the process of implantation, particularly the decidualization response.[494] LIF-deficient female mice failed to become pregnant or respond to a uterine decidualizing stimulus. However, transfer of their embryos to pseudopregnant, wild-type females resulted in viable pregnancies—as did infusion of LIF into the uteri of LIF-deficient females. The primary action of LIF appears to be on the uterus. However, in mice subsequent placentation is disrupted, perhaps because LIF's role in modulating trophoblast differentiation and expression of MMPs cannot be executed. Implantation of LIF receptor-deficient human embryos occurs but these offspring suffer from Stuve-Wiedemann/Schwartz-Jampel type 2 syndrome.[497]

LIF mRNA and protein are present in human endometrium, being most abundant in the glandular and luminal epithelium and peaking in the secretory phase of the cycle.[500-502] The cycle-dependent expression of LIF in human endometrium may be a function of other growth factors rather than a direct effect of steroid hormones. If implantation occurs, LIF expression by the endometrial glands is down-regulated while there is a concomitant increase in LIF expression by endometrial NK and T cells. LIF has been found to enhance human blastocyst formation and to modulate trophoblast differentiation *in vitro*.[493] LIF levels in uterine flushings rise 7 days after ovulation, reaching a maximum 5 days later. LIF levels in uterine flushings and secretion of LIF from cultured endometrium obtained from patients with repeated implantation failures or unexplained infertility is decreased,[372,503] and defects in LIF have been implicated in some cases of recurrent pregnancy loss.[493]

Leptin has been suggested as a regulator or LIF, through its receptor, OB-R.[504] LIF stimulates hCG in trophoblast.[498] LIF has been implicated in activation of Signal transducer and activator of transcription-3 (STAT-3); mice homozygous for STAT activation site on gp130 have a defect nearly identical to LIF deficient mice.[505] Suppressor of cytokine signaling protein-3 (SOCS-3) is stimulated by LIF and blocks phosphorylation of gp130 and STATs. In LIF null mice, stromal Cox-2 and epithelial HB-EGF is absent at the site of implantation.[506,507] Two other EGF family members, amphiregulin and epiregulin are also reduced in LIF knockout mice. IL-1 has been shown to induce Cox-2.[508,509] Prostacylin acting through the PPAR γ is essential for decidualizaton.[314,510] Cox-2 null mice have multiple defects in ovulation, fertilization, and implantation.[315] Together, LIF stimulation of luminal epithelium along with blastocyst may trigger IL-1 that triggers decidual changes.

Mutations in the coding sequence of one copy of the LIF gene were identified in a small number of infertile women (3 of 74 infertile nulligravid subjects), and a presumed polymorphism was found in one of 75 fertile controls and none of 131 non-obstetrical patients.[511] One of the mutations in the infertile group was in the 5′-regulatory region of the LIF gene; the two others were in the coding sequence in a domain thought to be important for LIF binding to its receptor. Unfortunately, the authors did not determine whether LIF levels or bioactivity in uterine flushings or endometrial biopsy material were correlated with genotype. Collectively, however, these observations are consistent with an important role for LIF in human implantation, trophoblast differentiation, or placentation. IL-11 is another member of the IL-6 family that is implicated in the decidual response.[492,512,513] As with the LIF knockout mice, female mice lacking the IL-11 receptor alpha chain are infertile because of defective decidualization.[512]

IL-11 is present in the human endometrium and it advances progesterone-induced decidualization of cultured endometrial stromal cells. Both relaxin and prostaglandin E2 increase IL-11 expression. An inhibitor of IL-11 (W147AIL-11) reduces prolactin secretion by ESC in response to RLX and PGE2 suggesting IL-11 is the critical factor in this signalling cascade.[514] Like LIF, IL-11 is an activator of the JAK/STAT signalling pathway through STAT3, which stimulates suppressor of cytokine signalling -3 (SOCS3), a negative feedback mechanism for receptor activity. Ovarian steroids and cAMP differentially stimulate STAT3 and SOCS3, respectively, *in vitro*, while IL-11 activates both by phosphorylation.[515] Treatment with an anti-progestin increases SOCS3, attenuating IL-11 induced STAT3, suggesting multiple regulatory components including progesterone. Recent investigations in women suggest that IL-11 and phosphorylated STAT3 are significantly lower in the infertile endometrium compared to controls, while IL-11 receptor and LIF were not different.[516]

EGF Family of Growth Factors

The EGF family of growth factors appears to play a major role in uterine development and physiology.[332,428] The EGF family of ligands is produced by a family of genes, epidermal growth factor (EGF), heparin-binding EGF-like growth factor (HB-EGF), amphiregulin (AMP), betacellulin (BTC), epiregulin (EPR), tumor growth factor α (TGF-α), and neuregulins (NRG). This EGF family of ligands has the ability to bind and activate one or more dimers of four structurally homologous ErbB receptor subunits via a conserved 60 amino acid "EGF-like" binding domain. The receptor subunits for the EGF ligand family, ErbB1, ErbB2, ErbB3, and ErbB4, are structurally homologous and specificity of ligand binding is determined by differences in extracellular domain sequences (Fig. 10.18). The ErbB proteins function as hetero- or homo-dimers and possibly also as higher order multimers.[517] ErbB2 lacks ligand-binding activity and ErbB3 lacks functional tyrosine kinase activity. Thus, ErbB2 and ErbB3 likely function only as heterodimers, with another ErbB protein supplying the missing function in a dimer.

Interacting with their receptors, EGF family members act as autocrine and juxtacrine factors, and some exist as membrane bound forms that are released by proteolytic cleavage to function in a paracrine or endocrine manner. The proteolytic cleavage is accomplished by cell-surface metalloproteinases, similar to those involved in L-selectin ligand and MUC-1 cleavage, suggesting an important role for metalloproteinase action at the maternal-fetal interface.[518-520]

EGF and TGF-α stimulate the proliferation of endometrial stromal cells.[428] The synthesis of fibronectin and vitronectin by epithelial cells is enhanced by EGF. EGF also stimulates stromal cell differentiation and enhances the synthesis of laminin and fibronectin. These growth factors also enhance the morphological and functional differentiation of decidual cells *in vitro*. EGF has not been identified in

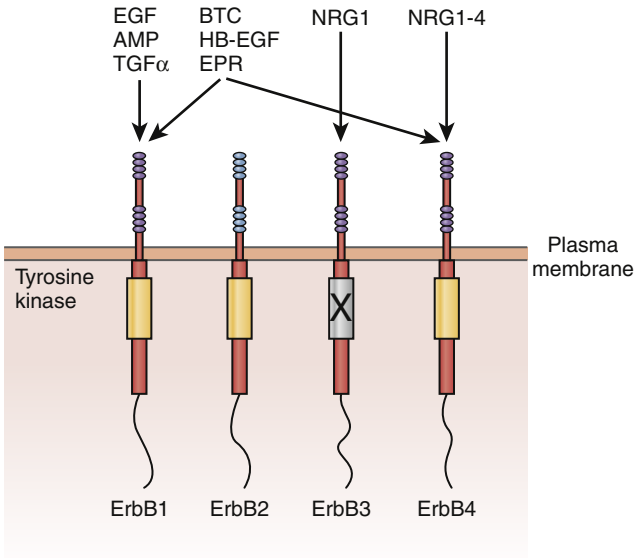

FIGURE 10.18 The EGF family of growth factors and receptors. EGF and its family members associate with specific receptors that signal through intracellular tyrosine kinase action. The 4 receptors can dimerize in predictable ways.

the circulation of cycling or menopausal women, but it has been detected in the serum of pregnant women with peak concentrations occurring in early pregnancy. Binding studies indicate that EGF-R peaks at the time of ovulation (or shortly thereafter) and declines during the secretory phase to a nadir immediately before menses. The binding sites are present on both stromal and epithelial cells, as well as in decidua of pregnancy. Studies using immunohistochemistry suggest that decidualization is associated with an increase in EGF-R. Abnormal EGF and EGF-R activity has been reported in cases of intrauterine growth retardation. It has been hypothesized that EGF and related molecules play a role in the induction of trophoblast differentiation.

Multiple EGF family members appear to directly participate in the process of implantation.[274] HBEGF exists as a membrane-anchored precursor (HB-EGF™) that gives rise to a soluble processed form. These proteins can bind to two different EGF receptors, HER1/ErbB1 and HER4/ErbB4. HB-EGF mRNA is found in the stroma during the proliferative phase, but in the midsecretory phase it is also detected in luminal and glandular epithelium.[521,522] This expression pattern appears to be driven by a combination of progesterone and estrogen.

HB-EGF is postulated to play roles both in adhesion via the membrane-anchored precursor (which binds to HER4/ErbB4 on the apical surface of the trophectoderm) and in stimulating embryo growth. In the rodent, HB-EGF is one of the first cytokines found around the implanting embryo.[523,524] In the human endometrium, mRNA levels of HB-EGF increase during the secretory phase, reaching a peak at the time of implantation.[521] HB-EGF™ can mediate attachment of human embryos in an *in vitro* assay of implantation.[525] HB-EGF also may promote embryonic development. When added to serum-free medium, it increases the number of embryos reaching the blastocyst stage and stimulates hatching. HB-EGF may also participate in paracrine actions within the endometrium. Stromal derived HB-EGF promotes expression of LIF, HOXA10, αvβ3 integrin, and DAF by endometrial cells *in vitro*. Other members of the EGF family likely play important roles during early pregnancy as well.[372]

The TGF-β Family

TGF-β family, multifunctional proteins that regulate cell growth and differentiation, includes five dimeric polypeptides encoded by related genes.[258,486,526-529] These growth factor members bind to three cell-surface proteins designated type I, II, and III receptors. The type I and type II receptors are thought to mediate the actions of TGF-β through the SMAD signaling pathway. All three isoforms of TGF-β can be found in human endometrium, including TGF-β1, TGF-β2, and TGF-β3. Null mutant mice bearing TGFβ mutations for each of the three genes produce a distinct phenotype suggesting a separate role for each member of this growth factor family.[530] All three and the type II receptor were identified in all cell types of the endometrium.[531] TGF-β1 and TGF-β3 are found on both epithelial and stromal cells, while TGF-β2 is found primarily on the stroma and increases during the secretory phase.[529,532] TGF-β3 increases at menstruation and remains high throughout the proliferative phase, while TGF-β1 is maximal at menstruation. Ovarian steroids strongly repress TGF-β2 and TGF-β3 in stroma but only TGF-β2 is repressed in glandular epithelium. cAMP prevents this inhibition of TGF-β2 by progesterone, while MAP kinase (MAPK) inhibitors differentially stimulated TGF-β2 and TGF-β3. These opposite effects provide insight into the discreet and highly temporal and spatial expression of the TGF cytokines during the menstrual cycle.

TGF-β has profound effects on the extracellular matrix, increasing the synthesis of collagen while decreasing its degradation.[195,533] In the secretory phase, TGF-β is a potent inhibitor of MMP activity in both stroma (MMP-3) and epithelium (MMP-7) while simultaneously promoting TIMP expression. This cytokine is induced by progesterone, acting in concert with retinoic acid to maintain these pro-fibrogenic activities. In the event of pregnancy, progesterone acting through TGF-β will maintain the integrity of the endometrium throughout gestation. In lieu of pregnancy, the fall in progesterone releases the MMP inhibitory factors, resulting in programmatic breakdown of the extracellular matrix and subsequent menstruation.

Other members of the TGF-β family are expressed in the endometrium.[486] EBAF (or Lefty) may participate in menstruation process, acting as a potent inhibitor to TGF-β.[253] Antagonism of TGFβ1 by over expression of EBAF (Lefty; a TGFβ antagonist) reduces the number of implantation sites in rodent models,[534] consistent with human data showing high levels of lefty in infertile women.[256]

Activins are highly abundant in the endometrium. Activin β (βA and βB) is found in the glandular epithelium with peak expression during the secretory phase. Activin A promotes decidualization *in vivo* while follistatin opposes the actions of activin.[535] Activin A enhances production of LIF and enhances MMP-2 during decidualization. MMP and LIF activity are both crucial for decidualization in rat and primate.

TGF-β1 and TGF-β2 have been reported at the interface between embryo and endometrium and likely plays multiple

roles during embryo attachment and invasion.[528,536] In pregnancy, TGF-β is most abundant in the decidua in the first trimester of pregnancy, where it is thought to restrain trophoblast invasion by promoting trophoblast differentiation away from the invasive phenotype. TGF-β is sequestered in the extracellular matrix where it can be activated by embryo-derived proteases. TGF-β up-regulates the expression of cellular fibronectin by trophoblast cells and induces integrins on the trophoblast that interact with the ECM during invasion promoting MMP activity.[537,538] TGF-β induces TIMPs and PAI-1 activity to counterbalance the invasiveness of the trophoblast. TGF-β as a potent immunosuppressant may prevent the maternal immune rejection of the fetal allograft. Its actions include suppression of chemotaxis and macrophage and T-cell activity. ADAMTS (A Disintegrin and Metalloproteinase with Thrombospondin repeats) has been thought to play a critical role in ECM remodelling during implantation. IL-1 increases, while the anti-inflammatory effects of TGF-β1 decreases ADAMTS expression.[539] These opposing actions illustrate the balance between factors favoring embryonic invasion and maternal efforts to control this invasion and reflects the essential role of TGF-β in this process.

Other Growth Factors and Cytokines Participate in Endometrial Growth, Differentiation, and Immune Function

Platelet derived growth factor (PDGF) is produced by endometrial stromal cells and also released in the endometrium by activated platelets.[540] PDGF is a potent mitogen that acts on endometrial receptors that are most abundant in the proliferative phase of the cycle.

FGFs encompass a family of growth factors that can stimulate growth of endometrial cells and smooth muscle cells.[541,542] Acidic and basic FGFs bind to proteoglycans. Because these proteins do not contain secretory signal sequences, they may be most important in the endometrium during menstruation when they could be released from dying cells. Basic FGF is angiogenic but also stimulates stromal cell proliferation in the presence of progesterone. FGF-7, also known as keratinocyte growth factor, stimulates epithelial cell proliferation. FGF-7 mRNA is expressed at highest level in the late secretory phase endometrium in the stroma; its receptor is most abundant in the glandular epithelium in the late proliferative phase. These findings suggest that FGF-7 is progesterone dependent, whereas its receptor is estrogen sensitive. FGF-8 is a uterine growth factor isolated from bovine uterus, and FGF-9 was recently described in the late proliferative phase of human endometrium.[542]

The IGF system of growth factors encompass not only IGF-1 and IGF-2 hormones, but also two distinct receptors and multiple different binding proteins that modulate IGF activity.[429,430,543-547] IGF-1 and IGF-2 are mitogenic growth factors that share structural similarities to insulin and are present in the mouse uterus and throughout the menstrual cycle in women.[548] Both hormones are present in the stroma, though the receptors are present in both epithelial and stromal cells. IGF-1 is more abundant in the proliferative phase and may function in epithelial proliferation, while IGF-2 is expressed in a more robust fashion in secretory phase and is thought to be a mitogen for the stroma of pregnancy.

IGF-1 binds to both the type 1 IGF receptor (IGF-1 receptor), structurally similar to the insulin receptor, and the type 2 receptor (IGF-2 receptor) with high affinity. IGF-2 binds the latter with higher affinity.[549]

IGF-1 mRNA is localized by *in situ* hybridization primarily in the syncytial trophoblast. IGF-2 mRNA has been demonstrated in mesenchymal fibroblasts of the villous core and also expressed in first-trimester and term cytotrophoblasts. The expression of IGFs in the placenta seems to be under the regulatory control of hormones (insulin, human placental lactogen, and estrogens) as well as growth factors, including PDGF. Type IGF-1 receptors have been detected in the placenta during the earliest periods of gestation, and it has been hypothesized that IGFs promote trophoblast proliferation.

TNF-α is a pleiotropic factor that exerts inflammatory, mitogenic, mitostatic, angiogenic, and immunomodulatory effects in a variety of tissues.[550] It is a membrane-bound 14-kDa polypeptide that is derived by proteolytic cleavage from the 26-kDa precursor. Expression of TNF-α mRNA and protein has been demonstrated in human endometrium, decidua, and trophoblasts; its receptors have also been found in all these tissues. TNF-α in the human endometrium is subject to regulation by steroid hormones—namely, estrogens and progesterone.

TNF-α and its receptors (TNF-R) are expressed by trophoblasts during both early and late gestation.[551] There is differential expression of the two genes encoding TNF-R, thus allowing some regulation of TNF-α activity. In cultured human chorionic cells, TNF-α affects cellular fibronectin secretion. Scientists have hypothesized that, along with other endometrial and trophoblast factors, TNF-α controls trophoblast adhesion and invasion and alters the integrin expression pattern in endometrial stroma.[552,553]

Colony-stimulating factors are a family of cytokines that were initially identified by their ability to stimulate hematopoietic stem cells to form colonies in semisolid culture media. CSF-1 is a glycosylated disulfide-linked homodimer. CSF-1 and its receptor are expressed in the endometrium, decidua, and placenta.[428,554] CSF-1 levels in the endometrial glands are higher in the secretory phase compared to the proliferative phase and the decidua expresses higher levels of CSF-1 mRNA and protein than the proliferative phase endometrium. The CSF-1 receptor (CSF1R encoded by FMS) is highly expressed by extravillous trophoblasts in the cell columns that anchor the placenta to the uterus.[555] The endometrial cells, both of local and of bone marrow origin, in proximity to the anchoring trophoblasts appear to be the major source of CSF-1 found at the placental-uterine interface. Lower serum levels of CSF-1 have been reported in women with recurrent spontaneous abortions. Although CSF-1 has been proposed to regulate trophoblast proliferation and differentiation, this role is not confirmed by the phenotype of the *op/op* (osteopetrotic) mouse that lacks CSF-1. This mouse has reduced fertility and smaller litter sizes, evidently due to a defect in ovulation, not implantation or placentation.

Human Chorionic Gonadotropin

In vitro studies demonstrate that the addition of follicle-stimulating hormone, luteinizing hormone (LH), hCG, thyroid-stimulating hormone, and free β subunit have an effect on human reproductive tract tissues, including the

stimulation of prolactin production, enhancement of decidualization, and myometrial relaxation.[556,557] The presence of LH/hCG receptors in the fallopian tube, myometrium, and endometrium has also been reported. However, the transcripts detected are smaller than those encoding the gonadal LH/hCG receptors; the proteins are also smaller, detected as 50 to 60 kDa molecules as compared with the observed receptor molecular weights in gonadal tissue (83 to 95 kDa). Thus, the extragonadal LH/hCG receptors appear to be truncated, evidently lacking extracellular domains, but still retaining the capacity to signal after binding LH and hCG. The primary signal transduction cascade initiated by the truncated endometrial LH/hCG receptors may not involve the classical cAMP-protein kinase A system as the primary pathway, but rather the mitogen-activated protein kinase pathway or the activation of prostaglandin synthesis.

Although extragonadal LH/hCG receptors have been proposed to play various roles in the reproductive tract, they are probably most important in the context of pregnancy where high levels of hCG are present. Thus, hCG could be an important embryonic signal in the bidirectional dialogue between conceptus and uterus. The best evidence that extragonadal LH-hCG receptors have an important role in primate reproduction is derived from the study of the baboon, where administration of recombinant hCG causes alterations in both epithelial and stromal cells. Preliminary studies in women indicate that hCG can also affect the human endometrium *in vivo*,[558] including prevention of endometrial apoptosis.[559]

In the baboon, the response to intra-uterine administration of hCG by osmotic minipump over a 4-day period starting on day 6 after ovulation includes the formation of an epithelial plaque, hypertrophy of the surface epithelium, and rounding off of the glands characteristic of pregnancy in this species.[557] Glycodelin expression in the endometrial glandular epithelium is enhanced, and α-smooth muscle cell actin is expressed in the stroma. *In vitro*, hCG inhibits stromal cell apoptosis and stimulates decidual changes—reflected by increased IGFBP-1 expression as well as increased expression of Cox-2. As previously noted, *in vitro* studies have shown that the glycoprotein α subunit stimulates production of prolactin, another uterine secretory product. Activation of myometrial LH/hCG receptors *in vitro* causes myometrial relaxation, which could facilitate nidation *in vivo*.[558] The response to hCG was blunted in animals with endometriosis.[560] Using intrauterine microdialysis in the human, it was shown that administration of hCG significantly reduces IGFBP1 and M-CSF expression in human after post-ovulatory day 10, while LIF, VEGF, and MMP-9 were all dramatically increased,[435,561] suggesting that hCG is an important modulating factor during early pregnancy. *In vitro* studies, using hCG coated beads, have demonstrated an induction of trophinin on the endometrial epithelium when IL-1 is present, suggesting a mechanism for enhanced embryo-endometrial interactions at the maternal-fetal interface.[562] LIF and its receptor are up-regulated in response to hCG treatment *in vitro*.[563] As an endocrine factor, hCG likely has independent effects on a wide variety of endometrial genes, independent of direct trophoblast interactions.[436]

Prostanoids and Other Lipids

The role of prostaglandins in the implantation process has long been suspected because of their effects on the vascular system and association with inflammatory processes. The fact that mice deficient in Cox-2 display abnormalities in the implantation process, particularly the early decidual response, is consistent with this notion.[558] Evidence suggestive of a role of prostanoids in human implantation includes the presence of Cox-1 and Cox-2 in the human endometrium (mainly the glandular epithelium) during the presumptive implantation period[564]; an examination of prenatal use of non-steroidal anti-inflammatory drugs (NSAIDs), drugs that inhibit Cox enzymes, indicated an increased risk of miscarriage in users of aspirin and other NSAIDs.[565] One of the key prostanoids involved in implantation is thought to be prostacyclin, a ligand for the peroxisome proliferators-activated receptor delta (PPARδ), a nuclear receptor family member expressed in subluminal stromal cells in the rodent uterus, whose role in implantation has been suggested.[510,566-568]

Another lipid implicated in implantation is the arachidonate derivative known as arichidonylethanolamide or anadamide, a ligand for the cannabinoid receptors.[569-572] Anandamide, referred to as an endocannabinoid, binds to cannabinoid receptors CB1-R and CB2-R, which are expressed in the preimplantation embryo and in the reproductive tract (CB1-R). The embryo is enriched in CB1-R, and in the blastocyst the expression of this receptor is most abundant in the trophectoderm. Uterine anandamide levels in the mouse are reduced at the time of implantation and are highest at inter-implantation sites. Endocannabinoids at low levels accelerate trophoblast differentiation but at high levels inhibit trophoblast differentiation and arrest embryo development. Tetrahydrocannabinol and synthetic agonists of the cannabinoid receptors have similar effects. Thus, it has been postulated that endocannabinoids play an important role in controlling the synchrony of embryo development for implantation in rodents. Anandamide is present in human reproductive tract fluids,[571] and high anandamide levels are associated with *in vitro* fertilization failures.[572]

Early Implantation Events in the Human

Prior to interaction with the surface epithelium, the blastocyst must hatch from the confines of the zona pellucida. Gradual zona thinning, as well as complete hatching of embryos, can be observed *in vitro*. The existence of ectopic implantation suggests that the endometrium is not obligatory for this process to be successfully completed. Nevertheless, there may be more subtle regulation of hatching within the endometrial cavity. Although degradation of the zona pellucida is a process controlled by the embryo, inhibitors or agents that induce "zona hardening" may affect the timing of the process.

