CHAPTER 32

Gamete and Embryo Manipulation

Charles L. Bormann*

Since the birth of the first test tube baby in 1978,[1] *in vitro* fertilization (IVF) has become a well-established treatment procedure for certain types of infertility, including long-standing infertility due to tubal disease, endometriosis, unexplained infertility, or infertility involving a male factor. However, soon it became obvious that certain couples with severe male factor infertility could not be helped by conventional IVF. Extremely low sperm counts, impaired motility, and poor morphology represent the main causes of failed fertilization in conventional IVF.

To tackle this problem, several procedures of assisted fertilization based on micromanipulation of oocytes and spermatozoa have been established. These strategies have culminated in intracytoplasmic sperm injection (ICSI), in which a single spermatozoon is directly injected into the ooplasma. In 1992, Palermo and colleagues reported the first human pregnancies and births after replacement of embryos generated by this novel procedure of assisted fertilization.[2] Since then, the number of worldwide centers offering ICSI has increased tremendously, as have the number of treatment cycles per year.[3] Because of the widespread use of ICSI as the ultimate and only option for successful treatment of severe male infertility due to impaired testicular function or obstruction of the excretory ducts, concern about its efficacy and safety is appropriate.

Whereas ICSI represents the major breakthrough for male infertility treatment, preimplantation genetic diagnosis (PGD) would be inconceivable without the establishment of embryo biopsy procedures. Initial attempts to penetrate or open the zona pellucida were undertaken to assist oocyte fertilization[4-6] or increase embryo implantation by facilitating the hatching process.[7,8] This very close access to oocytes or embryos soon resulted in the removal of cellular material (polar bodies or blastomeres, respectively), which allowed genetic testing in this very early developmental stage.[9,10]

As much as PGD relies on embryo biopsy, equally indispensable was the progress in molecular genetics leading to the development of diagnostic procedures at the single-cell level.[11-13] These procedures include gene amplification using polymerase chain reaction (PCR) for monogenic diseases, fluorescence *in situ* hybridization (FISH) for the evaluation of numeric and structural chromosome aberrations and for sex determination in cases of sex-linked diseases and more recently, comprehensive chromosome screening (CCS) methods which allow for the genome-wide analysis of DNA copy number variations.[14] Since the first pregnancy report from the clinical application of PGD,[15] there has been a steady increase in the number of PGD cycles and also in the number of centers performing PGD worldwide.[16]

This chapter surveys the current status of ICSI, emphasizing patient selection, oocyte and sperm handling before microinjection, the procedure and outcome parameters, and clinical application of these technologies. The clinical relevance of assisted hatching before embryo transfer is discussed. Embryo biopsy procedures and single-cell analysis (at the chromosomal level by FISH and CCS; at the monogenic level by PCR) as diagnostic tools for PGD and preimplantation genetic screening (PGS) are described.

Intracytoplasmic Sperm Injection

History of ICSI

Extremely low sperm counts, impaired motility, and abnormal morphological features are the main causes of failed fertilization in conventional IVF. Today, ICSI is the ultimate option to treat these cases of severe male factor infertility (see Chapter 24). One single viable spermatozoon, preferably with good morphological characteristics, is selected by the embryologist and injected into each oocyte available.

The ICSI procedure is based on micromanipulation of oocytes and spermatozoa. Initially, partial zona dissection (PZD) was established to facilitate sperm penetration.[4,6,17,18] The barrier to fertilization represented by the zona pellucida was disrupted mechanically to allow the inseminated sperm cells direct access to the perivitelline space of the oocyte. Subzonal insemination (SUZI) was the next step in micromanipulation techniques.[19-22] SUZI enabled the immediate delivery of several motile sperm cells into the perivitelline space by means of an injection pipette.[23] ICSI is even more invasive because a single spermatozoon is directly injected into the ooplasma, thereby crossing not only the zona pellucida but also the oolemma.

The first successful use of ICSI was to obtain live offspring in rabbits and cattle.[24] The first human pregnancies

*The author would like to acknowledge the contributions of Anick De Vos and André Van Steirteghem who where the authors of this chapter in the previous edition.

and births resulting from this novel assisted fertilization procedure were reported in 1992.[2] Shortly thereafter, ICSI was found to be superior to SUZI in terms of oocyte fertilization rate,[25-28] number of embryos produced, and embryo implantation rate.[25-28] As a result, ICSI has been used successfully worldwide to treat infertility due to severe oligo-asthenoteratozoospermia or azoospermia caused by impaired testicular function or obstructed excretory ducts.[29,30]

Since the first publication describing the ICSI procedure,[2,22,25,27,28] minor modifications have contributed to reduced rates of oocyte degeneration, oocyte activation (one-pronuclear [1-PN]), and abnormal fertilization (three-pronuclear [3-PN]).[31] Hyaluronidase may be responsible for oocyte activation; therefore, the concentration used during oocyte denudation and the exposure time of oocytes to the enzyme has been reduced.[32] The timing of denudation relative to oocyte pickup (immediately or 4 hours later) does not influence the ICSI results.[33] The orientation of the polar body during injection does, however, influence embryo quality.[34] Motile sperm cells are selected and immobilized before injection.[35] Cytoplasm aspiration to ensure oolemma rupture is critical to the success of the ICSI procedure, because the method of rupture has been correlated with oocyte degeneration.[34] Furthermore, the morphological features of the injected spermatozoon are related to the fertilization outcome of the procedure as well as to the pregnancy outcome.[36] The outcome of the ICSI procedure may benefit from the introduction of some new technical improvements. Noninvasive spindle imaging in human oocytes on the basis of its birefringence with a computer-assisted polarization microscopy system (PolScope™, Cambridge Research & Instrumentation, Woburn, MA) may serve as an accurate indicator of oocyte maturity, quality, and developmental potential.[37-44] High-magnification ICSI, on the other hand, may provide a better morphological selection of spermatozoa to be used for fertilization.[45-50]

Indications for ICSI

Before the era of ICSI, attempts were made to modify and refine conventional IVF to achieve increased rates of conception in cases of male infertility. Today, ICSI has clearly overshadowed the use of modified IVF procedures (including high insemination concentration) for the treatment of severe male factor infertility. ICSI requires only one spermatozoon with a functional genome and centrosome for the fertilization of each oocyte. Indications for ICSI are not restricted to morphologically impaired spermatozoa and include low sperm count and impaired kinetic quality of the sperm cells. ICSI can also be used with spermatozoa from the epididymis or testis when there is an obstruction in the excretory ducts. Azoospermia caused by testicular failure can be treated by ICSI if enough spermatozoa can be retrieved in testicular tissue samples. Box 32.1 gives an overview of the current indications for ICSI.

The ICSI procedure with ejaculated spermatozoa can be used successfully in patients with fertilization failures after conventional IVF, and also in patients with too few morphologically normal and progressive motile spermatozoa present in the ejaculate (less than 500,000). High fertilization and pregnancy rates can be obtained when a motile spermatozoon is injected.[28] Injection of only immotile or probably nonvital spermatozoa results in lower fertilization rates.[51] When only nonvital sperm cells are present in the ejaculate, the use of testicular sperm is indicated.[52] Other semen parameters, such as concentration, morphological features (except for globozoospermia),[53] and high titers of antisperm antibodies,[54] do not influence success rates.[53] Successful ICSI has also been described in patients with acrosomeless spermatozoa.[55,56]

Any form of infertility due to obstruction of the excretory ducts can be treated by ICSI with spermatozoa microsurgically recovered from either the epididymis[57-59] or the testis.[60-62] Obstructive azoospermia can result from congenital bilateral absence of the vas deferens, failed vasectomy reversal, or vasoepididymostomy. When no motile spermatozoa can be retrieved from the epididymis due to epididymal fibrosis, testicular spermatozoa can be isolated from a testicular biopsy specimen.

Testicular biopsy has also proven useful in cases of nonobstructive azoospermia.[63-66] In patients with severely impaired testicular function as a result of incomplete germ cell aplasia (Sertoli cell–only syndrome), hypospermatogenesis, or incomplete maturation arrest; spermatozoa may be recovered, sometimes only after multiple biopsy specimens are obtained. Cryopreservation of supernumerary spermatozoa recovered from the epididymis[67] or the testis[68] is an important issue because microinjection of cryothawed sperm cells can avoid repeated surgery in future ICSI cycles. The ICSI procedure cannot be carried out in approximately 3% of scheduled cycles. Most cancellations occur because no cumulus–oocyte complexes or metaphase II (MII) oocytes are available or because no spermatozoa are found in testicular biopsy specimens of patients with nonobstructive azoospermia.

Box 32.1 Current Indications for Intracytoplasmic Sperm Injection

EJACULATED SPERMATOZOA
- Oligozoospermia
- Asthenozoospermia (caveat for 100% immotile spermatozoa)
- Teratozoospermia (≤4% normal morphology using strict criteria—caveat for globozoospermia)
- High titers of antisperm antibodies
- Repeated fertilization failure after conventional *in vitro* fertilization and embryo transfer
- Autoconserved frozen sperm from patients with cancer in remission
- Ejaculatory disorders (e.g., electroejaculation, retrograde ejaculation)

EPIDIDYMAL SPERMATOZOA
- Congenital bilateral absence of the vas deferens
- Young syndrome
- Failed vasoepididymostomy
- Failed vasovasostomy
- Obstruction of both ejaculatory ducts

TESTICULAR SPERMATOZOA
- All indications for epididymal sperm
- Failure of epididymal sperm recovery because of fibrosis
- Azoospermia caused by testicular failure (maturation arrest, germ cell aplasia)
- Necrozoospermia

Oocyte Collection

A successful ICSI program depends on ovarian stimulation, which is essentially similar to methods used for conventional IVF (see Chapters 30 and 31). Current ovarian stimulation regimens use a combination of gonadotropin-releasing hormone (GnRH) agonists or antagonists, human menopausal gonadotropin, or recombinant follicle-stimulating hormone (FSH), and human chorionic gonadotropin (hCG). This treatment allows the retrieval of a high number of cumulus–oocyte complexes.[69,70] Administration of GnRH agonists allows pituitary down-regulation to occur before the initiation of exogenous FSH. A gonadotropin preparation or recombinant FSH is administered to stimulate development of multiple follicles. Ovulation is usually induced with hCG (10,000 IU). This drug is administered when the serum estradiol level exceeds 1000 pg/mL and when at least two follicles ≥18 mm in mean diameter plus two additional follicles ≥12 mm in one diameter are observed on ultrasound examination. The optimal time for ultrasound-guided transvaginal oocyte aspiration is 36 hours after hCG administration.[71] On average, 11 cumulus–oocyte complexes per cycle can be retrieved.[72] After cumulus and corona cell removal, approximately nine metaphase II oocytes per cycle are available for microinjection.[72]

Although hCG may be used for luteal-phase supplementation, exogenous progesterone (administered intravaginally or intramuscularly) is frequently applied in an attempt to avoid the risk of hCG stimulation of the remaining growing follicles. The clinical introduction of GnRH antagonists[73-75] allowed a powerful and immediate suppression of pituitary gonadotropin release and a rapid recovery of normal secretion of endogenous luteinizing hormone and FSH.[76] By making optimal use of endogenous FSH, the amount of exogenous FSH required for follicular growth could be substantially reduced. A rapid recovery of pituitary luteinizing hormone and FSH release after cessation of GnRH antagonist administration might eliminate the need for additional luteal-phase support.

Handling of Oocytes

It is essential that preparation of retrieved oocytes for ICSI must be carried out under tightly controlled conditions with a constant pH of 7.3 and stable temperature at 37° C. Fluctuations in temperature have been shown to be detrimental to the oocyte microtubular system, including reductions in spindle size, disorganization of microtubules within the spindle, and in some cases, even a complete absence of microtubules.[77,78] Interference with spindle organization can prevent chromosome disassociation, resulting in aneuploidy. For procedures which require extended periods outside of a low CO_2 incubator such as ICSI, it is important to maintain the appropriate pH using buffered culture media such as 4-(2-hydroxyethyl)-1-piperazineethane sulfonic acid (HEPES). The correct temperature can be maintained by properly equilibrating all media and by performing all manipulations on a heated stage. Also, covering all working media with equilibrated parafilm and mineral oil will prevent evaporation and minimize both temperature and pH shifts.[79]

Unlike conventional IVF, in which intact mature cumulus-oocyte complexes are inseminated, fertilization with micromanipulation requires denudation of oocytes (i.e., removal of the surrounding cumulus and corona cells). This strategy allows not only precise injection of the oocytes, but also assessment of their maturity, which is of critical importance for ICSI. Cumulus and corona cells are removed with a combination of enzymatic and mechanical procedures.[32]

Hyaluronidase-purified preparations of bovine origin digest the hyaluronic acid interspersed between the cumulus cells, liberating the oocyte for maturity grading and microinjection. Both the enzyme concentration and the duration of exposure to the enzyme should be limited because they can result in parthenogenetic activation of the oocytes.[80] Because of its purity, recombinant human hyaluronidase, ICSI Cumulase® (Origio), may be used at higher concentrations; as a result, the incubation time becomes less critical.[81] For these reasons, this product may reduce, if not eliminate, the risk of damage or trauma to the oocytes by the mechanical denudation step. Additionally, the risk of animal pathogen contamination is alleviated. Microscopic observations of the denuded oocytes include assessment of the zona pellucida and oocyte and determination of the presence or absence of a germinal vesicle (GV) or first polar body. In 95% of cases, the retrieved cumulus–oocyte complexes usually contain an intact oocyte. The remaining 5% are empty zonae, cracked zonae, or morphologically abnormal oocytes.

Figure 32.1 shows three stages of oocyte maturation. On average, 3.9% of the intact oocytes are at the metaphase I (MI) stage, having undergone breakdown of the germinal vesicle, but not yet extrusion of the first polar body.[72] Approximately 10.3% of the intact oocytes are at the germinal vesicle stage, and approximately 85.8% are in the metaphase II stage, showing the presence of the first polar body.[72] ICSI is carried out only on metaphase II oocytes,

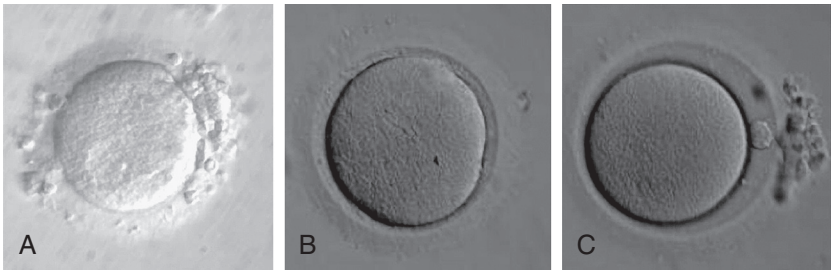

FIGURE 32.1 Oocyte maturity after cumulus and corona cell removal. **A,** A germinal vesicle–stage oocyte is recognized by the presence of a typical germinal vesicle. **B,** Oocytes that have undergone germinal vesicle breakdown but have not yet extruded the first polar body are called "metaphase I oocytes." **C,** A typical metaphase II oocyte shows a first polar body, which indicates that the oocyte is mature and has reached the haploid state. Only metaphase II oocytes are submitted to intracytoplasmic sperm injection.

because only such oocytes have reached the haploid state and thus can be fertilized normally. It has been reported that 74% of the MI oocytes completed meiosis within 20 hours after retrieval.[82] Another study reported that 27% of MI oocytes extruded their polar bodies within 4 hours of the egg retrieval.[83] Oocytes from this study were injected on the day of the egg retrieval in parallel to the oocytes retrieved at MII. This study demonstrated that MI oocytes that completed their maturation *in vitro* had a lower fertilization rate compared to those aspirated at MII. However, there were no differences observed in embryo quality between the two groups of oocytes.[83] Additional studies support these observations, showing that *in vitro* matured oocytes can be normally fertilized, however embryos derived from these oocytes rarely result in pregnancies.[84,85] These results suggest that rescue of MI oocytes of patients with few MII oocytes may increase the number of embryos for transfer; however, the chance to improve pregnancy rates by this procedure is minimal. Germinal vesicle-stage oocytes require overnight (30 hours) incubation in order to reach the MII stage. Few pregnancies have been reported from oocytes that were retrieved at the GV stage although standard IVF treatment with controlled ovarian hyperstimulation was performed.[84,86] Because of the poor results, GV oocytes are usually discarded. Denuded and rinsed oocytes are incubated until the time of microinjection.

PolScope™

As previously mentioned, the integrity of the meiotic spindle in MII oocytes is crucial for normal fertilization and subsequent development. Therefore, it is thought that the morphology of the spindle may serve as a marker of oocyte quality. A modification of the polarized light microscope "PolScope™," has been developed as a noninvasive instrument to view the meiotic spindle in living oocytes.[87] The image of the spindle is based on the highly birefringent characteristic of the microtubule filaments under a polarization microscope. The presence of a birefringent spindle in human oocytes can predict not only a higher fertilization rate, but also greater embryo developmental competence.[40,43,88] Meiotic spindles can be detected in up to 91% of human metaphase II oocytes at the time of ICSI.[42] Because most oocytes possess spindles, the mere presence of a spindle is of limited value. High degrees of misalignment between the meiotic spindle and the first polar body have been described,[42] probably due to polar body displacement during manipulations for cumulus corona removal.[41] The relative position of the spindle within the oocyte, however, has little influence on the developmental potential of the resulting embryos.[40,42] Whether quantitative spindle analysis (estimating the density of tubules within the spindle) offers added value needs to be seen.[38] So far, spindle imaging, in addition to the appearance of the first polar body, is an accurate indicator of oocyte maturity[37] and can help to determine the timing of ICSI.[39,89] Additionally, meiotic spindle dynamics[89] and possible meiotic spindle destruction due to cryopreservation can be monitored.[41]

Sperm Collection

For microinjection, spermatozoa from three different origins are processed: ejaculated sperm and surgically retrieved sperm from either the epididymis or the testis. For all three categories, ICSI, in combination with sperm cryopreservation, is currently used successfully.[67,90,91] All patients selected for ICSI with ejaculated semen undergo a preliminary semen assessment before treatment to verify whether enough spermatozoa (preferably motile) are present to perform ICSI.

Routinely, sperm samples for ICSI are processed by density-gradient centrifugation (using silane-coated silica particle colloid solutions),[92] enriching the number of motile and morphologically normal sperm cells needed for assisted reproduction. Only in cases of extreme oligozoospermia (i.e., when gradient centrifugation results in an insufficient yield of sperm cells for ICSI) is simple washing of the sperm sample performed to reduce the loss of sperm cells for injection. Immediate injection of the oocytes is then indicated because sperm cells lose their initial motility and often die when the sample is simply washed. This consequence can be attributed to the presence of reactive oxygen species and other damaging substances.[93,94]

During microsurgical epididymal sperm aspiration,[62,95] several sperm fractions are collected into separate tubes. Sperm fractions with similar concentration and motility are pooled, and a density-gradient centrifugation is performed. Microdroplets of the resuspended pellet are placed in separate medium droplets adjacent to a central polyvinylpyrrolidone (PVP) droplet in the injection dish. This facilitates the search for and selection of single motile spermatozoa. Spermatozoa are collected using a testicular sperm extraction pipette, which is larger in diameter than an injection pipette (outer diameter 8 to 10 μm instead of 6 to 7 μm). The spermatozoa are then transferred to the PVP droplet and immobilized before injection. Whenever possible, some of the freshly recovered sperm should be frozen for later use in subsequent ICSI cycles, thereby avoiding the need for repeated surgical procedures.[95]

Testicular biopsy specimens, usually obtained with surgical excisional biopsy,[96] are shredded into small pieces with sterile microscope slides[97] or with fine needles on the heated stage of a stereomicroscope. The presence of spermatozoa is assessed with an inverted microscope, which determines whether the surgical procedure can be stopped or whether extra biopsy specimens must be taken. The pieces of biopsy tissue are removed, and the medium is centrifuged at 300 × *g* for 5 minutes. The pellet is then resuspended for the ICSI procedure. Single motile spermatozoa are collected in a manner similar to that used for epididymal sperm, using separate medium droplets that contain fractions of the testicular sperm suspension. If no sperm cells can be found, the tissue pieces can be treated with red blood cell lysis buffer[98] or an enzymatic collagen digestion medium.[99] Lysis of excess red blood cells may facilitate the search for sperm cells, and the use of enzymes may result in the recovery of otherwise inaccessible sperm cells that are initially attached to the tissue. It is not always possible to retrieve testicular spermatozoa from biopsy specimens in patients with nonobstructive azoospermia due to germ cell aplasia or maturation arrest.[100] When testicular spermatozoa are retrieved under local anesthesia with fine-needle aspiration,[101] the aspirated fractions are immediately collected in the injection dish. No further sample processing, except collecting the single motile spermatozoa with a microneedle (testicular sperm extraction pipette), is needed before ICSI.

Sperm Selection

Pentoxifylline

The goal in any ICSI procedure is to use spermatozoa that are viable. Sperm motility is the best indicator that both the functional (protective) plasma membrane and the metabolical processes are in place. Spermatozoa retrieved from the testis are in a different physiological state than sperm that have been transported through the epididymis. Many times these sperm (fresh or frozen-thawed) have extremely low motility or are immobile making it difficult to identify viable sperm for injection. Sperm motility can be stimulated with a variety of chemicals. One of the most commonly utilized chemicals for stimulating sperm motility is pentoxifylline. Pentoxifylline is a nonspecific inhibitor of phosphodiesterase that has stimulatory effects on sperm motility. The stimulatory effect is attributed to elevated intracellular levels of cyclic adenosine monophosphate (cAMP) via inhibition of its breakdown by cAMP phosphodiesterase. Pentoxifylline is also reported to enhance the acrosome reaction due to the increased levels of cAMP.[59] Overstimulation of sperm with pentoxifylline can induce premature acrosome reaction.[24] Therefore, this chemical should only be used on a limited basis in which no motile sperm can be readily identified.

Hypo-Osmotic Swell Test

In cases where there is an absence of native of stimulated sperm motility, assessment of viability is essential. The hypo-osmotic swell test (HOST) is a simple viability test based on the semi-permeability of the intact and physiologically functional plasma membrane. When sperm are exposed to hypo-osmotic conditions, an influx of water to the sperm tail results in an expansion of the cell volume.[17] Cells that are viable will respond to the osmotic pressure of the external solution by attempting to attain equilibrium with the solution. If the solution is hyper-osmotic, the cell will shrink, if the solution is hypo-osmotic, the cell will swell. When viable sperm are bathed in hypo-osmotic solution, the tails coil and the heads swell within 10 seconds. Nonviable sperm will not undergo these changes. Therefore, this assay is effective in identifying viable non-motile sperm for ICSI use. Exposure of sperm for more than 2 to 5 minutes to a hypo-osmotic solution may be damaging and should be avoided. Once a viable sperm is identified, wash the sperm 2 to 3 times in your handling solution and then move them into the PVP solution before they are used for ICSI. Recently, Stanger and colleagues showed a significant correlation between the HOST score and the degree of DNA fragmentation. They observed the lowest level of DNA fragmentation in the sperm's presenting pattern or grade D or E tail (World Health Organization [WHO] criteria) folding during a HOST.[102] Given the simplicity and low cost of this technique, Stanger and colleagues proposed that this test may provide a method of standardizing the selection of sperm for ICSI.[102]

Morphologically Selected Sperm Injection

Conventional ICSI involves sperm selection at an optical magnification of approximately 400X.[36] However, spermatozoa appearing morphologically normal at this magnification may carry various structural abnormalities at the subcellular level, which then remain undetected by the embryologist. Bartoov and colleagues developed a method to evaluate sperm in real-time at high magnification called *motile sperm organelle morphology examination* (MSOME).[46,47] MSOME is performed on an inverted microscope equipped with Normarski interference contrast optics, which allows observation at high magnification (greater than 6000X).[47] This method led to the development of the intracytoplasmic morphologically selected sperm injection (IMSI) procedure, which is based on sperm normality as defined by MSOME classification. The aim of this technology is to improve ICSI outcomes by selecting against sperm that have abnormalities that are associated with DNA damage.[46,103-110] Numerous studies have demonstrated that IMSI significantly improves fertilization rates,[111] embryo quality,[46,48,50,110] blastocyst development,[112] implantation, and pregnancy after cleavage stage embryo transfers[46,48,49,103,113-115] or at the blastocyst stage.[112] In addition, IMSI has been shown to reduce miscarriage rates.[46,48,49,103,114-117] In small prospective randomized trials in unselected infertile populations, IMSI did not provide significant improvements in clinical outcomes when compared with routine ICSI;[113,118] however, severe male factor patients significantly improved embryo development and implantation with IMSI.[111,113,117,118] Large-scale prospective randomized trials are needed to determine the effects of sperm selection using IMSI.

Hyaluronic Acid–Mediated Sperm Selection

In contrast to visually selected spermatozoa, hyaluronic acid–mediated sperm selection is a novel and efficient technique that may alleviate potential problems related to ICSI fertilization with sperm of diminished maturity.[119-121] Hyaluronic acid (HA) is a high molecular weight glycosaminoglycan and is the main component of the extracellular matrix of the cumulus oophorous. Spermatozoa that are able to permanently bind to HA *in vitro* are mature and have completed the spermiogenetic process of plasma membrane remodeling, cytoplasmic extrusion, and nuclear maturity.[122] Hyaluronan bound (HB) sperm exhibit decreased levels of cytoplasmic inclusions, residual histones, and chromosomal aneuploidy,[121] and an increased expression of the heat shock-related 70 kDa protein 2 (HspA2) chaperone protein.[122] Bound sperm have also been shown to have a high density of HA receptors.[123] In contrast, immature spermatozoa with deficient plasma membrane remodeling are not able to bind to HA as there is a deficiency in the zona and HA binding sites.[123] These unbound and immature sperm have a high retention of creatine kinase, are associated with meiotic defects and possibly higher rates of aneuploidy.[123] Sperm bound to HA have also been shown to have lower levels of DNA fragmentation and have a higher percentage of nuclear normalcy compared to those selected with traditional ICSI techniques.[124] Overall, HB-sperm demonstrate increased developmental maturity and enhanced levels of functional competence over their nonbinding counterparts.

Several studies have demonstrated that the injection of HA-sperm improves fertilization rates[125] embryo quality and implantation capacity,[124,126] while others found no differences in fertilization, pregnancy, and implantation rates.[127] What is clear is that HA-sperm injection has not been shown to cause detrimental effects on ICSI outcome parameters.[128] Large multicenter, prospective, randomized studies are needed to determine if the perceived benefits of

Table 32.1 Methods for Selecting the Best Sperm for ICSI: Advantages and Disadvantages

Sperm Selection	Advantages	Disadvantages
Standard ICSI Selection	Simple and inexpensive Fastest method of sperm selection; reduces manipulation time of oocytes and sperm	Selection of sperm is based on motility and morphology, does not exclude spermatozoa with DNA damage
Morphologically Selected Sperm Injection	May increase implantation and pregnancy rates	Sperm selection can be time consuming Equipment cost can be prohibitive Sperm selection should take place at room temperature to prevent DNA damage
HOST	Simple and inexpensive test Differentiates viable and nonviable sperm May be able to differentiate degree of DNA fragmentation	Time consuming Over exposure of sperm to hypo-osmotic conditions can affect viability Can be difficult to use on frozen/thawed samples
Hyaluronic Acid Binding	Assists in selecting mature sperm with normal morphology Selects sperm with increased DNA integrity May reduce rates of aneuploidy	Difficulty micro-manipulating sperm without using a viscous media Sperm selection can be time consuming Relatively expensive
Sperm Head Birefringence	Selects mature sperm that have undergone the acrosome reaction Helps select sperm with lower DNA fragmentation and have a higher degree of nuclear normalcy May improve Day 3 embryo quality and increase implantation rates	Equipment cost can be prohibitive Sperm selection can be time consuming

selecting "physiological" sperm improve clinical results and if HA should be considered a useful tool for sperm selection (Table 32.1).

ICSI Procedure

For the ICSI procedure itself, an inverted microscope equipped with micromanipulators and microinjectors should be available.[31] Magnification capability of 200X and 400X is a prerequisite for precise procedures such as ICSI. A heating stage on the inverted microscope maintains the temperature at 37° C. Ambient temperature control is of vital importance for the survival of oocytes, which are very sensitive to a decrease in temperature that can cause irreversible damage to the meiotic spindle.[77] Micromanipulators allow three-dimensional manipulation (coarse and fine movements) of the holding and injection pipette on the left-hand and right-hand sides, respectively. Microinjectors are used to either fix or release the oocyte with the holding pipette, or to aspirate and inject a spermatozoon with the injection pipette. The injectors can be filled with air or mineral oil. A micrometer controls the plunger. The whole setup is placed on a vibration-proof table to avoid possible interfering motion. Several companies supply microtools for holding and injection; however, some centers continue to prepare their own microtools, which demands extra effort, time, and specialized equipment.[31]

The ICSI procedure involves the injection of a single immobilized spermatozoon into the oocyte. The procedure is carried out in a plastic microinjection dish containing microdroplets covered with mineral oil. A fraction (±1 μL) of the sperm suspension is added to the periphery of the central PVP droplet. Separate medium droplets are used in cases of epididymal or testicular sperm. The oocytes, denuded from their surrounding cumulus and corona cells, are placed in several surrounding medium droplets. The viscous character of the PVP solution slows the motility of sperm cells, thereby facilitating manipulation. The PVP solution also allows for better control of the fluid in the injection needle and prevents sperm cells from sticking to the pipette.

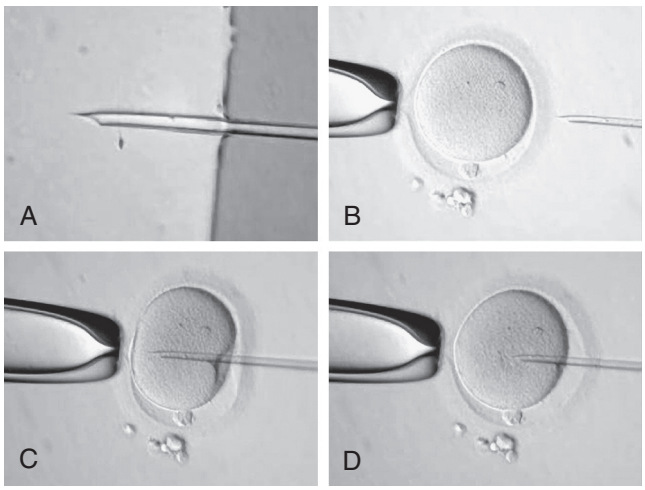

FIGURE 32.2 Intracytoplasmic sperm injection procedure. **A,** A single motile spermatozoon is selected and immobilized by pressing its tail between the microneedle and the bottom of the dish. The sperm cell is then aspirated tail-first into the injection pipette. **B,** Using the holding pipette, the mature oocyte is fixed with the polar body at the 6 o'clock position. The sperm cell is brought to the tip of the injection pipette. **C,** The injection pipette is introduced at the 3 o'clock position and rupture of the oolemma is ascertained by slight suction. Then the sperm cell is delivered into the oocyte with a minimal volume of medium; afterward, the pipette can be carefully withdrawn. **D,** A single sperm cell can be appreciated in the center of the ooplasma.

During ICSI, the following steps can be distinguished: selection and immobilization of a viable sperm cell, correct positioning of the oocyte before injection, and rupture of the oolemma before the release of the sperm cell into the oocyte. Figure 32.2 shows the whole injection procedure. In the injection pipette, which is filled with PVP, a single living, morphologically normal spermatozoon is aspirated. Viability is evidenced by the motility of the sperm cell, even if

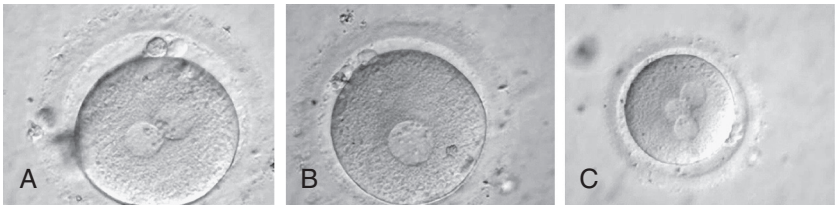

FIGURE 32.3 Fertilization outcome after intracytoplasmic sperm injection. **A,** Oocytes are considered normally fertilized when two individualized or fragmented polar bodies are present, together with two clearly visible pronuclei that contain nucleoli. **B,** Abnormal fertilization may occur as one pronuclear oocyte, probably due to parthenogenic activation. **C,** The occasional finding of three pronuclear oocytes after injection of a single spermatozoon into the ooplasm is probably caused by nonextrusion of the second polar body at the time of fertilization.

it is only a slight twitching of the tail. The sperm cell is then released in a perpendicular position to the injection pipette, which facilitates immobilization. Immobilization of a sperm cell involves rubbing the tail with the pipette against the bottom of the dish, which results in a breakage at one point, preferably below the midpiece. Immobilization of spermatozoa has been proven to be important for oocyte activation, which is achieved by release of sperm cytosolic factors via the ruptured membrane. Increased fertilization rates with ICSI have been reported after aggressive damage to the sperm tail plasma membrane[35,129] especially in the case of testicular or epididymal retrieved sperm. Changes in the sperm plasma membrane and acrosome after immobilization before ICSI have been confirmed by transmission electron microscopy[130] and scanning electron microscopy.[131] Although sperm immobilization is usually performed mechanically with the ICSI needle, laser-induced immobilization has also been described,[132-134] resulting in identical fertilization rates.[132,133]

After immobilization, the sperm cell is again aspirated (now tail-first) to allow the injection of a minimal volume of medium together with the sperm cell. The oocyte is held in position with minimal suction by the holding pipette. The polar body is located at the 6 or 12 o'clock position, which avoids damage to the spindle.[34] Unpublished reports from Palermo's laboratory using Hoechst dye–stained oocytes for microinjection clearly showed no interference with the spindle if oocytes are injected with the polar body at the 6 o'clock position. Although the first polar body does not always coincide with spindle localization, no reports so far describe spindle monitoring during ICSI to reduce spindle damage and increase the chance of fertilization. If both the holding pipette and the oocyte are in perfect focus, the injection needle, containing the immobilized sperm cell near the tip, can be introduced in the equatorial plane of the oocyte at the 3 o'clock position. Permanent focus of the injection pipette tip ensures that the needle remains in the equatorial plane of the oocyte. Passing through the zona pellucida is fairly easy and is achieved by simply advancing the injection pipette. In contrast, the oolemma is not always immediately pierced by simple injection of the needle, and often, minimal suction must be applied. The ooplasm then enters the injection pipette, and sudden acceleration of the flow indicates membrane rupture. Aspiration is immediately stopped, the sperm cell is slowly released into the oocyte with a minimal volume of medium, and the pipette is withdrawn carefully.

Different patterns of oolemma breakage have been described, depending on whether the ooplasm breaks during insertion of the pipette, whether slight or stronger aspiration of the ooplasm is needed, or whether breakage of the oolemma in another place must be attempted.[34,129] Immediate rupture of the oolemma without aspiration has been associated with lower oocyte survival rates.[34,129]

After the injection procedure, oocytes are rinsed and cultured in microdroplets covered with lightweight paraffin oil. The conditions are similar to those used for IVF-inseminated oocytes. The oocytes are kept at 37° C in an atmosphere of 5% O_2, 5% CO_2, and 90% N_2. Injected oocytes are examined for integrity and fertilization approximately 16 to 18 hours after ICSI.[135] An average damage rate of approximately 9% of injected oocytes can be expected, regardless of the origin of the sperm used.[72] Oocytes are considered normally fertilized when two individualized or fragmented polar bodies are present together with two clearly visible pronuclei (2-PN) that contain nucleoli (Fig. 32.3).

The fertilization rate after ICSI is usually expressed per number of injected oocytes and ranges from 57% to 67%, according to the sperm origin.[72] As shown in Figure 32.3, abnormal fertilization may occur, reflected by 1-PN oocytes (approximately 3% of injected oocytes).[72] These oocytes are likely to be parthenogenetically activated as a result of mechanical or chemical factors.[136,137] The occasional finding of 3-PN oocytes (approximately 4%)[72] after injection of a single spermatozoon into the ooplasm is probably caused by failure of extrusion of the second polar body at the time of fertilization.[136] Neither type of embryo resulting from 1-PN or 3-PN oocytes is transferred to patients.

As early as the pronuclear stage, morphological scoring, including alignment and size of pronuclei, alignment and number of nucleoli, and halo effect of the cytoplasm, can serve as a valuable noninvasive selection method in addition to the morphological characteristics on the day of transfer. The morphological features of the pronuclear zygote are related to implantation and pregnancy rates.[138-140] Pronuclear evaluation, therefore, is considered useful in determining the most suitable embryos for transfer, thus achieving an optimal chance of conception.[141,142] Postfertilization, approximately 90% of 2-PN oocytes obtained by ICSI enter cleavage, resulting in multicellular embryos. Cleavage characteristics of the fertilized oocytes are evaluated daily. Early cleavage into the two-cell stage approximately 25 to 27 hours after ICSI seems to be a strong biological indicator of embryonic potential, and may be used as an additional criterion for embryo selection.[143-145]

Normally developing, good-quality embryos reach the four-cell and eight-cell stages, respectively, on day 2 and on the morning of day 3 postmicroinjection (Fig. 32.4). Numbers and sizes of blastomeres and the presence of anucleate cytoplasmic fragments are recorded. The cleaving embryos

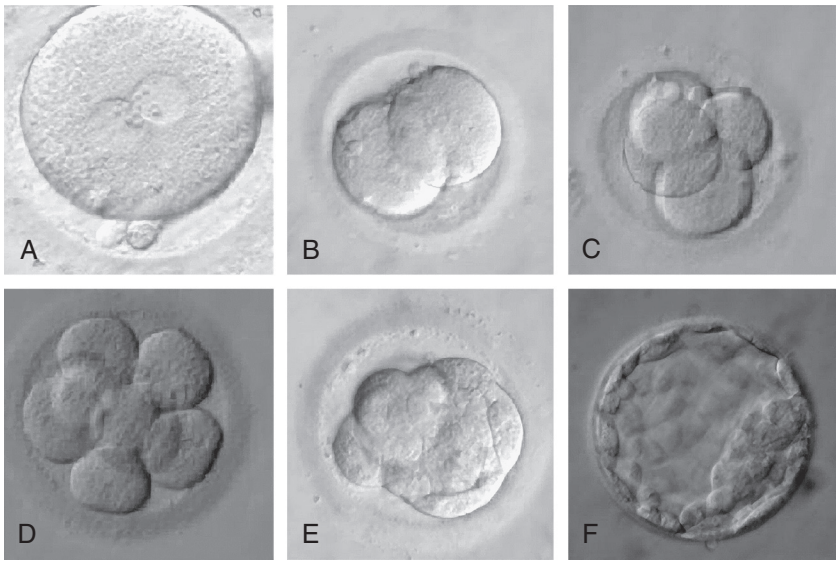

FIGURE 32.4 Embryo cleavage after intracytoplasmic sperm injection. Only embryos resulting from normally fertilized oocytes **(A)** will be transferred to patients. Embryo cleavage is evaluated daily. Two-cell embryos **(B),** four-cell embryos **(C),** and eight-cell embryos **(D)** are usually obtained on day 1 (late afternoon), on day 2, and on the morning of day 3, respectively. The blastomere number is recorded and the embryos are scored according to equality of size of the blastomeres and the presence of anucleate cytoplasmic fragments. On day 4 (sometimes on day 3), a certain degree of compaction can be observed **(E).** For blastocyst **(F)** scoring, the classification system introduced by Gardner and Schoolcraft is used. Embryo transfer is usually done on day 3 (eight-cell stage) or day 5 (blastocyst stage).

are scored according to equality of size of the blastomeres and proportion of anucleate fragments.[146,147] Type A (excellent) embryos do not contain anuclear fragments. Type B (good-quality) embryos have a maximum of 20% of the volume of the embryo filled with anucleate fragments. In type C (fair-quality) embryos, anucleate fragments represent 21% to 50% of the volume of the embryo. Type D (poor-quality) embryos have anucleate fragments present in more than 50% of the volume of the embryo. These embryos cannot be used for transfer to patients. Embryos of types A, B, and C are eligible for transfer. Because embryos with uneven cell cleavage have a lower developmental capacity in comparison with evenly cleaved embryos, emphasis on blastomere size within embryo scoring systems seems appropriate.[148,149] Assessing the degree of compaction is valuable as well because early compaction on day 3 may be associated with increased implantation potential.[150] Multinucleation is a frequently observed phenomenon in cleavage-stage embryos.[151] It may occur as early as the two-cell stage,[152] but has also been observed on days 2 and 3 of preimplantation development.[153,154] Of course, the proportion of multinucleated blastomeres within one embryo is an important parameter. Embryos presenting more than 50% of their blastomeres with multinucleation are not considered for transfer, regardless of the developmental stage at first detection. The presence of one or more multinucleated blastomeres (≤50%) has been associated with impaired cleavage and increased fragmentation,[151] a poor prognosis for blastocyst formation,[154] and reduces the ongoing implantation rate,[151] probably due to chromosomal abnormalities.[155] Excluding these embryos for transfer (if other mononucleated embryos are available) seems prudent practice.

Currently, most centers perform embryo transfers on day 3 after oocyte retrieval. At that time, the embryos are expected to be at the eight-cell stage. Because the embryonic genome is fully activated after the eight-cell stage,[156] it may be beneficial to continue to evaluate embryos at least until after the transition from the maternal to the embryonic genome, making it possible to identify embryos with better developmental potential. The number of embryos transferred depends on the age of the woman and the rank of trial. The only possible strategy to prevent multiple pregnancies in IVF and ICSI is to transfer a single embryo, especially in young women in their first or second attempt.[157-161] In women older than 36 years of age who are undergoing a first or second ICSI attempt, the preference is to transfer two excellent or good-quality embryos. In other cases, three or more embryos may be placed into the uterus. Higher pregnancy rates can be obtained when elective transfer of two or three embryos is possible.[72,162]

Advancements in commercially available culture media allow the culture of human embryos up to the blastocyst stage (day 5 or day 6).[163-166] On day 4 (sometimes on day 3), a certain degree of compaction can be observed. Compaction in the mammalian pre-embryo is a fundamental event that leads to the formation of the trophectoderm, the inner cell mass, and the blastocoele. Full compaction (16-cell to 32-cell stage) is followed by immediate cavitation and blastocoele expansion.[167] For blastocyst scoring, the classification system introduced by Gardner and colleagues can be used.[168] A distinction between early and expanded blastocysts is made, and the latter category is further scored according to the quality of the inner cell mass and the trophectoderm. The possibility of prolonged human embryo culture allows for day 5 or blastocyst transfers. Preferably, expanded blastocysts with a cohesive trophectoderm and a clear inner cell mass are transferred.

Possible advantages of blastocyst transfer are better embryo selection and better synchronization between embryo and endometrium, which may result in higher implantation rates per blastocyst transferred.[169,170] This, in turn, would allow transfer of fewer embryos, thereby decreasing the number of multiple pregnancies.[171-173] However, the superiority of blastocyst transfer over early embryo transfer remains to be proven. A limited number of randomized controlled studies are available. Some show the benefit of blastocyst transfer, whereas others show no advantage of day 5 transfers over day 3 transfers.[170-181] A recent Cochrane review examined the differences in live birth rates between cleavage and blastocyst stage embryo transfer. This extensive review of 23 randomized controlled trials (RCTs) demonstrated that there is a small significant difference in live

birth rates in favor of blastocyst transfer (day 5 or 6) compared to cleavage stage transfer (day 2 or 3).[182] However, it was found that the cumulative clinical pregnancy rates from cleavage (derived from fresh and thawed cycles) resulted in higher clinical pregnancy rates than from blastocyst cycles. The authors point out that this is most likely due to the higher rates of freezing and lower failure to transfer rates in the cleavage-stage transfer protocols.[182]

The cumulative success of a single embryo transfer policy, either on day 3 or on day 5, depends on a good cryopreservation program of cleavage-stage embryos or blastocysts. Supernumerary embryos with less than 20% of anucleate fragments (types A and B) can be cryopreserved on day 2 or day 3 after oocyte retrieval by means of a slow-freezing protocol with dimethylsulfoxide.[183] Alternatively, embryos can be frozen at the blastocyst stage on day 5 or day 6, with glycerol and sucrose used as cryoprotectant agents[184] or vitrified using ethylene glycol.[185-188]

Assisted Hatching

It is generally accepted that human embryos generated by IVF have a low implantation potential: a 10% to 15% rate of implantation per embryo is routinely reported in the literature.[189] Some researchers have suggested that premature transfer of the human embryo into the uterus may account for these low implantation rates. Data on the transfer of human cavitating morulae or blastocysts on day 4 or day 5 of development indicate that such embryos have a higher implantation rate.[169,190] In the case of blastocysts, implantation rates that are twice those of cleavage-stage embryos have been reported.[170] However, many cleavage-stage embryos do not reach the blastocyst stage in *in vitro* culture conditions, and it is not clear how many of these embryos would have implanted had they been transferred at the cleavage stage.[191]

Consequently, a remaining challenge in assisted reproduction is to overcome the obstacle of low implantation rates. Several factors, apart from synchronization between the endometrium and replaced embryos, are responsible. On one hand, endometrial receptivity is a factor in successful embryo implantation,[192] on the other hand, two embryonic factors play a major role in the implantation process. First, implantation failure may result from developmental arrest due to aneuploidy observed in human preimplantation embryos.[193,194] PGS programs, especially in older patients, have been proposed and are undertaken to address this issue (described in more detail later). Second, to implant, the preimplantation embryo must escape from its zona pellucida by means of a process called *hatching*. Following fertilization, the main function of the zona is protection of the embryo and the maintenance of its integrity.[195]

Developing embryos show a gradual thinning of the zona pellucida during culture. The mammalian late blastocyst both expands and thins its zona pellucida through alternating expansion and contraction.[196] Intrinsic processes allowing this thinning before successful hatching include pressure of the blastocyst as it expands against the zona and a lytic mechanism mediated by zona lysins.[197-199] Finally, the zona pellucida ruptures, allowing the embryo to hatch and implant itself into the endometrium.

An important observation leading to the clinical introduction of assisted hatching was the finding that there were higher implantation rates from embryos that were fertilized using microsurgical techniques.[200] In addition, it was observed that cleaved embryos with thinner zonae had higher implantation rates then those with thick zona pellucidas.[201] Many embryos may not succeed in hatching from the zona for different reasons. A naturally thick zona pellucida or hardening of the zona pellucida due to prolonged (suboptimal) *in vitro* culture conditions may interfere with (and prevent) the natural hatching process,[7] leading to implantation failure. Suboptimal culture conditions may cause trophectoderm lysin production to fall below the threshold level needed to promote zona thinning before successful hatching and subsequent implantation.[199] Alternatively, intrinsic lysin production failure unrelated to culture conditions may inhibit normal hatching.[199]

To overcome hatching failure, three different micromanipulation procedures (mechanical, chemical, and laser-induced hatching) have been used to produce holes in the zona pellucida of cleavage-stage embryos or to thin the zona pellucida superficially. Partial zona dissection (PZD) is a form of mechanical hatching that was developed to create an artificial opening of the zona pellucida of early cleaved embryos.[6] This technique is performed by stabilizing the embryo with a holding pipette, while the zona is pierced with a microneedle that is pushed tangentially through the space between the zona pellucida and blastomeres until it pierces the zona again. This spearing leaves a small part of the zona trapped against the microneedle. Rubbing this part of the zona against a holding pipette leaves a narrow incision in the zona. The mechanism of PZD is quick to perform; however, it produces holes of variable sizes that may not always be optimal.[202] A modification of PZD has been described where a second cut is made in the zona below the first cut at a right angle. This leaves a cross-shaped hole on the surface of the zona pellucida (3D-PZD).[203] This technique allows for the creation of a larger opening while maintaining the protection of the zona flaps during embryo transfer.

Chemical-assisted hatching involves the use of acidic Tyrode solution (pH 2.35) to "drill" the zona pellucida.[7] A micro-needle filled with acidic Tyrode solution is used to produce an opening at the 3 o'clock position, facing either empty perivitelline space or extracellular anucleate fragments. The acidic solution is expelled gently over a small area (30 μm), with the tip of the needle held very close to the zona until an opening is obtained. The mean diameter of the gap thus created is 20 ± 6.7 μm (range, 10-36 μm). It should be noted that the acidic Tyrode solution is embryotoxic and may alter the viability of the embryos.

Chemical-assisted hatching may be carried out with extracellular fragment removal.[204,205] However, the real benefit of this procedure must be shown in controlled randomized studies, which are lacking. Cruciate thinning of the zona pellucida using acidic Tyrode solution has been described, but chemical removal of the outside of the zona pellucida of day 3 human embryos has no effect on the implantation rate,[206] whereas the creation of a hole in the zona pellucida has been shown to increase embryo implantation.[7] The limiting factor for successful hatching is, therefore, not the overall thickness, but the resilience of the thin inner layer of the double-layered human zona pellucida.[206]

Table 32.2 Embryo Biopsy Methods: Advantages and Disadvantages

Hatching Methods	Advantages	Disadvantages
Mechanical	There are no effects of chemicals or heat during the drilling procedure Has not been shown to negatively affect fertilization or embryo development Inexpensive	Requires a double tool holder Time consuming Requires high technical skill PZD openings can be narrow and can induce more trauma to blastomeres during biopsy as well as lower hatching rates
Chemical	The size of the hole in the zona pellucida can be increased, which may enhance hatching Relatively inexpensive	Requires a double tool holder Difficult to regulate hole size Acid Tyrodes can be toxic and can change intracellular pH leading to cytoplasmic degeneration
Laser	No need for disposable micropipettes Consistent results and hole sizes Lower degree of blastomere lysis compared with acid Tyrodes Fast and easy to perform	Increased exposure time can damage embryo Equipment cost can be prohibitive Laser drilling creates an aperture in the shape of a groove which can cause constriction of the blastomere and result in lysis

More recently, laser-assisted zona pellucida drilling has been introduced and has been shown to be a suitable alternative to the use of acidic Tyrode's solution for zona drilling.[207,208] Several types of laser sources have been investigated. In a most convenient setup, the laser beam is guided through an optical lens and focused on the biological specimen. There is no need for holding and cutting tools. Lasers with different wavelengths have been proposed to operate in this no touch mode; however, infrared radiation is the most appropriate, especially when mutagenic risks are taken into account. The 1.48-μm diode laser allows rapid, precise, and easily controlled lysis of the zona pellucida.[209-212] The size of the hole can be chosen by varying the irradiation time; typically, a hole with a diameter of 20 μm is produced within 12 to 30 msec irradiation time. Larger diameter holes are obtained by increasing the irradiation time.

Piezo technology, an alternative to laser technology, also produces a precise and controllable defect in the zona, without chemicals that are potentially embryotoxic.[213] The vibration produced by the piezoelectric pulse is used for the assisted hatching. The zona pellucida is carved easily in a limited area that is conical and approximately 30 μm in diameter. Five to eight applications in adjacent areas are needed to treat approximately one third of the visible circumference of the zona pellucida. Thereafter, weaker vibrations are used to create an opening 20 μm in diameter in the thinned zona at the junction between blastomeres (Table 32.2).

Assisted hatching techniques, designed to facilitate embryo escape from the zona, have been used in IVF centers since 1992. The initial indications for assisted hatching were patient age, zona thickness, high basal FSH value, and repeated IVF failure. Several retrospective and prospective studies assessing assisted hatching in these cases have given disparate results. Therefore, the clinical relevance of assisted hatching in cleavage-stage embryos within an assisted reproduction program is heavily debated. Some of the controversy may be due to the different methods used for assisted hatching and, consequently, the irreproducibility of the hole sizes obtained. Patient selection may also be an important origin of conflicting findings. Moreover, many studies are uncontrolled and retrospective. In summarizing the existing randomized studies, several conclusions can be drawn.

Assisted hatching might be beneficial in women with a poor prognosis for IVF or ICSI, particularly those with repeated implantation failure.[214-218] However, there remains conflicting evidence of an age-related benefit of assisted hatching in patients with advanced maternal age.[219,220] In an unselected population of patients, assisted hatching did not increase pregnancy and implantation rates.[221-224] A recent meta-analysis that included randomized controlled trials of assisted hatching versus no assisted hatching and reported live births, clinical pregnancies, or implantation rates, concluded that there is some evidence that assisted hatching may increase the chance of pregnancy beginning in women for whom IVF has been repeatedly unsuccessful, and possibly in older women.[218]

There has been tremendous interest in improving the results of assisted reproduction through transfer of blastocysts after extended culture. Although human blastocysts expand readily *in vitro*, most blastocysts have hatching problems or cannot completely hatch out of the zona, and subsequently degenerate by day 6 or day 7. If the zona is softened enzymatically and zona-free blastocysts can be replaced, better cell–cell interactions and anchoring of the embryo to the endometrium may be expected, hopefully with improved implantation rates, reduced embryonic losses, and fewer embryos replaced.[225] Before transfer, blastocysts are exposed to pronase (10 IU at 37° C) for no longer than 90 seconds, which is the optimal time for softening or complete removal of the zona.[226]

The safety of this procedure was evaluated by light microscopy and transmission electron microscopy, showing that the human embryonic trophectoderm is a very hardy, robust epithelium that withstands pronase treatment.[226] Initial reports are promising, in that improved pregnancy and implantation results were shown with zona-free blastocyst transfers.[225,227-229] In the first randomized controlled study,[230] no statistically significant differences were found in clinical pregnancy, ongoing pregnancy, and implantation rates between zona-intact, blastocyst-stage transfers and zona-manipulated (enzymatic treatment), blastocyst-stage transfers. However, further studies with larger groups of patients are needed to clarify the real effect of this zona manipulation on pregnancy outcome. Whether a possible benefit may be differential for good-quality or poor-quality blastocysts, as reported by Urman and colleagues[231] must also be confirmed.

It is well known that the implantation potential of a frozen/vitrified-thawed/warmed embryo is lower than a fresh embryo. It is thought that the process of cryopreservation

may damage the embryo and cause the zona pellucida to harden, thus preventing the hatching and subsequent implantation from occurring. Several randomized studies investigating the clinical benefit of assisted hatching in cryopreservation cycles have shown both clinical benefits of assisted hatching[232-235] while other groups have shown no effect on implantation rates per embryo transferred.[236-240] A Cochrane database[218] on the effect of assisted hatching (AH) on frozen-thawed embryos including data from four randomized trials showed a significant improvement on the clinical pregnancy rate of frozen embryo transfer cycles; however, there was no evidence that assisted hatching had any effect on live birth rates.[218]

Embryo Biopsy

In 1990, preimplantation genetic diagnosis (PGD) was introduced as a method to genetically screen human embryos during an IVF cycle.[15] These procedures allow us to help couples who are at risk of transmitting inherited diseases to their children and more recently to improve pregnancy rates for certain groups of IVF patients. Genetic analysis of preimplantation developmental stages before transfer into the uterus inevitably involves removal of some cellular material at one of these stages. There are three different sources of genetic material potentially available for PGD: polar bodies from the initial conception, blastomeres from early cleaving embryos, and trophectoderm cells from embryos reaching the blastocyst stage.

Polar Body Biopsy

Polar bodies are byproducts of meiosis and have no biological role in fertilization or in embryo development. Therefore, removal of either the first or second polar body or both for the purpose of genetic testing should not have any deleterious effect on developing embryos. Genetic analysis of the first polar body was first performed by Verlinsky and colleagues[9] and has since been used to successfully screen for maternal mutations in cases of many single-gene defects.[241-246]

Polar body analysis is an indirect method in which the genotype or chromosomal constitution of the oocyte is derived from the complement present in the polar bodies. One challenge associated with polar body chromosome analysis is related to making the decision to discard oocytes with aneuploid polar bodies or based on the aneuploidy of the first polar body.[247] It is thought that both first and second maternal meiotic errors can be excluded only if information on the two polar bodies is obtained.[248] In a recent preclinical study, the ESHRE PGS Task Force aCGH data indicated that 4% of aneuploid polar bodies resulted in euploid zygotes.[249] Recently, Scott and colleagues reported the birth of a chromosomally normal child resulting from an oocyte with reciprocal aneuploid polar bodies.[250] Results from these reports challenge the idea of using polar bodies alone for aneuploid screening. These studies suggest performing aneuploid testing on the developing embryo for more definitive results.

A major limitation of polar body analysis is that only the maternal genetic contribution to the future embryo can be evaluated. This eliminates the possibility of determining the sex of the embryo. In addition, diseases that are detected by assessing changes in gene products are not candidates for this biopsy method. For single-gene disorders, occasional recombination of homologous chromosomes also requires information on both polar bodies. High accuracy in PGD of single-gene disorders can be achieved by application of sequential analysis of the first and second polar bodies in combination with multiplex PCR to detect possible allele dropout and contamination.[251,252] This process is very labor intensive.

The first polar body can be removed from the oocyte on the day of the oocyte collection between 36 and 42 hours after injection of hCG, as long as the oocyte has extruded the first polar body.[9] The second polar body can be removed from the zygote between 18 and 22 hours postinsemination. It is not recommended that both the first and second polar bodies be removed simultaneously as the first polar body may have degenerated by this time, leading to possible diagnostic errors. There are several ways to biopsy polar bodies. The most common method is by mechanical means. A beveled pipette (12 to 15 μm in diameter) can be used for mechanical perforation of the zona pellucida, and once inside the perivitelline space, the polar body can be drawn out by aspiration into the pipette.[243] If the polar body is still attached to the ooplasm, additional incubation may be required to permit complete extrusion.[9] In addition, it has been shown that the use of a laser for biopsy was safe and equivalent regarding the development of blastocysts compared with no biopsy.[253,254] Montag and colleagues also demonstrated equivalent results when comparing laser and standard zona drilling.[255] The use of acid Tyrodes for polar body biopsy should be avoided. Studies using human oocytes showed that, despite fertilization, there is an inhibitory effect on embryo development.[5] This is thought to be primarily due to the direct effect of acid on the oocyte spindle.

Cleavage Stage Biopsy

It seems essential to determine the developmental stage, to allow maximum retrieval of cells at biopsy with minimum reduction in the pregnancy potential of the embryos after the procedure. In humans, one of the best times to perform embryo biopsy is at the eight-cell stage, which is normally on the morning of day 3. At this stage, all of the cells are still totipotent (as confirmed by lineage tracing)[256] and the embryos are not yet compacting. It is believed that allocation to the two lineages of the blastocyst is initiated in the early eight-cell stage. Cells then become polarized at both the membrane and cytoplasmic levels.

It appears that removal of cells after the initiation of polarization does not compromise allocation to the inner cell mass.[257] However, cellular totipotency wanes with further embryonic development and may not be an all-or-none property (i.e., sister blastomeres could express it to different degrees).[258] Blastomeres of cleaving mammalian embryos can replace the loss of one or two blastomeres; this property presumably lasts, whereas blastomeres are allocated to, but not committed to, specific pathways. Apart from the reduction in cellular mass, the development of human embryos to the blastocyst stage *in vitro* is unaffected by biopsy and removal of one cell at the eight-cell stage.[259] This means

that up to one eighth of the embryo can be removed without impairment of its further *in vitro* development. Similar results were obtained in a mouse model.[260]

When Handyside and colleagues[15] reported the first pregnancies from the clinical application of PGD, it became clear that *in vivo* development was not impaired by the biopsy procedure either. In 1994, 32 pregnancies worldwide were reported after all types of preimplantation diagnosis using cleavage-stage biopsy, with 29 infants born and no evidence of adverse effects on development.[261] Moreover, it became evident that pregnancy rates after PGD were comparable to those obtained after standard IVF.[262,263]

Despite the reassuring clinical results so far, however, the discussion remains as to whether the removal of two cells from a seven-cell–stage embryo (or larger) reduces its capacity to implant more than if only one cell were removed.[264] A recent randomized controlled trial showed that removal of two blastomeres significantly decreases the likelihood of blastocyst formation compared with removal of one blastomere, although this did not translate into a significant difference in implantation rate (23.5% versus 17.3% for one-cell and two-cell biopsy, respectively, $P = 0.216$).[265] Taking live births per started cycle as an end point of this study (including 592 biopsy cycles), no significant difference was obtained between one-cell (20.2%) and two-cell biopsy (17.2%, $P = 0.358$). The recommendation is the removal of only one blastomere, provided that diagnostic safety measures are in place to ensure a correct diagnosis on one cell. If these are not available, two cells are needed for diagnosis.

One possible way to estimate the effect of removing blastomeres from cleavage stage embryos can be derived from experience with cryopreservation at the cleavage stage and associated cell loss.[266] It has been shown that the loss of viability after freezing is proportional to the number of blastomeres that lyse during the freezing and thawing process.[267,268] For example, if the expected implantation is 15%, then the loss of one blastomere from an 8-cell embryo would result in an implantation equal to $\frac{7}{8} \times 15 = 13.1\%$. Likewise, the removal of 2 blastomeres from the same embryo would result in an implantation equal to $\frac{6}{8} \times 15 = 11.3\%$.

Currently, cleavage stage embryo biopsy is the most widely practiced form of embryo biopsy worldwide, accounting for around 90% of all reported PGD cycles.[269,270] The latest ESHRE PGD Consortium reported the efficiency of successful embryo biopsy was 98% in over 70,000 cleavage stage embryos in clinical PGD cycles.[269]

Blastocyst Stage Biopsy

The advantage of biopsy at later developmental stages, such as the morula or blastocyst stage, is that relatively more cells can be collected than with biopsy at earlier developmental stages. However, the morula stage is an inappropriate stage for embryo biopsy because of extensive compaction, which occurs at the 16-cell to 32-cell stage in human embryos.[167] The blastocyst stage, on the other hand, offers the advantage that extra embryonic trophectoderm cells can be removed, leaving the inner cell mass (representing the future fetus) fully intact. The ability to biopsy more genetic material has been shown to reduce the risk of amplification failure and allele dropout (ADO).[271] Kokkali and colleagues prospectively compared genotyping success and implantation rates in PGD cycles after the biopsy of cleavage and blastocyst stage embryos.[271] The results of this study show a marked improvement in the successful genotyping of embryos biopsied at the blastocyst stage compared to those biopsied at the cleavage stage (94% versus 75%).[271] This study did not show any differences in the implantation potential of embryos biopsied at either stage.[271] In a more recent paired prospective trial using microarray-based DNA fingerprinting[272] to track the outcome of transferred embryos showed that cleavage-stage biopsy reduces the reproductive potential of embryos whereas biopsy of the trophectoderm does not.[273] In this study there was a significant reduction in implantation rates of biopsied cleavage-stage embryos compared with nonbiopsied controls (31% versus 54%, respectively). In contrast, implantation rates after trophectoderm biopsy were equivalent (52% versus 54%).[273]

A major limitation of PGD at the blastocyst stage is our lack of knowledge of whether the trophectoderm cells are representative of the embryo proper. The degree of blastocyst mosaicism seems lower than in cleavage-stage embryos[274,275]; however, no evidence exists to support the hypothesis of a preferential allocation of euploid cells to the inner cell mass and aneuploid cells to the trophectoderm.[274,276] No single study has compared the genetic constitution of the trophectoderm and that of the inner cell mass of single human blastocysts, which could finally help to clarify the uncertainty about the representation of a trophectoderm cell sample. Another disadvantage of blastocyst biopsy is the time limitation to obtain the diagnostic result if a fresh transfer is attempted. This might necessitate cryopreservation of biopsied blastocysts for transfer in a later unstimulated thaw cycle (Table 32.3).

Embryo Biopsy Procedures

According to the developmental stage, three different biopsy procedures have been well established: polar body removal from oocytes and zygotes, cleavage-stage embryo biopsy, and biopsy at the blastocyst stage (reviewed in De Vos and Van Steirteghem).[277] The biopsy procedure always involves two steps: opening of the zona pellucida and removal of the cellular material. Opening of the zona pellucida can be done in three ways:

1. Mechanically by direct puncture,[243] conventional PZD,[278,279] or three-dimensional PZD[203]
2. Chemically, using acidic Tyrode's solution[280]
3. Laser technology[210,211,281]

Polar body removal has, so far, been primarily linked with mechanical opening of the zona pellucida.[243] Cleavage-stage biopsy mainly involves the use of acidic Tyrode's solution or drilling or laser opening of the zona pellucida[16]; for blastocyst biopsy, both mechanical PZD[282] and laser drilling[283] have been described. Removal of polar bodies and biopsy of blastomeres is performed mainly by aspiration.[243] Extraembryonic trophectoderm cells are often removed by needle dissection at the moment of herniation through the slit created in the zona pellucida.[282,283] Animal models have been used to evaluate the efficacy and safety of most, if not all, of these procedures. Experimental work with human embryos donated for research has confirmed the feasibility and

Table 32.3 Preimplantation Genetic Diagnosis Biopsy at Different Developmental Stages: Advantages and Disadvantages

Developmental Stage	Advantages	Disadvantages
Polar Body	Considered ethically acceptable in many countries The 1st and 2nd polar body are not required for embryo development Increased time to perform diagnosis	Increased risk of oocyte lysis Can only be applied to maternally inherited diseases Requires sequential manipulations Gender determination not possible Increased risk of misdiagnosis compared to cleavage stage embryos
Cleavage Stage	Diagnosis of maternally and paternally inherited diseases Gender determination possible 95% of embryo cohort available for analysis Removal of 1-2 cells still results in viable development	Chromosomal mosaicism compromises accuracy Blastomere selection is critical Single cell sensitive analysis required Possible selected cell allocation to TE/ICM Reduced embryo implantation potential
Blastocyst Stage	Embryo quality is preselected Biopsy of TE cells more ethically acceptable More cells available for biopsy Increased amplification efficiency Decreased chance of misdiagnosis	Fewer embryos to biopsy Embryos must be extended in culture May require multiple manipulations There is a very limited time to perform diagnosis May require embryos to be cryopreserved and transferred at a future cycle

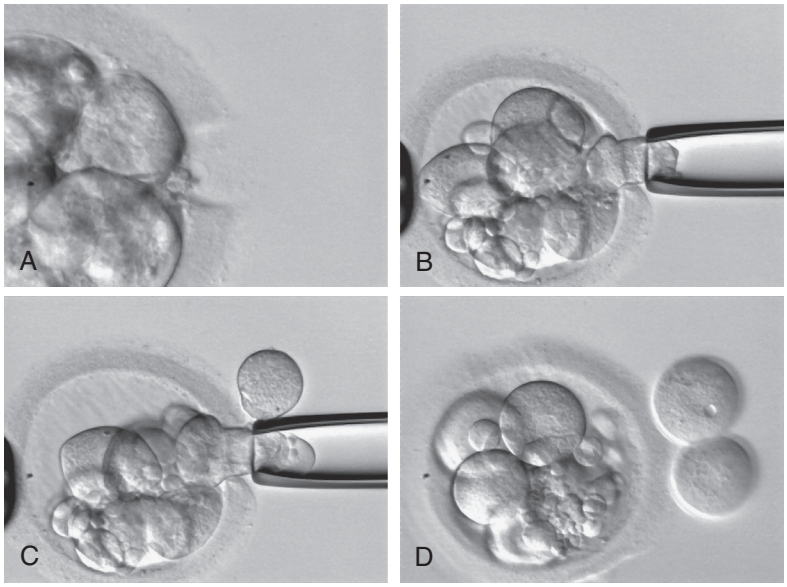

FIGURE 32.5 Cleavage-stage embryo biopsy. **A,** Laser-assisted zona drilling results in an opening in the zona pellucida with an average size of 20 to 30 μm. **B,** A biopsy pipette is introduced through the hole and a first blastomere is aspirated. **C,** Aspiration of a second blastomere can be done in a similar way. **D,** Preferentially, blastomeres with a clearly visible nucleus are aspirated.

efficacy of the procedures; however, safety evaluation has been limited to *in vitro* development.

Cleavage-stage biopsy remains the main approach to the removal of genomic DNA for genetic analysis at preimplantation stages.[15,270,284] Cleavage-stage biopsy is performed in the morning of day 3 after oocyte retrieval (Fig. 32.5). Unfortunately, not all human embryos reach the seven-cell or eight-cell stage by that time. Six-cell–stage embryos may, therefore, be included for one- or two-cell removal, although they are suspected of being of inferior quality because of delayed cleavage.[285]

At the moment of oocyte denudation, care is taken to remove all of the remaining cumulus and corona cells, which can also represent a source of DNA contamination. Chemical zona drilling, followed by blastomere aspiration, is normally done with separate pipettes, using a double-holder setup: one drilling pipette with an inner diameter of approximately 5 to 7 μm and one aspiration or biopsy pipette with an inner diameter of 35 to 40 μm. The target site for drilling is chosen between two blastomeres or in front of anucleate fragments to minimize the deleterious effect of the acidic medium on the cells. Zona drilling for embryo biopsy[280] is not different from the zona drilling technique described earlier for assisted hatching.[7]

Chemical zona drilling is in itself an extremely simple procedure in terms of equipment, but some technical skill may be required when exposing the embryo to an acidified solution. The opening should be of appropriate size, while limiting the extent and duration of exposure of the embryo. The mean diameter of the gap thus created is approximately 20 μm (range, 10 to 36 μm).[7] The rate of dissolution of the zona may vary, and the time taken to complete this process varies accordingly (30 seconds to 2 minutes). Acidic drilling, despite its toxicity and cytoplasmic acidification, is considered safe on the basis of the pregnancies and births reported in the literature.[16]

As an alternative to chemical zona opening, laser-assisted zona pellucida drilling has been introduced for cleavage-stage biopsy[281] (which is similar to the laser drilling technique previously described for assisted hatching). Using the X-Y

microscope stage, the embryo is positioned to place a region of the zona pellucida on the aiming spot. Typically, a trench-like hole with a diameter of 5 to 10 µm is produced in 10 to 15 msec.[211] For embryo biopsy, on average, two to three pulses of 7 msec are applied, resulting in 20 to 30 µm openings. It is important to perforate the zona completely without harming the embryonic cells with the laser. The holes obtained with a laser are more precise than the ones obtained with acidic Tyrode solution. Laser zona opening results in more intact blastomeres compared with the use of acidic Tyrode solution, and because similar pregnancy rates were obtained, it seems advantageous to use a laser for zona drilling.[286]

Blastomere Removal

Blastomere removal involves the introduction of the biopsy pipette into the perivitelline space through the hole in the zona, allowing one or two blastomeres to be removed by gentle aspiration. Cells can be aspirated completely and then removed; alternatively, cells are only partially aspirated and pulled out (given full decompaction and thus no adherence to other blastomeres). Whereas full compaction does not occur before the 16- to 32-cell stage,[167] relatively early assembly of tight junctions occurs between human blastomeres, as shown by ultrastructural studies.[287,288] Because of these membrane adhesions, the biopsy procedure at the seven-cell to eight-cell stage may be difficult to perform because the blastomeres show a strong tendency to adhere to each other. Manipulating the embryos as such may result in a high lysis rate of cells.

A calcium- and magnesium-free medium has been used to loosen the membrane adhesions between blastomeres,[289,290] which allows easier removal of cells and results in less lysis. Embryo biopsy can be performed completely in this medium or, to limit exposure time, embryos can be preincubated for 5 to 10 minutes (normally sufficient for full decompaction) before biopsy in calcium- and magnesium-containing medium. Whether the implantation rate or postimplantation development is affected by the use of calcium- and magnesium-free medium for biopsy remains to be assessed. Therefore, the long-term safety of its clinical application should be further substantiated.

Cleavage stage embryo biopsy offers the advantage of choice of cells to biopsy whereas polar body and blastocyst stage biopsy do not. When selecting the blastomere to biopsy, it is critical to select cells with visible nuclei. Visualization of nuclei can be difficult when cells overlap each other or when the cytoplasm is granular or pitted. However, under high magnification most nuclei should be discernable. Visualization of the nucleus will greatly reduce the risk of biopsying large anucleate fragments. It is also advisable to select the smaller blastomeres for biopsy. The small size indicates that the cell has undergone its mitotic division. Large blastomeres may not have undergone mitotic division or could be in the process of cytokinesis. Biopsying of large cells will greatly reduce the mass of the embryo and reduce to subsequent developmental viability of the embryo. Furthermore, larger cells are at higher risks of being in metaphase which in turn may make the chromosomes more prone to loss during fixation. Finally, multinucleated blastomeres should be avoided during biopsy as they are likely to result in unclear diagnoses.

Trophectoderm Biopsy

With the improvements in embryo culture, blastocyst conversion and high success rates with blastocyst vitrification, an increasing number of labs are performing blastocyst-stage biopsy. The human blastocyst, depending upon developmental stage, can contain more than 100 cells. As such, the biopsy of 6 to 10 cells from the outer layer of the trophectoderm is less likely to have a detrimental effect on the blastocyst's mass of the developing fetus which originates from the inner cell mass (ICM).[282,283,291] The technique of zona slitting (similar to partial zona dissection) can be used to open the zona pellucida with a microneedle.[282] The blastocyst zona can also be opened using a laser.[283] In both cases, care must be taken to avoid touching the trophectoderm cells, and the slit or opening is made opposite the inner cell mass. After definite herniation, trophectoderm cell removal is performed by excision using a glass needle[282,292] or laser energy.[283] Serial biopsy specimens can even be taken from the same blastocyst[293,294] to maximize the number of cells available for PCR or FISH analysis. Several recent studies report promising clinical results with trophectoderm biopsy.[271,295,296]

Preimplantation Genetic Testing

Preimplantation genetic testing (PGT) includes preimplantation genetic diagnosis (PGD) performed for monogenic diseases and translocations, as well as preimplantation genetic screening (PGS) for aneuploid screening. The PGT procedure is a very early form of prenatal diagnosis for patients with a preexisting genetic risk. Oocytes or embryos obtained *in vitro* through assisted reproductive techniques, in particular, ICSI, undergo biopsy and the cells obtained (polar bodies, blastomeres, or trophectoderm cells) are used for genetic diagnosis. In principle, the indications for PGT are similar to those for prenatal diagnosis after chorionic villus sampling or amniocentesis, given that PGT at the single-cell level is technically possible. The main reasons for PGT (in addition to the genetic risk) are previous termination of pregnancy and objection to pregnancy termination. The genetic risk can also be combined with subfertility or infertility.

Preimplantation Genetic Diagnosis

The PGD procedure is used for couples at risk for monogenic disorders. Three disease groups can be distinguished according to the mode of inheritance: X-linked disorders (e.g., Duchenne and Becker muscular dystrophy, fragile X syndrome, hemophilia); autosomal recessive disorders (e.g., cystic fibrosis, thalassemia, spinal muscular atrophy, sickle cell anaemia); and autosomal dominant disorders (e.g., myotonic dystrophy, Huntington disease, Charcot-Marie-Tooth disease, Marfan syndrome).[16] Several laboratories offer patients custom-made PGD tests for monogenic disease, so the exact number of indications for which PGD is offered would be difficult to establish. A prerequisite for PGD is that the mutation is known or otherwise can be analyzed through linked markers. Appropriate primer sets are designed and tested on genomic DNA of the couple and family members. Lymphoblasts of the couple or an affected child allow determination of the amplification efficiency as

well as the contamination and allele dropout rate for each PCR protocol.

More recently, combined PGD and human leukocyte antigen (HLA) matching has been reported,[297] representing a novel way to preselect an unaffected potential donor for an affected sibling requiring stem cell transplantation. Transplantation of hematopoietic stem cells from an HLA-identical sibling donor may be the best treatment option for children with neoplastic and congenital diseases affecting hematopoiesis, such as Fanconi anemia,[298] leukemia, Wiskott-Aldrich syndrome, and β-thalassemia. Cord blood collected at birth is an established source of hematopoietic stem cells. In contrast to individual establishment of protocols for each requesting couple, indirect HLA typing using markers evenly distributed in the HLA polymorphic region is a more elegant and time-saving approach.[299]

The PCR procedure involves exponential amplification of short DNA fragments using two short, single-stranded DNA pieces (primers) that are complementary to the boundaries of the sequence to be amplified. A standard PCR protocol involves 20 to 45 cycles of repeated denaturation (of the double-stranded template DNA) at high temperature, annealing (of the primers to the template DNA) at a lower temperature, and elongation using Taq DNA polymerase. PCR allows analysis of the genetic content of a single cell.[300] In PGD, DNA amplification is used to detect single-gene defects (so-called *monogenic diseases*).

However, PCR protocols are subject to a variety of pitfalls, such as variable amplification efficiency, contamination, and allele dropout.[301] Fluorescent single-cell PCR has not only a higher sensitivity, but also a higher resolution.[12,302] Different measures are taken to avoid or at least detect contamination from genomic DNA (patient or operator) or carry-over contamination (from PCR products amplified earlier).[303] To show contaminating DNA, an increasing number of PCR-based tests now include amplification of hypervariable fragments of DNA in addition to the loci used for diagnosis. These hypervariable polymorphisms are essentially the same as those used for DNA fingerprinting. The presence of more than the expected two alleles indicates contamination (either from an external source or from parental origin). Contamination with parental DNA can occur as a result of inadvertent sampling of a sperm or cumulus cell at the time of embryo biopsy. The management of amplification failure and allele dropout (i.e., nonamplification of one of the two alleles in a single cell) is of extreme importance because it may result in misdiagnosis. Multiplex PCR with linked markers, with or without fluorescent detection,[251,304] is a straightforward strategy. Today, multiplex PCR (i.e., simultaneous amplification of two or more DNA sequences) is used extensively in PGD, especially for more frequently occurring diseases.[305,306] Usually, attempts are made to combine a specific mutation with ideally linked markers or otherwise unlinked markers.[251,306] Allowing simultaneous testing of linked markers alongside the mutation test significantly increases the accuracy of single-cell PCR.[307,308]

The more recent advent of highly effective whole-genome amplification methods, generating abundant assay-ready DNA from single cells for diagnosis of any known single-gene defect, marks a new era for preimplantation genetic testing.[309] The ideal whole-genome amplification technique should have high yield, faithful representation of the original template, and complete coverage of the genome.[310] The use of whole-genome amplification as a universal first step allows subsequent simultaneous analysis of more than one mutation by standard PCR protocols[311-313] or microarrays.[314] The inclusion of several polymorphic markers allows haplotype analysis.[315,316] Preimplantation genetic haplotyping definitely widens the scope and availability of preimplantation testing because one panel of markers can be used for all carriers of the same monogenic disease, bypassing the need for the development of mutation-specific tests.[316]

Preimplantation Genetic Screening

In PGS, embryos are screened for chromosomal abnormalities in patients with impaired fertility, patients of advanced maternal age, patients with several failed IVF cycles (i.e., recurrent implantation failure), patients with recurrent miscarriages, or male patients with nonobstructive azoospermia. Selecting chromosomally normal embryos for replacement should increase implantation rates, reduce spontaneous miscarriage rates, reduce aneuploid conceptions, and improve delivery rates in assisted reproductive technology cycles.[299,317-319] The number of referrals for PGS has only increased since its first clinical application,[320] as evidenced by the European Society of Human Reproduction and Embryology PGD Consortium data collection,[16] but the benefits of PGS are still under debate.

FISH

In FISH, fluorochrome-labeled DNA probes are used that are complementary to DNA sequences specific to individual chromosomes. Simultaneous analysis of several chromosomes is possible, even in interphase cells.[321-323] Polar bodies or blastomeres obtained for biopsy are spread on a glass slide and fixed.[322-324] The labeled probes are added and allowed to hybridize to the chromosomes. Excess probe is removed, and the result can be analyzed using fluorescence microscopy with different filters for different fluorochromes.

At least one FISH probe is now available for every chromosome, although the limited number of fluorochromes available restricts the number of probes that can be simultaneously applied to a single interphase nucleus. Additionally, misdiagnosis due to overlapping signals would become a problem. Commercially available kits containing 9 chromosome-specific probes are often used in a first round; after probe removal, a second round of hybridization for even more chromosomes can be performed.[322]

For Robertsonian translocations (in which a whole chromosome is translocated), simple enumeration of the chromosomes leads to a reliable diagnosis,[325,326] but the situation is more complex for reciprocal translocations (exchange of fragments between chromosomes). A generally adopted practice is the simultaneous use of two differentially labeled subtelomeric probes distal to the breakpoint (one for each chromosome), together with a centromeric probe (to one of the chromosomes involved). This strategy allows for the distinction between normal, balanced genotypes and unbalanced genotypes.[327]

The obvious limitation of FISH is that a restricted number of chromosomes can be tested in a single cell. Aneuploidies at the level of chromosomes that have not been analyzed,

undoubtedly existing, are overlooked.[328] Data from spontaneous abortions suggests that 9 to 12 probe FISH assays detect only 57% to 67% of aneuploid embryos.[329-332] In addition, Munné and colleagues strongly suggests that centers not using probes for chromosomes 15, 16, and 22 have poorer results than those using those probes.[332] If more chromosomes could be analyzed, the value of PGS could likely be increased. Another limitation of FISH is due to the high error rates. PGS error rates using FISH range from 5% to 7% in large studies[333,334] to 50% in smaller studies.[335] Many of these errors are thought to be center- and technique-related and not related to the number of probes. Colls and colleagues demonstrated that there were similar error rates in a 9-probe panel as in a 12-probe panel.[333] These results indicate that the addition of 3 probes to the 9-probe panel does not increase the error rate. Recently, Munné and colleagues published optimized techniques for performing FISH.[332] These techniques have been fully validated, thousands of clinical cycles have been conducted and accuracy rates have been well established.[332]

The initial goal of FISH was to improve pregnancy rates and to reduce miscarriage rates. Despite promising results from studies with matched controls,[318,336] recent randomized prospective clinical trials failed to observe a significantly increased live birth rate after transfer of chromosomally "normal" embryos selected by FISH following PGS.[337-346] As a result of many of these trials, the Practice Committee for the Society for Assisted Reproductive Technology and the Practice Committee of the American Society for Reproductive Medicine issued the following recommendations for PGS[346]:

1. Before PGS is performed, thorough education and counseling must be provided to ensure that patients fully understand the limitations of the technique, the risk of error, and the lack of evidence that PGS improves live-birth rates.
2. Available evidence does not support the use of PGS as currently performed to improve live-birth rates in patients with advanced maternal age.
3. Available evidence does not support the use of PGS as currently performed to improve live-birth rates in patients with previous implantation failure.
4. Because the prevalence of aneuploidy is high in the embryos of patients with recurrent implantation failure, decisions concerning future treatment should not be based on the results of PGS in one or more cycles.
5. Available evidence does not support the use of PGS as currently performed to improve live-birth rates in patients with recurrent pregnancy loss.
6. Available evidence does not support the use of PGS as currently performed to reduce miscarriage rates in patients with recurrent pregnancy loss related to aneuploidy.

This report does not invalidate the concept of aneuploidy screening. However, findings from this report should caution programs from adopting new technologies without adequate preclinical validation and proven clinical benefit.

Comprehensive Chromosome Screening (CCS)

The most successful technique for complete karyotyping of single cells is comparative genomic hybridization (CGH).[347] Differentially labeled tests, DNA (green) and normal reference DNA (red), obtained by whole-genome amplification are hybridized simultaneously to normal metaphase chromosomes. The relative green-to-red ratio for each chromosome is measured using a cooled charge-coupled device camera and image analysis. Deviations from a 1:1 ratio (which in itself lights up as yellow) are indicative of loss (red) or gain (green) of chromosomal material in the tested cell. The obvious advantage of CGH over FISH is that the copy number of all chromosomes can be determined. In addition, CGH provides a more detailed picture of the entire length of each chromosome. Although FISH is routinely used to determine the ploidy of particular chromosomes, all that it really shows is that the target sequence of the probe (often located in the centromere) is present. It does not provide information about the rest of the chromosome. CGH has been successfully applied to single cells[348,349] and interphase blastomeres.[350,351] The early clinical applications[352-354] in view of aneuploidy testing are promising, and CGH showed great potential for translocation carriers as well.[355] One of the biggest drawbacks of CGH has been that it was relatively labor-intensive procedure, and that it took several days to obtain a result. This was longer than 3-day-old embryos could be maintained in culture and required embryos undergoing biopsy to be frozen until results become available. Microarray CGH has been shown to alleviate this time constraint.[247,356-359]

Microarray CGH is made up of DNA sequences specific to human chromosomes spotted onto a glass slide. The principle is the same as metaphase chromosome CGH in that differentially labeled reference DNA and test DNA are hybridized to the slide and differences in the fluorescence ratio are indicative of changes in DNA copy number. Array CGH takes less time, primarily because less than 9 hours is required for hybridization. The benefit of complete karyotyping for PGD is that all CGH studies on blastomeres have identified chromosome errors that would not have been detected if the cells had been analyzed by FISH; however, the procedure remains technically challenging.[347]

The use of single-nucleotide polymorphism (SNP) genotyping arrays has been pioneered by Kearns[360] and Treff and their colleagues, and extensively validated for both whole chromosome and segmental imbalance by the latter group.[361-363] This technology uses complex bioinformatic modeling algorithms to detect whole-chromosome and segmental copy-number changes and to distinguish between meiotic and mitotic errors. The advantage of this technique is that it is possible to analyze hundreds of thousands of loci across the genome using a single array, with an average spacing of 5 kb, enabling high-resolution analysis. At the same time, the genotype information allows the parental origin of any abnormalities to be identified by reference to the genotypes of the two parents.[364] The major drawbacks from this technique is due to the high cost of equipment and the lengthy protocol which can take up to 24 hours for results.[364] More recently, Treff and colleagues have developed and fully validated a real-time PCR based SNP approach which can be completed within 4 hours.[362,365] Preliminary randomized control trial results of 24-chromosome aneuploidy screening with qPCR on trophectoderm biopsies and subsequent fresh euploid blastocyst transfer indicate a significant increase in the success of IVF.[296]

Despite conflicting reports using FISH, aneuploid screening remains an important tool for embryo selection for a large

segment of the infertile population. Recently there have been many advancements in CCS technologies. Many of these screening methods have or are currently undergoing exhaustive preclinical validation to ensure accuracy and to determine positive predictive values prior to their clinical application.[366] Harper and colleagues suggest that these trials should be designed to assess the anticipated benefits (a substantial improvement in live birth rate and reduction in miscarriage rates), in relation to the risk and cost for the couple, while addressing biopsy safety, test accuracy, and diagnostic efficiency, in order to identify appropriate indications for PGS.[367]

Blastocyst Collapse for Cryopreservation

Recent advances in culture systems have made it possible to routinely develop high percentages of human IVF embryos to the blastocyst stage. Transferring viable blastocysts offers high efficiency for maintaining pregnancy rates while minimizing multiple gestations in the human.[177] As culture systems improve and more and more clinics move toward single blastocyst stage transfer, there is an increased need to develop methods of blastocyst cryopreservation that have high rates of survival and has minimal impact on the embryo's viability. Conventional slow freeze methods of freezing applied to human blastocysts had moderate success[368] and the vitrification procedure improved the viability of post-warm blastocysts.[369] The difference in success rates between slow freeze and vitrification methods is likely due to the formation of intracellular ice. An increased rate of cooling and warming with vitrification has helped circumvent this problem, though not eliminate it entirely. Previous reports have shown that warmed blastocyst survival rates were dependant on the developmental stage of the blastocyst and were negatively correlated with the expansion of the blastocoele.[370] Early blastocyst stage embryos grade 1 to 3[371] had a total survival rate of 91%, while more expanded blastocysts grades 4 and 5 had significantly lower survival at 85%.[370] It is thought that the large blastocoele might reduce the success of the vitrification process due to insufficient dehydration and ice crystal formation. To overcome this problem and improve cryotolerance, many programs artificially shrink or collapse the blastocyst.

Collapsing of the blastocoele is utilized prior to cryopreservation, including both slow rate or vitrification procedures, with the intent of removing the blastocoele fluid to prevent harmful ice crystal formation. Though use of nonpermeating and permeating cryoprotectants used in various protocols are meant to remove and replace this blastocoele fluid, efficacy of this exchange may be compromised depending on blastocyst stage, quality of the embryo, type of cryoprotectants, or the length of cryoprotectant exposure time. For example, expanded blastocysts with a high intrablastocoele fluid pressure may not have the same fluid exchange as a hatching or early blastocyst with lower pressure. In these cases especially, collapse of the blastocoele may help standardize cryoprotectant exposure times and ensure less variation in cryoprotectant exchange.

Artificial blastocoele collapse may be performed several different ways. Treatment with hyperosmotic sucrose solutions makes it possible to induce artificial shrinkage without special equipment, instruments, or micromanipulation skills.[372] Collapsing can also be induced by using a holding pipette and an ICSI needle, with the needle being carefully placed between trophectoderm cells to disrupt tight junctions and permit fluid release.[373,374] Slight suction may be required to facilitate blastocoele collapse. Use of this approach entails a lengthy set-up and often necessitates set up of additional culture dishes utilizing a zwitterionic buffer handling media. Blastocysts can also be mechanically collapsed using 29-gauge needles[375] and by rigorously pipetting blastocysts up and down.[376] Alternatively, a pulse of a laser between trophectoderm cells can also facilitate blastocoele collapse and can be performed directly in the embryo culture dish.[374] In both cases, it often takes several minutes for complete collapse to occur. Regardless of the method utilized, embryos should be placed back into the CO_2 incubator until collapse is complete. During the procedure, care should be taken to avoid the ICM and to minimize the amount of trophectoderm cells damaged. Furthermore, use of a laser to facilitate collapse may also entail use of assisted hatching to enlarge the hole made in the zona pellucida. Following blastocoele collapse, there may be cellular debris attached to the inside of the zona pellucida, but the majority of the blastocyst should appear as a centrally located tight cluster of cells. Blastocoele cavities begin to re-expand within 1 hour after the thaw or warming. These observations can be used to assess the survival of cryopreserved blastocysts prior to embryo transfer.

CHAPTER 33

Fertility Preservation

Francesca E. Duncan
Robert E. Brannigan
Teresa K. Woodruff

Infertility and Cancer

Oncofertility lies at the intersection of infertility and cancer. Though both are ancient human concerns, it has only been within the past decade that the two conditions have come together, largely because of significant changes in the perception of and advances in each field. Until very recently, infertility was seen as a social issue rather than a medical condition that warranted intervention, while cancer was thought to lead to unavoidable death. Today, technological and therapeutic advances in oncology and reproductive medicine have changed the lives of patients with these conditions.

The word "cancer" refers to a broad category of abnormal neoplastic diseases, affecting virtually all tissues and organ systems within the human body.[1] Cancer will affect approximately one half of all men and one third of all women in the course of their lifetimes. The 20th century was a time of significant advances in oncological diagnosis and treatment, with improvements in cancer detection and in all oncological treatment modalities (chemotherapy, radiation therapy, and surgery).[1] While cancer remains the second leading cause of death in the United States, in men, cancer death rates declined by 21% between 1990 and 2006, with decreases in rates of death from lung, prostate, and colorectal cancer, specifically.[2] In women, cancer death rates declined by 12% between 1991 and 2006, primarily due to decreased rates of death from breast and colorectal cancer.[2]

The History of Fertility Preservation and Development of Oncofertility

Despite the significant advances made in cancer diagnosis and treatment, a host of undesirable health changes can occur secondary to the cancer itself and/or as side effects of cancer therapy. Among these detrimental effects are alterations in normal reproductive processes in males and females—including fertility, endocrine health, sexuality, or the ability to carry an offspring to term. Injury to the endocrine system, nervous system, vascular system, gonads, and genitalia can all lead to altered reproductive health. As mortality rates from cancer decline, survivorship issues such as post-treatment infertility have become increasingly important.

Fertility management or preservation specifically in the setting of cancer is a recent construct that developed based on the increased survivorship of young cancer patients that has been made possible by extraordinary advances in cancer diagnosis and therapy. For men facing a cancer diagnosis, fertility management primarily involves sperm banking, or sperm cryopreservation. While sperm banking was first described in the 1960s,[3] the first reference to sperm cryopreservation in the cancer setting did not appear until 1980, when 22 men with testicular carcinoma or lymphoma were referred for semen cryopreservation prior to undergoing fertility-threatening cancer therapy.[4] The first case of a successful pregnancy with in vitro fertilization (IVF) using cryopreserved sperm from a man with a testicular malignancy was reported in 1985.[5] Additional successes with IVF using cryopreserved sperm from cancer patients throughout the 1990s were reported.[6,7] Awareness of fertility preservation in men with cancer was hurled into the spotlight in 1996 with the highly publicized use of sperm banking by the cyclist Lance Armstrong—performed prior to undergoing chemotherapy and radiation therapy for testicular cancer—which later allowed him to build a family as a cancer survivor.

While IVF techniques and cryopreservation of embryos had taken hold by the late 1980s, use of these techniques specifically to preserve the fertility of female cancer patients was not reported until 1996, by Brown and colleagues.[8] The authors described a patient with breast carcinoma who underwent natural cycle IVF prior to undergoing chemotherapy. The earliest report of a pregnancy using cryopreserved oocytes for IVF was published by Chen in 1986,[9] though the use of this technique in a cancer patient to achieve pregnancy and live birth was not reported until 2007.[10] Cryopreservation of ovarian tissue was first reported in 1996 by Hovatta and colleagues,[11] and the potential applications of this procedure in fertility preservation for cancer patients was discussed in the same year by Newton and colleagues.[12] Somewhat surprisingly, the first reference to ovarian tissue transplant is in 1895, described in a thesis by Dr. Robert Morris.[13] Yet it wasn't until 2008 that Silber and colleagues transplanted cryopreserved-thawed ovarian tissue to restore fertility in patients with premature ovarian failure,[14] and Andersen and colleagues—using cryopreserved ovarian tissue from patients with malignancy who had undergone gonadotoxic treatments—were able to restore fertility that resulted in successful pregnancies after ovarian tissue transplantation.[15]

In 2006, the field of oncofertility was developed with the express purpose of preserving, expanding, and restoring the reproductive future of individuals—adults as well as children and young adults—whose cancer treatment may compromise their fertility.[16] To ensure that these reproductive needs would be met, the Oncofertility Consortium was established and funded by a National

Institutes of Health Roadmap Grant.[17] In an exemplary model of team science, the Oncofertility Consortium has advanced the field of fertility preservation by coordinating the work of clinicians, basic science researchers, social scientists, ethicists, and humanists so that breakthroughs at the bench would continue to efficiently and safely transform patient care (Fig. 33.1).[17] Over the past decade, the mission of fertility preservation has gained national and international momentum, including partnerships with the European Society of Human Reproduction and Embryology (ESHRE). Moreover, the field of fertility preservation is expanding to include not only patients with cancer but also those with other diseases or conditions or undergoing treatments that may result in compromised reproductive function.

Parallel developments in fertility interventions and advances in cancer diagnostics and therapeutics have led to the convergence of fertility management and oncology and the search for new fertility preservation options for an increasing population of young cancer survivors. Yet it is hoped that with better preventative care, earlier diagnosis of cancer, and targeted cancer therapeutics, fertility preservation in the cancer setting will one day become another footnote in the history of reproductive medicine.

In this chapter, we provide a comprehensive overview of the current state of the field, including how cancer and its treatment impact gonadal and reproductive function; the current fertility preservation strategies for men, women, and children diagnosed with cancer; medical and patient management in the setting of oncofertility; special cases in fertility preservation; legal and ethical issues in the field; and the next frontiers in the basic science that drives oncofertility.

Reproductive Dysfunction as a Result of Cancer or Its Treatment

With greater numbers of patients winning their battle against cancer, there is an increased demand that quality of life for survivors be as close to normal as possible. For young men and women, a high quality of life includes regaining reproductive function and preserving the option to have a family. Yet an unfortunate consequence of the treatments that will preserve these patients' lives is that nearly all aspects of both the male and female reproductive axis can be compromised. In the female, the hypothalamic-pituitary-gonadal (HPG) axis, the ovaries and ovarian follicles, and the uterus are directly affected by cancer treatments; in the male, the testes are at risk, specifically the germinal epithelium and Leydig cells.

Cancer and Reproductive Function

Cancer itself may negatively impact reproductive function. For example, semen quality parameters tend to be poor prior to treatment in men with testicular cancer, leukemia, or lymphoma.[18-20] In females, the association is less clear. In one recent study, the success of ovarian stimulation was compared in women with malignancies prior to cancer treatment to a similar group of women seeking assisted reproduction for male-factor infertility.[21] No differences were found between these two groups of patients in terms of the number of dominant follicles and retrieved oocytes, proportion of mature eggs, or fertilization rates. However, a small meta-analysis that examined all types of malignancies found that there were fewer numbers of oocytes retrieved from women with breast and hormone-dependent cancers.[22]

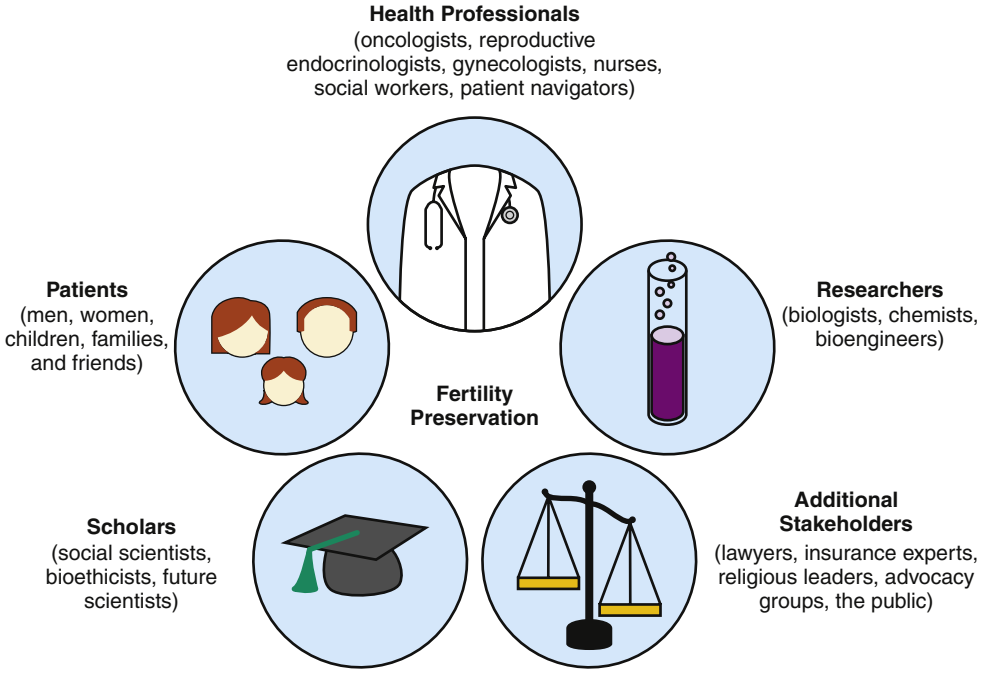

FIGURE 33.1 It has long been known that cancer and iatrogenic insults such as chemotherapy, radiation therapy, and surgery can negatively impact reproductive function; and fertility preservation has a long-standing history in the field of reproductive science. A large, committed, integrated, and multidisciplinary team consisting of health professionals, researchers, scholars, patients, and legal and ethical experts is required to transform the concept of fertility preservation into a clinical reality. With the inception of the Oncofertility Consortium in 2006, the mission of exploring and expanding the reproductive options for men, women, and children with cancer was put into motion with the creation of the required team to address this unmet need nationally and internationally. This movement is now expanding to include patients with any condition or undergoing any treatment that may threaten fertility.

Cancer Treatment and Female Reproductive Function

Several common cancer therapies are known to impair reproductive health. A fertile woman must have: (1) a functioning neuroendocrine system that regulates the menstrual cycle and can maintain a pregnancy; (2) a healthy pool of ovarian follicles that will grow in response to hormonal cues and produce mature and fertilizable gametes; and (3) a receptive uterus that will support embryo implantation and fetal development to term. Cancer treatment can affect each of these (Fig. 33.2). For example, radiotherapy can damage

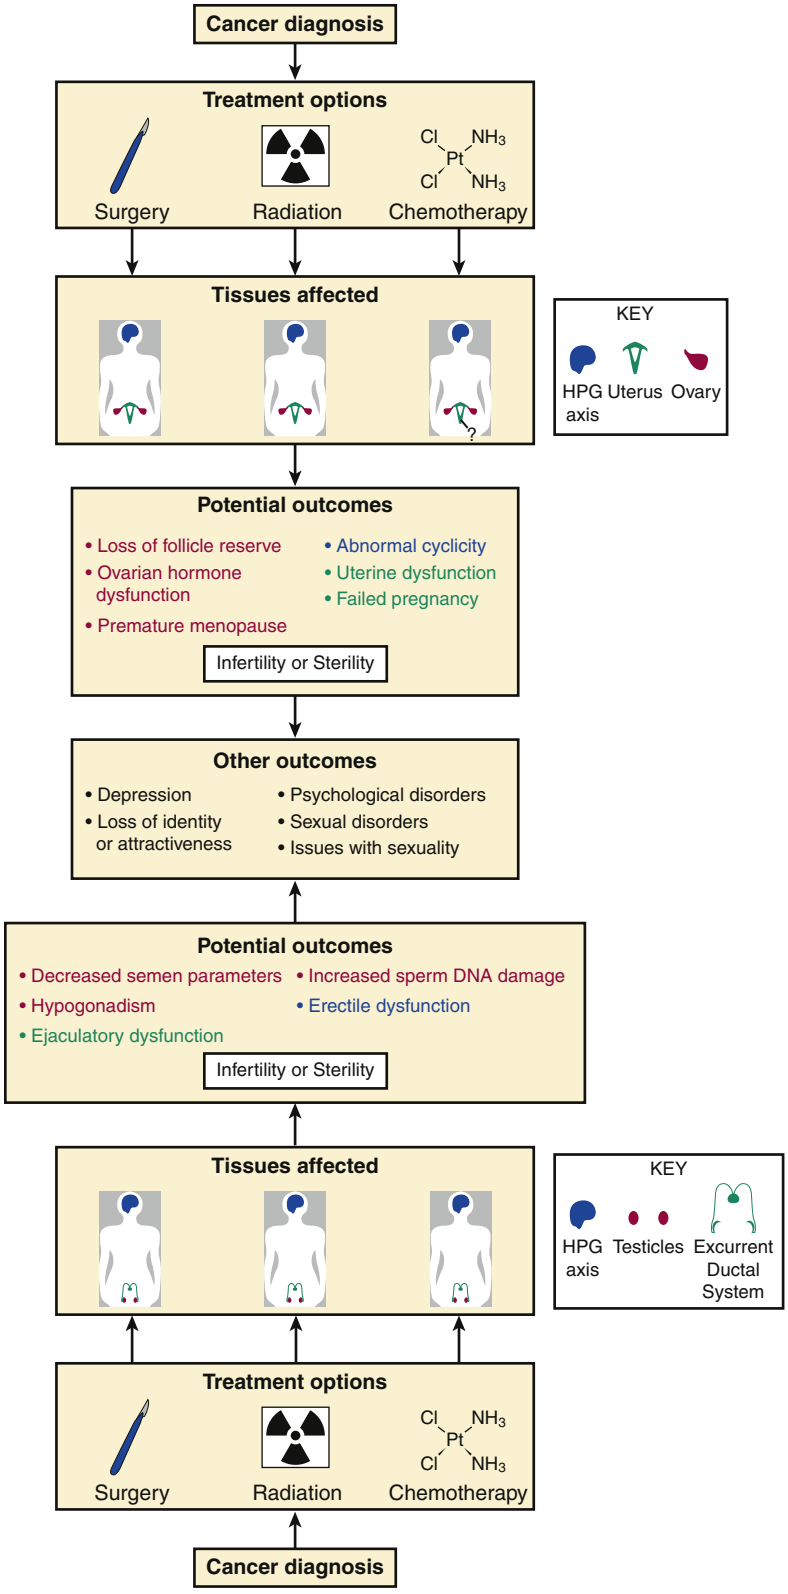

FIGURE 33.2 Major female reproductive systems, including the hypothalamic-pituitary-gonadal (HPG) axis, the uterus, and the ovary, can be negatively impacted by common cancer treatments. In fact, it has been demonstrated that chemotherapy, radiation, and surgery can directly affect all three of these systems with the only question being the effect of chemotherapy on uterine function. Such iatrogenic insults can result in adverse reproductive outcomes ranging from sexual disorders to infertility. Similar to the female, the male gonads and endocrine system are also highly sensitive to common cancer therapies.

growing follicles, which triggers either repair or elimination pathways.[23] In general, actively dividing cells are more susceptible to radiation-induced death, and because oocytes in the young adult are arrested in prophase of meiosis I, they are more resistant to radiation than cells in mitosis. Primordial follicles, which are quiescent, also appear to be more resistant to radiation compared with growing follicles.[23] Nevertheless, the human oocyte is sensitive to radiation therapy. The LD_{50}, or the radiation dose required to destroy 50% of immature human oocytes, is less than 2 Gy.[24] Mathematical modeling predicts that the effective sterilizing dose of radiation is inversely correlated with age: it is 20.3 Gy at birth and 16.5 Gy at 20 years of age.[25]

In addition to being radiosensitive, the ovary is also chemosensitive. Alkylating agents, especially cyclophosphamide and busulphan, are more gonadotoxic compared to other chemotherapeutic agents, including platinum-based drugs, plant alkaloids, and anti-metabolites (Table 33.1).[26,27] Alkylating agents, which cause DNA breaks irrespective of cell cycle stage, are associated with a high risk of primordial follicle death and compromised stromal cell function.[28] Follicle destruction, whether by radiation- or chemotherapy-induced mechanisms, not only leads to gamete loss, but also results in impaired ovarian hormone production and uterine dysfunction. Although follicles may resist cancer therapies, the ovarian reserve may be compromised and depleted early, resulting in premature menopause.

The female neuroendocrine axis (or HPG axis) is also vulnerable to off-target effects of cancer therapies. The HPG axis controls the menstrual cycle and pregnancy by regulating the secretion of hormones, including gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol, progesterone, and prolactin. Radiation therapy, particularly targeting the cranium, can cause altered hypothalamic and pituitary function.[23,29,30] There is also evidence that hypothalamic dysfunction can occur after chemotherapy in the absence of cranial irradiation.[31] At the level of the ovary, the negative effects of radiation and chemotherapy on estrogen-producing growing follicles can severely impair the menstrual cycle.

The uterus functions primarily to support embryo implantation as well as fetal growth and development. Although chemotherapy alone does not appear to adversely impact the uterus, radiotherapy can have negative long-term consequences on the ability of the uterus to support a future pregnancy.[32,33] Radiotherapy can reduce uterine volume and elasticity, damage the uterine musculature and endometrium, and decrease the vasculature.[34-36] If women are able to conceive following radiotherapy, they may have an increased risk of adverse pregnancy outcomes, including miscarriage, placental abnormalities, preterm birth, and delivery of infants with low birth weights.[35,37]

Cancer Treatment and Male Reproductive Function

Normal male reproduction is also dependent on a tightly regulated HPG axis. In males, the pulsatile release of GnRH from the hypothalamus acts on cells within the anterior pituitary gland to stimulate the production and release of FSH. FSH is secreted into the bloodstream and binds to FSH receptors on the basolateral aspect of Sertoli cells within the testicle, which stimulates the production of androgen-binding protein by Sertoli cells and the initiation of spermatogenesis. FSH production is modulated by inhibin B, a glycoprotein produced by the Sertoli cells that feeds back to the hypothalamus and pituitary to suppress FSH production and hypothalamic secretion of GnRH. LH is also produced by gonadotroph cells within the anterior pituitary gland; like FSH, the secretion of LH is also regulated by the pulsatile release of GnRH. LH is secreted and stimulates Leydig cells to produce testosterone, and testosterone and FSH act synergistically on the Sertoli cells to initiate and support spermatogenesis. The precise endocrine relationship between the hypothalamus, pituitary gland, and testicles is essential to the normal production of sperm. Disturbance of this balance can have detrimental effects on spermatogenesis, resulting in decreased sperm number and quality.

At the time of cancer diagnosis, patients often present with impairment of the normal HPG axis. These findings are commonly noted in men with testicular tumors that produce alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (β-hCG). Carroll and colleagues reported in 1987 that two thirds of men with testicular cancer had abnormal FSH, LH, and/or β-hCG levels.[38] Specifically, decreased FSH levels and elevated LH and β-hCG levels were observed in men with poor semen parameters. The study authors asserted that β-hCG might have an inhibitory effect on FSH in some patients, resulting in impaired spermatogenesis. Other etiological mechanisms have been proposed for the endocrine disruption that is sometimes seen in patients with cancer, including central cytokine effects.[39] While this pathway has been suggested to play a role in oncological anorexia-cachexia syndrome, it has not been specifically studied in terms of hormonal reproductive regulation. More work is needed to specifically elucidate the mechanisms by which oncological disease processes disrupt the normal HPG axis.

The testis, like the ovary, is both radiosensitive and chemosensitive. Chemotherapy is widely used in the treatment of cancers affecting males, but its cytotoxic effects on normal tissue can transiently or permanently deplete rapidly dividing cell populations, such as the testicular germinal epithelium. Chemotherapeutic regimens that include alkylating agents are among the most gonadotoxic and often lead to permanent oligospermia or azoospermia. These changes in spermatogenesis are typically seen within 90 to 120 days after administration of the alkylating agent. Platinum-based chemotherapy, such as cisplatin and carboplatin, predominately affect spermatogonia and spermatocytes. While most men treated with platinum regimens will experience an associated decline in semen parameters, the majority (80%) will have return of sperm in the ejaculate within 5 years of completion of chemotherapy.[40] Antimetabolites such as 5-fluorouracil, methotrexate, gemcitabine, and 6-mercaptopurine can also impair spermatogenesis, although the effects are usually transient. Clinicians should be mindful of the fact that, while patients might start on a "fertility friendly" chemotherapeutic regimen, transition to other regimens is not uncommon in the course of cancer

Table 33.1 Infertility Risk Associated with Specific Cancer Treatments and Regimens

High Risk	Intermediate Risk	Low Risk	No Risk	Unknown Risk
Female				
• Whole abdominal or pelvic radiation doses >6 Gy in adult women • Whole abdominal or pelvic radiation doses >10 Gy in postpubertal girls • Total body irradiation (TBI) • Cranial/brain irradiation >40 Gy • CMF, CEF, or CAF x 6 cycles in women >40 years • Cyclophosphamide 5 g/m^2 in women >40 years • Cyclophosphamide 7.5 g/m^2 in girls <20 years • Alkylating chemotherapy (e.g., cyclophosphamide, busulfan, melaphan) conditioning for transplant • Any alkylating agent (e.g., cyclophosphamide, ifosfamide, busulfan, BCNU [carmustine], CCNU [lomustine]) + TBI or pelvic radiation • Protocols containing procarbazine: MOPP, MVPP, COPP, ChlVPP, ChlVPP/EVA, BEACOPP, MOPP/ABVD, COPP/ABVD	• Whole abdominal or pelvic radiation 5 to <10 Gy in postpubertal girls • Spinal radiation doses >25 Gy CMF, CEF, or CAF x 6 cycles in women 30-39 years • AC in women >40 years	• AC in women 30-39 years • CMF, CEF, or CAF x 6 cycles in women <30 years • Nonalkylating chemotherapy: ABVD, CHOP, COP • AC	• Radioactive iodine • MF • Vincristine	• Paclitaxel, docetaxel (taxanes used in AC protocols) • Oxaliplatin • Irinotecan • Bevacizumab • Cetuximab • Trastuzumab • Erlotinib • Imatinib
Male				
• TBI • Testicular radiation dose >2.5 Gy in men • Testicular radiation dose ≥6 Gy in boys • Cranial/brain radiation ≥40 Gy • Protocols containing procarbazine: COPP, MOPP, MVPP, ChlVPP, ChlVPP/EVA, MOPP/ABVD, COPP/ABVD • Alkylating chemotherapy for transplant conditioning (cyclophosphamide, busulfan, melphalan) • Any alkylating agent (e.g., procarbazine, nitrogen mustard, cyclophosphamide) + TBI, pelvic radiation, or testicular radiation • Cyclophosphamide >7.5 g/m^2 • Surgical removal of one or both testicles or the pituitary gland	• Testicular radiation dose 1-6 Gy (due to scatter from abdominal/pelvic radiation) • BEP x 2-4 cycles • Cumulative cisplatin dose <400 mg/m^2 • Cumulative carboplatin dose ≤2g/m^2 • Hormone treatments (prostate cancer) • Surgical procedures within in the pelvis (prostate, bladder, lower large intestine, rectum)	• Testicular radiation dose 0.2-0.7 Gy • Nonalkylating chemotherapy: ABVD, OEPA, NOVP, CHOP, COP	• Testicular radiation dose <0.2 Gy • Radioactive iodine • Interferon-α	• Irinotecan • Bevacizumab • Cetuximab • Trastuzumab • Erlotinib • Imatinib
Pediatric				
• TBI • Whole abdominal or pelvic radiation doses >15 Gy in prepubertal girls or >10 Gy in post-pubertal girls • Testicular radiation dose ≥3 Gy in boys • Cranial/brain irradiation >40 Gy • Spinal irradiation 24-36 Gy • Cyclophosphamide >7.5 g/m^2 in boys • Cyclophosphamide >15-20 g/m^2 in girls • Alkylating chemotherapy (e.g., cyclophosphamide, busulfan, melaphan) conditioning for transplant • Any alkylating agent (e.g., cyclophosphamide, ifosfamide, busulfan, carmustine, lomustine) + TBI, pelvic radiation, or testicular radiation • Protocols containing procarbazine • Surgical removal of one or both testicles	• Whole abdominal or pelvic radiation 10 to <15 Gy in prepubertal girls • Whole abdominal or pelvic radiation 5 to <10 Gy in postpubertal girls • Spinal radiation doses 18-24 Gy • Testicular radiation dose 1-2 Gy (due to scatter from abdominal/pelvic radiation) • Cumulative cisplatin dose of about 500 mg/m^2 (boys only) • Surgical removal of an ovary	• Testicular radiation dose 0.2-0.7 Gy • Nonalkylating chemotherapy	• Testicular radiation dose <0.2 Gy • Radioactive iodine • Methotrexate/5-FU • Vincristine • Interferon-α	• Oxaliplatin • Irinotecan • Bevacizumab • Cetuximab • Trastuzumab • Erlotinib • Imatinib

CMF, cyclophosphamide/methotrexate/fluorouracil; CEF, cyclophosphamide/epirubicin/fluorouracil; CAF, cyclophosphamide/adriamycin (doxorubicin)/fluorouracil; MOPP, mechlorethamine/oncovin; MVPP, mechlorethamine/vinblastine/procarbazine/prednisolone (vincristine)/procarbazine/prednisone; COPP, cyclophosphamide/oncovin/procarbazine/prednisone; ChlVPP, chlorambucil/vinblastine/procarbazine/prednisolone; EVA, etoposide/vinblastine/Adriamycin; BEACOPP, bleomycin/etoposide/adriamycin/cyclophosphamide/oncovin/procarbazine/prednisone; ABVD, adriamycin/bleomycin/vinblastine/dacarbazine; AC, adriamycin/cyclophosphamide; CHOP, cyclophosphamide/hydroxydaunomycin/oncovin/prednisone; COP, cyclophosphamide/oncovin/prednisone; MF, methotrexate/5-fluorouracil; BEP,bleomycin/etoposide/cisplatin; OEPA, oncovin/etoposide/prednisone/adriamycin (doxorubicin); NOVP, novantrone (mitoxantrone)/oncovin/vinblastine/prednisone

care. The best time for sperm cryopreservation to ensure optimal fertility preservation is prior to the initiation of chemotherapy.

The testis is a highly radiosensitive organ, and radiation-associated declines in semen parameters are commonly seen within 60 to 70 days after radiation treatment. Doses as small as 0.1 Gy can impair spermatogenesis, while doses of just 1.2 Gy have the potential to cause permanent azoospermia.[41-44] Nadir sperm concentration is typically observed 4 to 6 months after completion of radiation treatment, and recovery of spermatogenesis is often noted within 10 to 24 months. Fractionated radiation regimens result in more pronounced spermatogenesis impairment than nonfractionated regimens; the belief is that repeated injury to the germ cells impairs recovery and thus leads to more severe and lasting damage than caused by single, larger doses.

In contrast to germ cells, Leydig cells are relatively radioresistant. While germinal epithelial damage is observed at low doses of radiation, Leydig cell injury is generally not evident until radiation exposure is 20 Gy or more, at which point serum LH elevation and serum testosterone decline are commonly seen.[45]

In addition to the effects of chemotherapy and radiation therapy, surgical procedures can also lead to iatrogenic impairment of male reproductive potential. Orchiectomy leads to loss of testicular mass and thus germ cell mass, diminishing sperm production capability. Patients undergoing radical prostatectomy for prostate cancer, the most common solid cancer in males, sustain disruption of their excurrent ductal system via removal of their prostate gland and seminal vesicles. Men being treated with cystoprostatectomy for bladder cancer are subjected similar excurrent ductal disruption. Retroperitoneal surgery can often result in disruption of the sympathetic nerves that control seminal emission and ejaculation. Retroperitoneal lymph node dissection (RPLND) for men with testicular cancer is one example of this kind of surgery. Template-driven, nerve-sparing approaches are now widely used in the course of RPLND, and these methods represent a technical approach to fertility preservation in males. Finally, pelvic and abdominal exenterative procedures can necessitate resection of gonadal tissue and/or the components of the excurrent ductal system. If the possibility of such a resection arises during surgical planning, preoperative sperm cryopreservation should be carefully considered.

Additional Adverse Reproductive Outcomes

As described above, cancer and its treatments may lead to infertility or sterility due to premature ovarian failure, oligomenorrhea, uterine dysfunction, or altered endocrine function in females and testicular failure, disruption of the excurrent ductal system, and impaired endocrine function in males. However, there are also a number of other side effects of cancer or its treatment that can alter reproductive function. These effects are often overlooked or dismissed but pose a significant challenge to the re-establishment of a high quality of life in cancer survivors (Fig. 33.2). These include increased depression, psychological disorders, and sexuality issues.[46-48] Often patients report loss of identity or attractiveness.

Factors That Contribute to Reproductive Outcomes Following Cancer and Its Treatment

It is quite difficult to predict precisely how a given individual's reproductive potential will be affected by cancer or cancer treatments, as there are many case-dependent variables that contribute to reproductive risk. These factors include but are not limited to a patient's age, genetic background, medical history, and fertility potential prior to cancer diagnosis and treatment. In addition, the radiation and/or chemotherapy treatment regimen used—including dose, duration, frequency, field of treatment, and combination—has a significant bearing on future reproductive function.

Oncofertility Medical Management

Relevant Innate Biological Differences Between Male and Female Reproduction

Fortunately for males and females, the gonads provide a tremendous source of reproductive material for diverse fertility preservation options, ranging from standard to investigational. Innate biological differences in gametogenesis between males and females, especially with respect to age, have largely dictated the types of fertility preservation methods that are currently available or are being developed. In females, it is commonly accepted that oocyte production ceases during mid-gestation, resulting in a fixed number of approximately 1 million follicle-enclosed oocytes at birth that set an individual's reproductive lifespan.[49] The fate of these follicles is to remain quiescent, to activate, or to die. Of those primordial follicles that are activated, only a small fraction will develop to the terminal Graafian follicle stage and produce oocytes that will be ovulated. Once destroyed, there is no mechanism to replace these follicles, as replenishment by ovarian germline stem cells does not appear to be physiologically relevant.[50-54] By puberty, the primordial follicle number decreases to approximately 400,000, and reproductive senescence occurs at the time of menopause, when approximately 1000 primordial follicles remain in the follicle pool.[49] Thus, female oocytes are rare and precious, in addition to requiring relatively invasive techniques to access.

In contrast to oocytes, sperm are continuously generated in the adult testis.[55] The process begins when type A pale spermatogonia differentiate into type B spermatogonia. The type B spermatogonia then differentiate into spermatocytes, which undergo meiosis to form spermatids and ultimately mature haploid spermatozoa. This process results in the production of millions of sperm daily. Because germline stem cells are very active in the male, there is an increased potential for slow recovery of fertility post-treatment if the spermatogonial stem cells (SSCs) are not irreversibly damaged, and the mitotically quiescent type A dark spermatogonia are able to transform into actively dividing and differentiating type A pale spermatogonia.[56] Compared with oocytes, sperm are numerous and can be obtained using relatively simple and noninvasive methods.

Because their gonads are not fully developed, there are much fewer fertility preservation options for prepubertal males and females. Testes of prepubertal males do not contain mature haploid gametes but instead are populated with SSCs that are poised to initiate spermatogenesis and generate sperm

at the onset of puberty. Prepubertal females have follicles that develop in waves until the secondary stage but are then eliminated. It is not until puberty, when cyclic production of gonadotropins promotes the development of follicles to the mature stages, that fertilization-competent eggs are ovulated. Thus, prepubertal populations cannot make use of more standard technologies (e.g., hormone stimulation and IVF) that involve the collection of mature gametes. Instead, current fertility preservation treatments in this population rely primarily on removing and cryopreserving gonadal tissue (see sections on *Special Cases and Investigational Methods & Basic Science*).

Established Fertility Preservation Strategies

National organizations including the American Society of Clinical Oncology (ASCO), the American Society of Reproductive Medicine (ASRM), and the American Academy of Pediatrics (AAP) support the practice of oncofertility. These societies have issued guidelines, listed in Table 33.2, which recommend that oncologists make their patients aware of threats to their fertility, provide them with fertility preservation options, or refer them to reproductive specialists.[57-59] Global statements on oncofertility are forthcoming and will likely parallel those of the U.S. -based physician groups. The Oncofertility Consortium, together with other advocacy groups (Table 33.3), is meeting the urgent need of providing cancer patients with information and developing options to protect their fertility, but its continued success requires that clinicians understand and can discuss currently available fertility preservation technologies with their patients. The following is a brief overview of the standard fertility preservation techniques used in the medical management of both female and male oncofertility patients.

Fertility Preservation for Female Patients

For females, the menu of fertility preservation options is constantly expanding as research breakthroughs are being translated into clinical use (Table 33.4 and Fig. 33.3). Although there are many approaches to fertility preservation, ranging from standard to experimental to theoretical, the unique set of patient- and case-based factors will dictate the best course of action. These factors include a patient's age, ovarian reserve prior to the start of treatment, and type of cancer, as well as the dose, duration, and timing of cancer therapy.[60] It should also be emphasized that female cancer patients who seek fertility preservation are typically young. The average age of patients who have sought fertility preservation methods through the Oncofertility Consortium since 2007 is 27 (unpublished data). Thus, the well-documented decline in egg quality and fertility with advanced maternal age is unlikely to be a compounding factor for these young women.[61-63]

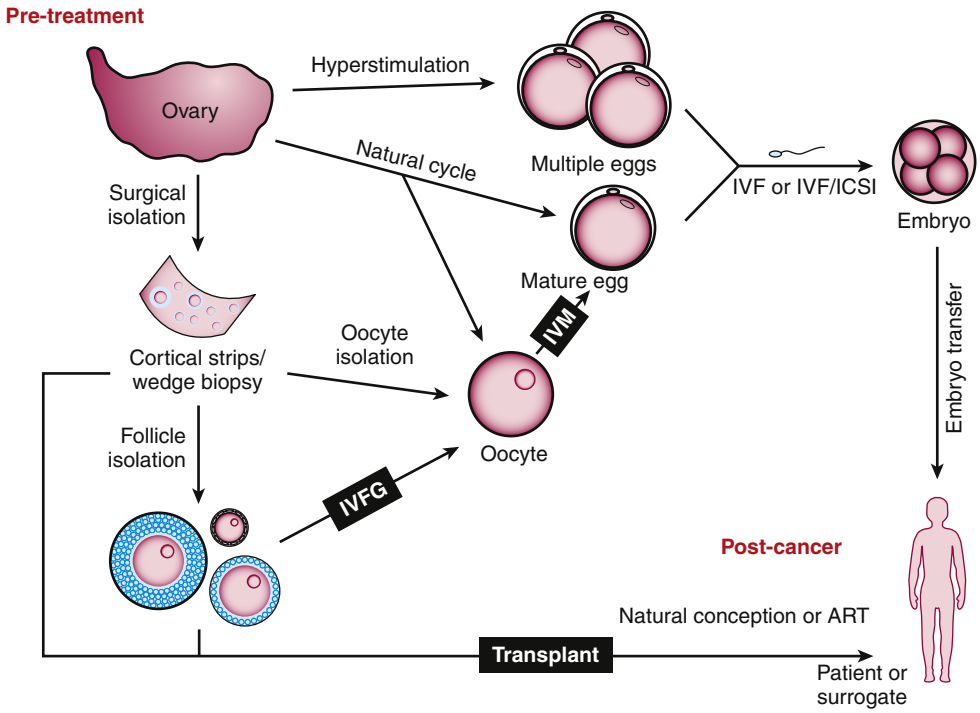

FIGURE 33.3 The ovary contains thousands of oocytes enclosed in follicles, which offers a rich source of gametes for fertility preservation options in females. Pieces of intact ovarian tissue or isolated follicles, immature oocytes, mature eggs, or fertilized embryos obtained prior to the initiation of cancer treatment can be cryopreserved and later thawed and used in standard and investigational technologies to ultimately restore endocrine function and fertility after cancer. The fertility option used is patient-specific and depends on factors such as age, type of cancer, baseline fertility measures, and others. Black boxes highlight investigational techniques that are not yet routine in clinical practice. IVF, *in vitro* fertilization; ICSI, intracytoplasmic sperm injection; IVFG, *in vitro* follicle growth; IVM, *in vitro* maturation.

Embryo Cryopreservation

Despite the broad spectrum of fertility preservation options available to patients, embryo cryopreservation is the only established method recognized by the ASRM.[57] In this method, which is initiated prior to cancer treatment, a woman typically undergoes hormone-induced hyperstimulation to recruit multiple follicles to grow and produce fertilizable eggs (Fig. 33.3). These eggs are then aspirated and fertilized using assisted reproductive technologies (ART) such as IVF or intracytoplasmic sperm injection (ISCI). Embryos are then cryopreserved by slow-freezing or vitrification and stored for the patient's future use.[60,64] Following cancer treatment, these embryos can be thawed and transferred back to the patient's (or a surrogate's) uterus. Cryopreservation of embryos is generally successful. It is estimated that 3.5 million children worldwide have been born to date using ART procedures, and a quarter of these have been generated using cryopreserved and thawed embryos.[65] Furthermore, the obstetrical outcomes of children born after implantation of cryopreserved embryos are comparable to those born after implantation of embryos produced in fresh IVF and ICSI cycles, although long-term follow-up child health studies are still needed.[66]

Despite the success of embryo cryopreservation for fertility preservation, there are several drawbacks of this method in the context of oncofertility. First, this procedure requires time. An ART cycle can take anywhere between 2 to 5 weeks to complete, and this potential delay in cancer treatment may be detrimental for women with aggressive or advanced cancers.[60] In addition, embryo cryopreservation requires ovarian hyperstimulation, which is contraindicated for women with hormone-sensitive cancers.[67,68] This technique also presupposes that a patient is willing to use a sperm donor or has an existing partner who has agreed to create embryos, an issue that is an obstacle for pediatric patients. Finally, a myriad of ethical and potential legal concerns exist surrounding the generation and cryopreservation of embryos that may or may not be used.[69,70]

Oocyte and Ovarian Tissue Cryopreservation and Additional Methods

Beyond embryo cryopreservation, the ASRM maintains that all other fertility preservation methods are experimental and should only be performed in a research setting under Institutional Review Board (IRB) approval.[57] However, the experimental nature of these procedures might not be a barrier to use in specific medical circumstances, such as oncofertility, where they may be a patient's only choice to preserve their future fertility.[71] The ovary contains thousands of follicles in different stages of development, and is a rich source of tissue that can be used in a number of fertility preservation procedures (Fig. 33.3).

For women who want to maintain their reproductive autonomy but do not want to create embryos at the time of cancer diagnosis, oocyte cryopreservation is a potential option (Table 33.4). In this technique, a woman undergoes hormone-induced hyperstimulation to recruit multiple follicles to grow, and the mature eggs are aspirated and cryopreserved for later fertilization.[60,72] Accumulating data suggests this procedure is a viable option, especially in an

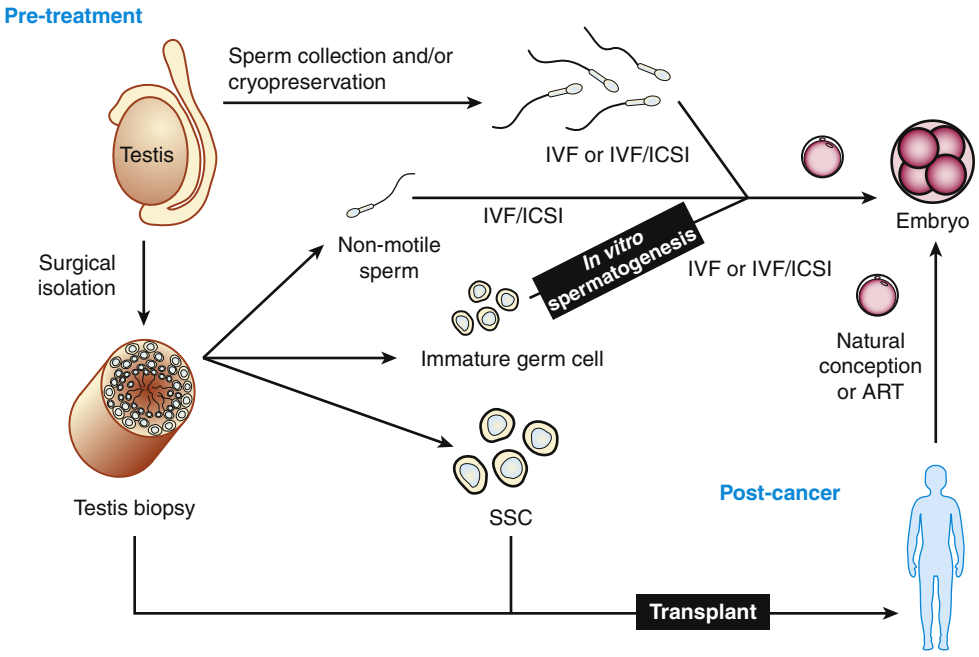

FIGURE 33.4 All fertility preservation options for postpubertal males involve collection of sperm or tissue containing sperm progenitors. Sperm may be used to create embryos via IVF or ICSI, or they may be cryopreserved for later use. Investigational options for prepubertal boys include testicular tissue biopsy and cryopreservation, with transplantation of thawed spermatogonial stem cells (SSCs). Black boxes highlight investigational techniques that are not yet used in clinical practice. IVF, *in vitro* fertilization; ICSI, intracytoplasmic sperm injection.

oncofertility setting.[73] When performed at experienced fertility centers, the live birth rate of IVF using cryopreserved eggs is comparable to that of conventional IVF using fresh eggs,[72] making this a viable option for biological preservation of gametes without the need to have a known or selected sperm donor.

For women who cannot delay their cancer treatment or who cannot be exposed to supraphysiological hormone levels, ovarian tissue cryopreservation for future use is their only option (Table 33.4 and discussed in detail in the *Investigational Methods & Basic Science*). Finally, intraoperative methods, such as ovarian transposition and gonadal shielding, can minimize the impact of radiation on the ovary; however, these techniques do not protect the uterus (Table 33.4). Female patients who have undergone radiotherapy should be counseled adequately about the well-documented negative impact this treatment may have on the uterus and their potential for achieving pregnancy with ART. Patients who have sustained damage to their uterus from radiation therapy may have to use a surrogate, whether they use their own cryopreserved gametes or embryos or decide to use a donor. In addition to these fertility preservation methods, there are also nonbiological strategies to having a family after cancer, such as adoption (Table 33.4 and described in the *Legal and Ethical Issues* section).

Fertility Preservation for Male Patients

Fertility preservation in males is generally more feasible and less invasive than fertility preservation measures available to females. This dichotomy arises due to the fact that most males, despite their oncological diagnosis, are able to provide ejaculated semen samples with viable sperm for cryopreservation. Even very small quantities of sperm can be frozen and used in IVF or ICSI after cancer to achieve biological paternity. Yet while most patients facing a cancer diagnosis can produce an ejaculate suitable for cryopreservation, some patients encounter anejaculation (the inability to ejaculate), aspermia (the lack of an antegrade ejaculate), retrograde ejaculation, necrospermia (only dead sperm present in the ejaculate), or azoospermia. Each of these scenarios can hamper standard male fertility preservation measures. Fortunately, the armamentarium of male reproductive therapeutics that are commonly used to treat such conditions in males without cancer can similarly be applied to oncological patients who experience these problems (Fig. 33.4).

Masturbation and Ejaculation

The ejaculate is the preferred source of sperm for cryopreservation. Men are typically asked to abstain from ejaculation for 2 to 3 days prior to collection of each sample. Patients are discouraged from use of lubricants, jellies, and saliva during the collection process, as these all have spermatotoxic properties. Semen collection can be performed on an inpatient or outpatient basis. Coordination of semen collection in the context of oncological care is essential. Narcotics and sedatives are commonly used in diagnostic and therapeutic procedures for males recently diagnosed with cancer, and these agents can hamper semen collection efforts. Assuring the patient that his privacy will be maintained during semen collection is also critical, as anxiety can impair efforts to produce a semen sample by masturbation.

Penile Vibratory Stimulation (PVS)

Some men experience difficulty reaching climax and are thus unable to produce an ejaculated semen sample by masturbation. Patients at risk for this problem include men on narcotics and sedatives, with peripheral neuropathy, or with significant pelvic, perineal, or genital edema. For these individuals, PVS can help optimize genital tactile stimulatory input and trigger the ejaculatory reflex. To facilitate PVS, a vibratory stimulation device is applied to the ventral surface of the penis, just proximal to the corona. Commercially available vibratory devices commonly feature variable

amplitude and frequency settings, allowing patients to modulate these parameters in order to optimize their stimulatory input. Care must be taken in patients with edema or peripheral neuropathy, as penile skin damage or breakdown can occur in these individuals. Patients are usually able to use these devices successfully alone or in private with their partner. If these efforts are not successful, a healthcare provider can perform the PVS procedure.

Electroejaculation (EEJ)

In some instances, vibratory stimulation does not result in ejaculation. For such cases, another option is EEJ, in which a probe is inserted transrectally to deliver an electrical current to the pelvic structures in a rhythmic fashion. The resultant electrical stimulation of the seminal vesicles and prostate gland usually leads to antegrade seminal expulsion via the urethra. In some cases, the semen may travel in a retrograde fashion back into the bladder. In these instances, sperm wash media can be instilled into the bladder prior to EEJ, and the bladder can be drained after the procedure via catheter to allow isolation of viable sperm. EEJ requires the use of an anesthetic, except in patients with a history of a complete spinal cord injury. Care must be taken during the EEJ procedure to monitor rectal temperature in order to avoid rectal mucosal burns. Anoscopy is usually performed immediately prior to and after EEJ procedures. Monitoring of the rectal mucosa in this fashion is highly recommended. As noted in the above section on PVS, patients at particular risk for anejaculation include those taking narcotics and sedatives, males with peripheral neuropathy, and men with significant pelvic, perineal, or genital edema.

Recovery of Retrograde Sperm Ejaculation From the Urine

As mentioned above, some patients experience the retrograde passage of their ejaculate back into the bladder instead of antegrade out the tip of the penis. Patients at increased risk for retrograde ejaculation include men with autonomic neuropathy, men who have sustained sympathetic nerve injury due to prior surgical procedures such as RPLND or pelvic exenteration, and men with bladder neck incompetence due to a history of bladder neck surgery. Generally, the bladder is a hostile environment for sperm, as urine is highly spermatotoxic. In some cases, sympathomimetic agents such as pseudoephedrine can facilitate conversion from retrograde to antegrade ejaculation. However, in cases where medical therapy is unsuccessful, recovery of viable sperm from the bladder can be achieved by urethral catheterization to drain urine and instill sperm wash media into the bladder prior to ejaculation. After ejaculation, the patient can either urinate out the media, or the urethral catheter can be replaced to allow collection of media from the bladder. The media is then centrifuged, and the sperm are isolated in the resultant pellet. These sperm can then be resuspended in media and cryopreserved.

Surgical Sperm Extraction Procedures

A number of surgical sperm extraction procedures are available to permit sperm retrieval from the testicular tissue or the epididymis. Surgical sperm extraction is generally reserved for those patients with obstruction of their excurrent ductal system, men with ejaculatory dysfunction nonresponsive to PVS and/or EEJ, and men with necrospermia or nonobstructive azoospermia. A number of sperm extraction procedures are available, and surgeon preference often dictates which approach is used.

For men with obstructive azoospermia, a blockage in the sperm delivery system (i.e., epididymis, vas deferens, or ejaculatory duct) prevents passage of sperm in the semen. One example seen occasionally is a man with newly diagnosed cancer who has a history of vasectomy but wishes to preserve future fertility potential. For these men, the ejaculate contains no sperm, so sperm extraction from either the epididymis (Percutaneous Epididymal Sperm Aspiration [PESA] or Microsurgical Epididymal Sperm Aspiration [MESA]) or from the testicle (Microsurgical Testicular Sperm Extraction [Micro-TESE], Testicular Sperm Extraction [TESE], or Testicular Fine Needle Aspiration [TFNA]) are all options. Sperm retrieval rates are generally high in patients with obstruction, but the underlying systemic response to cancer in oncological patients can markedly inhibit sperm production in some cases, as was previously described.

For men with nonobstructive azoospermia, the underlying problem is sperm production. Nonobstructive azoospermia can arise due to endocrine abnormalities such as hypogonadism, which is often associated with oncological diagnoses. As was described earlier in this chapter, low testosterone is frequently seen in cancer patients even before the initiation of cancer therapy. Hypogonadism can also result from narcotic use, which leads to suppression of LH secretion and decreased production of testosterone by Leydig cells. Another common cause of nonobstructive azoospermia is germ cell sloughing. This can occur in men after a febrile systemic response to cancer, as is sometimes seen in lymphoma. These men will often be found to have either nonobstructive azoosperma or necrospermia at the time of attempted sperm cryopreservation. Finally, men with testicular cancer are sometimes found to have nonobstructive azoospermia at the time of semen collection. In some men, impaired spermatogenesis may be associated with a local inflammatory response to the testicular neoplasia, and in others, germ cell absence may have preceded the development of cancer.

For all men with nonobstructive azoospermia, the aim is to isolate and extract sperm from the testicular tissue. "Onco-TESE," described by Schrader and colleagues, involves surgical extraction of sperm from the testicle in male cancer patients with azoospermia.[74] Most clinicians prefer the Micro-TESE technique in such cases, as this microsurgical approach enables the systematic inspection of the seminiferous tubules in search of dilated, opaque tubules that often bear sperm. Clinicians should realize that spermatogenesis is often "patchy" and heterogeneous, and so careful, methodical inspection of the tissue is important technically. As reported by Schrader and colleagues, published sperm retrieval rates for Onco-TESE are approximately 50%.[74]

In addition to sperm cryopreservation, gonadal shielding is also a means to preserve fertility in males who must undergo radiation therapy. Gonadal shielding is a particularly important consideration when pelvic or lower abdominal fields are being treated, as these can result in significant gonadal exposure through radiation scatter.

Gamete and Reproductive Tissue Cryopreservation and Storage

Cryopreservation is a central component of fertility preservation, as reproductive tissues must be harvested before fertility-threatening treatment is initiated and must be stored until treatment is completed.[75] As the array of fertility preservation options expand for both males and females, so does the need to develop long-term storage methods for diverse cell types (oocytes, eggs, spermatogonia, spermatids, spermatozoa, and embryos) and complex tissues containing these cell types (testicular tissue, ovarian tissue, and follicles).[76,77] Although there has been some success with preserving sperm through freeze-drying, most reproductive tissues are stored using cryotechniques.[78-80] In general, these methods require that a tissue is cooled from its physiological temperature to subzero temperatures, is maintained at that temperature for an extended time, and is able to regain cellular viability upon thawing.

The two main types of cryopreservation techniques that are routinely used in ART are slow freezing and vitrification.[75,81] With slow freezing, cells or tissues are exposed to low concentrations of cryoprotectants, which results in a lowering of the intracellular water content during a slow cooling process. The main risk of slow freezing is ice crystal formation during both freezing and thawing.[76] Vitrification was developed to avoid ice crystal formation; in this method, the cells or tissues are equilibrated in high concentrations of cryoprotectants, and then plunged directly in liquid nitrogen. Vitrification is simple, rapid, and economical; however, its main drawback is that it is performed in an open system in which the cells or tissues are in direct contact with liquid nitrogen.[80] Current efforts are focused on developing adequate closed systems to ensure safety. Whether slow freezing or vitrification methods are employed, the greatest risk of cryodamage occurs during either the cooling or the thawing process. Little damage to cells and tissues is thought to occur during extended storage.[75]

In the field of ART, embryo and sperm cryopreservation are considered standard technologies. Preimplantation stage embryos can be cryopreserved at any stage of development (pronuclear, cleavage, or blastocyst). Although the use of embryo vitrification is increasing, to date most embryo cryopreservation cases have used slow-freezing methods. The post-thaw incidence of embryo survival and implantation is 60% to 80% and 15% to 20%, respectively, and there have been approximately half a million babies born worldwide from embryo banking using slow freezing.[75,82,83]

Although the freezing of mature seminal sperm has been routine for decades, it is not a perfect process.[83] In fact, sperm motility and several key sperm structures, including the acrosome, tail, and plasma membrane, are highly sensitive to cryodamage.[84] In the majority of cases, the loss of sperm to cryodamage is negligible since a normal ejaculate contains sufficient sperm to compensate for the loss. However, cryopreservation can become more challenging in cases of oligozoospermia. In these situations, additional procedures such as swim-up tests or centrifugation are typically performed to enrich the population for higher quality sperm.[85]

In contrast to embryos and sperm, unfertilized eggs have been difficult to cryopreserve, with a post-thaw survival rate of only approximately 30% to 50%.[75] This is likely due to the sensitivity of key cellular structures necessary for future fertilization, including cortical granules, the zona pellucida, and the meiotic spindle.[76] Nonetheless, some highly trained laboratories that specialize in egg cryopreservation have reported fertilization and developmental capacity of slow-frozen or vitrified human eggs at a rate that is on par to what has been achieved using fresh eggs, highlighting the potential of this technology.[72,73,86-88] More challenging has been the cryopreservation of immature or germinal vesicle-intact oocytes, since these cells must undergo the additional step of *in vitro* maturation after thawing before they can be fertilized.

Recently, the cryopreservation of ovarian and testicular tissue has become more widespread in the field of fertility preservation, especially in cases involving prepubertal males and females whose gametes are not yet mature.[89,90] Gonadal tissue can be frozen as cell suspensions, tissue pieces, or whole organs. Most tissue has been frozen using slow-freezing protocols, although promising results have also been obtained with vitrification.[91,92] Freezing and thawing tissues versus individual cells is complex as it must be done in such a way that maintains cell-to-cell interactions in a characteristic architecture. This is essential if both endocrine and reproductive function are to be restored when thawed tissues are re-introduced into the patient. Both somatic cells (male: Leydig and Sertoli; female: granulosa, cumulus, and theca) and germ cells (male: spermatogonia and spermatids; female: oocytes) and their arrangement within the tissue must be protected. As discussed in the *Investigational Methods & Basic Science* section, approximately 28 live births have been reported following transplantation of frozen and thawed cortical ovarian tissue.[93,94]

Coupled with the freezing of gonadal tissue is the need to develop and optimize methods for transplantation or isolation of immature gametes from the thawed tissue followed by *in vitro* growth to maturity. In the male, the advent of ICSI has allowed different types of samples to be stored. With ICSI, pregnancies and live births can be achieved with ejaculated, seminal, and testicular spermatozoa, even in cases of low sperm number or quality.[95] In addition, injection of immature round spermatids can be performed clinically.[96]

Because reproductive cells and tissues differ in their size, number, composition, and structure, there is no standard protocol for cryopreservation. The success of this technology is highly site dependent, and patients should be referred to specialized centers with trained staff who can address their specific needs.

Assessing Reproductive Potential Before, During, and After Cancer and Treatment

Assessing a patient's reproductive function in an oncofertility setting is best performed before cancer treatment begins because doing so can help predict how vulnerable a patient may be to cancer therapies and evaluate the most beneficial fertility preservation option. Measuring reproductive function after cancer therapy may indicate whether a potential for restored natural fertility exists or whether the patient must rely on previously performed fertility preservation methods.

In females, ovarian reserve is defined as the functional potential of the ovary and reflects the number and quality of oocytes it contains.[97] Although there is no single predictive

marker of ovarian reserve, several tests have been developed (Table 33.5). Currently, serum anti-müllerian hormone (AMH) levels combined with antral follicle counts (AFC) are the most robust markers for evaluating ovarian reserve.[98-101] AMH is produced by the granulosa cells in developing ovarian follicles,[102,103] and AMH levels do not vary with menstrual cycle day, oral contraceptive use, or pregnancy.[102] Serum AMH levels decrease rapidly after the age of 37, and this drop precedes but is related to the onset of menopause.[104,105] A study performed in regularly menstruating women assessed several hormonal markers of aging and found that serum AMH was the most accurate in predicting the occurrence of the menopausal transition within 4 years.[105]

Serum AMH also correlates with the number of antral follicles, which can be determined by counting the number

Table 33.5 Common Clinical Tests for Assessing Fertility

Reproductive Function Test	Significance
Female	
Anti-müllerian hormone (AMH)	• Blood test performed on any day of the menstrual cycle to measure AMH levels in the bloodstream • AMH is produced by granulosa cells of growing follicles in the ovary • Indicates the size of the pool of growing follicles in the ovary (Lower levels correlate to fewer growing follicles) • This test is best performed in combination with antral follicle counts in the ovary
Day 3 estradiol	• Blood test performed on day 3 of the menstrual cycle to measure estradiol levels in the bloodstream • Estradiol is produced by the granulosa cells of the ovary and the adrenal cortex • High estradiol can suppress FSH or cause problems with ovulation • Always performed in combination with a Day 3 FSH test to reaffirm FSH results
Day 3 follicle-stimulating hormone (FSH)	• Blood test performed on day 3 of the menstrual cycle to measure FSH levels in the body • FSH is synthesized and secreted by the anterior pituitary gland • High FSH correlates to low egg count in the ovary; however, normal FSH does not necessarily correlate to sufficient egg quantity • Performed in combination with a Day 3 Estradiol blood test
Day 3 inhibin B	• Blood test performed on day 3 of the menstrual cycle to measure inhibin B levels in the body • Produced by the granulosa cells in the ovary to inhibit FSH • Lower inhibin B levels may indicate higher FSH levels, which may account for a lower egg count • Used in combination with Day 3 Estradiol and Day 3 FSH test • Inhibin B decreases with age
Antral follicle counts (AFC)	• Transvaginal ultrasound test in which antral follicles approximately 2-10 mm in diameter are counted • Correlates to the number of dormant primordial follicles remaining in the ovary • Best performed in combination with an AMH blood test
Ovarian volume	• Transvaginal ultrasound test to measure the length, width, and depth of both ovaries • Ovarian size decreases with age, so a smaller ovary may indicate a smaller ovarian reserve • Though the difference in ovarian volume may be statistically significant, AFC is a better predictor of ovarian reserve and the clinical value of this test is controversial
Uterine ultrasound	• Ultrasound scan test used to assess uterine size and shape, blood supply, and endometrial thickness • Problems with these uterine characteristics may impact implantation and the ability to conceive • A more invasive follow-up endometrial biopsy may be performed to further assess the quality of the uterus • The clinical value of this test is controversial
Clomiphene citrate challenge test	• Patient is given clomiphene for 5 days to induce ovulation and then a blood test is performed to measure levels of estradiol, FSH, and LH • Causes the release of more than one egg • If FSH levels are elevated, may indicate a diminished ovarian reserve • The clinical value of this test is controversial
Menstruation	• Evaluation of a patient's return to or lack of menstruation post-treatment • May indicate that normal fertility has been restored if a patient begins to cycle post-treatment • A return to menstruation does not guarantee that a person has ovulated or is able to conceive • Does not account for potential early menopause
Male	
Semen analysis	• Parameters measured are ejaculate volume, sperm concentration, sperm motility, and sperm morphology • These can be assessed longitudinally to track testicular function over time and gain insight into reproductive potential
Serum FSH	• Blood test that measures FSH levels to give insight into spermatogenesis • FSH is synthesized and secreted by the anterior pituitary gland • Elevated serum FSH levels (>7.0 mIU/mL) can signal spermatogenic impairment
Sperm DNA damage	• Measured in a variety of ways including the sperm chromatin structure assay, the comet assay, the TUNEL (terminal deoxynucleotidyl transferase dUTP nick end labeling) assay, the DFI (DNA fragmentation index) assay, FISH (fluorescence *in situ* hybridization), and the SCD (sperm chromatin dispersion) test • Sperm DNA damage typically increases during the course of cancer treatment but returns to baseline levels over time

From Duncan FE, Jozefik JK, Kim AM, Hirshfeld-Cytron J & Woodruff TK. The gynecologist has a unique role in providing oncofertility care to young cancer patients. *US Obstetrics & Gynaecology* **6**:24–34, 2011 and Meistrich ML. of 2- to 10-mm diameter follicles by transvaginal ultrasound.[105,106] A strong correlation between AMH levels and AFC has been well established in clinical studies.[106-108] The number of small antral follicles is one of the best markers of ovarian age related to the ovarian reserve.[106] It has also been shown that serum AMH levels and AFC, when analyzed together, are indicative of primordial follicle number independent of age.[109] Thus, in combination, serum AMH levels and AFC are strong correlates of ovarian age and the remaining ovarian reserve.