Work on subhuman primates demonstrates that mononuclear cytotrophoblasts of the trophectoderm of the blastocyst have fused into syncytia before the attachment of these cells to the endometrial epithelium.[573] Careful histological descriptions of very early human implantation sites (such as those studied by Hertig and colleagues)[268] indicate that the syncytial trophoblast layer of the human embryo comprises the invading front during the first few days of implantation. Thus, the consensus appears to be that it is a syncytial trophoblast cell that initially interacts with and adheres to the endometrial epithelium; only after the human embryo is completely embedded in the endometrium do the cytotrophoblast cell columns start to stream out of the trophoblastic

shell and further invade the uterus.[574,575] This process starts approximately 1 week after the initiation of implantation and continues well into the second trimester of pregnancy.

The early human implantation sites that have been examined histologically demonstrate that by day 12 after ovulation, the embryo is almost completely covered by endometrium. The endometrial stroma around the implantation site displays the predecidual reaction and is edematous. By the classic histological criteria of Noyes and associates,[576] the endometrium of the implantation site is not that different from the non-pregnant midsecretory phase endometrium. The glands adjacent to the embryo are themselves deflected by invading trophoblasts but maintain the tortuosity and secretion-filled appearance typical for this stage of the menstrual cycle. *In vitro* observations using human embryos or human trophoblasts have attempted to characterize some morphological features of the early events of trophoblast-endometrial interactions.[577-581]

There is growing consensus that initial apposition and attachment is an evanescent and rate limiting step in the initiation of implantation. A receptor-mediated paradigm for embryo attachment and invasion has long been postulated.[582] Numerous endometrial and trophoblast cell-adhesion molecules and associated moieties have been suggested as candidates to serve as attachment receptors.[525,583-586] Historically, surface modification of the glycocalyx was a subject of much interest,[587-589] but more recently the molecules that populate the luminal surface have come under scrutiny. The actual number of receptors and ligands on this surface appear to be somewhat restricted compared with the other cells in the endometrium. As shown in Figure 10.19, a limited number of adhesion-attachment components have been suggested. MUC-1 (not shown) is a large glycoprotein that is downregulated on the endometrial surface in most species at the time of implantation,[590] but expressed throughout the menstrual cycle in humans.[586] Nevertheless, debate continues regarding this large glycoprotein as a possible attachment receptor for the human embryo. Other smaller molecules are present and may serve the purpose of initial attachment, including trophinin, integrins, CD44, L-selectins, and HB-EGF™.[109,591]

The cascade of events leading to successful implantation likely requires many critical proteins with different functional contributions. A novel cell surface protein called *trophinin* has been suggested as a homologous pairing partner between trophoblast and endometrium during implantation.[584] The αvβ3 integrin and its ligand osteopontin, are expressed at the time of implantation on the luminal surface of receptive endometrium. Secreted osteopontin binds to this integrin through an RGD sequence.[440,592] Since osteopontin can also bind to the CD44 hyaluronate receptor through non-RGD binding sites, it has been suggested that these serve in a "sandwich"-pairing mechanism at the point of interface.[593,594] In the human, surface epithelial cells on both the embryo and endometrium express the αvβ3 integrin *and* CD44.[595] There is also ample evidence that RGD binding is vital to the process of implantation,[596,597] peptides containing this sequence reduce implantation efficiency in animal models, including the rabbit and mouse.[598,599] Thus, integrin-mediated adhesion may somehow play a role in successful implantation. More recently it has been suggested that osteopontin, αvβ3 integrin, and CD44 binding serves to suppress the innate immune system through decay-accelerating factor (DAF)-mediated interference with complement subunit C3,[438,442] a role that could be critical for the protection of the embryo at the time of initial attachment and invasion.

The transmembrane form of HB-EGF and its receptor ErbB-4 are expressed on the surface of endometrium and on the outer cells of the embryo, respectively. Evidence in both rodents and human suggests that these molecules could serve as an attachment receptor-ligand pair during implantation.[523,525] Soluble HB-EGF interferes with this process, perhaps through competitive inhibition. Transmembrane HB-EGF could also play a paracrine role especially if cleaved from its transmembrane location when the embryo enters the uterine cavity.

Perhaps the most promising mechanism involves that previously elucidated for leukocyte-endothelial interaction. L-selectin and an oligosaccharide ligand are expressed on the blastocyst and endometrial surface in the human, respectively.[585] This type of adhesion reaction between embryo and endometrium at the time of implantation is quite appealing and likely involves integrin mechanisms for embryo invasion, similar to leukocyte intercalation at sites of inflammation.

Evidence from humans illustrate a temporal and spatial regulation of L-selectin ligand expression on the luminal and glandular epithelium.[600] Likewise, each mechanism could be disrupted in infertile women, leading to a failure

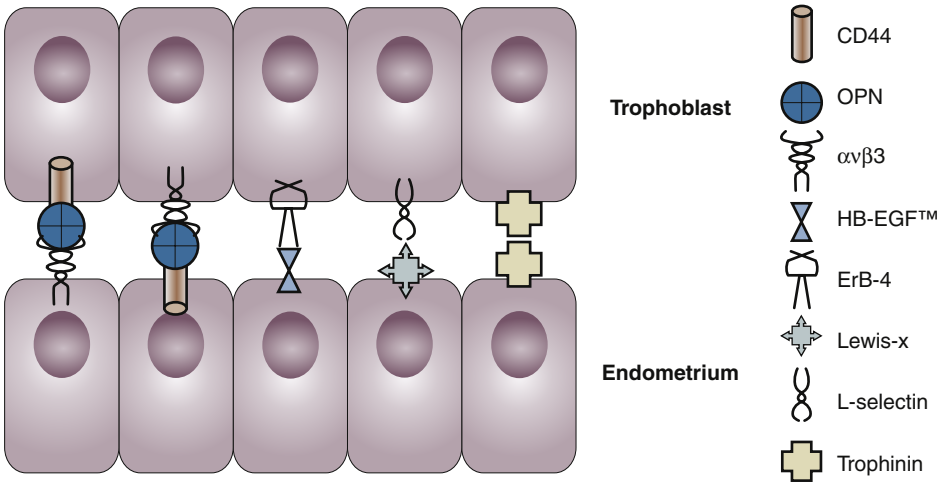

FIGURE 10.19 Luminal surface proteins that may interact with complementary proteins on the embryonic surface. Experimental evidence exists for each of these possible attachment reactions. It is likely that there is redundancy in these systems and that each may serve specific functions, such as signaling or attachment during the initial stages of implantation.

of implantation.[601] Methods to diagnose and correct such defects may provide new hope for those with otherwise unexplained infertility or recurrent pregnancy loss.

Structural alterations accompany the biochemical changes noted on the surface epithelium. Scanning electron microscopy reveals that the human endometrial epithelium consists of secretory and ciliated cells (Fig. 10.20). The ratio of non-ciliated to ciliated cells changes during the menstrual cycle, decreasing in the late proliferative phase and increasing in the secretory phase. In general, estradiol levels correlate directly with the presence of ciliated cells, and withdrawal of estrogen is associated with loss of cilia. The ciliated cells do not undergo surface morphology changes during the menstrual cycle, whereas the secretory cells display significant cycle-dependent surface modifications.

Transient surface specializations of the secretory cells called *pinopodes*, also known as pinopods or uterodomes, have been a focus of research, because the temporal patterns of expression seemed to coincide with the time of maximal uterine receptivity.[602] These surface structures were first identified on the luminal epithelium of rodent endometrium during the limited period (approximately 12 hours) when the uterus is receptive to implantation; they were shown to be involved in pinocytosis, hence the appellation of pinopode (from the Greek "drinking foot").[603] Similar structures, although with different morphologies, were subsequently discovered in numerous species, including humans; their appearance again generally correlated with the time of implantation.

While it is certain that pinopodes are involved in pinocytosis in the rodent uterus, *in vitro* studies failed to show that they serve this function in women—hence the suggestion that the structures should be designated "uterodomes" as opposed to "pinopodes."[604,605] Mechanisms underlying the formation of pinopodes in the human endometrium have not been elucidated. They may form from the accumulation of membrane components, as a consequence of secretory activity, or from reorganization of the cell cytoskeleton. Some researchers have suggested that they serve to elevate the endometrium above the ciliated cells, providing a platform with the necessary complement of surface adhesion receptors.

The role of pinopodes in human embryo implantation (beyond the temporal correlation between their appearance and the estimated time of nidation) is supported by *in vitro* studies demonstrating that human blastocysts implant on human endometrial epithelial cells only in areas bearing pinopodes (Fig. 10.21). Other studies have demonstrated that surface biomarkers are present on the pinopodes. HB-EGF, a molecule implicated as a membrane bound ligand and juxtacrine-paracrine factor important in signaling to the embryo, is on the surface of pinopodes at the expected time of implantation.[371] The αvβ3 integrin and its ligand are also both present on these apical protrusions during the window of implantation (Figs. 10.20 and 10.22).[606] MUC-1 and osteopontin appear to be on different cell types of the luminal surface, based on electron immunohistochemistry; MUC-1 is present solely on the ciliated cells while osteopontin is present on the secretory or pinopode-bearing cells.

The formation of pinopodes appears to be dependent on progesterone, while estrogen causes them to regress. The earlier appearance of pinopodes in controlled ovarian stimulation cycles is correlated with the preovulatory rise in plasma progesterone. Administration of a low dose of the progesterone receptor antagonist mifepristone on days

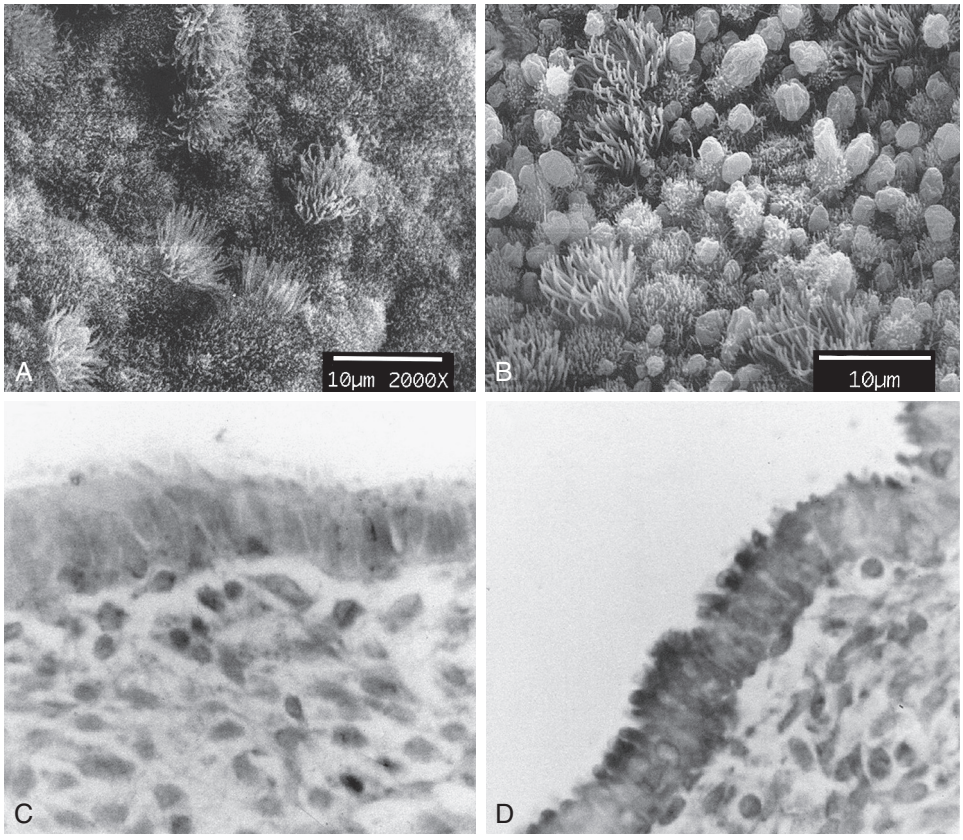

FIGURE 10.20 **A,** The surface epithelium of human endometrium is composed of ciliated and secretory cell types. **B,** During the time of maximal receptivity, the surface of these cells transform into a sac-like protrusion seen in many species, now called pinopodes. During the prereceptive phase, surface receptors such as the αvβ3 integrin are not present **(C),** but are expressed during the window of implantation on these pinopode structures **(D).** *(Used with permission of Human Reproduction.)*

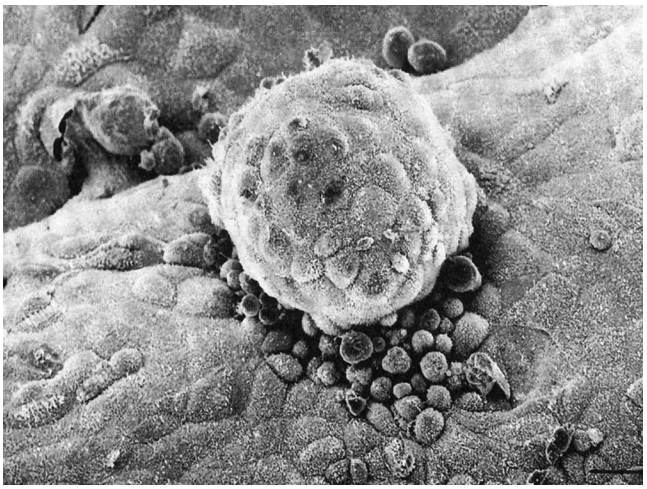

FIGURE 10.21 *In vitro* culture of human embryos on cultured endometrial epithelium appears to show that embryos prefer to attach to areas with pinopode expression. *(Reproduced with permission from Bentin-Ley U. Relevance of endometrial pinopodes for human blastocyst implantation.* Hum Reprod *15[Suppl 6]:67–73, 2000.)*

14 and 15 of a cycle delays pinopode formation. Studies in the mouse suggest that *HOXA*10, a progesterone-regulated gene, is required for pinopode formation,[607] though pinopodes have been described in both *LIF* and *HOXA10* null mice.[608] The actual temporal distribution of pinopodes has also been brought into question in the past several years, with several studies showing little correlation with the actual window of implantation.[609-611] While likely involved in embryo-endometrial interactions, the utility of these structures as markers of uterine receptivity appears limited.

Biochemical Evaluation of the Endometrium

Biomarkers of Endometrial Receptivity

Attempts have been made to find suitable biomarkers of endometrial receptivity.[470,612,613] A list of major biomarkers of receptivity are listed in Table 10.1. These endometrial factors appear relevant on the basis of their temporal patterns of expression that correlate with the putative window of implantation on cycle days 20 to 24. While certain biomarkers, such as calcitonin or LIF, are aligned closely within

Table 10.1 Endometrial Biomarkers Used for Assessment of Endometrial Receptivity

FUNCTIONAL CATEGORY	BIOMARKER	EXPRESSION PATTERN	COMMENTS
Chemokine/cytokine	LIF	m---------o---------m	All essential for implantation
	IL1,11	m---------o---------m	
Enzymes	17HSD-II	m---------o---------m	Converts E2 to less active E1;
	Aromatase	m---------o---------m	Should not be present in normal endometrium
Extracellular matrix/ receptors/ligands	Integrins		These 3 integrins frame the window of implantation;
	α1β1	m---------o---------m	
	α4β4	m---------o---------m	MMPs and lefty (EBAF) come up at menses;
	αvβ3	m---------o---------m	
	MMPs	m---------o---------m	Epithelial glycoprotein
	EBAF (lefty)	m---------o---------m	Binds L-selection;
	MUC-1	m---------o---------m	Stromal marker
	L-selectin ligand	m---------o---------m	
	Cadherin-11	m---------o---------m	
Growth factors	TGFβ	m---------o---------m	Mediates P action;
	EGF Ligand family	m---------o---------m	Involved in both proliferation and implantation;
	Hepatocyte growth factor (HGF)	m---------o---------m	
	Heparin binding-EGF like growth factor (HB-EGF)	m---------o---------m	Involved in decidualization Stromal and epithelial expression;
	IGF-I	m---------o---------m	Proliferative phase
	IGF-II	m---------o---------m	Secretory phase
Major secreted proteins	Glycodelin	m---------o---------m	All 3 are epithelial proteins
	Calcitonin	m---------o---------m	
	Osteopontin	m---------o---------m	
Paracrine or autocrine	Indian hedgehog (IHH)	m---------o---------m	Induced by P;
	Bone morphogenic protein 2 (BMP2/TGFb1)	m---------o---------m	Induced by IHH
Steroid receptors and related cofactors	ERα	m---------o---------m	Estrogen induced and P inhibited; *PRA persists in decidua
	PR-A/PR-B	m---------o---------m	
	FKBP51, FKPB52	m---------o---------m	Each induced by P;
	MAGE-11	m---------o---------m	Expressed in midsecretory phase
Transcription factors	HOXA10	m---------o---------m	Both essential for implantation;
	HOXA11	m---------o---------m	Expressed during WOI
	CCAAT enhancer binding protein- β (C/EBPβ)	m---------o---------m	Essential for decidualization; Expressed during proliferation
	Forkhead box O1 (FOXO1)	m---------o---------m	
	Beta catenin	m---------o---------m	
Miscellaneous	CD44	m---------o---------m	During WOI;
	Prolactin	m---------o---------m	Marker of decidualization

this window, others have a pattern of expression that is inversely related to the time of maximal endometrial receptivity (ERα, PRs, and telomerase).

Some of the best-characterized biomarkers for assessment of uterine receptivity are the integrins. As shown in Figure 10.22, three epithelial integrins undergo changes in expression during the luteal phase. This pattern has now been consistently observed in multiple studies.[109,614-619] Of these, αvβ3 is the most studied. Dyssynchronous or delayed maturation of the endometrium is associated with delayed expression of the αvβ3 integrin. While patterns of integrin expression suggest roles in cell adhesion and maintenance of tissue architecture, the αvβ3 integrin is present on the upper most portion of the luminal epithelium corresponding to the localization of osteopontin and pinopodes. This integrin has been used for the assessment of the endometrium in women with endometriosis and other benign conditions,including hydrosalpinges, unexplained infertility, and polycystic ovary syndrome, although not all studies agree on their usefulness.[109]

Based on the use of biomarkers like the integrins, two distinct types of deficiencies have been identified in women with infertility. This model fits well with data presented by Wilcox and colleagues that suggests delayed implantation may reduce cycle fecundability.[267] The normal uterine receptivity provides the opportunity for the embryo to attach and invade the maternal lining. In some cases, such as in luteal phase defect, this window may be shifted or delayed, resulting in pregnancy loss or failure to conceive. This might occur when progesterone levels are suboptimal or when the response to progesterone is decreased. In other cases, the histological development is normal but the biochemical changes associated with a receptive endometrium fail to develop in a timely fashion. Such a mechanism of occult defects has been suggested as the underlying implantation defect in women with endometriosis and hydrosalpinges.[109] The cause of this type of receptivity defect remains a topic of debate and an active area of research.

Clinical Evaluation of the Endometrium

Endometrial Biopsy

The endometrial biopsy is used to assess endometrial histology. While used extensively in the setting of abnormal bleeding as a diagnostic tool for endometrial cancer or hyperplasia, its primary role in the evaluation of the infertile couple has been the assessment of the luteal phase. However, as described below the clinical utility of the endometrial biopsy as a routine test is questionable. The existing literature reflects a wide range of opinions regarding the use of this test,[620-623] including when to perform the biopsy, the

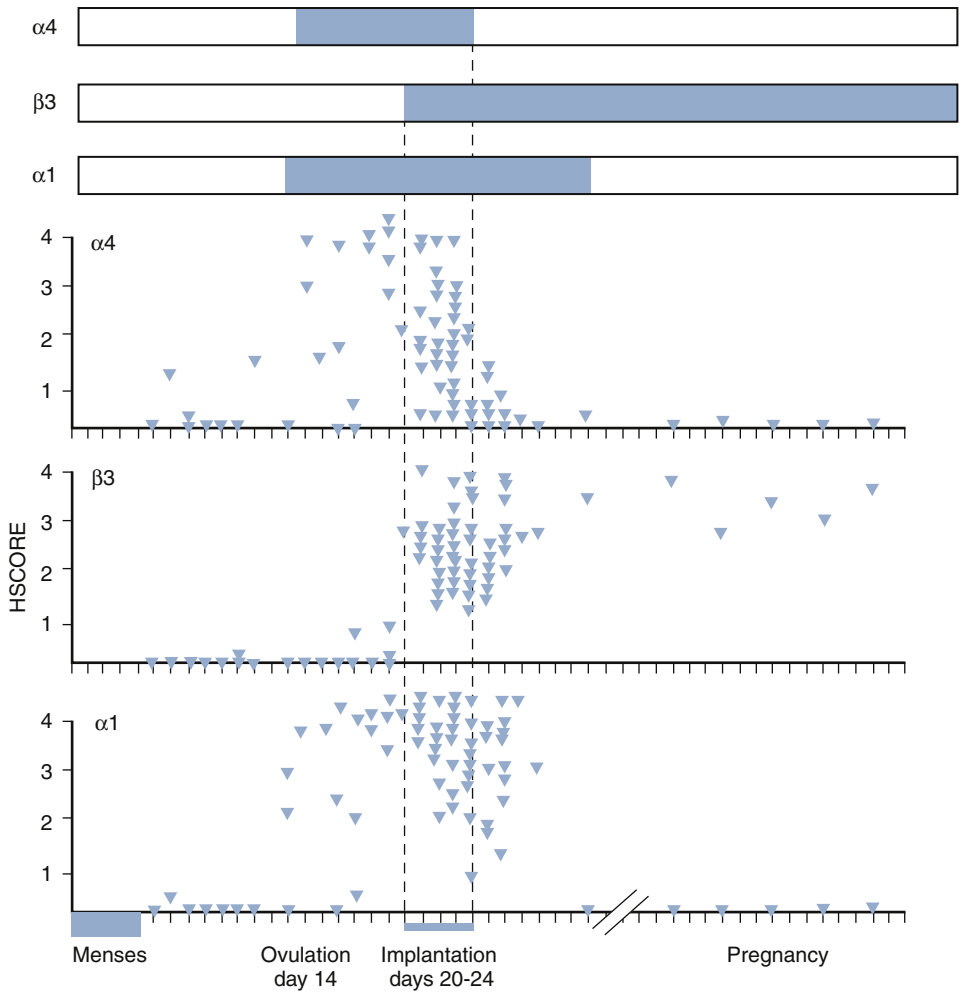

FIGURE 10.22 Scattergram showing distribution of three cycle-dependent epithelial integrin subunits in cycling endometrium. While each of the integrin subunits has a unique pattern of expression, all three are coexpressed during the time of maximal receptivity between cycle days 20 and 24. *(From Lessey BA. Two pathways of progesterone action in the human endometrium: implications for implantation and contraception.* Steroids. *68: 809-815, 2003.)*

number of days' lag time that should be required to consider a sample abnormal, and the utility of other modalities to evaluate the luteal phase.[624] True standardization of the endometrial biopsy to evaluate histological criteria has never been established despite over 50 years of use, and recent studies have questioned its value.[620,625] The chronological reference point, crucial to the interpretation of results, has shifted from retrospective to prospective determination during that time.[626] These variations in the use of the endometrial "dating" may explain, in part, the wide diversity of opinion in the literature regarding the incidence and clinical importance of luteal phase deficiency (LPD).[621]

LPD is uncommon and probably accounts for no more than 3% to 5% of infertile population judging from many studies. The high prevalence of LPD in some reports is understandable given the variability of endometrial histology between women and even in the same woman in subsequent cycles. Add to that the variation in timing of the biopsy and inter- and intraobserver variation in reading histology, the real significance of luteal phase biopsies may become of historic interest only.