The use of serum AMH levels and AFC to test ovarian reserve has been effectively translated into the oncofertility setting, where various cancer treatments have been shown to compromise the follicle pool.[101,110-112] Clinical studies have shown that serum AMH levels and AFC measured in cancer patients post-treatment were highly correlated to each other and significantly lower than in control patients without cancer.[101,108,113] In a recent longitudinal study, AFC, ovarian volume, and levels of FSH, LH, estrogen, inhibin A and B, activin A, and AMH were compared between regularly menstruating breast cancer patients (ages 22 to 42 years) and patients without cancer.[114] This study demonstrated that, although the breast cancer patients had normal ovarian reserve prior to cancer treatment, there was a significant decrease in AFC and a drastic reduction in AMH levels post-treatment. Being able to correlate markers, such as serum AMH levels and AFC, with a diminished ovarian reserve is critical in the fertility preservation decision-making process.

Performing these tests helps to assess the need for fertility intervention in patients who may be susceptible to early menopause or a decreased ovarian reserve both before and after treatment. Although these tests are an appropriate measure of the remaining developing follicle pool, it is important to remember that they do not guarantee that pregnancy—the ultimate proof of fertility—will occur.[97,99,100] While AMH and AFC are one of the better test combinations for predicting the ovarian reserve, a number of other tests are commonly used to evaluate a woman's fertility status (Table 33.5).[63,100] For example, additional hormonal assays include tests of Day 3 estradiol, FSH, and inhibin B. Dynamic tests such as the clomiphene citrate challenge test can be used to test a patient's ability to ovulate. It is of critical importance to counsel patients that a return to normal menstruation is not necessarily indicative of fertility, because there is still a possibility of anovulation or diminished ovarian reserve.[115,116] In addition to fertility, measures of endocrine function are an important consideration because of the severity of symptoms related to endocrine dysfunction, including precocious puberty, hot flashes, loss of bone density, and loss of sexual function.[117-119]

In males, accurate assessment of reproductive potential throughout the course of cancer therapy is typically easier than in females, given that most males can provide ejaculated semen samples for analysis. Ejaculate volume, sperm concentration, sperm motility, and sperm morphology can be assessed longitudinally to track testicular function and gain insight into reproductive potential. Serum FSH levels provide insight into spermatogenesis, with elevated serum FSH levels (greater than 7.0 mIU/mL) typically signaling spermatogenic impairment. Over the last several years, sperm DNA damage in the wake of cancer therapy has garnered increasing attention. Cancer therapies can indeed result in increased levels of sperm DNA damage, and numerous methods to assess sperm DNA breaks are commercially available. Examples of these tests include the sperm chromatin structure assay, the comet assay, TUNEL (Terminal deoxynucleotidyl transferase dUTP nick end labeling) assay, DFI (DNA fragmentation index) assay, FISH (fluorescence *in situ* hybridization), and SCD (sperm chromatin dispersion) test. Meistrich has authored an excellent review that includes a discussion of sperm DNA damage resulting from cancer therapy.[120] While sperm DNA damage and aneuploidy often increase during the course of cancer therapy, most patients experience a return to baseline levels over time. Furthermore, numerous studies have shown no increase in genetic anomalies or birth defects when comparing the offspring of cancer survivors with those of individuals unaffected by cancer.[121-124] As Meistrich notes, most pregnancies considered in the above studies were conceived well after completion of cancer therapy.[123]

Risks and Limitations of Fertility Preservation Techniques

Regardless of which fertility preservation method is employed, patients should be counseled regarding each method's limitations and the risks that may be encountered. ART procedures, which are broadly used in the setting of oncofertility, do not guarantee live births, even in patients without cancer. Currently, the cumulative live-birth rate following IVF is approximately 50%.[61] Recent data describing the outcomes of almost half a million ART cycles are encouraging, and suggest that with favorable patient and embryo characteristics, live birth rates following ART are approaching those of natural fecundity.[125] However, there are potential risks associated with ART procedures. It has been suggested that singletons born following IVF may have an increased risk of low birth weight, prematurity, and perinatal mortality.[126] ART procedures are also associated with a ten-fold increase in the number of multiple births compared with natural conceptions.[126] Furthermore, three imprinting disorders—Beckwith-Wiedemann syndrome, Angelman syndrome, and maternal hypomethylation syndrome—have been linked to ART procedures.[127] Finally, one of the reasons that cancer patients choose not to pursue fertility preservation is their fear of passing their cancer onto their offspring.[128] However, only between 5% to 10% of all cancers are hereditary.[129]

Additionally, cancer survivors may fear pregnancy because of the possibility of cancer recurrence or potential detrimental maternal and fetal health outcomes during the pregnancy. However, multiple studies to date suggest that even for women with hormone-responsive malignancies such as breast cancer, there were no adverse outcomes with regard to cancer recurrence or survival due to pregnancy.[130] It is encouraging that children born to cancer survivors are not at increased risk of genetic abnormalities, birth defects, or cancers compared to those born to parents without a cancer history.[131] There may, however, be an increased risk for miscarriage, low birth weight, and prematurity, largely related to pelvic radiation.[131-133]

Minimizing or avoiding risks of treatment-related infertility exist and counseling should begin before cancer

treatment is initiated if at all possible. There are ways to minimize the risks associated with ART procedures and maximize the likelihood of successful fertility preservation. To increase the chances of a live birth following cancer treatment, patients should be counseled to seek ART and fertility preservation procedures at the most established institutions possible, as not all centers are equivalent (Table 33.2; Assisted Reproductive Technology Resources). For women with hereditary cancers, one way to avoid the risk of potentially transmitting gene mutations is to combine fertility preservation methods with preimplantation genetic testing (PGT). In PGT, genetic testing is performed on a biopsy from a preimplantation stage embryo to ensure that only embryos free of the specific mutation are transferred back into the uterus.[134] PGT has been used to screen for several cancer predisposition gene mutations, including adenomatous polyposis of the colon (APC), neurofibromatosis type 2 (NF2), and inherited breast cancer (BRCA1 and BRCA2).[135]

Investigational Methods and Basic Science

The current standard methods for fertility preservation, which include embryo and sperm cryopreservation, are suitable for only a fraction of cancer patients (i.e., males who can provide a sperm sample and adult women with a partner or sperm donor who have sufficient time and appropriate hormone receptor status). Thus, the research community has been charged with the mission to explore and broaden fertility preservation options to include a greater number of cancer patients, including prepubertal patients. Investigational methods that hold tremendous promise for both males and females include: (1) protecting gonads *in vivo* from iatrogenic insults (fertoprotective adjuvant therapies), (2) developing robust ways to harness the reproductive potential of cells within gonadal tissue (transplantation and *in vitro* gametogenesis), and (3) creating gametes *de novo* through differentiation of embryonic stem cells (ESCs) or induced pluripotent stem cells (iPSCs) (Table 33.4). All of these methods are described below, and are either being tested in preclinical studies or are investigational and should be performed clinically only under IRB approval.

Investigational Methods That Protect Gonadal Tissue *In Vivo*

The current practice of fertility preservation is based on the removal and storage of an individual's reproductive tissues or cells prior to exposure to destructive treatments to preserve fertility. However, another option—"adjuvant" fertoprotection—is an area of active research. With fertoprotective therapy, an individual's existing reproductive tissue remains in the body but is protected from damage caused by cancer treatment using pharmacological interventions. To date, fertoprotection has been attempted in both males and females using two methods. The first involves the use of GnRH analogs to suppress gonadotropins, thereby keeping spermatogenesis and folliculogenesis in a state of suspended animation.[136] This method has been used clinically, and sex-dependent differences in treatment response are evident. In men, only one out of eight clinical trials reported successful protection or restoration of spermatogenesis with GnRH analogs in patients exposed to cytotoxic agents.[136,137] In females, the results remain inconsistent and controversial.[138] Moreover, the mechanism by which GnRH analogs protect fertility is largely unknown.

The second approach to fertoprotective adjuvant therapy is based on preventing gametes from eliciting DNA damage and cell death pathways in response to radiation or chemotherapy. Although promising, this method is still investigational and limited to preclinical studies in animal models. In one study, direct and controlled long-term treatment of nonhuman primate ovaries with the anti-apoptotic factor sphingosine-1-phosphate (S1P) or its long-acting mimetic, FTY720, protected against irradiation-mediated oocyte death.[139] Moreover, adult female primates whose ovaries were exposed to FTY720 prior to irradiation were able to deliver healthy offspring following natural conception. Whether or not these anti-apoptotic agents are also protective against chemotherapy-induced damage in nonhuman primates is unknown. Another potential fertoprotective adjuvant is Gleevec® (imatinib mesylate); in mice, imatinib has been shown to block cisplatin-mediated apoptosis in small ovarian follicles, likely through inhibition of the c-Abl pathway.[140-142] In fact, follicle loss and infertility due to cisplatin exposure was partially prevented if mice were co-treated with imatinib, demonstrating the fertoprotective properties of this approach. Similar fertoprotective strategies may be functional in the male. Treatment of male mice with the immunomodulator AS101 partially protected against cyclophosphamide-induced damage of the testis and sperm.[143] With all these agents, the precise molecular pathways being affected are not known.

Fertoprotection is an attractive option clinically because it has the potential to maintain not only fertility but also endocrine function. However, it is also important to note that all gametes in the body at the time of cancer treatment will be exposed to DNA damaging agents, putting them at risk for defects in genetic integrity that may be passed to the next generation. Therefore, it is equally important that researchers and the pharmaceutical industry continue to focus their efforts on drug development to create "smart" cancer therapies that target the cancer while sparing the reproductive organs.

Investigational Methods That Harness the Reproductive Potential of Cells Within the Testis or Ovary

In males, there are three main investigational methods based on harnessing the potential of diploid gamete precursor cells present in testicular tissue.[144] These methods include: (1) autologous transplantation or xenotransplantation of testicular tissue, (2) transplantation of isolated spermatogonial stem cells (SSCs), and (3) *in vitro* spermatogenesis (Fig. 33.4). Much of the development of these techniques has been performed in animal models with varying degrees of success; of note, none have been proven safe or efficient in humans to date.[145-147] These investigational techniques, their benefits, and their limitations are briefly discussed below, followed by an overview of parallel approaches in females.

Testicular tissue transplantation can be accomplished with the use of either testicular cell suspensions or fragments of testicular tissue. Transplantation can be categorized as either autotransplantation, involving procedures where the gametes are replaced back into the original donor, or xenotransplantation, involving procedures where gametes are placed into an organism from another species, typically an immune-deficient mouse. Schlatt and colleagues have described the successful autotransplantation of primate testicular cell suspensions after testicular irradiation. Their technique involved injection of the cell suspension back into the testicle via the rete testis.[148] The injected germ cell stem cells then repopulated the seminiferous tubules and differentiated in the testicular microenvironment into mature spermatozoa. Although successful autotransplantation has not yet been reported in humans, this technique has been successful in primates, as noted in the above study.

Autologous transplantation has been performed using both cell suspensions and fragments of testicular tissue. When cell suspensions are used, as noted above, the fluid is typically injected into the testicle of the recipient organism via the rete testis. When fragments of testicular tissue are used, they have commonly been surgically placed in a subcutaneous location within an immune-deficient recipient organism. Both approaches have been used in a number of different organisms.[149,150] The benefit of this method is that the stem cell niche is maintained and the SSCs within the tissue can develop and differentiate in their initial intact microenvironment. Although autologous testis grafting has not yet been reported in humans, this technique has been successful in several other species, resulting in restored spermatogenesis and fertility.[148] The drawback to this technology is that there is a risk of reintroducing cancer cells because the testis is an immunologically privileged site. In fact, in a rat model, injection of only 20 leukemic cells into the testis was sufficient to reintroduce disease.[151] Another limitation is that tissue grafting appears to only function optimally when immature testicular tissue is used as the graft because adult tissue undergoes almost complete degeneration after transplantation.

As an alternative approach, xenotransplantation is a procedure in which the testicular tissue is transplanted and allowed to develop *in vivo*, within a niche of a host animal.[145,146,152,153] Mature sperm are then extracted and used in ART. Immunodeficient mice and rats are common hosts. Xenotransplantation has been attempted in several species with varying degrees of success of donor-driven spermatogenesis.[153] Blocks in spermatogenesis are common when the host and donor species are dissimilar, likely because of various biological differences between the two species, such as hormone levels, timing of spermatogenesis, or testis structure. The field of xenotransplantation also faces significant ethical barriers to translation into clinical practice. Although xenotransplantation would eliminate the risk of reseeding cancer cells, there is a risk of transmitting viruses or infectious agents from animals to humans. It is also not known how the genome or epigenetics of human gametes may be impacted following development in another organism. Even if it is not used for clinical purposes, xenotransplantation still provides a useful model to assess the risk of reintroducing malignant cells following transplant, to test the effects of gonadotoxic treatments on human gamete development, to determine the efficacy of cryopreservation techniques, to understand the mechanisms of tissue revascularization after transplant, and to optimize grafting conditions.[154]

A second investigational approach is the transplantation of SSCs isolated either from fresh or cryopreserved testicular tissue.[146,153,155,156] These cells can be transplanted back as a suspension into a testicular environment that is depleted of germ cells. Because of the high colonization potential of SSCs spermatogenesis can be reinitiated in the optimal environment. In this case, the patient's seminiferous epithelium provides the microenvironment for germ cell differentiation. Based on animal studies, the success of SSC transplantation is linearly correlated with the quantity and quality of transplanted cells and on the corresponding quantity and quality of stem cell niches in the recipient testis. For SSC transplantation to be successful, several events must occur. The SSC population must be enriched and purified from other cell populations, including cancer cells. This can be accomplished by cell sorting techniques that make use of SSC-specific markers. The SSC population must also be expanded in culture to increase the number of SSCs available for transplant. Although in humans it has been difficult to identify SSC markers for cell sorting, methods have been developed to expand these cells *in vitro*.[157,158] Once purified and expanded, SSCs need to be injected into the seminiferous tubules or infused into the rete testis. For spermatogenesis to initiate, the SSCs must associate with Sertoli cells and relocate from the lumen to the basement membrane in the seminiferous epithelium. A limitation of this technique is that it requires a suitable stem cell niche, which might be compromised in men with advanced age or who have been exposed to iatrogenic insults. A human clinical trial of germ cell transplantation was initiated in Hodgkin lymphoma patients at Christie hospital in Manchester (UK) in 1999, but no information has been published to date on the fertility outcomes of these patients.[159]

The third approach that holds promise for male fertility preservation is *in vitro* gametogenesis, in which the events required to produce functional spermatozoa are recapitulated entirely outside the body. Such methods are quite challenging because many cell types and signaling pathways must be coordinated over a protracted time frame of several weeks. For more than a century, there have been myriad strategies developed to differentiate male germ cells from multiple species *in vitro*, ranging from tissue and organ culture on permeable supports or encapsulation in hydrogels to Sertoli cell co-culture.[160-163] Although all of these systems have provided key insights into the basic biology of spermatogenesis, they have either failed to recapitulate the whole process or were not able to produce sperm capable of fertilization. Recently, however, significant progress has been reported: fertilization-competent haploid mouse sperm were derived from organ culture on a semi-solid agarose support of testis fragments from 2.5 to 3.5 day old mice.[164] Using this culture method, combined with a gas-liquid interface, round spermatids and sperm were obtained after 23 and 42 days of culture, respectively. Through round spermatid injection (ROSI) or ISCI, live offspring were generated.[164]

Similar to the fertility preservation approaches being investigated for males, transplantation of gonadal cells or tissue (follicles or ovarian cortex) as well as *in vitro* gametogenesis

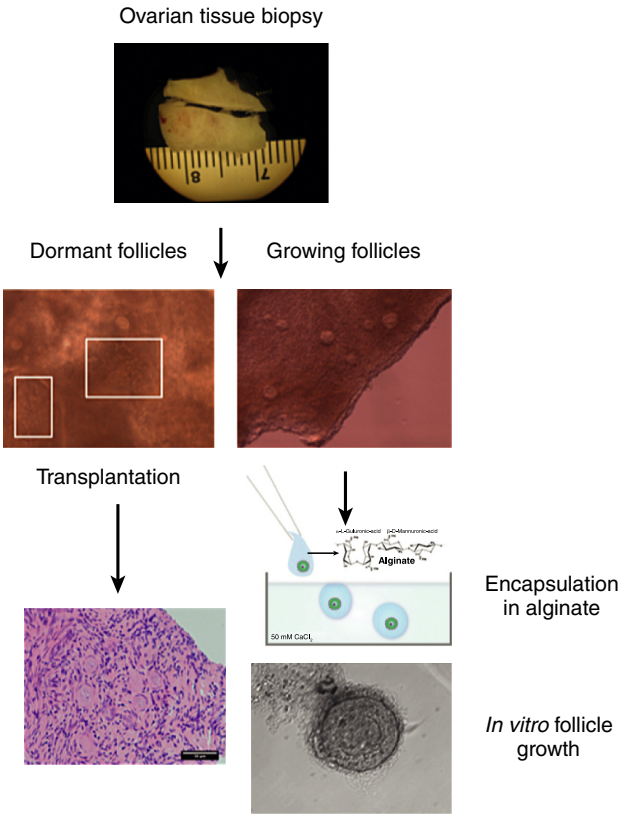

FIGURE 33.5 Ovarian tissue removal (either biopsy or whole organ) followed by cryopreservation is the only current option for prepubertal girls and certain patients who have hormone-responsive cancers or who cannot delay their cancer treatment. The ovarian tissue contains both dormant primordial follicles and growing follicles. The dormant follicles within this tissue will re-establish endocrine function and fertility if the ovarian tissue is transplanted back to the patient. The growing follicles could ultimately be used in methods such as *in vitro* follicle growth, which is currently being developed to obtain mature eggs. This ovarian tissue was obtained from a 15-year-old patient with idiopathic aplastic anemia who had already received immunosuppressive therapy. Her ovary contained visible dormant follicles *(left)* and growing follicles *(right)*.

(ovary and follicle culture) are emerging fertility preservation options for females (Figs. 33.3, 33.5, and 33.6). In fact, in some cases, these technologies are more advanced in females and have already been applied successfully clinically as described below. For certain female populations, removal of ovarian tissue prior to cancer treatment may be the only option for fertility preservation. These populations include prepubertal females, those who do not have time to undergo ART prior to starting cancer treatment, or those who cannot tolerate the supraphysiological hormone exposure required for most ART procedures. Following surgical removal, ovarian tissue is cryopreserved and can be used later for transplantation once the patient has been deemed cancer-free. Although the current approach is to cryopreserve ovarian cortical strips, methods are being developed to freeze whole ovaries for later transplantation through vascular anastomosis.[165,166] The goals of ovarian tissue transplantation are both to restore fertility and endocrine function.

The notion of ovarian transplantation originally gained ground as a viable fertility preservation option when autotransplantation of both fresh and frozen-thawed cortical strips in oophorectomized sheep restored fertility and resulted in the birth of two lambs.[167] In the human, ovarian transplantation was first tested through a series of heterologous transplants, using either fresh cortical tissue or whole ovaries, between nine pairs of monozygotic twins who were discordant for premature ovarian failure.[14] These heterologous transplants of fresh ovarian tissue resulted in 14 pregnancies and 11 live births in 7 of the 9 recipients.[14] In an oncofertility setting, the ovarian tissue is cryopreserved and stored for an indeterminate amount of time prior to transplant.[91] To date, 17 live births have been obtained following autologous transplant of frozen-thawed ovarian tissue, for a total of 28 live births following ovarian tissue grafting.[93,94] Of note, following transplant, these women reported resumption of normal menstrual cycles and several were able to conceive without the use of ART.

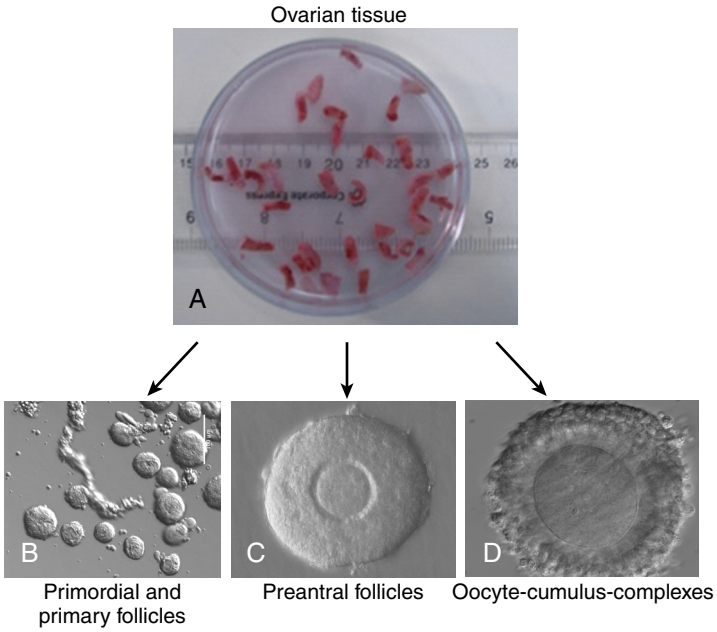

FIGURE 33.6 Human ovarian tissue that is surgically removed for cryopreservation (**A**) contains follicles at early stages of development that can be grown *in vitro* (**B-C**) as well as small antral follicles with oocyte-cumulus-complexes (**D**) that can be used in *in vitro* maturation protocols to obtain mature eggs.

All human live births to date have occurred following orthotopic ovarian transplantation, in which human ovarian tissue is transplanted back to its original location either on the remaining ovary or near the infundibulopelvic ligament or ovarian fossa.[168] An active area of research is heterotopic transplantation, in which the ovarian tissue is grafted subcutaneously at various sites, including the brachioradialis fascia of the forearm or under the rectus sheet in the lower abdomen.[169-171] Heterotopic transplantation is an attractive option because it can be performed in patients who have had pelvic irradiation and may have ovarian scarring, can be performed at the same time the ovarian tissue is removed, and allows for simple monitoring of follicle development.[168] Thus far, heterotopic transplantation in women has had varying degrees of reproductive success, resulting in restored endocrine function, follicle development, gametes capable of fertilization, and preimplantation embryo development.[170-172] Although biochemical pregnancies have been reported from gametes derived from heterotopic transplantation, no live births have occurred in humans.[173] However, there has been a live birth in the nonhuman primate following ectopic transplantation, demonstrating the potential of this technology.[174]

As is true in the field of testicular tissue transplantation, there are several risks and concerns in ovarian tissue transplantation. First, it is difficult to estimate the true efficacy of this technique because, although live births have been reported worldwide following this procedure, it is not known how many total transplants have been attempted that may not have been successful. In addition, the number, quality, and distribution of follicles within the cortical tissue from each patient cannot be predicted, and it is not known how long the transplants will remain functional. Finally, there is a lack of robust methods to detect residual cancer cells in the ovarian tissue, and thus there is an inherent risk of introducing cancer cells upon transplantation.[175-177] Obtaining definitive data about ovarian tissue transplantation will be a slow process because it could be decades before children who have frozen their tissue return to use it.

To overcome some of the risks of ovarian tissue transplantation, methods including xenotransplantation and follicle transplantation are also under investigation. Varying degrees of follicle development have been reported after xenotransplantation of human ovarian tissue. In short-term studies, xenografting human ovarian cortical tissue or isolated follicles for 1 week resulted in significant follicle activation and growth.[178] In a longer-term study, human ovarian tissue xenografts were transplanted under the kidney capsule of mice for 11 and 17 weeks in the presence or absence of FSH.[179] It was determined that follicles could survive and grow during this period and that FSH was required for growth of follicles beyond the secondary stage. Consistent with these findings, when ovarian biopsies from women 26 to 29 years of age were xenografted into mice for 5 months with FSH administered during the final 2 weeks, primordial, primary, secondary, and antral follicles were observed in the harvested tissue.[180] Xenotransplantation of human ovarian tissue into the back muscle of mice has resulted in the formation of large antral follicles and MII eggs.[181] Current studies are focused on determining the optimal sites (intraperitoneal, subcutaneous, intramuscular, beneath the ovarian bursa, or under the kidney capsule) and conditions for xenotransplantation.[182]

Similar to xenotransplantation, transplanting isolated ovarian follicles would reduce the likelihood of reintroducing cancer cells into the patient. Follicles could be isolated from fresh ovarian tissue, cryopreserved, and then thawed at the time of transplant.[183] Alternatively, follicles could be isolated from previously cryopreserved tissue upon thawing.[183] In mice, single-cell suspensions derived from primordial follicles from either fresh or frozen and thawed tissue were aggregated in plasma clots and transplanted into the ovarian bursa.[184,185] These cells reassembled into follicle structures that restored estrous cyclicity and fertility. Whether this approach will also work in nonhuman primates and humans is not known. In addition, although these findings are intriguing, it remains to be determined whether intact isolated follicles are sufficient to restore reproductive function.

Research is currently focused on ways to improve transplantation outcomes by optimizing how the ovarian tissue is cryopreserved and processed prior to transplantation. For example, ovarian tissue cryopreservation using slow-rate freezing is standard in most clinics, but this method is inefficient partly due to significant follicle loss that occurs during the freeze-thaw procedure.[186] Ongoing studies in several species including the bovine, rhesus macaque, and human indicate that vitrification may be a more effective method to cryopreserve both the follicles and the stroma within ovarian tissue.[92,186] Additional challenges with ovarian tissue transplant are slow graft revascularization and ischemia, which can also lead to follicle loss. Methods that decrease inflammation, reduce oxidative damage, inhibit apoptosis, and promote angiogenesis appear to improve the survival and quality of grafts.[187,188] Transplantation of vitrified and thawed mouse ovarian tissue encapsulated in fibrin, which was modified with heparin-binding protein, heparin, and VEGF, resulted in significantly increased blood vessel formation and twice the number of surviving primordial follicles compared to controls in which no biomaterial was used.[187] Increased graft survival was also observed when cryopreserved and thawed human ovarian tissue was pretreated with VEGF-A, vitamin E, and hyaluronan-rich biological glue prior to grafting into immunodeficient mice that had been pretreated with melatonin.[188]

In Vitro Follicle Growth

Though ovarian tissue banking is performed globally, the major hurdle faced by the research community is what to do with the tissue once it is thawed, especially when there is a risk of disseminated disease or genetic predisposition to cancer conversion (e.g., BRCA mutation) with autotransplantation. One approach that is still under development is *in vitro* follicle growth (IVFG), which has resulted in live birth in model organisms. While IVFG has theoretical and practical advantages, it also has technical limitations (Table 33.4), and it is very important that a patient who opts for ovarian tissue banking is aware of these issues.

Many IVFG methods are under development around the globe, reflecting the significant interest within the biomedical community to provide next-generation ART options for cancer patients who have banked their ovarian tissue.[189-214] In all cases, ovarian tissue is recovered from patients and stored for their later use (Figs. 33.5 and 33.6). The majority of follicle types in the removed tissue

are primordial and secondary follicles (Fig. 33.6). Growing follicles can be isolated and cultured on flat plastic, in a hemi-dome, or in a three-dimensional environment (Fig. 33.7). Primate follicles require extended periods of time in culture and the support of dynamic somatic cell-germ cell interactions; this "architectural" requirement led to the development of alginate and other biomaterials that mimic the natural ovarian structure in the late stages of follicle maturation (Figs. 33.5 and 33.7). The alginate hydrogel system has been tested in mouse and has been successfully applied to rhesus monkey, baboon, and human follicles.[215-223] The terminal meiotic maturation of the human oocyte, its fertilization, and its transfer to a human recipient await development. The primary advantage of this system is that follicle growth is carried out completely *in vitro*, producing a mature egg that can be fertilized. Thus, the embryo, which contains no somatic cells from the donor, can be transferred to the patient or to a gestational carrier without the risk of re-introducing cancer to the patient who has just survived her disease. However, this method does not restore endocrine function, and the patient will need endocrine management for pregnancy and the duration of her life.

Investigational Methods to Create Male and Female Gametes *De Novo*

While the derivation of mature sperm and oocytes from stem cells is outside the scope of this chapter, work is progressing on this front and may one day hold promise for young cancer patients who wish to preserve their fertility (Table 33.4).[224]

The Future

As research advances continue to be made, it is likely that many of the investigational procedures highlighted here will be translated clinically if they are not already. Often these procedures require highly trained staff or specialized equipment to perform, and there may be only few centers worldwide with the necessary expertise to do so. Fortunately, recent studies have demonstrated that both male and female mammalian reproductive tissues can be maintained at cold temperatures for extended periods of time, with preserved morphology and function, which would permit transfer of the tissues. For example, in the rhesus macaque, spermatogenic induction to spermatocytes was observed after xenografting of immature testicular tissue that had been kept in ice-cold medium for 24 hours.[225] Ovaries from rhesus macaque kept on ice for between 18 to 24 hours were indistinguishable from fresh ovaries in terms of stroma and follicle morphology and levels of apoptosis.[226] In the human, cortical ovarian tissue that was kept on ice for 4 hours prior to cryopreservation contained follicles that survived following xenografting.[227] Moreover, human ovaries kept on ice for up to 24 hours contain follicles that, when isolated and used for *in vitro* follicle growth, are able to survive, grow, and form antral cavities similarly to those isolated from fresh tissue (unpublished data). The gametes produced by ovarian tissue maintained at cold temperatures for transport purposes

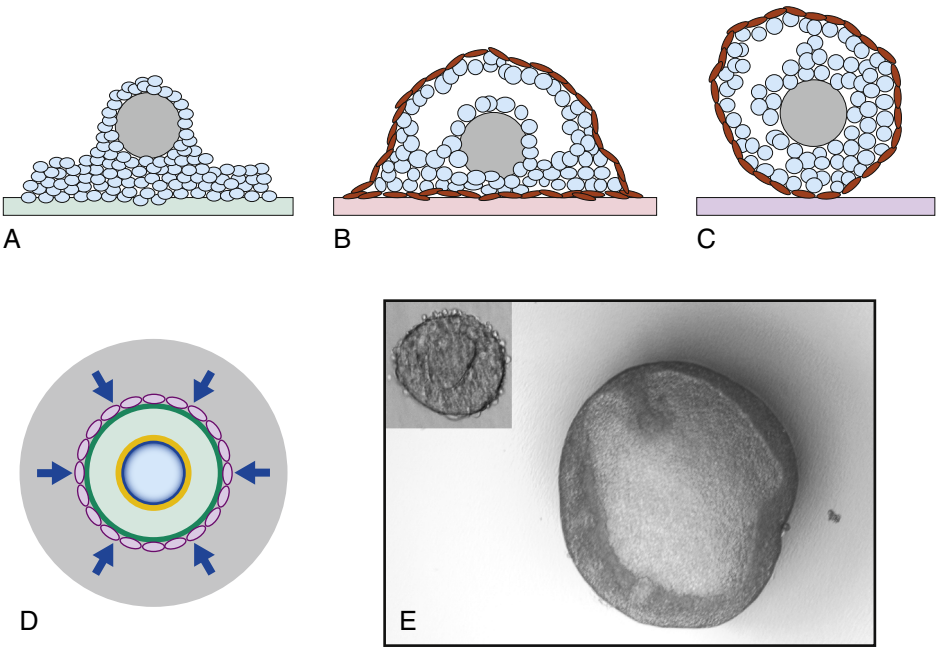

FIGURE 33.7 *In vitro* gametogenesis is a promising fertility preservation option that is actively being developed for both males and females. Several culture systems have been developed over the past decades to support coordinated folliculogenesis and oogenesis outside of the body. These systems include (**A**) growing granulosa-oocyte complexes on collagen transwells or growing isolated follicles on (**B**) adherent or (**C**) nonadherent surfaces. (**D**) Follicles can also be encapsulated and grown in hydrogels such as alginate. This biomaterial allows follicles to maintain their characteristic spherical structure and relative geometry (central oocyte surrounded by granulosa and theca cells) throughout development *in vitro*. Notably, this system is the only one to date that robustly supports the growth and differentiation of ovarian follicles from several large mammalian species, including dog, nonhuman primate, and human (**E**).

appear to be developmentally competent. In fact, a live birth was obtained following autotransplantation of ovarian tissue that had been kept on ice for more than 20 hours prior to cryopreservation.[218,228] Thus, patients seeking these investigational procedures may not have to be limited by their proximity to specialized centers to receive treatment.

The number of clinicians and basic scientists working in the field of oncofertility is growing exponentially. As the field grows, it is imperative that promising work developed in model organisms is first tested using human tissue whenever possible before being translated clinically, as there are known examples where even nonhuman primates may not be adequate models for humans.[218] In addition, researchers working independently on female and male fertility preservation strategies must maintain open lines of communication.

Oncofertility Patient Management

Although they are faced with the stresses inherent in a new cancer diagnosis, adolescent and young adult cancer patients list future fertility as one of their most important concerns. Discussions about fertility preservation are most beneficial when they occur as early as possible after the cancer diagnosis. Unfortunately, few cancer patients have the opportunity to discuss fertility issues with their oncologist or to be referred to a reproductive specialist at or soon after their diagnosis. Both provider- and patient-related issues contribute to the poor communication of fertility concerns and preservation options. Provider barriers include a lack of knowledge of the impact of cancer therapies on fertility and lack of resources for referring patients to reproductive specialists. Increasing providers' awareness of current guidelines regarding fertility preservation for cancer patients, as well as the patient resources that are available, can facilitate timely referral of patients to a consultation with a reproductive specialist. Patients may benefit from educational resources on basic concepts and issues in reproduction and fertility that they can access before their visit to the reproductive specialist. Each of these issues is discussed in more detail in this section.

Fertility Matters to Adolescents and Young Adults Diagnosed with Cancer

After a new cancer diagnosis, patients are focused on understanding prognosis, their impending treatments, the financial burdens, and family and work obligations, yet many young people diagnosed with cancer also have significant concerns about their future fertility. Cancer survivors recall that fertility concerns were influential enough to alter their cancer treatment decisions.[229-231] Fertility concerns can have a substantial impact on patients, both at the time of diagnosis and years later. Several studies have indicated that cancer survivors who are infertile due to their treatments are more likely to have emotional distress.[230,232,233]

Communication Barriers

While it is clear that many patients have questions and concerns about future fertility, it is also clear that these needs are not adequately addressed for a significant number of patients. The time around the initial diagnosis of cancer is stressful for patients, families, and providers, and discussions about the cancer diagnosis, acute risks, prompt treatment, and survival often take priority. Studies have shown that many oncology professionals do not routinely discuss fertility with their reproductive-age patients.[234-237] A 2009 survey found that only 47% of responding oncologists routinely refer patients for fertility preservation counseling, and that female physicians and those who had a favorable attitude about fertility preservation were more likely to refer.[237] Similarly, a 2010 survey of 249 oncologists found that more than half rarely refer patients to a fertility specialist, though 82% have referred patients at some point.[235] When planning cancer treatments, 30% of providers state that they rarely consider a woman's desire for fertility.[235]

There are many factors that may inhibit the oncology team from adequately discussing fertility concerns with patients, including both provider-related issues (e.g., little knowledge about fertility preservation options[238-241] and lack of interprofessional networks that include fertility specialists) and patient-related issues, such as poor survival prognosis, the need for immediate initiation of treatment, the patient's age, pubertal status, parity, marital status, and financial situation.[234,236,239,240] A 2007 qualitative study of 16 oncologists found that physician barriers included lack of knowledge about fertility preservation options, limited awareness of referral information for fertility specialists, the length of time the physician had been practicing (younger providers were more likely to refer patients for a fertility preservation consultation), and the physician's specialty (oncologists who administer chemotherapy were more likely than surgical oncologists to discuss fertility).[239] Patient factors that limited fertility preservation discussions included urgency in need for cancer treatment, perception of fertility preservation as being a low priority, female gender, increased parity, and greater disease progression.

Provider Communication

In 2006, ASCO convened a multidisciplinary panel that drafted and issued guidelines on fertility preservation for cancer patients.[59] These guidelines state "as part of education and informed consent before cancer therapy, oncologists should address the possibility of infertility…and be prepared to discuss possible fertility preservation options or refer appropriate and interested patients to fertility specialists." While clinical judgment should be employed in determining when to raise issues of fertility and fertility preservation with patients, having this discussion at the earliest possible opportunity is encouraged. Other professional societies and organizations, such as ASRM, the American Academy of Pediatrics, and the Oncofertility Consortium, have also developed "best-practice" guidelines and educational resources designed for patients and providers.[17,57,242-244] Improving providers' awareness of these guidelines and resources will improve patient awareness of cancer-related fertility concerns and facilitate timely referral of interested patients to a fertility preservation specialist. Specifically, patient care will likely be improved if earlier referral to a reproductive specialist is implemented.[245]

These provider-focused guidelines and educational tools also include flow diagrams and identify "points of

discussion" between the oncology team and the patient. At a minimum, two essential points that the oncology team must communicate successfully to all reproductive-age cancer patients are that (1) cancer treatments may cause future fertility problems; and (2) patients who express any interest in their future reproductive options can be referred to a reproductive specialist and/or a psychosocial counselor. These two points can be initiated by nonphysician members of the oncology team (such as nurses, a patient navigator, social workers, therapists, etc.).

Once a patient has been referred, the reproductive specialist should also provide a comprehensive consultation to interested patients, detailing risks of their cancer or cancer treatment to fertility, pregnancy after cancer, and all appropriate fertility preservation treatment options. If members of the oncology team feel comfortable discussing fertility in more detail, the ASCO guidelines provide additional "talking points."[59] These points may be discussed early after diagnosis, as patients decide whether to pursue a fertility preservation consultation, or later in the process, if patients request their oncologist's opinion regarding their fertility preservation options. If the oncology team does not initiate the topic of fertility and cancer, ideally, patients can access information on patient-facing web sites, such as MyOncofertilty.org, the Oncofertility Consortium blog, and SaveMyFertility.org (Fig. 33.8A-D), where they can obtain handouts, important contact information, and even download smartphone applications (Fig. 33.8E), that can help start a discussion about fertility with their oncology team (Table 33.3).[246-248] Many of the resources have been translated into Spanish and Italian to ensure broad distribution of information globally (see respective web sites).

Improving the Process

Ideally, the practice of oncofertility can be improved in ways that will decrease decisional conflict, improve patient satisfaction, and allow patients to make well- informed decisions. The first step is to improve patient comprehension about fertility preservation. It has been shown that knowledge and understanding of disease and treatment are closely linked to patient outcomes and quality of life.[249] Potentially, education about fertility preservation could begin at the time that the oncologist offers their patient a referral to a reproductive specialist. Patient knowledge about fertility preservation prior to their consultation with the reproductive specialist is currently very limited, which means that patients are asked to process a great deal of complex medical information during their initial meeting with the fertility preservation specialist. Not surprisingly, patients who sought out web sites such as fertilehope.org prior to their fertility preservation consultation had greater pre-visit knowledge than those who did not seek out this information.[246] One possible approach to improving cancer patients' understanding of fertility preservation issues is for the oncologist to direct patients to educational resources that should be accessed prior to the consultation with the reproductive specialist (Table 33.3); these resources would introduce vocabulary and general concepts in reproduction and fertility that would prepare patients to comprehend and participate in a discussion of the complex concepts and issues of fertility preservation with the reproductive specialist.

The development of innovative communication approaches is essential for further improving patient understanding of their fertility preservation options, especially in the challenging context of a recent cancer diagnosis. Web-based interactive educational tools and decision aids directed at patients may further improve access to fertility preservation information and allow for higher decisional satisfaction for reproductive-age cancer patients. In addition, the inclusion of discussions about fertility concerns as part of the standard of care for all patients will help avoid current biases in referral patterns based on patient characteristics, such as parity and prognosis. Effective oncofertility care is also dependent upon communication across departmental divisions, with the oncology team working closely with reproductive specialists to coordinate care on an individual patient basis. Multidisciplinary clinics have become more common in disciplines such as breast cancer, where surgeons, genetics counselors, medical oncologists, and others come together

FIGURE 33.8 Online resources, such as those developed by the Oncofertility Consortium, offer patients and providers a wealth of information about fertility preservation. Patients can visit various web sites to learn about how cancer may affect their fertility, what current clinical options are available, where to obtain the best care, and how to find support. Providers can keep abreast of basic research advances, find information on how to establish a fertility preservation program, and determine where to refer a patient. **A**, myoncofertility.org; **B**, myoncofertility.org (Spanish); **C**, savemyfertility.org; **D**, fertilitypreservation.northwestern.edu; **E**, oncofertility.northwestern.edu; and **F**, the iSaveFertility smartphone application that provides physicians with pocket guides and fact sheets.

to provide comprehensive care. Oncofertility should strive for a similar multidisciplinary approach to patient care.

An Example of Integrated Care Network: The National Physicians Cooperative

The National Physicians Cooperative is a nationwide network of 56 fertility preservation centers across the United States that consult with approximately 2700 young cancer patients each year (Supplemental Fig. S33.1A, which can be found on the companion Expert Consult Web site at www.expertconsultbook.com). This is an example of integrated care that exists in the U.S. that is also emerging across the globe, including the German group FertiProtekt (Table 33.2). Much like other global programs, the National Physicians Cooperative was established to provide a collaborative forum for the exchange of ideas, clinical research methods, and technologies in order to drive breakthroughs in basic reproductive physiology that may be translated directly to clinical medicine. It also provides a wide range of resources for oncology teams that treat young cancer patients, such as guidance on how to refer patients for fertility preservation, practical advice on how to navigate financial/billing issues, and information on new developments in fertility preservation research and practice that may affect patients. Clinically, these efforts have produced more than 400 annual consultations of young cancer patients with the fertility preservation patient navigator.

The Fertility Preservation Patient Navigator

A patient navigator is an individual who guides patients through and around barriers in the complex healthcare system to help ensure timely diagnosis and treatment. Often nurses or social workers within the health system play a patient navigator role.[247] In fertility preservation, a patient navigator serves as the primary contact for patients and clinicians, facilitating a cohesive relationship between patients and the various health care professionals who are involved in their care. Importantly, the oncofertility patient navigator serves as a bridge between departmental and disciplinary boundaries so that cancer patients are able to receive timely information regarding fertility preservation options and receive coordinated care from both the oncology team and reproductive specialists. The oncofertility patient navigator makes it possible for patients to make well-informed decisions in the window of time prior to starting their cancer treatment.

The navigator's role is to make contact with the patient, collect important clinical information, and set up an appointment for fertility preservation counseling with a reproductive endocrinologist or urologist as appropriate. In addition, there is a 24-hour telephone service called the Oncofertility FERTline, which allows patients and providers to call one number to obtain free, individualized information and referrals for fertility preservation services (Supplemental Fig. S33.1B, which can be found on the companion Expert Consult Web site at www.expertconsultbook.com). Calls from patients and providers throughout the world are triaged and navigated to the physician service in the most geographically favorable location.

With a good referral system and an effective navigator in place, oncology professionals do not need to become experts in fertility. The oncofertility patient navigator can help patients move between the complex specialties of oncology, urology, and reproductive endocrinology, as well as help make a complex topic more understandable and accessible to both clinicians and patients. The navigator can ensure that patients don't get lost between specialties.

In addition to facilitating referrals for fertility preservation consultations, navigators help educate patients about available fertility preservation options and can direct patients to the online educational resources described above (Figs. 33.8A-D). As more educational materials become available, the oncofertility patient navigator is able to sort through what information would be most helpful for a given practice or provider, deliver appropriate materials to patients, inform program developers about gaps in current educational materials, and help drive the next generation of web, print, and smartphone materials.

The oncofertility patient navigator can also provide important financial information and advice regarding fertility preservation procedures. Costs for fertility preservation services vary widely throughout the globe and are often not covered by insurance or country/state healthcare systems. A well-informed patient navigator who stays in touch with patients can ensure that expectations regarding coverage and reimbursement are managed up front and that follow-up letters to insurers are provided. Cost is a big issue for young patients, and fertility specialists and their office staff may not have the capacity to work closely on the special needs of cancer patients. Dedicated oncofertility patient navigators can provide the level of personalized care and interaction that these patients require. They may not be able to alter the payer decision, but they will provide the patient with the knowledge that everything that could be done was done to ease their financial burden. Navigators can also point patients to available programs that may defray the costs of fertility preservation. In these arrangements, fertility centers agree to offer cancer patients heavily discounted IVF cycles and pharmaceutical companies provide patients fertility medications at no cost. This can result in thousands of dollars of savings and put fertility preservation within a patient's financial reach. Unlike ordinary IVF patients who have time to save money for an eventual IVF procedure, the cost management for young cancer patients who are often at the earliest stages of their earning potential represents a barrier and an issue that the overall field must continue to consider on a country-by-country, payer-by-payer basis.

Decision Aids and Patient and Provider Information

Oncofertility strives to give cancer patients options when they are confronting potential infertility as a consequence of cancer treatment. Ideally, fertility preservation decisions must be made before treatment begins, adding stress to the decision-making process. Decisions aids that help navigate both patients and providers through all plausible relationships, alternatives, and outcomes for a given decision provide an ideal platform to convey the importance of each decision within the overall spectrum of care (Figs. 33.9 and 33.10).[248-249]

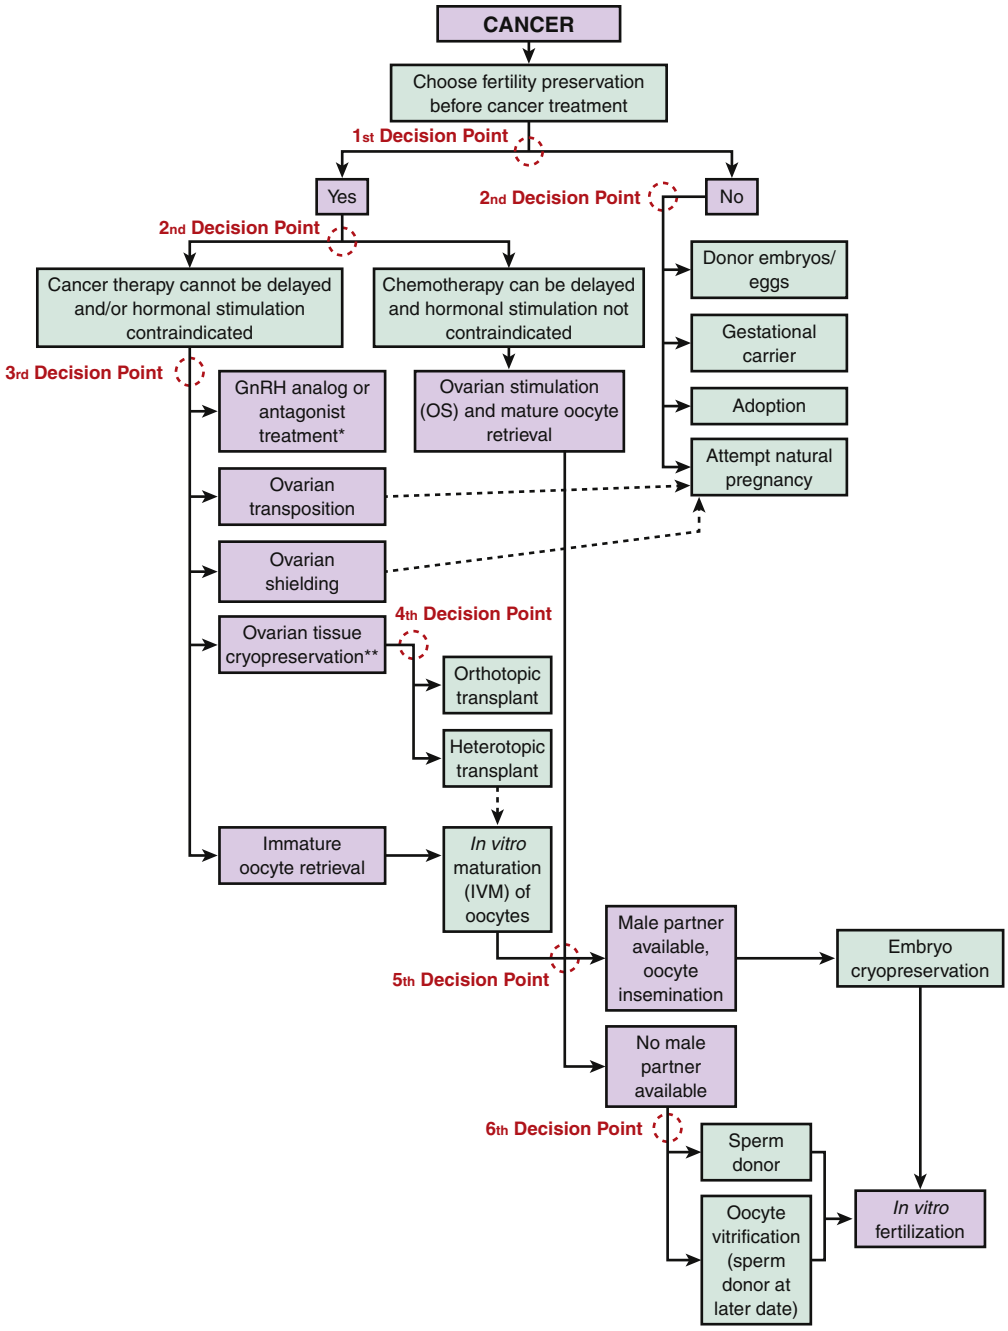

FIGURE 33.9 Decision trees can be useful tools for guiding cancer patients through the complex array of fertility preservation options. This is an example of a decision tree that could be used for females who are seeking fertility information either before or after cancer. Critical decision points are highlighted in red, and *asterisks* mark investigational methods. The female decision tree is more complex than that of males (Fig. 33.10). If using such decision aids, physicians should periodically reassess these trees to ensure that options are current given the rapid pace at which the field is evolving.

Advocacy

It is well known that cancer advocacy groups help educate patients, but many also provide patients and survivors with financial assistance, such as for costly fertility preservation procedures prior to cancer treatment and infertility treatments after cancer. There are several programs in the U.S. that are fairly prominent and are examples of the kinds of programs that are needed throughout the world. The Sharing Hope program of the Lance Armstrong Foundation donates fertility medications to females and assists with on-site or mail-based sperm banking for males. One year of cryopreservation storage fees and reproductive endocrinology costs may also be discounted through this program. Financial programs such as Verna's Purse also help survivors pay for storage fees for existing cryopreserved gametes or tissues. Additional programs may help patients navigate reproductive options after cancer, such as surrogacy. Fertile Action negotiates waived costs for some prescriptions prior to egg and embryo banking and awards grants to provide

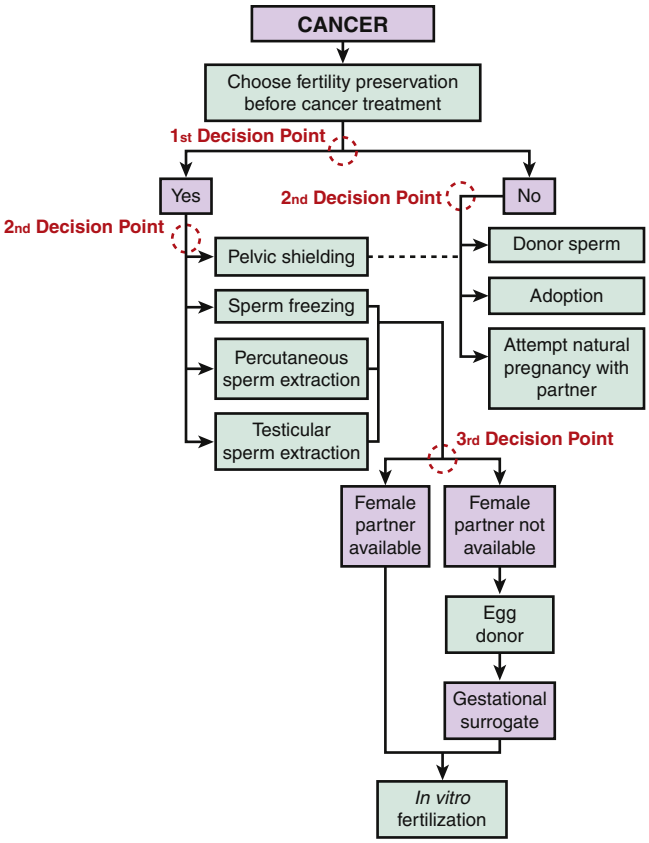

FIGURE 33.10 A decision tree that could be used for males who are seeking fertility information either before or after cancer. Critical decision points are highlighted in red. If using such decision aids, physicians should periodically reassess these trees to ensure that options are current given the rapid pace at which the field is evolving.

financial support during the surrogacy process. Young adult cancer survivors may also apply to the SAM Fund for grants to cover such services.

Establishing an Oncofertility Program

The primary goal of a clinical oncofertility program is to help young cancer patients and their physicians consider the impact of their cancer treatment on future fertility, discuss fertility preservation options soon after diagnosis but before treatment begins, and ensure that cancer patients are given the best opportunity to achieve their fertility goals. Oncofertility programs must provide physicians and patients with timely and comprehensive fertility preservation information, as well as efficiently coordinate the care of cancer patients between healthcare providers in oncology and reproductive endocrinology. A successful oncofertility program requires the establishment of a multidisciplinary team that includes medical specialists (e.g., oncologists, hematologists, rheumatologists, reproductive endocrinologists, urologists, surgeons, anesthesiologists, and pathologists) and their staff, genetic counselors, mental health counselors, the embryology lab team, and the scientific team (Box 33.1). A dedicated patient navigator is an invaluable part of the oncofertility team who not only helps physicians optimally integrate fertility preservation into their patients' cancer treatment plans, but also helps patients become better informed as they move from cancer diagnosis to discussions of future fertility.

Box 33.1 Key Oncofertility Healthcare Team Members

- Medical oncologists and hematologists
- Surgical oncologists
- Radiation oncologists
- Urologists
- Primary care physicians
- Reproductive endocrinologists and infertility specialists
- Bone marrow and stem cell transplant specialists
- Physicians' nurses and staff for all of the above specialties
- Social workers
- Mental health staff
- Patient navigators
- Financial counselors
- Genetic counselors
- Survivorship staff
- Cryopreservation storage representatives
- Institutional review board for investigational procedures

Various healthcare providers, the available facilities and staff, and associated organizations (e.g., cryopreservation facilities, financial aid sources) must work together to best meet the fertility needs of each cancer patient. To do this, oncofertility team members must understand the importance of quick, early fertility preservation referrals prior to cancer treatment; the unique fertility needs of young oncology patients; and how to refer a patient between members of the oncofertility team. Establishing and maintaining multiple lines of communication between various healthcare providers, the patient navigator, and patients is essential to the success of an oncofertility program.[59,70,71,238] An individual patient's oncofertility team is chosen based on patient demographics, cancer diagnosis, the planned cancer treatment, location, available providers, and available facilities and agencies. The National Physicians Cooperative and the FERTline are valuable resources for those who wish to establish a new oncofertility program at their institution, providing advice on everything from staffing to processes to documentation.

Special Cases in Fertility Preservation

The types of patients who seek fertility preservation are diverse, and each patient requires highly personalized care that can be provided by a multidisciplinary oncofertility team, and coordinated by an oncofertility patient navigator. Yet some oncofertility cases are particularly challenging and warrant a more detailed discussion. These include fertility preservation for pediatric and obstetrical patients as well as those who may have nononcological conditions that impact reproductive function.

Prepubertal and Adolescent Populations

Although reproductive-age men and women facing a cancer diagnosis have the option of banking sperm, eggs, or embryos, fertility preservation options for pediatric cancer patients are limited. Once a boy has reached puberty, he can

choose to bank mature sperm.[250] But for prepubertal boys, only experimental or more invasive methods are available, including immature sperm collection by surgical extraction, electroejaculation performed under sedation, or testicular tissue biopsy that is banked with the possibility for transplantation back to the testis to restore spermatogenesis (Table 33.4 and Fig. 33.4).[251] In all boys undergoing cancer treatment, the risk of infertility can be reduced through testicular shielding during radiation therapy and the use of fertility-sparing surgical techniques.

In postpubertal girls, ovarian hyperstimulation followed by IVF and embryo cryopreservation is the most successful option for preserving fertility;[59] however, the lack of a male partner presents a significant obstacle and the process can be emotionally and physically demanding for adolescent girls and their families. For prepubertal girls, hormone treatment and IVF is simply not an option. Experimental ovarian tissue cryopreservation is available to these patients at certain centers.[252] After cancer treatment, this ovarian tissue can potentially be used in one of several techniques discussed in the *Investigational Methods & Basic Science* section.

Because the fertility preservation technologies that are suitable for prepubertal males and females rely on the removal of gonadal tissue, a highly debated issue that must be carefully considered is how much reproductive tissue should be removed for use in potential downstream fertility preservation applications. A risk-benefit analysis must be undertaken and discussed with the patient and/or the patient's parents. Removal of too much tissue is invasive, reduces the possibility that natural reproductive function will be restored, and can result in several other health problems that are associated with reduced or absent gonadal function. On the other hand, enough tissue must be removed in order for fertility preservation to be feasible. This decision is further complicated by several factors. For many of the investigational technologies described, we do not know the minimum amount of tissue required for successful fertility preservation. This is in large part due to the innate patient-specific heterogeneity of the tissue as well as our inability to quantify the reproductive potential of the tissue (i.e., number and quality of gametes present).[253] In females, for example, follicular density in the ovarian cortex is linearly but inversely correlated to patient age,[254] yet in a single ovary, cortical follicle distribution can be very uneven with follicle density varying by up to two orders of magnitude between pieces of tissue.[254] In males, a biopsy might be sufficient in the prepubertal population because the immature testis is enriched in SSCs.[153] In preliminary xenotransplantation studies, tissue from male fetuses or prepubertal boys showed better graft and germ cell survival compared with adult tissues.[255,256] As investigational technologies to utilize the gametes within cryopreserved tissue are developed and translated into routine clinical use, guidelines will have to establish when it is best to perform tissue biopsy or whole organ removal for fertility preservation.

The ovary and testis are unique in that they are organs that contain gametes, and thus the potential for new life.[257] Thus, the ethical and legal uses of organs and gametes are complex, especially in the case of minors where there is a question of who owns the cryopreserved tissue. Furthermore, consent for all medical procedures, including ovarian or testicular tissue removal for banking, must be obtained; however, the act of consent for experimental procedures is particularly complicated for pediatric patients.[70] The parent or legal guardian has the authority to provide consent, but the procedure, if not medically necessary, must not be harmful and it must benefit the patient. Less invasive methods, such as laparoscopic removal of the gonad, are used to minimize risk to the patient. Moreover, it can be argued that ovarian or testicular tissue cryopreservation, though investigational, may one day benefit the patient in terms of allowing him or her to have genetically related offspring. Nevertheless, in some cases—such as in very young patients—additional surgical procedures may introduce added risk that does not outweigh the potential future benefit.[258] Finally, in addition to obtaining consent, when possible, it is also important to have the assent of the child for removal of ovarian or testicular tissue, particularly for adolescent patients who are able to understand the procedure and its risks but are legally unable to provide consent.[257]

Regardless of fertility preservation status, all adolescent and prepubertal patients who have been exposed to gonadotoxic cancer treatments should be followed yearly to monitor the onset and timing of puberty, menstrual, and pregnancy history and to assess sexual function, and a genitourinary exam should be performed.[129] For those at risk of hypogonadism, laboratory screening should include measurement of FSH, LH, testosterone for boys, and estrogen for girls. In boys, semen analysis may also be performed to assess fertility. In girls who received pelvic radiation, high-level ultrasound can be used to assess the uterus. As girls age into womanhood, their gynecologists are often their primary care physicians, and thus are in the position to provide such follow-up care to young female cancer survivors prior to childbearing. Obstetricians can also continue this care for survivors during the gestational period.

Obstetrical Oncology

The obstetrical care of pregnant women, either cancer survivors or women who are diagnosed with cancer during pregnancy, is challenging. For cancer survivors, clinical care requires knowledge of the effects of past cancer treatment exposure on reproductive function—particularly the effects on the uterus—as well as an understanding of the compounded risks associated with pregnancy and cancer. Past exposure to radiation or certain chemotherapeutic agents can damage cardiovascular and pulmonary capacity, two systems that must accommodate the needs of the growing fetus.[259] For these patients, it is critical that the obstetrician work closely with the oncologist to provide integrated care for each patient, not only to ensure a safe delivery of a healthy baby but also to preserve the health of the mother.[260]

Fertility management in a patient diagnosed with cancer during pregnancy is an additional unique and complex situation, but with the additional component of concern for the fetus. A cancer diagnosis is made in approximately 1 out of every 1000 pregnancies and this is expected to rise due to the increasing trend of delayed childbearing.[261-263] Care of these patients involves a difficult balance between treating the woman for cancer and preserving the well-being of the fetus and the possibility of future pregnancy. Aside from the effects of cancer treatment on fertility, factors these

Box 33.2 Potential Nononcological Needs for Fertility Preservation or Counseling

- Autoimmune diseases
  - Systemic lupus erythematosus, multiple sclerosis, chronic kidney disease
- Postsurgical etiologies
  - Inflammatory bowel disease, ulcerative colitis, familiar adenomatous polyposis, endometriosis
- Transplantation and transfusion related disorders
  - Thalassemia major, sickle cell anemia, aplastic anemia, Fanconi anemia, myoproliferative diseases transplant (renal, liver, pancreas), hemochromatosis
- Genetic diseases
  - Turner syndrome, fragile X syndrome, X chromosome deletions
- Metabolic conditions
  - Galactosemia, diabetes, polycystic ovary syndrome

patients and their physicians must consider are the possible risk of fetal toxicity from cancer treatment, patient prognosis, and ability to care for offspring.

Nononcological Applications

In addition to cancer, several other diseases and conditions and their treatments are associated with reduced reproductive function in women and men (Box 33.2).[264] Rheumatological disease and autoimmune diseases such as systemic lupus erythematosus are treated with highly gonadotoxic agents; these patients may preserve their fertility by banking gametes or embryos prior to treatment or between treatment cycles. Nonmalignant hematological disorders such as thalassemia major, sickle cell anemia, aplastic anemia, Fanconi anemia, and myeloproliferative diseases are treated with bone marrow transplantation or hematopoietic stem cell transplant, and patients are exposed to alkylating chemotherapy and radiation that increases the risk of infertility. In boys, cryptorchidism, even after orchiopexy, can significantly decrease fertility later in life. Testicular tissue biopsy cryopreservation has been performed in boys with cryptorchidism, with spermatogonial survival and normal hormone production achieved after thawing.[265] Men with Klinefelter syndrome (XXY) have normal testes development up to puberty, but then develop hypergonadotrophic hypogonadism with degeneration of the seminiferous tubules and almost total loss of sperm production. Small areas of the tubules may still produce viable sperm that are recoverable by micro-TESE (Table 33.4);[266] the sperm can be banked or ICSI can be performed to produce embryos.[267]

Women with Turner syndrome—who have either partial or complete absence of one X chromosome—are at risk of premature ovarian failure. In mosaic Turner syndrome, an X chromosome is lost during embryonic development, such that some proportion of the body's cells contains two normal X chromosomes. Rare cases of pregnancy have been reported in women with mosaic Turner syndrome, and recent work suggests that women with mosaic Turner syndrome may be candidates for fertility preservation by either tissue cryopreservation (in prepubertal girls) or hormone stimulation followed by oocyte cryopreservation (in postpubertal girls and women).[268] Spontaneous puberty and normal gonadotropin and estrogen levels were found to be predictive for the presence of mature follicles in girls with Turner mosaicism,[269] and several case reports have described fertility preservation efforts in this population.[270-273]

Legal and Ethical Issues Surrounding Fertility Preservation

From legal and ethical perspectives, fertility preservation is an inherently complex field because it involves rapid decision-making at a difficult time; the input of multiple stakeholders; the manipulation of reproductive cells, tissue, and organs; and the potential creation of new life. Below is an overview of key legal and ethical issues that have arisen from the advent of oncofertility.

Adoption

Cancer survivors who are infertile may wish to start a family through adoption and there are different hurdles placed on patients depending on the state or country in which the individual resides. Some adoption agencies may be reluctant to work with prospective parents who have a history of cancer due to concerns about the long-term welfare of the child.[274] In the U.S., adoption policies that take into account the health of adoptive parents vary from state to state, and individual adoption agencies use their own discretion in considering the health status of adoptive parents. In a recent survey of 27 agencies in the U.S., only 1 had a policy in place regarding adoption by cancer survivors, another agency required a "reasonable life expectancy," and a third required a doctor's assessment of health.[274] Though no international agencies regard a history of cancer as a disqualifier for adoption, health assessments may be used to determine whether a potential adoptive parent is physically capable of caring for a child.[274] Navigating adoption agency-specific policies can be difficult and frustrating for cancer survivors, and it is clear that discrimination exists; however, there are a number of "cancer-friendly" adoption agencies in the U.S. that have expressed a willingness to work with prospective parents who have a cancer history (Supplemental Table S33.1, which can be found on the companion Expert Consult Web site at *www.expertconsultbook.com*).

Surrogacy

For women who had a reproductive cancer that required hysterectomy, or for women who were exposed to radiation or chemotherapy that impaired their ability to carry a pregnancy to term, gestational surrogacy may be an option for starting a family after cancer.[275-277] If a patient is able to bank either oocytes or embryos prior to their cancer treatment, the surrogate could carry the patient's genetically related baby to term (Table 33.4 and Fig. 33.3). Similar to the topic of adoption, there are state and country-specific laws that may create barriers to surrogacy that must be considered.

Insurance

In the U.S., the lack of insurance coverage is one reason oncologists do not offer fertility preservation as an option

to their patients.[59] There is controversy regarding whether infertility insurance mandates should also cover fertility preservation for cancer patients. One major issue is that cancer patients are not considered to be infertile at the time that treatment is given. The widely accepted definition of infertility stipulates the inability to become pregnant after a period of time, usually 1 year,[17,278] yet this definition does not apply to cancer patients seeking fertility preservation within the small window of opportunity before gonadotoxic treatment begins. Current coverage of infertility treatments assumes that the condition already exists, rather than that the condition can be prevented. In terms of insurance coverage, fertility preservation would be analogous to other measures taken to prevent iatrogenic conditions;[71,279] for example, storing blood in case of an emergency transfusion. In a recent review of the issue, Basco and colleagues suggested that either the existing definition of infertility be changed to include cancer patients; a new definition be created specifically for cancer survivors; or a new insurance mandate be put in place for fertility preservation services provided to cancer patients.[280] The issue of coverage and reimbursement varies globally and is a topic that must be discussed as a global community in order to improve access for all.

Access to Care

Cancer and infertility do not discriminate based on social class or ethnicity; however, in countries where economic barriers determine healthcare access, fertility preservation is simply out of reach for many patients. In the U.S., only some states have mandates for infertility coverage, and many of these may not cover fertility preservation. In the current economic climate, many states may find that IVF is difficult to finance. Under the Affordable Care Act, insurance coverage will be extended to many more Americans, but again, whether this coverage will include fertility preservation in patients with cancer is not clear with the existing definition of infertility. Furthermore, experimental procedures such as ovarian or testicular tissue cryopreservation are performed only under IRB approval and only at certain centers, which may limit regional access to these options for many patients.

Ownership of Biological Material

The infertility field and the legal systems of many countries have grappled with the issue of embryo ownership, particularly in cases of divorce, death of a partner, and same-sex couples. The same issues will be encountered by cancer survivors, particularly as these patients have a higher risk of death than healthy infertile individuals. In addition, ownership of ovarian or testicular tissues may present special obstacles, as the tissue itself contains the potential for many future offspring. New laws will need to be created to define who can acquire and dispose of these tissues. These laws may be particularly complex with regard to ownership of gonadal tissues removed from pediatric cancer patients.

Should We Be Doing Fertility Preservation?

Provider concerns about cancer progression, life expectancy, and the stress of additional interventions have been cited as issues that limit the clinical provision of fertility preservation.[281,282] Many argue that reproduction is a basic right of the patient, and as long as the potential risks to a patient's offspring are discussed, then fertility preservation should be offered. Others have suggested that it is not in the best interest of potential future children to allow patients with cancer—who may have a shorter lifespan—to reproduce. In his ethical analysis, Robertson found that the stress associated with a loss of a parent is no greater than other forms of stress that will be experienced during a child's life, and therefore should not be a reason to withhold options for fertility preservation from cancer patients.[283]

Interestingly, provider beliefs and actions regarding the provision of fertility interventions to cancer patients show a gender disparity. In a survey of pediatric oncologists, a majority of respondents acknowledged that fertility threats to female patients are a major concern for them (83%) and agreed that all pubertal female cancer patients should be offered fertility consultation (73%).[236] However, only 12% reported that they refer female cancer patients to a fertility specialist prior to cancer treatment more than 50% of the time, compared with a 46% referral rate for males. The barriers to referrals for women included a lack of knowledge about fertility management options or referral centers, the concern that fertility preservation procedures take too much time, biases toward the marital status of the cancer patient, the notion that banking embryos is not appropriate for a cancer patient who might not survive her disease, and concerns about the ability of the patient to survive the disease. Note that these issues are all based on provider bias and not on informed decision-making by the patient. Ongoing work to understand the boundary conditions for patients, partners, parents, the interested public (including policymakers), and providers represents an important next chapter in this field.

Summary and Outlook

Fertility preservation has emerged over the last decade as a topic that young cancer patients want addressed. With guidelines from medical societies instructing physicians to act on behalf of their patients' future fertility, the emergence of new options that provide hope to a greater number of patients, and new medical management plans that connect physician services across disciplinary boundaries, the field of oncofertility can address these patients' needs. The global oncofertility community faces immediate challenges of access and affordability, which must be addressed in order to reduce or eliminate disparities based on finances or geo-political concerns. Future work to eliminate the off-target effects of cancer treatment will one day reduce the need for this field, which would be the best outcome for all.

FIGURE S33-1 Improving patient access to fertility preservation information in a rapid and efficient manner is essential to ensuring future quality-of-life for patients and their families. To facilitate this communication, the Oncofertility Consortium has created and disseminated several physician-focused tools including **A**, the National Physicians Cooperative (NPC), a nationwide network of clinical sites (research, pediatric, and adult) that are committed to providing patients with fertility preservation information and treatment; and **B**, a hotline where both providers and patients can receive the most up-to-date information and referrals regarding fertility preservation.

CHAPTER 34

Laboratory Assessment

Enrico Carmina
Frank Z. Stanczyk
Rogerio A. Lobo

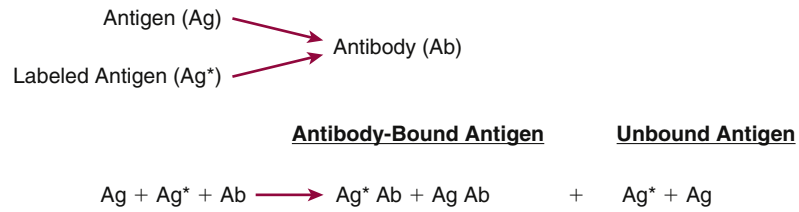
This chapter reviews the assessment of hormonal status in the practice of reproductive endocrinology. It is acknowledged that the patient will often provide useful biological information, such as changes induced by hypoestrogenism, skin changes with androgen excess, and galactorrhea in hyperprolactinemia. The clinically relevant symptoms and signs associated with various disorders are discussed in other chapters in this text. Here we will describe various types of hormonal assays and dynamic tests used in the evaluation of reproductive disorders, as well as diagnostic radiographic techniques. In this new edition, we have updated different types of measurements, particularly for steroids and have discussed in more detail aspects of metabolism. We have revised various algorithms used for diagnosis, with an emphasis on what factors need to be measured.

Immunoassays

The predominant assays used to measure steroid, peptide, and protein hormones in serum, plasma, and urine samples during the past 40 years have been immunoassays. These assays have been widely used in both clinical diagnostic and research settings.