The histological changes that serve as the basis for this technique were described in 1950 in the now classic paper by Noyes and associates.[576] Unfortunately, these criteria are only an approximation of the cumulative effect of progesterone on the endometrium. Cycle-to-cycle variability, high inter- and intra-observer variation, and uncertainty as to the timing of ovulation also reduces the overall reliability of these dating criteria. The original indices, as defined, were only obtained in an *infertile* population, making it somewhat difficult to know whether the same histological changes occur in normal fertile women. Indeed, recent studies in normal fertile controls do not support this technique of dating endometrium as a precise or reproducible method of endometrial assessment.[620] Currently the best method for diagnosing luteal phase defect may be the presence of a shortened luteal phase, as shown by methods such as basal body temperature charting (Fig. 10.23). While the normal luteal phase should be approximately 12 to 14 days in length, premature luteolysis could potentially compromise the establishment of pregnancy. Such charting can also demonstrate anovulatory cycles.

Of note, there may be a basis for some of the observations regarding luteal function that is worthy of further consideration. With the completion of the human genome project and the availability of high throughput DNA microarray analyses, it appears that progesterone resistance does occur, based on patterns of gene expression in women with endometriosis compared to fertile controls.[114] Whether this precedes or is a result of endometrial pathology has not been settled. And while women with endometriosis are the first group associated with this phenomenon, it also appears to be common in ovulatory women with PCOS.[48] Such changes may account for the infertility or pregnancy loss associated with these conditions. Defects in progesterone receptors or in progesterone-mediated regulators of cell growth or differentiation have all been implicated in progesterone resistance, including changes in *HOXA* genes, integrins, Mig-6, FKBP4, PR-B, or DKK-1.[18,59,90,183,627-629] These findings provide new underpinnings of understanding subtle defects in progesterone responsiveness and promises to keep attention focused on LPD, even 60 years after its original description.

Ultrasonography

Abnormalities of the structure of the uterus from congenital defects, neoplasia, or synechiae can impair fertility. Diagnostic imaging methods play an important role in the assessment of these uterine defects.[630]

Transvaginal sonography (TVS) has become widely accepted as a tool for high-resolution imaging of the female internal reproductive organs, because it is non-invasive, convenient, and safe and provides rapid diagnoses with high correlation with pathology.[631] This non-invasive, convenient, and safe technology provides rapid diagnoses with high correlation with pathology. TVS is used primarily to monitor follicular development and endometrial thickness during exogenous hormone treatments of infertile patients. The method might offer significant advantage for use as a diagnostic aid in various other endometrial conditions, such as endometrial polyps, submucus and intramural leiomyomata, endometrial hyperplasia, and carcinoma. TVS has certainly found its use in the assessment of early pregnancy.

Growth of the endometrium can easily be measured using ultrasound. Endometrial thickness and texture is commonly assessed, especially when women are sequentially monitored as part of their treatment with human menopausal gonadotropins. Endometrium in the early proliferative phase immediately following menses is typically thin; in response to estrogen, the endometrium thickens and becomes trilaminar in appearance, growing between 0.1 to 0.5 mm daily. Following ovulation, the endometrium becomes hyperechoic as secretory changes ensue. Various attempts have been made to classify these patterns on the basis of thickness and texture. Most authors suggest that a thickness of 8 mm or greater with a trilaminar appearance is adequate for implantation in an *in vitro* fertilization cycle.[632-636] Beyond a certain threshold, however, there is no correlation between implantation rates and endometrial thickness.

The cyclic endometrial changes induced by varying estrogen and progesterone levels result in predictable sonographic changes, in both blood flow and vessel density. Both endometrial thickness and echogenic pattern have been studied as potential markers of uterine receptivity and predictors of successful embryo implantation. Transvaginal pulsed Doppler ultrasound measures uterine artery blood flow (or the impedance to flow) and is expressed as the *pulsutility index* (PI). The PI varies across the menstrual cycle and may be an additional index to predict implantation after assisted reproductive techniques. Aside from endometrial thickness, morphology, blood flow, and uterine artery pulsatility have all been examined as possible markers of a receptive endometrium. Increased PI has been associated with elevated markers of pregnancy loss, including anti-cardiolipin antibodies.[637,638] Studies in pregnancy using Doppler flow ultrasound and pregnancy outcomes have been inconclusive.[639]

Sonohysterography and Three-Dimensional Ultrasound

Identification of uterine fibroids, endometriomas, and uterine septa are now fairly routine (see Chapter 27). Lesions such as polyps within the uterine cavity may be misinterpreted as thickened endometrium and therefore go

undiagnosed. Instillation of sterile saline into the uterine cavity as part of sonohysterography provides an enhanced view of the uterine cavity and may detect even small lesions. This approach is valuable in assessing the effects of selective estrogen receptor modulators like tamoxifen on the endometrium.[640] A sonohystogram in a normal uterus shows a smooth contour (Fig. 10.24A). In some cases, abnormalities can be more clearly seen with sterile saline installation (Fig. 10.24B). Three-dimensional sonohysterography can provide dramatic 3-D rendering of the uterine cavity, giving a better overall appreciation of such lesions, and better determine the location and point of attachment (Fig. 10.24C).[641] This evolving technology may further improve the sensitivity and specificity of the technique used to detect small polyps or fibroids. With the advent of three-dimensional ultrasound, differential diagnoses between a septate versus a bicornuate uterus can also be more readily determined, avoiding the need for more expensive modalities like MRI. The use of three-dimensional ultrasound for the assessment of uterine receptivity is also evolving.[642]

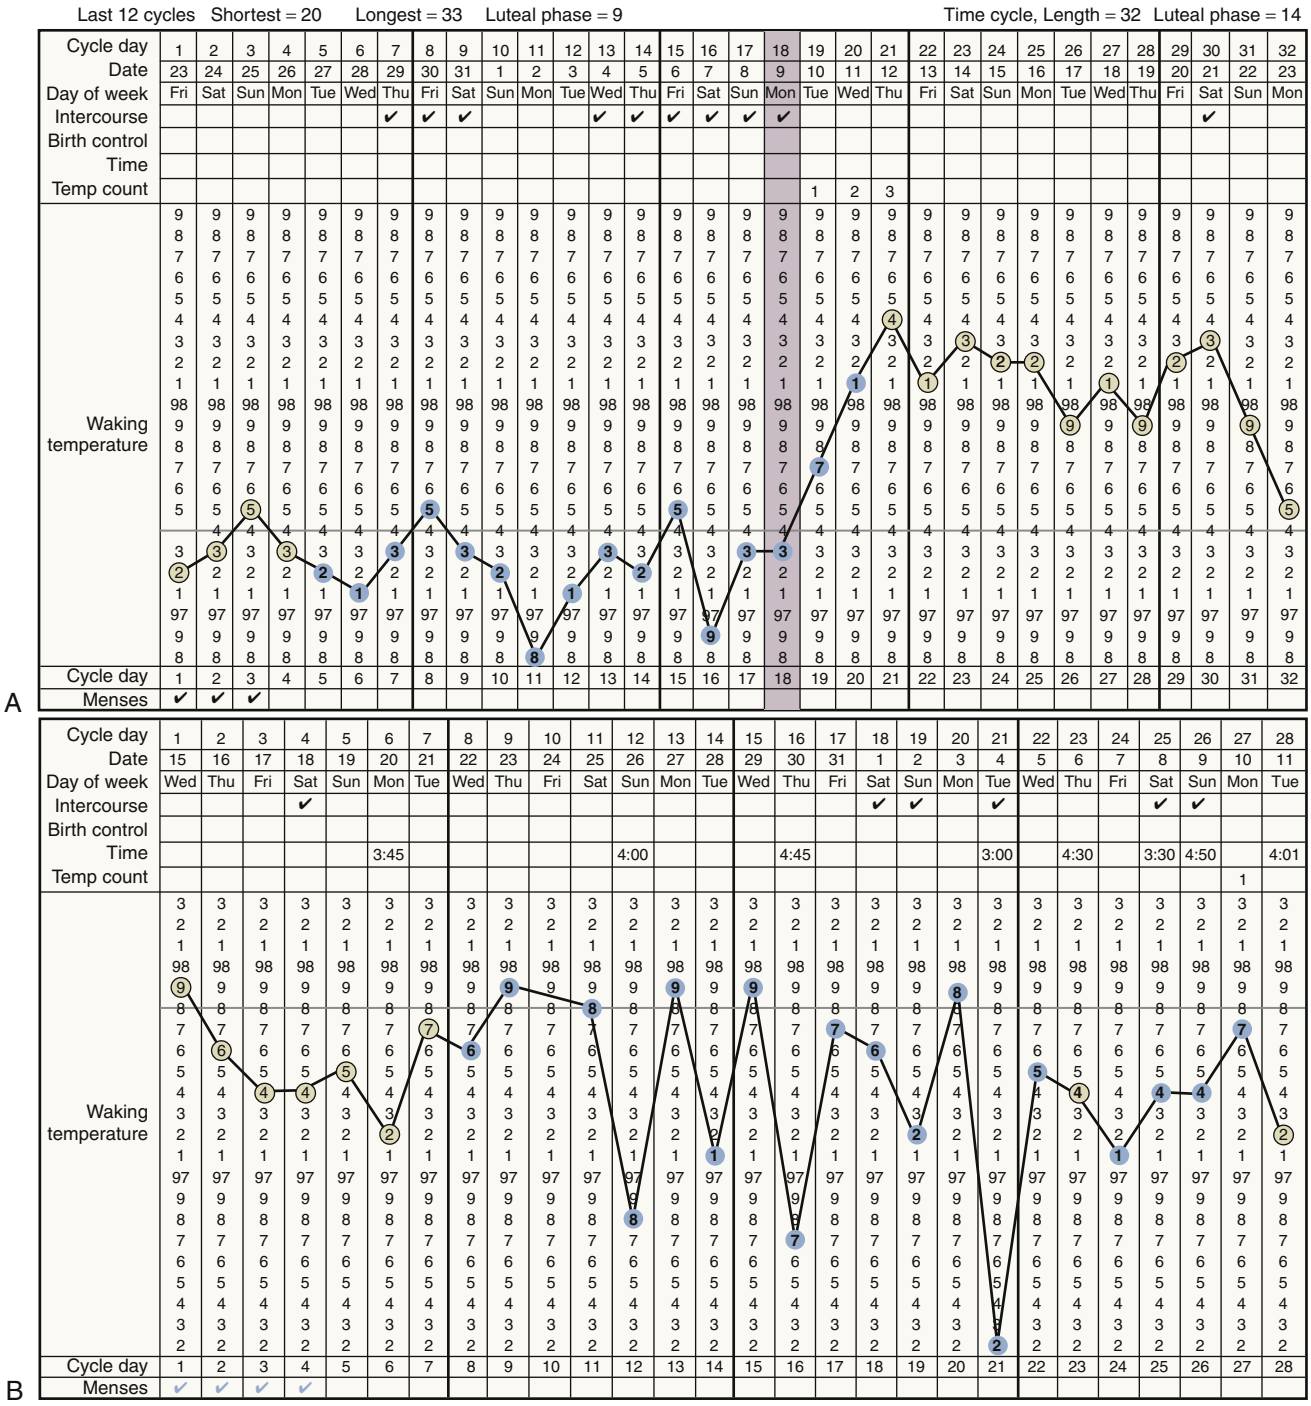

FIGURE 10.23 Basal body temperature charts can be helpful for the diagnosis of ovulatory dysfunction. Compared with normal 14-day luteal phase **(A)**, anovulatory cycles fail to show a normal thermogenic shift **(B)**.

FIGURE 10.23, cont'd In some cases, a short luteal phase is evident **(C).**

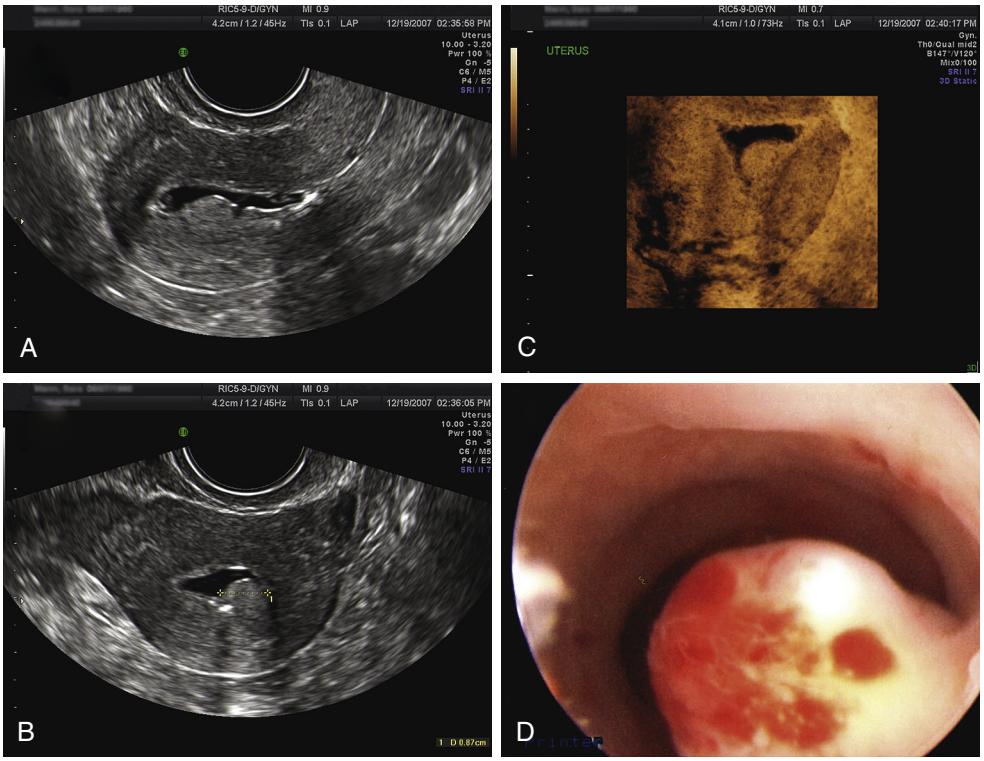

FIGURE 10.24 Sonohysterography can be used to visualize intracavitary lesions. Injection of sterile saline shows the uterine cavity to be free of polyps or fibroids **(A).** In the case of intrauterine pathology, lesions such as a polyp can be easily delineated either in 2-D **(B)** or 3-D rendering **(C).** Hysteroscopy confirms the polyp **(D)** that can then be easily resected.

Hysteroscopy

Hysteroscopy is a highly useful tool to identify and correct lesions identified by hysterosalpingography or sonohysterography (Fig. 10.24D).[643,644] Visualization of the endometrial cavity has proven useful for the inspection of the uterine cavity in women with abnormal bleeding, infertility, and recurrent pregnancy loss. Direct visualization allows the operator to resect or biopsy lesions, once identified. Resection of uterine septa in müllerian fusion defects is commonly performed. More recently, sterilization techniques through hysteroscopy have been refined to a point that challenges

other techniques and are readily available in many centers around the world.[645]

Magnetic Resonance Imaging

MRI may occasionally be useful for diagnosis of myometrial lesions, including fibroids and adenomyosis (see Chapter 27). T2-weighted images may provide evidence for endometriotic lesions outside the uterine fundus and aid in the diagnosis of congenital uterine anomalies prior to surgical correction.

Uterine Transplantation

Aside from generation of a female reproductive tract using stem cell technologies,[646] restoration of a cervix and uterus for purposes of reproduction may soon be an option for women who have lost or due to müllerian agenesis never had normal uterine anatomy.[647] Transplantation surgery of many organs including heart, lung, liver, and even the face or hands has become routine. Further, women with acquired gynecological disease such as fibroids and adenomyosis and gynecological malignancy, Asherman syndrome, or congenital absence of the uterus may one day be able to undergo a uterine transplant with reasonable chances for success. The first (and currently only) attempt at uterine transplantation in the human was performed in 2000, which ended with graft removal due to thrombosis.[648] Of greatest concern is the immune suppression required to prevent graft vs. host reaction and graft rejection. While pregnancy itself may be considered an immunotolerant state, graft rejection for other organs has been reported to be higher during pregnancy.[648] Further, it is not yet clear what the effect cyclosporine or other immunosuppressant therapies might have on the recipient, her fetus, or on the graft during pregnancy.[649]

CHAPTER 11

The Breast

Robert L. Barbieri

The main biological function of the breast is to produce milk to nurture newborns. Mammals are differentiated from other animal classes by the presence of hair on the skin and the production of breast milk to nurture newborns. The word, mammal, is derived form the Latin *mamma* which means, "resembling the milk gland or breast." The breast overlies the second to the sixth ribs. The medial border of the breast is the sternum, and the lateral border is the latissimus dorsi. The superior and inferior borders are the clavicle and the costal margin and upper rectus sheath. The breast consists of glandular, adipose, and connective tissues. The left breast is often somewhat larger than the right breast.

The glandular tissue of the breast is arranged in approximately 15 to 20 lobes (Fig. 11.1). Each lobe consists of a branching structure made up of lobules and acini (also referred to as *alveoli*). The acini are lined by a single layer of milk-secreting epithelial cells. Each acinus is surrounded by an interwoven pattern of contractile myoepithelial cells. The lumens of the acini connect to collecting intralobular ducts, which empty into the main 15 to 20 lobar collecting ducts. In turn, each lobe drains into the nipple. The nipple is surrounded by a pigmented areola. The sebaceous glands located on the perimeter of the areola are referred to as the *glands of Montgomery*. The glandular tissue is embedded in fat, which accounts for most of the mass of the breast. The lobules are separated by connective tissue septa (Cooper's ligaments) that run from the subcutaneous tissue to the chest wall.

The breast is sensitive to the sex steroids estradiol, progesterone, and testosterone, and to numerous protein hormones, including prolactin and oxytocin. During puberty and pregnancy, the breast is stimulated to grow. In many mammals, estradiol is especially important in stimulating the growth of the ductal system, and progesterone is important in stimulating the growth of the acini and stromal elements. During pregnancy, estradiol, progesterone, and prolactin are important factors stimulating breast growth. Androgens tend to inhibit breast growth, an effect that can be characterized as antiestrogenic.

Development of the Breast

The development of the breast occurs in three major phases: *in utero*, at puberty, and during pregnancy. This process has been best studied in mice. During *in utero* development of the breast, the growth of epithelial elements into the underlying mesenchyme results in the development of a rudimentary ductal system. This process occurs independent of stimulation by estradiol, progesterone, prolactin, or growth hormone. Immediately after birth, the rudimentary mammary ducts are quiescent. In the mouse, the majority of mammary duct morphogenesis occurs during puberty.

The mammary gland is a tubular structure that fully develops during puberty through branching morphogenesis. The branched ductal network that forms extends into the stromal fat pad and the branching process is led by the terminal end bud which consists of epithelial progenitor cells. The differentiated mammary gland is composed of luminal epithelial cells and surrounding basal myoepithelial cells. Estradiol stimulation of estrogen receptor alpha (ERα) is critical for pubertal mammary gland development. ERα-null mice do not have mammary development.[1] Estrogen receptor beta (ERβ) is abundantly expressed in mammary glands but mice lacking ERβ have normal mammary development.[2] Forkhead box protein A1 (FOXA1) helps open up chromatin so that transcription regulatory factors, such as the estrogen receptor, can gain access and better bind to deoxyribonucleic acid (DNA) regulatory elements. FOXA1 null mice do not have normal mammary development but develop stunted ductal structures with end buds.[3] The coactivators and corepressors that modulate ER and progesterone receptor (PR) action are described in detail in Chapter 5, Steroid Hormone Action.

In the mouse, knock-out of the prolactin gene by homologous recombination causes infertility in female mice, but not in male mice. The mammary glands of prolactin knock-out mice have a normal ductal tree, but the ducts fail to develop lobules.[4] In the mouse, knock-out of the prolactin receptor gene by homologous recombination causes infertility and mammary development is normal up to puberty. At puberty ducts develop but branch less frequently and the terminal end buds do not differentiate to alveolar structures.[5]

In pubertal mice, trans-acting T-cell-specific transcription factor GATA3 (GATA3), a transcription factor involved in cell fate specification, is highly expressed in luminal cells. Conditional deletion of GATA3 results in the failure of terminal end bud formation in breast tissue.[6] In addition, mammary duct development is highly dependent on the release of amphiregulin from luminal epithelial cells by the action of the transmembrane metalloproteinase, a disintegrin and metalloproteinase domain 17 (ADAM17). In turn, amphiregulin binds to the epidermal growth factor receptor (EGFR) located on stromal cells which stimulates duct formation. In the adult mouse, tertiary side-branching of the ductal system is stimulated by progesterone.

With the onset of pregnancy, a round of breast epithelial and gland proliferation occurs. Numerous hormones play roles in this process, including estradiol, progesterone, androgens, prolactin and other lactogenic factors, thyroxine, glucocorticoid, insulin, growth hormone, transforming

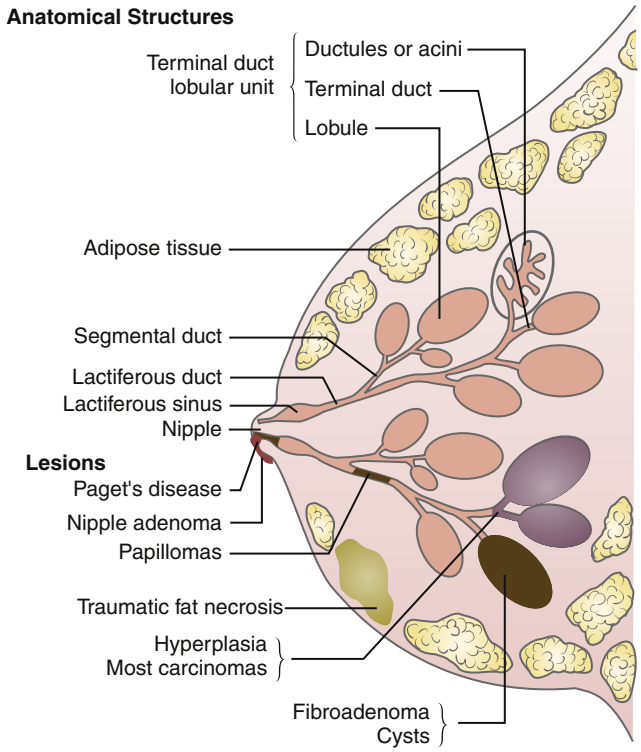

FIGURE 11.1 Anatomy of the breast and major lesions at each site within the breast. *(From Cotran RS, Kumar V, Robbins SL.* Pathologic Basis of Disease, *5th ed. Philadelphia: WB Saunders, 1994, p 1090.)*

growth factor-β, and epidermal growth factor (EGF). In the mouse, conditional knock out of ERα during pregnancy or lactation causes a loss of ductal side-branching and a decrease in the number of lobuloalveolar units.[7]

During the normal menstrual cycle, the breast undergoes cycles of growth and quiescence. In the early follicular phase, the ductal cells proliferate and continue to develop throughout the remainder of the cycle. In the luteal phase of the cycle, progesterone stimulates the proliferation of the terminal duct structure, basal epithelial cells, and stromal cells. Accompanying these proliferative changes are an increase in stromal edema and vacuolization of epithelial cells. These effects may account, in part, for the sense of breast fullness women experience during the late luteal phase. At menses, the decrease in estradiol and progesterone is associated with a decrease in cell proliferation, stromal edema, and the size of the ducts and acini.