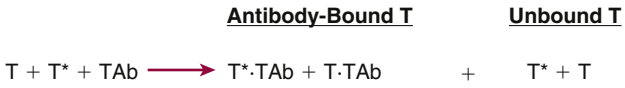
As the term "immunoassay" implies, this method of measuring hormones involves an antigen-antibody reaction, where the antigen is the hormone to be measured and the antibody, which is prepared against the hormone, binds to the hormone. The hormone can be a steroid, protein, and peptide. There are two types of hormone immunoassay methods: one uses excess hormone and a limited amount of antibody, whereas the other uses excess antibody. For quantification purposes, immunoassay methods require a labeled marker which can be the radioactive [usually iodine-125(^{125}I)] or nonradioactive (chemiluminescent, fluorescent, or enzymatic) form of the hormone being measured, or a suitable chemical derivative of the hormone.

General Principles of Immunoassays



Principle of Antigen-Excess Hormone Immunoassays

The principle of an antigen-excess type of hormone immunoassay involves competition between the hormone being measured and the labeled form of the hormone for a limited amount of the antibody prepared against the hormone. When all three components are combined in a test tube, the net result is a mixture of labeled and unlabeled hormone bound to the antibody, and unbound labeled and unlabeled hormone (Fig. 34.1). From the practical standpoint in the assay, the bound hormone is separated from unbound hormone and the activity of the bound fraction is quantified (e.g., by determining the counts per minute of radioactive iodine in a gamma counter if a ^{125}I-labeled hormone is used as the marker). Separation of hormone-bound and unbound antibody is achieved by one of a variety of different methods, including use of a second antibody (prepared against the first antibody) when an iodinated hormone is used as the labeled antigen, or by magnetic particles when a nonradioactive hormone is used. In this manner, by using different concentrations of a pure hormone (standard), one can generate a standard curve of the hormone. As the concentration of the standard is increased, the antibody-bound labeled marker is displaced; the higher the amount of standard that is added, the lower the amount of marker will be obtained. Thus, in an antigen-excess immunoassay, the standard curve shows an inverse relationship between the different amounts of antibody-bound labeled antigen (hormone) and the different concentrations of the standard (Fig. 34.2). A standard curve is essential in any immunoassay method used to measure the levels of a hormone in a biological fluid.



Measurement of a hormone in serum, plasma, or urine by an antigen-excess immunoassay is obtained by first determining the amount of the hormone that is antibody-bound in the sample. The concentration of the hormone is then extrapolated off the standard curve, as shown in Figure 34.2. An appropriate computer program can be used to generate the data rapidly.

Principle of Antibody-Excess Hormone Immunoassays

In contrast to antigen-excess immunoassays, which utilize a limited amount of antibody resulting in competition between labeled and unlabeled antigens, there is no competition between these antigens in antibody-excess immunoassays (often referred to as immunometric assays). Generally, two different antibodies that recognize two different parts of the antigen are used in antibody excess immunoassays, forming a "sandwich," with the antigen in the middle. Thus, this assay method is useful for large molecules such as protein and peptide hormones. Quantitation is achieved

by labeling one of the antibodies with a radioactive or nonradioactive marker. One of the most widely used antibody-excess immunoassays is the enzyme-linked immunosorbent assay (ELISA) in which quantitation is achieved by attaching an enzyme to one of the antibodies and measuring the optical density of a product formed by reaction of the enzyme with a specific substrate (Fig. 34.3). When one of the antibodies is labeled with a radioactive tracer, this type of assay is referred to as an immunoradiometric assay (IRMA), and when the labeling involves a chemiluminescent or fluorescent tag, it is referred to as an immunochemiluminometric assay (ICMA) or immunofluorometric assay (IFMA), respectively. In contrast to the inverse relationship between antibody-bound labeled antigen and concentration of antigen in the standard curve in an antigen-excess immunoassay, there is a direct relationship between the labeled antibody and antigen concentration in an antibody-excess immunoassay (Fig. 34.4).

Major Components of Immunoassay Systems

There are three major components of immunoassay methods: the antibody, unlabeled antigen (standard or substance to be measured in a biological fluid sample), and labeled

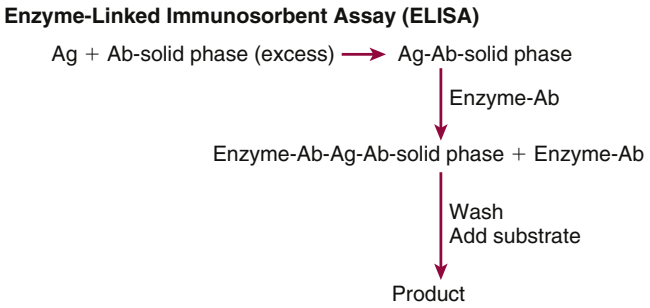

FIGURE 34.3 Principle of the antibody excess immunoassay: Theoretical consideration shown for the ELISA. *(Modified from Stanczyk FZ, Glob. libr.* women's med. *[ISSN:1756-2228] 2009; DOI 10.343/GLOWM.10278.)*

antigen. These are essential in every immunoassay and are discussed below.

Antibody

The antibody is perhaps the most important component of an immunoassay method. If an antibody in an immunoassay recognizes only the compound that it is intended to measure, then it is likely that the assay will be highly accurate.

Antibodies are commonly produced in animals (polyclonal) or via cell culture (monoclonal). The typical protocol for production of polyclonal antibodies is to disperse a small amount of antigen into an adjuvant (e.g., Freund's) and to inject it intradermally at multiple sites into an animal such as the rabbit. After approximately 3 months, a blood (serum) sample is obtained from the animal and the antibody titer is determined. This procedure involves addition of a fixed amount of labeled antigen to serially diluted aliquots of the serum obtained from the animal. The antibody dilutions start at 1:1000 and cover a range of at least two orders of magnitude. After the bound antigen is separated from the unbound antigen, the antibody dilution that binds between 30% and 70% (usually 40%-50%) of the total activity of the labeled antigen is formed and used for the assay.

To obtain a monoclonal antibody, it is first essential to inject the antigen into a mouse to induce an immunological reaction in the spleen. Each immunized spleen cell can produce an antibody with specific characteristics. The most important step in the production of monoclonal antibodies is screening the spleen cells to separate those capable of secreting a single antibody type. When a myeloma cell from the same species of mouse is fused with the selected spleen cell, a "hypridoma" is produced. This hybridoma continuously secretes antibodies with the same characteristics as the selected spleen cell. A hybridoma cell is capable of producing hundreds of specific antibody molecules per second. Thus, a continuous clone line can be maintained in culture, becoming a source for the production of homogeneous monoclonal antibody molecules.

Antigen

Here, the term "antigen" can refer to the substance that is injected into an animal to produce an antibody or to the standard that is used to generate a standard curve in an immunoassay. In addition, the term "antigen" can refer to the substance that is being measured in a biological fluid (e.g., serum).

Antigen Used to Prepare an Antibody

In general, any molecule larger than 10,000 daltons can elicit an antibody response. With molecules in the 1000 to 10,000 dalton range, eliciting an immune response becomes more difficult. Molecules smaller than 1000 daltons are generally nonantigenic and are coupled to a large protein molecule (e.g., albumin); these small molecules are referred to as haptens. Thus, steroids and some peptides, but not proteins, are prepared as hapten-proteins and injected into the animal to produce a polyclonal or monoclonal antibody.

The site of attachment of the protein carrier (e.g., albumin) is important because it determines the specificity of the antibody. In general, specific antibodies are formed when the attachment site does not involve any functional group on the steroid molecule. A commonly used approach is to prepare a carboxyl derivative at the carbon-6 position of the steroid molecule and to couple it to an amino group of the protein carrier.

Antigen Used as Standard

Steroids and peptides are available commercially and in most instances can now be obtained in a relatively pure state. However, it should never be assumed that these products are 100% pure when developing an immunoassay. If necessary, the compounds can be purified (e.g., by use of high performance-liquid chromatography [HPLC]). In contrast, proteins are generally considered to be more difficult to purify.

Labeled Antigen

Use of an optimum labeled antigen is also important in an immunoassay, as this determines how the compound being measured in a biological fluid, such as serum, is quantified in the assay. The labeled antigen must not only be identifiable by some physical or chemical method (e.g., a radioactivity counter or spectrophotometer) but also must bind to the antibody.

The classical labeled antigens for immunoassays have been radioactive antigens. For example, insulin, the first hormone measured for an RIA, was labeled with radioactive iodine (^{131}I). This isotope had a very short half-life (8 days) and was soon replaced with iodine-125 (^{131}I), which has a half-life of 60 days. Peptides have also been labeled with ^{125}I. For steroids, tritium (^{3}H) was the initial isotope used in RIAs, but was subsequently replaced with ^{125}I. It's important to realize that, unlike proteins and peptides, the steroid molecule itself cannot be iodinated. Instead, the steroid molecule is attached chemically to an iodinated carrier molecule such as histamine or tyrosine methyl ester.

In order to eliminate the high cost of storage and disposal of radioactive material and to allow immunoassays to be carried out on an automated platform, nonradioactive labeled antigens began to be used in these assays. The predominant labels that were attached to antigens were chemiluminescent, fluorescent, and enzyme (which required a substrate); these labels were detected by use of a luminometer, fluorometer, and spectrophotometer, respectively. Presently, there is wide use of the chemiluminescent label in immunoassays on automated platforms and the enzyme label in ELISAs carried out manually.

Automated Immunoassays

Over the past 30 years or so, highly sophisticated automated immunoassay systems have been developed. These systems consist of instruments that not only detect spectral properties of nonradioactive ligands (e.g., chemiluminescence) but also are able to analyze multiple analytes as well as to process multiple samples rapidly and efficiently. These immunoassay systems are capable of utilizing both antigen excess and antibody-excess methodology.

Currently a widely used immunoassay system is the Immulite analyzer (Siemens Healthcare Diagnostics, Deerfield, Illinois). The Immulite system employs enzyme-amplified chemiluminescent technology. The mechanism involves hydrolysis of a stable chemiluminescent substrate, through the action of the enzyme alkaline phosphatase, resulting in an unstable anion that gives rise to sustained emission of light. The emitted light is quantified by use of a luminometer in the instrument.

As an example, the Immulite LH assay utilizes a solid-phase, two-site ICMA. The solid phase 3 consists of a polystyrene bead coated with a monoclonal antibody against LH. The bead is sealed into an Immulite test unit, to which LH standard or serum sample, together with a polyclonal antibody conjugated to alkaline phosphatase, are added simultaneously. During an incubation period, LH is bound to the monoclonal antibody coating the bead and the polyclonal antibody-enzyme conjugate, forming a "sandwich complex." After unbound conjugated antibody is removed by a wash, the amount of complex, which is directly proportional to the LH standard or LH in the sample, is quantified by use of the chemiluminescent substrate described above.

Steroid Hormone Immunoassays

The first RIA was developed in 1969 by Guy Abraham[1] and that was for measurement of estradiol (E_2) in serum or plasma. The E_2 RIA method involved separation of E_2 from interfering metabolites by organic solvent extraction and Celite or Sephadex column chromatography, prior to its quantitation by RIA. The purification steps were added to remove most of the estrogen metabolites. E_2 is readily converted to estrone (E_1) and both E_2 and E_1 are converted to a total of approximately 90 metabolites. The extraction step removes the conjugated steroids, whereas the chromatographic step separates E_2 from potential interfering unconjugated metabolites. The E_2 RIA included a specific antiserum against RIA in conjunction with tritiated E_2, and separation of the antibody-bound and unbound E_2 fractions using charcoal. This method, which is often referred to as a conventional RIA, was shown to be sensitive, specific, precise, and accurate. Soon afterwards it was applied successfully to other sex steroid hormones, such as testosterone and progesterone.

During the decade of the 1970s, RIAs were developed for a variety of natural and synthetic steroid hormones. A notable change in the RIA method during those years was replacement of tritium with iodine in the labeled antigen to improve assay sensitivity. Because of their relatively low cost, RIAs became widely used in diagnostic and research laboratories.

Impact of the Conventional Steroid RIA Method

The immediate impact of the conventional steroid RIA method was that it allowed measurement of an immensely wide range of compounds of clinical and biological importance, and it opened new horizons in endocrinology. The long-term impact of the steroid RIA method was that its use in numerous studies enriched the field of endocrinology with new knowledge, and its use in diagnostic testing provided physicians with valuable information for diagnosing and treating countless patients. The steroid RIA methodology also allowed substantial research into the physiological and pathophysiological roles of steroid hormones in applications such as sexual differentiation, puberty, neuroendocrinology, the menstrual cycle, pregnancy, menopause, and male endocrinology. In addition, the RIA method opened the door for epidemiological studies that permitted us to better understand the role of steroid hormones in the etiology of numerous diseases, notably the hormone-dependent breast and prostate cancers.

Advantages and Disadvantages of Conventional Steroid Radioimmunoassays

Steroid RIA methods with purification steps have the following advantages: First, steroid-binding proteins (e.g., SHBG) are denatured, thereby releasing the steroids (e.g., E_2 and testosterone) that they bind. Second, the purification steps remove numerous potentially interfering metabolites prior to RIA. Third, the RIAs are accurate and reliable when properly validated. Finally, multiple steroids (usually up to five) can be measured in a single aliquot of serum.

Conventional steroid RIAs also have disadvantages. They are cumbersome, time-consuming, costly, and require relatively large sample volumes, especially when the steroid is present in low concentrations. Also, although multiple steroids can be measured in a single aliquot of serum, the measurements have to be done very carefully and are especially time-consuming. In addition, as with all antibody-based assays, since the measurement of the analyte is a

surrogate approach (i.e., radioactivity is measured rather than the actual analyte itself), there is always the possibility of antibody cross-reactivity giving an erroneous result. Furthermore, the presence of auto-antibodies within patients can further affect an assay, leading to falsely high or low values depending on the type of antibody interaction that occurs. Despite these concerns, a well-validated RIA preceded by organic solvent extraction and chromatography is typically an accurate and precise assay for the majority of applications.

Direct Steroid Immunoassays and Their Advantages and Disadvantages

Due to the time-consuming limitations of conventional RIAs, in the late 1970s the radioligands in RIAs were replaced with nonradioactive ligands (chemiluminescent, fluorescent, or enzymatic) and the organic solvent extraction and chromatography steps used prior to RIA were eliminated, allowing direct immunoassays to be performed on an automated platform; this resulted in rapid measurements of steroid hormones. Conventional RIAs continued to be used, but their use was overwhelmingly surpassed by direct immunoassays, particularly in clinical diagnostic laboratories.

The development of automated platforms gave direct assays, such as chemiluminescent immunoassays, the advantages of being convenient, simple, rapid, and relatively inexpensive, and requiring a lower sample volume (usually 0.1 mL). However, these assays also have serious disadvantages. They often overestimate the measurements due to lack of specificity of the antibody, especially in samples obtained from women treated with exogenous steroid hormones.[2] Also, matrix differences may exist between serum samples (particularly hemolyzed and lipemic samples) and solutions of the standard used to prepare the standard curve in the assay. In addition, steroids such as testosterone and E_2 may not be released efficiently from proteins such as sex hormone-binding globulin to which they bind with high affinity in blood. Furthermore, direct immunoassays generally lack the sensitivity to measure accurately low levels of certain steroid hormones such as E_2 and testosterone. Limitations of direct immunoassays for quantifying E_2 in postmenopausal women and testosterone in both premenopausal and postmenopausal women are now well documented in the literature.[3]

Protein and Peptide Hormone Immunoassays

The first protein hormone RIA was developed for insulin and preceded the first steroid hormone RIA, which was for E_2, by about 10 years. The basis for the first protein RIA method was described in 1959 by Yalow and Berson, who showed that ^{131}I-insulin could be displaced by nonradioactive insulin from insulin-binding protein, and that ^{131}I-insulin was inversely and quantitatively related to the total amount of insulin present. This is the same principle that was described earlier for the steroid hormone RIA, and was subsequently used to develop RIAs for protein hormones other than insulin, as well as for peptide hormones. In 1967, Odell and co-workers reported the first RIAs for luteinizing hormone (LH) and follicle stimulating hormone (FSH). Subsequently, RIAs were developed for a variety of other protein hormones, such as human chorionic gonadotropin (hCG), prolactin and thyroid-stimulating, and for peptide hormones such as gonatropin releasing hormone (GnRH) and adrenocorticotropic hormone (ACTH). The protein and peptide hormone RIAs utilized specific antisera in conjunction with the relevant ^{125}I-proteins and peptides. The change from the ^{131}I label to the ^{125}I label provided a longer-life for the labeled material (8 days versus 60 days, respectively), so that the proteins and peptides did not require iodination as often for the RIAs.

Immunoradiometric Assay (IRMA)

In the late 1960s and early 1970s, the IRMA method was developed for measurement of proteins, which included insulin, FSH, and LH. Subsequently, the IRMA was also used to measure peptides such as GnRH and ACTH. The IRMA differed from the RIA in that the compound to be measured is assayed directly by combination with a specific labeled antibody rather than in competition with a labeled antigen for a limited amount of antibody.

Current two-site immunometric assays depend on the use of two antibodies directed to distinct antigenic epitopes on the protein or peptide being measured. This assay method is ideal for use of monoclonal antibodies, thereby increasing assay specificity. In addition, two-site immunometric assays offer greater sensitivity because they are much less dependent on the affinity of the antibody than RIAs. An appropriate choice of antibodies directed to different antigenic sites can further enhance the affinity and thereby the sensitivity of the assay. Thus, highly sensitive immunometric assays opened up new clinical opportunities (e.g., use of the sensitive TSH assay to diagnose hypothyroidism).

Two-site immunometric assays also have certain limitations. They cannot be used to measure small ligand molecules such as steroids and very small peptides since they display only one antigenic site at a time. Also, immunometric assays are liable to high-dose "hook" effects. This results from very high levels of antigen that saturate the binding sites on the capture antibody and still leave antigen free to bind to the tracer antibody.

Enzyme-Linked Immunosorbent Assay (ELISA)

The ELISA differs from the IRMA in that the ELISA utilizes a solid-phase procedure and an enzyme-labeled instead of a radioactively-labeled antibody. The most common format used for the ELISA is the multi-well plate made of polystyrene or polyvinyl. This is convenient to handle since centrifugation is not required and multiple wash steps are readily automated. Antibody is coated on the wall of each well and this antibody binds the corresponding antigen in the test sample. The antigen-antibody complex is quantified by addition of an enzyme-labeled specific antibody. Following addition of the appropriate substrate, the end-point (product) can be "read" spectrophotometrically, using an automated reader.

Standards Used in Protein Immunoassays

Unlike steroids and small peptides (e.g., GnRH), proteins are considerably more difficult to purify. Although some proteins such as insulin are available in a highly purified state for use as standards in immunoassays, others such as

FSH, LH, and hCG have not yet been prepared in sufficient amounts in a highly purified form. Although the latter proteins are available from international agencies, their purity based on biological potency per unit weight, is often less than that of highly purified preparations reported by individual investigators. In order to be able to compare results obtained in different laboratories and at different times in the same laboratory, considerable effort has been made to use a single material as a standard.

Reference materials are available for FSH, LH, and hCAG. They are provided by the World Health Organization (WHO), which obtains them from the National Institute for Biological Standards and Controls in Hertfordshire, England. Two types of reference materials are available, namely, an International Standard (IS) and an International Reference Preparation (IRP). The IS is a material that has a potency established in 10 to 20 expert laboratories throughout the world, whereas the potency of an IRP is established by only several laboratories.

With the advent of RIAs for gonadotropins, a partially purified extract of human pituitary glands (code name LER-907) was made available by the National Institute of Health in the United States. This preparation was provided in large amounts to the WHO, which purified it further in 1976 and called it the First International Reference Preparation of Pituitary FSH and LH (1st IRP-FSH and LH). Subsequently, another partially purified extract of LER-907 was prepared in 1980 to replace the 1st IRP-FSH and LH. It was called the 2nd International Reference Preparation of Pituitary FSH and LH (2nd IRP-FSH and LH) and was assigned the code number 78/549. Highly purified preparations of pituitary FSH and LH have also been prepared. The First International Reference Preparation for Human Pituitary LH (1st IRP-LH, code number 68/40) was available in 1974. Subsequently (in 1988), this material was replaced by the Second International Standard for Pituitary LH (2nd IS-LH; code number 80/552). In 1986, the First International Standard for Pituitary FSH (1st IS-FSH, code number 83/575) was established. Presently, both the 2nd IRP-FSH and LH and 2nd IS-LH are used as standards in gonadotropin immunoassays.

The initial standard used in hCG immunoassays was a partially purified hCG preparation obtained from urine of women in their first trimester of pregnancy and was called the Second International Standard for hCG. Subsequently, a highly purified preparation was developed and was referred to as the Third International Standard. This preparation is presently used as the standard in hCG immunoassays.

Validation of Immunoassays

Before an immunoassay can be used to measure any compound, it must first be validated with respect to sensitivity, specificity, accuracy, and precision. Procedures used to validate immunoassays are described below.

Sensitivity

The sensitivity of an assay is defined as the smallest amount of the substance being measured that can be distinguished from zero. In practice, assay sensitivity depends on the precision of the standard curve, which can be measured by assaying 10 replicates of each concentration of standard and the "zero" standard, which contains no standard. This allows calculation of the mean ± standard deviation (SD) amount of the antibody-bound marker, corresponding to each concentration of standard. The sensitivity of an assay is the lowest standard concentration that yields a mean amount (e.g., counts per minute) of antibody-bound marker differing by two SDs from the mean amount of antibody-bound marker associated with the zero standard.

Assay sensitivity expressed in that manner, in practical terms, refers to the sensitivity of the standard curve. However, it is important to know the assay sensitivity in terms of the lowest amount of analyte that can be measured per milliliter of sample. This can be determined by calculating the product of the lowest standard concentration (based on standard curve sensitivity) and, if applicable, dilution factors, as well as the factor accounting for procedural loss (in assays using an extraction and/or chromatographic step).

The sensitivity of an assay is especially important when very low serum levels of a compound are being analyzed (e.g., measurement E_2 in samples from postmenopausal women or from patients treated with an aromatase inhibitor).

Specificity

Assay specificity refers to the degree of interference from cross-reaction that is encountered from substances other than the target analyte. The specificity of an immunoassay is usually assessed in two different ways. First, the cross-reactivity (expressed as a percentage) of the antibody is determined by comparing the dose-response standard curve of the substance being measured with dose-response curves obtained for compounds that may be present in the same sample as the analyte, and that may bind to the antibody. The percent cross-reaction of an antiserum with a substance is calculated from the mass of standard that yields 50% inhibition of binding of the assay marker to the antibody, divided by the mass of the cross-reacting substance that gives the same percentage of inhibition (50%), and multiplied by 100%.

A second approach for defining immunoassay specificity is to compare the analyte values of a group of samples measured by a specific immunoassay method with those obtained by a classic method, such as mass spectrometry. If this is not possible and the analytes are being measured in an immunoassay without chromatography, the analyte values should be compared with the values obtained by an immunoassay that uses a chromatographic step (e.g., Celite column partition chromatography) to separate the analyte in question from interfering metabolites.

Accuracy

Assay accuracy defines the extent to which a given measurement agrees with the actual value. One commonly used method to establish the accuracy of an immunoassay is based on the finding of linearity (parallelism) between the assay standard curve and serial dilutions (using assay buffer) of several samples containing known high concentrations of the analyte. Another method for establishing immunoassay accuracy is based on the recovery of added ("spiked") standard, at different levels, from patient samples. This method is often used for assays that require an extraction or a chromatographic step (e.g., steroid hormone assays). Both the parallelism and the "spiked" sample methods are limited by the precision of carrying out the dilutions or "spiking."

Precision

The precision of an assay refers to the variability that exists when multiple measurements of the compound are made on the same sample. In practice, both intraassay precision and interassay precision are determined and are usually expressed as the coefficient of variation of replicate measures. The coefficient of variation (expressed as a percentage) is calculated by dividing the standard deviation by the mean of replicate determinations of an analyte, and then multiplying by 100. Intraassay precision is assessed by measuring the analyte in replicate samples (usually 7 to 10) within the same assay. Interassay precision is determined by measuring the analyte in replicate samples (at least five), each of which is included in a different assay. Both intraassay and interassay precision should be determined in three different concentrations of the analyte (high, midrange, and low).

Interferences in Immunoassays

Circulating human antibodies that react with animal proteins (anti-animal antibodies) are often an unrecognized and unsuspected source of interference in immunoassays. This is particularly true with two-site immunoassays. The most common human anti-animal antibody interference is caused by human antimouse antibodies (HAMA). HAMA can cause either positive or negative interference in two-site mouse monoclonal antibody-based immunoassays. Strategies for preventing the development of anti-animal antibodies have been proposed. Awareness of laboratory personnel and clinicians of the problems associated with this type of interference in immunoassay methods is important.

Mass Spectrometry Assays

Measurements of steroid hormones by mass spectrometry (MS) assays actually preceded their measurements by RIA. As early as 1966, the first comprehensive urinary steroid profile was produced by gas chromatography-mass spectrometry (GC-MS). This method combines the resolving power of gas chromatography with the high sensitivity and specificity of the mass spectrometer. Separation of steroids by gas chromatography requires that they be first derivatized to increase their volatility, selectivity, and detectability. The mass spectrometer functions as a unique detector that provides structural information on individual solutes as they elute from the gas chromatography column. The MS technique first involves ionization of the compound being measured at the ionization source, and is followed by separation and detection of the ions in the mass analyzer. A mass spectrum is produced in which the relative abundance of a particular ion is plotted as a function of the mass-to-charge (m/z) ratio, and the concentration of the compound is then obtained.

Due to the complexity of the methodology and associated costs of the instrumentation and reagents, as well as the need for a highly trained individual to carry out the assays, use of GC-MS assays was restricted to a limited number of laboratories, primarily at pharmaceutical companies. Thus, for a period of about 30 years after the development of the first RIA in 1969, conventional RIAs and direct immunoassays were the predominant methods used to quantify steroid hormones in clinical diagnostic and research laboratories due to their relative ease of performance and considerably lower overall costs. However, advances in liquid chromatography technology in the 1980s led to the development of a high performance liquid chromatography-MS (LC-MS) instrument in 1987. In addition, invention of an electrospray source by Nobel laureate, John B. Fenn, in 1990, and the subsequent development of chemical ionization greatly improved routine analysis of steroids. This technology facilitates ionization of compounds present in liquid droplets and sprays the molecules directly into the mass spectrometer from the HPLC unit. The advancements allowed for simple coupling of the liquid chromatography eluent with the mass spectrometer and often negated the need for derivatizing the steroid, thereby reducing the complexity of the assay and shortening the assay run time dramatically. These factors greatly increased the throughput of patient samples, while still providing highly accurate and precise results.

In recent years, there has been a large increase in the use of assays that utilize either liquid chromatography or gas chromatography with tandem MS (LC-MS and MS or GC-MS and MS). Tandem MS consists of two mass spectrometers in series connected by a chamber (collision cell). After chromatography, the sample is processed in the first mass spectrometer to obtain the precursor ion which is then fragmented in the collision cell into product ions. The mass of the product ions is then determined in the detector of the second mass spectrometer. This method has high specificity, sensitivity and throughput.

During the past decade there has been a substantial increase in the use of LC-MS and MS assays, particularly in major diagnostic clinical laboratories, and to a lesser extent in some research laboratories. However, there are still situations where a GC-MS assay provides higher chromatographic resolution and even sensitivity than LC-MS. A particular strength of GC-MS and GC-MS and MS assays is their high applicability to measurement of large numbers of structurally similar compounds. They remain the most powerful assay method for defining defects in steroid hormone metabolism.

Because of the high validity and throughput of steroid hormone MS assays, there is a rapidly growing use of this methodology in both clinical and research laboratories. In larger reference laboratories, these assays have replaced the conventional RIAs, which are cumbersome and time-consuming, and direct immunoassays, which lack specificity and/or sensitivity. The MS technology has been implemented successfully for routine analysis of steroid hormones in major clinical diagnostic laboratories. Although the high-cost of MS instrumentation, related operating costs, and requirement for high technical expertise have prohibited smaller laboratories from using this instrumentation for high-throughput routine testing of steroid hormones, this situation is changing and MS assays are becoming much more widely used.

In addition to use of the MS methodology for routine analysis of steroid hormones, this methodology is now sufficiently rapid and robust for measuring these hormones in large epidemiological studies with high specificity and sensitivity. An important advantage of MS assays is their capability of measuring multiple steroids in a single aliquot of serum or urine. In contrast, generally only up to 5 different steroids

can be measured in a single serum aliquot (usually 1 mL) by conventional RIA. Several years ago, at the National Cancer Institute, MS assays were developed for quantifying as many as 15 different estrogens in only 0.5 of serum or urine.[4] Measurement of metabolite profiles of a steroid hormone has the potential to provide highly valuable information in diagnosing patients and in a variety of studies, particularly epidemiological studies. Quantitative analysis of metabolite profiles of small molecular weight molecules such as steroid hormones is referred to as metabolomics and is a rapidly growing field of research.

Standardization of Steroid Hormone Assays

Standardization in measuring steroid hormones is desirable so that test results are accurate and reliable, independent of the assay used and the time and place of measurement. Although there seems to be general agreement that MS assays will become the "gold standard" for steroid hormone measurements, there are many challenges to overcome before this occurs.[5] It is important to realize that the MS technology faces variability issues similar to those of conventional RIAs and direct immunoassays that need to be addressed. Differences in accuracy among MS assay methods appears to be attributable to variation in calibration of assay standards, whereas differences in assay precision may be explained, at least in part, by variations in sample preparation.

The Center for Disease Control and Prevention (CDC), with broad input from various professional societies, particularly the Endocrine Society, is leading a Hormone Standardization Program with an initial focus on standardizing testosterone measurements.[5] The conceptual approach of this program is built on experiences gained from successful standardization programs that CDC maintains or has supported (e.g., the cholesterol standardization program and national glycohemoglobin standardization program). The testosterone standardization program consists of three basic steps: calibrating individual assays, developing a reference system, and verifying end-user test performance. Although it is evident from previous efforts at the CDC that vast improvements in measurement performance can be achieved through assay standardization, based on their experience it could take years to accomplish such achievements.

Reference Intervals of Steroid, Protein, and Peptide Hormones

An important requirement in clinical diagnostic testing in which measurements of steroid, peptide, or protein hormones are determined by conventional and direct immunoassays or MS assays is reference intervals. These intervals should be derived from well-characterized, adequate-sized populations using standardized procedures such as those formulated by the Clinical and Laboratory Standards Institution. Frequently, only limited information is available about subjects used to establish reference intervals. Also, an often neglected aspect in establishing reference intervals for hormone measurements is biologically influencing factors that may affect these measurements. The major factors include gender, age, body mass index, pubertal stage, menopausal status, phase of menstrual cycle, pregnancy, and diurnal rhythm.

It is especially important to compare reference intervals for steroid hormones measured by MS assays to those obtained by conventional RIAs, since most of our knowledge about the role of steroid hormones in normal women and men, as well as in various endocrine diseases, is based on the data obtained by the latter methodology. Presently it appears that the reference intervals obtained by the two methods do not differ significantly.

Measurement of Specific Reproductive Protein and Peptide Hormones

Gonadotropins

Classic RIAs of gonadotropins have low specificity and sensitivity and often cannot distinguish low levels from low-normal values. This difficulty is compounded by the pulsatile nature of gonadotropin secretion. Thus, with RIAs it is not possible to detect the low levels of gonadotropins that would occur in cases of hypothalamic or pituitary failure or prior to puberty. Immunometric assays are more sensitive and specific and have improved the measurement of gonadotropins.[6] Therefore, IRMAs or ICMAs should be used in the evaluation of patients suspected of having hypogonadotropic hypogonadism and in pediatric patients. In contrast, the ELISA for gonadotropins is considered less sensitive and exhibits higher nonspecific binding.

A problem that may arise in measurements of LH includes significant cross-reactivity with hCG and its pulsatile secretion pattern (pulses approximately every 60 to 90 minutes). The requirement of precision in values would necessitate that samples, taken 15 to 20 minutes apart, be pooled for analysis. In the clinical setting, however, this is not necessary because low levels usually remain low and high values are not usually within the normal range. The concern about pulsatility is more for research purposes and is far less pronounced for FSH samples, where pulses are less frequent, occurring approximately every 3 hours.

Apart from alterations in FSH and LH associated with various disorders and physiological states, FSH levels are increased by levodopa and ketoconazole and decreased by the administration of estrogens and phenothiazines. LH is increased by ketoconazole and decreased by administration of sex steroids, phenothiazines, digoxin, and propranolol.

Blood Levels of LH and FSH in Women and Children

In most clinical diagnostic laboratories, serum FSH and LH measurements are determined by ICMAs. In our laboratory, the FSH reference ranges for the follicular, midcycle, and luteal phases are 2.8 to 14.4 mIU/mL, 5.8 to 21 mIU/mL, and 1.2 to 9.0 mIU/mL, respectively; the corresponding ranges for LH are 1.1 to 11.6 mIU/mL, 17 to 77 mIU/mL, and 1 to 14.7 mIU/mL. For postmenopausal women, the FSH and LH reference ranges are 21.7 to 153 mIU/mL and 11.3 to 39.8 mIU/mL, respectively.

During midcycle, serum LH levels increase fourfold to sixfold, whereas serum FSH levels increase twofold to threefold. The midcycle increase of gonadotropins lasts approximately 2 days.

During the luteal phase, serum LH and FSH levels are similar to or slightly lower than their respective levels during the follicular phase. Therefore, in healthy women, the LH to FSH ratio is approximately 1.0 during the follicular phase, but increases during ovulation.

Before puberty, gonadotropin levels are lower than in adult women, and the LH to FSH ratio is less than 1 because of the relative predominance of FSH secretion. At this age, RIAs have not been helpful in distinguishing patients with low gonadotropin secretion from healthy children; therefore, the third-generation LH and FSH IRMA or ICMA is used. These assays are also useful for measuring changes in LH and FSH during the pubertal progression. From Tanner stages P1 to P5, LH concentrations using the IRMA increase more than thirtyfold, but increase only twofold to fourfold when measured by RIA. Therefore, the third-generation immunometric assays are the preferred techniques when measuring LH in serum samples from prepubertal patients, patients with suspected precocious puberty, and those with suspected hypogonadotropic hypogonadism. It has been reported that, using a third-generation fluorometric immunoassay, values of LH higher than 0.6 mUI/mL are sufficient to suggest the diagnosis of gonadotropin-dependent precocious puberty and may permit this diagnosis to be made in two thirds of such patients.

During the perimenopausal period, serum FSH levels increase substantially, whereas LH levels remain within the normal range. After menopause, levels of both gonadotropins are high, but serum FSH levels are higher than LH levels. In older women, LH levels progressively decrease, approaching premenopausal levels.

High values of LH, with increased LH/FSH ratios, are found in 50% of women with polycystic ovary syndrome (PCOS). In the past, some clinicians based the diagnosis of PCOS on the finding of elevated LH levels and LH to FSH ratios higher than 2 or 3. Although an increased LH level or LH to FSH ratio may be useful for confirming the diagnosis of PCOS, many patients with PCOS have normal serum LH levels and LH to FSH ratios.

High levels of serum LH and FSH are typical of ovarian failure and may be found in patients with gonadal dysgenesis. Rarely, pituitary tumors may produce FSH or LH. Measurement of α-subunits and determination of the gonadotropin responses to thyrotropin-releasing hormone (TRH) may be useful for the diagnosis of gonadotropin adenomas.

Dynamic Tests for Gonadotropin Evaluation

Gonadotropin-Releasing Hormone Test

Synthetic gonadotropin-releasing hormone (GnRH), the hypothalamic decapeptide, has been used to stimulate LH and FSH secretion to identify abnormalities that cannot be diagnosed with baseline determinations. This test is primarily used to differentiate between hypothalamic and pituitary causes of gonadotropin deficiency and to uncover a maturational delay in secretion at the time of puberty. Otherwise, the test largely reflects baseline measurements. For example, in patients with PCOS and women with ovarian failure, GnRH stimulation results in exaggerated increases in LH in the setting of PCOS and in FSH elevations in women with ovarian failure.

When differentiating hypothalamic from pituitary defects in gonadotropin secretion, the test requires initial GnRH priming. The priming may be accomplished by daily intramuscular administration of 100 μg GnRH for 1 week before testing. With this approach, an absent or low response distinguishes the more common patient with a hypothalamic problem from a rare patient with a congenital or acquired pituitary defect of gonadotropin secretion.

The GnRH test is also used to probe the maturational state of the hypothalamic-pituitary-gonadal axis. Pubertal LH and FSH responses are observed in patients with gonadotropin-dependent precocious puberty (GDPP) and this test is needed when no third-generation assays are available.[7] The test may be performed in many ways, but requires at least two baseline samples obtained 15 minutes apart before GnRH administration. Intravenous doses of 25 or 100 μg are then administered, and blood samples are obtained at 20, 30, 60, 90, and 120 minutes. For practical purposes, samples obtained at 30 minutes and 60 minutes are sufficient for clinical interpretation. Using conventional RIA methods, after administration of 100 μg GnRH, an LH peak of more than 15 mIU/mL in girls and greater than 25 mIU/mL in boys is suggestive of GDPP. Using the CMA LH assay, after the same dose of GnRH, the cutoff value is greater than 8.0 mIU/mL. Similar cutoff values are observed when using LH IFMA (greater than 6.9 mIU/mL in girls and greater than 9.6 mIU/mL in boys).[8] Another approach is to use LH responses 2 hours after a long-acting GnRH analog is administered. LH values of greater than 10 mIU/mL (by IFMA) suggest GDPP.[9]

The only validated method to assess hypothalamic GnRH release is by measuring the spontaneous pulsatility of gonadotropins, which is generally reserved for research purposes. Blood samples are obtained at 10- to 15-minute intervals for 6 to 24 hours, depending on whether diurnal changes are being assessed.

Clomiphene Citrate Test

In the past, the ability of the hypothalamic-pituitary axis to respond to negative feedback of estrogen was assessed with clomiphene citrate (Clomiphene). Clomiphene (50 to 100 mg daily) is given orally for 5 days, and LH and FSH levels are measured before and at the end of the test. A normal response is an LH response of greater than 50 mIU/mL. This test lacks sensitivity and specificity and should be abandoned for this purpose.

The clomiphene citrate test is most frequently used in the assessment of ovarian reserve. In the past the clomiphene test was considered to be more valuable than a single measurement of FSH and estradiol on day 3 of the cycle. Clomiphene (100 mg) is administered on days 5 through 9 of the cycle, and the FSH level is measured initially on day 3 and again on day 10. Any value (day 3 or 10) above the threshold for the laboratory is considered a positive test result. Generally, an abnormal FSH level in this setting is a value greater than 10 to 12 mIU/mL; however, it is important that each laboratory define its own abnormal cutoff point because of the considerable variability among the different FSH assays. Some recent data, however, suggest that this test may not be more valuable than baseline FSH assessments.[10]

Human Chorionic Gonadotropin

Many tissues, including the pituitary, produce hCG at very low levels, whereas the placenta produces it in large quantities. Most assays are standardized to measure only the large quantities produced by the placenta or by hCG-secreting tumors. It should be considered that hCG, in effect, refers to four different structural moieties: hCG, which most people refer to, is produced by the villous syncytiotrophoblast; hyperglycosylated hCG is produced by the cytotrophoblast and has more of an aggressive role in implantation and trophoblastic disease; free β-subunit which is often produced in malignancies; and pituitary hCG which is secreted similarly to LH in a pulsatile fashion from the pituitary at low levels, noted most commonly in postmenopausal women.[11] Cross-reactivity between these moieties occurs to various degrees in different clinical assays for hCG, warranting more specific assays when clinically needed. For example the hyperglycosylated form of hCG which usually denotes a more successful pregnancy and implantation early in pregnancy may be reflected in a "routine" hCG clinical assay to varying degress, from 50% to 90%. The currently used Immulite system reflects hyperglycosylated hCG quite well, ~ 90%, while other immunoassays may not.

During pregnancy, hCG levels increase rapidly, doubling approximately every 2 days until 12 weeks. After the third month of pregnancy, hCG levels decrease and plateau at a constant level until term. Measurements of hCG are used widely to confirm pregnancy and monitor trophoblastic function in complications of pregnancy, such as spontaneous abortion and ectopic pregnancy. Measurements of β-hCG during pregnancy, when combined with other tests (nuchal translucency, pregnancy-associated plasma protein A, inhibin A, or estriol), may be useful for screening for trisomies, such as Down's syndrome.

High quantities of hCG are produced in trophoblastic disease and by nongestational trophoblastic tumors and in men by germ cell tumors. In general, all of these tumors may produce the intact hormone, but most produce only β-hCG. Patients with elevated β-hCG levels should be evaluated extensively to exclude an underlying malignant process. Measurement of β-hCG levels by sensitive assays is also useful for monitoring for a recurrence after tumor extirpation and may aid in the diagnosis of the tumor and reflect disease prognosis.

A special issue exists with measurement of low levels of βhCG in normal women. When low levels are found (usually in the range of 5 to 20 mIU/mL), possibilities include pregnancy, an hCG-producing tumor (including choriocarcinoma), normal pituitary secretion (usually in a postmenopausal woman), and interference in the assay (often encountered with "sandwich"-type assays). The first approach is to repeat the value with a different assay system, and to measure hCG in urine. More specific assays such as that of β-subunit may be used and if this explains the source, a malignancy should be sought. By the process of elimination, low levels of hCG which are not explained by differences in assays most likely reflect pituitary secretion, and the proof of this occurrence is by the use of pituitary suppression, as with oral contraceptive pills, which will suppress the hCG levels.

Prolactin

Serum prolactin (PRL) is generally measured by ICMA. The upper limit of the normal range is generally reported as 15 to 20 ng/mL in men and 20 to 25 ng/mL in women; although the true normal levels are usually lower (up to 18 ng/mL in women). Serum PRL values are influenced by estrogens, drugs (e.g., phenothiazines, metoclopramide), stress, food consumption, breast stimulation, and even venipuncture. Because of diurnal changes and transient increases after meals, samples should routinely be obtained at midmorning.

The presence in blood of macroprolactin (monomeric PRL + PRL autoantibody) or dimeric forms of PRL (so-called big-PRL forms) may lead to elevated PRL levels that are not associated with biological activity. In particular, macroprolactinemia may be an important clinical problem resulting in up to 10% of cases of misdiagnosed hyperprolactinemia. When macroprolactinemia is suspected (e.g., in patients with autoimmune diseases), polyethylene glycol precipitation should be carried out before the immunoassay.[12] Recently, new commercial methods for the measurement of PRL that involve ultrafiltration have been introduced and may be useful to detect macroprolactin or big prolactin in clinical practice.[13] In normal women, immunoreactive blood prolactin results mostly from monomeric prolactin (≥95%). Dimeric prolactin forms (so called big-prolactin) and macroprolactin (a prolactin-antibody complex of molecular weight greater than 100 kDa) are generally present in low concentrations (less than 1%). However, macroprolactinemia is present in more than 15% of subjects having increased immunoreactive prolactin and in some patients hyperprolactinemia is the result of elevated macroprolactin levels, misleading the medical approach.

The gold standard method for detecting macroprolactin is gel filtration chromatography, a procedure that allows for quantification of all three variants of PRL. However, this method is labor intensive and most clinical laboratories prefer using precipitation with polyethylene glycol (PEG). A low PRL recovery after PEG treatment indicates the presence of macroprolactin.

While it has been suggested to screen for macroprolactin in all hyperprolactinemic patients, PRL blood levels greater 85 ng/mL are not generally explained by macroprolactinemia and the Pituitary Society has published guidelines indicating that values of blood prolactin ≥150 ng/mL are always suggestive of a pituitary prolactinoma.[14] Therefore, it is reasonable to screen for macroprolactin only in patients having PRL values between 25 and 150 ng/mL. PRL recovery ≤30% following PEG precipitation indicates the presence of macroprolactinemia.[13] Because true hyperprolactinemia and macroprolactinemia may coexist, post PEG PRL values should not exceed 13 ng/mL.

In pregnancy, serum PRL levels begin to increase by 6 weeks of gestation and rise progressively to reach approximately 200 ng/mL at term. In nonlactating women, PRL levels return to normal 2 to 3 weeks postpartum.[15] With menopause, serum PRL declines slightly as a result of the reduction of estrogen.

Serum PRL levels greater than 200 ng/mL are diagnostic of pituitary adenoma, but patients with microadenomas often have levels that are considerably lower. Levels between 50 and 200 ng/mL may be found in patients with

non-PRL-secreting adenomas compressing the pituitary stalk. If moderately elevated PRL levels are found, evaluation of thyroid function is necessary because hypothyroidism results in elevations of serum PRL.

Dynamic Tests for Prolactin Evaluation

Dynamic tests for the evaluation of PRL secretion are seldom used and were popular when brain imaging was less sophisticated. Computed tomography (CT) or magnetic resonance imaging (MRI) is much more valuable for the diagnosis and assessment of a pituitary microadenoma or macroadenoma.

Thyrotropin-releasing hormone, the hypothalamic peptide that stimulates the secretion of thyroid-stimulating hormone (TSH), may be used to evaluate the pituitary secretion of PRL. In general, patients with a prolactinoma do not experience further increases in serum PRL after TRH stimulation. Therefore, this test has been used to differentiate between functional forms of hyperprolactinemia and PRL-secreting pituitary adenomas. However, the utility of the TRH test has been questioned because the PRL response largely depends on basal PRL levels. The test is carried out after an overnight fast, with TRH (200 μg) being administered intravenously. Blood samples for PRL are taken at the initiation of the test and again at 30, 60, and 90 minutes. A normal PRL response is an increase of at least 100% of basal levels. Psychiatric disorders and ingestion of thyroid hormone, corticosteroids, and tranquilizers may affect the PRL response. The TRH test is still used to diagnose pituitary thyroid disorders and for subtle forms of hypothyroidism; for these purposes, TSH levels are measured.

An alternative to the TRH test for the assessment of PRL disorders is the use of metoclopramide (10 mg intravenously). A blood sample is obtained immediately after metoclopramide administration, and again at 30, 60, 90, and 120 minutes. A PRL increment of 100 ng/mL at 60 to 120 minutes is considered normal.

Inhibins and Activin

Activin A and B have significant roles in the ovary. In general, Activin opposes the role of Inhibin and is a major binding protein of follistatin which neutralizes its biological activity. Nevertheless, there is no major role for the measurement of Activin at present in clinical practice. Recent experimental evidence, however points to its potential clinical role in disorders of pregnancy such as preeclampsia, as well as being a marker in endometriosis, although this has been questioned recently.[16]

Serum inhibin A and B levels may be measured by specific ELISA, and reflect the secretion from various populations of granulosa cells. As previously noted, a characteristic of peptide assays is that multiple subunits make assays difficult. This is particularly true in the case of inhibin assays, which have been highly variable and imprecise. Serum values vary in adult women during the menstrual cycle, with inhibin A being lowest during the follicular phase and peaking during the midluteal phase; inhibin B exhibits an opposite pattern (Fig. 34.5). During pregnancy, inhibin A decreases during the second trimester, whereas inhibin B rises from the third

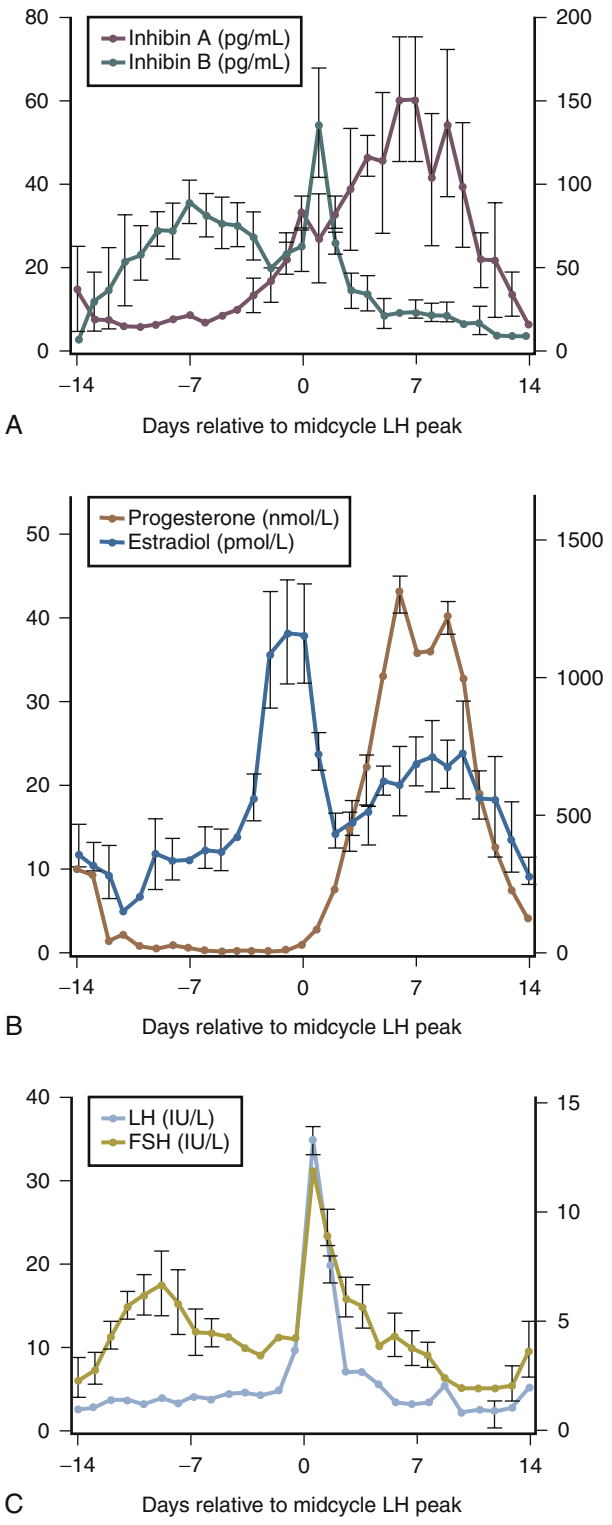

FIGURE 34.5 Plasma concentrations of inhibin A and inhibin B. **A**, estradiol and progesterone **B**, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) **C**, during the female menstrual cycle. Data displayed with respect to the day of midcycle LH peak. Mean concentrations are shown ± standard error of the mean. *(Adapted from Groome NP, Illingworth PJ, O'Brien M, et al. Measurement of dimeric inhibin B throughout the human menstrual cycle.* J Clin Endocrinol Metab *81:1401–1405, 1996.)*

trimester to peak at term. After menopause, levels of both inhibins decline markedly.

The measurement of inhibin may be useful in several conditions. Some granulosa cell tumors produce high quantities of inhibin B, which may be useful preoperatively and for postoperative surveillance, because it may detect tumor recurrence. Measurement of inhibin B also has been proposed for monitoring certain complications of pregnancy and for evaluating the number of small follicles present in the ovary in the early follicular phase. The measurement may be useful in assessing reproductive aging because a low level of inhibin B on day 3 may indicate a declining ovarian reserve. Lack of standardization of inhibin B measurements has made this difficult.

In men, inhibin B is produced by Sertoli cells and has been considered a good marker of spermatogenesis, beginning to rise after puberty. It has also been used in the differential diagnosis of cryptorchidism versus anorchia where levels are not detectable in anorchia. It may also be helpful in distinguishing between various types of hypogonadism.

Anti-Müllerian Hormone: General Utility and in the Assessment of Ovarian Reserve

Anti-müllerian hormone (AMH) is a homodimeric glycoprotein linked by disulfide bonds with a molecular weight of 140kDa that belongs to the Transforming Growth Factor-B (TGF-B) superfamily. AMH plays an important role in male sex differentiation as its production by the embryonic Sertoli cells induces the regression of müllerian ducts.

In the past, AMH has been measured by two different commercial enzyme-linked immunosorbent (ELISA) assays provided by Diagnostics Systems Laboratory (DSL 10-14400) and by Immunotech. Because of the consolidation of DSL by Beckman Coulter, the Beckman assay is now used (AMH Gen II assay) and values obtained by AMH Gen II assay are 40% higher than previous DSL values.[17]

In women, AMH is produced by the granulosa cells of pre-antral and small antral follicles and its values are virtually undetectable at the birth but increase gradually until puberty and then remain relatively stable during the early reproductive period. In the third decade (30s), AMH levels start declining and become very low during perimenopausal period.[18] The measurement of AMH in blood is mainly used to assess ovarian reserve but may be useful also to diagnose alterations of follicle recruitment and initial growth. In fact, measurement of AMH has been used in evaluation of sexual ambiguity (male neonates have much higher levels than female neonates)[19] and to distinguish between hypogonadism and delayed puberty. Low levels of AMH are found in Turner syndrome and hypogonadotropic hypogonadism.

Serum AMH levels are 2 to 3 fold higher in PCOS, consistent with the presence of an increased number of preantral and small antral follicles.[20] It has been reported that serum AMH values greater than 35 pmol/L (or greater than 5 ng/mL) are a sensitive marker of PCOS [21] and may be useful for the diagnosis of this disorder, mostly when ovarian sonography is not available. In PCOS as in normal women, serum levels of AMH begin to decline in the third decade and the decline becomes more marked after the 40s. Not having an age-specific level of AMH is one of the difficulties in using AMH in isolation for the diagnosis of PCOS. We have observed that women with PCOS who have the lowest

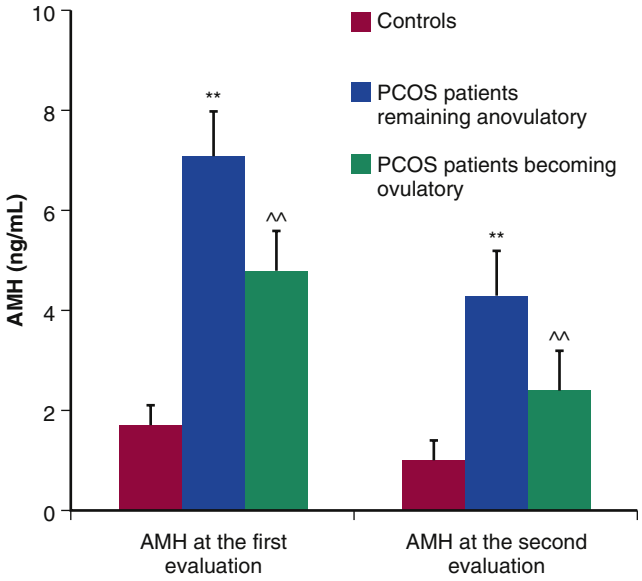

FIGURE 34.6 *P* less than 0.01 versus controls and PCOS becoming ovulatory, *p*, 0.01 versus controls. *(Adapted From Carmina E, Campagne AM, Mansueto P, Vitale G, Kort D, Lobo R. Does the level of serum antimüllerian hormone predict ovulatory function in women with PCOS with aging?* Fertil Steril *98(4):1043-1046, 2012.)*

AMH values have the highest probability of having more normal menstrual cycles with aging[22] (Fig. 34.6).

Assessing ovarian reserve has become an extremely important part of the management of women with reproductive disorders. Whereas ovarian aging becomes accelerated in the late 30s, even younger women, particularly those who have undergone cancer treatment, may have diminished ovarian reserve.[23]

Although measurement of serum FSH and estradiol levels on day 2 to 3 has been used widely, other tests include the clomiphene challenge test (described earlier), counting antral follicles on ultrasound, measuring levels of inhibin B, and measuring anti-müllerian hormone (AMH). Although some have suggested using a combination of these to provide a composite score criterion of ovarian reserve, in our hands, AMH level has proved to be the most useful, as suggested by others (Fig. 34.7).[24] Levels of AMH are cycle-dependent and tend not to fluctuate as much as FSH levels. Receiver operating characteristic curves have been constructed to assess the probability of pregnancy. Our experience suggests that a value of less than 0.4 ng/mL carries a poor prognosis, although lab values vary considerably. Figure 34.8 depicts the age-specific decline in AMH levels associated with aging from a large database of women presenting for fertility treatment.[25] Both Inhibin B and AMH may be helpful in predicting the onset of menopause, but the data for AMH are more robust because of less variability between assays. Several groups have confirmed that once AMH levels become undetectable (usually less than 0.05 ng/mL) menopause will occur within 5 years[26] (Fig. 34.9).

It is important to note that protracted storage of whole blood at room temperature profoundly influences the AMH concentration (incremental increase of 40% over approximately 3.5 days) measured in the subsequently separated serum.[27] However, when samples are collected into maintained tubes with a gel separator, the AMH remains unaffected for many days at room temperature.

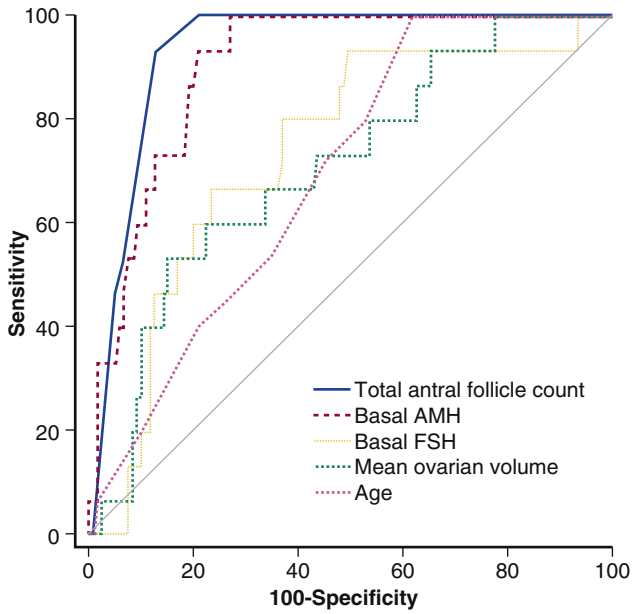

FIGURE 34.7 Prediction of poor response to COH: AFC and AMH are best; the combination is not better. *(Adapted from Jayaprakasan K, Deb S, Batcha M, et al. The cohort of antral follicles measuring 2-6 mm reflects the quantitative status of ovarian reserve as assessed by serum levels of anti-müllerian hormone and response to controlled stimulation.* Fertil Steril *94(5):1775–1781, 2010.)*

Measurement of Sex Steroid Hormones

Estrogens

Measurement of serum levels of E_2, the major active estrogen, plays an important role in clinical diagnostic and research laboratories. In women, diagnostic applications of E_2 assays include assessment of ovarian function in a wide variety of clinical situations such as menstrual disorders, precocious or delayed puberty, and assisted reproduction protocols. In men, E_2 measurements may be useful for evaluation of gynecomastia. In research laboratories, quantitation of E_2 has played an important role in many different studies (e.g., epidemiological studies of breast cancer).

Other estrogens such as estrone (E_1) and estrone sulfate (E_1S) are measured in clinical diagnostic laboratories much less frequently than E_2; this is especially true of E_1S. E_1 has substantial biological activity and is often measured together with E_2 when determining estrogen status in women or men. In contrast, E_1S has no biological activity but is quantitatively the most important estrogen in either premenopausal or postmenopausal women, or in men, and reflects the reservoir of estrogen in the circulation.[28]

Although direct RIA kits are available commercially to measure E_1 and E_1S, there are deficiencies associated with the assays obtained with these kits. Thus, conventional RIAs are recommended to measure E_1 and E_1S (measurement of E1 after sulfatase incubation of serum).

Estriol (E_3) is a very weak estrogen, which was measured frequently by RIA in the 1970s to assess fetal well-being in late pregnancy. However, diagnostic use of the E_3 assay

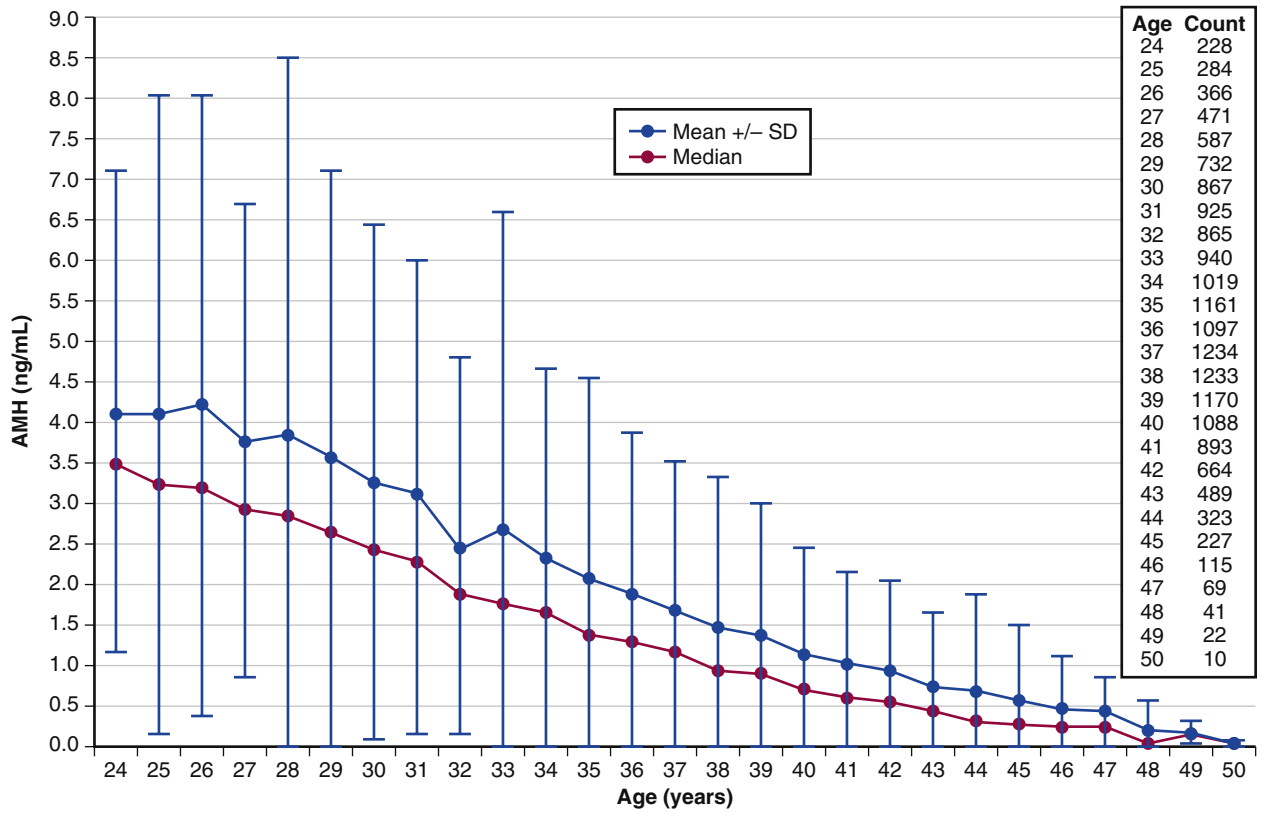

FIGURE 34.8 Data from 17,120 women—single assay site: BC-DSL. *(Adapted from Seifer DB, Baker VL, Leader B. Age-specific serum anti-müllerian hormone values for 17,120 women presenting to fertility centers within the United States.* Fertil Steril *95(2):747–750, 2011.)*

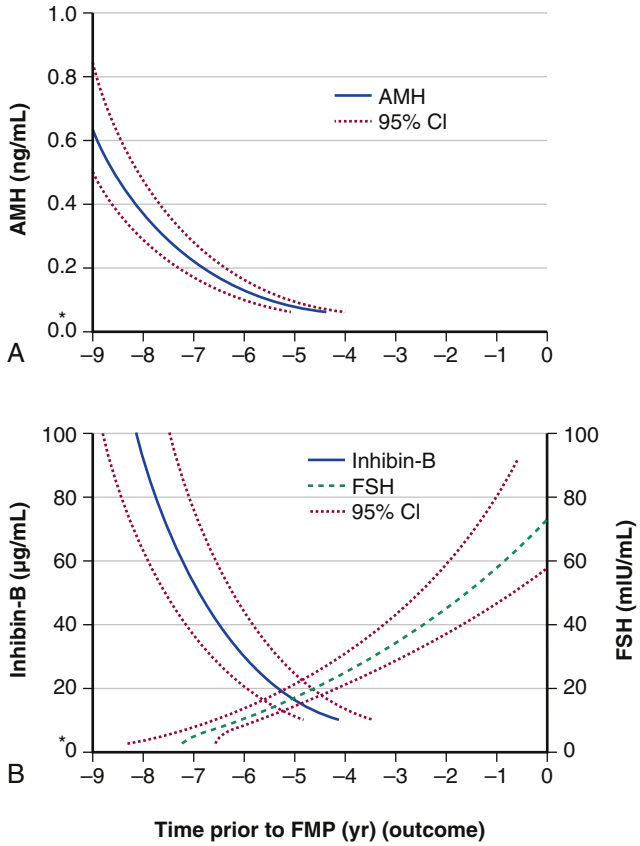

FIGURE 34.9 Anti-müllerian hormone (AMH) and inhibin-B concentrations in relation to the last menstrual period. *(Adapted from Sowers MR, et al.* J Clin Endocrinol Metab *93(9):L34768–L34783, 2008.)*

was replaced with ultrasound and fetal heart rate testing and now has re-surfaced as part of a genetic panel for aneuploidy testing.

As discussed earlier, E_2 was measured initially by conventional RIA in both clinical diagnostic and research laboratories. However, once immunoassays were developed for use on automated platforms, most clinical diagnostic laboratories began to use this methodology on a routine basis, and this methodology is still used by many of these laboratories. Although these assays can be used to measure higher E_2 levels (greater than 50 pg/mL), they lack the sensitivity to measure precisely low E_2 levels, such as those found in postmenopausal women and in men. In addition, direct E_2 immunoassays are not specific. This is evident when E_2 is measured in postmenopausal women using estrogen therapy (e.g., conjugated equine estrogens); the serum levels in these women are overestimated threefold to fivefold. Overestimation of serum E_2 levels may result in inappropriate treatment of a patient and potential adverse effects. This is especially important when E_2 is measured by direct immunoassay in patients treated with aromatase inhibitors. Some aromatase inhibitors cross-react with the antibody in those assays, resulting in falsely elevated E_2 levels. Based on these results, an inappropriate clinical decision may be made to increase unnecessarily the dosage of the drug.

To obtain accurate data, low E_2 levels should be measured by conventional RIA or by LC-MS and MS or GC-MS and MS.[29] These assays separate out potential interfering E_2 metabolites prior to the quantification step, as discussed earlier.

Circulating Estrogen Levels

It is important to realize that the reference ranges of the different estrogens will vary somewhat, particularly when different assay methodology is used. Serum levels of E_2 and E_1 during various stages of a woman's lifetime were established in the 1970s and 1980s using conventional RIAs. Laboratories using direct immunoassays have generally adjusted their reference ranges for E_2 and E_1 to match those obtained by conventional RIAs.

E_2 levels range from 20 to 80 pg/mL during the early to midfollicular phase of the menstrual cycle and peak at 200 to 500 pg/mL or higher during the preovulatory LH surge. During the midluteal phase, E_2 levels range from 60 to 200 pg/mL.

Before puberty, E_2 levels are less than 20 pg/mL, indistinguishable from cases of hypogonadism. After menopause, E_2 levels fall to prepubertal levels; the mean E_2 level is typically 10 to 20 pg/mL, and levels are lower than 10 pg/mL in women who have undergone oophorectomy.

In men, serum E_2 levels are less than 40 pg/mL, but may be increased in several testicular and non-testicular diseases. Male E_2 levels are relatively constant and, unlike testosterone, are unchanged with age.

As for serum E_1 levels, they generally follow the profile of E_2 levels but are a little lower, except in postmenopausal women where the levels are approximately threefold higher than E_2 levels. Also, when postmenopausal women are treated orally with any estrogen, E_1 levels are 3 to 5 times higher due to the high activity of 17β-hydroxysteroid dehydrogenase (type 2) present during hepatic first pass metabolism.

Progesterone

Serum progesterone levels may be measured by a variety of immunoassay methods. Although progesterone is metabolized to many different metabolites, use of direct immunoassays has generally not resulted in overestimated values due to the relatively high levels that are being measured and the development of highly specific antibodies against progesterone, which are used in these assays.

Serum progesterone is low during the follicular phase, (less than 1.5 ng/mL). Levels begin to increase just before the onset of the LH surge and then increase progressively to peak levels 6 to 8 days after ovulation. After menopause, serum progesterone of adrenal origin is less than 0.5 ng/mL.

The measurement of serum progesterone during the midluteal phase (days 21 and 22) is most frequently used to assess ovulatory status. During that time, serum progesterone levels are usually higher than 7 ng/mL. Some physicians have proposed using three luteal determinations with a total serum value of 15 ng/mL or more to indicate normal luteal function. For patients being monitored for fertility, other assessments may be used, including basal body temperature charts, urinary LH kits, and timed endometrial biopsy. In conception cycles, properly timed midluteal progesterone levels are more than 10 ng/mL.[30] Progesterone is also often used to assess ovulation after induction of ovulation. In clomiphene cycles, midluteal progesterone levels should be higher than 15 ng/mL.[31]

During pregnancy, serum progesterone may be useful to assess corpus luteum and placental function.[32] Maternal serum progesterone levels rise slowly to 40 ng/mL near the end of the first trimester and then increase progressively to reach 150 ng/mL, at term. Low levels of progesterone (less than 10 ng/mL) at 6 to 8 weeks signify an abnormal intrauterine pregnancy or an ectopic pregnancy.

Androgens

Androgens in women arise from three different sources: the ovaries, adrenal glands, and peripheral compartment. Most androgens are produced or metabolized in more than one compartment and, in evaluating women with androgen excess, several androgens are usually measured.[33] In the past, the measurement of urinary 17-ketosteroids was the most common method used to evaluate androgen production in women. However, 17-ketosteroid measurements reflect adrenal androgen production poorly reflect testosterone production, and are nonspecific; therefore, they have been abandoned for use in current practice.

Most commonly, serum testosterone (T) and dehydroepiandrosterone sulfate (DHEAS) levels are measured. These levels largely reflect ovarian and adrenal contributions, respectively.[34] Testosterone reflects mostly ovarian androgen production, with two thirds of circulating levels resulting from the peripheral conversion of androstenedione; therefore, increases in either ovarian or adrenal androstenedione production results in elevated serum testosterone levels. On the other hand, whereas DHEAS reflects adrenal androgen secretion well, its levels may be normal in certain cases of adrenal androgen hypersecretion (as in 21-hydroxylase deficiency).[34] The pathway of adrenal enzymatic blockade (affecting the Δ^4 pathway) explains this discrepancy. Conversely, serum DHEAS may be elevated in many patients with a prevalent ovarian source of hyperandrogenemia (as in PCOS).[34] Accordingly, increased levels of serum DHEAS do not predict androgen responses to dexamethasone suppression which has been used as a test to determine adrenal responsivity to suppression.

Total, Free, and Bioavailable Testosterone

When measuring total testosterone in female serum samples, it is essential to use either a conventional RIA or a MS assay. Direct immunoassays have no or poor validity for quantifying testosterone in female serum samples.[35] However, they can be used to measure testosterone in male serum samples due to the relatively higher circulating testosterone levels in men.

In premenopausal women, approximately 66% and 30% of total testosterone is bound to SHBG and albumin, respectively and the free fraction generally comprises less than 2% of the total.[36] Free testosterone is the fraction of circulating testosterone that is available for metabolism or binding to the androgen receptor in target cells.[37] The "gold standard" for quantifying free testosterone is the equilibrium dialysis method.

This method involves the addition of a small amount of ^{3}H-testosterone to a serum or plasma sample, which is then transformed to a vessel divided by a membrane and containing buffer. After a suitable incubation period, separation of the protein (SHBG and albumin)-bound fractions from the free fraction of testosterone by means of a membrane. The membrane retains the protein-bound fractions but allows free testosterone to pass through. The percentage of tritiated free testosterone is then calculated on the basis of the total ^{3}H-testosterone added.

Although the equilibrium dialysis method is commonly regarded as the "gold standard" for quantifying free testosterone, it is subject to technical limitations. The method is influenced by dilution of the serum sample and can be affected by impurities of tritiated testosterone not bound by SHBG or albumin; these impurities may increase the percentage of free testosterone. Also, the use of too large an amount of ^{3}H-testosterone in the assays may increase the concentration of total testosterone and possibly disturb the equilibrium of endogenous testosterone.

For many years it was accepted that only the free fraction of testosterone in the circulation can be taken up by tissues and that the protein-bound testosterone complex is inactive. However, some investigators observed that the fraction of testosterone bound to albumin dissociates rapidly and is taken up by tissues in a manner similar to that of the free steroid. Testosterone bound to the large pool of albumin, together with the small amount of the free steroid, most likely forms the circulating pool of bioavailable (non-SHBG-bound) testosterone. The bioavailable fraction of testosterone enters cells where it may undergo metabolism or binds to the androgen receptor and exerts biological activity.

A relatively simple method to determine bioavailable testosterone involves addition of a small amount of ^{3}H-testosterone to a serum sample and, after a suitable incubation period, precipitation of the globulins (including the SHBG-testosterone complex) with saturated ammonium sulfate, centrifugation, counting the tritium in the supernatant, and calculating the percentage of the tritium in the supernatant (which represents the "bioavailable" testosterone fraction) based on the total amount of ^{3}H-testosterone added initially. The most frequently encountered sources of error in the ammonium sulfate precipitation assay are due to use of impure tritiated testosterone, insufficient counting time of the small amount of radiolabeled testosterone, and incomplete precipitation of globulins.