The two most common congenital anomalies of the breast are supernumerary nipples and accessory axillary breast tissue. Supernumerary nipples result from the persistence of epidermal thickenings along the embryologic milk line. Supernumerary nipples can extend from the axilla to the suprapubic area. On occasion, breast tissue extends into the axillary fossa. Ectopic breast tissue in this region can be mistaken for an axillary mass or may cause pain after pregnancy because of the engorgement of the tissue with milk.[8-10]

Mammary Stem Cells

Mammary epithelial structures in both mice and women contain cells spanning a developmental hierarch from pluripotential stem cells, to progenitor cells committed to populate the epithelial structures to mature terminally differentiated luminal cells.[11] Mammary stem cells (MaSCs) become highly activated during pubertal development and pregnancy. MaSCs which are located in the basal epithelium do not express ERα or the progesterone receptor, but administration of estradiol, progesterone, or prolactin to female mice increases the number and clonogenicity of MaSCs.[12] This suggests the presence of paracrine cross-talk between the luminal epithelium and the basal MaSCs. Progesterone and prolactin appear to stimulate luminal epithelial cells to produce and secrete receptor activator of nuclear factor kappa-B ligand (RANKL) and Wnt4 which in turn stimulate the clonogenicity of MaSCs.[13,14]

Estradiol and Testosterone: Duelling Steroids

A genetic experiment of nature, *androgen insensitivity syndrome*, provides a clinical example of the important interplay between estrogens and androgens in the regulation of breast growth.[15] In androgen insensitivity due to mutations in the androgen receptor, genetic males (46,XY) do not have a fully functional androgen receptor. Testosterone is produced by the testis, but target tissues are not capable of responding to the high levels of circulating androgens. In this syndrome, estradiol levels are in the range of 50 pg/mL, comparable to early follicular-phase levels. Breast volume in individuals with androgen insensitivity is typically above average. This suggests that, in the complete absence of androgen inhibition, modest levels of estradiol are capable of stimulating significant breast growth. Progesterone levels are low in individuals with loss of the androgen receptor. This suggests that breast volume is not absolutely dependent on progesterone stimulation.

In the mouse, androgen receptors are present in mammary luminal epithelial cells, stromal fibroblasts, and adipocytes.[16] In female mice, administering androgen antagonists during puberty markedly increases the number of proliferating breast epithelial cells.[17] In the adult female monkey, administering androgen antagonists enhances estrogen-stimulated breast epithelial cell proliferation.[18] In cultures of human breast tissue, dihydrotestosterone (DHT) and testosterone inhibit estradiol induced stimulation of cell proliferation, cell survival, and the density of ERα containing cells.[19] The antagonist effect of androgens on estrogen stimulation of breast epithelial proliferation is the basis for the use of androgens to treat breast pain syndromes (see section titled, Cyclical Mastalgia).

Lactation

In reproduction, the main role of the breast is secretion of milk. Breastfeeding is very important for infants because it reduces the risk of infectious, immune, and atopic diseases and reduces neonatal mortality.[20] For mothers, breastfeeding protects against breast and ovarian cancer, type 2 diabetes, cardiovascular disease, and postmenopausal hip fractures. Breast milk consists of milk proteins, including casein and lactalbumin, free fatty acids, the milk sugar lactose, water, minerals, and vitamins. Lactose is a disaccharide consisting of glucose and galactose. During pregnancy, the breast is prepared for lactation by the actions of estradiol, progesterone, prolactin, and other factors—including placental lactogen. Lactose, water, and some proteins

accumulate in Golgi bodies and are then secreted into the duct system through a process of exocytosis. Many proteins and circulating hormones, including immunoglobulins and albumin, enter the duct system through a process of protein mediated transcytosis. Lipids are secreted into the duct system through a process of reverse pinocytosis. Lipids accumulate in the endoplasmic reticulum, form droplets, and then become enveloped in the apical plasma membrane leading to the emptying of the droplets into the duct system.

In pregnancy, the breast is exposed to high levels of lactogenic hormones, including prolactin, human placental lactogen, and placental growth hormone. In nonpregnant women, prolactin levels are typically below 25 ng/mL. During the third trimester of pregnancy, prolactin levels are typically fifteenfold higher, in the range of 200 to 300 ng/mL.[21] Human placental lactogen reaches concentrations in the range of 6000 ng/mL during the third trimester.

These lactogenic stimuli cause the breast to grow and prepare the alveoli for lactation. During pregnancy, the high concentration of progesterone blocks lactogenesis. After delivery, the decrease in circulating estradiol and progesterone concentrations and the continued elevated prolactin concentration result in an increase in the production of all of the components of milk.[22] The molecular mechanisms subserving these effects are discussed later in this chapter.

After the decrease in estradiol and progesterone, milk production requires 2 to 5 days to become established. In the postpartum interval, milk production can be suppressed by replacing estradiol and progesterone, or by suppressing prolactin secretion.[23] Milk production also requires the synergistic action of growth hormone, insulin, thyroxine, and cortisol.

During suckling, sensory signals originating in the nipple travel through thoracic nerves 4, 5, and 6 to the central nervous system. When the suckling-induced signals reach the paraventricular and supraoptic nuclei, they stimulate the release of oxytocin from the posterior pituitary. Noradrenergic, histaminergic, and excitatory amino acids play a role in oxytocin release.[24] Oxytocin release during suckling causes the contraction of the myoepithelial cells of the mammary acini and ducts, which induces the flow of milk. In addition to suckling, oxytocin can be released from the posterior pituitary by visual and auditory stimuli.

Prolactin maintains lactogenesis by stimulating the transcription of the casein and lactalbumin genes and other genes needed for the synthesis of free fatty acids and lactose. Suckling-induced signals also cause the hypothalamus to induce an acute release of prolactin, in part by suppressing dopamine secretion.[25] In lactating women, in the first 6 weeks postpartum, basal prolactin levels are elevated and each episode of breastfeeding initiates a pulsatile increase in prolactin which peaks at levels 8 times higher than basal concentration.[26,27] From 7 to 28 weeks postpartum, basal prolactin levels are in the normal range and the magnitude of the spike in prolactin levels is about sixfold above baseline. Use of a breast pump produced spikes in prolactin similar to those seen with suckling, but manual stimulation of the areola did not reliably produce a spike in prolactin. Having breastfeeding mothers play with their infants caused milk let-down, but did not produce a spike in prolactin levels. As the frequency and duration of suckling diminishes, the magnitude of the spike in prolactin level following suckling declines, eventually becoming extinguished.[26,27]

The Effect of Prolactin on β-Casein Gene Function

The cellular mechanisms that control milk protein production have been best elucidated for the β-casein and whey acidic protein genes. For the β-casein gene, gene function is regulated by prolactin, progesterone, estradiol, insulin, glucocorticoids, thyroxine, cell substratum proteins, and growth factors like EGF. In the murine mammary epithelial cell line HC11, expression of the β-casein milk protein gene is largely regulated at the transcriptional level.

Prolactin is the key endocrine regulator of β-casein gene transcription. The prolactin receptor is a class 1 receptor with extracellular cysteine motifs, a single transmembrane-spanning domain, and the absence of an intrinsic receptor-associated tyrosine kinase in the intracellular domain. Prolactin binding to its cognate receptor results in dimerization of the receptor and activation of the tyrosine Janus kinase 2 (JAK2) associated with the membrane-proximal, intracellular domain of the receptor (see Chapter 3, Prolactin in Human Reproduction).[28]

In turn, JAK2 phosphorylates and activates STAT5, a member of the signal transducers and activators of transcription (STAT) family. STAT5, previously known as mammary growth factor (MGF), increases transcription of the β-casein gene.[29] Various phosphatases, which are themselves regulated, de-phosphorylate STAT5 and reduce the transcription of β-casein gene transcription.[30]

The addition of prolactin to cultures of mammary epithelial cells results in casein gene transcription within 30 minutes. This effect requires the presence of both insulin and glucocorticoid. Deletion and point mutagenesis studies in mouse mammary epithelial HC11 cells transfected with the rat β-casein promoter have demonstrated that a region of approximately 340 bases immediately upstream of the transcription start site is a major site for gene regulation.[31,32] The 340 bases 5′ of the transcription start site contain the bases that confer gene inducibility by insulin, glucocorticoids, and prolactin.

Lactation and Amenorrhea

In mammals, suckling activates multiple systems that inhibit gonadotropin-releasing hormone (GnRH) secretion (see Chapters 1 and 3). The inhibitory systems activated during suckling include dopamine, serotonin, gamma-aminobutyric acid, and corticotropin-releasing factor. In turn, inhibition of GnRH secretion results in oligoovulation or anovulation. In rats, lactation reduces the number of kisspeptin containing neurons in the arcuate nucleus and median eminence, thereby suppressing GnRH secretion.[33,34] The degree to which breastfeeding suppresses GnRH secretion is modulated by the intensity of the breastfeeding, the nutritional status of the mother, and the body mass of the mother.[35-37] Lactation represents a metabolical energy burden. When nutrition is adequate and the basal body mass and composition is normal, intensive lactation is less likely to result in prolonged suppression of GnRH. When nutrition is

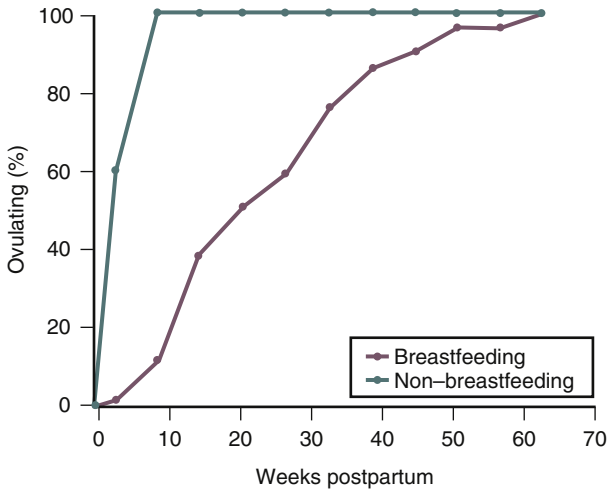

FIGURE 11.2 Cumulative proportion of ovulation by time postpartum for non–breastfeeding and breastfeeding women. *(From Campbell OMR, Gray RH. Characteristics and determinants of postpartum ovarian function in women in the United States.* Am J Obstet Gynecol *169:55, 1993.)*

inadequate to meet the energy demands of both daily living and lactation, oligoovulation or anovulation is more likely to persist for an extended time period.[38,39]

During exclusive breastfeeding, approximately 40% of women will remain amenorrheic at 6 months postpartum (Fig. 11.2).[40] In observational studies performed in the United Arab Emirates, the median duration of postpartum amenorrhea in breastfeeding women was 7 months.[41] Women who remain amenorrheic during breastfeeding may have higher prolactin levels than do women who become ovulatory while breastfeeding.[42] Among postpartum women who do not breastfeed, return of ovulation occurs between 45 and 94 days postpartum.[43] In some women who exclusively breastfeed, with at least six episodes of suckling per day, totaling more than 80 minutes in 24 hours, basal prolactin levels remain elevated up to 52 weeks postpartum and amenorrhea can persist for up to 1 year.[44]

The Effect of Steroid Contraceptives on Lactation

The available data indicate that (1) estrogen-progestin contraceptives reduce milk volume and change breast milk composition, (2) progestin-only contraceptives have no effects on milk volume and minimal effects on breast milk composition, and (3) long-term studies of the infants of breastfeeding mothers who used either estrogen-progestin contraceptives or progestin-only contraceptives show no detrimental effects of contraceptive steroid use on infant growth or neurodevelopment. Taken together, these data indicate that there is no proven effect of the use of contraceptive steroids by breastfeeding mothers on the development of infants who were breastfed. However, if a patient remains concerned about the possible impact of steroid contraceptives on breastfeeding and infant development a progestin-only contraceptive can be recommended. The progestin-only contraceptives include the progestin-only minipill, an etonogestrel releasing implant or depot medroxyprogesterone acetate.[45]

Most studies, but not all, report that estrogen-progestin contraceptives reduce breast milk volume more than progestin-only contraceptives. For example, in one study of more than 170 lactating women, the combination of 30 μg of ethinyl estradiol and 150 μg of levonorgestrel reduced daily milk volume by 31%. In contrast, a progestin-only minipill containing 75 μg of norgestrel increased daily milk volume by 10%. Similarly the use of depot medroxyprogesterone acetate increased milk volume by 10%.[46] Combination estrogen–progestin contraceptives also decrease the concentration of nitrogen, lactalbumin, lactoferrin, and lactose in breast milk. These changes in the composition of breast milk are modest and within the normal range of physiological variation observed in lactating women who are not taking contraceptive steroids.[47] In contrast to these findings, a recent, short-term randomized trial of the effects of a progestin-only minipill (norethindrone 0.35 mg daily) versus a cyclic estrogen-progestin contraceptive (35 μg ethinyl estradiol plus 1 mg of norethindrone in a 21/7 regimen) on breastfeeding reported no differences in the mother's perception of an adequate milk supply by contraceptive regimen.[48] In addition, consistent with other studies, the growth of the infants was similar with the two contraceptive methods.

The development of the newborn does not appear to be significantly affected by the changes in milk composition and volume associated with the use of combination estrogen–progestin oral contraceptives. In one study, the weight and neurological development of newborns of lactating mothers who took estrogen-progestin contraceptives were similar to those whose mothers did not.[46,49] A comparative study of the effects on lactation of a progestin-only contraceptive implant versus a copper intrauterine device (IUD) reported that infant growth was similar for both treatments.[50] Medicated and non-medicated IUDs do not appear to affect the growth of breastfed children.[51] The combination of lactation plus a progestin-only contraceptive is likely to be associated with a prolonged interval of amenorrhea compared to lactating women who use an IUD for contraception.[52]

Suppression of Lactation

Prolactin secretion is crucial to the maintenance of lactation. Suppression of prolactin secretion with dopamine agonists such as bromocriptine will suppress lactation.[53] The frequency of adverse effects associated with bromocriptine use in the puerperium is low.[54] However, there are a few case reports of severe hypertension and seizures that occurred in postpartum women who used bromocriptine.[55,56] Owing to these adverse outcomes, many authorities do not recommend bromocriptine as a first-line agent to suppress lactation. There may be a few clinical situations, such as mothers assigning their newborn for adoption, in which bromocriptine or cabergoline could be considered for the suppression of lactation. In most mothers, lactation suppression can be achieved with minimization of the mechanical stimulation of the breast and nipple, ice packs, and antiprostaglandin treatment. Milk stasis appears to decrease the production of STAT5, the main intracellular activator of milk protein production.[31,32]

Induction of Lactation

Induced lactation is defined as breastfeeding in the absence of a recent pregnancy. On occasion, adoptive mothers desire to breastfeed.[57] In countries where access to formula is limited, induced lactation in a surrogate may be important if the biological mother cannot continue to breastfeed.[58] The key hormone involved in lactation is prolactin. Medications that raise prolactin levels can be used to help induce lactation. For example, metoclopramide, 10 mg three times daily, will cause an increase in prolactin secretion.[59] When metoclopramide is coupled with nipple stimulation every few hours using an electronic breast pump, lactation can be established in the majority of women. In many cases the amount of milk produced may be insufficient to breastfeed the baby exclusively. Agents such as sulpiride (50 mg daily) and chlorpromazine can also be used to induce lactation, but these agents may be associated with drowsiness and extrapyramidal symptoms.[60,61]

Recombinant prolactin has been reported to effectively treat insufficient milk production in mothers with documented prolactin deficiency and mothers who cannot pump sufficient quantities of breast milk to feed their preterm children. At a prolactin dose of 60 μg/kg administered subcutaneously every 12 hours, prolactin levels and breast milk volume significantly increased in both groups of women.[62] The prolactin treatment also caused breast milk lactose and calcium concentrations to increase.[63]

Lactation and Hormone Responsive Reproductive Disorders

Women who are breastfeeding and are amenorrheic have circulating estradiol levels in the range of 20 to 40 pg/mL. In contrast, normally cycling women have a preovulatory estradiol concentration in the range of 250 to 300 pg/mL. Many gynecological diseases, such as endometriosis and uterine leiomyomas, are stimulated by high estradiol levels. The hypoestrogenic effect associated with amenorrhea and breastfeeding may have a beneficial effect on these estrogen-dependent disease processes and may account for the experimental and epidemiological observations that the risk of estrogen-dependent disease is reduced in women who have breastfed.[64,65] In one study of the relationship between lactation and the risk of developing laparoscopically proven endometriosis, a lifetime duration of lactation of greater than 23 months resulted in an 80% decrease in the risk of being diagnosed with endometriosis.[66] The protective effect of lactation was no longer apparent 5 years after the woman's last birth.

Lactation is associated with a reduced life-time risk of developing breast cancer (Fig. 11.3)[67,68] and ovarian cancer.[69]

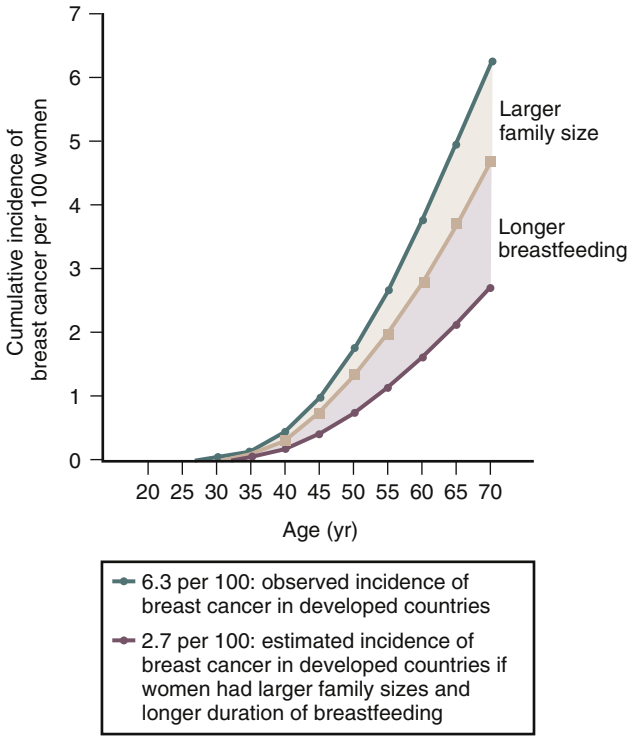

FIGURE 11.3 Estimated cumulative incidence of breast cancer in developed countries if women had family sizes and breastfeeding patterns typical for developing countries. Estimated incidence of breast cancer in developed countries if women had, on average, 6.5 births instead of 2.5 births, and if women breastfed each child, on average, for 24 months instead of a lifetime mean of 8.7 months. *(From Collaborative Group on Hormonal Risk Factors in Breast Cancer. Breast cancer and breastfeeding.* Lancet *360:187–195, 2002.)*

Lactation and the Risk of Developing Diabetes or Cardiovascular Disease

Lactation has been reported to reduce a women's risk of developing type 2 diabetes mellitus and the risk of cardiovascular disease. In the Nurses Health Study, a history of at least 1 year of lactation was associated with a 15% reduction in the risk of being diagnosed with diabetes.[70] In another prospective study of 522 women with an index pregnancy where gestational diabetes was diagnosed, women who breastfed their child, had lower fasting glucose, fasting insulin and 2-hour insulin after a glucose challenge than women who did not breastfeed their child.[71] In addition, with continued follow-up, the women who breastfed their child had a lower prevalence of diabetes and prediabetes. In another large prospective cohort, mothers who did not exclusively breastfeed their children had an increased risk of being diagnosed with diabetes compared with mothers who exclusively breastfed all their children (odds ratio [OR] 1.52, 95% confidence interval [CI] 1.11 to 2.10).[72] Breastfeeding, by increasing metabolical rate and energy expenditure, may help postpartum women achieve a lower body weight and waist circumference compared to non-breastfeeding mothers thereby improving metabolical function and reducing the risk of developing diabetes.[73]

Breastfeeding appears to reduce the risk of developing arteriosclerosis and having a cardiovascular event. In the Study of Women Across the Nation, women who reported breastfeeding all their children for at least 3 months had less carotid artery, coronary artery, and aortic calcifications than women who had never breastfed.[74] In the Women and Infants Healthy Hearts study, women who had breastfed for ≥3 months after every birth had less carotid artery narrowing as determined by high-resolution sonography than women who had never breastfed.[75] In the Nurses Health Study, women who breastfed for ≥2 years had a 37% lower risk of having a myocardial infarction than women

who had never breastfed (95% confidence interval 23% to 49%, p<0.001).[76] The mechanisms by which breastfeeding reduces the severity of atherosclerosis and coronary artery events is unknown, but in animal models, lactation reduces circulating triglyceride and increases high-density lipoprotein cholesterol.[77,78] In humans and animals, lactation reduces blood pressure and heart rate.[79]

Lactation and Bone Metabolism

During pregnancy, calcium is mobilized from bone, in part, to provide a stable source of calcium for fetal development. Pregnancy is associated with a 1% to 2% decrease in bone mineral density as determines by dual x-ray absorptiometry. Following birth, women who breastfeed lose additional bone mineral from the lumbar spine. Women who bottle feed their infants typically regain the bone they lost during pregnancy. After discontinuing breastfeeding, bone density returns to prepregnancy values.[80] Although breastfeeding may be associated with a reduction in bone density while breastfeeding, long-term follow-up studies report that a history of breastfeeding may slightly reduce the risk of hip fracture in postmenopausal women.[81,82]

Lactation and the Transmission of Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) can be transmitted from mother to child by breast milk.[83,84] In developed countries where women have access to clean water and the rate of infant death from diarrheal-related illnesses is low, the consensus recommendation is for HIV-infected women to not breastfeed their children. However, in countries with a high rate of infant death from diarrheal-related illnesses due to lack of access to clean water, breastfeeding is preferred to formula feeding.[85]

If access to clean water *is* possible, formula feeding is probably better than breastfeeding. For example, in one study in Kenya, HIV-positive, postpartum women were randomized to use formula or to breastfeed their infants. The women assigned to the formula feeding group were educated about diarrheal illnesses and given access to clean water. In this study, the rate of HIV infection in the infants at follow-up 2 years later was 17% in the formula-fed group and 33% in the breastfed group. In this study, where the women had access to clean water, there was no increase in diarrheal-related illnesses in the formula-fed group.[86] Lactating HIV-positive women who are administered highly active antiretroviral drugs have a low rate of vertical transmission of HIV to their breastfeeding child.[87] The metabolical energy burden of HIV disease plus lactation is often associated with weight loss among these women.[88]

Galactorrhea

Galactorrhea is the secretion of breast milk at a time remote from nursing. In contrast to other breast secretions, the unique feature of galactorrhea is that the secretion contains milk. This can be demonstrated by drying the secretion on a glass slide and staining for the presence of fat. Galactorrhea is usually due to hyperprolactinemia or excessive sensitivity of the breast to normal circulating levels of prolactin. When galactorrhea is associated with normal ovulatory menses, the most likely cause of the galactorrhea is excessive sensitivity of the breast to normal circulating levels of prolactin. When galactorrhea is associated with amenorrhea, it is likely that the circulating prolactin level is elevated. Approximately 75% of women with both galactorrhea and amenorrhea have hyperprolactinemia. The causes of hyperprolactinemia are reviewed in detail in Chapter 3. Briefly, the most common causes of hyperprolactinemia are a prolactin-secreting pituitary tumor, the use of a dopamine antagonist (such as metoclopramide, phenothiazines, resperidone), the use of other neuroactive medications (selective serotonin reuptake inhibitors), pregnancy, renal disease, and primary hypothyroidism.

Galactorrhea of any cause can be suppressed by the use of dopamine agonist medications such as bromocriptine or cabergoline. In women with galactorrhea, normal ovulatory menses, and normal prolactin concentration, low doses of bromocriptine (1.25 to 2.5 mg) or cabergoline (0.25 mg once or twice weekly) are often effective in the suppression of galactorrhea. The presence of a unilateral nipple discharge, or the presence of blood in nipple discharge should be evaluated by referring the patient to a breast specialist.