Using the methods described above, the concentration of free or bioavailable testosterone is usually calculated from the percentage of free or bioavailable testosterone multiplied by the total testosterone concentration. Thus, it is essential to determine the total testosterone concentration accurately, either by a conventional RIA or MS assay.[38]

It is most practical, for clinical purposes, to calculate a free testosterone index (free androgen index [FAI]) using levels of testosterone and SHBG. The calculation is made using the ratio between testosterone and SHBG (in units of nanomole per liter): T [ng/mL] $\times$ 3.467/SHBG $\times$ 100).[39] At least in females, FAI values correlate well with free testosterone determined by equilibrium dialysis. However, FAI values have low validity in men[40] and are strongly dependent on the accuracy of testosterone and SHBG assays. In general, FAI should be used primarily for clinical rather than research purposes, when conventional RIAs or MS assays for total testosterone are not available.

Other Androgens

There are other androgens that may be useful to measure under different circumstances. These include 11β-hydroxyandrostenedione,[41] which reflects adrenal production of

androstenedione because 11β-hydroxylase activity is usually absent in the ovary. Also, assessment of peripheral androgen production requires the measurement of products of 5α-reductase activity. Although serum dihydrotestosterone (DHT) does not appropriately reflect increases in peripheral 5α-reductase activity, more distal metabolites may be helpful. Serum 3α-androstanediol glucuronide best reflects peripheral testosterone metabolism in hirsutism[42] and androsterone glucuronide best reflects the state in androgenic acne.[43]

Blood Levels of Androgens in Women

In women of reproductive age, an accurate range for serum testosterone is 20 to 50 ng/dL. With direct immunoassays, the upper end of the normal range is approximately 70 to 80 ng/dL, or even higher. Serum testosterone levels higher than 200 ng/dL are suggestive of ovarian neoplasms, but some tumors may present with lower levels.[44] Because upper normal ranges vary, a rule of thumb is to be concerned about a tumor in women whose values exceed *2.5* times the upper normal range of a particular assay. Patients with PCOS have mildly increased serum testosterone (usually less than 100 ng/dL), whereas markedly increased levels may be found in patients with hyperthecosis and in those who have adrenal enzymatic deficiencies.

The range for bioavailable testosterone is 0.6 to 5 ng/dL, whereas free testosterone levels are between 1 and *8.5* pg/mL. Normal ranges for SHBG in women are between 30 and 90 nmol/L.

Serum androgens are low before puberty, with adrenal androgen levels beginning to increase 1 or 2 years before the onset of puberty. Serum DHEAS values higher than 0.8 μg/mL, indicate the presence of adrenarche.[45] After menopause, serum androgens decline slightly. Aging is the principal determinant of this decline.[46] Serum DHEAS levels have been suggested to be useful in excluding adrenal deficiency in young women with autoimmune ovarian failure.[47]

The normal range of serum DHEAS is 0.8 to 2.8 μg/mL, Values greater than 8 μg/mL, are suggestive of an adrenal neoplasm; if the adrenal tumor produces testosterone, however, only modestly elevated values (3 to 4 μg/mL) may be found.[48]

Normal serum androstenedione levels range from 1 to *2.5* ng/mL. The pattern of serum androstenedione levels during the menstrual cycle is similar to that described for testosterone. However, in contrast to testosterone, androstenedione levels show some circadian rhythm.

Measurement of Circulating Androgen Precursors in Women

Measurements of intermediates in steroid metabolism are useful for the diagnosis of adrenal enzymatic deficiencies. Serum 17α-OHP is used in the diagnosis of 21-hydroxylase deficiency.[49] Because 17α-OHP is secreted by the corpus luteum, the measurement should be carried out in the morning during the follicular phase. In healthy women, serum 17α-OHP is generally lower than 1 ng/mL, but hyperandrogenic patients (mostly those with PCOS) generally have slightly higher levels. Therefore, values up to 2 to 3 ng/mL are not indicative of an adrenal enzymatic deficiency. Patients with classic neonatal forms of 21-hydroxylase deficiency have very high levels of 17α-OHP (50 to 200 ng/mL), while most patients with non-classic, late-onset 21-hydroxylase deficiency have serum 17α-OHP levels between 10 and 20 ng/mL. The adrenocorticotropin hormone (ACTH) stimulation test, which will be described later in this chapter, can be used to diagnose 21-hydroxylase deficiency. From a practical standpoint, most suspected patients can now have genotyping for the various mutations in the *CYP21β* gene, particularly when there is pertinent family history.[50]

The measurement of serum 11-deoxycortisol may be used to diagnose 11β-hydroxylase deficiency when 17α-OHP is elevated. This is a rarer condition that may be associated with hypertension. The measurement of serum 17α-hydroxypregnenolone (and the ratio 17α-OHP to 17α-hydroxypregnelone), as well as the ratio for DHEA to androstenedione is useful in the diagnosis of 3β-hydroxysteroid deficiency.[51] In adults, this latter diagnosis is controversial in that no genetic mutations in the *3βol* gene have been uncovered and most patients seem to have a variant of Polycystic Ovary Syndrome.[52]

Tests to Establish the Source of Hyperandrogenism

Because serum androgens may arise from different sources in women, several tests have been established to distinguish adrenal from ovarian hyperandrogenism. However, most tests are not specific and their use is generally limited. Currently clinical guidelines, for example for the evaluation of hirsutism, do not suggest the need to determine the source of androgen excess; however there may be an investigational interest in pursuing a more specific diagnosis.

The tests may be divided into two groups: tests to assess adrenal androgen secretion, and those that assess ovarian androgen secretion. The first group of tests includes the dexamethasone suppression test and the ACTH stimulation test.

Dexamethasone Suppression Test

For evaluation of hyperandrogenism, a prolonged test may be used in which dexamethasone (0.5 mg) is given orally every 6 hours for 3 to 7 days. Evaluation of the suppression of serum DHEAS requires 7 days because of the prolonged half-life of this steroid; for the evaluation of the suppression of testosterone and free testosterone, however, 3 days of dexamethasone administration is sufficient. For practical reasons, the measurement of testosterone and free testosterone are sufficient because DHEAS is always profoundly suppressed by dexamethasone unless an adrenal tumor is present. In most common forms of hyperandrogenism, a decrease of total and unbound testosterone of at least 60% of basal values suggests an adrenal cause of hyperandrogenism.[53] The test is not specific and is now rarely used.

Adrenocorticotropic Hormone Stimulation Test

The ACTH stimulation test is generally used for the diagnosis of cortisol deficiency or to uncover mild adrenal enzymatic deficiencies. Also, in the past this test has been used to distinguish between adrenal and ovarian sources of hyperandrogenism, but is not generally used for this purpose because of its lack of specificity. ACTH stimulation is not recommended for uncovering subtle defects in hyperandrogenism unless there is a strong suggestion that

21-hydroxylase deficiency (congenital adrenal hyperplasia) may be present. For example, the ACTH stimulation test would be indicated in adult women with hyperandrogenism who have baseline levels of 17α-OHP over 3 mg/mL but less than 10 mg/mL—the 17α-OHP level above which the diagnosis of 21-hydroxylase deficiency would be obvious.[54] Some authors have suggested a baseline 17α-OHP value cut-off of greater than 2 ng/mL as a threshold for ACTH stimulation testing. The index of suspicion should be higher in certain ethnic groups: Yupik Eskimos, Ashkenazi Jews, and certain Southern European groups. As stated earlier in the chapter, many patients now get genotyping done.[55]

The test is best performed between 8 and 9 AM, with 0.25 mg of cosyntropin injected intravenously. While the test may also be accomplished by intramuscular injection, more consistent results have been obtained with intravenous administration. Blood samples are generally obtained at 30 minutes and 60 minutes, but the 60-minute value suffices as a single time point for practical purposes. For the diagnosis of non-classic 21-hydroxylase deficiency, serum cortisol and 17α-OHP are measured. Serum 11-deoxycortisol may be evaluated if the rare 11-hydroxylase defect is suspected.

Non-classic 21-hydroxylase deficiency may be diagnosed using the New nomogram (Fig. 34.10),[50] in which the log of the baseline 17α-OHP level is plotted against the log of 17α-OHP at 60 minutes after ACTH administration. However, most laboratories diagnose 21-hydroxylase deficiency if peak 17α-OHP is higher than 10 ng/mL with an increase from baseline of at least 5 ng/mL.

Δ^5 and Δ^4 intermediate steroid measurements after ACTH stimulation have been used to diagnose 3-beta-hydroxysteroid deficiency,[52] however women so identified do not have a genetic form of enzyme deficiency, and it is likely that these women constitute a variant of PCOS.

Gonadotropin-Releasing Hormone-Agonist Test

GnRH-agonists (GnRH-A) are generally used to down-regulate the secretion of pituitary gonadotropins and to inhibit ovarian steroid secretion. However, prior to down-regulation, the early agonistic action of GnRH-A causes prolonged stimulation of gonadotropin secretion, which in turn, stimulates the ovary. The test has been used in the setting of PCOS.[56]

The original test was performed using nafarelin,[56] but other GnRH agonists may be used with no substantial differences. Generally, leuprolide (500 or 1000 μg) is given subcutaneously in the morning between the fifth and the eighth day of the cycle. Blood samples are taken at 0 minutes and after 8 and 24 hours. A delta (increase from baseline) in serum 17α-OHP greater than 2.6 ng/mL suggests an increased or exaggerated response that is characteristic of women with PCOS.

Hormonal Evaluation of Hirsutism

Hirsutism is excessive hair growth in women where it is not normally found, usually with a central body distribution. When this biological signal is manifest, laboratory tests may be indicated to pinpoint the abnormality.

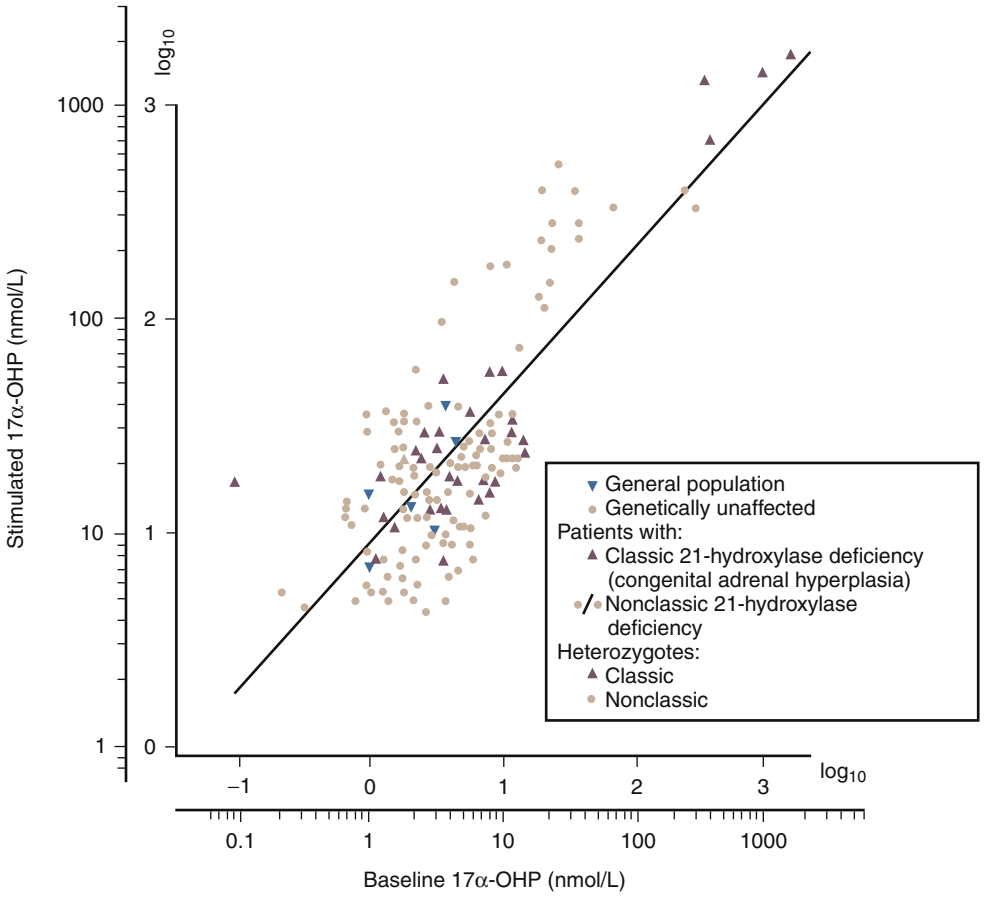

FIGURE 34.10 Nomogram of 17α-hydroxyprogesterone (17α-OHP) in different types of patients with congenital adrenal hyperplasia. *(Adapted from New MI, Lorenzen F, Lamer AJ, et al. Genotyping steroid 21-hydroxylase deficiency: hormonal reference data.* J Clin Endocrinol Metab *57:320–326, 1983.)*

Most commonly, total testosterone, DHEAS, and SHBG are measured (as well as 17α-OHP to exclude non-classic congenital adrenal hyperplasia). In about 10% to 15% of hirsute women, all of these hormone levels are in the normal range and a diagnosis of "idiopathic hirsutism" is made.[57] While it is not our intent to discuss the differential diagnosis of hirsutism, a simple algorithm is provided in Figure 34.11.

Blood Levels of Androgens in Men

In adult men, total testosterone and unbound testosterone are the only androgens measured in the evaluation of testicular function. Serum testosterone levels range between 300 and 1000 ng/dL. Serum testosterone decreases during the day and in the evening the levels are approximately 15% lower.

The normal range for bioavailable testosterone is between 66 to 417 ng/dL; for free testosterone, normal values are between 50 and 210 pg/mL. These assays may be useful in patients with low testosterone values. Serum DHT values range between 30 and 86 ng/dL, but this assay is not recommended on a routine basis. In evaluating children and neonates for 5α-reductase deficiency, serum DHT assays have been useful.

Assessment of Glucose Metabolism and Insulin Activity

Normal fasting blood glucose levels are lower than 100 mg/dL and values of 125 mg/dL and higher are diagnostic of diabetes mellitus. Prediabetes represents an elevation of plasma glucose above the normal range but below that of clinical diabetes.[58] Prediabetes is diagnosed as either impaired fasting glucose (IFG) (fasting blood glucose levels between 100 and 125 mg/dL) or impaired glucose tolerance (IGT). The latter is detected by oral glucose tolerance testing (see later in the chapter) with blood glucose levels greater than 140 mg/dL 2 hours after glucose administration indicating IGT. Both IFG and IGT are risk factors for type 2 diabetes, and the risk is even greater when IFG and IGT occur together.

Glycated haemoglobin A1c (HbA1c) represents a useful tool for predicting and diagnosing diabetes mellitus.[59] HbA(1c) has slightly lower sensitivity than fasting plasma glucose (FPG) in detecting diabetes, but slightly higher specificity with a cut-off value of greater than 6.1% for the diagnosis of diabetes mellitus. However, because optimum cut-off values vary by ethnic group, age, gender, and population prevalence of diabetes, a slightly higher value of 6.5% may be used.[60]

Measurement of Serum Insulin

Serum insulin may be measured by different immunoassays. Use of heparin causes falsely elevated values, while hemolysis of the blood may result in falsely low values. Insulin antibodies in blood result in low levels in some assays and high levels in others.

Using commercial assays, normal fasting insulin levels range between 5 and 15 μU/mL but with more sensitive assays normal fasting insulin should be lower than 12 μU/mL. Obese subjects have increased values, while very high circulating levels are found in patients with severe insulin resistance. 40% to 50% of women with a normal body mass index who have classic PCOS have slightly increased insulin levels,[61] higher levels are observed in obese women with PCOS.[62]

Evaluation of Insulin Resistance

Insulin resistance is considered to be extremely important in health and disease and has an important role in the pathophysiology of PCOS. There are several ways to assess peripheral insulin sensitivity.[62,63] The most precise methods involve the use of glycemic clamps.[64] However, these methods are very cumbersome and should be reserved for research purposes. Use of the minimal model of Bergman applied to a frequently sampled intravenous glucose tolerance (FSIGT) test is considered to be the "gold standard" for assessing insulin resistance.[65] This method is as sensitive as the euglycemic insulin clamp.[66,67] An insulin tolerance test (ITT) is a good alternative for use in clinical practice.

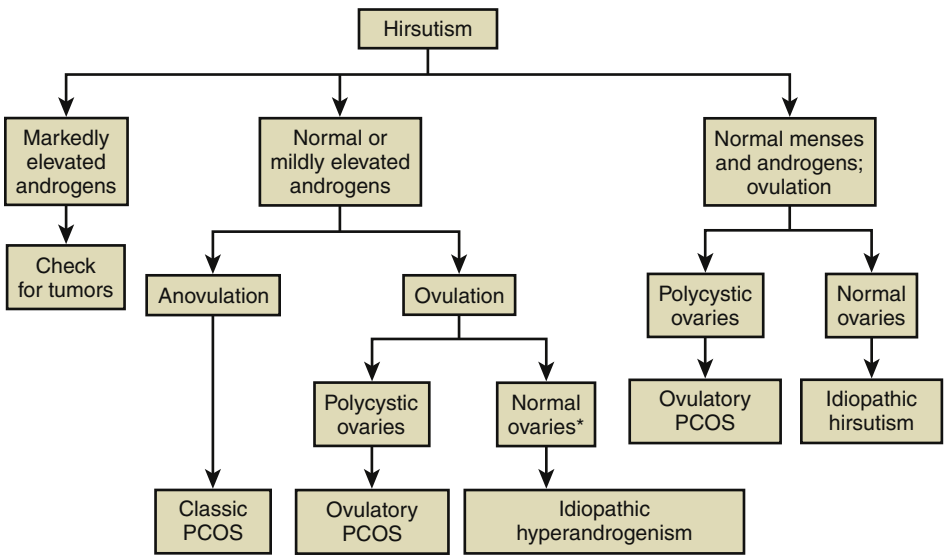

FIGURE 34.11 Diagnosis of hirsutism. *Note that the ultrasound diagnosis of polycystic ovaries is somewhat subjective. Therefore, the diagnostic distinction between ovulatory polycystic ovary syndrome (PCOS) and idiopathic hyperandrogenism is fluid.

Methods based on fasting blood concentrations for glucose and insulin with the use of various calculations, are highly dependent on the quality of the insulin assay and should not be used when β cell function is impaired as occurs in diabetes mellitus, or in the elderly. In addition, these methods measure mostly hepatic, and not peripheral, insulin sensitivity. With all these limitations, these methods may be useful in a clinical setting, for example in patients with PCOS without diabetes. Methods based on OGTT have similar limitations and clinical usefulness but presents the advantage of giving other important clinical information such as the presence of glucose tolerance.

Frequently Sampled Intravenous Glucose Test (FSIGT)

Two different catheters (one for glucose and insulin administration and one for blood samples) are placed in two antecubital veins.[68] Glucose (0.3 g/kg) is injected over 1 minute intravenously, followed 20 minutes later by an intravenous insulin bolus (0.03 U/kg). In the original method, blood samples were taken at 15, 10, 5, and 1 minute before the glucose load; additional samples were taken every minute for 10 minutes after loading, and again at 12, 14, 16, 20, 22, 23, 24, 25, 27, 30, 40, 50, 60, 70, 80, 90, 100, 120, 150, and 180 minutes. Because of the great number of blood samples required ($n = 33$), the test has been modified to require only 12 samples: 5 minutes before the glucose load, then 2, 4, 8, 20, 22, 30, 40, 50, 70, 100, and 180 minutes afterwards. In all samples, glucose and insulin are measured and insulin sensitivity (SI), which is reciprocally inversely related to insulin resistance, is calculated with the minimal model method by using a computerized algorithm. According to ADA, this test and the euglycemic insulin clamp are the only two methods that accurately estimate peripheral resistance to insulin.

Insulin Tolerance Test

The ITT also has been used to assess insulin resistance[69] and has shown a good correlation with both the FSIGT and the clamps.[70] After an overnight fast, regular insulin (0.1 U/kg) is infused intravenously over 1 minute. Blood glucose is measured at 0, 2, 5, 8, 10, and 15 minutes after insulin administration. Hypoglycemia generally occurs after 15 minutes, and therefore a solution of dextrose 50% in water ($D_{50}W$) is injected at 15 minutes to block this reaction. Because the test is so rapid (15 minutes), the usual counter regulatory factors (growth hormone, cortisol, catecholamine release) that can affect insulin sensitivity are not yet in play. The linear slope of the declining blood glucose concentrations (between 2 and 15 minutes after insulin administration) is calculated and expressed as KITT % per minute. Young healthy women have KITT values between 5 and 6, while patients with PCOS generally have values lower than 4 (Fig. 34.12). Although the ADA considers the ITT to be less sensitive than the FSIGT test, several researchers have reported that it gives comparable results. We have used this test widely because it requires only six blood samples for blood glucose determinations—thus reducing time and cost, particularly for repeated testing in clinical research (Fig. 34.13).

Oral Glucose Tolerance Test

The OGTT is generally used to evaluate glucose tolerance, but may also be used to obtain an estimate of insulin resistance. The test is generally performed giving orally 75 g of glucose, after an overnight fast. Blood samples are taken before the glucose administration and each 30 minutes for 2 to 3 hours. For evaluating glucose tolerance, a blood glucose measurement 120' after glucose administration is sufficient with values >140 mg/dL indicating IGT and values >200 mg/dL indicating type 2 diabetes. For assessing insulin resistance, serum insulin should also be measured and blood samples at 30', 60' and 120' are needed. At least nine indices have been proposed to measure insulin sensitivity by OGTT but only few show a sufficient correlation with the clamps. The Matsuda index (fasting glucose × fasting insulin) × (mean glucose × mean insulin during OGTT) and the log sum insulin give the best estimate of insulin sensitivity.[71]

Dynamic tests for hormone evaluation. In Lobo RA, Mishell DR, Paulson Rj, Shoupe D [eds].* Mishell's Textbook of Infertility, Contraception, and Reproductive Endocrinology, *4th ed. Oxford, Blackwell Science, 1997.)*

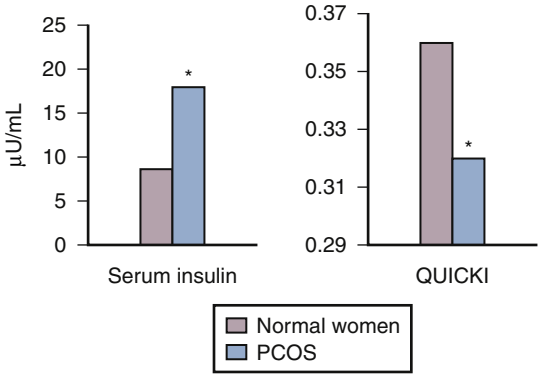

FIGURE 34.13 Serum insulin levels and quantitative insulin sensitivity check index (QUICKI) values in normal women and women with polycystic ovaries. QUICKI values less than 0.33 are suggestive of insulin resistance. PCOS, polycystic ovary syndrome. *(Data from Carmina E, Longo RA, Rini GB, Lobo RA. Phenotypic variation in hyperandrogenic women influences the finding of abnormal metabolic and cardiovascular risk parameters.* J Clin Endocrinol Metab *90:2545–2549, 2005.)*

Fasting Glucose and Insulin Calculations

These methods are based on mathematical calculations applied on simultaneously obtained fasting glucose and insulin values. The most frequently used methods are:

- Glucose-to-insulin ratio[72]
- Homeostasis model assessment of insulin resistance (HOMA-IR)[73] = (glucose × insulin) ÷ 22.5
- Quantitative insulin sensitivity check index (QUICKI)[74] = 1 ÷ (log glucose + log insulin)

As already stated, these methods are easy to perform and useful in a clinical setting but present several limitations. In general, methods using logarithmic transformation should be preferred because the relationships between the insulin and the glucose level are hyperbolic rather than linear. We generally prefer to use the QUICKI method because it is easy to perform and correlates reasonably well with the euglycemic clamp. Values lower than 0.335 suggest insulin resistance and may be found in most women with PCOS (Fig. 34.13).[62]

Measurement of Adipose Tissue Hormones

Adipose tissue is a complex endocrine organ that secretes hormones, cytokines, free fatty acids and various proteins that have profound effects on metabolism and the cardiovascular system.[75] In recent years, many of these factors have been characterized and measured in various endocrine disorders, including PCOS.[76] While most assays are useful only for research purposes, the measurement of two adipose hormones, leptin and adiponectin, also may be useful in clinical practice.

Leptin is a 146 amino acid protein which acts mostly as a signaling factor from adipose tissue to the central nervous system to serve as a metabolical indicator of energy sufficiency.[77] It may be measured by RIA or ELISA and in our laboratory, in adult women with normal body weight, leptin values are between 10 and 30 pg/mL. Serum levels of leptin increase in obese subjects, probably because in obesity there is a condition of leptin resistance. However, some massively obese subjects have a genetically determined leptin deficiency and the finding of low leptin in severe obesity suggested the possibility of using leptin in the treatment of these subjects. In PCOS, the levels of leptin are strictly related to body weight, and are not different when compared to weight matched normal women. Finally leptin levels are lower in children than in adults and increase progressively during puberty.

Adiponectin is a large protein comprised of 244 amino acids which has a major role in preventing or counteracting the development of diet-induced insulin resistance.[78] Moreover, adiponectin has been reported to have an important function in protecting endothelial cells from injury.[79] Adiponectin may be measured by RIA or ELISA and in our laboratory, in adult women with normal body weight, adiponectin values are between 8 and 18 μg/mL. Adiponectin is decreased in metabolically active obesity, probably because of the increased cytokine production in visceral and ectopic adipose tissue,[80] and this reduction has an important role in determining the effects of obesity on insulin resistance, endothelial disease, and cardiovascular risks.[81]

In PCOS, adiponectin is lower than that in weight matched controls, and serum levels less than 8 μg/mL may suggest the particular risk for developing early endothelial disease.[82]

Evaluation of Fat Quantity and Distribution

Because excess fat and/or altered fat distribution represent very important factors in determining insulin resistance and metabolical and cardiovascular risk,[83] many methods have been developed to assess these parameters.

The most simple way to assess fat quantity is to calculate the body mass index (BMI) by the formula: body weight (kg)/height^2 (cm). Values of 30 or higher indicate obesity with values over 40 indicating severe obesity. Values between ≥25 and less than 30 suggest an overweight status while values between 19 and less than 25 indicate normal body mass. However, BMI does not take in account differences in lean and bone mass and in particular patients it may be useful to measure fat quantity directly by total body dual x-ray absorptiometry (DEXA).[84,85] This method permits the measurement of fat quantity in the total body and in several different areas. Particularly important is the measurement of fat quantity in the trunk because this represents a way to assess abdominal fat mass. An increase in abdominal fat, mainly visceral fat, has been suggested to be the main cause of cardiovascular and metabolical risks of obesity.

Because of the role of abdominal fat, it has been suggested that the measurement of waist circumference is more important than the evaluation of body weight in assessing the health problems linked to obesity. In women, values ≥88 cm indicate excessive abdominal fat accumulation and increased metabolical and cardiovascular risks. However, in young women, a normal waist circumference is less than 80 cm and values greater than 80 and less than 88 cm may indicate some abdominal fat increase.

To assess abdominal fat more accurately, other methods may be useful. Abdominal CT or MRI are very sensitive tests but cannot be used routinely in clinical practice for this purpose, and, therefore, abdominal ultrasound or DEXA are generally the preferred methods. Ultrasound is a simple method to assess abdominal fat but is very skills dependent. With this method, omental thickness in centimeters is assessed by using the distance between the posterior surface of the aponeurosis of the rectus abdominal muscle and the anterior wall of the aorta, 5 cm above the umbilicus.

DEXA scans are simple and sensitive but the software used generally measures fat in the trunk that includes the thorax. The sensitivity of this method may therefore be enhanced by measuring abdominal fat in an area of 50 cm^2 around the central point of the midline between the lateral iliac crests and the lowest rib margins at the end of a normal expiration.[125] This point generally corresponds to the umbilicus (but may not) and is located in the midline. Other authors have preferred to measure fat quantity between L1 and L4. Because DEXA measures total body fat and trunk (or central abdominal) fat, it is possible to calculate with the same examination, the percentage of abdominal fat.

We have recently determined normal values and the upper limits (Table 34.1) of fat parameters (by DEXA) in young normal weight women. In general, vales ≥40% of trunk fat indicate the presence of abdominal obesity.[85]

Depending on the population studied, 30% to 60% of women with PCOS may be considered obese and most of them will have abdominal obesity. However, 60% of overweight women with PCOS and 30% of normal weight women with PCOS will exhibit an increase in abdominal fat.

Table 34.1 Evaluation of Abdominal Fat by Dual X-Ray Absorptiometry (DEXA)*

	Mean	Upper Normal Limits	
Trunk fat (g)	5200	8000	High values indicate abdominal fat accumulation
Trunk fat (%)	31.4	38	High values indicate abnormal fat distribution (abdominal obesity)
Central abdominal fat (g)	300	520	High values indicate abdominal fat accumulation. More sensitive index than trunk fat

*Modified from Reference 125.

Metabolical Syndrome

In recent years, the term metabolical syndrome has become popular to denote a condition of increased risk for atherosclerosis and cardiovascular risk. This is based primarily on the findings of insulin resistance and/or abdominal obesity.[86] According to National Cholesterol Education Program Adult treatment guidelines,[87] the syndrome is present if an individual has altered values of at least three of five parameters (blood glucose, blood triglycerides, blood HDL-cholesterol, waist circumference, and blood pressure). The concept of metabolical syndrome has been debated because the health risk may merely be the sum of the single risks. However, the diagnosis of metabolical syndrome may be useful in that it helps to identify subjects who have a particularly high metabolical and CV risk. In PCOS, metabolical syndrome is very common and its prevalence ranges between 10% and 50% depending on body weight and the lifestyle variables of the different populations.[88,89]

Measurement of Growth Hormone and Growth Factors

Circulating growth hormone (GH) may be measured by conventional RIA or immunoradiometric assays. With any method, because of very low basal values and pulsatile secretion, measurement of an unstimulated random GH is usually not very meaningful.[90] Overnight urinary GH may be useful,[91] but the urinary concentrations of GH are also very low and may not be detectable in some assays. There is also a high degree of variability in GH renal excretion.

Insulin-like growth factor 1 (IGF-1) is measured by specific immunoassays and, because these values reflect the integrated 24-hour concentrations of serum GH, IGF-1 may be used for screening of GH-deficiency.[92] However, circulating IGF-1 levels are low in prepubertal children, making differentiation between healthy and GH-deficient children difficult and also in adults IGF-1 determination has a low accuracy for diagnosis of GH deficiency.[93] Moreover, several conditions result in low IGF-1 concentrations—including malnutrition, hypothyroidism, renal failure, and diabetes mellitus—and therefore the confirmation of the diagnosis requires at least two GH provocative tests.

Serum IGF-1 is more useful in the screening evaluation of GH hypersecretion.[94] Persistently elevated serum IGF-1 can identify acromegaly better than several random GH serum measurements and overnight urinary GH tests; however, some acromegalic patients may have normal IGF-1 levels, requiring other investigations to be done if acromegaly is suspected. IGF-1 assessment is particularly useful in evaluating the effects of treatment in acromegalic subjects: finding increased levels of IGF-1 indicates that the disease is not well controlled. Finally, because IGF-1 is low in malnutrition, this assay also may be useful in assessing the general nutritional status of patients.

Insulin-like growth factor 2 (IGF-II) may be evaluated by specific IRMAs, but this level is less dependent on growth hormone secretion. The measurement of IGF-II is useful only in islet-cell tumor hypoglycemia (NICTH), an uncommon syndrome caused by some tumors (generally mesenchimal tumors) and associated with low levels of insulin, IGF-I, and IGF-BP3.[95]

There are six IGF-binding proteins. Among these, circulating IGFBP-1, IGF-BP2, and IGFBP-3 have been the subject of evaluation for clinical purposes. IGFBP-3 is GH-dependent and reflects changes in GH levels. Its long half-life and nonpulsatile secretion make IGFBP-3 measurements an alternative to IGF-1 measurement for the screening of perturbations in GH.[95a]

Levels of serum IGFBP-1 are significantly influenced by hyperinsulinemia, with low levels being found in insulin resistance; in PCOS, where IGF-1 levels are found to be normal, "free" IGF-1 is increased because of a reduced level of IGFBP-1.[96] Serum IGFBP-1 may be measured in diabetes to evaluate whether hyperglycemia is due to inadequate insulin dosage or to other factors.

Serum IGFBP-2 correlates inversely with growth hormone secretion and the ratio IGFBP-2 to IGFBP-3 is a marker of growth hormone action. Serum IGFBP-2 also increases in patients with some tumors (mostly gliomas and prostate cancers) and may be used to assess the growth of these tumours and in conjunction with PSA in the management of certain patients with prostatic carcinoma.[97]

Dynamic Tests for Evaluation of Growth Hormone Secretion

Many provocative or inhibitory tests to diagnose GH-deficiency or excess have been described.[98] Reduced responses to at least two provocative tests are diagnostic of GH deficiency. Although differences exist in expert recommendations and guidelines, using new GH assays, the cut-off for a normal peak GH level in response to provocative tests is generally 7 ng/mL.[99]

Insulin Tolerance Test

This test is the preferred first choice for the diagnosis of GH deficiency. Blood samples are taken at 0, 15, 30, 60, and 90 minutes and glucose and GH are measured. The measurement of glucose is required for validation of hypoglycemia (less than 40 mg/dL), which is necessary to evoke a GH response.

Clonidine Stimulation Test

Clonidine, a well-known antihypertensive drug, may be used for the diagnosis of GH deficiency. Oral clonidine (0.15 mg/m^2) is administered after an overnight fast. Blood

pressure must be monitored during the test because a modest decrease in blood pressure is often observed.

Growth Hormone Releasing Hormone *(GHRH)* and Arginine Test

This test is considered to be an alternative to the ITT for the diagnosis of adult growth hormone deficiency (AGHD) in patients for whom insulin hypoglycemia is contraindicated.[100] GHRH (1 μg/kg) and arginine (0.5 g/kg to a maximum of 30 g in 30 minutes) are combined in the same stimulation test.

Oral Glucose Tolerance Test

The OGTT is the primary test used for the diagnosis of GH hypersecretion. After an overnight fast, 75 to 100 g of oral glucose will cause a suppression of serum GH. Blood samples are taken every 30 minutes for 2 hours. With usual polyclonal RIAs, a GH decrease to below 2 ng/mL is found in normal subjects while 80% of acromegalic subjects will not suppress to this level. The monoclonal assays are much more sensitive for testing, and failure of GH to suppress to below 1 ng/mL is diagnostic of acromegaly.[101]

Measurement of Calcium-Regulating Hormones and Bone Markers

In humans, the main calcium-regulating hormones are parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D. The measurement of PTH is complicated by the complex metabolism of this hormone, which results in a multiplicity of circulating molecular forms with different bioactivities as well as the presence in blood of PTH fragments. The bioactive forms (intact PTH molecule and the amino-terminal fragment) circulate in small quantities because of their shorter half-lives. Therefore, immunoassays using antibodies that recognize the mid or carboxylterminal regions of PTH may be useful in subjects with primary hyperparathyroidism because they provide an index of integrated secretory function of the parathyroid gland. On the contrary, assays that use antibodies against the intact molecule or amino-terminal fragment should be preferred in studies of patients with renal failure, or when studying physiological changes of PTH function.

An important advance has been the development of two site IRMAs for intact PTH. This assay uses antibodies directed against the amino-terminal and mid-region (or carboxyl-terminal) fragments.[102] Because intact PTH is labile at room temperature, specimens should be frozen within 2 to 4 hours of collection. Normal PTH values range from 10 to 65 pg/mL but have to be correlated with circulating calcium levels. The finding of increased serum PTH and calcium is diagnostic of hyperparathyroidism, although some patients may have normocalcemic hyperparathyroidism that results in a form of osteoporosis that is often clinically indistinguishable from postmenopausal osteoporosis. This condition has to be differentiated from the more common mild deficiency of vitamin D, where PTH levels are moderately increased but calcium blood values are normal. In these patients, the administration of vitamin D normalizes serum PTH values.

The clinical assay techniques for circulating monohydroxylated (25-OH) and dihydroxylated (1,25-OH) D-vitamin have progressed from competitive protein binding assay to radioimmunoassay (RIAs) that utilize both ^{125}I and chemiluminescent reporters. These methods are used in the screening of osteoporotic women for underlying vitamin D deficiency.[103] It has been suggested that a large percentage of the female population, particularly in the northern hemisphere, is vitamin D deficient but disagreement exists on 25-OH-D values indicating vitamin D deficiency. The Institute of Medicine has suggested that serum 25-hydroxyvitamin D values lower than 20 ng/mL suggest vitamin D deficiency while guidelines of the Endocrine Society have indicated that all 25-OH-D values lower than 30 ng/mL are to be considered low.[104] This disagreement may depend on different perspectives on vitamin D function with IOM experts focusing on the role of vitamin D in bone metabolism[105] and the Endocrine Society experts also considering extra bone activities of vitamin D.

Determination of Vitamin D Status

The principal circulating form of vitamin D is 25-hydroxyvitamin D [25(OH)D], and is overall the best indicator of vitamin D status. There are two forms of 25(OH)D, namely $25(OH)D_2$ and $25(OH)D_3$. The predominant form is 25(OH)D, which is derived mainly from actions of ultraviolet light on the skin, whereas $25(OH)D_2$ is derived solely from dietary and pharmaceutical sources. Since the two parent compounds provide various contributions to the overall vitamin D status of an individual, it is essential that both the D_2 and D_3 forms of 25(OH)D be recognized equally by the testing system used in treatment monitoring. Failure of the testing system to detect the D_2 form may lead the clinician to the erroneous conclusion that additional supplementation is required, which could possibly result in hypervitaminosis D and hypercalcemia.

Two assays that have been widely used to measure 25(OH)D include a manual RIA and an automated LIAISON® chemiluminescent immunoassay (DiaSorin, Stillwater, Minnesota). Both assays utilize an antibody-based detection system with 100% recognition of both the D_2 and D_3 forms. However, in the last few years the state of the art assay method utilizes LC-MS and MS. This assay measures both forms of 25(OH)D with high accuracy and precision, as well as high throughput. In comparisons with LC-MS and MS as the gold standard, several automated assays in clinical use were variable in terms of performance. However, the LIASON system performed well.[106]

Several biochemical markers of bone turnover are measurable and may be useful in assessing bone formation and resorption (Box 34.1).[107] Improved immunoassays have increased their role in studying bone metabolism and clinical consequences of osteoporosis. The most sensitive and specific markers of bone formation include serum bone alkaline phosphatase, total osteocalcin, and the procollagen type I N-terminal propeptide assay. Among the various markers of bone resorption, serum C-terminal cross-linked telopeptides are the most sensitive and specific. Markers of bone turnover can be used to predict the rate of bone loss in post-menopausal women and can also be used to assess the risk of fractures. In osteoporosis-treatment studies, markers of bone turnover appear even more strongly associated with fracture risk reduction than bone mineral density (BMD).[108]

Box 34.1 Markers of Bone Turnover

FORMATION (SERUM)
- Bone alkaline phosphatase
- Osteocalcin
- Propeptides of type I collagen:
  - Carboxyterminal (PICP)
  - Aminoterminal (PINP)

RESORPTION (SERUM)
- Telopeptides of collagen cross-links:
  - Carboxytelopeptides (CTX)
  - Aminotelopeptides (NTX)
  - Tartrate resistant acid phosphatase (TRAP)

RESORPTION (URINE)
- Pyridinolines cross-links (PyD)
- Deoxypiridinolines cross-links (DpD)
- CTX
- NTX
- Hydroxyproline

Methods for Measurement of Bone Density

Measurement of bone density is essential for the diagnosis of osteopenia and osteoporosis. While many methods have been widely used, including ultrasound evaluation of the calcaneus, a precise determination of bone density requires DEXA. The lumbar spine, the hip, and the femoral/neck are the most important regions to be evaluated. The data are expressed as a T-score, which provides the number of standard deviations below the mean peak bone density of a normal adult. Values between −1.0 and −2.5 are indicative of osteopenia, and values less than −2.5 indicate osteoporosis. DEXA of peripheral bones (e.g., forearm) is possible and is sometimes used as an additional assessment, particularly in metabolical disease. Osteoarthritis and other degenerative bone diseases may result in artificially higher T scores, therefore this condition can be suspected when there is a discrepancy in T scores between different lumbar vertebrate in the spine.

Measurement and Blood Levels of Thyroid Hormones

Circulating TSH is measured by two-site non-competitive immunometric assays (IMAs) utilizing enzymes, luminescent compounds, or ^{125}I as labels.[109] These assays have completely replaced the original RIAs because of the need for greater sensitivity to distinguish the low levels in hyperthyroid individuals from suppressed levels carrying some other significance.

Normal serum TSH ranges between 0.5 and 4.0 μU/mL. Values between 0.1 and 0.45 and 4.5 and 10 μU/mL, although abnormal are usually associated with normal levels of thyroid hormones.[110] On the basis of population based large surveys, a much narrower range of TSH levels, between 0.3 and 2.5 μU/mL has been suggested.[111] These observations have been confirmed by longitudinal studies that have shown a low risk of developing hypothyroidism (defined as TSH greater than 4 μU/mL) in subjects with a baseline TSH of 2.5 or less followed for 13 years but a significant risk in subjects presenting with TSH levels between 2.5 and 4 μU/mL (mostly if antithyroid antibodies are also present).[111] However, because increased morbidity is not present in patients with these mild TSH elevations and TSH determinations are subject to modulations due to endogenous and exogenous factors including substantial variations due to the laboratory methods, there is a general agreement that therapeutic intervention should not be considered when TSH levels are below 4 μU/mL. In such patients, only careful follow up is needed. Nevertheless, there remains some controversy about treating women with infertility who have values above 2.5 μU/mL. While this has not been definitively settled, there are some data suggesting that treatment outcomes in infertility are not different with values less than 2.5 and greater than 2.5 μU/mL.

During pregnancy, it is particularly important to maintain serum levels of TSH in the strict normal range (less than 2.5 μU/mL) because subclinical maternal hypothyroidism is associated with complications of pregnancy and adverse effects on the fetus.[112-113] The upper range in pregnancy is 2.5 μU/mL, in part because of some TSH activity afforded by hCG, particularly in the first trimester. In these women, l-thyroxine at low doses is started immediately at the beginning of pregnancy and serum TSH is monitored each month, increasing the treatment if TSH levels increase. For a more complete evaluation of thyroid function the measurement of thyroid hormones is necessary. Circulating total thyroxine (T_4) and triiodothyronine (T_3) and their free fractions may be measured. Many laboratories prefer to measure only total T_4, but in some conditions (such as pregnancy), free thyroid hormones have to be evaluated. Any condition that increases circulating thyroxine-binding globulin (TBG)—as occurs in pregnancy and with estrogen treatment—also increases total thyroid hormone. During pregnancy, TBG increases approximately 2.5 times, with peak levels at 15 to 20 weeks' gestation and normal T_4 levels are higher than 7.8 μg/dL. Free thyroid hormones remain in the normal range; the only exception being late in the first trimester, when a transient increase may occur.

The most precise determination of free T_4 is obtained by equilibrium dialysis, while some commercial RIA kits—which use a T_4 analogue—may give inaccurate results.[114]

Because the most common causes of thyroid disorders are autoimmune disorders, assay of thyroid autoantibodies is often useful.[115] Several autoantibodies may be measured but the most used in clinical practice are the measurements of thyroid peroxidase antibody (TPO) and thyroid stimulating immunoglobulins (TRab or TSI). TPO are useful for diagnosing autoimmune chronic thyroiditis but may be increased also in Graves disease. With improved immunoassays and high sensitivity, the TRab assay has become a hallmark in the diagnosis of Graves disease.[116] During pregnancy, the TRab assay also may be useful to predict neonatal Graves disease.

Thyrotropin-Releasing Hormone (TRH) Stimulation Test

With the improvement and sensitivity of TSH assays, the TRH stimulation test is not required in the evaluation of primary hypothyroidism or hyperthyroidism with low TSH levels. The test is still useful in the evaluation of central hypothyroidism, in rare patients with TSH-dependent hyperthyroidism, and in patients with pituitary tumors.

After an overnight fast, a 200-μg dose of TRH is administered intravenously. Blood samples for TSH are then taken

at 0, 30, and 60 minutes. The mean peak TSH response is a value 8 to 9.5 times the basal values; however, the range in euthyroid subjects is large (3 to 23 times baseline).

Evaluation of Glucocorticoids and Adrenal Function

Cortisol, the main glucocorticoid produced by the adrenal, is conveniently measured by immunoassay. Several corticosteroids, including prednisone, prednisolone, and cortisone, cross-react in the assay.[117] Because cortisol secretion is highly pulsatile and exhibits circadian variations, with the highest values occurring in the morning and the lowest levels in the late evening, a single random serum cortisol determination is not diagnostic for adrenal disorders.

Plasma ACTH is measured by immunoradiometric assays. Plasma ACTH levels over 100 pg/mL in the presence of low serum cortisol are suggestive of primary adrenal insufficiency (Addison syndrome).[118] In patients with Cushing syndrome, a plasma ACTH level above 20 pg/mL at 9 AM is highly indicative of ACTH-dependent Cushing syndrome. A level below 10 pg/mL suggests ACTH-independence and primary adrenal pathology.[119] However, in many individuals, the evaluation of blood ACTH and cortisol are not sufficient to diagnose adrenal disorders; therefore specific diagnostic procedures have to be performed.

Diagnosis of Pathological Hypercortisolism (Cushing Syndrome)

Cushing syndrome results from prolonged and inappropriately high exposure of tissues to glucocorticoids. The clinical features are variable and include abnormal fat distribution, proximal muscle weakness, wide purple striae, and decreased linear growth with continued weight gain in a child. Clinical presentation of the disorder may be florid and in this case the diagnosis is usually straightforward. However, the diagnosis is often difficult particularly in states of mild or cyclical or periodical hypercortisolism (Fig. 34.14).

Several tests have been used for diagnosing Cushing syndrome, but none has proven fully capable of distinguishing all affected patients from normal and/or pseudo-Cushing individuals. Three first-line diagnostic tests are currently used to screen for Cushing syndrome:[120-121] measurement of free cortisol in 24-hour urine (UFC), cortisol suppression by low doses of dexamethasone, and assessment of cortisol circadian rhythm using late-night serum and/or salivary cortisol. While in the past, urinary free cortisol assessment has been the screening test of choice, late-night salivary cortisol is actually preferred.

If the diagnosis is confirmed, the search for the responsible tumor then relies on the assessment of corticotroph function, and imaging studies[122]: suppressed ACTH plasma levels indicate an 'adrenal' source of the hypercortisolism while the distinction between unilateral adrenal tumour, primary pigmented nodular adrenal dysplasia associated with Carney complex, and ACTH-independent macronodular adrenocortical hyperplasia will require a careful imaging study by CT.

Measurable or increased ACTH plasma levels indicate either Cushing's disease (pituitary adenoma) or the ectopic ACTH syndrome and requires further dynamic tests (high-dose dexamethasone suppression test and/or the CRH test). When the results of these tests are equivocal, and/or the imaging is nondiagnostic, it may be difficult to distinguish between the two. This is the situation where sampling ACTH plasma levels in the inferior petrosal sinus may be necessary.

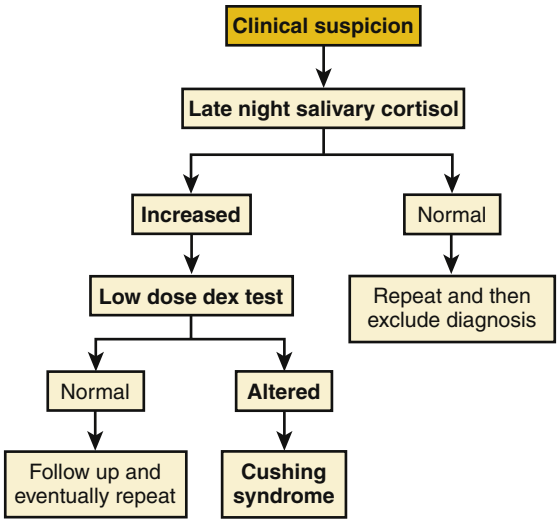

FIGURE 34.14 Diagnostic algorithm for Cushing syndrome

In general for the clinician the main problem is to distinguish patients with pathological hypercortisolism from normal subjects. Therefore, we will describe shortly only the screening tests. Because the complexity of the complete diagnosis, if pathological hypercortisolism has been demonstrated, the patient should be evaluated by a specialized endocrinological center.

Late Night Salivary Cortisol Measurement

Loss of circadian rhythmicity is the most sensitive indicator of pathological hypercortisolism. Ideally, midnight sleeping cortisol should be a very sensitive indicator of Cushing syndrome but it is impractical for screening purposes. Assessment of late-night salivary cortisol is being increasingly considered as the simplest and more convenient outpatient procedure. This method is also useful for the diagnosis of early or mild Cushing syndrome.[123]

Saliva samples are collected at LATE-NIGHT (11 PM) in a commercially available device and assayed for CORTISOL by radioimmunoassay. The cut-off level of 1.5 μg/mL shows high sensitivity and specificity in both subclinical and overt Cushing syndrome.

Urinary Free Cortisol

Twenty-four-hour urinary free cortisol provides an index of cortisol secretion during the day. While the upper normal range of urinary cortisol should be 50 to 60 μg/day, some commercial assays report normal ranges as high as 100 to 130 μg/day. Urinary free cortisol may be measured by high-performance liquid chromatography combined with RIA or a competitive binding assay. In general, 3 to 4 completely normal 24 hours collections exclude the diagnosis, while a value more than 4 times the upper limit of the normal suggests the finding of Cushing syndrome. Usually urinary creatinine is also measured to account for the completeness of the urinary collection.

The methodological difficulties in 24-hour urine collection and in assay precision have rendered this screening technique increasingly unpopular.[124,125] Furthermore, the increased prevalence of mild, preclinical, or cyclic Cushing syndrome along with the fact that cortisol is not uniformly secreted during the day do not support its use as a screening test, although strikingly high levels can be useful.

Low Dose Dexamethasone Suppression Test

As a simple screening test for hypercortisolism, overnight dexamethasone suppression has been largely used. Dexamethasone (1 mg) is given at 11 PM and serum cortisol is measured the morning after. Serum cortisol below 5 μg/dL generally indicates a normal response, but one out of five of patients with Cushing syndrome have been shown to suppress serum cortisol to these levels after overnight dexamethasone. Although lower cut-offs have been suggested, the specificity of the test remains low and is therefore not helpful for screening purposes.

The classic low-dose dexamethasone suppression test has greater diagnostic accuracy and may be used in screening of Cushing syndrome, often together with late night salivary cortisol measurement. The test is performed reliably even in outpatients and involves the administration of dexamethasone, 0.5 mg every 6 hours for 2 days, then collection of blood for cortisol measurement on the morning of the third day. Serum cortisol levels greater than 1.8 μg/dL is a sensitive indicator of Cushing syndrome. Some drugs that increase hepatic clearance of dexamethasone, such as carbamazepine, phenytoin, nifedipine, rifampicin, and phenobarbital may interfere with the dexamethasone tests and should be stopped prior to investigation. Estrogens may give falsely elevated cortisol levels (increasing CBG) and should be stopped at least 6 weeks before testing.

Tests for Adrenal Insufficiency

ACTH Test

Stimulation with ACTH (250 μg), administered intravenously with measurements of cortisol at 0, 30, and 60 minutes, is an excellent test for primary adrenocortical insufficiency. Serum cortisol levels lower than 13 μg/dL after ACTH ensure the diagnosis of adrenal glucocorticoid insufficiency. Levels between 13 and 18 μg/dL are intermediate and require additional diagnostic evaluation. Serum cortisol levels higher than 18 μg/dL after ACTH stimulation excludes the diagnosis. Low-dose ACTH (1 μg intravenously) may also be used, and researchers have suggested that this protocol uncovers milder forms of adrenal insufficiency that are not diagnosed with the classic ACTH stimulation test.

Tests for Secondary Adrenal Insufficiency

Insulin Tolerance Test

After an overnight fast, regular insulin (0.1 U/kg) is infused intravenously over 1 minute. Blood glucose and cortisol are measured at 0, 15, 30, 45, 60, 75, and 90 minutes. Once hypoglycemia (blood glucose of less than 40 mg/dL) has to be documented, serum cortisol levels over 18 g/dL excludes adrenal insufficiency. The test is contraindicated in elderly patients and in patients with cardiovascular, psychiatric, or seizure disorders.

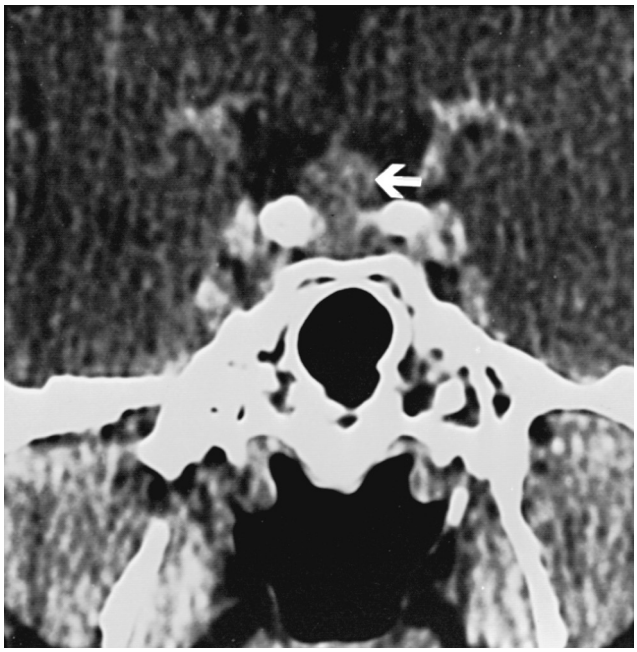

FIGURE 34.15 Typical close-up coronal view of a pituitary microadenoma by computed tomography (CT). The neoplasm cannot be distinguished from normal pituitary. Thus, the arrow indicates an enlarged abnormal pituitary bulging superiorly. The stalk is seen superior to the gland in the midline. The bone appears white on CT scan. Magnetic resonance imaging may allow better resolution of neoplasms from normal pituitary. *(Adapted from Rebar RW. Practical evaluation of hormonal status. In Yen SC, Jaffe RB, Barbieri RL [eds].* Reproductive Endocrinology, Physiology, Pathophysiology, and Clinical Management, *4th ed. Philadelphia, WB Saunders, 1999, p 709.)*

Metyrapone Test

Metyrapone, which blocks 11β-hydroxylation, is used to test the adrenal response to endogenous ACTH. This agent further reduces serum cortisol, however, and may induce adrenal insufficiency. For this reason, many endocrinologists prefer to perform an ITT test. Metyrapone is generally used when an ITT test is contraindicated. Metyrapone, 30 mg/kg, is given orally at midnight with a snack; a blood sample for cortisol and 11-deoxycortisol are obtained at 8 AM the following morning. After the blood sample, a prophylactic dose of prednisone or hydrocortisone is usually given. To be valid, cortisol has to decrease to less than 5 μg/dL. Peak values of 11-deoxycortisol below 7 μg/dL suggest reduced activity of the pituitary adrenal axis.

Diagnostic Procedure in Suspected Pituitary Tumors

Patients with pituitary tumors seek evaluation because of the symptoms (e.g., headache, diabetes insipidus, visual field alterations) or because of the finding of increased hormone secretion (e.g., acromegaly Cushing syndrome, amenorrhea with or without galactorrhea). Once a pituitary lesion is suspected, radiographical investigation is required.

Magnetic resonance imaging (MRI) with gadolinium enhancement is the preferred technique to evaluate hypothalamic—pituitary lesions; however, CT scanning with intravenous contrast and thin coronal sections may also be used. Examples of MRI and CT techniques may be found in Figures 34.15 and 34.16. Table 34.2 lists the major MRI

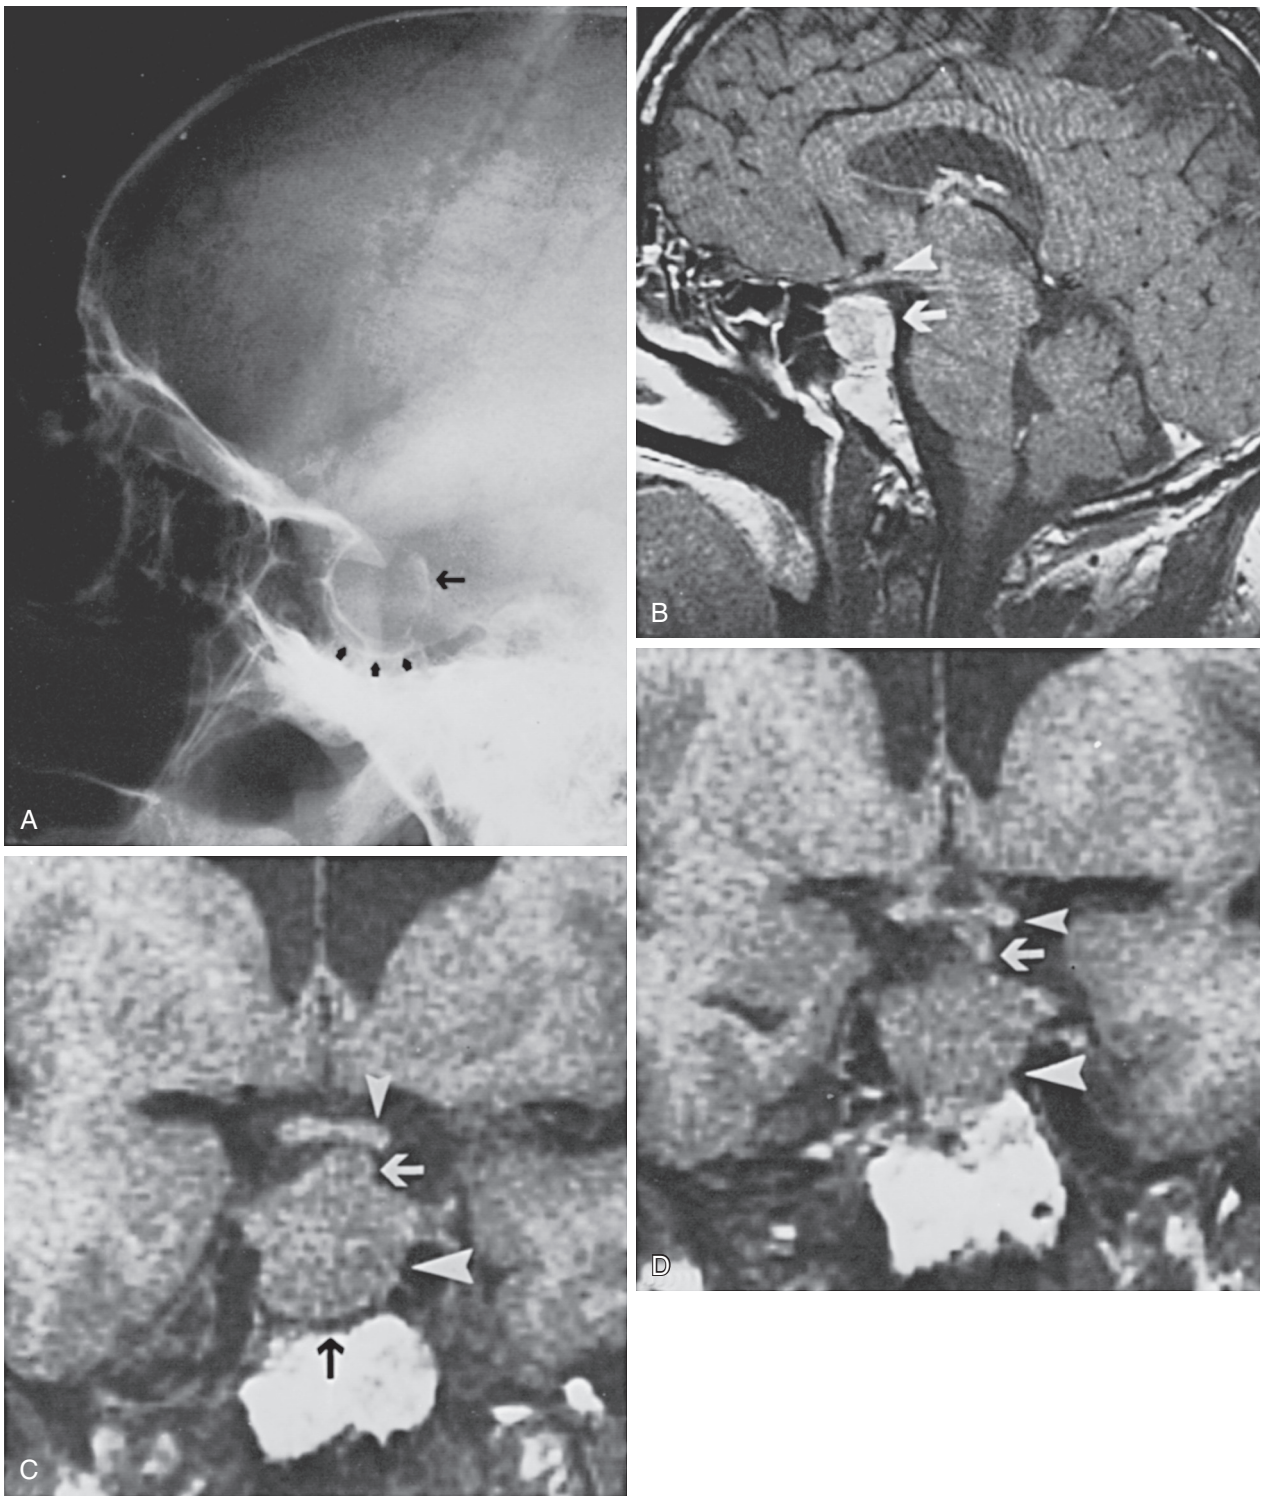

FIGURE 34.16 Selected views in a 39-year-old woman with a probable nonsecreting neoplasm who has amenorrhea, galactorrhea, and prolactin levels of approximately 50 ng/mL. The radiographs suggest that the mild hyperprolactinemia is due to stalk compression. **A,** Lateral skull film showing ballooning of the sella turcica with a thin double floor *(small arrows)* and erosion of the clinoid processes posteriorly *(large arrow)*. **B,** Sagittal view of magnetic resonance imaging with contrast material showing the large pituitary tumor *(arrow)* and normally positioned optic chiasm *(arrowhead)*. **C,** Coronal view showing the large neoplasm *(large arrowhead)* bulging superiorly *(white arrow)* toward the optic chiasm *(small arrowhead)*. The *black arrow* shows the diaphragm sella. **D,** Another view of the neoplasm shows displacement of the optic chiasm *(arrow)* below the optic nerves and chiasm *(small arrowhead)*. The *large arrowhead* indicates the lesion. The diaphragm is indistinct and there is the suggestion of bony erosion. *(Adapted from Rebar RW. Practical evaluation of hormonal status. In Yen SC, Jaffe RB, Barbieri RL [eds].* Reproductive Endocrinology, Physiology, Pathophysiology, and Clinical Management, *4th ed. Philadelphia: WB Saunders, 1999, p 709.)*

Table 34.2 Magnetic Resonance Imaging Characteristics of Some Hypothalamic-Pituitary Lesions

Type of Mass	*MRI Images*	*MRI with Contrast Images*	*Particular Features*
Pituitary adenoma	Hypointense	Hypointense	Hyperintense with hemorrhage
Pituitary cyst	Hyperintense	No change	Cystic; may be hypointense if CSF is in the cyst
Craniopharyngioma	Hyperintense	No change	Cystic with iso-hypointense solid portions
Meningioma	Isointense	Hyperintense	Hyperostosis of adjacent bone

MRI, magnetic resonance imaging; CSF, cerebrospinal fluid.

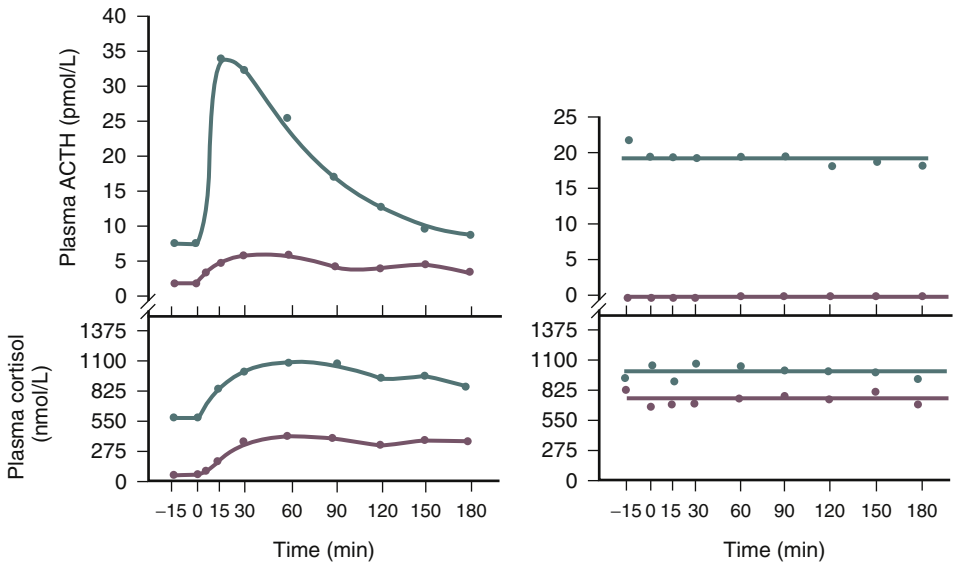

FIGURE 34.17 Adrenocorticotropin hormone (ACTH) response to corticotropin-releasing hormone. Colored lines represent different patients. *(Adapted from Kaye TB, Crapo L. Cushing's syndrome: an update on diagnostic tests.* Ann Intern Med *112:435-444, 1990.)*

characteristics of the more common hypothalamic-pituitary lesions.[126-128] Dynamic pituitary MRI may increase the number of microadenomas that may be visualized.

If hypothalamic or pituitary lesions are found, detailed evaluation of all pituitary hormones should be performed. Regardless of the size of the lesion, patients should initially be evaluated for hormone hypersecretion. Serum PRL, GH with IGF-1, and 24-hour urinary free cortisol could be used for the initial screening. In selected patients, basal and TRH-stimulated gonadotropins and α-subunits should be measured for the evaluation of possible gonadotroph adenomas. Hyperthyroid patients should be screened for rare TSH adenomas. In a large series of 1043 pituitary tumors, the most common pituitary hormone secreting adenomas were prolactinomas (27.2%), followed by GH-secreting adenomas (14%), GH- and PRL-secreting adenomas (8.4%), and ACTH-secreting adenomas (8%).

Some pituitary adenomas produce only α-subunit, a component of glycoprotein pituitary hormones (LH, FSH, TSH). Therefore, in patients with pituitary tumors and no increase of pituitary hormones, the assay of α-subunit may be used. The subunit is measured by an RIA method and in young adults the circulating values are less than 1 ng/mL. Some gonadotropin secreting pituitary tumours produce high quantities of α-subunit and this assay may be useful in postmenopausal women with pituitary adenomas. However, it has to be remembered that normal values of α-subunit are higher in postmenopausal women (less than 3.6 ng/mL) than in young women.

Pituitary microadenomas do not generally cause disruption of pituitary function; therefore, pituitary hypofunction should be assessed only in those patients with large sellar masses that do not have increased secretion. GnRH, TRH, growth hormone-releasing hormone, and CRH tests (all four releasing factors) may be performed together for contemporaneous evaluation of gonadotropins TSH, PRL, GH, and ACTH[129] (Fig. 34.17).

Pelvic Imaging Evaluation

Pelvic ultrasound has become an extremely important tool for the reproductive endocrinologist. Assessment of ovarian function and monitoring for endometrial development are useful for clinical management and have been discussed elsewhere (see Chapters 9, 20, and 21). The finding of polycystic ovaries on ultrasound now have been included as a criterion for the diagnosis of PCOS and therefore a pelvic ultrasound evaluation should be performed in all patients with androgen excess, as well as those with persistently irregular cycles.

The ultrasound diagnosis of polycystic ovaries has shifted somewhat from the classical criteria to the newer Rotterdam criteria where ovarian size, alone, is sufficient for the diagnosis;[130-132] this, too, has been scaled back recently from requiring a size of 10 cc to that of 7.5 cc.[131-134] Figure 34.18 depicts the transvaginal ultrasound appearance of a polycystic ovary with assessment of ovarian blood flow, which is increased in PCOS. If androgen excess is the central issue in the disorder of PCOS, then a more meaningful criterion in the ovarian stromal and total surface area (S/F) ratio.[133] As shown in the Figure 34.19, some authors have suggested that a cut-off value to 0.32 correlate well with the presence of androgen excess (values greater than this being significant).[134]

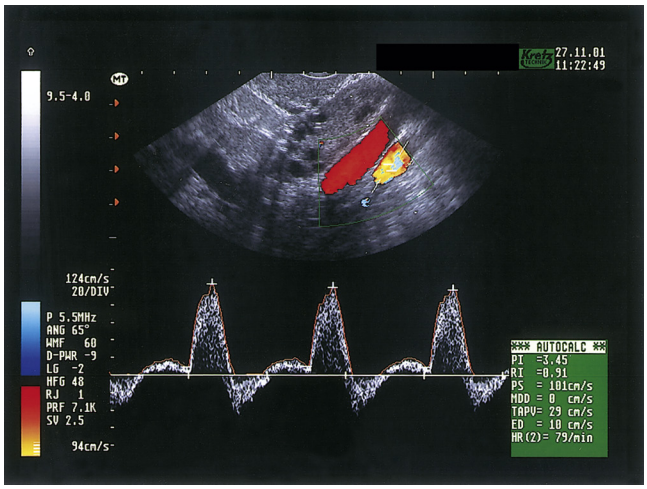

FIGURE 34.18 Typical color Doppler ultrasound of a polycystic ovary showing increased blood flow.

FIGURE 34.19 Example of median ovarian section with outlined ovarian and stroma areas. A1 is the total area and A2 is the stroma area. *(From Fulghesu AM, Angioni S, Frau E, et al. FIGURE 34.20 McGill nomogram for antral follicle count (AFC). *(From Almog B, Shehata F, Shalom-Paz E, et al:* Fertil Steril *95[2] 663-666, 2011).*

Using three-dimensional ultrasound (3-D US), which has also been found to be useful for the diagnosis of PCOS, müllerian anomalies can be detected. While routine two-dimensional ultrasound is not able to distinguish between various müllerian anomalies, 3D US is as sensitive as MRI in this regard. Nevertheless, MRI may still have an advantage over US when differentiating between fibroids and adenomyosis.

More recently, ultrasound evaluation of antral follicle counts has been used as an assessment of ovarian reserve. In this regard, current data suggest that it has equal efficacy to serum AMH, and yet the combination of both does not necessarily improve predictability of ovarian response to stimulation. An effort has been made to standardize the technique because of its more subjective nature. By consensus it has been suggested that it be carried out on days 2 to 4 of the cycle, have well trained personnel using vaginal ultrasound and a 7 MHz transducer.[135] Systematic counting of all follicular structures should be carried out, and then those over 10 mm should be subtracted.[136] Each ovary should be measured in turn. A normal AFC is usually greater than 8, and age specific nomograms have been established (Fig. 34.20).[136]

CHAPTER 35

Pelvic Imaging in Reproductive Endocrinology

Dominique de Ziegler
Isabelle Streuli
Pietro Santulli
Charles Chapron

Vaginal Ultrasound and In Vitro *Fertilization*

The advent of vaginal ultrasound a quarter century ago revolutionized imaging of the pelvic cavity and in particular visualization of the ovaries and uterus. A limiting principal in ultrasound is that lower frequency ultrasound has greater penetration (less attenuation) but lower spatial resolution, while higher frequency ultrasound has lower penetration (greater attenuation) but greater spatial resolution. Vaginal ultrasound takes advantage of the ability to place a probe close to the structures of interest. This permits the use of higher frequency ultrasound and improves the resolution over that possible with lower frequency abdominal ultrasound probes. The original purpose of vaginal ultrasound was not diagnostic imaging, but to simplify oocyte aspiration for *in vitro* fertilization (IVF), which was originally performed by a transvesical route.[1] To facilitate this process, probes were designed for vaginal use and equipped with needle holders to permit transvaginal oocyte aspiration.[2-4] The practical advantages of vaginal ultrasound for guiding oocyte retrieval were obvious and it rapidly became the primary mode of oocyte retrieval.[5]

Improvements in image resolution that resulted from the use of high-frequency probes sparked an instant interest for use of vaginal ultrasound in general gynecology.[6-8] Subsequently, all the technological improvements incorporated into general ultrasound equipment, such as pulsed, color and power Doppler functions,[9,10] and later, three-dimensional (3D) capabilities[11,12] became available on vaginal probes. Ultimately, the increase in image resolution provided by vaginal ultrasound and its multiple refinements allowed for meticulous assessment of parameters that reflect the anatomical characteristics of pelvic organs, but also their functional status.[13] For example, the antral follicular count (AFC) stands at par with hormonal parameters (anti-müllerian hormone [AMH] and/or day-3 follicle stimulating hormone [FSH] and estradiol [E_2] levels) for assessing the functional state of the ovaries or *ovarian reserve*, and vaginal ultrasound is the main tool for monitoring ovarian response and follicular growth in controlled ovarian stimulation (COS).[14]

Vaginal Ultrasound and Pelvic Examination

Beyond improving image resolution and quality, it rapidly became evident that vaginal ultrasound could provide information about functional interactions that exist between pelvic organs and nearby structures. This possibility stems from the fact that a vaginal ultrasound examination, as opposed to abdominal ultrasound, does not require a full bladder preparation. Consequently, it is possible to freely slide pelvic organs against one another, and move them about the pelvic cavity under direct ultrasound vision by gentle pressure applied to the vaginal probe. This approach offers a glimpse of the functional status of the pelvic cavity not available with static images.