Benign Breast Disease

Cyclical Mastalgia

Many women experience cyclic breast discomfort that begins during the late luteal phase and resolves within a few days of the onset of menses. Cyclical mastalgia is a more severe and persistent presentation of breast pain that interferes with daily activity. The hormonal basis for cyclical mastalgia is unclear, but estrogen and progesterone are likely involved. Diet interventions such as reducing caffeine intake may be effective in some women with cyclical mastalgia. Danazol, an attenuated androgen, and tamoxifen, an antiestrogen, are effective endocrine treatments for cyclical mastalgia. In women with cyclical breast pain, danazol, at doses of 100 to 400 mg daily is effective in reducing pain in about 80% of women.[89] Danazol is a teratogen, and doses less than 400 mg daily do not reliably suppress ovulation and women taking danazol should use a barrier contraceptive. Tamoxifen at a dose of 10 mg daily for 3 months has been reported to reduce breast pain in about 90% of women with cyclical mastalgia.[90] Bromocriptine, 2.5 mg twice daily, may also be moderately effective in reducing cyclical breast pain.[91,92]

Fibroadenoma of the Breast

Fibroadenomas are the most common benign tumor of the breast. They are characterized by a proliferation of both epithelial and mesenchymal cells. Stromal cells proliferate around tubular glands or compressed ducts. Women with a fibroadenoma present with a firm, usually non-tender, mobile breast mass. In 80% of cases, they present as a unifocal lesion. In 20% of cases, they present with two or more tumors in the same breast or tumors in both breasts. A core biopsy is required to make the diagnosis. The growth of fibroadenomas appears to be stimulated by estrogen and they typically regress in the postmenopause. The use

of estrogen-progestin contraceptives has been reported to reduce the risk of developing a fibroadenoma.[93]

The molecular mechanisms that cause fibroadenomas to develop are unknown. In some cases, fibroadenoma tissue appears to contain a somatic mutation in the prolactin receptor gene (I146L) that causes constitutive activation of the receptor.[94] In a study of 74 women with more than three fibroadenomas in one breast, 4 women were identified who had an A to C substitution in exon 6 of the prolactin receptor gene causing a substitution of Leu for Ile_{146} that was detected in the fibroadenoma tissue but not healthy tissue. The investigators reported that this allele resulted in constitutive activation of the prolactin receptor in three different cell models. This study suggests that prolactin receptor antagonists may be potential therapeutic agents to treat fibroadenomas.[95]

Breast Cancer

Risk factors for breast cancer include advancing age, genetic mutations, family history of breast cancer, breast density, personal reproductive history (early menarche, late menopause, parity, duration of lactation), and body mass.[96,97] The endocrine factors which modify the risk of breast cancer and the endocrine treatment of breast cancer are reviewed in Chapter 29, Hormone Responsive Cancers.

CHAPTER 12

The Endocrinology of Human Pregnancy and Fetal-Placental Neuroendocrine Development

Sam Mesiano

The birth of a healthy baby is dependent on an ordered sequence of biological events during pregnancy. Important among these are:

1. Successful implantation of the developing embryo
2. Adaptation of maternal physiology to accept the fetal allograft and satisfy its nutritional, metabolical, and physical demands
3. Appropriate growth and functional development of key organ and homeostatic control systems in the fetus in preparation for life outside the uterus
4. Proper timing of birth so that it occurs when the fetus is mature enough to survive outside the uterus

The hormonal interactions between the fetus, placenta, and mother that control these processes are discussed in this chapter.

The chapter begins with a brief review of the hormonal events that control endometrial growth and function during the menstrual cycle so that it becomes receptive to blastocyst implantation and the establishment of pregnancy. The processes of implantation and placental development and the mechanism by which the fetal allograft overcomes attack by the maternal immune system are also discussed.

Once pregnancy is established, the fetus, placenta, and mother initiate and maintain communication via the endocrine system. The endocrine milieu of human pregnancy is dominated by placental hormones, the major function of which is to modify maternal physiology to satisfy the nutritional, metabolical, and physical demands of the growing fetus. In this context, the physiological role of the principal placental hormones is discussed.

The fetal neuroendocrine system must become functionally competent by term so that the neonate can maintain homeostasis after birth. These systems are also critical for the fetus' future health. The fetal programming hypothesis posits that adaptation of key fetal neuroendocrine systems to the intrauterine environment affects their function during postnatal life and in some cases this adaptation can be the origins of adult diseases such as metabolical syndrome and obesity. Development of fetal neuroendocrine systems and the influence of the fetal-maternal environment is therefore discussed separately.

Finally, the endocrine interactions between the fetus, placenta, and mother that culminate in the induction of parturition are reviewed. The appropriate timing of birth, so that it occurs when the fetus is sufficiently mature to survive as a newborn, is a major determinant of postnatal survival in all viviparous species. Current understanding of the hormonal interactions that control the process and timing of human parturition is described.

Establishment of Pregnancy

The first step in the establishment of pregnancy is implantation of the blastocyst into the endometrium. The goal of the embryo is to establish a conduit through which it can access a supply of nutrients from the mother. The process of embryo apposition, adhesion, and invasion into the endometrium involves a complex bidirectional hormonal dialogue between the blastocyst and the endometrium such that embryo viability and endometrial receptivity are synchronized to allow for successful implantation and the establishment of pregnancy. As the embryo is semi-allogeneic with respect to the mother, its invasion into the endometrium represents a major breach of the maternal immune system. The hormonal dialogue between the embryo and the mother at the implantation site is critical in preventing attacked by the maternal immune system.

Endometrial Receptivity

During the menstrual cycle, the ovarian steroid hormones, estradiol and progesterone, induce structural and functional changes in the endometrium essential for implantation and the establishment of pregnancy (see Chapter 10). During the luteal phase and under the influence primarily of progesterone, the proliferative endometrium is converted to a secretory phenotype. It becomes thick (5 to 6 mm) and spongy and highly vascularized. Secretions from the glandular epithelium establish an intrauterine environment that favors embryo survival and the epithelial cells produce a variety of chemokines, growth factors, and cell adhesion

molecules (CAMs) that attract the blastocyst to specific docking sites for implantation. Increased vascularization and the development of spiral arterioles within the endometrial stroma provide an optimal substrate for invasion and placentation.

Receptivity of the endometrium to blastocyst adhesion and implantation has temporal and spatial characteristics.[1-3] In humans, implantation between days 21 and 24 of the menstrual cycle is associated with a high (~85%) success rate for continuing pregnancy, whereas implantation after day 25 has a low success rate (~11%).[4] The receptive phase of endometrial development is termed the implantation window which opens 5 to 6 days after ovulation and closes 3 to 4 days later. During the implantation window, the endometrial epithelium develops domelike structures known as pinopodes, which correlate with implantation sites.[5] The tips of the pinopodes express chemokines and CAMs that attract the embryo and appear to be the preferred site for embryo adherence. Interestingly, areas between the pinopodes produce a repellent molecule, MUC-1, that prevents embryo adhesion.[6] Analysis of the human endometrial transcriptome during the implantation window has revealed numerous genes that are up- and down-regulated in comparison with late proliferative phase endometrium,[7,8] demonstrating the remarkable complexity of molecular interactions underlying endometrial differentiation.

Implantation

After fertilization, the embryo undergoes an intrinsic developmental program. The sequence of cell divisions and differentiation is not dependent on the hormonal milieu of the fallopian tube or the uterus, as fertilization and early embryonic development occur successfully *in vitro*. By the third to fourth day after fertilization, the embryo comprises a solid ball of cells encapsulated by the translucent remnant of the zona pellucida. At about the fifth day after fertilization, a fluid filled cavity, the blastocele, forms within the embryo. At this stage the embryo is referred to as a blastocyst. The outer layer of blastocyst cells adjacent to the zona pellucida is known as the trophectoderm. These cells eventually give rise to the placenta and chorion. The fetus, amnion and mesenchymal, and vascular components of the placenta are derived from the inner cell mass, a group of cells lying under the trophectoderm at one end of the blastocele.

Although there is considerable variation in the process of implantation between eutherian mammals, the end result is the same: the blastocyst becomes fixed in position and forms a physical and functional contact with the uterus.

In humans, the blastocyst enters the uterus at around the fifth day after fertilization and floats freely for 2 to 3 days. By this stage, the blastocyst escapes the confines of the zona pellucida (i.e., it hatches) and is in an optimal condition to implant. The developing blastocyst interacts in a paracrine manner with the endometrial epithelium by producing multiple cytokines, chemokines, and CAMs that facilitate adherence.

Almost immediately after fertilization, hormonal signals from the conceptus are transmitted to the mother. During its journey through the fallopian tube the cumulus cells surrounding the embryo produces progesterone and estrogen. These steroids are thought to act locally to modulate tubal motility to facilitate transport of the conceptus toward the uterine cavity.[9] Studies of the secreted proteins (the secretome) produced by the preimplantation embryo show that the profile of secreted proteins changes every 24 hours and with the different embryonic stages.[10-12] Thus, a specifically orchestrated sequence of secretions from the embryo plays a key role in the paracrine interaction between the embryo and epithelial cells of the endometrium. Any delay in embryo development or in its transit through the oviduct disrupts the synchrony between blastocyst development and endometrial receptivity and increases the likelihood of reproductive failure. Thus, development of the "seed" and conditioning of the "soil" are synchronized. Given this delicate balance, it is not surprising that the highest rate of embryo loss occurs during the peri-implantation period.

The embryo implants in a polarized fashion. After hatching from the zona pellucida, trophoblast cells overlying the embryonic pole are the first to interact with the uterine epithelium (Fig. 12.1). Those cells dock with specific sites in the epithelial lining of the endometrium, most likely at the pinopodes.[13-16] The trophoblast cells proliferate and secrete proteases that degrade the extracellular matrix between endometrial cells forming a path for the blastocyst to enter the uterine stroma. At this stage the trophoblast cells are referred to as cytotrophoblasts and differentiate along two distinct paths: villous and extravillious. The extravillious cytotrophoblasts become highly invasive and form columns penetrating to the basal membrane beneath the decidual cells and into the myometrium. Eventually the entire embryo is embedded in the uterine stroma and anchored by villous cytotrophoblasts. During this time some villous cytotrophoblasts fuse their plasma membranes to become a single multinucleated cell known as the syncytiotrophoblast, which becomes the outer layer of the functional floating villi in direct contact with maternal blood.

As with adhesion, implantation also involves a complex paracrine dialogue between the embryo and the endometrium-decidua. Many of the molecules (produced by the endometrial cells or the blastocyst) involved in the implantation process have been identified.[3,12,17-19] These include:

- Leukemia inhibiting factor
- Interleukin–11
- Heparin-binding epidermal growth factor-like growth factor
- Prostacyclin
- Prostaglandin E_2
- Peroxisome-proliferator-activator receptor
- HOXA10 and HOXA11
- Metalloproteinase-2 and -9
- Basic and acidic fibroblast growth factor
- Bone morphogenetic proteins (BMPs) and the BMP antagonist Noggin
- Wnt and Indian Hedgehog signaling molecules

Decidualization of the Endometrium

Late in the luteal phase the endometrial stroma undergoes a series of morphological and functional changes collectively referred to as decidualization.[20,21] The process of decidualization is dependent on progesterone and occurs independently of conception and implantation. It begins around blood vessels during the midsecretory phase and

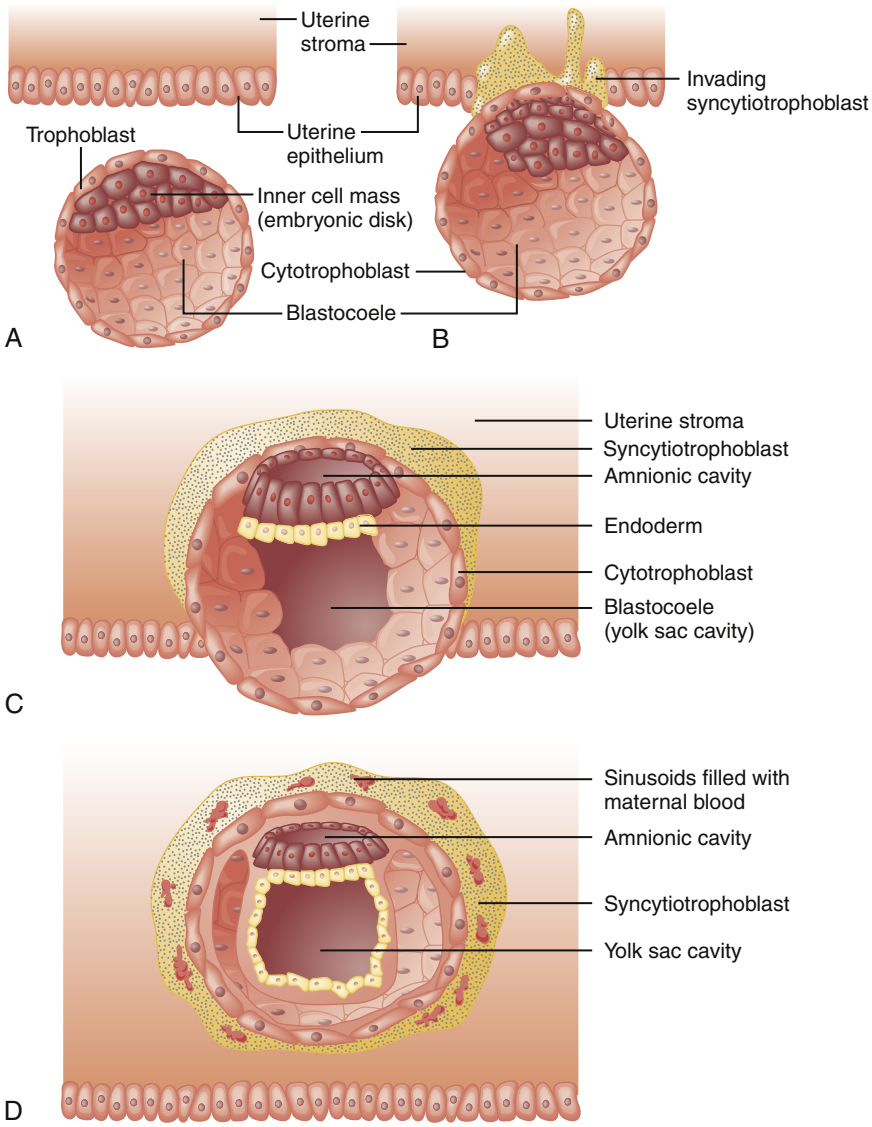

FIGURE 12.1 Implantation of the human embryo. **A,** Floating blastocyst. **B,** Attachment to the uterine epithelium and initial invasion of the syncytiotrophoblast cells. **C,** The blastocyst penetrates deeper into the uterine stroma and develops an amniotic cavity. **D,** The fully implanted embryo invades the maternal vasculature and the uterine epithelium grows over the implantation site and undergoes the decidualization. *(From Jones RE. 1997 Human Reproductive Biology by Academic Press,* San Diego, *p 189.)*

progressively encompasses the entire endometrial stroma during the latter part of the secretory phase. The fully decidualized endometrial stroma is composed of large polyhedral cells, containing high levels of glycogen and lipids that secrete a tough pericellular capsule composed of collagen, laminin, fibronectin, and heparan sulfate proteoglycan. Bone marrow-derived immune cells, primarily large granular lymphocytes (LGLs), also accumulate and extensive cell to cell contacts between the lymphocytes and the stromal cells form, especially in the vicinity of blood vessels.

The decidualized endometrium is hostile to implantation. Therefore, the blastocyst has a limited window of opportunity to establish a successful implantation before the decidual barrier is established. Attachment of the blastocyst to the uterine epithelium accelerates the decidualization process further limiting the window of opportunity for implantation. In an infertile cycle, menstruation occurs to eliminate the nonreceptive decidualized endometrium. The endometrium is renewed to a receptive state in the subsequent cycle. Thus, the term decidua is highly appropriate because this tissue is cast off at menstruation, miscarriage, and delivery.

The decidua is thought to form a critical barrier between the mother and the conceptus and represent an attempt by the mother to restrict blastocyst invasion. The large component of immune cells (mainly LGLs) within the decidual tissue may also restrict the passage of fetal antigens to the maternal compartment.[22,23] Interestingly, decidualization of the endometrium appears limited to species with interstitial implantation in which the blastocyst is completely imbedded in the endometrial stroma, further supporting the argument that it limits the invasiveness of the blastocyst during implantation.

Once pregnancy is established the decidua can be divided into three types, depending upon anatomical location: (1) The decidua basalis, which underlies the site of implantation and forms the maternal component of the placenta; (2) The decidua capsularis, which overlies the gestational sac (this portion disappears in the later stages of pregnancy); (3) The decidua vera, which lines the remainder of the uterine cavity and becomes intimately approximated to the chorion.

The decidua of pregnancy, in association with the fetal membranes, is considered to be an endocrine organ. Hormones produced by the decidua can act on the adjacent

tissue (chorion and myometrium) or communicate with the fetus via the amniotic fluid. The decidua produces prolactin, relaxin and prostaglandins that are thought to be involved in the process of parturition (discussed later in the chapter). Its close proximity to the myometrium is ideal in this regard.

Placentation

Early in the implantation process some cytotrophoblast cells aggregate and form migrating columns that penetrate into the inner third of the myometrium. The invading cytotrophoblasts target maternal blood vessels and, via interstitial and endovascular routes, completely surround and plug spiral arterioles. They then displace maternal endothelial cells and musculoelastic tissue and effectively create a low-resistance arteriolar system by increasing vessel diameter. Blood flowing from those vessels fills spaces known as lacunae, between the invading columns of cytotrophoblast cells, and leave through venous connections. Eventually, the syncytiotrophoblasts come into contact with maternal blood and form chorionic villi that are bathed in maternal blood within the lacunae.

According to Poiseuille's law of fluid dynamics, flow through a cylinder is proportional to the radius multiplied to the fourth power. On average the radii of arterioles in the pregnant human uterus are around 10-fold greater than in the nonpregnancy state. Such a change would increase flow 10,000-fold, which is ample to serve the future requirements of the growing fetus. Cytotrophoblasts within the spiral arterioles not only facilitate this large diversion of maternal blood flow to the conceptus, but also prevent maternal vasomotor control. Through this process the supply of resources to the conceptus is optimized and the capacity for maternal restriction of uterine blood flow is subverted.

Placentation across all eutherian mammals is characterized by high angiogenic activity and blood vessel growth. This is particularly the case for the site of placental attachment. The human placenta produces several known angiogenic factors, including platelet-derived endothelial cell growth factor, vascular endothelial growth factor (VEGF), angiopoietin-1 and angiopoietin-2.[24,25] In addition, two potent inhibitors of angiogenesis have been isolated from mouse placenta.[26] The specific interplay between angiogenic factors and their inhibitors in the placenta is not well understood. However, it is possible that the presence of anti-angiogenic factors within the placenta may serve to control vessel growth. This may be important for preventing maternal endothelial cells from resealing the ends of spiral arterioles that have been occupied by trophoblasts. In addition, anti-angiogenic factors may prevent the overgrowth of maternal and fetal vessels, thereby preventing maternal blood vessels from entering the fetal compartment and fetal vessels from growing out into the uterus.

The extent and depth of the placental incursion appears to be the sum of the intrinsic pro-invasive characteristics of trophoblasts and the physical and biochemical barriers mounted by the maternal tissues. Imbalances in this equation can lead to failed implantation and pathological conditions. The angiogenic events occurring during implantation and placentation likely are critical factors in the etiology of hemodynamic disorders in pregnancy. For example, in preeclampsia, cytotrophoblast invasion is restricted to the superficial decidual segments, leaving the myometrial spiral arterioles undisturbed and still responsive to maternal vasomotor influences.[27] These pathological changes result in shallow implantation and impaired blood supply to the placental unit, which then attempts to compensate by increasing maternal systemic blood pressure, leading to hypertensive disorders such as preeclampsia (Fig. 12.2).

Because cytotrophoblasts are genetically distinct from maternal tissue, implantation represents an extraordinary breach of maternal immune defenses. The mother must distinguish between the fetal allograft as being immunogenically foreign or self and/or the placental trophoblasts must protect themselves from immune destruction by activated maternal immune cells. The decidua is composed mainly of a uterus-specific subset of LGLs with natural killer (NK) cell phenotype.[23,28-30] NK cells preferentially attack targets lacking polymorphic Class I or Class II human leukocyte antigens (HLAs). Trophoblasts do not express polymorphic Class I or Class II HLAs and therefore are highly susceptible to attack by decidual NK cells.[31] However, differentiated cytotrophoblasts that lie at the maternal-fetal interface produces a unique Class I molecule known as HLA-G.[32-34] Because of its reduced polymorphism, HLA-G is less immunogenic and could prevent immunological recognition by NK cells. In addition, trophoblasts express the Fas ligand, which induces apoptosis in immune cells that carry the Fas receptor.[35] Thus, the fetal allograft may escape immune attack by presenting the unique HLA-G camouflage or by actively subverting immune recognition via the Fas ligand.

The functional unit of the human placenta is the chorionic villus, which is formed by a sprouting of syncytiotrophoblasts that project into a pool of maternal blood surrounding the blastocyst. The fingerlike chorionic villi have a central core of loose connective tissue with an extensive capillary network linking it with the fetal circulation. Surrounding the core are the outer syncytiotrophoblast and inner cytotrophoblast cells that form the functional barrier between the maternal and fetal circulations. This arrangement is referred to as hemochorial placentation since the syncytiotrophoblast layer separates the maternal and fetal circulations.

The Endocrine Placenta

Placental hormones dominate the endocrine milieu of human pregnancy.[36] This remarkable organ produces a plethora of protein (including cytokines and growth factors) and steroid hormones, which it secretes in large quantities primarily into the maternal circulation (Table 12.1). The hemochorial anatomical arrangement of the human placenta is ideal for this purpose. Cytotrophoblast and syncytiotrophoblast cells of the placenta have direct access to the maternal circulation. In contrast, the syncytiotrophoblast layer prevents most maternal hormones from entering the fetal compartment. Consequently, the fetal-placental endocrine system generally develops and functions independently of that of the mother.