- It can precisely determine the limits of pathological structures, such as an ovarian cyst. This is done by determining how the identified structure—the ovarian cyst in our example—moves with respect to other nearby organs when pelvic structures are mobilized by the vaginal probe. At times, the help of pressure exerted by an "abdominal hand" may be necessary in order to mobilize the organ(s) being studied.
- The ability to slide organs also provides clues about the possible presence of pelvic adhesions. For example, the ovary and nearby loops of bowel may move together when mobilized by the probe.
- While pelvic organs are mobilized by pressure exerted either by the vaginal probe and/or with the help of an abdominal hand, the examiner can assess pain that this maneuver may generate. The dynamic vision provided by vaginal ultrasound allows the examiner to pinpoint the cause of the pain and its anatomical location.

This functional dimension provides a true pelvic examination with a view, fusing various forms of information to provide a global assessment of pelvic status.

Technical Refinements of Vaginal Ultrasound: Doppler and 3D Reconstruction

As vaginal ultrasound progressively became a primary diagnostic tool in gynecology, two technical refinements have

come to enrich its capabilities and scope: Doppler-based analyses of organ perfusion and the *off-line* and later *built-in* 3D image reconstruction systems. In the case of 3D image reconstruction from saved 3D volumes, the technical novelty also offers new possibilities for improving the quality control of diagnostic ultrasound through secondary exploration of saved 3D volumes.

Contrast-Enhanced Vision of the Uterus and Tubes

It struck many that the ultrasound images of the uterine cavity obtained in early pregnancy largely surpass in quality those of the nonpregnant uterus. The improved image quality of the pregnant as opposed to nonpregnant uterus was attributed to the presence of amniotic fluid, playing the role of a contrast enhancer that facilitates embryo visualization. Being sono-transparent like water, amniotic fluid creates a *black* interphase between the walls of the gestational sac and the developing embryo, which enhances image resolution.

To reproduce the early pregnancy conditions, infusion of isotonic saline or other solutions into the uterine cavity of the nonpregnant uterus was introduced to create greater contrast. This procedure has several designations including saline infusion sonography (SIS), hysterosonography (HySo), or hysterosalpingocontrastsonography (HyCoSy).[15,16] Numerous variants of the original procedure have been proposed that employ either sono-transparent[17,18] or sono-refractory contrast media, such as Echovist®, Levovist® or Albumex®,[19-21] which provide *black* and *white* contrast enhancement, respectively. Black contrast exploration of the uterine cavity has been found to be particularly helpful for exploring uterine malformations,[22] favorably comparing with magnetic resonance imaging (MRI).[23] While *black* contrast is superior for exploring the uterine cavity, *white* contrast offers the advantage of imaging the fallopian tubes.[21] Another approach to contrast-enhanced ultrasound utilizes microbubbles manufactured with a hydrophilic shell of albumin, galactose, lipids or polymers and a hydrophobic gas core. When the gas bubbles interact with ultrasound energy, they alternately compress and expand, generating a strong, unique signal. Ultrasound devices can be specially tuned to enhance the detection of these unique signals.

Endometriosis and Adenomyosis: Ultrasound and Magnetic Resonance Imaging (MRI)

Endometriosis can affect all pelvic organs, associated with various degrees of extension and infiltration. Exploring endometriosis often requires MRI. Likewise, a variant of endometriosis, adenomyosis—the diffuse and focal forms—can be reliably diagnosed on MRI with good correlation with anatomical findings.

Functional Pelvic Imaging in Reproductive Endocrinology and Infertility

Anatomy and Morphological Measurements

The two primary constituents of the uterus—the outer muscle or myometrium and its mucosa, the endometrium—present an interphase that is easily identifiable on ultrasound. The lower end of the endometrium delineates the internal os of the cervix, which provides a landmark for individual measurements of the cervix and uterine corpus. The total length of the cervical canal is measured after identifying the external os of the cervix. The endometrium, which is hormonally sensitive, changes in thickness, volume, and aspect (echogenicity) during the menstrual cycle, and in response to hormonal treatments.

The myometrium is composed of three layers.[24,25] The inner, or sub endometrial layer of the myometrium, is of müellerian origin. It is endowed with estrogen receptors (ER) and progesterone receptors (PR) showing cyclical changes that mimic those encountered in the endometrium.[26] The two outer nonmüllerian layers of the myometrium have constant concentrations of ER and PR throughout the menstrual cycle.[24] In the nonpregnant uterus, the outer layer of the myometrium participates in uterine contractions encountered at the time of menses in response to progesterone withdrawal, but not in the retrograde contractions seen in the late follicular phase of the menstrual cycle. Disturbances of the contractile processes at the time of menses may cause dysmenorrhea or endometriosis, whereas alterations in the follicular phase may interfere with sperm transport.[27]

Current imaging is capable of identifying the subendometrial layer of the myometrium where the peristaltic contractions that culminate in the late follicular phase are initiated. High-resolution vaginal ultrasound defines this myometrial segment, the intermediate layer of lighter echogenic appearance, or *subendometrial halo*. It lies between the echoic basal layer of the endometrium and the underlying myometrium. Similarly, but using a different terminology, MRI identifies the subendometrial layer of the myometrium as a hypointense layer that separates the endometrium from the myometrium on T_2-weighed images or the *junctional zone* (JZ) (see section on endometriosis and adenomyosis).[28]

Video recordings have identified that uterine contractions during the late follicular phase under the stimulus of rising E_2 levels originate from the *subendometrial halo* or JZ area.[29,30] In an ex-vivo trial, Lesny and colleagues[29] studied six uteri obtained from fertile women 32.9 to 48.5 years old. Following hysterectomy, all uteri were needle-biopsied in the subendometrial halo under ultrasound guidance. The results indicate that the subendometrial halo, or JZ area, is a distinct section of the myometrium with increased vascularitiy and more tightly packed myometrial cells that is now also identifiable on ultrasound.[31] As discussed later, endometriosis and adenomyosis are thought to be associated with dysfunction of the endometrial-subendometrial unit.[24]

The boundaries between the cervix and the uterine corpus, and between the endometrium and myometrium, are easily identifiable, so that the uterus can be measured on ultrasound scans (Fig. 35.1). In adult women, uterine length ranges from 5 to 8 cm[32] following growth at the time of puberty. In a prospective trial examining 139 girls between the ages of 1 and 13 years of age with radiological bone age measurements, uterine volume was calculated from transabdominal scan images taking the measured values of length, width, and depth and using the ellipse formula.[33] Uterine measurements and volume were markedly smaller in pretelarchial girls at 1.8 ± 1.2 cm^3 as compared to 8.1 ± 6.6 cm^3 after telarche.[34] In a large prospective trial conducted on 380 school girls 6 to18 years of age, Holm

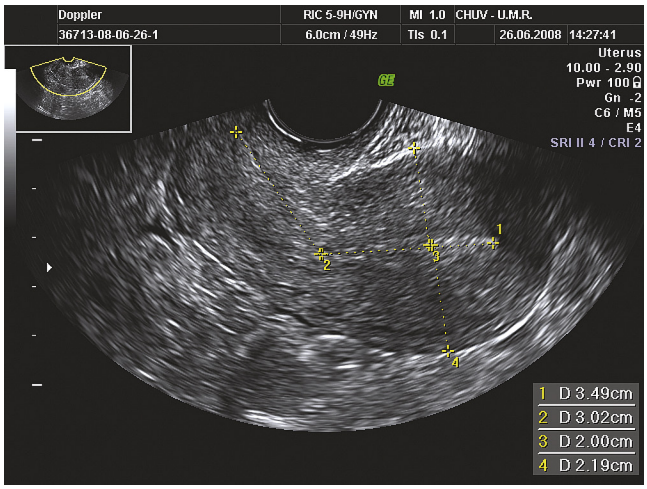

FIGURE 35.1 Uterine size. The interphase between the endometrium and myometrium is identifiable on ultrasound images. The lower end of endometrial development identifies the internal os of the cervix, which delineates the limits of the uterine corpus and cervix. The yellow marks define the cavity interphase in the inner cervix and uterine corpus. The two outer marks define the outer uterine limits at the level of the corpus.

FIGURE 35.2 Effects of *in utero* exposure to diethylstilbestrol (DES): T-shaped uterus with characteristic mid-uterine ridges.

and colleagues observed no age-related differences in uterine and ovarian size in 44 prepubertal girls, whereas a direct correlation with Tanner stages was observed in 163 prepubertal girls.[35] A further enlargement of the uterus was observed between Tanner stage 3 and adult girls (mean age of 19).

Looking at 114 premenarchial girls, Orsini and colleagues observed that until the age of 7, the uterus and cervix were of similar size with the corpus gradually becoming larger than the cervix thereafter.[36] These authors observed that the uterus continued to grow after menarche for several years, with uterine size correlating with the number of postmenarchial years, but not with height, a finding that has been challenged by others.[35]

There are clinical conditions in which the uterus was believed to be smaller than normal, a finding not always verified by measurements. Doerr and colleagues report on a series of 75 women affected by Turner syndrome. Of 50 women with a karyotype 45,X0 who had received estrogen replacement, 42 (84%) had a normal size uterus, whereas it was smaller (length less than 5 cm) in the remaining 8 women (16%).[37] In this study, uterine size might have been affected by the age at which estrogen therapy was initiated, but showed no correlation with other factors, notably the final height.[37] The impact of growth hormone (GH) treatment on uterine size remains a matter for debate, with Sampaolo and colleagues[38] showing a positive effect whereas, Snajderova and colleagues found none.[39]

We know from Herbst and colleagues[40,41] that *in utero* exposure to diethylstilbestrol (DES) may affect the genitalia. These authors linked seven cases of adenocarcinoma of the vagina, an otherwise excessively rare tumor, with *in utero* DES exposure. All these cases occurred at a single hospital in DES-exposed women between the ages of 7 and 22 years,[41] a finding later confirmed by others.[42] Further studies of DES-exposed women revealed many benign morphological abnormalities of the genital tract. These abnormalities, stemming from epigenic alterations[43] of the *HOX* gene family[44] include transverse ridges in the vagina, vaginal adenosis, and morphological anomalies of the uterus, such as the characteristic T-shaped uterus (Fig. 35.2).[45] Viscomi and colleagues analyzed the echographic appearance of the uterus in cases of DES exposure.[46] An abnormal T-shape uterus was found in 3 of the 18 (16%) women exposed to DES, a percentage in agreement with an incidence of 12% observed on hysterosalpingogram (HSG).[47] Furthermore, Viscomi and colleagues reported a reduced uterine size with a mean uterine length of 6.8 ± 0.4 cm in 18 DES-exposed women as compared to 8.1 ± 0.8 cm in 20 age-matched controls, even in the absence of gross morphological anomalies.[47] Calculated uterine volume was 49.4 and 90 cm^3 in DES-exposed women and controls, respectively. Salle and colleagues have reported altered uterine vascularity in women exposed to DES, with higher uterine artery pulsatility (PI) and resistance index (RI), and an absence of the cycle related changes.[48] However, the true impact of these uterine flow differences are difficult to interpret.

Several authors have proposed surgical correction (metroplasty) of uterine anomalies related to DES exposure, including T-shaped distortion[49] or simple overall reduction of uterine size.[50] Although authors reporting on small series recount positive impressions about the impact of surgery on subsequent reproductive outcome,[51] the efficacy of these procedures remains to be rigorously evaluated.

The Uterine Cervix

Vaginal ultrasound studies can precisely delineate the anatomical limits of the cervix. The cervical canal can easily be identified. When aqueous mucus is produced—under the influence of E_2 in the follicular phase—the cervical canal appears sono-transparent and hypoechoic. Early in the luteal phase, the mucus changes its ionic constitution under the influence of progesterone and the canal appears hyperechogenic (white) on ultrasounds.

We use a semiquantitative grading system in which hyperechogenic mucus is either not seen (–) or seen and graded as +, ++, and +++ when a sonotransparent dilatation of the cervical canal can be measured at less than 1 mm, 1 to 2 mm,

and greater than 2 mm, respectively, an approach close, if not similar, to that of others.[52]

The presence of cervical mucus visible on ultrasound serves as a biomarker for estrogen exposure, as well as an indicator of the absence of progesterone effects.[21] This latter parameter is particularly helpful when following patients treated with assisted reproductive technologies (ART). Identifying sonotransprent (black) cervical mucus on ultrasound makes it possible to disregard increases in plasma progesterone levels. This biomarker of progesterone's effects is particularly handy when monitoring ovarian responses.[21] An abrupt disappearance of cervical mucus observed concomitantly with plasma progesterone elevation in late stages of controlled ovarian hyperstimulation (COH), as sometimes encountered in poor ovarian responders, is an ominous sign.[53] The sudden disappearance of cervical mucus on ultrasound associated with pre-human chorionic gnonadotropin (hCG) progesterone elevation constitutes grounds for canceling an ART cycle, or freezing embryos and deferring transfer.[54]

Changes in echographic characteristics of the cervix have received little attention.[55] As expected from visual examination of the outer cervix, 3D assessment of the whole cervix reveals size differences between nulliparus and multiparous women.[56]

Links between cervical length and the risk of preterm labor (PTL) and delivery have been evaluated with new image-based screening for PTL.[57-63] More pertinent to infertility is the early identification of cervical insufficiency and its corollary, clinical indications for preemptive cervical cerclage. This clinical topic remains controversial, in spite of the quality cervical length measurements and the number of well designed studies. A well-established indication for cervical length measurement in the decision for cervical cerclage is during the midtrimester in women with a past history of pregnancy losses due to cervical insufficiency and prior short cervix measurements on ultrasound.[64] Various technical refinements may help in assessing cervical length using sonoelastography[65] or harmonic imaging.[66] A recent study indicated that assessing cervical length for reinforcing an existing cerclage may actually be counterproductive.[67]

The Endometrium: Biomarker of the Hormonal Environment

Endometrial Thickness: a Biomarker for Estrogen Action

By convention, the endometrial thickness is measured on ultrasound from one myometrial-endometrial interphase to the next, on the thickest point of the endometrium (Fig. 35.3). This widely accepted practice amounts to measuring a double endometrial thickness, something that has become a universally acepted convention.

From being relatively thin at the time of menses, the endometrium progressively thickens during the proliferative phase of the menstrual cycle, commonly peaking at 7 to 9 mm on the day of the luteinizing hormone (LH) surge.[68-70] Prior to ovulation, the endometrium takes on a multilayered or three line appearance formed by the echogenic basal layers and the two hypoechoic functional layers, separated by the hyperechoic interphase of the virtual uterine cavity (Fig. 35.4). The increase in endometrial thickness seen

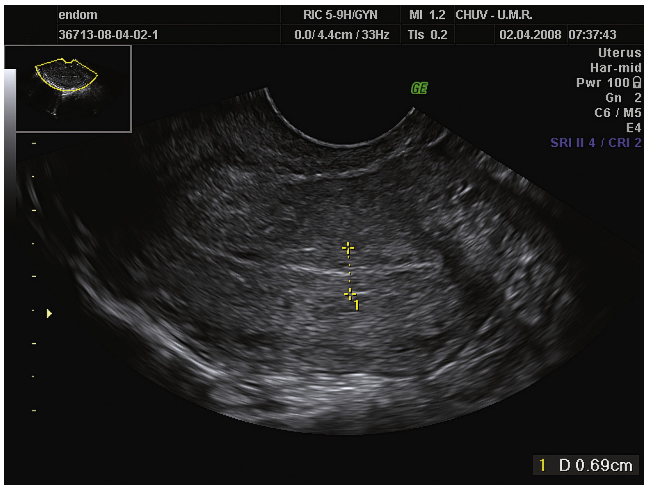

FIGURE 35.3 Endometrial thickness. Measurements are made from one endometrial to myometrial interphase to the one on the opposite side, therefore amounting to a double endometrial thickness measurement.

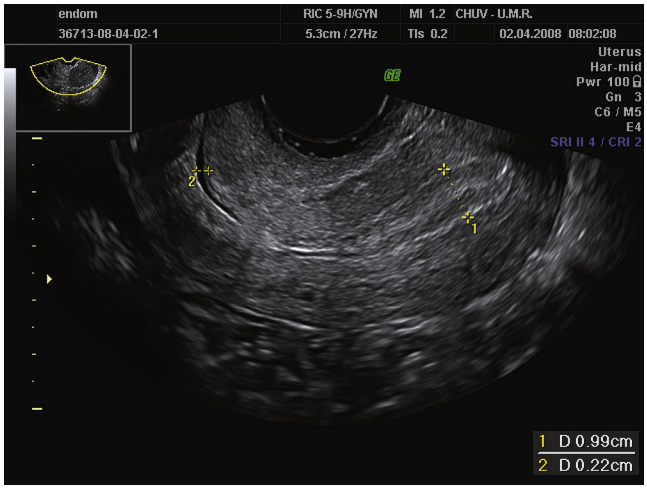

FIGURE 35.4 Hypoechogenic or type I endometrium: Echographic appearance of the endometrium during the follicular phase. Between the hyperechogenic layer of the endometrial basalis and the echogenic line of the virtual endometrial cavity lies a characteristically hypogenic endometrium. Taken together, this constitutes the characteristic three-layer pattern of the proliferative endometrium. On this figure one can also identify mucus present in the cervical canal. With our semi-quantitative grading system, this corresponds to a +++ score for the quantity of mucus because the mean diameter of the dilated cervical canal is dilated at 2.2 mm.

throughout the follicular phase represents the endometrial proliferation induced by E_2. This effect of estrogen, leading to the deployment of ER and PR, primes the endometrium for its response to progesterone. Under the influence of E_2, endometrial glands develop vertically with strait lumens. The donor-egg ART model revealed the respective roles of E_2 and progesterone in the priming of endometrial receptivity. Donor-egg ART taught us, in particular, the exceptional leeway that exists for the duration of the E_2 priming phase, which can range from 10[71] to 100 days without consequences on ART outcome.[72] Provided that E_2 priming is sufficient,[54] the duration of E_2 priming duration has

little impact on endometrial thickness or other endometrial parameters of estrogen effects on the uterus such as contractility.[73] As discussed later in this chapter, an endometrial thickness of ≥7 mm, or a volume of 2.9 mL,[74,75] is seen as reflecting sufficient endometrial priming by E_2. Extending treatment duration rather than increasing E_2 administration is seen as the better option for managing the excessively thin endometrium.[76]

McWilliams and Frattarelli looked at the dynamic changes in endometrial thickness in ART rather than static data (endometrial thickness at a single given point).[77] Fresh IVF cycles were studied in which the changes in endometrial thickness were analyzed from baseline to day 6 and from there to the day of hCG administration. Increments in endometrial thickness from baseline to day 6 and from day 6 to day of hCG were of 3.6 ± 2.4 and 2.0 ± 2.2 and of 2.3 ± 2.6 and 2.5 ± 2.1 in women who became pregnant (n = 70) and those who did not (n = 62), respectively. This comparison suggested that increments in endometrial thickness from baseline to day 6 were more predictive of pregnancy since there were no differences in the increment taking place from day 6 to the day of hCG. These dynamic changes in endometrial thickness point out the positive bias that exists with the quality of the ovarian response to COS, which can be wrongly interpretated as reflecting endometrial receptivity. This, therefore, constitutes a bias that must be remembered when interpreting an apparent link between endometrial thickness and endometrial receptivity[78] drawn from analyses of ART data. Ng and colleagues studied standardized endometrial preparations used for frozen embryo transfers (FET).[78a] These authors found no differences in endometrial thickness or Doppler-assessed blood flow between pregnant and nonpregnant women after receiving similar E_2 priming,[78a] a finding confirmed by others.[79]

Comparisons of endometrial thickness in the late follicular phase of the menstrual cycle, following physiological E_2 and progesterone replacement or mild ovarian stimulation for FET revealed similar findings.[80,81] This suggests that similar forms of hormonal priming have similar effects on endometrial thickness. Furthermore, exposure of the endometrium to E_2 levels that are more than 10 times higher than menstrual cycle values, as encountered in ART[82] and following the vaginal administration of 2 mg of E2/day[83] barely resulted in a 20% thicker endometrium. This suggests that E_2 priming that results from menstrual cycle levels of E_2 is nearly maximum. As noted earlier, the same leeway that exists for the amount of E_2 used for endometrial priming is also seen for the duration during which the priming is applied. In a retrospective analysis of their donor egg data, Pellicer's group showed that extending the E_2 priming phase for up to 100 days had no significant impact on ART outcome[84] and endometrial thickness[72] a finding confirmed by others.[85,86] The minimal effects of increased and/or prolonged E_2 priming on endometrial thickness conflicts with reports indicating that excessive ovarian responses to COS negatively impacts on pregnancy and embryo implantation rates.[84,87] To account for these divergent findings, we proposed that in strong responses to COS, it is the excessive production of ovarian factors other than E_2 that are responsible for any adverse endometrial effect, not a direct action of high E_2 levels per se.[54,88]

A consensus exists today that women whose endometrium is less than 7 mm in ART have markedly decreased chances of becoming pregnant,[89,90] particularly if no triple line pattern was seen.[91] In rare cases, albeit disturbing ones, this condition may persist, and be found in menstrual cycles and stimulated and E_2-supplemented cycles.[92] This condition is typically resistant to markedly elevated estrogenic exposure.[83] It may be encountered in the aftermath of total body irradiation or other cancer treatments,[93] or in the absence of readily available explanations. The treatments that have been proposed for these women include low dose aspirin,[94] an estriol challenge test,[95] locally active vasodilators,[96] and the combination of pentoxifylline and tocopherol (vitamin E).[92,97] The latter products, pentoxifylline and tocopherol, were tested on the grounds that they had been reported to be effective at reducing fibrosis induced by radiation therapy.[98] While some reports speak for possible improvements in results in donor-egg ART recipients,[99] no rigorous evidence for efficacy exists.

The possible poor predictive value of a thickened endometrium in ART reported by Casper's team[100] remains a matter for debate. While confirmed by some,[89] a larger group of publications failed to observe that a thicker endometrium has an overt negative impact on ART outcome.[101-104]

Endometrial Echogenicity: a Biomarker for Progesterone Action

Echogenicity reflects the different tissue interactions with ultrasound. Tissue echogenicity ranges from near sonotransparent as encountered in certain constituents of the body, notably water, to the highest echogenicity, produced by air (present in the bowel). On gray scale imaging, low echogenicity, as that of water, is commonly depicted in black, while high echogenicity appears in white. Typically, solid tissues with intermediate echogenic characteristics are depicted by degrees of gray with final grade depending on the water and/or air content and the number of such interphases. In the uterus, the echogenicity of the myometrium remains constant throughout the menstrual cycle and following various hormonal treatments. In contrast, the echogenicity of the endometrium varies between the follicular and luteal phases of the menstrual cycle and in response to exogenous hormones.

In a prospective trial on 80 infertile patients, Forrest and colleagues[105] showed that endometrial echogenicity increases after ovulation under the influence of progesterone. These authors were first to recognize the hypoechoic characteristics of the follicular phase endometrium (Fig. 35.4). The endometrium is characterized by a hypoechoic functional layer bordered by the hyperechoic basal layers with the center hyperechoic line produced by the interphase of the virtual endometrial cavity. Together, the hypoechoic functional layer of the endometrium and its outer limits produce the typical *three-line pattern*.

Changes in endometrial echogenicity are seen soon after ovulation. The endometrium progressively acquires its hyperechoic features characteristic of the luteal phase, starting from the endometrium basalis layer and expanding upward. Forrest and colleagues[105] observed a hyperechoic endometrium in 78% of women scanned during the luteal phase. Likewise, Templeton's group identified a similar

sequence of changes from hypoechogenic endometrium in the follicular phase to a primarily hyperechogenic pattern in the luteal phase of stimulated cycles.[68] The sonographic changes from the follicular phase to those characteristic of the luteal phase start to be visible within 48 hours of ovulation. The hyperechoic transformation of the functional layer of the endometrium takes 4 to 7 days to complete.

Grunfeld and colleagues studied the changes in endometrial echogenicity that took place in 18 women receiving sequential E_2 (0.2 to 04 mg/day, transdermally) and progesterone (50 mg/day IM) treatment in preparation for donor egg IVF.[106] Vaginal ultrasounds were performed starting before the onset of progesterone administration, and every 3 days thereafter until the 8th day of progesterone, when an endometrial biopsy was performed. Endometrial echogenicity was scored as pattern I, showing a triple-line pattern before the start of progesterone treatment, to pattern III, showing full hyperechoic transformation of the layer fucntionalis from the lamina basalis all the way to the endometrial lumen (Fig. 35.5). These authors concluded that endometrial thickness was a poor discriminator between advanced and retarded stromal changes on endometrial biopsies. Conversely, the degree of hyperechogenic changes on ultrasound (complete or partial) correlated with the degree of advancement of luteal changes (condensation, predecidualization) in the endometrial stroma. All women whose endometrial biopsy revealed delayed secretory changes in endometrial glands and stroma had ultrasounds showing partial hypoechogenic images (pattern II) (Fig. 35.6).

Analyzing endometrial echogenicity on the day after hCG administration in ART, Gonen and Casper observed a typical hypoechogenic triple-line pattern in 49% (60/123) of subjects.[107] In this subgroup of ART participants, the pregnancy rate was 30% (18/60), which was significantly higher than the figure obtained in the whole cohort (19.5%). Conversely, a full and partially hyperechogenic endometrium was found in 33% (41/123) and 18% (22/123) of women in whom pregnancy rates at 9% and 9.1%, respectively, were markedly lower than in their hypoechogenic counter parts. The original data of Casper and Gonen on the poor prognosis value of a hyperechoic endometrium in the late follicular phase of ART were largely confirmed in other publications,[108-113] while others failed to find this relationship.[114-115]

In an effort to analyze how ultrasound data, namely, echogenicity, could reflect endometrial receptivity, we studied the endometrial appearance on ultrasound on the day of hCG administration in 228 consecutive COH cycles.[116] We only included women younger than 38 years of age whose uteri were morphologically normal, and in a position that offered optimal visualization on ultrasound. Ultrasound images were digitized and analyzed using a computer-assisted system designed for measuring the degree of endometrial echogenicity (Fig. 35.7). Specifically, we studied the degree of the hyperechogenic changes that develop from the basal endometrium upward during the follicular-luteal transition, as described in E_2 and progesterone cycles,[106] but at times reported in ART before exposure to progesterone, at the time of hCG administration.[107] Our results indicated that in the selected population of IVF candidates 34/228 (14%) had a fully hypoechoic *triple-line* endometrium (less than 30% hyperechoic at the base of the endometrium) while 28/228 (12%) had a fully hyperechoic endometrium (greater than 70% of hyperechoic invasion of the functionalis layer).[116] The remaining 166 women had 4 degrees of progressive hyperechoic changes that extended from 31% to 40% to 61% to 70% of the full functionalis layer. Demographic, hormonal and biological characteristic of each of these groups were similar, including, endometrial thickness and plasma progesterone levels,

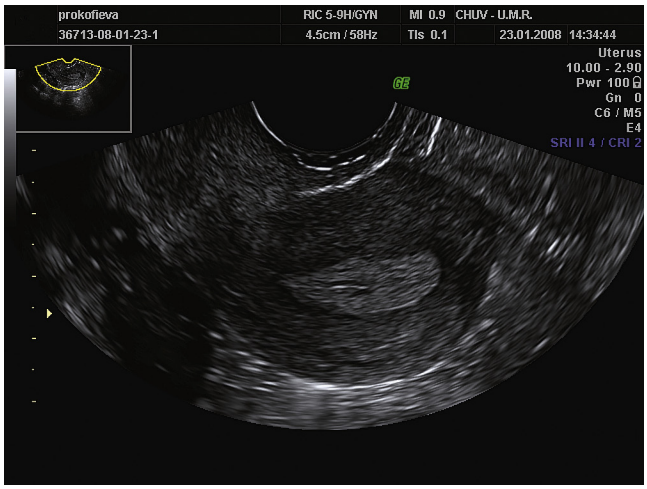

FIGURE 35.5 Hyperchogenic or type III endometrium: Under the influence of progesterone, the endometrium becomes hyperechogenic in relation to the surrounding myometrium during the luteal phase. From studies conducted in estradiol (E_2) and progesterone substitution cycles, it has been determined that the endometrium becomes fully hyperechogenic, usually after 4 days of exposure to luteal phase levels of progesterone. The hyperechogenic characteristics of the secretory endometrium are believed to result from the abundance of mucus-filled tortuous glands, which generate many ultrasound interphases and, therefore, increase the overall echogenicity of the endometrium.

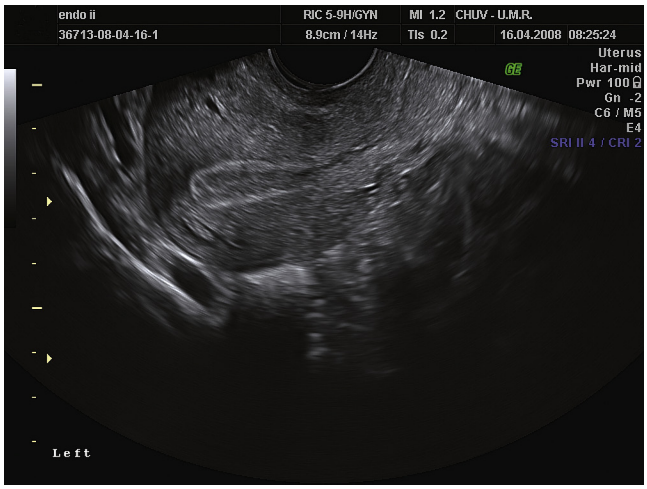

FIGURE 35.6 Intermediate or type II endometrium: During the first days of the luteal phase there is a characteristic thickening of the endometrial basalis, which progressively spreads upward to ultimately reach the hyperechogenic interphase of the virtual endometrial cavity. The condition encountered after 2 days of exposure to progesterone when the hyperechogenic endometrial basalis extends over approximately 50% of the whole endometrial layer is described as a type II endometrium.

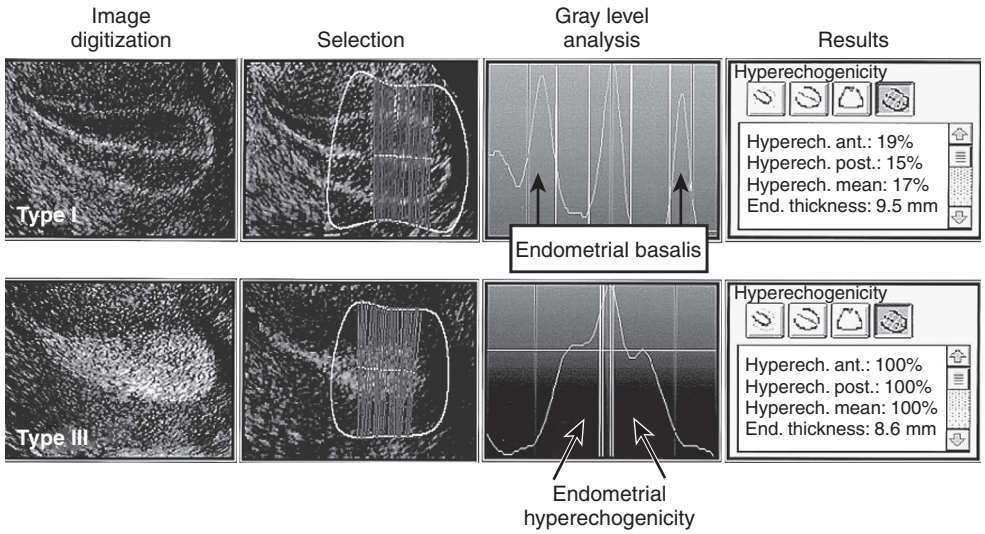

FIGURE 35.7 Computer assisted measurement of endometrial echogenicity. Endometrial echogenicity was studied on transverse slices. In the follicular phase (type I endometrium), one recognizes the characteristic hyperechogenicity of the endometrial basalis and that generated by the virtual endometrial cavity, outlining the hypoechogenic functionalis. In the luteal phase (type III endometrium), the hyperechogenicity pattern spreads to ultimately reach the virtual endometrial cavity, producing the characteristic hyperechogenic appearance of the endometrium. *(From Fanchin R, Righini C, Ayoubi JM, et al. New look at endometrial echogenicity: objective computer-assisted measurements predict endometrial receptivity in in vitro fertilization-embryo transfer.* Fertil Steril *74:274, 2000.)*

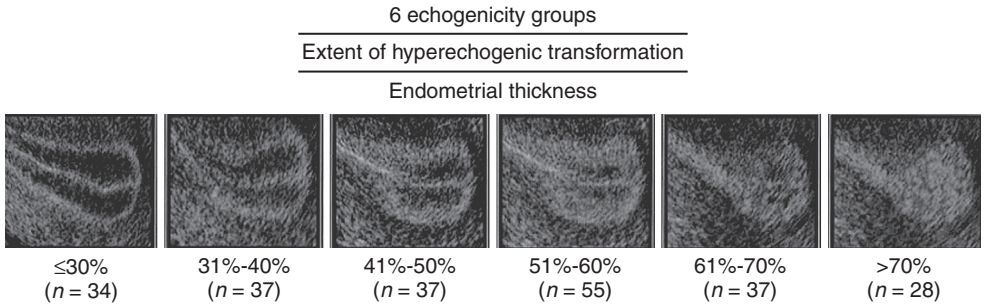

FIGURE 35.8 Computer assisted endometrial echogenicity showing the extent of hyperechogenic transformation on the day of human chorionic gonadotropin (hCG) and pregnancy and implantation rates. The figure shows six echogenic groups of increasing endometrial echogenicity. Pregnancy and implantation rates (59%, 57%, 35%, 20%, 16%, and 11%, respectively) and implantation rates declined from 59% to 11% and 35% to 3%, respectively when hyperechogenicity ranged from <30% to >70% of endometrial thickness. *(From Fanchin R, Righini C, Ayoubi JM, et al. New look at endometrial echogenicity: objective computer-assisted measurements predict endometrial receptivity in in vitro fertilization-embryo transfer.* Fertil Steril *74:274, 2000.)*

which remained less than 1 ng/mL in each group. This latter observation indicates that the *premature* increase in echogenicity seen in certain IVF patients is not the result of premature luteinization with increased progesterone production. Finally, the number of embryos transferred was also similar in all six groups; in each case two to four embryos were transferred (as commonly done in the 1990s). Pregnancy and embryo implantation rates varied greatly, however, between the different echogenicity-based groups. From a highest value of 59% and 16%, respectively, for the hypoechogenic group, it decreased to 23% and 3%, respectively, for the hyperechoic group, with progressively diminishing results for increasing echogenicity in the intermediate groups (Fig. 35.8).

In a different study, we assessed endometrial echogenicity on the day of hCG administration, oocyte retrieval, and embryo transfer (day 2) in patients whose plasma progesterone was below or above the cut off value of 0.9 ng/mL.[117] On the day of hCG, the mean hyperechoic transformation of the functionalis layer of the endometrium was similar in the two groups at 40% and 41%, respectively. During the 4 days that followed hCG administration, the hyperechoic transformation was much faster, however, in the high-progesterone group, with values of 70% versus 63% at oocyte retrieval and 90% versus 79% at the time of embryo transfer (ET), respectively.

The histological basis for the premature hyperechogenic transformation seen in certain IVF women remains unclear. During the follicular-luteal transition, it has been hypothesized that the development of spiral arteries and the coiling of the glands which takes place under the influence of progesterone causes the increase in echogenicity. The fact that progesterone was low (less than 1 ng/mL) in women showing premature echogenicity excluded this simple explanation. Work from Devroey's team performing endometrial biopsies on the day of oocyte retrieval in the cycle of embryo transfer confirmed that premature lutenization did not explain the early hyperechogenic transformation.[118,119] This leaves us with no explanation for the increase in echogenicity found in certain women on the day of hCG

administration in ART, an observation bearing ominous predictive value for ART outcome.

There are considerable inter-study differences in the predictive value of various echogenic patterns on the day of hCG, oocyte retrieval and embryo transfer for which no explanations are readily available.[120] We believe that some of the variability in the ultrasound patterns reported stems from methodological issues. For example, the endometrium of women whose uteri are in an intermediate position is likely to erroneously appear hyperechoic due to the fact that the ultrasound beam tends to hit endometrial glands at an angle rather than being parallel with the glands when the uterus is in a marked anteverted or retroverted position. In an unpublished trial, we performed manual rotations of freshly removed uteri before an ultrasound probing. This confirmed that the hypoechoic pattern obtained when the uterus is held in the anteverted or retroverted position before the probe becomes hyperechoic when the intermediate position is mimicked.[73] Recently, Dietterich and colleagues indicated that transabdominal screening likely limits the possibility of false interpetation.[101]

Three-Dimensional Volume Reconstruction of the Endometrium

Interest in measuring endometrial volume rather than its thickness is based on obtaining a more global parameter for assessing endometrial priming by estrogens.[11] Progress made in 3D technology allows the subendometrial junctional zone to be assessed.[121] Early assessment of endometrial volume estimated from 2D ultrasound images by simple formulae such as the prolate ellipsoid[122,123] were of little help for studying the uterus, probably because of the irregular shapes of this organ which made volume calculation based on theoretical formulas inaccurate. Off-line and later, built-in 3D volume reconstruction systems incorporated in the ultrasound machine offer supperior approaches for ultrasound-based volume measurements.

3D-based volume calculation of territories such as the endometrium use either of the two following methods: (1) The simplest or *multiplanar approach* consists of scrolling through multiple serial slices, which allows more measurements of irregularly shaped objects.[124] (2) A more elaborate approach is based on using a virtual organ computer-aided analysis imaging program (VOCAL) developed by a 3D ultrasound manufacturer, GE-Kretz, Zipf, Austria. A detailed description is provided by Raine-Fenning and colleagues.[12] Briefly, 3D reconstruction encompasses two primary steps. First, the relevant boundaries of the volume to be studied are identified on 2D gray-scale images in order to delineate the limits of the 3D reconstruction. For the endometrium volume, the endometrial to myometrial interface is either manually, or semi-automatically identified by the examiner on 2D images, using the B (transverse) or C (coronal) plane. Second, the 3D volume is rotated about a central axis through sets of user-defined steps ranging from 6 degrees to 30 degrees at a time. It takes from 30 to 6 planes, depending on the rotating pattern chosen, to complete a full 180-degree rotation. Finally, volume acquisition is generated automatically upon completion of a full 180-degree rotation (Fig. 35.9A-C). Experimental calculations indicated that the volume is measured with increasing precision with the increased number of rotation steps.[125] Practically, 9-degree rotations leading to a total of 15-degree rotation steps[73] are preferred.

From a first volume of reference (i.e., the endometrial volume), it is possible to generate secondary volumes that extend to set distances of the primary reference. For example, 1 to 5 mm outer extensions of the primary endometrium volume, using the *shelling* properties of the VOCAL system, can define subendometrium volumes.

In a prospective trial, Raine-Fenning and colleagues scanned a population of 30 presumably fertile volunteers on alternate days until evidence of ovulation was obtained and collapse of the follicle was witnessed, and every 4 days thereafter.[126] 3D volumes of the uterus were acquired using a Voluson 530D ultrasound machine from an appropriate longitudinal scan of the uterus. 3D volume measurements were performed off-line using the VOCAL system with endometrium boundary identification conducted on the coronal C plane in successive manual 9-degree rotation steps. As illustrated in Figure 35.9B, the changes in endometrial thickness and volume throughout the menstrual cycle followed similar patterns with progressive increments during the follicular phase and stable values throughout the luteal phase. The changes in endometrial thickness and volume were highly correlated ($R^2 = 0.767$; $P < 0.001$). Studies looking at correlations between endometrial volume and ART outcome revealed the same kind of relationship already described for endometrial thickness. Like their endometrial thickness counterparts, 3D endometrial volume studies revealed poor pregnancy rates in cases of marginal endometrial volume. Specifically, pregnancy rates were directly related to endometrial volume for values from 2 to 4 mL, significantly reduced when the endometrium was less than 2 mL, with no pregnancy if less than 1 mL. Conversely, further increases in endometrial volume greater than 4 mL were not associated with better outcomes, as compared to 2 to 4 mL.[11] In a study of 47 women, Schild and colleagues showed no correlation between endometrial volume and pregnancy rates,[124] as did Yaman and colleagues.[127]

Uterine Doppler

Principles and Applications

The Doppler effect (named after the German physicist, Christian Doppler) refers to the phenomenon whereby an apparent change in frequency is perceived when relative motion exists between the wave source (in our case, the reflected ultrasounds) and the receiver. Yet, the emitted frequency (here, the ultrasounds refected to the receiver) does not change. The frequency change is only perceived by the receiver, as the source-receiver distance changes due to movement. If ultrasounds are emitted (or reflected) from a source that moves toward the receiver, an increase in frequency will be perceived. The reverse will be perceived if the ultrasound source moves away from the receiver. In both cases, the perceived frequency change (i.e., the intensity of Doppler effect) is proportional to the speed of displacement of the target on which ultrasounds are reflected.

The primary application of the Doppler effect has been for analyzing the movement of blood particles on which ultrasounds are reflected for studying blood flow. Depending on the methodological approach used, Doppler-based

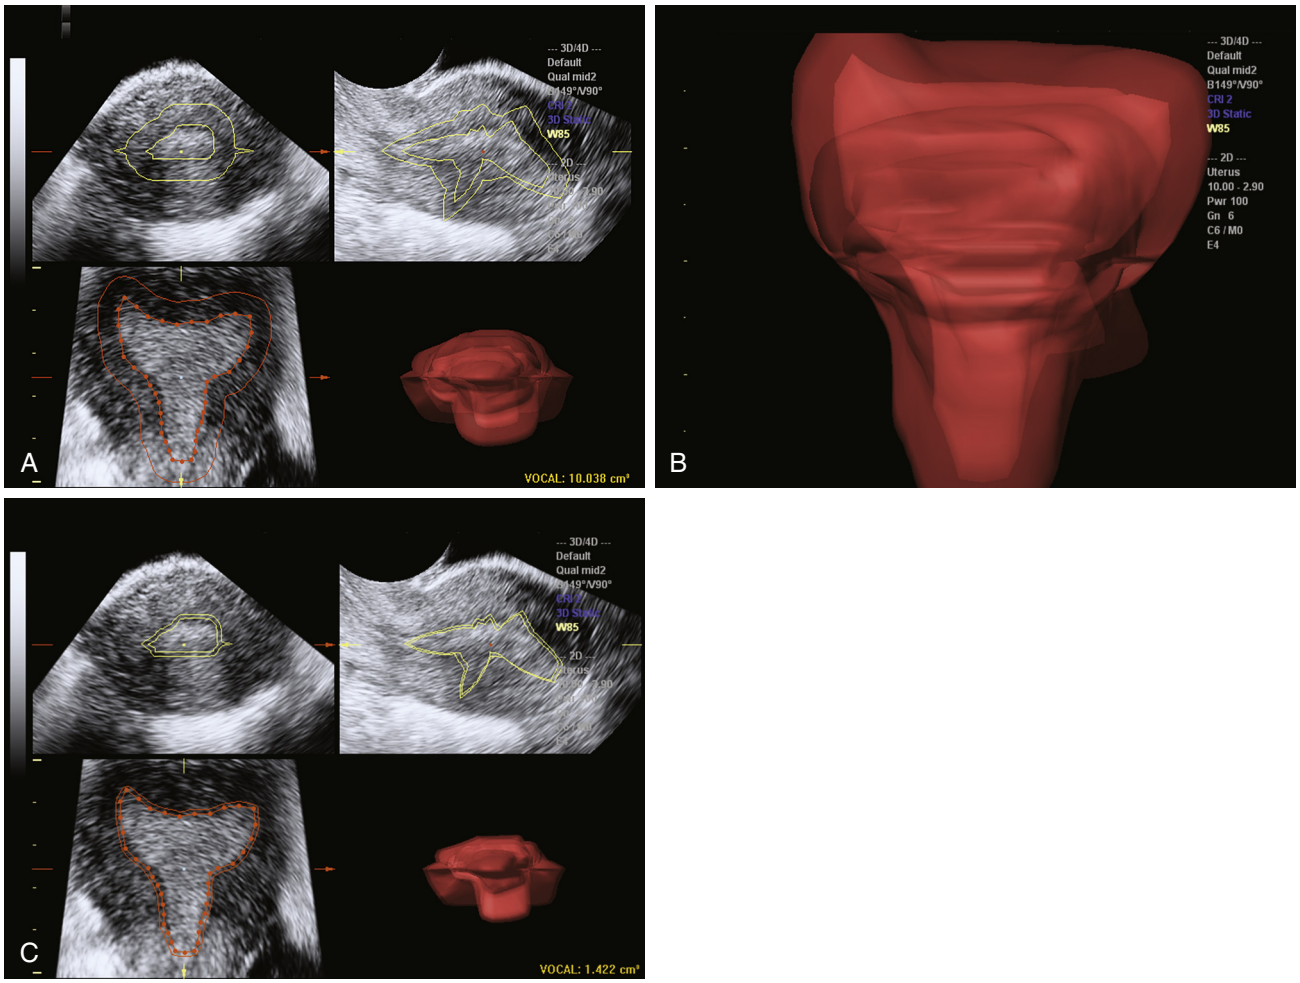

FIGURE 35.9 Endometrial volume calculation using a virtual organ computer-aided analysis (VOCAL) imaging program also allows the calculation of a secondary subendometrial volume extending at 5 mm **(A** and **B)** or 1 mm **(C)** outside from the endometrial myometrial interphase.

analyses may (1) look at individual vessels or; (2) measure perfusion in a whole tissue area. The former approach assessing flow in specific vessels (i.e., the uterine artery) rely on the pulsed-Doppler technique. This consists of sending sound signals at timed intervals in a defined volume or *sampling gate*, and studying the perceived frequency changes of the return signal or Doppler *waveform*.

Doppler-based blood flow analyses stem from advances in cardiology, which established the methodological foundation for all Doppler analyses performed today.[128] Pulse Doppler (Fig. 35.10) involves first physically locating the vessel to be studied in order to properly position the Doppler sampling gate. This can be done using a duplex system, which provides concomitant gray scale or *color Doppler* imaging for vessel identification (see later in the chapter). Once the emitting signal is targeted at the designated vessel, blood flow and resistance are calculated by analyzing the frequency changes perceived or Doppler waveform. The intensity of the Doppler effect reflects the speed of displacement of the blood particles toward or away from the probe, which emits and receives the return signal. An exact computation of blood flow and resistance implies, however, that the angle between the ultrasound wave and the great axis of the vessel is known. This is needed for determining the true displacement speed of the blood-borne particles.

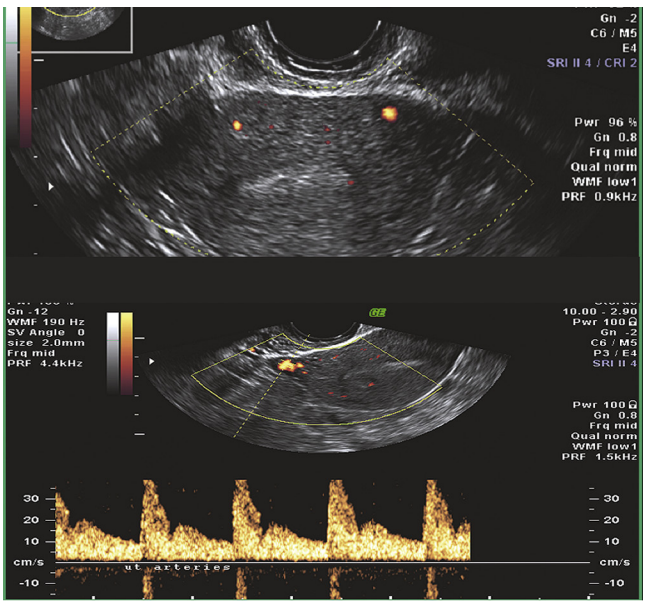

FIGURE 35.10 Pulsed Doppler waveform analyzed by computation of the semiquantitative pulsatility index (PI), which reflects the impedance to flow in the territory downstream from the area of measurement.

This calculation is, unfortunately, impossible in gynecological organs because uterine and ovarian vessels are far too tortuous.

The pulsed-Doppler technology in gynecology must, therefore, rely on approximations for assessing the Doppler signal, as an accurate determination of blood flow and resistance are impossible.[9,10,129,130] Practically, the impedance to flow, a reflection of vascular resistance, is assessed by descriptive analysis of how the *Doppler flow wave* is modulated through the systolic and diastolic phases of the cardiac cycle. This permits semiquantitative measurements of systolic and diastolic signal ratios, or Doppler indices. The most common of these indices are the resistance indices (RI) and pulsatility indices (PI). RI (values from 0 to 1) and PI (values from 0 upward) are directly related to vascular resistance, with higher values corresponding to lower flow.

The alternate approach for Doppler analysis uses more complex real-time assessment of the Doppler effect directly on the return ultrasound signal serving gray scale imaging. This approach applies color-coding to voxels that are subjected to Doppler effect, while the rest of the voxels serve for gray scale imaging. The end result or *color Doppler* function and its variant angle-independent *power Doppler,* provide direct imaging (or mapping) of vascular flow overlying gray-scale ultrasound images. Color and power Doppler, therefore, offer a novel way for assessing vascularity in a given organ or territory. Color and power Doppler also permit global assessment of vascularization in a given area by direct computer-based visual analysis of colored voxels present over the total number of voxels, or *power* Doppler *angiography* (PDA).[87] Unlike PI and RI, PDA values are directly related to local flow, with higher values indicating higher flow. Various systems have been developed for filtering nonspecific color Doppler signals or "flash" artifacts that are triggered by displacements of the targeted tissue as a result of bowel or respiration-linked movements.

More recently, computer-assisted power Doppler assessments have been coupled with 3D volume reconstruction (3D-PDA) for automated operator-independent measurement of vascularity in a precisely defined volume.[131] (Fig. 35.11A and B). This approach offers improved reproducibility, because measurements are conducted in an anatomically and electronically defined territory, such as the endometrium or ovary.[12] 3D-PDA is measured in the volume of interest previously defined using VOCAL.[12] The results of 3D-PDA are displayed on a histogram from which three indices, the vascular (VI), flow (FI), and vascular/flow indices (VFI), are derived. VI (%) represents the proportion of lighted voxels over all voxels, thus reflecting the degree of vascularity of the studied volume. FI (0-100) represents the mean power Doppler intensity of the lighted voxels, a parameter meant to reflect the vascularization flow rate. VFI (0-100) is a product of the two indices VI and FI (Fig. 35.12).

The Doppler function of ultrasound makes it possible to extend the diagnostic usefulness of gray-scale imaging. Doppler data have been used for two main purposes: (1) refining cancer detection by identifying or excluding suspicious vascularitiy in relation with gray-scale findings (i.e., an ovarian cyst); (2) assessing the effects of hormones (endogenous or exogenous) on blood flow in an attempt to identify markers of endometrial receptivity.

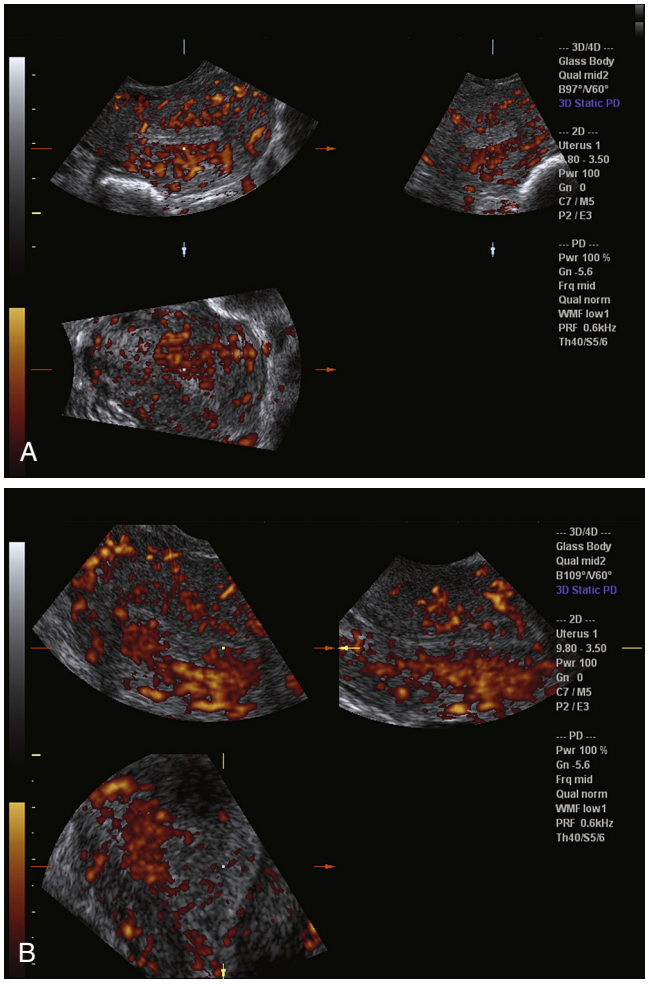

FIGURE 35.11 Computation of color Doppler finding in a given area by computation power Doppler angiography (PDA) in a 3D defined territory, as for example, the endometrium and subendometrial volume using the virtual organ computer-aided analysis (VOCAL) and shelling functions. PDA score is directly related to flow. Three primary indices are computed, the vascularization (VI), flow (FI), and vascularization-flow index (VFI). VI reflects the number of vessels in a given area whereas FI is proportional to blood flow in these vessels and VFI constitutes a product of VI and FI. **A**, In normal conditions, color Doppler shows no to minimal vascular entries in the endometrium. **B**, Endometrial polyp vessels are shown entering inside a given territory of the endometrium (right cornua).

Vascular Changes Related to the Menstrual Cycle and Hormonal Effects

Investigators have tried to follow the changes in uterine vascularization that are tied to hormonal changes in the menstrual cycle. Early studies using pulsed Doppler looked at changes in Doppler waveforms recorded from the uterine artery[9] and its major branches.[129,132,133] Later, Raine-Fenning and colleagues used 3D-PDA to quantify changes taking place in endometrial and subendometrial blood flow during the menstrual cycle.[126] These authors observed that both endometrial and subendometrial blood flow increased during the follicular phase, peaking 3 days prior to ovulation, and decreased to a nadir 5 days post-ovulation (Fig. 35.13). This pattern differs, however, from prior findings made with pulsed Doppler showing a steady increase of blood flow throughout

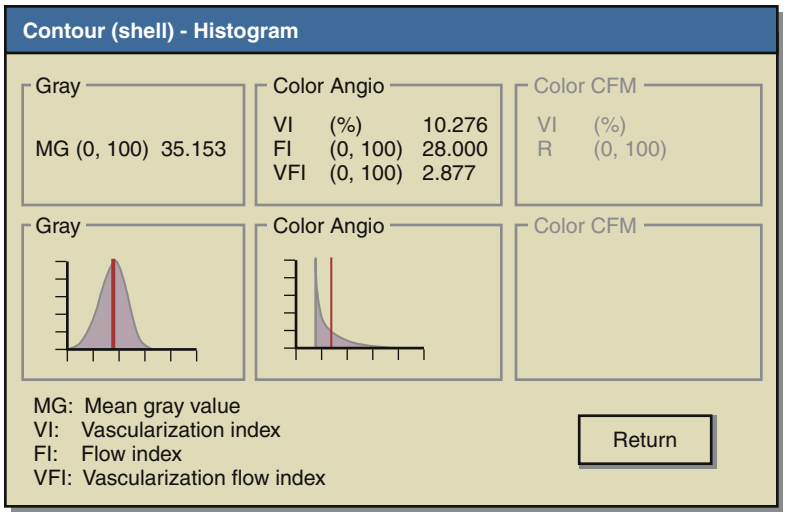

FIGURE 35.12 Computer assisted analysis of "lighted" voxels in a given territory leads to the computation of two distinct indices, the vascular (VI) and flow indices (FI), with VFI being of a product of both. VI represents the number of vessels in a given territory whereas FI is proportional to the intensity of blood flow in these vessels.

the menstrual cycle.[126,129,134-137] In Raine-Fenning's trial, smoking was associated with significantly lower VI and VFI throughout the menstrual cycle, whereas parous women had higher values than their nulliparus counterparts.[126]

Exogenous hormones administered to women suffering from premature[10,133] or normally occurring menopause[132] induced a prompt and profound decrease in uterine PI and RI indices. This was interpreted as reflecting the vasodilatory effects of E_2. Menopausal[138] and donor-egg IVF regimens[10] were associated with similar vasodilation of uterine arteries, suggesting that maximal vasodilation is achieved at levels of E_2 found within menopause treatments. Conversely, exposure to higher E_2 doses as used in donor-egg regimens caused no further increase in flow. In these studies, the vasodilation of uterine arteries induced by E_2 administration was partially antagonized by synthetic progestins,[138] but not by progesterone administration.[10]

Vascular changes observed in the uterus during COH do not parallel those that would be anticipated from the mere increased exposure to E_2. These findings indicate that the stimulated ovaries produce vasoactive factors other than E_2. In a prospective trial, Ng and colleagues[138a] compared endometrial and subendometrial blood flow measured using the 3D-PDA approach in menstrual and COH cycles of the same women. Their findings showed a significant decrease of endometrial and subendometrial blood flow during the stimulated cycle,[138a] with excessive responders having further reductions in endometrial blood flow as compared to moderate responders.[138a] These findings suggest that vasoconstrictive substances are released by the stimulated ovaries that antagonize the vasodilatory properties of E_2.[88,139] Among the putative factors possibly responsible for the decrease in uterine flow during COH are ovarian androgens, which are produced in increased amounts under the influence of exogenous follicle-stimulating hormone (FSH).[53,140] Supporting the concept that ovarian androgens interfere with the vasodilatory properties of E_2 is the observation of increased uterine artery resistance in case of polycystic ovary syndrome (PCOS) made by some,[141] but not all investigators.[142] Further supporting the vasoconstrictive role of androgens, or of a substance released in conjunction with androgens, is the report of an improvement of uterine flow in PCOS following administration of the antiandrogen, flutamide.[141] In a different study, Ng and colleagues[142a] observed a negative correlation between E_2 levels and blood flow suggesting that the putative vasoactive factor produced during COH is triggered by FSH administration in a proportional manner to that of E_2. This is further supported by the observation that the decrease in endometrial flow is more pronounced in women whose response to COH is excessive as compared to moderate responders.[142b]

The promising findings of early Doppler studies indicating that Doppler values predicted endometrial receptivity[143] have not been confirmed by recent 3D-PDA data from either fresh[5] or frozen embryo transfer cycles.[5] Yet, increased vascularitiy may be predictive of lesser risk of miscarriage.[82]

Dysfunctional Uterine Bleeding: Benign and Malignant Endometrial Pathology

Endometrial pathology, such as polyps or submucosal fibroids, are sought in cases of: (1) dysfunctional uterine bleeding (DUB) or; (2) as part of an infertility workup.

Odeh and colleagues prospectively evaluated DUB in 89 perimenopausal and 56 menopausal women.[144] In their hands, endometrial volume measurement more accurately predicted endometrial hyperplasia and/or carcinoma than simple endometrial thickness measurement. Receiver Operating Characteristics (ROC) curve analysis indicated that a sensitivity of 100% with a cut off value of 1.45 mL, which resulted in low sensitivity of 0.08%. A cut off value of 3.56 mL for the endometrium volume offered a sensitivity of 93% and a specificity of 36%. With this value, two carcinomas would have been missed in the patient cohort; one with alarming 3D-PDA data, the other with negative 3D-PDA results. Consequently, new tools such as 3D-based volume measurements should not cause us to ignore careful analysis of the endometrium. Irrespective of endometrial thickness or volume values, a heterogeneous echogenicity with close juxtaposition of hyperechoic and hypoechoic aspects warrants histological exploration. When endometrial polyps are suspected based on an irregular endometrium on plain ultrasound, direct power Doppler may identify the feeding vessel entering the polyp. Conversely, endometrial vessels are normally not viewed on power Doppler.[145] Suspicious findings on plain ultrasound justify a contrast-enhanced study.

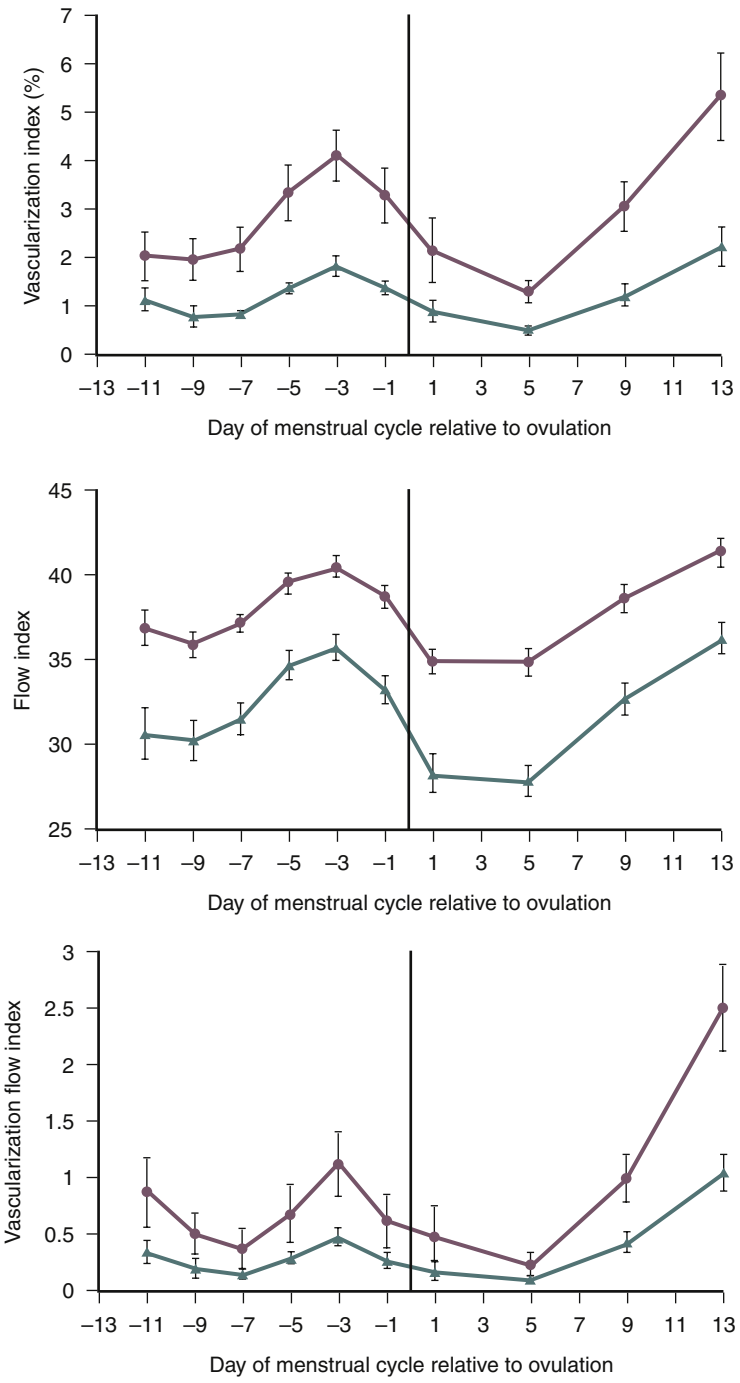

FIGURE 35.13 Temporal variation of three-dimensional-power Doppler angiography (3D-PDA) vascularization index (VI), flow index (FI), and vascularization flow index (VFI) throughout the menstrual cycle in endometrial and subendometrial territories. A characteristic postovulatory decrease in blood flow is observed in both endometrial and subendometrial territories. *(Raine-Fenning NJ, Campbell BK, Kendall NR, et al. Quantifying the changes in endometrial vascularity throughout the normal menstrual cycle with three-dimensional power Doppler angiography.* Hum Reprod *19:330–338, 2004.)*

The cardinal sign of endometrial carcinoma is an abnormally thick endometrium,[146,147] often with irregular and erratic echogenicity.[148] In 339 menopausal women presenting with DUB, there was no endometrial cancer developing over a 10-year follow-up with an endometrial thickness of ≤4 mm.[149] A more recent meta-analysis concluded that earlier studies probably overestimated the diagnostic accuracy of endometrial thickness.[150] A more conservative cutoff level of 3 mm was recommended for exclusion of endometrial carcinoma in women with postmenopausal bleeding.[150] Doppler has been claimed to differentiate between cancer and noncancerous lesions. While noncancerous lesions tend to have higher Doppler indices, there is an overlap between the PI and RI values of benign and malignant lesions.[151] Based on these findings, Tabor and colleagues concluded that postmenopausal bleeding requires an endometrial sampling irrespective of the thickness measured on ultrasounds.[152] Finally, in cases of endometrial cancer, vaginal ultrasound and MRI were equivalent for determining the depth of myometrial invasion.[153]

The Myometrium: Physiological and Pathological Findings

Uterine leiomyomas or fibroids are the most common solid tumor, occurring in 20% to 40% of women in their

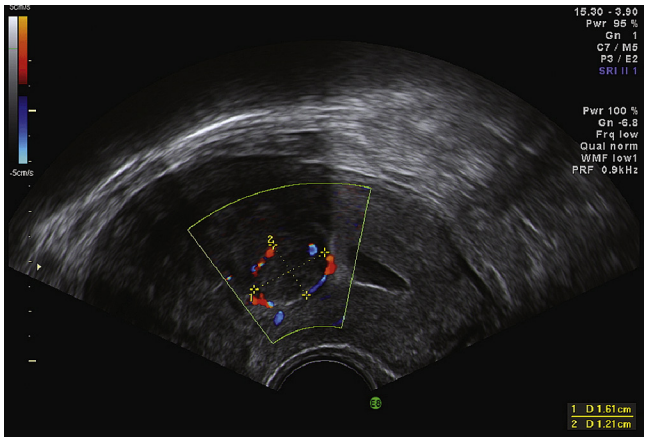

FIGURE 35.14 Uterine fibroid. Characteristically, vessels run around the surface of the fibroid from which radiating branches penetrate vertically into the tumor.

reproductive life.[154] Fibroids are well-circumscribed lesions, often with a pseudo capsule containing feeding vessels running at the surface of the fibroid, which penetrate into the fibroid in a radiating manner (Fig. 35.14). This pattern differs from that of adenomyosis, in which vessels are sparse and scattered, and the borders of the lesion typically indistinct. Fibroids originate from the middle layer of the myometrium from which they tend to expand either inward toward the cavity to become submucosal or outward toward the serosa, possibly to the point of becoming pedunculated.

The possibility that fibroids may cause infertility and constitute a predisposing factor for miscarriages depends primarily on their location and degree of extension. First, fibroids may alter fertility by interfering with sperm transport and embryo implantation.[155] This detrimental effect of fibroids on sperm transport has recently been supported by MRI-based studies of uterine contractility.[156,157] Kido and colleagues observed that submucosal fibroids were more likely to affect uterine peristalsis than their intramural counterparts.[157] Second, the possibility that fibroids alter endometrial receptivity has been entertained for many years. Fibroids may hamper embryo implantation, in part by physical effects when present in a subendometrial location, in part by focal endometrial disturbances[158] and local inflammation through the release of vasoactive and other substances.[159]

The possibility that fibroids cause miscarriages remains a subject of debate. In a recent study, miscarriages were more frequent in a population that experienced fibroids than in their unaffected counterparts.[160] There are many other studies, however, that failed to find such an association.[161] There are new therapeutic avenues for treating fibroids medically using selective progesterone receptor modulators (SPRMs).[162] However, the role of SPRMs in infertility treatment remains to be explored.

Contrast-Enhanced Imaging of the Uterine Cavity

History, Principle and Practical Issues

Early in the use of vaginal ultrasound it became apparent that uterine exploration in early pregnancy offered images of the developing embryo of outstanding quality.[163,164] The remarkable definition of fetal images obtained in early pregnancy using vaginal ultrasound is crucial for early detection of fetal malformations.[165-167] However, ultrasound images of the nonpregnant uterine cavity yield lower quality because of the lack of intrauterine fluid playing the role of contrast enhancer.[15] This led to the design of a new diagnostic procedure in which 0.9% NaCl or similar products are instilled in the uterine cavity for improving image quality. This procedure has been called hystero salpingo-contrast-sonography (HyCoSy), saline infusion sonography (SIS), or hysterosonography (HySo) (Fig. 35.15).[15,17,18,168,169]

Two types of contrast products provide either negative (black) or positive (white) contrast enhancement of the uterine cavity on grey scale imaging.[170] Negative contrast solutions have the acoustic properties of water (sonotransparent) with normal saline being the most commonly used agent. Positive contrast solutions consist of preparations that gain sonorefracting properties from air entrapped in various microparticle systems from which it is progressively released over time.[171-173] This is achieved through albumin (Albumex®) or saccharide microparticles (Echovist® later replaced by Levovist®, BR1, EchoGen, etc.). These positive ultrasound contrast products are injectable solutions available for various medical indications, but are used intrauterinely for gynecological imaging.[174]

Positive contrast solutions instilled in the uterine cavity provide *white* contrast enhancement of the uterine cavity. Unfortunately, this often obscures vision of the far-sided uterine wall because of shadowing effects created by the contrast product in the uterine cavity.[175] Negative contrast solutions, such as normal saline, provide *black* contrast enhancement of the uterine cavity. This leaves the vision of the far side of the uterus totally unobstructed which is better for identifying intracavitary lesions.[173,176,177] From these findings, it was rapidly recognized that negative contrast using saline is the preferred option for exploring the uterine cavity, whereas, positive contrast solutions are best for visualizing the fallopian tubes, organs that evade scrutiny on ultrasound examinatiton.[178]

Positive echographic contrast solutions have also been employed for enhancing the Doppler signal and improving the assessment of tissue perfusion when administered systemically.[179] Yet, Doppler enhancement that requires IV administration of these contrast products has not yet provided clinically relevant advantages that would justify their use for diagnostic purposes. Lastly, a variety of harmonic imaging techniques with and without pulse sequencing methods have been developed for improving the signal-to-noise relationship.[180,181] The approaches currently in development in various domains of ultrasonography may generate practical applications in gynecological assessment in the future.[182]

The relative complexity of the contrast-enhanced procedures, which requires the help of an assistant, limits the use of these methods, despite the quality of the images obtained and the reliability of the diagnoses.[169,183] Two options exist for assuring the proper distension of the uterine cavity during the procedure: (1) A simple catheter of the type used for intra-uterine insemination (IUI) or one equipped with a specially designed cone-shaped stopper for better fit against

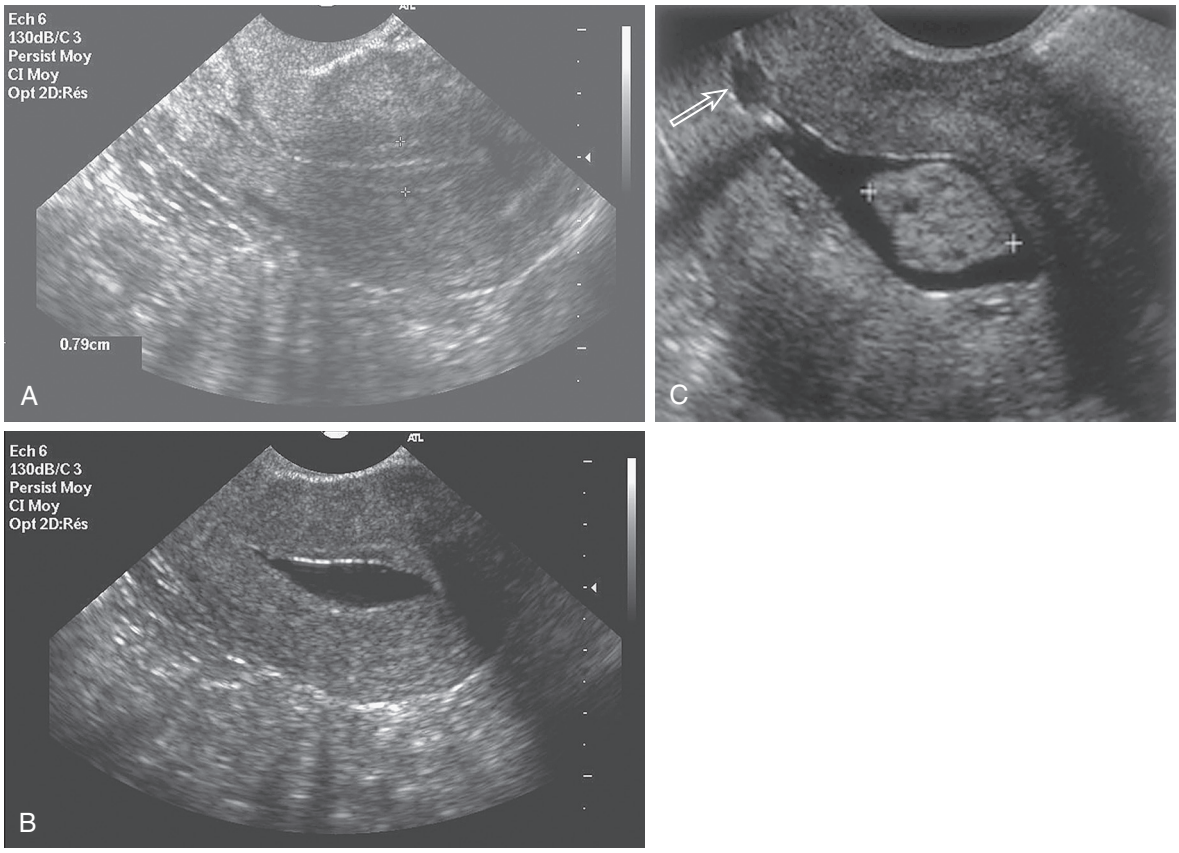

FIGURE 35.15 Hysterosonography (HySo): Intrauterine infusion of a contrast solution improves vision of the uterine cavity provided by plain ultrasound **(A).** Provides an interphase that enhances contrast **(B).** Facilitates the detection of intrauterine pathologies such as polyps or fibroids **(C).**

the external os of the cervix.[8] (2) A balloon-equipped catheter, which is inflated after positioning in the uterine cavity in order to prevent displacement. With the former, the speculum needs to be removed very carefully after placement of the catheter in order to not displace it from its proper intrauterine position. If the catheter is not firmly held in place, it most often justifies using a speculum that is articulated on one side only, which facilitates extraction, but is notoriously uncomfortable for the patient. The balloon catheter is itself capable of creating some degree of discomfort when it expands in the lower uterine segment. Moreover, it may hinder visualization of pathology lying in the lower uterine segment. In short, albeit providing images of remarkable resolution, HySo is a three-hand procedure (one for holding the probe, one for instilling medium, and the third for making image adjustments and measurements). HySo, therefore, most often requires the help of an assistant. Recently, an innovative option has been proposed in which a phase shifting medium is used.[168] This medium has a gel consistency at room temperature and the acoustic characteristics of water. Intrauterine instillation of 1 to 3 mL creates a slight distension of the cavity, thus offering negative or *black* contrast vision during the time necessary for ultrasound examination, which is conducted in the absence of any instrument present in the uterus. The medium later liquefies and is expelled naturally. In a pilot trial, this novel technique provided classical HySo-like images.[184]

Hysterosonography for Visualizing Endometrial Polyps and Fibroids

Using HySo for visualizing intrauterine pathologies, as in cases of DUB, has advantages and pitfalls that have been recognized.[185,186] In these women, HySo is in direct competition with other noninvasive diagnostic procedures such as diagnostic hysteroscopy.[187]

In a prospective trial, de Kroon and colleagues[188] reported that HySo provided conclusive information in 84% of 180 consecutive women presenting with DUB. In all these cases, the positive and negative findings of HySo were confirmed in women undergoing surgery, for a sensitivity and specificity of 100%. In 5.6% of cases, however, HySo could not be performed because of cervical stenosis and its results were judged inconclusive in a further 10.3%. A meta-analysis of trials looking at the value of HySo in women with DUB reported pooled sensitivity and specificity of HySo in the 24 retained trials of 0.95 (95% CI: 0.93, 0.97) and 0.88 (95% CI: 0.85, 0.92), respectively.[188] These results were confirmed by further trials and meta-analyses.[189,190] Furthermore, HySo-targeted endometrial biopsies have been described that allow direct endometrial sampling in the area of interest.[191] A survey found, however, that patients generally preferred office hysteroscopy over HySo.[192]

Concomitent use of 3D-reconstruction of uterine imaging further enhances the clinical value of HySo.[193] 3D volume acquisition allows for limited duration of uterine

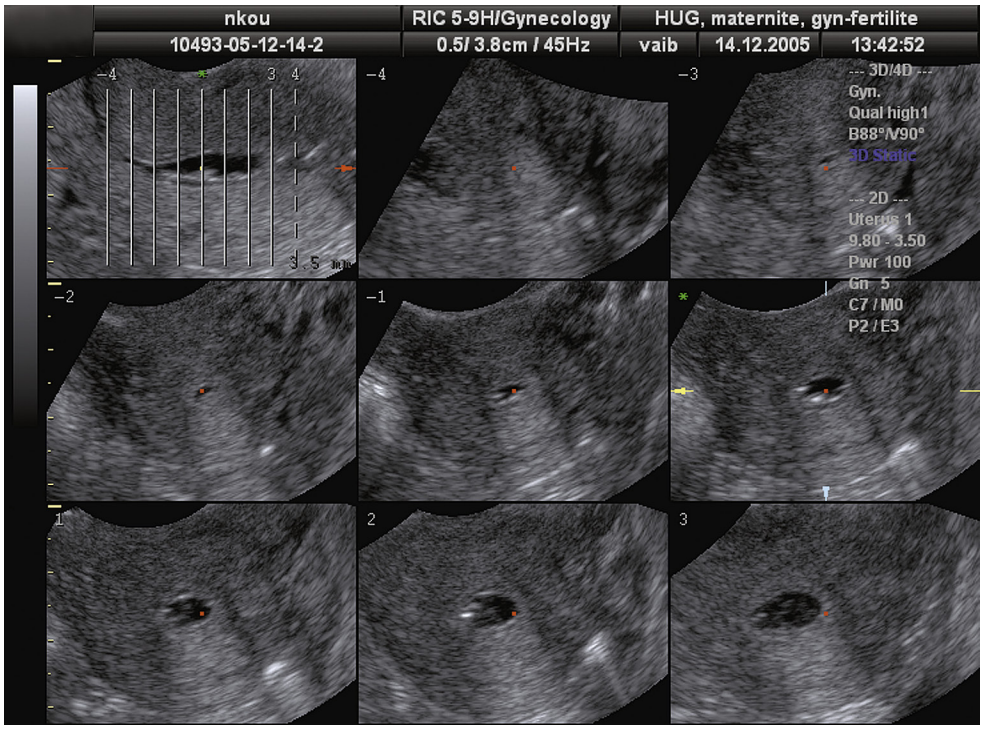

FIGURE 35.16 Three-dimensional-hysterosonography (3D-HySo) allows secondary review of images for detailed analysis of intrauterine contents.

distension to the time necessary for carrying out the electronic acquisition of a 3D volume. Furthermore, 3D reconstruction permits review of HySo images after uterine distension has subsided (Fig. 35.16).