Most placental hormones are counterparts to those produced in the nonpregnant adult and therefore bind to maternal hormone receptors. In this context, placental hormones may be regarded as allocrine factors, i.e., hormones produced by one organism—the fetus—to act on the receptors

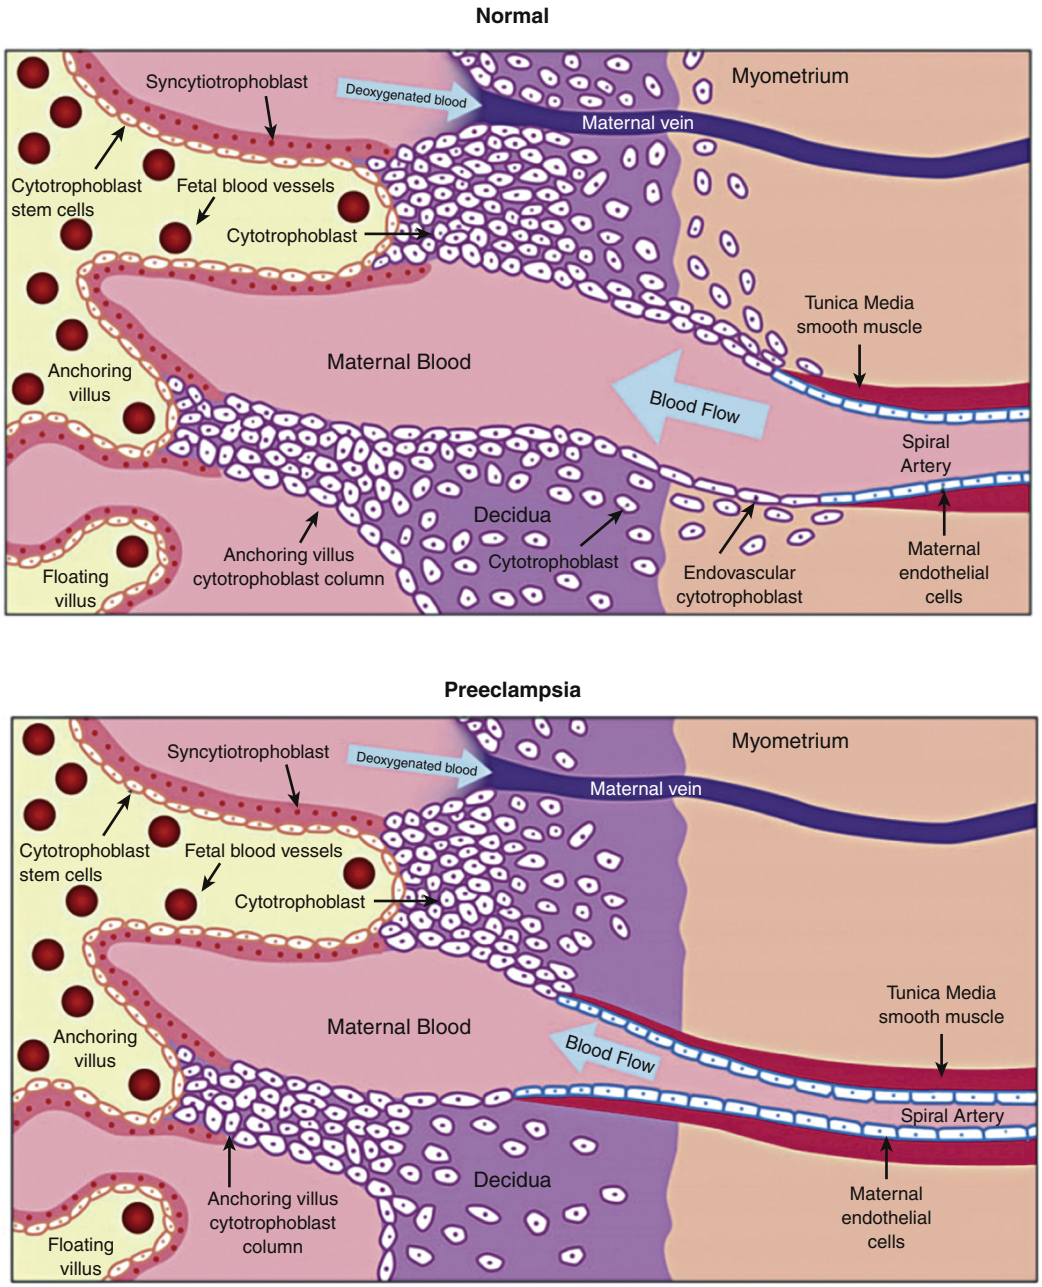

FIGURE 12.2 Invasion of cytotrophoblast cells into the spiral arteries. Shallow invasion restricts blood flow to the placenta and is thought to be a precursor for the development of preeclampsia. *(From Circulating angiogenic factors in the pathogenesis and prediction of preeclampsia. of another—the mother. Importantly, the placenta produces and responds to functional cohorts of hypothalamic and pituitary hormones and functions as a secondary neuroendocrine control center.[37] This extra brain in many instances overrides the maternal system to adjust maternal physiology usually in favor of supporting the needs of the fetus. The role of some of the principal placental hormones in the endocrine control of human pregnancy is discussed below.

Placental Gonadotropin

Gonadotropins are glycoprotein hormones produced by the anterior pituitary and the placenta that primarily affect growth and function of the gonads. Chorionic gonadotropin (CG, designated hCG in humans) is the primary embryonic endocrine signal for the establishment of pregnancy. hCG produced by the trophoblastic cells of the early embryo acts on the corpus luteum (CL) to prevent luteolysis and maintain steroidogenic function. This causes progesterone levels to be sustained which prevents sloughing of the endometrial lining. In nonconceptive cycles, the CL usually regresses at about the second week after ovulation and the subsequent decline in progesterone leads to menstruation. For pregnancy to establish, demise of the CL and the associated withdrawal of progesterone must be prevented. Thus, one of the first endocrine interactions between the conceptus

Table 12.1 Peptides, Steroid Hormones, and Monoamines Produced by the Human Placenta

Neuropeptides	Pituitary-like Hormones	Steroid Hormones	Monoamines and Adrenal-like Peptides
CRH	ACTH	Progesterone	Epinephrine
TRH	TSH	Estradiol	Norepinepherine
GnRH	GH	Estrone	Dopamine
Melatonin	PL	Estriol	Serotonin
Cholecystokinin	CG	Estetrol	Adrenomedullin
Met-enkephalin	LH	2-Methoxyestradiol	
Dynorphin	FSH	Allopregnanolone	
Neurotensin	B-Endorphin	Pregnenolone	
VIP	Prolactin	5α-Dihydroprogesterone	
Galanin	Oxytocin		
Somatostatin	Leptin		
CGRP	Activin		
Neuropeptide Y	Follistatin		
Substance P	Inhibin		
Endothelin			
ANP			
Renin			
Angiotensin			
Urocortin			

VIP, vasoactive intestinal peptide; CGRP, calcitonin gene-related peptide; ANP, atrial natriuretic peptide.

and the mother involves signaling by the early embryo that pregnancy is occurring and that the functional life span of the CL must be extended. This event is referred to as the maternal recognition of pregnancy and is mediated by hCG.

As with other glycoprotein hormones such as luteinizing hormone (LH) and follicle stimulating hormone (FSH), hCG is a heterodimer composed of α and β subunits. The α-subunits of hCG, LH, and FSH are identical, whereas the β-subunits differ, conferring specificity to each hormone. hCG is biologically and immunologically similar to pituitary LH. The α subunit of hCG is produced by cytotrophoblast cells especially as they differentiate during implantation. The β subunit of hCG and is primarily produced by syncytiotrophoblast cells but can also be detected in mature cytotrophoblast cells just before they fuse to form the syncytiotrophoblast. The syncytiotrophoblast produces both subunits and is the principal source of functional hCG.

Multiple variants of hCG have been identified in the human placenta.[38] In addition to native hCG, the human placenta produced a hyperglycosylated hCG and the free monomeric β-subunit of the hyperglycosylated hCG. hCG variants are produced by different trophoblast cells. The syncytiotrophoblast produces native hCG, extravillious invasive cytotrophoblasts produce hyperglycosylated hCG, and the free hyperglycosylated β subunit is produced by non-trophoblastic advanced malignancies.[39]

The three hCG variants have distinct physiological functions. Like LH, native hCG is a potent luteotropin, and as such, it stimulates progesterone secretion by the CL. Importantly, hCG prolongs the functional life of the CL and converts the CL of the menstrual cycle into the CL of pregnancy, insuring the production of progesterone necessary for the establishment of pregnancy. In an evolutionary context, this may provide a basis for selection as pregnancy will not ensue if the embryo is defective and cannot gain control of the CL. The capacity of the embryo to produce large amounts of hCG may represent a selective test of the embryo's endocrine competence. The maternal level of resistance to the embryo's efforts to control the CL would select embryos with more robust endocrine function.[40] The hyperglycosylated hCG and the monomeric β-subunit are thought to exert primarily extragonadal actions and are associated with malignancies.[41,42] The actions of all hCG variants are mediated through interaction with the LH receptor.

During the first 5 to 7 weeks of pregnancy progesterone is produced exclusively by the CL in response to hCG. Consequently, the ovaries are obligate organs for pregnancy maintenance during this time, and abortion rapidly ensues if they are removed. However, after weeks 6 to 7 of pregnancy the placenta begins producing large amounts of progesterone and at around the same time progesterone production by the CL decreases. This transition in the source of progesterone is referred to as the luteal-placental shift. The placenta supplies the bulk of progesterone for the remainder of pregnancy.

In normal pregnancies, hCG is detectable 9 to 11 days after the midcycle LH peak, which is around 8 days after ovulation and only 1 day after implantation.[43] Therefore, pregnancy can be detected before the first missed menstrual period. This has clinical utility when it is important to determine the presence of pregnancy at an early stage. In early pregnancy, there is an approximate doubling of circulating hCG levels every 2 to 3 days and concentrations of hCG rise to peak values by 60 to 90 days of gestation. Thereafter, hCG levels decrease to a plateau that is maintained during the remainder of the pregnancy (Fig. 12.3). Assayable LH and FSH levels in the maternal blood are virtually undetectable throughout pregnancy.

Extragonadal Actions of hCG

The actions of hCG may not be limited to maintaining progesterone production by the CL.[42] Much of the increased thyroid activity that occurs in pregnancy has been attributed to hCG,[44] which binds specifically to thyroid cell membranes and displaces thyroid-stimulating hormone (TSH).[45] hCG also influences the development and function of

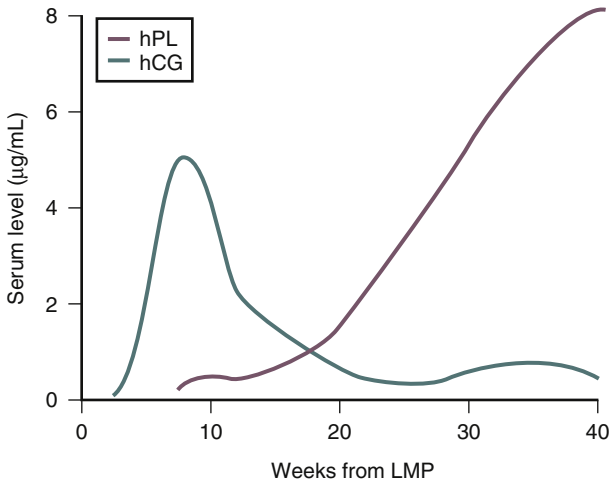

FIGURE 12.3 Schematic representation of concentrations of human chorionic gonadotropin (hCG) and placental lactogen (hPL) throughout gestation. Note differences in the magnitude of the concentrations of the two hormones in early and late gestation. LMP, last menstrual period.

the fetal adrenals and testes.[46] In addition, hCG may have actions on the maternal reproductive tract, including the decidual response,[47] relaxin production by the CL,[48] and relaxation of uterine smooth muscle.[49] hCG receptors have been detected in fetal membranes[50] and *in vitro* hCG inhibits spontaneous contractility in strips of human myometrium.[51]

Production of hCG by the invading blastocyst may contribute in a paracrine manner to the implantation process. *In vitro* and *in vivo* studies in nonhuman primates demonstrate that hCG can promote decidualization of the endometrial stroma.[52] The hormone appears to have marked effects on endometrial physiology at the implantation site before its levels are detectable in the circulation. Studies suggest that hCG produced by the blastocyst prolongs the window of implantation by inhibiting endometrial insulin-like growth factor binding protein -1 (IGFBP-1) production, augmenting angiogenesis at the implantation site by increasing VEGF expression, modulating local cytokine and chemokine expression, augmenting local protease activity and, via an autocrine effects on the trophoblasts themselves, promoting differentiation and augmenting invasive potential.[42,47]

The placenta may not be the only source of hCG. The fetal kidney and fetal pituitary gland synthesize and secrete biologically active hCG.[53] The function of extraplacental hCG in human pregnancy is unclear.

Placental trophoblasts may have an autoregulatory mechanism for hCG synthesis that involves intrinsic hormonal axes analogous to those operating in the hypothalamic-pituitary-gonadal (HPG) axis. Regulators of pituitary gonadotropin can also influence placental hCG production (at least *in vitro*). These regulators include progesterone, inhibin, activin, and gonadotropin-releasing hormone (GnRH).

Gonadotropin-Releasing Hormone

The human placenta produces GnRH, which is identical to that produced by the hypothalamus.[54] Levels of GnRH in the circulation of pregnant women are highest in the first trimester and correlate closely with hCG levels.[55] The close relation between GnRH and hCG suggests a role for GnRH in regulating hCG production.[56] GnRH stimulates the production of both the α-subunit and β-subunit of hCG in placental explants and specific GnRH-binding sites are present in the human placenta.[57] Thus, there appears to be autoregulation of hCG production within the placenta suggesting that placental GnRH is essential for the establishment and maintenance of early pregnancy.

hCG also may influence placental steroidogenesis, suggesting a complete internal regulatory system within the placenta. This concept is further strengthened by the presence of other regulators of GnRH expression including inhibins and activins, in the human placenta.

Inhibins and Activins

Inhibin is a heterodimer composed of an α-subunit and one of two β-subunits, βA or βB. Inhibins (αβA and αβB) derive their name from their ability to preferentially inhibit pituitary FSH secretion. In contrast to inhibins, the homodimers βA βA and βB βB stimulate FSH production. These compounds have been termed activins.

Inhibins are produced by the human placenta—all three subunits are expressed in the syncytiotrophoblast and the levels of expression do not change with advancing gestation.[58,59] Activin-A is also produced by the CL, decidua, and fetal membranes during human pregnancy.[60] The placenta also produces follistatin, the binding protein for activin.[61] These factors are secreted into the maternal and fetal circulations and amniotic fluid and their production varies with stage of gestation.[62]

Although the exact function of the inhibin-activin system in human pregnancy is not known, several studies indicate their involvement in the pathogenesis of gestational diseases. Levels of inhibin-A and activin-A in the maternal circulation can be indicative, albeit with relatively weak predictive value, of pathologies such as placental tumors, hypertensive disorders of pregnancy, intrauterine growth restriction, fetal hypoxia, Down syndrome, fetal demise, preterm delivery, and intrauterine growth restriction.[63]

Because inhibin and activin are synthesized in the cytotrophoblast, they may be involved in autoregulating placental hCG production by modulating local GnRH activity. *In vitro* studies have shown that inhibin decreases GnRH-stimulated hCG production by placental cell cultures whereas, inhibin antiserum increases GnRH release and causes a parallel rise in hCG secretion.[64] Further, this effect of blocking endogenous inhibin action is reduced by the addition of a GnRH antagonist, pointing to an interaction of endogenous inhibin and GnRH on hCG secretion.[65] Therefore, it is possible that inhibin exerts an autocrine or paracrine effect on hCG secretion by suppressing GnRH action. In contrast, activin augments the GnRH-induced release of hCG in cultured trophoblast cells, an effect that can be reduced by the addition of inhibin.[64] Thus, at least *in vitro*, activin and inhibin via their paracrine effect on placental GnRH production, contribute to the regulation of hCG secretion.

Placental Somatotropins

In most eutherian mammals, the placenta expresses and secretes members of the growth hormone (GH)-placental

lactogen (PL) gene family.[66] These genes are encoded by a 66 kb segment of chromosome 17q22-q24. This locus includes five closely related genes: *GH1*, *GH2*, *CSH1*, *CSH2*, and *CSHL1*, each derived from the duplication of a common ancestral gene. The *GH1* gene encodes pituitary GH and is expressed only in the pituitary. The other four are expressed exclusively in the placenta. The *GH2* gene encodes a placental GH variant, which differs from human pituitary GH by 13 amino acids. The *CSH1* and *CSH2* genes are identical and encode human placental lactogen (hPL). The *CSHL1* gene has a high degree of homology with *CSH1* and *CSH2*, however, it is considered a pseudogene due to a G to A transversion at the second intron splice site.

Human Placenta Lactogen

hPL is a single-chain polypeptide of 191 amino acids with two disulfide bridges and has a 96% homology with hGH. hPL can be detected in the placenta from around day 18 of pregnancy and in the maternal circulation by the third week of pregnancy. Low levels of hPL (7 to 10 ng/mL) are present in the maternal circulation by 20 to 40 days of gestation. Thereafter, hPL levels in the maternal circulation increase exponentially, reaching levels of 5 to 10 µg/mL at term.[67]

In contrast to the elevated levels of hPL in the maternal circulation, concentrations of hPL in the fetal circulation range from 4 to 500 ng/mL at midgestation and only 20 to 30 ng/mL at term.[68] This indicates that hPL is preferentially secreted into the maternal compartment. The concentration of hPL in maternal peripheral blood is about 300 times that in umbilical vein blood, and the concentration of hPL in the blood leaving the gravid uterus is markedly greater than that in the peripheral circulation.

hPL is detectable in the serum and urine in both normal and molar pregnancies, and it disappears rapidly from the serum and urine after delivery of the placenta—it cannot be detected after the first postpartum day. After removal of the placenta, the half-life of the disappearance of circulating hPL is 9 to 15 minutes. To maintain circulating concentrations, this would imply placental production of between 1 and 4 g of the hormone per day at term.[69] Thus, production of hPL represents one of the major metabolic and biosynthetic activities of the syncytiotrophoblast.

In normal pregnancy, hPL is first synthesized by the cytotrophoblasts of the developing placenta during the first 6 weeks of pregnancy. Thereafter, expression switches to the syncytiotrophoblasts, which eventually become the exclusive source of hPL. The extent of hPL expression by the syncytiotrophoblast does not change during the course of pregnancy, although total placental production increases substantially.[70] Therefore, the rise in hPL production is thought to be due to the increase in placental mass, as maternal hPL levels rises concordantly with the amount of syncytiotrophoblast tissue as gestation progresses (Fig. 12.4). Like hCG, hPL appears to be expressed by all types of trophoblastic tissue; it has also been found in the urine of patients harboring trophoblastic tumors and in men with choriocarcinoma of the testis.

Factors that regulate hPL production have been assessed in cultured cytotrophoblast cells. Insulin and growth hormone-releasing factor (GRF) stimulate hPL secretion, whereas somatostatin (SS) inhibits its secretion. The

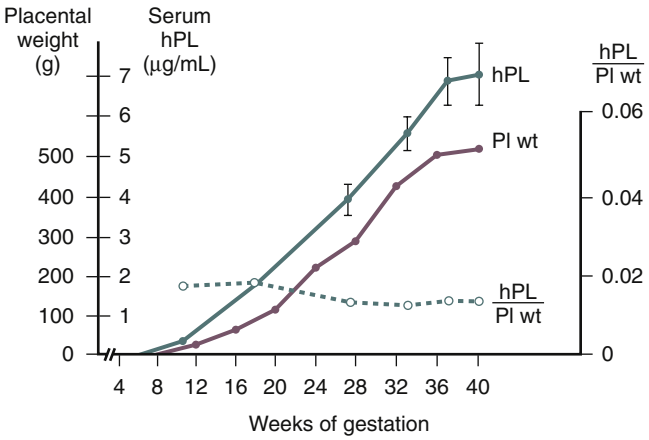

FIGURE 12.4 Levels of hPL in the maternal circulation in relation to placental weight (Pl wt). *(From Selenkow HA, Saxena BM, Dana CL, Emerson K Jr. Measurement and pathologic significance of human placental lactogen. In: Pecile A, Fenzi C [eds]. The foeto-placental Unit. Amsterdam Ecerpta Medica, 1969, pp 340–362. Elesvier Science Publishers).*

presence of hPL, hPGH, SS, and GRF in the same cell suggests that another autoregulatory loop analogous to the hypothalamic-pituitary axis, may operate within the placenta. In the third trimester, maternal hPL and GRF levels are closely correlated.[71] Interestingly, SS expression is maximal in early pregnancy and decreases during the second and third trimesters, a pattern opposite to that of hPL secretory activity.[72] Thus, locally produced GRF and SS may regulate placental hPL expression.

Several studies have demonstrated changes in maternal hPL levels in response to metabolic stress. Specifically, prolonged fasting at midgestation[73] and insulin-induced hypoglycemia raise maternal hPL concentrations.[74] However, hPL levels do not change in association with normal metabolic fluctuations during a typical 24-hour period.[75] Although extreme metabolic stress influences hPL production, hPL expression does not appear to be modulated by metabolic status within the normal range.

Human Placental Growth Hormone

Two forms of hPGH have been identified both of which are expressed in syncytiotrophoblast cells.[76] The smaller, 22 kDa form is almost identical to pituitary GH, differing by only 13 amino acids. The larger 26kDa hPGH is a splice variant that retains intron 4. The extent of hPGH production is significantly less than that of hPL, and hPGH is not secreted into the fetal compartment.[77] Consequently, circulating levels of hPGH are approximately 1000-fold less than hPL and can be detected in the maternal circulation later in gestation (between 21 and 26 weeks). During the third trimester, maternal hPGH levels increase exponentially, in concert with hPL, and reach a maximum of approximately 20 ng/mL by term.

During the course of human pregnancy, hPGH becomes the dominant GH, and maternal pituitary GH production gradually declines. In the first trimester, pituitary GH is measurable and secreted in a highly pulsatile manner.[78] However, pituitary GH production decreases progressively from about week 15, and by 30 weeks cannot be detected. During the same period, nonpulsatile secretion of hPGH by

the placenta increases markedly. Thus, maternal pituitary GH production declines during the second trimester and is not detectable during the third. By this stage, hPGH serves as the GH of pregnancy.

Biological Actions of hPL and hPGH

Several cases of hPL and hPGH deficiency have revealed their potential roles in human pregnancy.[79] In all cases of complete hPL deficiency (lack of detectable hPL in the mother's blood or in the placenta), pregnancy and fetal development were normal. Thus, despite the remarkably high levels of hPL, it is not essential for normal pregnancy. However, deficiency of both hPL and hPGH due to a mutation in the GH/PL gene cluster, results in severe fetal growth retardation, but an otherwise normal pregnancy. Pregnancies in which only hPGH is deficient have not been identified. These experiments of nature indicate that hPL is not necessary for normal pregnancy, whereas fetal growth is dependent on hPGH. Alternatively, this may indicate that fetal growth is dependent on either hPGH or hPL and that these hormones comprise a redundant system.

The initial identification of hPL was based in its lactogenic activity in bioassays; therefore, it would be reasonable to surmise that hPL acts as a lactogen in human pregnancy. However, it is important to distinguish "activity" in heterologous assays from "function" physiologically. Notably, administration of hPL to nonpregnant women in sufficient quantities to mimic pregnancy levels, did not induce lactation.[80] However, this does rule out hPL as a lactogen, as its actions on the mammary gland may be dependent on other factors in the endocrine milieu of pregnancy (e.g., estrogen and progesterone). Nevertheless, the *in vivo* lactogenic properties, if any, of hPL in human pregnancy remains to be established. In addition, maternal prolactin levels increase significantly in the later stages of pregnancy and, together with estrogen and progesterone, are likely sufficient to induce mammary growth and lactation. Thus, although hPL is produced in very large quantities, it appears to be a redundant hormone.

As hPL and hPGH share a high degree of homology, it would be reasonable to surmise that they act through a common membrane-bound receptor. Indeed, both hPGH and hPL bind the GH receptor, although, the affinity of hPL is around 2000-fold less than that of hGH.[81] However, the high levels of hPL in the maternal circulation compared with those of hPGH would, in part, compensate for the reduced receptor affinity. Both hormones have equal affinity for the prolactin receptor. To date, no specific hPL receptor has been identified.

As hPGH does not enter the fetal compartment, its principal action is likely on the mother. In contrast, hPL is present in the mother and the fetus. However, deficiency in hPL alone has no effect on fetal growth, whereas deficiency in both hPL and hPGH is associated with severe fetal growth retardation. Taken together, these observations indicate that hPL and hPGH influence fetal growth through effects on the mother. This is consistent with the thesis that hPL and hPGH modulate maternal metabolism to meet fetal energy requirements.[82]

Pregnancy is a diabetogenic state, with impaired maternal glucose tolerance, relative insulin insensitivity and elevated level of circulating free fatty-acids. Such a state is advantageous to the fetus, as it increases maternal energy supplies available for fetal use. This is particularly important for the fetal brain, which uses glucose exclusively as an energy source. In non-pregnant subjects, hPL impairs carbohydrate tolerance and increases insulin and free fatty-acid levels,[83] actions consistent with the diabetogenic state of pregnancy. These properties of hPL, together with its high level of secretion into the maternal compartment, suggest that it is an important regulator of metabolic homeostasis during pregnancy.

Soon after birth insulin resistance reverts to the normal nonpregnant state, suggesting that maternal glucose homeostasis is influenced by hormonal factors produced by the fetus-placenta. To maintain glucose homeostasis during pregnancy maternal insulin secretion increases to compensate for the decrease in insulin sensitivity. In women with gestational diabetes, insulin secretion is insufficient to balance the decrease in insulin sensitivity and consequently blood glucose levels increase leading to disorders such as fetal macrosomia.

As pregnancy progresses, the fetus increases its substrate requirements, which leads to an increased functional role for hPL and hPGH in the second and third trimesters. The GH-like and contra-insulin effects of these hormones would lead to impaired glucose uptake and stimulation of free fatty acid release. Free fatty acids can cross the placenta, and the increased ketones induced by their metabolism are an important energy source for the fetus. As a consequence of insulin resistance, muscle proteolysis and the formation of ketones may be enhanced. In addition, the decreased maternal glucose consumption induced by hPL and hPGH would insure a steady supply of glucose for the fetus. These effects of hPL and hPGH on fat and carbohydrate metabolism are similar to those after treatment with GH. In this manner, maternal metabolism would be directed toward mobilization of resources to furnish the needs of the developing fetus.

This hormonal interaction represents an example of fetal-maternal conflict as proposed by David Haig.[40] The model suggests that through natural selection the fetus has acquired traits, e.g., somatotropin production, that favor the extraction of resources from the maternal organism. Conversely, mothers have evolved mechanism to counteract fetal demand. Through natural selection a compromise is attained between fetal requirements and maternal health. Disorders on either side of this equation lead to pathophysiologies of pregnancy.

Placental Corticotropins

POMC and POMC-Derived Hormones

The human placenta expresses proopiomelanocortin (POMC).[84] In pituitary corticotropes, this 31-kDa glycoprotein is the precursor for the adrenocorticotropic hormone (ACTH)-endorphin family of peptides. POMC is enzymatically cleaved into several peptide hormones, including ACTH, β-lipotrophic hormone (β-LPH), α-melanocyte-stimulating hormone (α-MSH), and β-endorphin (β-EP). These neuroendocrine hormones play major roles in the physiological response to stress and the control of behavior. Each of these peptides, including full-length POMC, has been detected in the human placenta.[85-87]

Placental syncytiotrophoblasts express POMC in a transcriptional pattern similar to that of extrapituitary tumors.[86] However, the processing of POMC in placental cells is different than that in pituitary corticotropes. Although some placental POMC is cleaved, a significant amount of intact POMC is secreted by the placenta into the maternal circulation. This is unusual, as POMC, at least in pituitary corticotropes, is processed completely and in nonpregnant adults POMC is undetectable in the circulation.[87] During pregnancy, however, maternal circulating POMC levels are readily detectable by the third month and then increase steadily until midgestation, reaching a plateau of around 300 U/mL between 28 weeks and term. Soon after birth, POMC returns to undetectable levels. Placental POMC production is constant with no diurnal variability—unlike its pattern of secretion by the anterior pituitary—and it is not inhibited by glucocorticoids. Interestingly, maternal POMC levels do not correlate with plasma ACTH or cortisol levels. However, plasma POMC levels are closely correlated with plasma corticotropin releasing hormone (CRH) levels during the third trimester.[87]

The physiological role, if any, of placental ACTH and other POMC-derived proteins in the control of human pregnancy remains to be elucidated. With regard to fetal adrenal growth, placental ACTH plays a negligible role, because it is not sufficient to prevent adrenal hypoplasia in fetal hypopituitarism due to anencephaly. However, placental ACTH may influence maternal physiology and could be responsible for the relative resistance to negative feedback suppression of pituitary ACTH by glucocorticoids during pregnancy.[88]

Immunoreactive β-EP in the maternal circulation remains relatively low throughout pregnancy, with mean levels of approximately 15 pg/mL.[89] Levels rise to approximately 70 pg/mL during late labor and rise further (mean, 113 pg/mL) at delivery.[89] Similar concentrations of β-EP (mean: 105 pg/mL) also are detectable in cord plasma at term, suggesting secretion by the placenta into the fetal compartment or secretion by the fetal pituitary. Many factors that cause an increase in pituitary ACTH (e.g., hypoxia and acidosis) also increase β-EP production.[90]

In addition to β-EP and β-LPH, there are two other families of endogenous opioids: enkephalins and dynorphins. Immunoreactive methionine-enkephalin has been found in the human placenta and is chemically identical to the native molecule. Circulating levels of methionine-enkephalin do not change appreciably throughout pregnancy.[91] Three forms of dynorphin have been found in the human placenta.[92] The amount of dynorphin in the placenta at term is similar to that found in the pituitary gland and brain.[92] Relatively high concentrations of dynorphin are found in amniotic fluid and umbilical venous plasma, and maternal plasma levels in the third trimester and at delivery are higher than in nonpregnant women.[92] Dynorphin binds to kappa opiate receptors, which are abundant in the human placenta and increase at term. Because dynorphin receptor agonists stimulate the release of hPL,[93] it is possible that dynorphin exerts local regulatory effects on hPL production.

Corticotrophin-Releasing Hormone

First identified in the hypothalamus, CRH is a 41-amino acid peptide that stimulates the expression and processing of POMC by pituitary corticotropes and, as its name implies, the secretion of ACTH. The human placenta, fetal membranes, and decidua also express CRH that is identical to that produced by the hypothalamus.[94] Expression of placental CRH can be detected from the seventh week of pregnancy and increases progressively until term. In the last 5 to 7 weeks of pregnancy, placental expression of CRH increases more than twentyfold.[95]

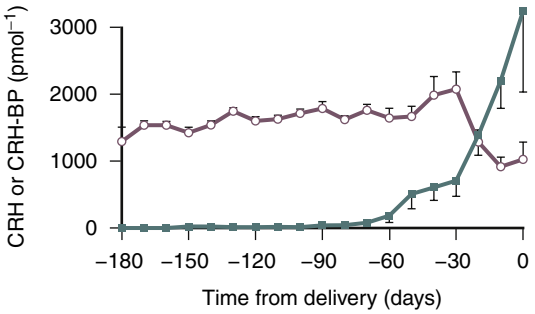

FIGURE 12.5 Levels of corticotropin-releasing hormone (CRH) and CRH binding protein (CRH-BP) in the maternal circulation during human pregnancy. *(From: McLean M, Bisits A, Davies J, et al. A placental clock controlling the length of human pregnancy.* Nature Med *1:460, 1995).*

Placental CRH is released mainly into the maternal compartment. Levels of CRH in the maternal circulation can be detected as early as 15 weeks of gestation and then increase through gestation reaching maximum levels of 1 to 10 ng/mL at term. Remarkably, this is about 1000-fold higher than peripheral CRH levels in nonpregnant women. Placental CRH also is secreted into the fetal circulation, albeit to a lesser extent.[96]

A binding protein (BP) for CRH also exists, and for most of pregnancy it is present in excess of CRH in the maternal circulation. As the CRH-BP binds CRH with greater affinity than the CRH receptor, it effectively suppresses CRH activity. Thus, for most of pregnancy the bulk of the placental CRH is sequestered and rendered inactive by CRH-BP. However, during the last 4 weeks of pregnancy CRH-BP levels decrease markedly.[97] This coincides with the exponential increase in placental CRH production, which could result in a dramatic increase in CRH biological activity (Fig. 12.5).

Despite the elevated concentrations of CRH during pregnancy, maternal ACTH secretion does not increase concordantly. In fact, pituitary ACTH levels remain low throughout pregnancy. The lack of CRH stimulation could be due to inhibition by the CRH-BP. However, maternal ACTH production remains low late in gestation when CRH increases and CRH-BP decreases. *In vivo* studies have shown that responsiveness of the maternal pituitary to CRH is markedly attenuated during pregnancy, and *in vitro* studies have shown that CRH down-regulates expression of its receptor in pituitary corticotropes.[98]

Actions of CRH are mediated by specific cell membrane receptors. Two major CRH receptor (CRH-R) subtypes have been identified, CRH-R1 and CRH-R2.[99-101] CRH binds to CRH-R1 with greater affinity than CRH-R2. These receptors and various subtypes within each group exhibit tissue-specific expression and possibly contribute to differential actions of CRH on different cell types.

In vitro studies indicate that agents that increase CRH production by the hypothalamus also increase CRH production by cultured placental cells.[102] These agents include prostaglandins E_2 and $F_{2\alpha}$ (PGE_2 and $PGF_{2\alpha}$), norepinephrine, acetylcholine, vasopressin, angiotensin-II, oxytocin (OT), interleukin-I, and NPY. In contrast, progesterone[102] and nitric oxide donors[103] inhibit placental CRH expression *in vitro*.

Interestingly, expression and secretion of placental CRH are increased by glucocorticoids. This is in contrast to hypothalamic CRH expression, which is decreased by glucocorticoids. This stimulatory action has been observed *in vivo* in women who receive glucocorticoid treatment during the third trimester[104,105] and *in vitro* in cultured placental cells.[106] As placental and hypothalamic CRH are products of the same gene, the molecular basis for this difference in glucocorticoid regulation is thought to involve placental-specific transcription factors acting through distinct response elements in the CRH promoter region.[107]

The stimulation of placental CRH production by glucocorticoids may result in a positive feedback endocrine loop. Placental CRH may stimulate ACTH production by the fetal pituitary, which would increase cortisol secretion by the fetal adrenals. Fetal adrenal cortisol could then further stimulate placental CRH production. The marked rise in placental CRH during the last 10 weeks of pregnancy could be due to such a positive feedback interaction. This endocrine loop may be involved in the process of parturition (discussed later in the chapter).

CRH also may influence fetal adrenal steroidogenesis by directly increasing dehydroepiandrosterone sulfate (DHEA-S) production.[108,109] Interestingly, CRH is as effective as ACTH in stimulating DHEA-S production, but 70% less potent than ACTH in stimulating cortisol production in primary cultures of midgestation human fetal adrenal cortical cells (Fig. 12.6). The capacity for CRH to act as an adrenal androgen secretagogue also has been demonstrated *in vivo* in adult men.[110] The preferential induction of adrenal androgen synthesis indicates that placental CRH indirectly augments placental estrogen synthesis, because fetal adrenal DHEA-S is the principal substrate for placental estrogen production (discussed later in the chapter). Placental CRH and fetal adrenal DHEA-S increase concordantly during the third trimester, suggesting that production of these two hormones is related. The implication of this endocrine axis in the regulation of parturition is discussed later in this chapter.

Several actions have been ascribed to placental CRH in the control of human pregnancy. CRH may serve an autocrine-paracrine function within the placenta by regulating expression and processing of POMC. The formation of ACTH, β-LPH, β-EP, and α-MSH by cultured placental cells can be stimulated by CRH, an effect that is inhibited by CRH antagonists.[111] Placental CRH may be part of the fetal-placental stress response mechanism. The placenta is comparable to the hypothalamus in its production of CRH in response to stress. Neurotransmitters and neuropeptides activated in response to stress stimulate placental CRH release *in vitro*.[112,113] The physiological implications of this are that the fetus may be able to mount a stress response via placental CRH. This may be critical in conditions such as preeclampsia, placental vascular insufficiency, and intrauterine infection.

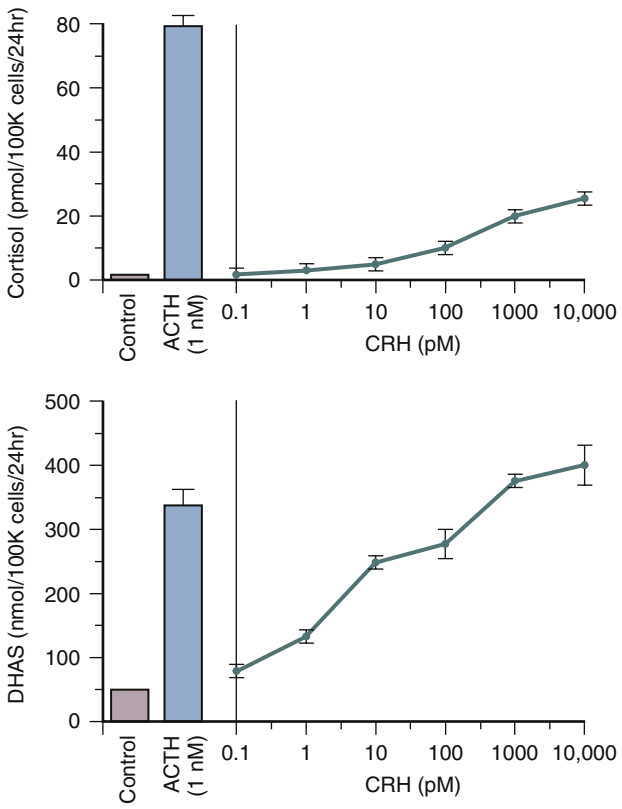

FIGURE 12.6 Effect of corticotropin-releasing hormone (CRH) on cortisol and DHEA-S production in cultured human fetal (midgestation) adrenal cortical cells *(Adapted from Smith R, Mesiano S, Chan EC, Brown S, Jaffe RB. 1998 Corticotropin-releasing hormone directly and preferentially stimulates dehydroepiandrosterone sulfate secretion by human fetal adrenal cortical cells.* J Clin Endocrinol Metab *83:2916–2920, 1998).*

Urocortin

The CRH-family of neuropeptides also includes a group of structurally and functionally related proteins known as urocortins.[114,115] Three urocortins have been identified: urocortin-1,[116] urocortin-2,[117] and urocortin-3.[118] Urocortin-1 binds with high affinity to both CRH receptors, CRH-R1 and CRH-R2, whereas urocortin-2 and urocortin-3 preferentially bind CRH-R2. Each of the three urocortins is expressed by syncytiotrophoblast and extravillous trophoblast cells and by the decidua and fetal membranes.[119,120] Circulating levels of urocortins are low compared with CRH during pregnancy[121] suggesting that the peptide acts mainly as a paracrine regulator within the gestational tissue.

Understanding of the function of placental urocortins in human pregnancy pertains mainly to urocortin-1.[115] Urocortin 1 stimulates ACTH and prostaglandin production by trophoblast cells[122] and causes vasodilation of the utero-placental vasculature via activation of the nitric oxide-cGMP system via CRH-R2.[123,124] In women with decreased uterine artery blood flow during midgestation, circulating urocortin-1 levels are reduced in proportion to the increase in uterine artery resistance.[125] Interestingly, placentas from women with preeclampsia have reduced cGMP-mediated responsiveness to urocortin-1 suggesting that a principal role of urocortin-1 is to facilitate vasodilation in the feto-placental circulation.[126] Studies in animal models also show

the vasodilatory effects of urocortin-1 on placental blood flow and suggest that one of its main functions is to protect the fetus from hypoxic insults.[127,128] Although the roles of placental urocortin-2 and -3 in human pregnancy remain unclear, studies of term myometrial cells show that urocortin-2 acting via CRH-R2 increases contractility[129] suggesting that it plays a role in parturition.

Thyrotropin-Releasing Hormone

A substance similar to the hypothalamic thyrotropin-releasing hormone (TRH) has been found in the human placenta.[54] It stimulates pituitary thyrotropin (TSH) release in the rat both *in vitro* and *in vivo*, but is not identical to hypothalamic TRH.[130] To date, a placental TSH has not been identified. Whether placental TRH plays a role in stimulating fetal or maternal pituitary TSH remains to be ascertained. As discussed above, the thyroid-stimulating activity of the placenta has been ascribed to hCG.

Leptin

Leptin, a 146-amino acid protein produced primarily by adipocytes, is a key regulator of satiety and body mass index and its levels are thought to reflect the amount of energy stores and nutritional state.[131] Leptin decreases food intake and body weight via its hypothalamic receptor.[132] In the reproductive system, leptin is thought to coordinate body mass status with reproductive function.[133] In general, leptin acts as a permissive factor in reproduction–pulsatile hypothalamic GnRH secretion does not occur unless leptin levels reach a threshold value. Such a mechanism may ensure that energy stores are sufficient to support a pregnancy.

The actions of leptin may not be limited to regulation of satiety and energy stores, as its expression and that of its receptor have been identified in a variety of tissue types. This multifocal distribution of expression and targets suggests that leptin plays a paracrine role in a variety of physiological processes.[134]

The placenta is the principal source of leptin during pregnancy.[135] Most of the leptin produced by the placenta is secreted into the maternal circulation, and as a consequence leptin levels are elevated during pregnancy. In the first trimester, maternal plasma leptin levels are double nonpregnant values and continue to increase during the second and third trimesters.[136] In the second and third trimesters, leptin is also expressed by the chorion and amnion.[137] The proportion of placental leptin directed to the fetus is uncertain and its role in fetal development is unknown. Leptin levels decline to normal nonpregnant values within 24 hours of delivery.[138]

The influence of placental leptin on maternal biology is unclear. Current data suggest that abnormally high placental leptin production is associated with maternal diabetes mellitus and hypertension and that umbilical leptin levels correlate with fetal adiposity.[139] Interestingly, leptin levels during pregnancy do not correlate with body mass index as they do in the nonpregnant state.[140] Pregnancy appears to be a state of hyperleptinemia and leptin resistance, with uncoupling of eating behavior, satiety, and metabolic activity.[141] Leptin is lipolytic and favors fatty acid mobilization from adipose tissue. Based on its actions in the hypothalamus, leptin may regulate satiety and maternal energy expenditure during pregnancy. It also may act in the liver, pancreas, and muscle to decrease insulin sensitivity and mobilize glucose. Thus, leptin appears to be another hormone utilized by the placenta to modulate maternal metabolism and partition energy supplies to the fetus.

The human placenta expresses leptin receptors and therefore leptin can act in a paracrine manner to modulate placental function. Leptin induces hCG production in trophoblast cells and is also thought to increase placental growth by augmenting mitogenesis, animo-acid uptake, and extracellular matrix synthesis.[142,143]

Neuropeptide Y

Found in the central and peripheral nervous systems, Neuropeptide Y (NPY) is a 36-amino acid protein that influences neuroendocrine function and behavioral events such as eating and satiety.[144] Immunoreactive NPY and binding sites for NPY have been found in the term human placenta.[145] In women with preeclampsia, placental NPY expression is decreased compared with normal pregnancies and is associated with increased expression of leptin.[146] The inverse relationship between placental NPY and leptin resembles hypothalamic regulation of NPY, whereby leptin suppresses hypothalamic NPY release.[147]

Maternal NPY levels are increased above those of nonpregnant women beginning early in gestation. They remain elevated until term and rise still further during labor, reaching their acme with cervical dilation and labor.[148] There is no significant change in NPY concentrations in the circulation of women undergoing cesarean section who are not in labor.[148] NPY levels decline rapidly after delivery, again suggesting a placental source of this neuropeptide.

Because NPY stimulates CRH release from cultured placental cells,[149] but not the release of GnRH, hCG, or hPL, it may play a role in the regulation of placental CRH production.

Growth Factors and Cytokines

Many growth factors, cytokines, and their cognate receptors have been found in the human placenta.[150-152] These factors likely play a role in controlling the growth and development of the fetus and placenta. In this regard the insulin-like growth factors (IGFs) are notable. Studies in mice, using homologous recombination, have shown that IGF-I and IGF-II are critical for placental and fetal growth. Disruption of placental IGF-II expression[153] or over-expression of decidual IGFBP-1–which inhibits IGF action–leads to restriction of placental and fetal growth.[154]

Interestingly, IGF-II is an imprinted gene only; the paternal allele is expressed.[155] The finding that a paternal gene promotes placental growth supports the concept of genetic conflict between the maternal and fetal genomes.[40] The size and ultimate health of the fetus depends greatly on the size of the placenta. Growth factors that increase placenta size are an advantage to the fetus because they

allow it to more efficiently extract resources from the mother. Passage of paternal genes to the next generation is favored if nutrient supply to the fetus is maximized. Maternal genes, on the other hand, not only must survive to the next generation, but they also must insure that the current pregnancy does not compromise the mother's future reproductive capacity. Maternal genes would therefore be selected to counter and control the effects of paternally imprinted genes such as IGF-II. Interestingly, IGFBP-1 is produced by the decidua, a maternal tissue, and essentially all of the IGFBP-1 in amniotic fluid is maternally derived.[154] Thus, placental, and ultimately fetal, growth appears to be the net result of a balance between factors that stimulate (e.g., IGF-II) and that restrict (e.g., IGFBP-1) growth.

Steroid Hormones and the Fetal-Placental Unit

Steroid hormone production and metabolism by the placenta is dependent on precursors provided by the fetus and mother. The interdependence of fetus, placenta, and mother for steroid hormone production in human pregnancy led to the concept of an integrated fetal-placental–maternal steroidogenic unit. To understand this concept, it will be useful to review the general steroid biosynthetic pathways (Fig. 12.7); (discussed in Chapter 4).

Progesterone

The human placenta produces large amounts of progesterone throughout pregnancy. It does this mainly by converting low-density lipoprotein cholesterol, extracted from the maternal circulation, to pregnenolone, which is then converted to progesterone.[156] Cholesterol is converted to pregnenolone in the mitochondria of trophoblast cells by the cytochrome P450scc enzyme. This is the rate-determining step for placenta progesterone production. The conversion of pregnenolone to progesterone also occurs in the mitochondria and is catalyzed by type-1 3β-hydroxysteroid dehydrogenase (3βHSD-I). The human placenta is highly inefficient at converting progesterone to 17α-hydroxyprogesterone. Consequently, placental steroidogenesis from cholesterol accumulates at progesterone. The original explanation for this block in the steroidogenic pathway was that the human placenta lacks the 17α-hydroxylase/17,20-lyase (P450c17) enzyme responsible for converting progesterone to 17α-hydroxyprogesterone and then androstenedione (i.e., the Δ_4 pathway).[157] However, recent studies have shown that the human placenta does indeed express P450c17 and has an intact Δ_4 steroidogenic pathway.[158] Nonetheless, the efficiency of progesterone synthesis is far greater than its metabolism through the Δ_4 pathway resulting in a net accumulation and secretion of progesterone. Production of progesterone approximates 250 mg/day by the end of pregnancy, at which time circulating levels are on the order of 130 ng/mL.[159]

As its name implies, progesterone is a pro-gestation hormone—it promotes and sustains the pregnant state. Progesterone has been aptly called the "hormone of pregnancy" because it is essential for pregnancy maintenance in all viviparous animals examined so far, and interference of its synthesis or action during pregnancy induces labor and delivery.