HySo can also benefit from the added information provided by Doppler, such as the detection of a vessel entering into a polyp or encircling the surface of a submucosal fibroid.[193] Unusual uses of Doppler in conjunction with HySo includes the identification of an uteroperitoneal fistula[194] and intrauterine vascular malformation.[195]

Besides DUB, other indications for HySo include evaluation of women receiving tamoxifen treatment,[196,197] and according to some authors, evaluation of asymptomatic women entering menopause and considering hormonal therapy.[198]

Discomfort generated by HySo examination is usually mild to minimal. In a prospective trial, Dessole and colleagues[199] looked at the side effects and complications of 1153 HySo procedures. In 93% of cases, HySo was successful. Side effects of moderate to severe pain, vaginal reactions, and nausea and vomiting occurred in 102 (8.8%) of cases. Severe complications such as fever and clinical signs of peritonitis were encountered in 0.95% of cases, with tubo-ovarian absesses having been reported.[200] We do not routinely perform cervical cultures or use routine antibiotics; a recommendation shared by the Amercan College of Obstetricians and Gynecologists (ACOG).[201]

The risk of propagating cancer in case of endometrial cancer has been examined.[202] Fluid spilling from the fallopian tubes was collected while HySo was conducted preoperatively in 32 women diagnosed with endometrial cancer. Malignant and suspicious cells were recovered from tubal spills in 2 (6.25%) and 6 (18.8%), respectively, for a total of 8 (25%) findings of suspicious or malignant cells recovered from the 32 subjects. These authors strongly recommended that HySo not be performed in case of proven or suspected endometrial cancer.[202]

The value of routine pre-ART screening of the uterine cavity using hysteroscopy or HySO is being discussed.[203-205] In our program, women are synchronized with a short 7- to 14-day course of oral contraceptive (OC) pills during which time routine HySo is performed. We commonly remove incidental polyps while the patient is still on the OC pill. Performing HySo while the patient is on the pill offers the advantage of having an atrophic mucosa which precludes confusing a mucosal fold for a polyp. HySo or hysteroscopy should be part of the regular workup in case of repeated miscarriages.[206]

It is important to underscore that a comparison between HySo and office hysteroscopy goes beyond the ability to detect polyps, as each technique offers respective advantages. On the one hand, office hysteroscopy provides information about possible chronic inflammation or infection of the endometrium not otherwise identifiable,[88] including by cervical cultures.[207] On the other, HySo combined with pelvic ultrasound offers information about organs other than the uterus, namely the ovaries and possible cysts, that may be pertinent for sorting out the cause of DUB. Hence, the choice between HySo and office hysteroscopy should result from a process that takes into account all the issues pertinent to each clinical situation.

Hysterosonography in ART

In light of ART costs, many recommend routine assessment of the uterine cavity for the presence of polyps prior to ART using either HySo or office hysteroscopy, which are equally effective.[208,209] A recent meta-analysis reported data that collectively supports the value of removing even small polyps.[210] Hysteroscopic removal of endometrial polyps of 16 mm (mean) detected by ultrasound doubles the pregnancy

rate in patients undergoing intrauterine insemination.[210] In patients with two failed ART cycles, diagnostic or operative hysteroscopy before a subsequent attempt appears to improve outcomes.[210,211] It should be noted, however, that such benefit may result from nonspecific effects of any type of endometrial injury.[212] Fearing that systematic pre-ART HySo may lead to false positive findings generated by mucosal folds, it is recommended that HySo be performed either in the first 10 days of the follicular phase or better while on OC pill.

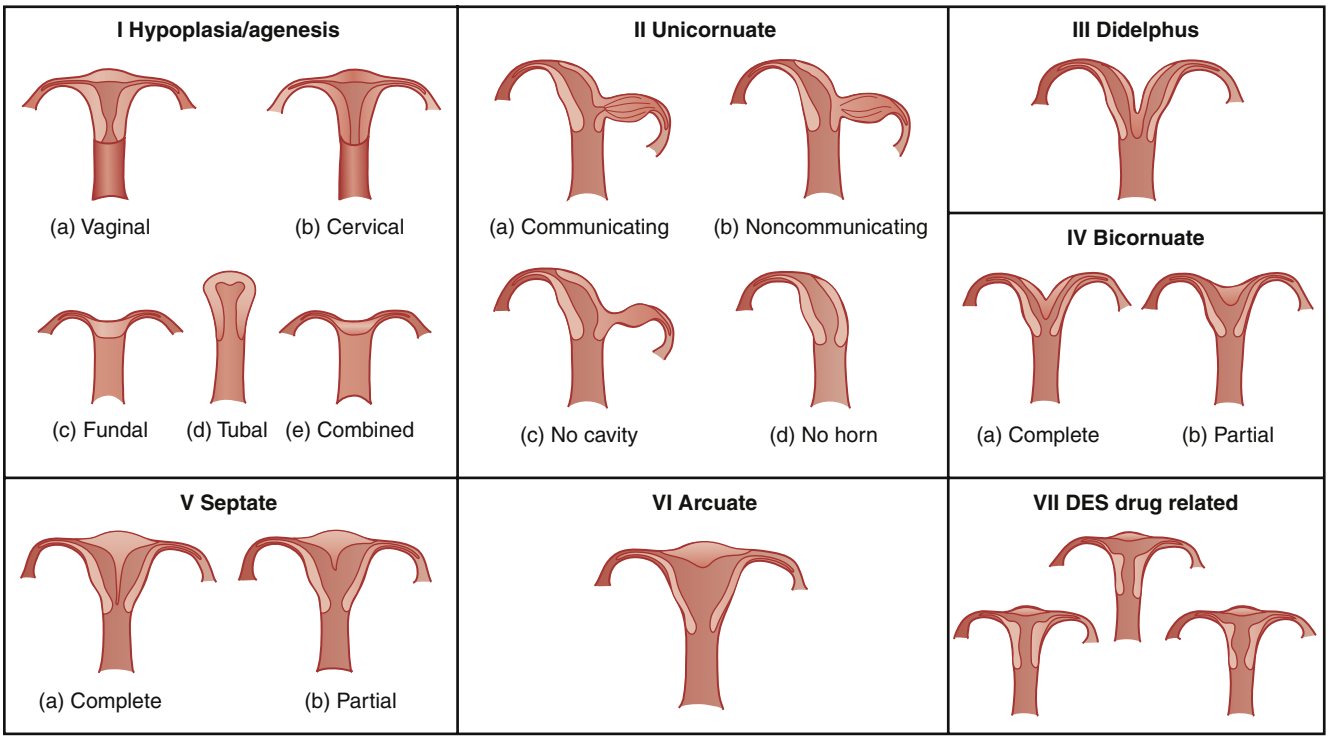
Müllerian Anomalies and Recurrent Pregnancy Loss

The true prevalence of uterine anomalies is uncertain because of the disparate reported numbers, with incidence ranging from 0.16% to 10%,[213] mainly based on interpretation of hysterosalpingograms. A selection of better structured studies reported a similar incidence of approximately 1% in infertile or presumably fertile women.[214-216] A higher incidence, approximating 3%, was found, however, in women having a history of recurrent pregnancy loss.[217-219]

Early in development (approximately 9 to 10 weeks), the common understanding has been that paramesonephric ducts fuse caudally while the uterine septum starts regressing in an unidirectional manner from the lower part of the uterocervical canal upward.[220] An alternate bidirectional regression theory exists, however.[221]

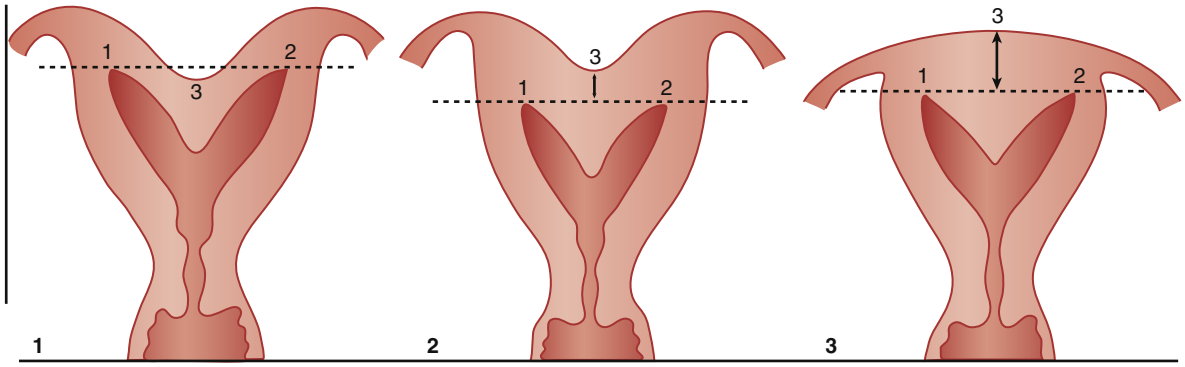
In a recent study, Mazouni and colleagues undertook a full evaluation of 110 women suspected of having a müllerian anomaly, using vaginal ultrasound, hysterosalpingography (HSG), computarized tomography (CT) scans, and in cases diagnosed in the later years, MRI.[222] Müllerian duct anomalies were reported according to the American Fertility Society (AFS) classification (Fig. 35.17).[223] Of the 110 patients referred for müllerian anomalies, 73 women had a septate uterus, 20 a bicornuate uterus, 10 uterine hypoplasia, 4 a unicornuate uterus, and 3 Mayer-Rokitansky-Kuster-Hauser syndrome. In 33% of the cases, the diagnosis was made as part of the infertility work-up, in 18.2% because of repeat early spontaneous abortion, and in 12.7% on the occasion of ultrasound performed during pregnancy. In cases of septate vagina, dyspareunia was a presenting symptom, accounting for 8.2% of all müllerian anomalies in this series.

The issue of how müllerian anomalies are best diagnosed has not yet been resolved. HSG was the traditional approach, and remains a useful if not indispensable examination in many cases. MRI, although helpful, should not be looked at as the primary means for diagnosing müllerian malformations, but rather used secondarily for defining cases too complex or atypical for definitive diagnosis on ultrasound.[222] 3D ultrasound with contrast enhancing solution stands as the diagnostic tool of choice for first-line screening for uterine malformations. Yet, admittedly, this novel approach has not been sufficiently challenged by use in low-prevalence populations. However, Woelfer and colleagues prospectively studied 1089 women with no history of infertility or recurrent early fetal losses using a 3D ultrasound.[224] The scanned uteri were analyzed in reconstructed coronal planes, looking at a series of parallel transverse sections and analyzed according to the AFS classification (Fig. 35.17). Briefly, normal and arcuate uteri were recognized by their convex external contour with indentation less than 10 mm. The fundal contour, which was straight or convex in the normal uterus, was concave in the case of arcuate uterus (indentation at obtuse angle) and showed the presence of a septum with the central point of the septum at an acute angle. In the bicornuate uterus, the external contour showed an indentation greater than 10 mm dividing the two cornua with a convex fundal contour in each. Of the original 1289 women recruited into the study, 200 were not suitable for analysis because of poorly visualized uterus primarily due to fibroids distorting the cavity. Of the remaining 1089 women, 983 had a normally shaped uterine cavity. Of the 106 (9.7%) uterine anomalies, there were 72 (68%) arcuate, 29 (27%) septate, and 5 (4.7%) bicornuate uteri.[211]



Extending their research on uterine malformations, this team looked at uterine anomalies in 509 women with a history of unexplained recurrent miscarriages and 1976 asymptomatic women in whom a uterine anomaly had been diagnosed fortuitously on ultrasound.[225] There was no difference in relative frequency of various müllerian anomalies or depth of fundal distortion between the two groups. However, in the case of both arcuate and septate uterus, the length of the remaing undisturbed uterine cavity was significantly shorter with more pronounced distortion in the recurrent miscarriage group. This observation is clinically important. It indicates that it is the degree of the müllerian malformation that bears the most important consequences on reproductive outcome rather than the type of malformation encountered.

Uterine Contractility: Direct Visualization on Ultrasound



Contractility of the Nonpregnant Uterus: Methodological Issues

Detection of contractions in the nonpregnant uterus previously required the invasive measurement of intra-uterine pressure (IUP). The ability to study uterine contractility by ultrasound has revived interest in this facet of uterine physiology, leading to multiple studies aimed at understanding the role of contractility in reproductive physiology. Uterine contractions (UC) are characterized by three parameters: frequency, amplitude, and direction of contraction. Also pertinent to the contractile status of the uterus is the IUP value that prevails between UCs or *resting tone*.

Identifying UC on ultrasound scans has benefited from various forms of image management, which were necessary because of the relatively slow frequency of UC (maximum of 5 UC per minute in the late follicular phase), making direct UC identification difficult. Most commonly, uterine scans are accelerated by 5 to 10 times for UC identification, using fast plays of VHS recordings[226,227] or digitized image sequences.[83] Some investigators have used custom computer assisted systems for UC recognition and computation of UC frequency. Ayoubi and colleagues[83] used an off-line 3D reconstruction system providing time mode image sequences depicting time-related changes of the myometrial to endometrial interphase (Fig. 35.18). On these sequences, UCs appear as successive waves created by the periodic displacement of the myometrial to endometrial interphase. We demonstrated in a prospective trial that the 3D-based approach and direct identification of UC on fast plays of digitized image sequences provide identical

The uterus is bicornuate when apex of the fundal external contour occurs below (1) or within 5 mm above (2) a straight line between the tubal ostia. The uterus is septate when apex is more than 5 mm above the line between the tubal ostia (3). DES, diethylstilbestrol.

UC frequency results.[83] More recently, Pierzynski and colleagues used a system based on image distortion recognition for UC identification.[228] In a prospective trial conducted in estrogenized women, Bulletti and colleagues reported perfect concordance between UC frequency measurements made by IUP analysis and UC recognition on ultrasound scans using a 3D-based approach.[229] This study provided definitive validation of the noninvasive ultrasound-based approach for UC frequency measurement.

The direction of contractions has been assessed by visualizing the displacement of the contractile process on fast plays of uterine scans. Based on direct UC visualization, various types of contractions have been described, ultimately leading to the recognition of two primary types: either retrograde, cervix to fundus; or antegrade, fundus to cervix. It is of note, however, that ultrasound-based analysis of UC displacement have never been validated by comparing ultrasound findings against the actual propagation of the pressure wave, as measured by multiple IUP recorders[230] or displacement of the uterine contents.[231] UC amplitude and uterine resting tone also evade ultrasound-based analyses.[157,232]

Uterine Contractility During the Menstrual Cycle: Three Characteristic Patterns

There are typically three patterns of uterine contractility that are recognized during the menstrual cycle. These are emblematic of the late follicular phase, luteal phase, and intercycle interval (i.e., during menses).[83,233] Each of these patterns is defined by sets of UC characteristic such as frequency, amplitude, and direction of contractions.

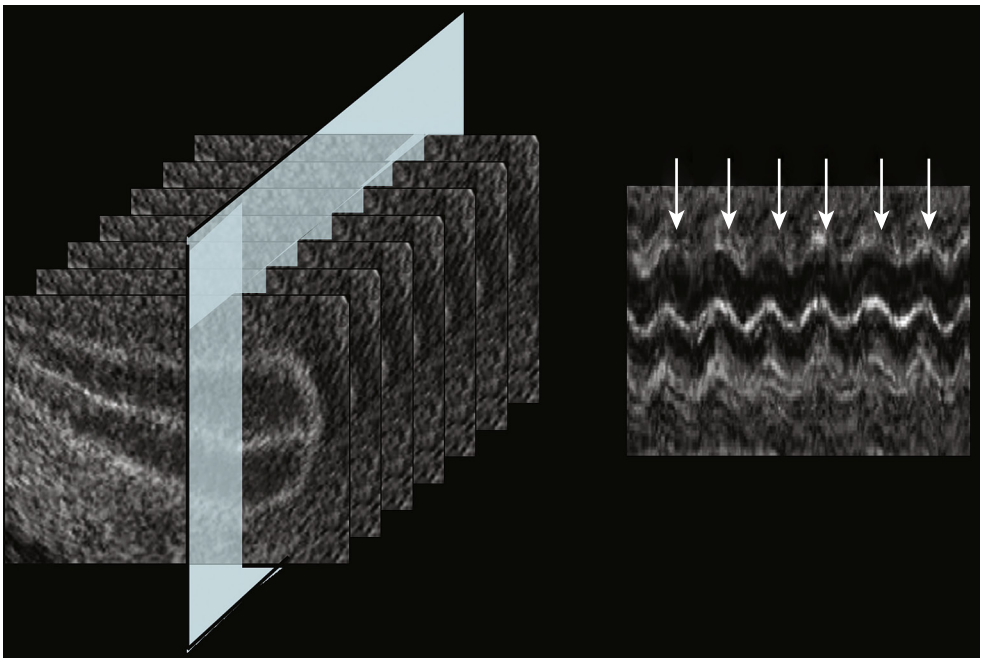

FIGURE 35.18 3D-based approach for uterine contraction (UC) assessment. 2D images are recorded over time without sweeping through a given territory. Hence, the z-axis represents time. On these electronically reconstructed time mode™ scans, displacements of the myometrial-endometrial interphase take the appearance of periodic waves, with each wave individually representing an actual contraction of the uterus.

Follicular Phase

During the follicular phase, there is a progressive increase in uterine contraction (UC) frequency under the influence of rising E_2 levels,[83,234,235] which culminates at approximately 5 UC per minute just prior to ovulation.[73] Characteristically, only the subendometrial layers of the myometrium are involved in these contractile events, which are never perceived by women despite UC frequency being higher at that time than at any other time in the menstrual cycle.[24]

The majority of investigators,[83,236] but not all,[237] have reported a clear predominance of UC dysplaying retrograde cervix-to-fundus displacement during the late follicular phase. In these studies, UC displacement was evaluated on fast plays of ultrasound sequences, or by analyzing the propagation of the increase in the IUP signal.[231] Yet, determining the UC direction is complicated by two unknowns: (1) While the contractile structure that is responsible for UCs is the subendometrial portion of the myometrium, the visualized phenomenon on ultrasound images is the result of the displacement of the endometrium. Hence, the parameter that is analyzed is an indirect reflection of the contractile process. (2) Ultrasound identifies the apparent retrograde displacement of contractile waves without establishing whether this does or does not result in true displacement of the uterine contents. In the case of sperm for example, retrograde transport will also depend on whether an appropriate opening takes place or does not take place at the utero-tubal junction when the contractile event reaches the junction.

Retrograde UCs identified during the late follicular phase are thought to be instrumental in the rapid transport of sperm that takes place from the vagina to the pelvic cavity following intercourse in the late follicular phase.[231,238,239] Thus, UCs and possible disruption of their patterns, may, therefore, play a key role in the reproductive process and in certain forms of infertility. However, as stated above, echographic analyses of UC direction have never been shown to correlate with the actual displacement of uterine contents.

Using ^{99}Te labeled macro-albumin aggregates (MAA), Leyendecker's team showed that contractions with retrograde displacement of uterine contents predominate during the late follicular phase.[235] These authors also observed that transport takes place toward the tube facing the developing follicle.[24,235] In various intervention trials, Leyendecker's team reported evidence for the involvement of oxytocin (OT) in the retrograde contractions encountered during the late follicular phase.[24,231] That OT, and possibly vasopressin (AVP), play a physiological role in late follicular phase UCs, and are instrumental in the control of sperm transport, remains to be determined. Retrograde displacement of uterine contents triggered by late follicular phase UCs appears to be disrupted in women suffering from endometriosis[235] or intramural uterine fibroids.[156,157] This could be responsible for the infertility that accompanies both conditions.

Luteal Phase

During the luteal phase, the UC pattern is characterized by a state of uterine quiescence brought about by the smooth muscle relaxing properties of progesterone. In a prospective trial, Wilcox and colleagues[240] showed that pregnancies never occurred when the single unprotected intercourse took place after the day of ovulation. This finding may be explained in part by the utero-relaxing properties of progesterone and the resulting decrease in uterine contractility, particularly the retrograde UCs that are thought to be involved in sperm transport. In experimental trials, exogenous E_2 and progesterone reproduce the UC patterns encountered in the follicular and luteal phases, respectively (Fig. 35.19). Ayoubi and colleagues observed that physiological E_2 replacement administered to young women suffering from premature ovarian failure (POF) resulted in UC

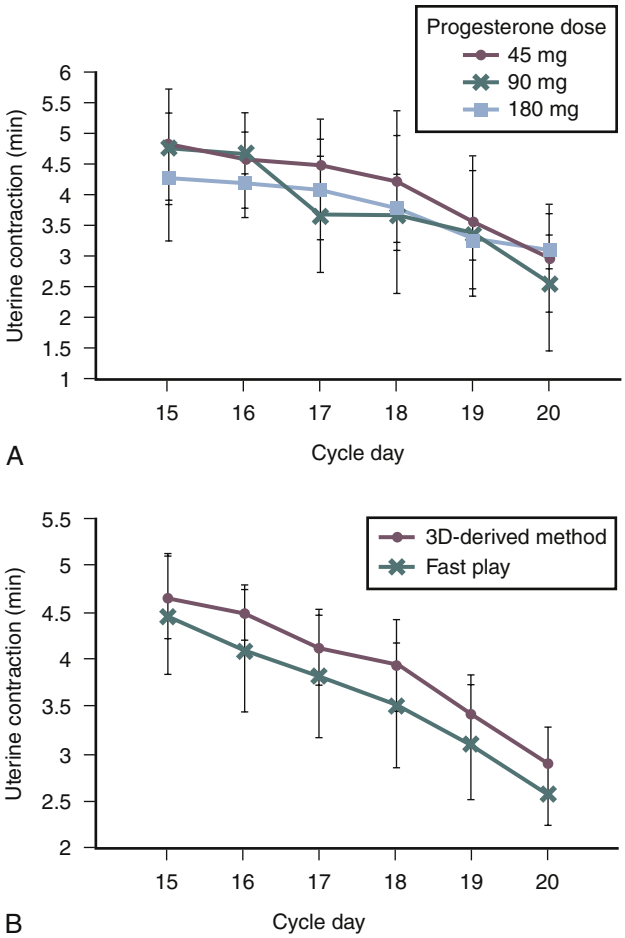

FIGURE 35.19 Effects of exogenous progesterone on uterine contractility. **A,** In estrogenized women, exogenous administration of 45, 90, and 180 mg of progesterone/day resulted in a prompt decrease in uterine contraction (UC) frequency without dose-related differences. **B,** Direct measurements from fast plays of ultrasound sequences or using the 3D-derived method gave similar results. *(Ayoubi JM, Fanchin R, Kaddouz D, et al. Uterorelaxing effects of vaginal progesterone: comparison of two methodologies for assessing uterine contraction frequency on ultrasound scans.* Fertil Steril *76:736, 2001.)*

frequency patterns that were similar to those encountered in the menstrual cycle particularly, during the follicular-luteal transition.[83] Transvaginal administration of 45, 90, and 180 mg of progesterone per day using a sustained release vaginal gel, Crinone, resulted in a prompt decrease in UC frequency with no dosage-related differences. This indicates that following physiological estrogen exposure, minimal amounts of progesterone suffice to induce full utero-quiescence, as seen in the luteal phase of the menstrual cycle.[83]

Intercycle Interval

During the intercycle interval (menses), uterine contractility increases in response to withdrawal from the utero-relaxing properties of progesterone upon demise of the corpus luteum, or discontinuation of exogenous progesterone or progestin administration. The role of concomitant withdrawal from E_2 also produced by the corpus luteum and supplied in most OC preparations remains a matter for debate. In contrast to the late follicular phase, all layers of the myometrium are involved in UC experienced by women at the time of menses. Moreover, UCs are commonly perceived by women at that stage of the cycle. At times, UCs occuring during the inter-cycle interval are painful enough to cause dysmenorrhea, characterized by painful uterine cramping. UC amplitude and resting tone are markedly higher during menses than at any other time during the menstrual cycle.[230,233,241] These are the two parameters that are most increased in dysmenorrhea.[241]

Using MRI-based analyses, Kataoka and colleagues showed an enlargement of the subendometrial layer of the myometrium in dysmenorrheic women on cycle day 1, at a time when these women experienced strong cramping. Uterine images returned to normal on day 3 of the cycle when cramping had subsided (Fig. 35.20).[232] In a prospective trial, Kido and colleagues compared the characteristics of MRI of the endometrium and subendometrial layer of the myometrium in 25 women on OC pills and 23 others having regular menstrual cycles.[157] This trial revealed that endometrial distortion was significantly less prominent, and the subendometrial low intensity area significantly thinner, in the OC group who also presented a lesser degree of cramping as compared to their cycling counterparts.[157] MRI is, therefore, the only imaging method providing noninvasive information on UCs that parallel clinical symptoms in dysmenorrhea.

Effects of Uterine Contractility on ART Outcome

Ayoubi and colleagues[83] were first to report an inverse correlation between UC frequency at the time of embryo transfer (ET) and IVF outcome (Fig. 35.21), a finding supported by data from others,[242] but not all groups.[243] More frequent uterine contractions had negative consequences for implantation and pregnancy rates. As UCs were measured prior to conducting embryo transfers (ETs), the study reflected the state of contractility prevailing prior to ET, not the impact of the ET procedure itself on contractility. In further trials, an inverse correlation between the progesterone levels on the day of ET and UC frequency was observed.[116] Furthermore, an earlier onset of progesterone treatment on the day of oocyte retrieval lowered UC frequency on the day of ET, with a trend toward better pregnancy rates.[83] Similarly, delaying ET to the fifth day after oocyte retrieval resulted in a profound reduction in UC frequency at the time of ET.[83]

Following extensive analyses of UC patterns as observed by ultrasound, Ijland and colleagues[237] reported that women in whom UCs were predomanantly retrograde had higher pregnancy rates. The observation that certain IVF patients have increased UC frequency at the time of ET raises questions about the mechanism(s) at play. In a prospective trial, we studied UC frequency in the same patients during the menstrual cycle that preceded IVF and the IVF cycle itself.[73] In these women, UC frequency reached a similar maximum on the day of the LH surge and hCG administration, despite E_2 levels being markedly higher in the IVF cycle as compared to the menstrual cycle. This suggests that the E_2 levels of the menstrual cycle already exert a maximal effect on UC frequency prior to the LH surge or hCG administration.[73] As illustrated in Figure 35.22, a marked difference in UC frequency exists after ovulation. In the menstrual cycle, uterine quiescence induced by progesterone is observed as early as day 4 after the LH surge, with a mean UC frequency of 1.1 per minute. In contrast, UC

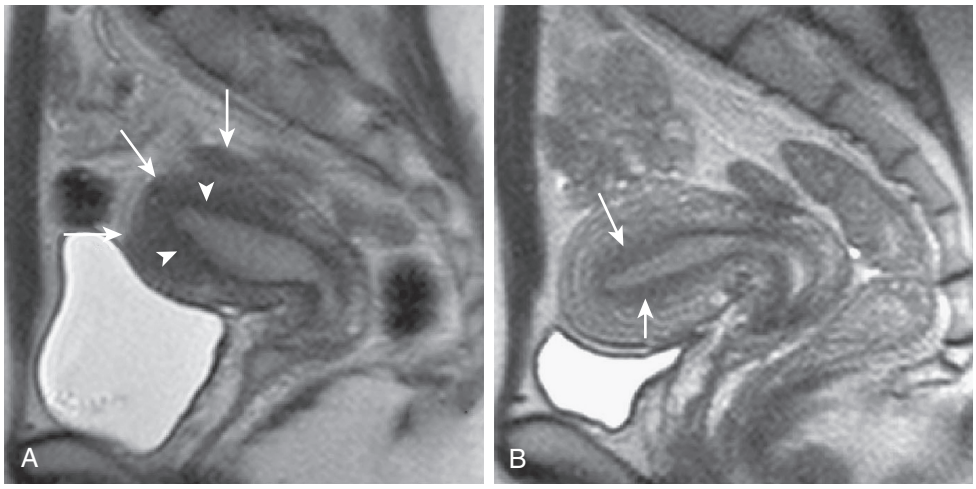

FIGURE 35.20 Using magnetic resonance imaging (MRI), differences were observed in the junctional zone between women experiencing severe dysmenorrhea on day 1 of the menstrual cycle **(A)** and the same women assessed on day 3 when cramping had subsided **(B).** On day 1 a characteristic distortion of the endometrium *(arrows)* and a thickened junctional zone *(arrowheads)* was noticed, a finding that paralleled the intensity of pain perceived. On day 3, when pain had subsided, the endometrium and junctional zone had returned to normal. *(From Kataoka M, Togashi K, Kido A, et al. Dysmenorrhea: evaluation with cine-mode-display MR imaging—initial experience.* Radiology *235:124, 2005.)*

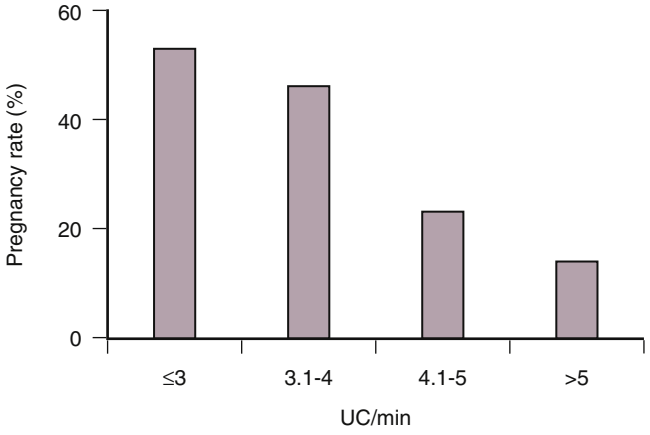

FIGURE 35.21 Uterine contractility (UC) just prior to embryo transfer and pregnancy rates. In women who all had three good embryos available for transfer, an inverse correlation was observed between UC frequency and pregnancy rates. *(From Fanchin R, Righini C, Olivennes F, et al. Uterine contractions at the time of embryo transfer alter pregnancy rates after in-vitro fertilization.* Hum Reprod *13:1968, 1998.)*

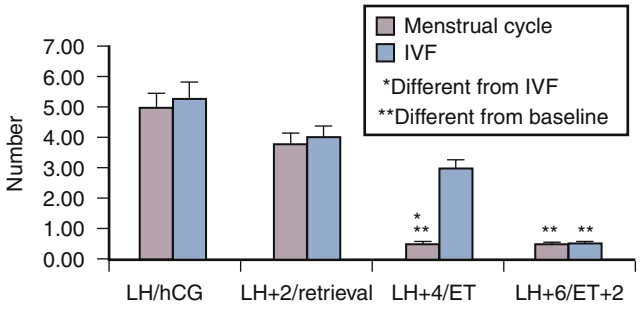

FIGURE 35.22 UC frequency was measured in the same patients, in the menstrual and IVF cycles. UC frequency was similar on the day of LH surge and hCG administration, indicating that the supraphysiological levels of E_2 encountered in ART do not further stimulate UC frequency over what is encountered in the menstrual cycle. Following ovulation, UC frequency decreased earlier in the menstrual cycle than it did in ART, indicating that a relative degree of resistance to the uterorelaxing properties of progesterone exists in ART, most likely as a result of elevated E_2 levels. UC, uterine contractility; E_2, estradiol; ART, artificial reproduction technology; hCG, human chorionic gonadotropin; IVF, *in vitro* fertilization; LH, luteinizing hormone; ET, embryo transfer. *(From Ayoubi JM, Fanchin R, Kaddouz D, et al. Uterorelaxing effects of vaginal progesterone: comparison of two methodologies for assessing uterine contraction frequency on ultrasound scans.* Fertil Steril *76:736, 2001.)*

frequency remained high at 3.6 per minute on the 4th day after hCG administration, ultimately declining on day 6. Of note, however, these women started receiving exogenous progesterone on day 4 after hCG (after the UC measurement). Exogenous progesterone, therefore, may have been instrumental in the decrease in UC frequency observed on the 6th day after hCG in IVF. Taken together, these findings suggest that some degree of resistance to the uterorelaxing properties of progesterone exists in IVF, possibly related to high E_2 levels.

Pierzynski and colleagues[228] provided pilot data suggesting that exogenous administration of the OT antagonist, atosiban, resulted in decreased UC frequency prior to ET. These findings open up new avenues for uterorelaxing therapy in relation to ET using OT and vasopressin receptor antagonists,[244] when other uterorelaxants have failed.[245]

Imaging Markers of Endometrial Receptivity

The endometrial parameters assessed by uterine imaging that have been proposed as markers of endometrial receptivity are endometrial thickness and volume, echogenicity, Doppler perfusion parameters, and contractile patterns. Endometrial thickness reflects endometrial priming by estrogen necessary for an appropriate response to progesterone and, in turn, endometrial receptivity. Rashidi and colleagues[246] reported no correlation between endometrial thickness on the day of hCG administration and pregnancy rate. Endometrial thickness was not different at 10.1 and 10.2 in pregnant and nonpregnant patients, respectively.

Okohue and colleagues reported that an endometrial thickness 7 to 14 mm was associated with better outcome than when the endometrium was either less than 7 mm ($P = 0.004$) or greater than 14 mm ($P < 0.0001$),[247] data in agreement with those of others.[246] The early report by Casper's group of poorer outcome in case of excessively thick endometrium[100] was not confirmed in later studies, such as that of Richter and colleagues on 1294 patients.[89]

The possibility of positive bias towards a thicker endometrium could result from its relationship to heftier responses to COH, a parameter that is associated with better IVF outcome.[248] By extension, a positive bias for Doppler findings of higher perfusion could be the consequence of an association with a more robust ovarian responses to hMG and FSH, and consequently increased oocyte quantity and quality. Whether different ovarian stimulation protocols had different impacts on endometrial thickness was loooked at by Imoedemhe and colleagues.[249] These authors compared the effects of regimens using clomiphene citrate (CC) alone (regimen I) or in combination with 75 IU (regimen II), or 150 IU of hMG (regimen III), and found no differences in endometrial thickness.

Raga and colleagues examined the predictive value of 3D endometrial volume calculations for the establishment of pregnancy in ART.[11] In a study on 72 IVF cycles, pregnancy rates were significantly lower when endometrial volume was less than 2 mL as compared to 2 to 4 mL or greater than 4 mL. Zohav and colleagues found no differences in endometrial volume in 60 women pregnant through IVF, but observed that endometrial volume of less than 2 mL was associated with a significant increase in pregnancy loss.[248] A recent study on E_2 and progesterone cycles for frozen embryo transfers came to similar conclusions that lower volumes are an ominous sign.[75] Ferriani's group reported on endometrial volume measured one week after ET.[250] A significant difference was found between the endometrial volume of pregnant (6.49 ± 1.97 mL) and nonpregnant women (3.4 ± 1.1 mL) and, but to a lesser extent, endometrial thickness. This latter observation of a difference in endometrial volume by a factor of nearly 2, 1 week after ET, between pregnant and nonpregnant women likely reflects a direct early influence of the developing pregnancy on the endometrium rather than preexisting differences. This finding is in agreement with the report of an early increase in E_2 production that even precedes that of hCG in the late luteal phase of conception cycles.[251]

Endometrial echogenicity or 'pattern' has been proposed as a marker of endometrial receptivity.[252] In early work, Casper's team, who observed no differences in endometrial thickness between pregnant and nonpregnant women, reported three different patterns of endometrial echogenicity on the day after hCG administration.[107] In these investigators' hands, a hypoechoic endometrium carried a good prognosis. Numerous publications support the notion that a hypoechoic endometrium with a full three-line pattern is associated with good ART outcomes,[108-113] although some failed to find a good predictive value of endometrial echogenicity.[114,115]

According to Rosenwaks' team, a hyperechoic endometrium is a particularly ominous sign in women exposed to DES.[253] Pregnancy outcome relative to endometrial thickness and pattern was evaluated in 540 cycles of IVF including DES (n = 50) and non-DES-exposed (n = 490) women. Endometrial patterns were designated as p1 = solid; p2 = ring; and p3 = intermediate. DES patients exhibited the 'p1' pattern more often than the majority of the non-DES-exposed group. There was no significant difference in endometrial thickness among the cycles where 'p1' was noted when comparing the DES (10.3 mm) with the non-DES-exposed (10.7 mm) groups. Notably, within the group exhibiting 'p1', no pregnancies occurred in the 18 cycles of DES-exposed women compared with a 39.2% clinical pregnancy and 36.5% delivery rate in the non-DES-exposed controls ($P < 0.0001$ and $P = 0.008$, respectively). The impact of uterine shape on pregnancy outcome was also investigated. A T-shaped uterine configuration was noted in 11 out of 18 (61.1%) cycles of DES-exposed women with pattern 'p1' compared with 9 out of 23 (39.1%) with pattern 'p2'. Of cycles where a T-shaped uterus was demonstrated, none out of 11 (0%) with pattern 'p1' compared with 4 out of 9 (44.4%) with pattern 'p2' resulted in pregnancy ($P = 0.026$). These data suggest that the endometrial pattern is one of the most significant variables for pregnancy outcome in DES-exposed women undergoing IVF.

The two last parameters proposed as markers of endometrial receptivity are Doppler data on endometrial and subendometrial vascularization and uterine contractility. Early Doppler studies that claimed to identify flow parameters that precluded the possibility of embryo implantation were never verified. Instead, all available studies that used either pulsed Doppler data or the more sophisticated and operator independent 3D-PDA failed to find differences between conception and nonconception cycles.[5] These findings showing that Doppler data—even using the newest and most sophisticated techniques—are not predictive of ART outcome were confirmed by recent reports.[21,254] Hence, Doppler data cannot be considered to be a marker of endometrial receptivity. In our experience, increased uterine contractility portends poor embryo implantation rates.[221] These findings have been confirmed by some researchers,[228] but have been challenged by others.[243]

Embryo Transfers

ET should be performed with utmost care. Sloppy practices and imprecise placement of the transferred embryos in the uterine cavity undermine the good clinical and biological work that came together to obtain these embryos.[255] Interestingly, it is the very person who first conceived oocyte retrieval under ultrasound guidance[256] who was the first to advocate in 1987 for ultrasound-directed embryo transfers.[4]

In 1991, a prospective trial reported higher pregnancy rates in 94 women who had an ultrasound-guided transfer as compared to 246 controls who had the classical approach. Similar benefit was found in donor egg recipients. In a retrospective comparison of 137 embryo transfers, Lindheim and colleagues showed that pregnancy and embryo implantation rates were higher in women whose transfers were ultrasound-guided as compared to their counterparts in whom ultrasound was not used,[257] a finding confirmed by Coroleu and colleagues with even greater differences.[258] These pioneering studies were later supported by numerous others, including sets of meta-analyses,[259-262] although a few reports failed to document the superiority of ultrasound-guided transfers.[263-265] Ata and Urman argued against the conclusions

of non-superiority.[266] They noted that no ultrasound-guided trial reported lower results than the classical "clinical touch" method. Ata and Urman also underscored the fact that not all ultrasound-guided trials placed the embryos where their chances of implantation were optimal.[266] Flisser and Grifo, whose own study showed no improvement in pregnancy rates with ultrasound-guided transfers, nonetheless recommended systematic use of ultrasound,[263] since it is impossible to preemptively determine who is likely to benefit from ultrasound-guided ET. A recent meta-analysis that retained 17 trials out of 59 identifed in the literature on ultrasound-guided transfers. In 7 out of 17 of these trials that reported on clinical pregnancy rate, ultrasound-guided ET resulted in improved ART outcomes.[267] Bodri and colleagues suggested that vaginal ultrasound may be used as effectively as the abdominal approach, while providing further comfort for the patient.[268]

With the ability to visualize the tip of the ET catheter, ultrasound-guided transfers beg the question: Which is the optimal location in the uterine cavity for transfer? Data from prospective trials unveiled a counterintuitive scenario: ETs are more successful when performed low rather than high in the uterine cavity. As early as 2002, Coroleu and colleagues reported a prospective trial in which embryos were transferred in 180 consecutive IVF patients at 1, 1.5, and 2 cm from the fundus.[259] Unequivocally, embryo transfers performed 2 mm and 1.5 mm from the fundus resulted in higher pregnancy rates than seen when embryos were placed 1 mm from the fundus. In agreement with these findings, Pope and colleagues observed in a retrospective analysis that the further away the tip of the catheter was from the fundus, the higher the pregnancy rate.[269] A regression analysis in this trial indicated that each millimeter in excess of 1 cm from the fundus translated in an 11% increase in pregnancy rate, a trend later confirmed by others.[5]

As interest in ultrasound-guided transfers gained momentum, industry designed catheters specially equipped with echogenic tips that facilitate visibility on ultrasound. A randomized controlled trial (RCT) comparing a standard ($n = 95$) and a new echogenic soft Wallace catheter ($n = 98$) revealed a trend ($P = 0.08$) for higher pregnancy rates with the echogenic catheter,[270] a finding confirmed by others,[271] but not all studies.[21] It appears, therefore, that while new echogenic catheters are easier to visualize, they do not necessarily bring higher pregnancy rates. Fang and colleagues recommended verifyng the proper positioning of the catheter on 3D-ultrasounds for fear that if the tip deviated from the 2D-plane it might not be properly identified.[272] These authors thoughtfully claim that in such a situation, the tip might be actually more advanced, which would be detriemental. The same argument would favor a catheter having its echogenic mark limited to its tip rather than full length of the catheter for best assurance that the echogenic mark represents the true tip of the catheter. A closing comment regarding the competitive comparisons between various ET catheters is offered by Yao and colleagues, who report that the results of such comparisons are operator-dependent.[273] In 1446 embryo transfers performed in 1155 women undergoing ART, 723 cycles were randomized to 'soft' (Cook) and 723 others to 'semi-soft' catheters (Frydman®). Overall, the odds ratio of clinical pregnancy for the Cook versus the Frydman catheter were not different at 1.11 (95% CI: 0.89 to 1.38). Yet, these differed significantly for two of the three operators, being at 1.19 (95% CI 0.84 t 1.69), 2.35 (95% CI 1.40 to 3.95), and 0.69 (95% CI 0.48 to 0.99) for each of them.[273]

Using ultrasound-guided ET in routine ART practice is a valuable tool for teaching the procedure to new operators.[274] At our institution, new operators have to demonstrate competance at performing mock ETs under ultrasound guidance before moving on to actually performing true ETs.

Ovaries

Unlike the uterus, which reaches a definitive and stable size at the time of puberty (short of developing tumors like fibroids), the ovaries change in size and aspect throughout the different phases of their function. Transvaginal ultrasound provides an unrestricted view of the ovaries with the fluid-filled follicles presenting a characteristic echographic signature to this organ. This makes ultrasound the first choice imaging approach for exploring the ovaries, even in cases of obesity.

Ultrasound identifies two ovarian constituents: the cortex and stroma.[165,275,276] Following a description by Pache and colleagues,[277] the total count of 2 to 10 mm follicles in each ovary constitutes the antral follicle count (AFC).[278] Remarkably, the AFC shows little intracycle variation,[279] and is not affected by hormonal treatments such as the OC pill.[279,280] Granulosa cells of antral follicles are endowed with FSH receptors, rendering these the cohort of follicles capable of responding to rising FSH. They are, therefore, the recruitable follicles.[281] Recruitment by FSH takes place either through the physiological intercycle FSH signal or with exogenous FSH and hMG treatments administered in the context of ART. Therefore, the number of antral follicle—the AFC—will affect the magnitude of the ovarian responses to stimulation in ART or COS.[281,282]

We know from the work of Gougeon's team[135,283] that the cohort of antral follicles identified on ultrasound examination represents a constant fraction of the pool of primordial follicles remaining in the ovary at any given time (Fig. 35.23).[284] Thus, there are grounds for assuming that

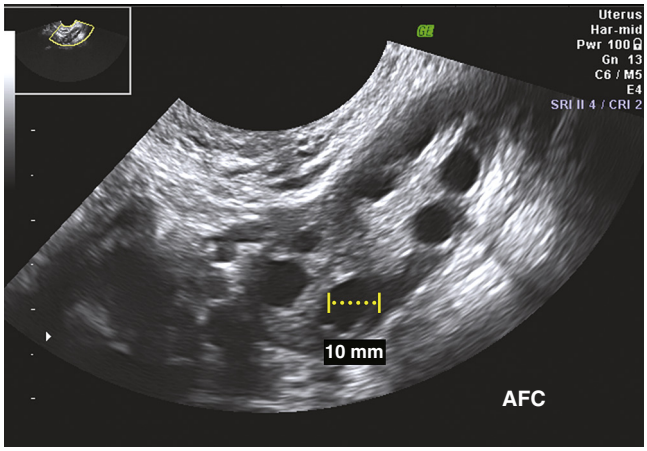

FIGURE 35.23 The antral follicle count (AFC). While the AFC does not fluctuate during the menstrual cycle, computation is classically done at baseline of the menstrual cycle (cycle day 2 to 4), because measurements are not hindered by a growing follicle or a corpus luteum. Traditionally, all follicles of 2 to 10 mm are counted.

the AFC reflects the number of remaining follicles, or ovarian reserve.[168,285] Therefore, the AFC aims at predicting: (1) the amplitude of the ovarian response to exogenous FSH and hMG or COS (for singling out excessive and poor responses and, therefore, adjustment of the doses of FSH and hMG accordingly) and; (2) ART outcome, on the assumption that it depends on the number of oocytes retrieved.[286] The latter point begs a question about whether oocyte quantity and quality are inherently linked or not. As discussed below, the nature of this link between oocyte quantity and quality differs based on whether a reduction in the AFC is age-dependent or independent.

The echographic characteristics of the ovaries (volume and/or AFC) are now taken into account when making the diagnosis of PCOS, per the joint ESHRE/ASRM Rotterdam consensus conference.[82] Ovarian volume and/or AFC represent one of the two of three criteria necessary for making the diagnosis of PCOS.

Large changes in blood flow take place in the ovaries during physiological (from follicular maturation to corpus luteum formation)[132] and abnormal function (ovarian stromal flow in PCOS),[287,288] or in the context of specific pathologies such as cancer.[289,290]

Ovarian Anatomy and Functional Changes

The Ovary Before and After Puberty

Ovarian growth in infants and children reflects functional changes rather than chronological age. In a prospective trial, Buzi and colleagues looked at 117 normal girls between the ages of 1.1 and 15.6 years, and 87 girls presenting with premature sexual maturation.[291] In girls showing no signs of abnormal sexual maturation, ovarian volume was 1.1, 2.3, and 5.3 mL in prepubertal, pubertal, and postmenarchial girls, respectively. These changes correlated better with Tanner stages of sexual development than with chronological age.[292]

In infancy and childhood, follicles begin their maturation and rapidly become atretic in the absence of gonadotropin stimulation, giving the ovary a microcystic pattern.[34,293] Before secondary sexual characteristics become visible, puberty-related changes take place with the ovaries showing changes in their morphology characterized by the presence of several follicles of 4 to 9 mm in size.[34] This appearance, sometimes referred to as megalocystic or multicystic,[294,295] needs to be distinguished from the polycystic ovary.[296-298]

The Ovary in the Menstrual Cycle

The intercycle interval constitutes the baseline state of the ovary in the menstrual cycle. Therefore, ovarian scans have been timed using this reference point for measuring the AFC for assessing the ovarian reserve and for predicting the response to COS in ART (Fig. 35.24). During the intercycle interval, the small 2 to 9 mm follicles, computed in the AFC, are the follicles capable of responding to FSH, whether naturally occurring or part of COS in ART.

Through daily evaluation of individual ovarian follicles on repeated transvaginal scans, Pierson's team identified bursts of synchronous growth in a cohort of follicles, or waves of follicle development.[299] These investigators identified minor waves of follicular growth leading to all the follicles ultimately undergoing atresia and major ones leading to further follicular growth and single follicular dominance.[299] The nature of the mechanisms controlling these successive waves encountered during the menstrual cycle still evades our understanding.

Follicular growth leading to follicular dominance can be ascertained by viewing follicles greater than 10 mm. From repeated measurements, it was determined that follicles reach the 12 to 13 mm mark on average by day 9 of the menstrual cycle.[299] At this stage, granulosa cells acquire LH receptors with evidence that follicular maturation can be promoted with LH only[300] or mini doses of hCG.[301-304] Follicular growth rate appears fairly constant in the menstrual cycle once follicles are greater than 13 mm, with a daily mean increment in diameter of 1.4 to 1.5 mm/day. Follicular growth is accelerated in COH, however, where it reaches 1.6 to 1.8 mm/day.[305]

The side of ovulation in the menstrual cycle and whether this regularly alternates from one cycle to the next has been a matter of enduring debate. Some reports based on histological evidence support the concept of alternating sides,[306] while others claim that it is not more frequent than expected by chance alone.[307] Finally, some propose that the side of follicular growth and ovulation only alternates in cases of short cycles,[308] while the ovulation side is randomly

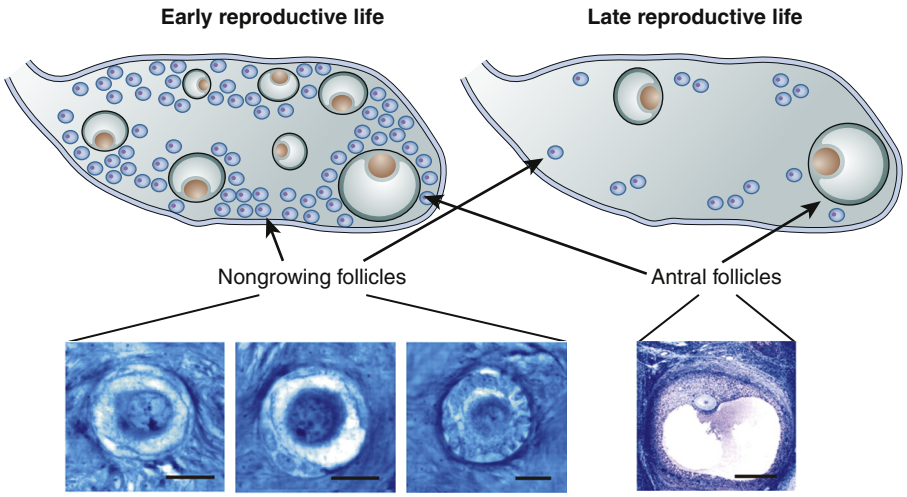

FIGURE 35.24 Nongrowing and antral follicles in early and late reproductive life. In early and late reproductive life, the antral follicle count (AFC) reflects the total number of follicles remaining, or ovarian reserve. *(From Hansen KR, Knowlton NS, Thyer AC, et al. A new model of reproductive aging: the decline in ovarian non-growing follicle number from birth to menopause.* Hum Reprod *23:699, 2008.)*

determined in cases of long cycles. Reassessing this latter paradigm, Fukuda and colleagues studied 410 natural cycles of 123 infertile women undergoing 267 IUI and 143 IVF natural-cycle treatments, respectively.[309] In this population, ovulation occurred contralaterally by reference to the preceding cycle in 57% of the 410 cycles, but in 72% of women whose follicular phase was less than 13 days. Conversely, ovulation occurred randomly on either side when the follicular phase was greater than 14 days, thereby giving credence to the concept that the side of ovulation only alternates in short cycles. From these authors' observation, ovulation appeared of better quality when occurring on the contralateral side with reference to the previous ovulation with better outcomes in both IUI and IVF cycles. This supports the concept that ovulation is of better "quality" when the dominant follicle is contralateral to the prior ovulation as compared to ipsilateral. Moreover, significantly higher estradiol to androstenedione and estradiol to testosterone ratios and lower androstenedione levels were observed in contralateral as compared to ipsilateral ovulation cycles. Practically speaking, therefore, the chance of conceiving during a natural cycle may be affected by the site of ovulation in the preceding cycle. The side of ovulation, however, did not influence Doppler blood flow in the ovarian stroma or follicular and uterine arteries.[310]

Pierson's team prospectively assessed imaging characteristics of the corpus luteum (CL) with daily ultrasounds in 50 normo-ovulatory women.[311] The CL was detectable on ultrasound scans in 100% of women during the luteal phase, with persistent structures found in 90% of women during the subsequent follicular phase. Two days after ovulation, a central fluid filled cavity was present in 88% of the cases, declining to 34% after 13 days and 2% after 27 days.[307]

The Ovary during Hormonal Contraception

The impact of OC treatment on ovarian follicles depends on the size of the follicles when OC treatment is initiated. In a prospective trial, Baerwald and colleagues determined that no follicular growth took place when all the follicles were less than 10 mm at the time of starting OC pills.[312] Conversely, approximately 30% of follicles that were greater than 14 mm at the onset of OC treatment went on to ovulate, while the rest regressed and became atretic. In parallel work, these investigators determined that follicular development takes place during the 1-week hormone-free interval of classical OC pill regimens.[313] In a trial looking at normal volunteers on OC pills, they determined that nearly half (47%) of women grew follicles greater than 10 mm, with 53% of them having follicles reaching 14 mm in diameter and an increase in E_2 production. Contrasting with these findings, echographic assessments showed similar rates of follicular growth in women using progestin only or barrier contraception in the postpartum period. Endometrial thickness was markedly reduced, however, in the progestin only contraception group, indicating that this form of contraception acts on the uterus and cervix rather than by blocking ovulation.[314]

Hormonal contraception causes a significant reduction in ovarian volume in normally cycling women[315] and in women suffering from PCOS.[290,316] In cycling women, the effect of hormonal contraception on ovarian volume was more profound in cases of continuous rather than cyclical administration of hormonal contraception.[317] Remarkably, however, AFC and AMH values remained unaltered in PCOS women receiving hormonal contraception, in spite of the reduction in ovarian volume observed.[290]

The Ovary Through Functional Aging and Menopausal Changes

Ovarian volume decreases with age. Early on in the high-resolution ultrasound era, their was optimism about the possible predictive value of ovarian volume measurements for future reproductive performance. Surveys of published data indicated that ovarian volume was a good and easily obtainable index of the primordial follicle population based on comparisons with Faddy's data.[318] Pavlik and colleagues retrospectively reviewed data from 58,673 ovarian scans obtained from 13,963 women 25 to 91 years of age who underwent annual scanning as part of ovarian cancer screening program. Ovarian volume was calculated using the prolate ellipsoid formula ($L \times H \times W \times 0.523$).[123] Mean ovarian volume was 6.6 ± 0.19 cm^3 in women younger than 30 years old with a decrease that reached statistical significance in women between the ages of 30 and 39 years old. Yet, the practicality of ovarian volume measurements for predicting ovarian reserve on an individual basis is somewhat limited, as clinically meaningful changes only materialize when women are at the boundaries of their entrance into the naturally infertile period of life. In Pavlik's analysis, it is in the group of women between 40 and 49 years of age that ovarian volume was found to be markedly reduced at $4.8 \pm 0.3 cm^3$. Ovarian volume decreased to 2.6 ± 0.01 cm^3 in postmenopausal women 50 to 59 years of age, with further decreases observed during the sixth and seventh decades of life.[123] In their extensive study, these authors also looked at relationships between height and ovarian volume. Their findings with no progressive increase with height, but a statistically significant break with higher volumes in women over 5 feet 8 inches tall. There was also a statistically significant reduction in ovarian volume in women younger than 50 years old taking estrogens, but not in postmenopausal women. In a retrospective chart review, Syrop and colleagues looked at possible different predictive values of the volume of the smallest and largest ovaries in individuals.[319] Their results indicated that the volume of the smallest ovary was a better predictor of peak E_2 levels and numbers of oocytes and embryos and clinical pregnancy in IVF.

By current definition, premature ovarian failure (POF) occurs when ovarian functions fail before the age of 40. This implies a complete form of hypergonadotropic hypogonadism with an implicit loss of fecundity. More commonly encountered in everyday ART practice are cases of premature ovarian insufficiency or occult POF (oPOF), which hide behind seemingly normal ovulatory cycles. In oPOF, the menstrual cycle is maintained and seemingly ovulatory, with no anomaly except maybe for a shortening of the cycle duration with a characteristically early ovulation.

Embedded amongst the classical POF and oPOF that results from early ovarian aging, there are sporadic cases of a variant disorder characterized by insensitive ovaries. The difference between oPOF and POF on the one hand, and the rare cases of insensitive ovaries on the other, is more than just an issue of terminology, as pregnancy is much more likely to be achieved in the case of insensitive ovaries. Assessing ovarian volume in POF or oPOF may identify the

subgroup of women suffering from insensitive ovaries for whom therapeutic efforts can be undertaken. In a prospective trial, Mehta and colleagues looked at 17 women with fully expressed POF.[320] Based on the ecographic appearance of their ovaries, these authors sorted POF women into two groups, with (n = 7) and without ovarian follicles (n =10). Hormonal parameters (FSH and E_2) and endometrial thickness were identical in the two groups, whereas ovarian volume was markedly larger at 2.8 ± 0.4 mL than in the no ovarian follicle group (1.4 ± 0.2 mL). On average, two follicles were identified in the "with follicles" group, whereas by definition none were identified in the "no follicle" group. These authors contend that ultrasound imaging of the ovaries allows identification of a subgroup of women presenting with hypergonadotropic hypogonadism who suffer from insensitive ovaries, rather than POF. Pregnancies are more likely to occur in insensitive ovaries than they are in POF following treatments aimed at lowering endgenous gonadotropins in order to resensitize FSH receptors. This is can be achieved by 2- to 3-month treatment with E_2 and progesterone for lowering FSH levels followed by FSH administration. Falsetti and colleagues observed normal ovarian volumes (3.1 ± 0.3 mL) in 14 out of 40 (35%) women with frank POF, whereas ovarian volume was significantly smaller in the remaining 26 (65%) women.[321] In all forms of POF and more importantly oPOF, screening for possible premutations of the *FMR1* gene should be considered. Ignored, these may transform to the full mutation in the next generation, possibly causing Fragile X syndrome in male offspring.[322]

In Turner syndrome, the number of primordial follicles has been estimated to be normal until at least the 18th week of fetal life, with uncertainties as to the time when atresia starts to accelerate.[323] The possibility of transplanting cryopreserved ovaries,[324] including the report of live-births,[325] has sparked interest in cryopreserving ovaries from Turner patients before follicle depletion is completed. In a prospective trial, Hreinsson and colleagues reported ovarian follicles present in eight of nine adolescent girls diagnosed with Turner syndrome, but who all underwent spontaneous onset of puberty.[326] In these adolescent girls, the density of primordial follicles in ovarian samples studied surgically showed an inverse correlation with plasma FSH levels. It would be probably more useful to cryopreserve ovaries in infancy or childhood, when the pool of primordial follicles remaining is likely to be much larger, provided that the diagnosis of Turner syndrome can be made that early. Unfortunately, normative data for infant and child ovary imaging (transvesical) have not been established, which creates challenges in the assessment of subjects who might be candidates for ovarian cryopreservation.

Assessing ovarian volume and particularly, differences in size between the two ovaries is useful when screening for ovarian cancer amongst other echographic criteria.[327] Based on their echographic analyses of postmenopausal ovaries, Campbell and colleagues concluded that the percentage mean difference between the two ovaries was 42.88% ± 32.05%.[328] These authors concluded that any finding showing an ovary with a volume that is greater than twice the size of the other ovary should be considered as suspicious of ovarian cancer.

Antral Follicle Count: A View of the Ovarian Reserve

For each woman, the endowment of primary oocytes is thought to be finite and established during intrauterine life. It progressively decreases to reach approximately 2 million at birth and 400,000 at puberty. Drawing from extensive histological studies of ovaries from women of all ages, Faddy and colleagues described a progressive decay of primordial follicles over time that followed a bimodal pattern (Fig. 35.25).[283] They identified a slow depletion rate that prevails until the age of approximately 37 years old. Then,

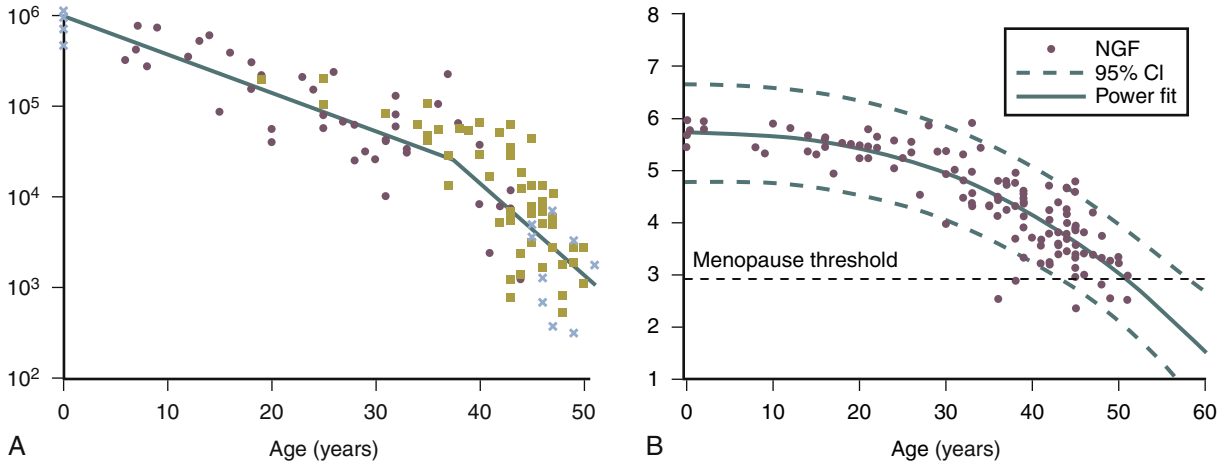

FIGURE 35.25 **A,** Depletion of primordial follicles over time. In their analysis, Faddy and colleagues observed an exponential decline of primordial follicles in a biphasic pattern. The first exponential rate parameter was calculated at –0.097 and the second at –0.237. The change from the first (slow decay) to the second (rapid decay) rate of follicular decline occurs when the number of remaining follicles falls under the critical figure of 25,000. On average this transition from the slow to the rapid follicular decline occurs at age 37.5 years, but occurs earlier in cases of of surgery for ovarian cyst. **B,** In contrast to the bimodal mode of follicular depletion, Hansen and colleagues propose a model with no sudden change in the rate of follicular decay, but rather a constantly increasing pattern. *(**A**, From Faddy MJ, Gosden RG, Gougeon A, et al. FIGURE 35.27 Method of AFC measurement. The AFC can be computed from 2D or 3D images. In the latter case, antral follicles can be counted using the multiplanar approach, scanning through the ovarian volume, or by automated analysis. The latter relies on an automatic antral follicle recognition system using the Sono-Automatic Volume Count technique based on a 3D-inversion mode rendering method. Using software that individually color codes each identified follicle and provides an objective measurement of its mean and absolute diameters and its volume. **A**, The initial fully automated assessment missed several antral follicles. **B**, The same ovary after these missed follicles have been manually identified through postprocessing. *(From Deb S, Jayaprakasan K, Campbell BK, et al. Intraobserver and interobserver reliability of automated antral follicle counts made using three-dimensional ultrasound and SonoAVC.* Ultrasound Obstet Gynecol *33[4]:477–483, 2009 Apr.)*

when the number of oocytes remaining becomes less than 25,000, an abrupt increase in oocyte depletion rate appears to take place, or fast depletion rate. The change from the slow to the fast depletion rate of primordial follicles takes place at approximately the age of 37 years. These authors suggested, however, that it is the number of remaining follicles—the critical number being 25,000—that triggers the acceleration in the depletion rate, not the age, per se. However, the claim that follicular depletion over time follows a bimodal pattern has been challenged by Hansen and colleagues.[284] These latter authors contend, on mathematical grounds, that follicular depletion over time follows a progressive acceleration pattern described by a power function, rather than the bimodal model (Fig. 35.26).

The methodology for AFC measurement has been the source debate. Both 2D or 3D approaches for AFC measurements showed good overall interobserver and intraobserver reliability.[329] Recently, a novel method of AFC assessment was developed based on automatic isolaton volumes of low echogenicity—the antral follicles—known as the 3D inversion mode rendering or SONO-AVC® method[330] (Fig. 35.27). AFC measurements made by classical 2D- or 3D-based approaches revealed that automated measurements took slightly more time and in general yielded lower values.[331] Jayaprakasan and colleagues determined that the variability AFC was significantly lower with inversion mode, while it was equivalent when measured with the 3D multiplanar and 2D equivalent methods. Yet, the authors determined that interobserver reliability was affected by image quality when using the 3D-rendered inversion method.[332] Moreover, mean time for measurement varied greatly with the methods used, ranging from 34 to 50 to 216 seconds for the three methods.[332]

AFC has been found to correlate with the number of oocytes retrieved in COH[333-335] and risk of developing

OHSS.[336] In a prospective trial, AFC was found superior to basal FSH for predicting ovarian response to COH.[337] Ng and colleagues[336a] compared AFC to serum FSH measured at baseline and post-clomiphene citrate challenge test (CCCT) for their predictive values regarding ART outcome. These authors found that AFC that remained unchanged after stimulation (CCCT) or after GnRH down-regulation, had the best predictive value for the quantitative outcome of COH expressed by the number of oocytes retrieved. This was followed by combined baseline and post-CCCT FSH concentration and age of the woman. Baseline and post-CCCT FSH concentration was a slightly better predictor of E_2 values.

In a prospective trial, Jayaprakasan and colleagues looked at the predictive value of AFC assessed from 3D data and compared their data to baseline FSH levels. One of three methods of measurement was used, including the new 3D-rendered inversion mode.[332] These authors' results indicated that total AFC was the best predictor of the number of oocytes retrieved in ART followed by baseline FSH. Moreover, AFC was significantly lower in the nonpregnant group. AFC less than 7 (less than 6 using 3D-rendered inversion mode) predicted poor ovarian response leading to cycle cancellation with sensitivity of 100% and specificity ranging from 93% to 96%, depending on the method used. Prediction of nonconception was low for all methods of AFC measurement. Data obtained from 3D-rendered inversion mode were the closest to the actual number of oocytes retrieved. More recently, SONO—AVC has been used for an automated assessment of the growing follicles in ART, which was demonstrated to be reproducible and reliable,[338] as well as acruate.[338]

Haadsma and colleagues proposed that amongst the cohort of 2 to 10 mm follicles retained for AFC computation, the subgroups of smaller and larger antral follicles had different predictive values.[339] In a cohort of 474 women, the number of very small follicles (2 to 6 mm) declined with age, while that of larger follicles (7 to 10 mm) remained fairly constant over time. Independent of age, the number of small follicles was related to the results of ovarian reserve tests. These authors claimed that the number of small antral follicle represents the functional ovarian reserve. Along these lines, Scheffer and colleagues observed a steeper yearly decline in the number of small antral follicles (2 to 5 mm) as compared to that seen for larger follicles (6 to 10 mm).[340]

Because a direct correlation has been established between the size of the antral follicle cohort and the number of remaining primordial follicles,[135] interest has been focused on determining the rate of depletion of antral follicles over time. In a prospective trial, Ng and colleagues determined that the rate of AFC decrease per year was of 0.35 follicle per year (95% CI 0.26, 0.45).[340a] These findings are of similar magnitude as the decline rate of 0.52 follicle per year (95% CI 0.26, 0.45) observed by the same group in a subsequent study conducted in a different cohort of women.[82] Yet, both results were obtained in Chinese women, and other publications reported faster AFC decays in Caucasian women where an annual loss of 0.95 follicles was observed,[341] or 8.2%.[342] There are no current explanations for the lower AFC losses observed in Chinese women as compared to their Caucasian counterparts.

Hendriks and colleagues conducted a meta-analysis looking at the respective values of ovarian volume versus AFC for predicting IVF outcome.[343] A total of 17 studies, 11 from prior meta-analysis[337] and 6 new ones were retained for looking at the predictive value of AFC. Comparison of ROC curves showed that the prediction of poor response was significantly better for AFC than for ovarian volume ($P < 0.005$) (Fig. 35.28). The prediction of nonpregnancy was poor for both tests, but the performance of AFC was slightly better than that of ovarian volume. This could have been predicted from the fact that both tests represent the quantitative aspect of ovarian reserve.