A major function of progesterone during pregnancy is to promote myometrial relaxation and quiescence. Progesterone relaxes the pregnancy myometrium genomically by modulating the expression of genes encoding contraction-associated proteins (CAPs) and by inhibiting estrogenic actions on the pregnancy myometrium.[160] It also may promote myometrial relaxation by functioning as an anti-inflammatory factor in the myometrium.[161] It is proposed that progesterone promotes the establishment of pregnancy by suppressing T-lymphocyte cell-mediated responses involved in tissue rejection and thus may contribute to preventing rejection of the conceptus by the maternal immune system.[162] Parturition is thought to be an inflammatory event and the onset of labor is considered to be secondary to tissue level inflammation within the myometrial compartment.[163-165] Thus, progesterone may block labor indirectly

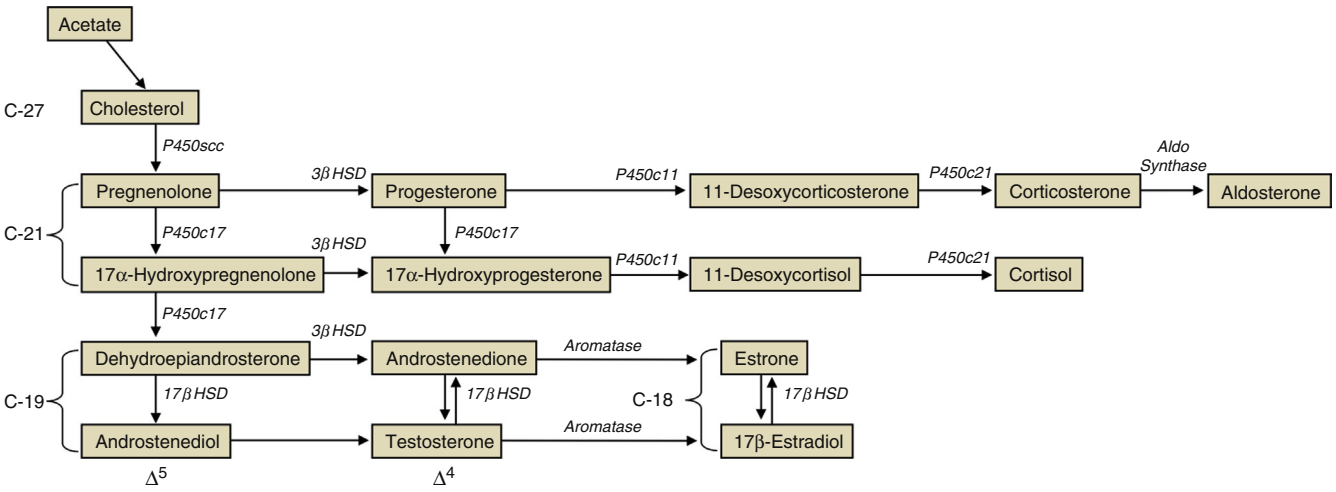

FIGURE 12.7 Biosynthetic pathways in steroid hormone formation. The C-21 compounds include progestins and the adrenal corticosteroids. The C-19 compounds include androgens, and the C-18 compounds include estrogens. Steroids with a double bond between the 5 and 6 positions in the steroid nucleus (Δ_5-steroids) are shown on the left, and those with a double bond between the 4 and 5 positions (Δ_4-steroids) are depicted on the right. The principal steroid metabolizing enzymes are shown in italics.

by repressing inflammation in the myometrium (discussed later in the chapter).

Discovery of the natural pro-gestational actions of progesterone were soon followed by efforts to exploit the activity clinically to prevent preterm birth. Studies in the 1950s and 1960s showed that administration of high doses of progesterone (as a bolus IV or into the amniotic fluid) decreased the frequency of spontaneous contractions and attenuated responsiveness to oxytocin.[166,167] Those findings suggested that progesterone could be used therapeutically to repress labor and prevent preterm birth, however, initial clinical studies to test this hypothesis produced mixed and conflicting results, largely due to insufficient patient numbers. Recent clinical trials of prophylactic progestin therapy to prevent preterm birth have produced more promising, but still somewhat equivocal, outcomes. Prophylactic treatment with natural progesterone administered vaginally[168] or a synthetic caproate ester of 17α-hydroxyprogesterone (17HPC) given as long-acting intramuscular injections[169] beginning at around midgestation decreased the incidence of preterm birth and improved neonatal outcome in women with an increased risk for preterm birth based on a prior preterm birth or a short cervix detected by ultrasound at midgestation.[170-173] Prophylactic vaginal administration of progesterone failed to alter preterm birth rates[174] in the general population and administration of 17HPC to women with twin pregnancies,who generally deliver preterm, failed to decrease the incidence of preterm birth.[175] The reason why progestin therapy is effective in only small subset of at-risk pregnancies is unclear and the value of prophylactic progestin therapy to prevent preterm birth in the general population is yet to be established.[176]

Estrogens

The principal role of estrogens in human pregnancy are to stimulate uterine growth and increase uterine blood flow. Estrogens also affect breast development in preparation for lactation. At parturition, estrogens oppose the actions of progesterone by augmenting uterine contractility and inducing cervical softening. The net physiological affects of estrogens during pregnancy that are central to the maternal adaptations for pregnancy and motherhood.

Estrogens are synthesized by the human placenta from C19 steroids.[177] The principal precursor used for placental estrogen formation is DHEA-S, supplied mainly by the fetal adrenal glands. Because the placenta has an abundance of the sulfatase (sulfate-cleaving) enzyme, DHEA-S is rapidly converted to free (unconjugated) DHEA which is then converted to androstenedione by 3ßHSD-I. The human placenta also expresses high levels of the aromatase enzyme which converts androstenedione estrone. The 17β hydroxysteroid dehydrogenase (17βHSD) enzymes then interconvert estrone and estradiol (Fig. 12.8).

By far the major estrogen formed during human pregnancy is estriol, which has an additional hydroxyl group at position 16. Estriol constitutes more than 90% of the estrogen in pregnancy urine, into which it is excreted as sulfate and glucuronide conjugates. Estriol concentrations increase with advancing gestation, and range from approximately 2 mg/24 hours at 26 weeks to 35 to 45 mg/24 hours at term.[178] At term, the concentration of estriol in the maternal circulation is 8 to 13 ng/dL.[179] In contrast, ovarian production of estriol in nonpregnant women is barely detectable.[179]

Placental estriol is formed by a biosynthetic process unique to human (and higher primate) pregnancy, that begins with DHEA-S from the fetal adrenal glands. When DHEA-S of either fetal or maternal origin reaches the placenta, estrone and estradiol are formed. However, little of either is converted to estriol by the placenta. Instead, some of the DHEA-S undergoes 16α-hydroxylation, primarily in the fetal liver and, to a limited extent, in the fetal adrenal itself. When the newly formed 16α-hydroxyDHEA-S (16α-OH-DHEA-S) reaches the placenta, the placental sulfatase enzyme cleaves the sulfate side chain and the unconjugated 16α-OH-DHEA, after further metabolism, is aromatized to form estriol, which is then secreted into the maternal circulation. Thus, level of estriol in the maternal blood reflects the activity of the fetal HPA axis and especially steroidogenic activity of the fetal zone of the fetal adrenal cortex. In the mother, estriol is conjugated to form estriol sulfate and estriol glucosiduronate in the liver and excreted via the urine.[180] Another placental estrogen derived from a fetal precursor is estetrol, formed after 15-hydroxylation of 16α-OH-DHEA-S. Its function is not known. Relative levels of progesterone and estrogens (estrone, estradiol, estriol, and estetrol) in the maternal circulation during human pregnancy are shown in Figure 12.9.

An interesting facet of steroid hormone metabolism in the human fetus is the formation of sulfate conjugates of the steroid hormones. The process of sulfoconjugation of hydroxylated steroids is ubiquitous in the fetus, occurring in a variety of sites, including lung, gut, liver, and adrenal gland. In the adrenal, sulfurylation leads to the formation of a variety of steroid sulfates, including pregnenolone sulfate, 17α-hydroxypregnenolone sulfate, and DHEA-S—quantitatively the most significant C19-androgen.[181]

Production of estrogens by the human placenta is extraordinarily high and circulating levels during pregnancy are several orders of magnitude higher than physiological levels in non-pregnancy women. A key question therefore is why does the human placenta make so much estrogen? Conditions in which placental estrogen synthesis is markedly decreased (e.g., anencephaly, congenital adrenal lipoid hyperplasia, placental aromatase deficiency, and placenta sulfatase deficiency) have provided some insight into the role of the placental estrogens in human pregnancy. Although pregnancy was prolonged in some cases of placental sulfatase deficiency[182-185] and anencephaly,[186-189] in most cases a marked decrease in placental estrogen synthesis had little effect on fetal and placental development and the timing of parturition. Likewise, there was minimal consequence of lowered estrogen levels in pregnancies with placental aromatase deficiency,[190,191] although mothers and female fetuses exhibited virilization signs due to androgen excess. Thus, high levels of estrogens of placental origin may not be essential for normal pregnancy and parturition, but rather a critical role of placental aromatase is to metabolize circulating androgens to protect the female fetus and mother from virilization.

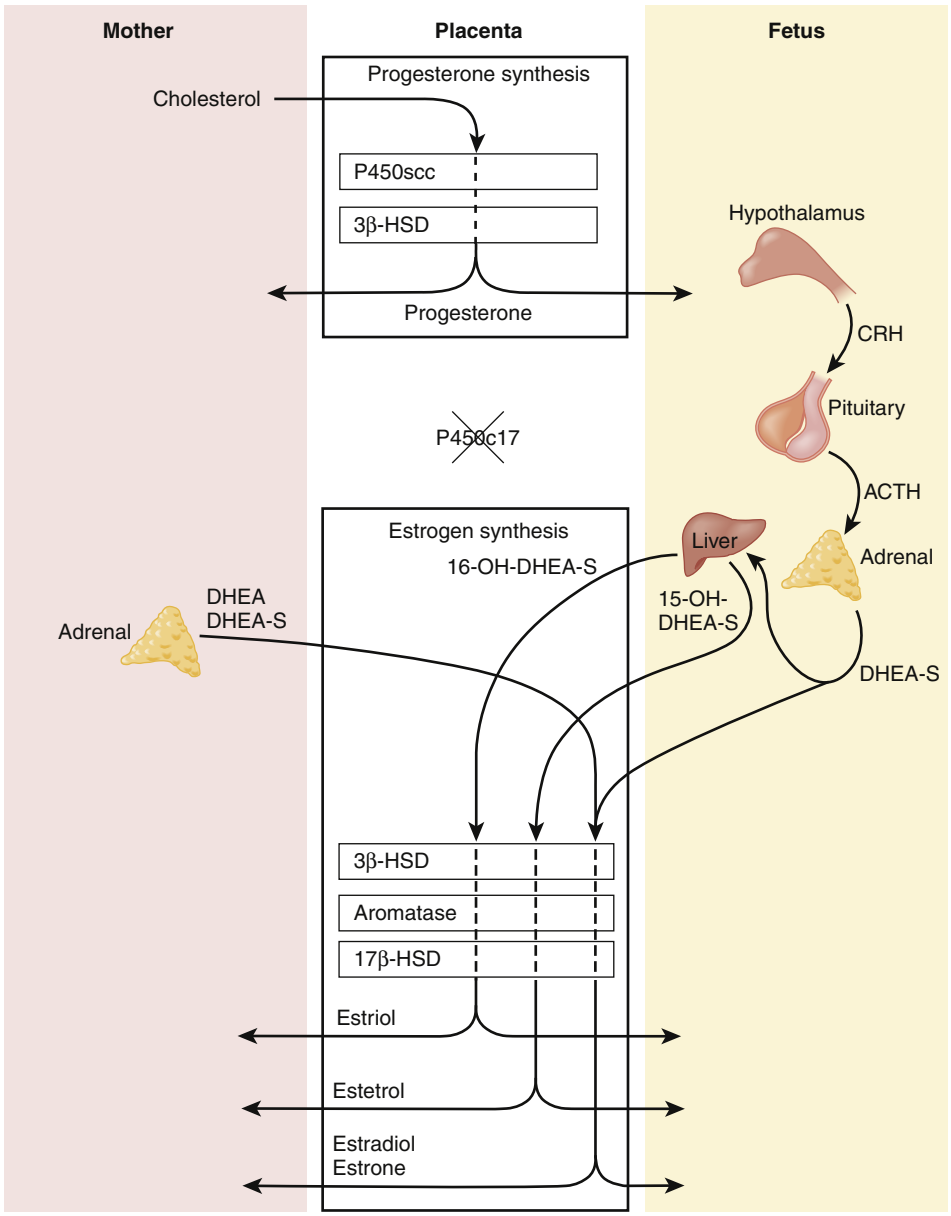

FIGURE 12.8 Biosynthesis of progesterone and estrogens by the human placenta. Progesterone is produced mainly from maternal cholesterol. P450c17 is not expressed in the human placenta and therefore, progesterone cannot be converted to C19 androgens. Instead, estrogens are biosynthesized from C19-androgen precursors (mainly DHEA-S) provided by the maternal and fetal adrenals. *(From Mesiano S. Roles of estrogen and progesterone in human parturition.* Front Horm Res *27:86, 2001.)*

These observations do not exclude a role for estrogen in the control of human pregnancy. Although levels of maternal estrogens in pregnancies with placental estrogen synthesis defects were low compared with normal pregnancies, they were still in a physiologically significant range (1 to 1.6 nmol/L) and comparable to levels reached in the midcycle and luteal phase of the menstrual cycle (0.6 to 2 nmol/L). Thus, despite the inability of the placenta to produce estrogens in certain abnormalities such as aromatase deficiency, the estrogen target tissues were still exposed to moderately high levels of estradiol. This suggests that a minimal level of estrogen is necessary for human pregnancy and that the excessive levels produced by the placenta are redundant. Indeed, no naturally occurring conditions have been described in which human pregnancy exists in the complete absence of estrogens.

The functional role of estriol in pregnancy has attracted a great deal of speculation. In many biological systems, estriol is a weak estrogen with approximately 1% the potency of estradiol and 10% that of estrone, on a weight basis. However, there is one function for which estriol appears to be as effective as the other estrogens: its ability to increase uteroplacental blood flow.[192] Therefore, this may be a primary function of the large amounts of placental estriol.

Placental Glucocorticoid Metabolism

For most of gestation the placenta expresses the 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD-2) enzyme, which inactivates cortisol by catalyzing its conversion to cortisone.[193-195] As maternal cortisol levels are three times those of the fetus, this biochemical barrier serves to prevent excess cortisol from entering the fetal compartment. This is important because exposure of the fetus to high levels of cortisol not only could interfere with the fetal hypothalamic-pituitary axis, but also is associated with decreased birth weight and hypertension.[196-198]

Studies in the baboon placenta suggest that estrogen upregulates 11β-HSD-2 expression in the placenta. Because

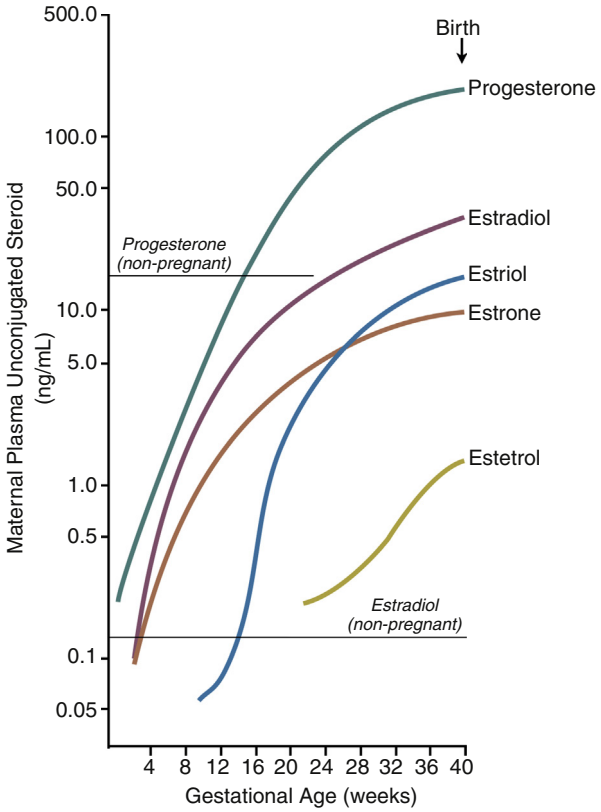

FIGURE 12.9 Schematic depiction of maternal progesterone and estrogen (estradiol, estrone, and estriol) concentrations through human pregnancy compared with average levels in normal cycling women.

estrogen synthesis by the placenta requires fetal adrenal androgen precursors (produced in part by fetal pituitary ACTH stimulation) the estrogen regulation of placental 11β-HSD-2 represents a regulatory loop that ensures that maternal cortisol does not affect the fetal HPA axis.[199]

Development of the Fetal Neuroendocrine System

Hypothalamic Hormones

By the end of the fifth week of pregnancy, the primitive hypothalamus can be identified as a swelling on the inner surface of the diencephalic neural canal. It then differentiates to form a complex of interconnecting nuclei. By 9 to 10 weeks, the median eminence of the hypothalamus is evident, and interconnecting fiber tracts of hypothalamic nuclei can be identified by 15 to 18 weeks. The hypophysiotropic hormones GnRH, TRH, CRH, growth hormone-releasing hormone (GHRH), and SS appear in the fetal hypothalamus during this period (Table 12.2).

Gonadotropin-Releasing Hormone

The human fetal hypothalamus produces immunoreactive and bioactive GnRH by 10 weeks of gestation. Between 10 and 22 weeks, the concentration of GnRH in the fetal hypothalamus remains constant (0.27-13.1 pg/mg) and is not different between the sexes. GnRH release from human fetal hypothalamic explants is pulsatile.[200,201] In male rhesus monkey fetuses during the last third of gestation, the pituitary-gonadal axis is active. The pituitary produces LH in response to GnRH and the testes produce testosterone in response to LH.[202] A similar situation likely exists in the human male fetus. Whether this also is the case for the female fetus is unresolved.

Table 12.2 Ontogeny of Human Fetal Hypothalamic and Pituitary Hormones

Hormone	Age Detected (wk)
Hypothalamic	
Gonadotropin-releasing hormone	14
Thyrotropin-releasing hormone	10
Somatostatin	14
Dopamine	11
Growth hormone–releasing hormone	18
Corticotropin-releasing hormone	16
Pituitary	
Prolactin	16.5
Growth hormone	10.5
Corticotropin (ACTH)	7
Thyroid-stimulating hormone (thyrotropin)	13
Luteinizing hormone	10.5
Follicle-stimulating hormone	10.5

Thyrotropin-Releasing Hormone

Significant levels of immunoreactive TRH are found in the human fetal hypothalamus early in gestation.[201] As with GnRH, fetal hypothalamic TRH levels do not correlate with sex or gestational age. The presence of TRH in the fetal hypothalamus in early gestation and midgestation suggests its role in the regulation of TSH, and possibly PRL, secretion.

Growth Hormone-Releasing Hormone and Somatostatin

GHRH can be detected in fetal hypothalamic neurons and fiber tracts at 18 weeks, with increasing levels found up to 30 weeks.[203] The simultaneous detection of GHRH in neuron cell bodies and fiber tracts indicates its release into portal vessels by midgestation. Immunoreactive SS can be identified in the hypothalamus of human fetuses from 10 to 22 weeks.[201] In contrast to GnRH and TRH, fetal hypothalamic SS increases with advancing gestational age.

Corticotropin-Releasing Hormone and Arginine Vasopressin

CRH is a potent secretagogue for ACTH and β-endorphin release by the human fetal pituitary gland.[204] Arginine vasopressin (AVP) also directly stimulates ACTH secretion by the fetal pituitary and can synergize with CRH.[200] CRH-immunoreactive fibers can be detected in the median eminence between 14 and 16 weeks.[205,206] CRH immunoactivity and bioactivity and AVP immunoactivity have been detected in human hypothalamic extracts from 12 to 13 weeks.[206]

Hypothalamic CRH and AVP increase with gestational age, and the CRH bioactivity of fetal hypothalamic extracts, measured in isolated rat anterior pituitary cells, is augmented by AVP. Thus, the human fetal hypothalamus has the capacity to regulate pituitary ACTH production from early in the second trimester. The extent to which fetal

hypothalamic CRH and AVP and placental CRH interact in regulating fetal ACTH release remains uncertain.

Catecholamine-Dopamine

Catecholamine fluorescence in cells projecting from the arcuate nuclei to the internal and external layers of the median eminence appears during the interval from 12 to 16 weeks.[207] Dopamine is present in the fetal hypothalamus at weeks 11 to 15 at a concentration twice that of the adult. Consistent with the effects of dopamine functioning as the PRL release-inhibiting factor, fetal hypothalami taken within this interval display a PRL release-inhibiting activity.[208]

Pituitary Hormones

The pituitary primordium appears as the epithelial evagination of Rathke pouch arising from a diverticulum of the stomadeum. The evaginated pituitary primordium appears at 4 weeks and separates from the stomadeum by 5 weeks. The floor of the sella turcica is in place by week 7 and separates the pituitary from its epithelial origins. The progenitors of pituitary hormone-secreting cells originate in the ventral neural ridges of the primitive neural tube. This region also gives rise to the diencephalon, suggesting that the hypothalamus and anterior pituitary share a common embryonic origin.

The pituitary increases in size and cell number through proliferation of cell cords into mesenchyme beginning during week 6. Capillaries interdigitate among the mesenchymal tissue of Rathke pouch and the diencephalon at 8 weeks and the median eminence is distinguishable by 9 weeks. The hypothalamic-hypophyseal vascular system in fetuses is intact by 11 to 16 weeks.

The anterior pituitary gland comprises five types of specialized epithelium-derived secretory cells: (1) lactotropes producing PRL; (2) somatotropes producing GH; (3) corticotropes producing ACTH; (4) thyrotropes producing TSH, and (5) gonadotropes producing LH and FSH.

Within the pituitary, cells containing:ACTH have been detected at 7 weeks, β-lipotropin and β-endorphin at 8 weeks, GH-containing and LH-containing cells both at 10.5 weeks, and TSH-containing cells at 13 weeks. Melanocyte-stimulating hormone (MSH)-containing cells, which probably contain β-lipotropin, have also been reported to appear at 14 weeks, and PRL-containing cells appear at 16.5 weeks (Table 12.2).[209] Many of the components required for the normal regulated function of the secretory cells of the anterior pituitary, the hypophysiotropic factors elaborated by the hypothalamus, and the neurohemal link connecting the hypothalamus and pituitary, are present in the fetus well before the end of the first half of pregnancy. The primate fetal pituitary is competent to respond *in vitro* to virtually all of the known hypophysiotropic factors by midgestation. Whether it responds to these compounds *in vivo* remains to be demonstrated directly, although studies in the catheterized rhesus monkey fetus *in utero* suggest that responses to at least one of the hypophysiotropic factors, GnRH, can occur.[202]

The Fetal Pituitary-Adrenal Axis

The anlage of the human adrenal cortex is first identified at about the fourth week of gestation as a thickening of the celomic epithelium in the notch between the primitive urogenital ridge and the dorsal mesentery. By the fifth week, these primitive cells begin to migrate toward the cranial end of the mesonephros where they condense to form the earliest recognizable manifestation of the adrenal gland. Cells destined to become the steroidogenic cells of the adrenal and gonad are derived from neighboring areas of the celomic epithelium and are morphologically identical. In general, the portion medial to the mesonephros produces cells destined for the adrenal cortex, whereas the portion ventral to the mesonephros produces cells destined for the gonad.

During the last two thirds of gestation in humans and higher primates, the fetal adrenal glands are disproportionately enlarged and exhibit extraordinary growth and steroidogenic activity. The growth is attributable to cortical hypertrophy controlled by locally produced growth factors including basic FGF and IGF-II in response to ACTH.[210-212]

For much of gestation, the human fetal adrenal cortex is composed of two morphologically distinct zones, the fetal zone and the definitive zone. The fetal zone accounts for 80% to 90% of the cortex and is the primary site of growth and steroidogenesis. During midgestation, the fetal zone produces 100 to 200 mg/day of DHEA-S, which is quantitatively the principal steroid product of the human fetal adrenal gland throughout gestation. As its name implies, the fetal zone exists only during fetal life; it involutes or undergoes remodeling soon after birth. Clusters of immature neuroblasts are present between the innermost fetal zone cells. These cells aggregate at birth to form a functional adrenal medulla.

The definitive zone (also referred to as the adult cortex, neocortex, or permanent zone) comprises a narrow band of small, tightly packed basophilic cells that exhibit structural characteristics typical of cells in a proliferative state. Its inner layers form arched cords that send fingerlike columns of cells into the outer rim of the fetal zone. Definitive zone cells begin to resemble steroidogenically active cells later in pregnancy, and appear to secrete mineralocorticoids late in the third trimester.