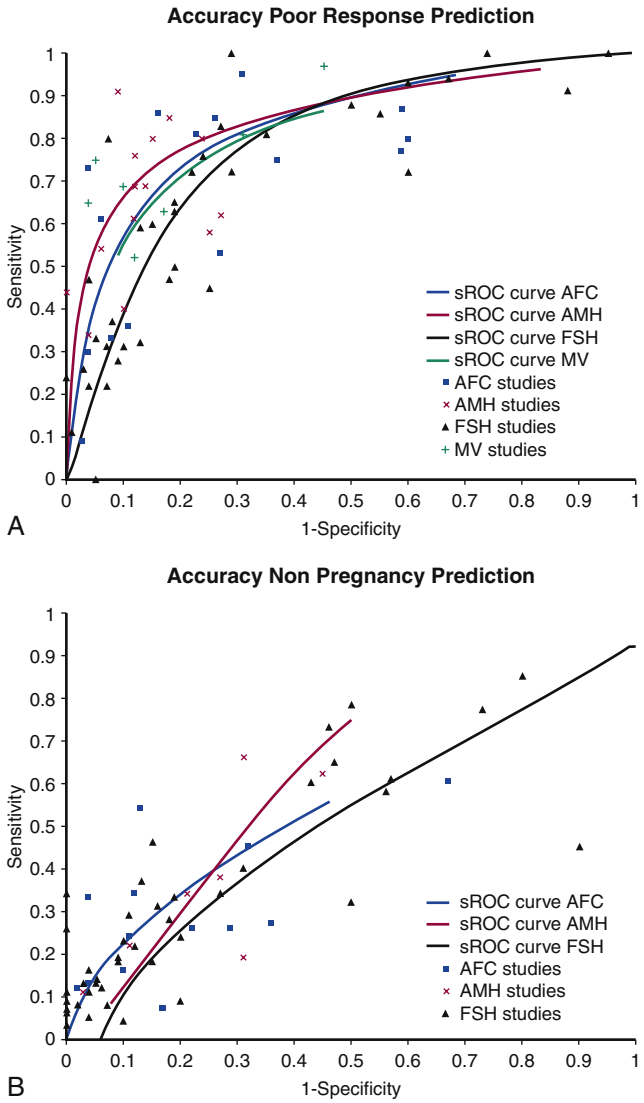

FIGURE 35.28 Prediction of ovarian response to COS and ART outcome. Ovarian reserve parameters (AFC calculation on ultrasound and AMH and FSH levels) predict the ovarian response to COS (data shown for poor response), but not ART outcome (data shown for non-pregnancy prediction). Ovarian aging: mechanisms and clinical consequences.* Endocr Rev *30[5]:465–493, 2009 Aug.)*

Sensitive assays for AMH, also referred to as müllerian inhibiting substance (MIS), have revealed that AMH is produced by growing pre-antral follicles.[344] The cohort of AMH-producing follicles (100 to 200) is markedly larger than that of antral follicles (10-20). Yet, both reflect the pool of primordial follicles present at any given time.

From Gougeon's work,[135,283] and that of others,[332] the cohort of antral follicles is believed to remain constant throughout the menstrual cycle, thus providing constant AFC throughout the menstrual cycle and limited intercycle variability as compared to day-3 FSH levels. Likewise, AMH levels show a high degree of correlation with AFC,[345] and remain essentially constant throughout the menstrual cycle[346-348] with limited intercycle variability.[73,349,350] AMH levels are not affected by prolonged treatment with oral contraceptives[348] in spite of the profound decrease observed in ovarian volume,[316] and remain constant in pregnancy and the postpartum period,[351] and following FSH administration in regularly ovulating women[352] and women suffering from PCOS.[353] Possible post-ovulatory fluctuations in AMH levels have been suggested.[354] We concluded that this discrepancy did not result from methodological differences, and that if a slight postovulation decrease truly occurs, it is of lesser magnitude than intercycle variability of AMH measurements and can, therefore, be ignored.[322]

Recent studies have questioned whether AMH measurements add any value over simple AFC determination.[343] AMH does offer practical advantages for identifying PCOS amongst women whose AFC are so elevated that follicles are too numerous to count, or when AFC cannot be obtained.

In conclusion, AFC is a readily available imaging-dependent index of ovarian reserve, which can predict ovarian responses to COS in ART. In the normal ovarian aging process, the decrease in the number of oocytes is paralleled by a decrease in oocyte quality. In this context, a correlation exists between lower AFC and lower oocyte quality. Yet, this link is not an inherent one, but rather reflects the confounding effects of age.

Ovarian Perfusion

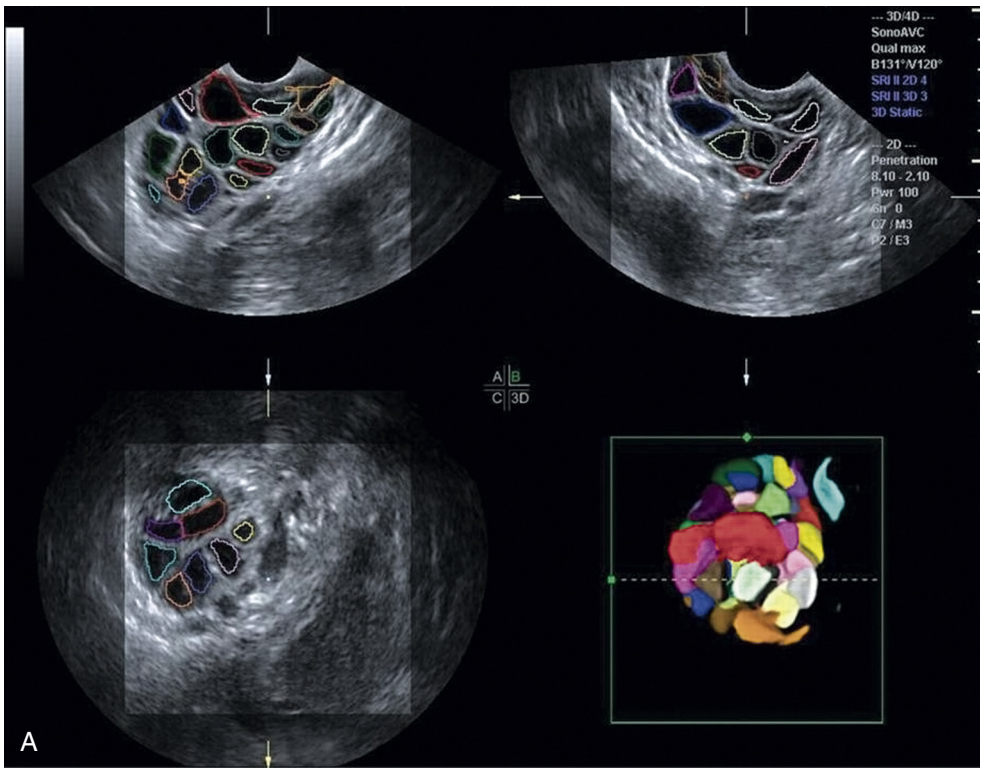
Perfusion of the Maturing Follicle and Corpus Luteum (CL)

Power Doppler has revealed the development of vessels in the wall of the dominant follicles in the later stages of the follicular phase[355] and in COH,[356-358] and a possible link with oocyte quality and reproductive outcome. Characteristically, this vascular development gives a colored annular ring that circles the maturing follicle. Typically, this is observed around certain but not all follicles developing in COH, starting on average 1 to 2 days prior to the time when hCG is commonly administered in COH (Fig. 35.29).[359]

Claims have been made that oocytes originating from well-vascularized follicles yield better reproductive outcomes than their counterparts originating from less vascularized follicles.[86,360,361] In line with this notion, a decrease in follicular blood flow in aging ovaries has been reported.[362] However, these results were challenged by Ragni and colleagues.[363] In a prospective trial on 318 women, these authors found that vascularity of the developing follicle did not predict the chance of pregnancy in women undergoing mild COS and IUI cycles. Pregnancy rates in the low-, medium-, and high-grade vascularity groups were 14.1, 10.0, and 11.8%, respectively.

Lozano and colleagues examined how follicular vascularization correlates with oocyte quality.[364] In their study, 61 normally ovulating women were prospectively studied. Their treatment consisted of daily GnRH antagonist (Cetrotid 0.5 mg/day) and 150 IU of hMG, starting when a growing follicle greater than 12 mm was observed. Ovulation was triggered as soon as the single dominant follicle reached 16 mm in diameter. Follicular vascularization was assessed just prior to oocyte retrieval, 34 to 36 hours after hCG (5000 IU) administration. Using 3D-based methodology, the vascularization index (VI) and flow index (FI) were taken as quantitative and qualitative reflections, respectively, of follicular vascularization. VI bore no predictive value to IVF outcome, but FI strongly predicted positive clinical pregnancies. These authors concluded that a qualitative rather than quantitative relationship exists between follicular vascularization and oocyte quality.

After ovulation the developing CL is the site of an intense neovascularization process, rapidly becomes the most vascularized organ of the body on a blood flow per tissue volume basis. On color and power Doppler images, the CL acquires the characteristic "ring of fire" appearance (Fig. 35.30). In a longitudinal study throughout the luteal phase and early pregnancy, Tamura and colleagues showed that the resistance index (luteal RI) was associated with corpus luteum function.[365]



Claims have been made that correlations exist between CL Doppler data and quality of the luteal phase,[366] leading to the proposal that Doppler data could be used for assessing the luteal phase[367] and predicting pregnancy outcome.[368] In spontaneously occurring singleton pregnancies, Frates and colleagues failed to find a correlation between the echographic characteristics of the CL and first trimester pregnancy outcome.[368]

On gray-scale images, we believe that an educated eye can easily identify the fine dual contours of vessels that run around the CL, an impression which is supported by the finding of a correlation between Doppler data and vascular density.[369] It should be noted that the increased vascularity of the CL may at times be confused with the vascular ring that characterizes certain ectopic pregnancies.[370]

Perfusion of the Ovarian Stroma

Color Doppler has revealed the presence of ovarian stromal vascularization. From the outset, it was suspected that a difference in the degree of vascularization exists between normally ovulating and PCOS women. According to Battaglia and colleagues, ovarian stromal vascularization is identified in 50% and 88% of the cases in normally cycling and PCOS women, respectively.[234]

A link has been claimed between the degree of stromal vascularization and the response to gonadotropin stimulation in ART.[371,372] According to Popovic-Todorovic and colleagues, ovarian power Doppler together with AFC are the two most significant predictors of ovarian response amongst 12 possible predictive factors investigated in normally cycling women.[373] The observation of significantly lower 3D power Doppler indices of ovarian stromal blood flow

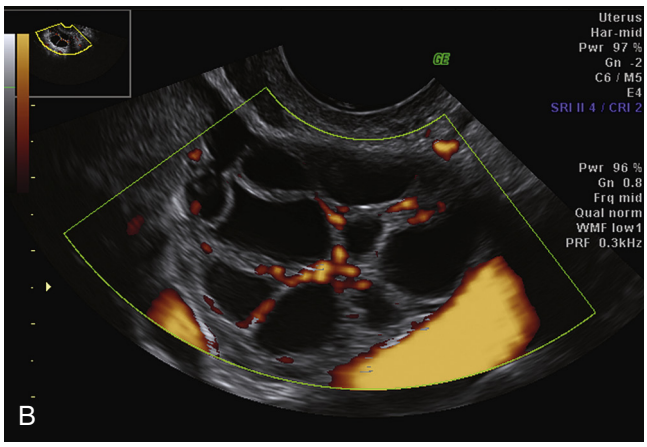


FIG. 35.29 **A**, Monitoring follicular growth in ART using the sonographic automated volume calculation worksheet. Each follicle and its measurements presented in the box at the lower right corner are coded with the same color for ease of interpretation. **B**, Vascularization of maturing ovarian follicles in COS induced for ART. In COS, starting 1 to 2 days prior to follicular maturity and hCG administration, color Doppler mode identifies the development of follicular vascularization. Characteristically, some but not all follicles display the development of end-follicular phase vascularization. *(**A** From Ata B, Seyhan A, Reinblatt SL, et al. Comparison of automated and manual follicle monitoring in an unrestricted population of 100 women undergoing controlled ovarian stimulation for IVF.* Hum Reprod *26[1]:127–133, 2011 Jan.)*

in poor responders as compared to normal responders[128] was taken as supporting evidence for the above. Studying the effect of age on ovarian stromal blood flow, Ng and colleagues observed that an age-related decrease was only observed in women 41 years of age or older.[340a] Using a 3D-based approach, Merce and colleagues found a correlation between ovarian VI and FI and the number of oocytes recovered.[74] Vascular parameters, however, were not independent predictors of the number of follicles developed and oocytes retrieved; ovarian volume and AFC were, a finding consonant with other reports.[5] Ng and colleagues observed that AFC, ovarian volume, and ovarian 3D Power Doppler flow indices did not significantly change after a short-term treatment with a GnRH agonist for pituitary down regulation.[374] Järvelä and colleagues studied the power Doppler signal in the ovaries after pituitary suppression by GnRH agonist. They observed that Doppler data did not provide any additional information beyond that of ovarian volume and AFC in terms of predicting the subsequent response to gonadotropin stimulation during IVF.[310]

The Ovary in Polycystic Ovary Syndrome

Echographic Characteristics of PCOS Ovary

In the original description by Stein and Leventhal, PCOS implied verification of the characteristic ovarian morphology,[375] a parameter which was later dropped.[376,377] In 2003, the Rotterdam conference[82] reinstituted an ovarian parameter in the diagnosis of PCOS when it included specific ovarian echographic criteria in the diagnostic criteria for PCOS. The Rotterdam consensus conference concluded that ovaries needed to hold more than 12 follicles of 2 to 9 mm each or measure more than 10 mL in volume to fulfill the PCOS criteria.

In PCOS, a characteristic feature is an increase in stromal volume[378,379] which in turn translates into an overall

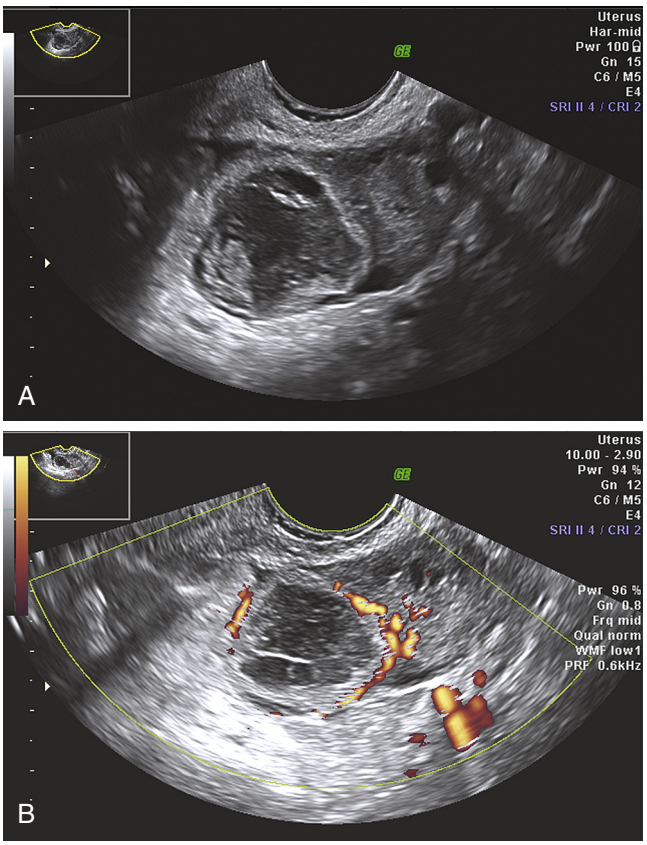

FIGURE 35.30 Corpus luteum appearance in gray-scale imaging **(A)** and color Doppler mode **(B).** On color Doppler mode, the characteristic intense vascularization of the corpus luteum confers the typical "ring-of-fire" appearance.

increase in ovarian volume.[378] Ovarian suppression achieved with the OC pill results in reduced ovarian volume,[315]—a finding not shared by everyone[380]—but without changes in either AFC and AMH levels.[353]

Ovarian volume measurement raises methodological issues. Originally, 2D measurements of ovarian volume used the simplified formula for the prolate ellipsoid (0.5 × width × length × thickness), which assumes a regular ovoid shape of the ovary.[381,382] Direct 3D measurements using the VOCAL-based rotation approach[12,383] surpass the classical 3-diameter-and-ellipse-formula approaches.[371]

The novelty of the Rotterdam criteria is the introduction of echographic criteria in the definition of PCOS.[384,385] However, the Rotterdam criteria have implicitly defined a category of women who do not qualify for PCOS diagnosis but have *PCO-like* ovaries, yet without androgen excess and the ovulatory dysfunction.[386] If exposed to COH for ART, these women are at risk of ovarian hyperstimulation syndrome (OHSS), just like true PCOS women.[174]

Franks argued that the Rotterdam conference did not settle the controversy concerning the diagnosis of PCOS.[387] He asserted that hyperandrogenism and anovulation are the mainstays of the definition of PCOS, while the Rotterdam criteria allowed for identification of PCOS women without clinical or biochemical androgen excess. Azziz stressed the fact that little is known about the degree of insulin resistance and long-term metabolical risk of oligo-anovulatory women with PCO ovaries, but without hyperandrogenism.[388] Allemand and colleagues[389] questioned the number of small follicles that had been retained in the Rotterdam citeria for diagnosing PCOS, opting for a higher number of follicles or ovarian volume as cut off criteria. Using ROC curves, these authors proposed to set the diagnostic cut off at more than 20 follicles per-ovary, offering a predictive value of 100% and negative predictive value of 91%. Dewailly and colleagues contend that the small 2 to 5 mm follicles found in PCOS are actually atretic follicles that reflect follicular arrest,[390] probably the result of an exaggerated inhibition of the terminal follicle growth.[391]

In PCOS, as in normally ovulating women, there is a strong correlation between AFC and AMH levels. Chen and colleagues observed that a significant correlation existed between the number of antral follicles and the ovarian volume on one hand and AMH on the other. AMH levels also correlated with total testosterone and the free androgen index.[392] AMH levels were inversely correlated with body mass index (BMI), fueling the argument that the ovarian expression of PCOS is more profound in lean individuals.[174] All findings indicate, however, that AMH levels parallel AFC and may do a better job defining PCOS and the degree of expression of this trait. AMH levels help when ultrasonographic data are not available.[393]

The Ovarian Stroma in PCOS

The description of the echographic characteristics of the PCOS ovary goes beyond the cardinal features of an increase in size and number of small 2 to 10 mm follicles.[394] An accessory echographic feature often put forth, yet more rarely objectively studied, is the increase in ovarian stromal echogenicity.[395,396] Buckett and colleagues[379] looked at the echographic appearance of 67 unselected women on no medication who were scheduled to undergo IVF. These authors measured total and stromal ovarian echogenicity, computing a stromal index as the ratio of stromal echogenicity over total echogenicity. Criteria for PCOS, AFC greater than 10, were found in 37% of the cases. Total ovarian volume and stromal volume were higher in PCOS ovaries, but contrary to expectation, there were no differences in mean stromal echogenicity between PCOS women and their normal cycling counterparts. There was, however, a reduction in mean echogenicity resulting from the increase in ovarian follicles, which accounted for a significant increase in stromal index in spite of the lack of change in stromal echogenicity per se. These results were confirmed with the most recent VOCAL-based volume measurements.[397] Lam and colleagues compared 40 Caucasian women identified as having PCOS by the Rotterdam criteria and 40 cycling controls having normal ovaries on ultrasound.[397a] Ovarian and stromal volumes were markedly larger in the PCO group (12.56 and 10.79 mL) as compared to controls (5.66 and 4.69 mL), but there was no significant difference in stromal echogenicity between PCOS and controls, respectively. Likewise, Jarvela and colleagues[398] failed to find a difference in echogenicity between 14 PCOS and 28 women with echographically normal ovaries. In subgroup analyses, Lam and colleagues observed that hirsute PCOS patients had larger stromal volume than the nonhirsute counterparts,[397a] but found no differences in ovarian stroma echogenicity between these subgroups. It can be concluded, therefore, that the impression of denser ovarian stroma in

PCOS results from a visual illusion linked to the increased stromal volume and a decreased echogenicity of the periphery of PCOS ovaries due to the increase in follicles.

Interestingly, AFC remains constant in PCOS women taking OC pills in spite of the profound decrease in ovarian volume.[316] This indicates that the effect of hormonal contraception is on ovaran stroma not follicles.[399]

The availability of pulsed and color Doppler functions on vaginal ultrasound probes led to the study of intra-ovarian stromal flow as a distinct phenomenon from changes in flow taking place in the follicular walls,[400] and after ovulation in the CL.[355,401,402] Stromal flow was found to be increased in women suffering from PCOS[371] as compared to findings in cycling controls.[130,136] Zaidi and colleagues compared ovarian stromal flow status measured by Doppler (peak systolic blood flow velocity) to ovarian responsiveness to FSH and hMG in ART cycles. Their observation found a positive correlation between blood flow at baseline measured by Doppler and ovarian response to COH with higher values in 13 POCS patients as compared to 63 cycling controls.[403] Conversely, ovarian blood flow was decreased at baseline in women found to have a poor response as compared to normal responders.[371]

In 2D-based studies, Balen and colleagues concluded that there is an increase in ovarian blood flow in PCOS,[386] a finding shared by some[288] but not by other investigators. Using 3D PDA, Jarvela and colleagues failed to find an increase in stromal vascularity in 14 women with PCOS as compared to 28 control women.[398] Lam and colleagues[88] compared ovarian flow assessed by 3D ultrasound in 40 women fulfilling the Rotterdam criteria for PCOS with those of 40 age-matched cycling controls. Ultrasound data were obtained on day 3 to 5 after spontaneous or induced bleeding. A 3D-based data set was acquired using a sweep angle set to 90 degrees and a slow-sweep mode. Per ovary AFC was significantly higher at 16.3; 9 to 35 (median; range) in the polycystic ovary group as compared to controls (5.5; 2 to 10). The results showed an increase in some (VI) but not in all 3D-PDA indices (FI). Interestingly, differences were observed among various phenotypes of PCOS. Ovarian blood flow was increased in a subgroup of 30 of 40 hirsute PCOS women as compared to their 10 nonhirsute PCOS counterparts. Likewise, blood flow was also higher in 14 lean PCOS women as compared to their overweight counterparts. Yet, there were no differences in AFC between lean and obese PCOS and hirsute and nonhirsute women. Ng and colleagues[403a] confirmed the differences in ovarian blood flow between different PCOS phenotypes. This team also found a significant increase in ovarian blood flow in women whose BMI was less than 25 as compared to their overweight counterparts with a significant negative correlation between total ovarian indices (VI, FI, and VFI) and BMI.[174] There was also a strong trend toward higher LH levels in lean PCOS women. Hirsute women with PCOS had increased stromal volume compared to nonhirsute women with PCOS.[404]

Early Diagnosis of PCOS in Adolescents and Prepubertal Girls

Chang and Coffler stressed the importance of diagnosing PCOS early in adolescent girls in order to offer treatments for the hormonal (hyperandrogenism and hirsutism) and metabolical expression of the disease.[298] Based on studying AMH levels through the pubertal process, Crisosto and colleagues observed that the increase in follicular mass is established during early development and persists during puberty.[405] First amongst individuals in whom an early diagnosis of PCOS is important are daughters of PCOS women. Sir-Petermann and colleagues determined that the daughters of women with PCOS are at increased risk of suffering from PCOS themselves.[406] These authors compared 14 female infants (2 to 3 months old) and 25 prepubertal girls (4 to 7 years old) born to PCOS mothers to a control group of 21 female infants and 24 prepubertal girls born to mothers with regular menses and without hyperandrogenism. Serum AMH levels were significantly higher in PCOS as compared to the control group during early infancy (20.4 ± 15.6 versus 9.16 ± 8.6 pmol/L; $P = 0.024$) and during childhood (14.8 ± 7.7 versus 9.61 ± 4.4 pmol/L; $P = 0.007$). Yet, gonadotropin and serum sex steroid concentrations were similar in both groups during the two study periods, except for FSH, which was lower during childhood in girls born to PCOS mothers. The discrepancy between the alteration of the follicular cohort, as expressed by the increase in AMH levels, and the lack of hormonal alteration in these infants and prepubertal girls suggests that the ovarian facet of PCOS precedes the altered gonadotropin pattern. That there is evidence of an altered follicular development during infancy and childhood speaks for the need of screening ovarian patterns either directly by ultrasound or through the surrogate for the follicular cohort, AMH levels.

Adnexal Cysts and Tumors

Ovarian versus Extra Ovarian Pathologies

Vaginal ultrasound has become the primary approach used for investigating adnexal masses. As stressed in a review by Brown[290] the primary question that pelvic imaging needs to answer is whether the adnexial mass is of ovarian or extraovarian origin. Most adnexal masses arise from the ovary. When the mass is of ovarian origin, malignancy is a concern. Once established that the mass is of extraovarian origin, short of rare cases of tubal cancer,[407] the mass is not likely of cancerous nature. The primary clinical presentation of tubal cancer is most commonly one of pelvic pain rather than an asymptomatic pelvic mass.[408] If the ovary and the tube are both involved with tumor, the bulk of the tumor should be in the tube.[409]

Identifying small antral follicles can help determine whether a mass is ovarian or not. Likewise, recognizing an ipsilateral ovary independent from the adnexal mass allows for recognition that the mass is nonovarian in nature. In postmenopausal women, the absence of visible ovarian follicles complicates ascertainment. Helpful tips for determining the ovarian or nonovarian nature of the mass include the possibility of mobilizing the structure that is being investigated by pressure applied with the vaginal probe. In case of a cystic mass, the impact of the pressure applied with the probe on the cystic dilatation should be followed. In case of an ovarian cyst, the probe usually bounces off the nondeformable cyst wall. When the cystic structure is a hydrosalpynx, the pressure of the probe will modify the shape of the cystic dilatation as fluid displaced by the probe will move elsewhere along the length of the tube.

The vascular supply of the lesion may also help in delineating the ovarian or extra-ovarian origin. In the case of pedunculated fibroids, one might identify vessels bridging with the uterus. The peripheral development of vessels can also help in recognizing the fibroid nature of an adnexal mass.

Extra-Ovarian Pathology

Paraovarian (or paratubal) cysts appear as simple cysts indistinguishable from ovarian cysts, if it were not for their nonovarian nature, which can normally be determined in premenopausal women because ovarian tissue can easily be identified,[410,411] including identification of an ipsilateral ovary.[412]

Hydrosalpinges are the most important para-ovarian structures encountered in clinical reproductive endocrinology. Typically, they appear as an elongated cystic mass.[413] Other typical features of hydrosalpinges include the waist sign and images evoking beads on a string. In a review of 67 cystic adnexal masses, Patel and colleagues observed hydrosalpinges in 26 (39%). These authors concluded that an elongated aspect, together with the waist sign, carried the highest probability for hydrosalpinx.[414] Ultrasound scans aimed at excluding the presence of hydrosalpinges in ART need to be performed at midcycle because fluid tends to accumulate during the follicular phase or after ovarian stimulation,[415] including in women with PCOS.[416] Peritoneal inclusion or pseudocysts are believed to result from fluid trapped within pelvic adhesions which may create the impression that the ovary lies within the cyst itself.[290,417]

Ovarian Cysts and Tumors

Brown described five primary findings for ovarian masses, each having their echographic characteristics, which most often permit a positive diagnosis.[290]

Simple Cysts

In premenopausal ovaries, a simple cyst is a structure greater than 3 cm in diameter with a thin anechoic wall free of protrusion and showing characteristic distal enhancement. Structures of lesser diameter are best described as follicles, which may have stopped developing or failed to regress because of isolated or recurrent ovarian dysfunction. Simple cysts most often disappear spontaneously, a process that may be hastened by suppressing ovarian function with the OC pills. The majority of persisting cysts treated surgically turned out to be serous cystadenomas.

The Corpus Luteum

The imaging characteristics of the CL may be so dramatic that they can easily be mistaken for cancer because of the intense low impedance blood flow. Baerwald and colleagues followed luteal images and serum E_2 and progesterone in 50 women daily from one ovulatory episode to the next.[311] The day of ovulation was defined as the day of follicle disappearance. The CL was detected on the day of ovulation and later in 100% of women, and during the subsequent follicular phase in 90% of them. Some CL presented as a central fluid filled cavity (identified in 88%), and some without (12%). A progressive decrease in echogenicity was observed throughout the luteal phase. The CL is intensely vascularized with an annular arrangement of vessels around the CL itself, which can be recognized on gray-scale images by a circular dual contour line.[132]

Hemorrhagic Cysts

Hemorrhagic cysts are common occurrences in premenopausal women. They can be associated with acute pain or they can constitute a fortuitous finding in routine scans done prior to ART. The internal echo pattern varies depending on the stage of the hemorrhage and the amount of fluid present. The acutely hemorrhagic cyst is typically more echogenic than the surrounding ovarian tissue. Characteristically, findings will evolve first to a sponge-like appearance, later followed by the development of irregular internal echos after the clot starts to retract after a few days, leaving a mesh-like maze of intertwined fine structures that are the echographic expression of fibrin strands.[418,419] These rarely run totally across the cyst. A gentle brisk pressure stroke applied with the vaginal probe may generate a disruption wave that propagates through the mesh-like network of internal echos with a characteristic jello-like effect where the wave rebounds backwards after hitting the cyst wall.

The retracted blood clot may mimic a mural nodule. The sharp angles of the retracting clot are different from solid tumors that do not tend to have acute angles.[419] To distinguish the clot from more ominous internal echos, it is most helpful to document the absence of vessels entering the solid area. MRI is classically of little help for diagnosing hemorrhagic cysts.[420] Most commonly, hemorrhagic cysts rapidly change their echographic appearance and ultimately disappear, a process that may be hastened by suppressing ovarian function with OC pills.[421,422] The pill is commonly started on day 2 of the menstrual cycle or arbitrarily, provided that endogenous progesterone is low (less than 1.5 ng/mL), which precludes the possibility of pregnancy. The differential diagnoses include endometrioma and dermoid cysts. Typically, the former has a homogeneous mixed echogenicity (gray) appearance, whereas the latter may add to that grayish appearance the finding of brightly echogenic calcifications, and on occasion, a denser mesh image when the dermoid cyst contains an accumulation of hair. Occassionally, a hemorrhagic CL may have a clinical course suggestive of ectopic pregnancy.

Endometriomas

Unlike other locations of endometrisosis which are difficult to identify, ultrasound examinations are efficient for diagnosing ovarian endometriosis, the endometriotic cyst or endometrioma. Out of 1170 scans yielding 252 adnexal masses the diagnosis of endometrioma was made in 40 cases (prevalence 16%).[423] Taken in isolation, low level internal echoes have a sensitivity of 93% and a specificity of 83%. At the other end of the spectrum, identifying all characteristic findings of endometriomas, namely low-level internal echoes, no neoplastic features, and hyperechoic wall foci or multilocularity, led to a specificity of 99%, whereas, sensitivity dropped to 45%. These data demonstrate that gray-scale vaginal ultrasounds can achieve a high degree of accuracy for diagnosing endometriomas. Hence, an adnexal mass with diffuse low-level internal echoes and no neoplastic features is most likely to be an endometrioma.

Mature Cystic Terratomas or Dermoid Cysts

Typical features of dermoid cysts include shadowing echodensity, regional diffuse bright hyperechoic areas with an attenuating effect, hyperechoic lines and dots and fat-fluid levels.[424] Because of the great variability in the appearance of cystic terratomas has been emphasized, it has been suggested that MRI is needed to rule out the possibility of ovarian cancer, except when the most typical echographic are observed. Suspecting that echographic findings are sufficiently specific, Patel and colleagues demonstrated in a prospective study that 55 of 74 cystic terratomas diagnosed amongst 252 adnexal masses had two or more sonographic features associated with dermoids.[425] These authors observed a positive predictive value of 80% for shadowing echogenicity, 75% for regionally bright echoes, 50% for hyperechoic lines and dots, and 20% for fat-fluid level. Taking these signs together, each reviewer had 98% positive predictive value, which reached 100% when an adnexal mass had two or more sonographic findings associated with dermoids.

Most ovarian cancers are epithelial neoplasms, which include serous, mucinous, endometrioid, and clear cell neoplasms. Additionally there are borderline-malignancy tumors or tumors of low malignant potential of all epithelial cell types with the mucinous and serous cell types being by far the most common. The presence of a solid component is the most common feature that reveals the cancerous nature of an ovarian tumor. In spite of the initial interest in color and power Doppler, there is a consensus that Doppler indices do not provide much more information than grey scale morphological assessment of suspected ovarian tumors.

Contrast Imaging of the Fallopian Tubes

The fallopian tubes are usually not identified on pelvic ultrasound, nor with other imaging approaches such as MRI or CT scans. Dilated tubes in case of hydrosalpinges are easily seen, however, by the contrast effect generated by fluid contained in the tubes. Exploring the fallopian tubes, therefore, requires some sort of contrast. Classically, the fallopian tubes are visualized on x-ray images by transcervical infusion of an opaque dye in HSG. Positive *(white)* contrast media are routinely used.[426]

Hysterosalpingography

Indications

Hysterosalpingography (HSG) is the ancestral imaging tool used for investigating infertility.[427,428]

The primacy of HSG for exploration of the uterine cavity is challenged by transvaginal ultrasound and HySo on one hand, and hysteroscopy on the other. The former offers the advantage of depicting both the cavity and the myometrial contour. This made HySo the undisputed primary imaging tool for investigating uterine malformations. The miniaturization of endoscopic instruments has allowed diagnostic hysteroscopy to become an office procedure, thereby leading to marked increases in its use. Diagnostic hysteroscopy offers the advantage of direct visualization of the pathological structures. Sonography using positive contrast products allows delineation of the tubal lumen, which appears white on grey scale images. Positive contrast agents used include Echovist®, Levovist®, and Albumex®, none of which is approved for use as fallopian tube contrast medium by the Food and Drug Administration (FDA).[429]

The need for HSG, traditionally included in all infertility workups, has been questioned for women whose serology for Chlamydia is negative. In these women, it has been claimed that HSG has a yield of tubal pathology that is so low that the routine use of HSG is not cost-effective.[430,431]

Technical Considerations

Classically, HSG is performed during a relatively short interval between cycle day 5 and days 12 to 14. This time limit achieves two objectives: (1) menses must be finished in order to minimize the risk of enhancing retrograde bleeding by the procedure; (2) The x-ray procedure is performed before ovulation in order to minimize the risk of irradiating a developing pregnancy. It may be handy to place the patient on a short course of OC pills for the sake of programming.

Several thorough reviews on HSG have been published which describe in detail practical aspects of this procedure.[432-434] Many groups routinely prescribe 600 mg of ibuprofen or other nonsteroidal anti-inflammatory drugs (NSAIDs) 30 minutes to 1 hour before the procedure in a effort to ease the uterine cramping that may be generated by the procedure.[433] Frishman and colleagues randomly compared the effects of intrauterine instillation of 2% lidocaine solution or saline before performing an HSG.[435] Moreover, Zhu and colleagues reported less pain after warming the contrast medium.[436] The issue of routine antibiotic prophylaxis has been much debated, with infectious complications being less than 1%.

With the patient in the dorsal lithotomy position and a speculum in place, the instillation device is positioned in order to provide a sealed connection with the cervix. The instillation instrument is either a Jarcho canula,[437] which is held to the cervix with tenaculums, or plastic catheters equipped with inflatable balloons, such as the 5-F HSG catheter (Cooper Surgical, Trumbull CT). The balloon is inflated once it has passed the internal os of the cervix. The balloon must be filled with the same contrast material as used for the examination. While the latter are probably easier to handle, they may create pain because of the balloon,[438] and in certain circumstances, may hinder the vision of the cervical canal. The speculum needs to be removed once the instillation instruments are in place. Air needs to be meticulously expelled from the instilling device so that only the contrast medium is pushed into the uterine cavity. Failing to do so could lead to a false diagnoses of filling defects.

Prior to instilling contrast medium, and after a mark identifies sides, a scout x-ray of the pelvic cavity is examined, looking for possible calcifications. Water-soluble contrast material is slowly instilled under intermittent control on fluoroscopic vision. A minimum of four spot radiographs are recommended.[434] The first image is obtained during early filling of the uterine cavity in search for filling defects, which may later be obscured when the uterus is totally opacified. The second image is obtained when the uterus appears fully distended. The third image aims at depicting the fallopian tubes. A fourth image is obtained to detect free spillage of dye into the pelvic cavity and proper mixing. Additional spot radiographs are obtained as necessary, including oblique views to avoid the superimposition of images.

Choice of Contrast Medium: Oil-Based or Water Soluble?

The original contrast media used in HSG was lipid based, with Lipiodol being used since it became available in the early 1920s.[439] In a pre-IVF era study, Mackey and colleagues compared the occurrence of spontaneous pregnancies when women had an HSG or not, sorting out results for when the oil-based Ethiodol or a water-soluble contrast medium was used.[440] In their study population of 460 women, the spontaneous pregnancy rate over 1 year following oil-based dye HSG was 58%, whereas it was 38% in women in whom a water-soluble dye was used. These puzzling results, which speak in favor of a fertility enhancing effect of HSG using lipid-based dye as compared to findings observed following HSG using water-soluble dyes, were confirmed in a number of other studies.[441-443] Oil-based contrast medium come with the risk of granulomas,[441] or the serious complications of a pulmonary or cerebral oil embolism.[444] A sequential combination of water-soluble dye for documenting tubal permeability followed later by instillation of oil-based Ethiodol has been proposed to benefit from the fertility enhancing effects of HSG using oil-based dyes while avoiding its risk. Alternatively, the use of the oil-based dye has been proposed in women whose tubal patency had been demonstrated by laparoscopy.[445] Water-soluble dyes offer better visualization of the distal regions of the fallopian tubes, allowing identification of striae.[443,434]

Attempting to provide an explanation for the pregnancy promoting properties of oil-based dye HSG, Goodman and colleagues proposed that the lipid dye inhibited the activity of peritoneal lymphocytes and macrophages.[446] That HSG was found to enhance fecundity in women whose infertility was of unknown etiology,[441] or due to endometriosis,[374] suggests that the inhibiting effect of the lipid dye on macrophages might be most significant in this subset of patients.[447]

The Uterine Cavity

Filling defects constitute a common finding in HSG. Once artifacts such as air bubbles or endometrial folds have been excluded, the differential diagnosis is synechiae as a result of post-traumatic or infectious endometrial scarring. Full fledge development of endometrial scarring leads to Asherman syndrome, classically associated with multiple scarring of the endometrium and clinically, amenorrhea.

Myomas may indent the uterine cavity. For practical purposes, the degree of distortion must be assessed to determine whether surgery is indicated in the absence of symptoms, and whether an intracavitary approach is feasible. HySo allows for simultaneous visualization of the whole fibroid and the portion that extends into the uterine cavity.

Assessment of the uterine cavity includes a search for congenital malformation of the organ. 3D sonography—with or without HySo—has taken the lead for diagnosing uterine malformations by offering simultaneous vision of the uterine cavity dilated by saline and the organ itself identified on gray-scale imaging.[448] The 3D reconstruction of the uterus in the frontal plane is of great practical help,[449] and even lends itself to virtual hysteroscopy exploration[450] (Fig. 35.31). Finally, the assessment of the uterus must include the cervical canal, notably to rule out cervical insufficiency.

Clues regarding the possibility of adenomyosis can arise from HSG images.[451] The characteristic image is one of diverticula filled with contrast medium that extends into the myometrium. This may exist in the context of an overall irregular contour with multiple outpouchings. The ultimate expression is the classical honeycomb pattern.[452,453] Although it is held as being diagnostic of adenomyosis, it is now recognized as not being specific.[451,454]

In cases of large adenomyomas, the image may be one of a mass-like filling defect, with contrast material filling the mass. Adenomyosis is more accurately diagnosed by MRI where it is characterized by a thickening of the junctional zone.[455] This is the only feature that has been fully validated against histological identification of adenomayosis in women undergoing hysterectomy.

The Fallopian Tubes

In spite of emerging approaches based on positive contrast enhanced ultrasound imaging, HSG remains the best method for visualizing and evaluating the fallopian tubes. Normal tubes appear thin, with smooth outlines and a characteristic distension in the ampullary area. Proximal disease that prevents the visualization of the tubes may be the reflection of salpingitis isthmica nodosa (SIN) or the result of a simple spasm. In the case of SIN, the penetration of the contrast medium into the thickened fallopian tube wall produces the typical honeycomb appearance (Fig. 35.32). SIN is usually the result of pelvic inflammatory disease that leads to fibrosis of the proximal tubal section with stricture of the lumen and tubal occlusion.[456] We now know that SIN may also result from a tubal form of endometriosis.[456] In this case, temporary treatment with a GnRH agonist has been documented to be effective,[457] offering alternatives to the surgical approach for SIN.[458] Our experience showed that 3 months of treatment with GnRH antagonist resulted in repermeabilization of 15 of 18 women who had bilateral proximal occlusion, and in whom a laparoscopy showed some endometriosis and no evidence of distal tubal disease.[73] We believe that medical treatment of SIN should be considered each time endometriosis is present and there is no evidence of distal tubal disease. Spastic constriction of the tube may result in complete tubal occlusion, opening the door to an erroneous diagnosis of proximal tubal disease. Timely administration of glucagon promotes uterine muscle relaxation and can be used to reverse spasms.[459]

Distal disease is usually associated with dilatation of the tube as a consequence of hydrosalpinges or the incomplete form, sactosalpinges. Pelvic inflammatory disease is the most common cause of distal tubal disease, but it may at times result from endometriosis.[460,461]

We believe that the diagnosis of hydrosalpinx should be made on visualizing dilated tubes on ultrasound at midcycle. This nuance is important, as it is commonly held that hydrosalpinges must be removed (salpingectomy) to optimize IVF outcome.[44] From the clinical trials that exist, there is now a consensus for recognizing that pregnancy rates in IVF are approximately halved when a hydrosalpynx is visible on ultrasound.[336,462] Taylor's group found that hydrosalpinges, probably by the release of fluid into the uterine cavity, interferes with the role of *HOXA10* in receptivity and implantation.[44,463-465]

Complications

Minor complications of HSG include pain and cramping, which is usually mild to moderate and subsides within hours of the procedure. The most serious complication is a pelvic infection. Albeit rare (less than 1%), the risk exists, particularly in cases with a past history of pelvic inflammatory disease.[466] Some have advocated for antibiotic prophylaxis, either systematically or in selected cases in which there is a higher risk of infection.[467] The most common regimen has been doxycycline 100 mg, twice a day, administered for 1.5 to 5 days. We commonly administer 100 mg immediately prior to the procedure, on the evening of the procedure, and the morning after the procedure in women at higher risk of infection by history or findings on HSG.

Other infrequent complications include allergic reaction to iodine based contrast agents. In the latter case, gadolinium can be used as a replacement.[468] Perforation of the uterus or fallopian tube has been reported with HSG, but it is extremely rare.

Infusion Sonography

Numerous publications have described the possibility of documenting tubal patency by infusion sonography.[469] A consensus has been reached over the fact that positive contrast solutions providing white visualization offer better and easier visualization of the tubes, particularly of the proximal tubal sections.[429,470] Solutions such as Echovist® or Levovist®, while offering unquestionable value for assessing tubal patency suffer from: (1) Not providing an image of the fallopian tubes that matches that of HSG, particularly of the distal tubal segment; (2) the not insignificant cost of the contrast product. 3D reconstruction capability is likely to facilitate tubal assessment by sonography, but without inherent changes to imaging capabilities.[471] It is our impression that while the proximal section of the fallopian tube can easily be identified, HSG images remain largely superior for assessing the distal ends of the tubes.

A key issue when attempting to assess tubal physiology is to determine whether retrograde transport of sperm takes place normally during the late follicular phase. Using a ^{99}Tc-labeled macroalbumin aggregates in a procedure referred as hysterosalpingo scintigraphy, Kissler and colleagues reported evidence of retrograde transport alterations in endometriosis and adenomyosis.[472,473] This approach is cumbersome, however, and does not lend itself to repeated measurements, nor to studies conducted in mock reproductive conditions.

An advantage of HySo over x-ray-based methods for assessing tubal function is the possibility of repeating examinations. Unfortunately, the ideal infusion preparation for assessing tubal function does not yet exist. An ideal preparation capable of fulfilling the expectations of infertility specialists would be a product that would have the following characteristics: (1) offer positive contrast imaging for identification of the fallopian tubes, (2) a consistency that permits lasting contrast properties for durations sufficient for studying whether actual transport takes place through the tubes, (3) nontoxicity to gametes. This latter characteristic would be helpful for studying retrograde tubal transport under intercourse-like conditions, when the uterotubal unit is exposed to prostaglandins and other constituents of semen. This is deemed necessary as constituents of semen may exert clinically relevant effects on retrograde contractility[474] or other uterine functions.[475] Uterine and tubal influences exerted by semen constituents may be facilitated by a direct vagina-to-uterus transport through the functional portal system, or *first uterine pass effect*.[476]

Endometriosis

The clinical expression of endometriosis is infertility[477] and pelvic pain,[478] which is notoriously exacerbated in cases with endometriomas.[479,480] One can distinguish the manifestations of endometriosis that are readily identifiable on ultrasound (i.e., endometriomas) from others that are known to evade conventional vaginal ultrasound scrutiny.

Identifying and staging endometriosis, and its possible deep pelvic infiltration, has been the primary basis for reverting to MRI in benign gynecology imaging.[481,482] In certain circumstances, rectal ultrasounds or special procedures such as sonovaginography[199] have been proposed for evaluating the presence and extension of deep infiltrating endometriosis. Preoperative staging is challenging, and requires exploring all the possible locations of endometriosis. Vaginal ultrasound, put in expert hands, is now competing with MRI to the point that it may become the first-line diagnostic tool.[483]

While endometriosis can affect all organs and structures of the pelvic cavity, its extension commonly follows known paths. It is widely accepted the ovary constitutes the most common site for the development of endometriosis, where endometriotic cysts or endometrioma are formed. In general, peritoneal lesions are classified as either superficial or deep, depending on whether penetration exceeds 5 mm or not. Anterior endometriosis includes invasion of the bladder, and particularly its detrusor muscle.[484] Posterior endometriosis includes the extension of the disease to the uterosacral ligament, the upper and posterior portion of the cervix (torus) and finally, the various forms of vaginal, bowel, and uretral endometriosis.[485,486]

Endometriotic Cysts (Endometriomas)

Endometriomas are best diagnosed and described on ultrasound, where they present as isolated or multiple cystic structures filled with homogenous low-level echos.[418,487] This gives what is commonly referred to as grayish fairly homogenous aspect to the cystic structure. The majority of endometriomas range from 30 to 60 mm.[487] Color Doppler helps establish the endometriotic nature of newly identified cysts, and can document the absence of blood vessels within the walls of the cyst, or penetrating inside the cyst.[485] Differential diagnosis includes benign teratomas[425] and hemorrhagic cysts, particularly CL cysts.[488] Benign teratomas because of their sebum content, which has the general consistency of the old blood found in endometriomas, may provide echographic characteristics that are fairly similar to those of endometriomas. The presence of echos of hairballs, or shadowing effects from calcified structures (bones), strongly speaks for a dermoid cyst.[489]

Hemorrhagic CL cysts vary in size (2.5 to 10 cm). They differ from endometriomas by the presence of complex internal architecture that reflects the presence of a retracted clot and its fibrin content,[419,490] a characteristic that can be appreciated with new automatic texture assessment.[491] Moreover, a sponge-like reticular pattern is often identified within the cyst.[365] These two findings are not encountered in endometriomas. The ultimate hemorrhagic nature of cysts is confirmed by witnessing their disappearance (or profound change) on repeat ultrasounds performed 2 to 4 weeks later, a measure mandatory in our eyes.[492]

Endometriomas are often multiple. The choice of surgical management or ART will be influenced by the unilateral or bilateral nature of the lesions.[493-495] They characteristically have hyperchoic wall foci that are clearly identified in nearly a third of the cases.[423] In a recent study conducted on 65 women suspected of having an endometrioma, Alcazar and colleagues observed that peripheral vascularization of the endometrioma's wall was more important when pelvic pain was present than when it was not.[496] Although ultrasound is the diagnostic tool of choice for exploring endometriomas, in certain circumstances, MRI may prove to be more helpful, let alone necessary when ultrasound findings are inconclusive or their interpretation is hampered by the presence of other disorders, notably uterine fibroids.[497,498]

Endometriosis of Pelvic Areas Other Than the Ovary

Deep endometriosis is defined by lesions that extend ≥5 mm beneath the surface of the endometrium[499] and are associated with increased nerve density.[500] Chapron and colleagues stressed the fact that pelvic examination does not suffice for reliably diagnosing and locating deep endometriosis prior to surgery.[288] While elements in the patient's history,[500] particularly at the time of adolescence,[500] such as an early use of OC pills for managing severe dysmenorrhea,[500] or phenotypic characteristics,[501] increase the risk of finding endometriosis, these alone or collectively do not suffice for making the diagnosis preoperatively.[502] Taken together, these elements mandate deploying an image-based workup aimed at diagnosing and mapping deep endometriosis,[288] using diagnostic criteria,[503,504] before undertaking surgery. While MRI remains the gold standard for diagnosing deep endometriosis preoperatively, vaginal ultrasound is becoming ever more efficient.[502,505,506] Deep endometriosis lesions are described as hypoechoic linear thickenings or nodular masses with and without regular contour in the cul-de-sac, retro-cervical region, and recto-vaginal septum, involving or not involving the vaginal wall.[502,505] Several groups stress the fact that vaginal ultrasound allows the visual identification of lesions to be correlated with pain generated by exerting pressure on the suspected lesions.[507,508] Abrao and colleagues found that transvaginal ultrasound offered better sensitivity and specificity for identifying deep endometriosis than pelvic examination and even MRI.[509] The fact that all patients had an enema prior to the ultrasound examination might have contributed to the positive findings. Dessole and colleagues underscore that saline placed in the vagina can improve the visualization of the vaginal wall.[199]

Anterior and bladder involvement of endometriosis is an extension that is found in nearly 20% of endometriosis cases.[510,511] Bladder endometriosis commonly declares itself by localized bladder wall thickening on ultrasound.[512,513] At times infiltration may be recognized by the presence of deep irregular hypoechogenic infiltration of the bladder wall, particularly in the area of the uterobladder flap, with protrusions that may extend inside the bladder.[288] At MRI, bladder lesions are identified as heterogeneous T_2 isointense thickening of the bladder wall,[485] with lesions varying from 10 to 40 mm.[504] In a study involving 195 patients, MRI had a sensitivity and specificity of 88% and 99%, respectively, for the diagnosis of bladder endometriosis.[481] Extension of endometriosis to the ureter can be identified on T_2-weighted sequences.[485,514]

Endometriosis of the uterosacral ligament and posterior aspect of the cervix could be assessed by transvaginal ultrasound in 64% of cases, a diagnosis confirmed surgically in 88% of cases.[481] MRI provides higher sensitivity, however, with reported values ranging from 76% to 86%.[481,504] Retrocervical endometriosis is identified when thick irregular nodular formations of hypoechoic nature are found in this area, with possible extension to one or both uterosacral ligaments. Signs of adhesion are looked for by sliding loops of bowel along the uterosacral ligament and retrocervical area. The sensitivity of ultrasound is notoriously weak, however, reaching 64% in Bazot's hands[481] for diagnosing retrocervical endometriosis. In contrast, MRI offers an improved sensitivity for diagnosing deep endometriosis of the retrocervix.[504] An elegant MRI-based study demonstrated that deep infiltrating endometriosis does not originate from the rectovaginal septum, but rather from the posterior of the cervix at the height of insertion of the uterosacral ligaments.[288]

Endometriosis of the bowel most often, but not exclusively, affects the rectosigmoid colon,[515] a finding in agreement with the intriguing, yet generally recognized assymetry of pelvic endometriosis.[516-518] It is characterized by long, nodular, predominantly solid hypoechogenic lesions with varying degrees of infiltration from the serosal layer down to the muscularis propria identified as two hypoechoic lines separated by a fine hyperechoic line.[502,509,514,519] On MRI, the reported sensitivity and specificity is of 84% and 99%, respectively, in women with documented intestinal involvement.[481] Diagnostic criteria for rectal invasion include rectal wall thickening and a characteristic triangular attraction of the rectum toward the posterior aspect of the cervix or torus uteri.[481,485,512,520] Preoperative staging of endometriosis extension, and particularly, identifying the presence and extent of deep lesions, is considered an obligation today.[521]

Adenomyosis

A variant of endometriosis, adenomyosis, is characterized by the heterotopic development of glands and stroma in the subendometrial myometrium with various degree of hyperplasia present amongst adjacent smooth muscle cells.[522] Adenomyosis can be either diffuse or focal.[523] In the diffuse form, glandular and stromal constituents of the endometrium extend throughout the sub-endometrial layers of the myometrium, resulting in an overall enlargement of the whole uterus.[522] In the localized variant, the affected area is isolated in the frontal or posterior wall of the uterus, taking on an appearance that may be difficult to distinguish from a fibroid.[524] While adenomyosis has been claimed to cause infertility, its contribution is debated.[455,525]

Various contemporary transvaginal ultrasound approaches are being tested and developed to identify and delineate the territorial extension of adenomyosis. The most commonly identified marker of diffuse adenomyosis on ultrasound is a poorly marginated hypoechoic extension in the subendometrial layers of the myometrium.[526] According to Devlieger and colleagues, localized adenomyosis can be distinguished from fibroids based on the following criteria: (1) absence of circular vascularization at the border of the lesion, which may be replaced by vessels actually penetrating into the lesion; (2) presence of a shaggy limit between the lesion and the outer myometrium that typically lacks the characteristic shell common to fibroids with its acoustic shadowing effect (Fig 35.33).[524]

MRI, especially through T_2-weighted images, provides excellent soft tissue differentiation. In the uterus, MRI delineates a subendometrial band of low-signal referred to as the junctional zone (JZ). Histological analyses have demonstrated that JZ corresponds to the subendometrial layer of the myometrium.[527,528] Yet, these studies failed to provide clues as to the nature of the histological basis that accounts for the low-signal on MRI. In contrast to the outer layers of the myometrium, the subendometrial layer of the myometrium is of müllerian origin and the site of changes

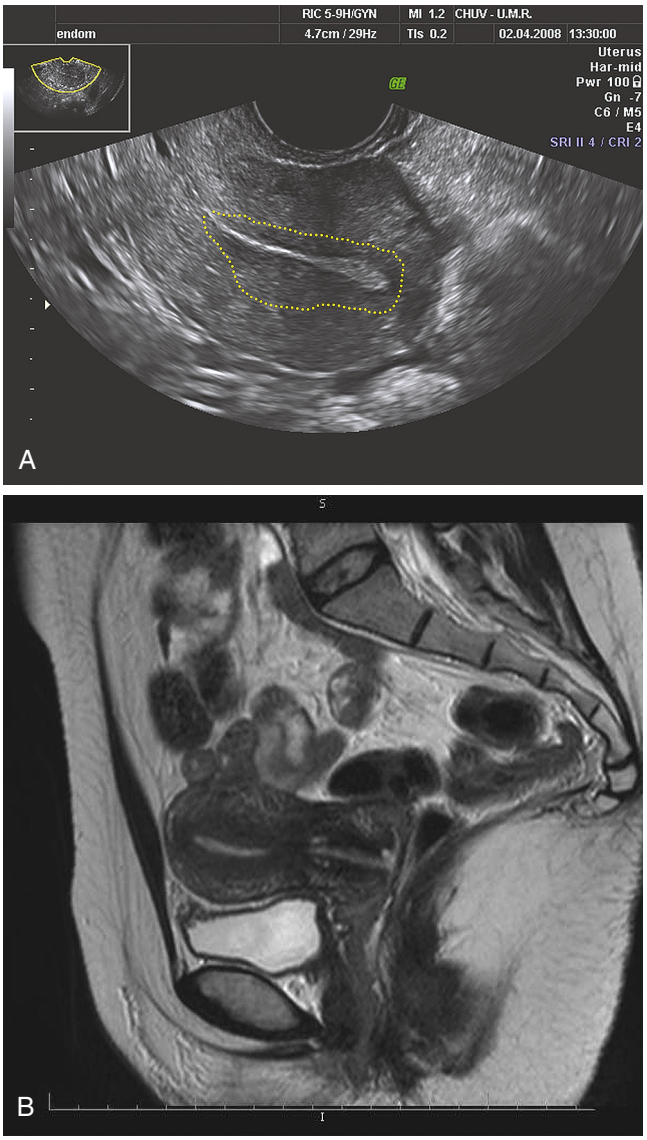

FIGURE 35.33 Diffuse adenomyosis. **A**, The ultrasound appearance is characterized by a thickened subendometrial sonoluscent area. **B**, Magnetic resonance imaging (MRI) is characterized by a diffuse and fairly regular thickened subendometrial transitional zone.

in E_2 and progesterone receptors that follows the pattern of changes encountered in the menstrual cycle.[26] Considerable variation in JZ thickness has been observed, with reported values that range from 2 to 8 mm.[529,530] In one report, transvaginal ultrasound was as effective as MRI in delineating the subendometrial layer of the myometrium.[531] Excessive local or diffuse thickening of the low-signal JZ with ill-defined boundaries has been the hallmark of adenomyosis, with many authors proposing 8 mm as the cutoff value between normal and overt diffuse adenomyosis.[532] In a study of 119 patients undergoing hysterectomy, the JZ was 7.7 mm in 91 women without adenomyosis, and 15 mm in 28 women with adenomyosis.[531] In women whose JZ was measured between 8 and 12 mm, associated findings such as focal thickening of the JZ or high-signal foci within areas of low signal on T_2-weighted sequences may represent island of ectopic endometrium.

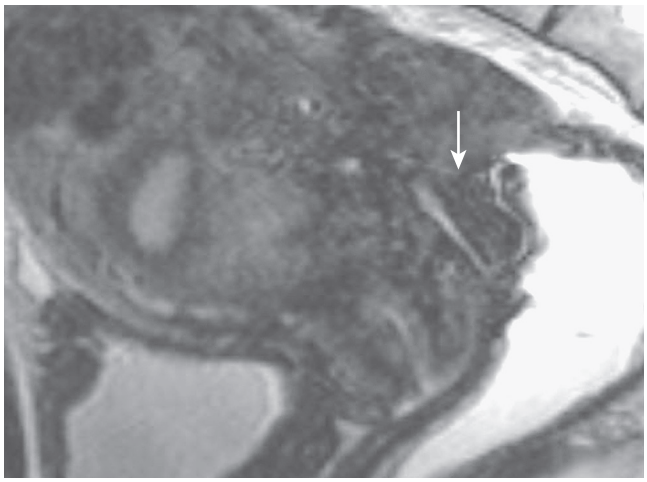

FIGURE 35.34 Endometriotic lesion: Sagittal T_2-weighted fast spin-echo magnetic resonance imaging (MRI) of the pelvis showing an infiltrative lesion (typical fibromuscular lesions of endometriosis) extending to the anterior rectal wall and posterior wall of the uterus *(arrow)*.

Focal adenomyosis in areas of low-signal intensity on T_2-weighted images was found to consist of smooth muscle hyperplasia associated with heterotopic endometrial tissue (Fig. 35.34).[454,533] It is important to distinguish focal adenomyosis from leiomyomas. In 21 women suspected to have focal adenomyosis, MRI adequately diagnosed signs of focal adenomyosis in 12 women. In 10 of these women, the diagnosis was ultimately confirmed by histological analysis of the pathological specimen.[534] According to Reinhold and colleagues,[454] features that favor the diagnosis of adenomyosis on MRI include: (1) lesions with poorly defined borders; (2) lesions that extend along the endometrium; (3) minimal mass effect on the endometrium relative to the size of the lesion; (4) linear striation radiating out of the endometrium into the myometrium; and (5) absence of large vessels at the margins of lesions contrary to the typical findings of leiomyomas. Furthermore, these authors stress the possibility that uterine contractions and the resulting deformation of the endometrial-myometrial interphase may generate images evocative of focal adenomyosis.[454] There is general agreement about the high sensitivity of MRI for detecting focal adenomyosis, with sensitivities of 88% and 86%, reported respectively, in studies by Ascher and colleagues[532] and Reinhold and colleagues.[531] These authors disagreed, however, about the ability of endovaginal ultrasound to detect focal adenomyosis, with the former and the latter groups reporting 53% and 89%, respectively.

Endometriosis and Uterine Contractility

Adenomyosis is likely associated with myometrial dysfunction,[535,536] possibly associated with endometriosis-types of alterations of the eutopic endometrium[537] and the JZ.[27] In a provocative series of publications, Leyendecker's team promoted the concept that endometriosis is associated with a hyperkinetic-dyskinetic condition of the uterus[473,538] as a result of structural abnormalities of the uterine wall,[539]

which impairs the retrograde transport of sperm during the follicular phase,[24,231,540] and the proper antegrade emptying of uterine content at the time of menses.[236] From their studies using the uterine displacement of ^{99}Tc-labeled MAA, these authors observed two pathological findings in endometriosis: (1) a pathological increase in retrograde transport at the time of menses; and (2) the loss of retrograde transport targeted toward the tube that faces the developing follicle during the late follicular phase of natural cycles.[24,235] Both phenomena could contribute to the infertility that accompanies even the milder forms of endometriosis. The original report of activation of the aromatase gene in the eutopic endometrium in case of endometriosis[541] that has been amply confirmed[542] offers a possible explanation for the local state of hyperestrogenism purported to be the cause for the relative progesterone resistance[542,543] and the dyskinetic alterations encountered in endometriosis.[241,544] That COH-IUI cycles have markedly lower pregnancy rates in endometriosis as compared to unaffected controls[545-547] is consistent with the concept that endometriosis is accompanied by a sperm transport problem stemming from uterine dyskinesia.

CHAPTER 36

Contraception

Courtney A. Schreiber
Kurt Barnhart

The use of modern contraceptives has contributed substantially to the reduction of maternal and infant morbidity and mortality and to the ability of women to contribute to society. However, evidence-based utilization of the methods has not been fully realized since approximately 50% of all pregnancies, 3 million pregnancies per year in the United States, are unintended.[1] Unintended pregnancy has negative effects on women's health and education and the health of newborns, and requires significant personal financial resources from individuals and society.[2] According to the U.S. census bureau, 62 million American women are in the childbearing years (15 to 44 years old). The vast majority (7 out of 10) of women age 18 to 44 are sexually active and trying to avoid pregnancy. The two contributors to unintended pregnancy are contraceptive non-use and contraceptive failure.[1] The importance of maximizing use of effective contraceptive methods cannot be overstated.

Table 36.1 demonstrates the changes over time in American contraceptive use and underscores that although long-term effective contraceptive methods are increasing in use, these methods still make up a slim minority of contraceptive technologies utilized by American couples. The oral contraceptive pill is the most widely used method by women in their teens and twenties, women who have never been married, and women who have at least a college degree. Poor and low income women are twice as likely as higher income women to use the 3-month injectable method, with depo-medroxyprogesterone acetate. Fifty percent of all women age 40 to 44 years old who practice contraception have been sterilized. The proportion of women who use a contraceptive method at first intercourse has doubled in recent times to 79% at present.[2-5] The majority of these couples use condoms at first intercourse. Teenagers who do not use a contraceptive at first intercourse are twice as likely to become teen mothers as teenagers who do use a contraceptive method. As demonstrated by Table 36.1, contraceptive use has increased overall among American women. Recently, after years of under-utilization, intrauterine contraceptive use has increased among American women. Since long-acting reversible contraception is superior to the most commonly used oral contraceptive pills, continued uptake of these methods should ultimately decrease the unintended pregnancy rate in the U.S.[6]

Contraceptive Effectiveness versus Efficacy

Contraceptive clinical trials typically report their failure rates either by the Pearl Index or Life Table Analysis. The Pearl Index is defined as the number of contraceptive failures per 100 women-years of exposure, and uses as the denominator the total months or cycles of exposure from the initiation of the product to the end of the study or the discontinuation of the product. Life Table Analysis, on the other hand, provides the contraceptive failure rate for each month of use and can provide a cumulative failure rate for any specific length of exposure. A recent Food and Drug Administration (FDA) briefing reviewed the actual utility of the Pearl Index, noting that it does not take into account the effect of failures over time (www.fda.gov/ohrms/dockets/ac/07/briefing/2007-4274b1-01-FDA.pdf). The Life Table Analysis method of reporting effectiveness is considered an actuarial method. Effectiveness can be difficult to compute because there are many factors that influence contraceptive use. The term "effectiveness" is defined as the ability of a contraceptive to prevent pregnancy in a clinical trial setting, meaning a failure or success that occurs when a product is used perfectly in accordance with the recommended dose regimen. "Efficacy" is a term used to define the ability of a contraceptive to prevent pregnancy in typical use, for example, when the subject does not completely follow the recommended dosing regimen. The terms "typical use failure rate" and "perfect use failure rate" are also used to describe these differences. Table 36.2 demonstrates the differences in the typical use failure rate from the perfect use failure rate in the different contraceptive methods. It is critical to note that typical use applies to the population in general whereas perfect use refers to the clinical trial setting.

Intrauterine Contraception

Intrauterine contraception is a widely used method of reversible birth control globally. Benefits of intrauterine devices (IUDs) include a high level of effectiveness, lack of associated systemic metabolic effects, and the need for only a single act of motivation for long-term use, as well as its ability to be used over several years. The United States has seen a recent uptick in the prevalence of IUD use.[7] If this continues, it is likely that the increased use of IUDs will lower the unplanned pregnancy rate in the U.S.[6] Historically, a major barrier to uptake has been cost.

Currently there are two intrauterine contraceptives available on the United States market: The copper ParaGard IUD and the levonorgestrel-containing Mirena intrauterine system. Over the past 35 years, however, many intrauterine contraceptives have been designed and used clinically throughout the world. The design of IUDs has evolved since

their original use in the 1960s. IUDs were initially developed in the 1980s as T-shaped plastic devices covered with copper wire. The amount of copper in the IUD accounts for the length of time of efficacy. Each IUD does have a certain rate of copper dissolution, which accounts for its need to be replaced over time. In the United States, the T380A IUD is the only copper-bearing IUD. The multi-load CU375 is widely used in Europe. The T380A has a frame of polyethylene with a vertical length of 36 mm and a horizontal length of 32 mm. The exposed surface area of copper is 380 mm^2, hence its name. The amount of copper dissolution daily amounts to less than what the ingested amount of copper is in the normal diet. The copper T380A is currently approved in the United States for 10 years, but evidence has shown that it is effective for up to at least 12 years.[8] All copper-containing IUDs have a number as a part of their name and this indicates the surface area of copper that the IUD provides.

Copper Intrauterine Devices

Copper T IUDs have failure rates of less than 1% per year and cumulative 10-year failure rates of approximately 2% to 6%. A large World Health Organization (WHO) trial[8] reported a cumulative 12-year failure rate of 2.2% for the T380A (ParaGard). This is an average of 0.18% per year over 12 years of use. This failure rate is equivalent to the failure rate seen with female sterilization methods. The mechanism of action is not fully understood for the copper IUD. The presence of in intrauterine device has been shown to prompt the release of leukocytes and prostaglandins by the endometrium.[9] This creates a hostile milieu to both sperm and eggs. The presence of copper increases the spermicidal effect.

Hormonal Intrauterine Devices

A reservoir of progestin in the vertical arm of the T-shaped IUD increases its efficacy. The progestin-releasing IUD was marketed initially as a 1-year device but is no longer manufactured. Currently, a T-shaped IUD containing a levonorgestrel in the vertical arm has been developed and has undergone extensive clinical testing. It is available in the United States and other countries as the levonorgestrel intrauterine system (LNG-IUS), or Mirena. A large comparative trial of the copper T380A and the levonorgestrel-releasing IUD found that the efficacy of the two methods is similar, as are the continuation rates. The LNG-IUS measures 32 mm both horizontally and vertically. It is made with a silicone reservoir containing 52 mg of levonorgestrel in the vertical stem. There is an initial burst release of levonorgestrel of 20 μg/day, resulting in plasma levels of 150 to 200 pg/mL.[10] The plasma concentrations of levonorgestrel decrease over the number of years it is used. There is sufficient levonorgestrel in the intrauterine system to last for the estimated duration of 5 years.[11] The levonorgestrel-releasing intrauterine system produces high concentrations of progestins in the endometrium. The progestin-dominant effect allows the endometrium to remain thin and not proliferate. In addition to the contraceptive efficacy that is obtained, bleeding patterns change. Approximately 20% of women who use this device become amenorrheic at 1 year.[11]

A new progestin-releasing IUD that contains 13.5 mg of levonorgestrel has recently become available (Skyla). This device provides 3 years of contraceptive efficacy. The device releases about 14 μg of levonorgestrel per day shortly after insertion. After 3 years, the device releases about 5 μg of levonorgestrel per day. The inserter has a diameter of 3.8 mm, which is about 1 mm smaller than the Mirena inserter. This device may be of use for women who do not need 5 years of contraception and for some nulliparous women where a narrower inserter may facilitate the placement of the device.

The mechanism of action of the levonorgestrel intrauterine system is better understood than is that of the copper intrauterine device. The LNG-IUS works primarily by changing the endometrial lining and thickening the cervical mucus. This thick cervical mucus obstructs the passage of

Table 36.2 Percentage of Women Experiencing an Unintended Pregnancy During the First Year of Typical Use and the First Year of Perfect Use of Contraception and the Percentage Continuing Use at the End of the First Year: United States

Emergency contraceptive pills: Treatment initiated within 72 hours after unprotected intercourse reduces the risk of pregnancy by at least 75%.[i] Lactational amenorrhea method (LAM) is a highly effective, *temporary* method of contraception.[j]			

[a]Among *typical* couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

[b]Among couples who initiate use of a method (not necessarily for the first time) and who use it *perfectly* (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

[c]Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

[d]The percentages becoming pregnant in columns 2 and 3 are based on data from populations where contraception is not used and from women who cease using contraception in order to become pregnant. Among such populations, about 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentage who would become pregnant within 1 year among women now relying on reversible methods of contraception if they abandoned contraception altogether.

[e]Foams, creams, gels, vaginal suppositories, and vaginal film.

[f]Cervical mucus (ovulation) method supplemented by calendar in the preovulatory phase and basal body temperature in the postovulatory phase.

[g]With spermicidal cream or jelly.

[h]Without spermicides.

[i]The treatment schedule is one dose within 120 hours after unprotected intercourse, and a second dose 12 hours after the first dose. Both doses of Plan B can be taken at the same time. Plan B (1 dose is 1 white pill) and Preven (1 dose is 2 blue pills) are the only dedicated products specifically marketed for emergency contraception. The Food and Drug Administration has in addition declared the following 17 brands of oral contraceptives to be safe and effective for emergency contraception: Ogestrel or Ovral (1 dose is 2 white pills), Alesse, Lessina, or Levlite (1 dose is 5 pink pills), Levlen or Nordette (1 dose is 4 light-orange pills), Cryselle, Levora, Low-Ogestrel, or Lo/Ovral (1 dose is 4 white pills), Tri-Levlen or Triphasil (1 dose is 4 yellow pills), Portia or Trivora (1 dose is 4 pink pills), Aviane (1 dose is 5 orange pills), and Empresse (1 dose is 4 orange pills).

[j]However, to maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breastfeeding is reduced, bottle feeds are introduced, or the baby reaches 6 months of age.

From Trussell J. Chapter 13. *In* Hatcher RA, Trussell J, Stewart F, et al (eds). *Contraceptive Technology,* 18th rev. New York, Ardent Media, 2004.

sperm through the cervix. The foreign body reaction also makes the environment hostile to sperm and eggs. The frequency of ovulation is reduced with the LNG-IUS overall. However, this is not the primary mechanism of action. Women may ovulate variably with the LNG-IUS in place. All the effects that render both intrauterine contraceptives effective are reversed promptly upon their removal.

Resumption of fertility seems to occur at the same rate as discontinuation of barrier methods of contraception,[12,13] although the data on the contemporary IUDs are limited. Pregnancy outcomes including term delivery, spontaneous abortion, and ectopic pregnancies after IUD removal is unchanged from the baseline incidence of these events in the population.

Considerations for IUD Placement

Considerations that should be reviewed with patients before IUD placement include the timing of insertion, the bleeding patterns to be expected, the side effects of the method, and the expected interval of use. There are very few contraindications to IUD use; appropriate candidates for the IUD include women who desire long-term contraception regardless of age of parity.[6] The insertion of an IUD during the menstrual period does lend some benefits which include lubrication and slight opening of the cervical os from the menstrual flow, a decrease in bleeding symptoms after IUD placement due to the pre-existing bleeding from the menses, and the assurance that the patient is not pregnant. However, IUDs may be inserted at any time during the cycle so long as pregnancy has been excluded. The copper IUD is an effective post-coital contraceptive as well so it can be placed after unprotected intercourse and then used long-term.[14,15]

Bleeding patterns may change with both intrauterine contraceptive methods. The copper-T 380A is associated with approximately a 55% increase in menstrual blood loss.[16] In contrast, the amount of blood loss is significantly reduced to about 5 mL per cycle with the LNG-IUS.[17] The bleeding patterns with the T380A IUD may be most increased during the first few months of use, and some patients may require supplemental iron and prostaglandin synthetase inhibitors during menses to help counteract these effects. Bleeding patterns with the LNG-IUS are variable. The general picture of bleeding patterns is unscheduled bleeding during the first few months of use due to the erratic thinning of the endometrium. Over time, bleeding days decrease and approximately 20% of women are amenorrheic at 1 year of use. Women who do experience menstrual periods with the LNG-IUS in place generally have light periods or perhaps even spotting as opposed to longer and full menstrual flow.

Rare but potential complications of IUD insertion include expulsion, infection, and perforation. Expulsion is the most common risk of IUD placement, and while not particularly dangerous, the detection of the expiation is important so that the woman can use a back-up method of pregnancy prevention. Risk factors for expulsion include: nulliparity, menorrhagia, prior expulsion, age less than 20 years, insertion immediately after a second trimester abortion, or postpartum.[7,18,19] Patients can be quoted a 3% to 10% annual risk of this occurrence. Monthly string checks and warning signs should be reviewed so that early detection of expulsion is maximized. There has been a documented transient increase in the risk of infection within the first 20 days of intrauterine device placement.[12] This is likely due to the introduction of bacteria into the upper genital tract with the placement of the IUD or with the sounding of the uterus. However, over time Pelvic Inflammatory Disease (PID) prevalence is the same with IUD users as in the general population. One study has shown a decreased risk of PID among LNG-IUS users when compared to those who use the T380A. For this reason, some have advocated the levonorgestrel intrauterine system as an optimal method for younger women who may be at a baseline increased risk of PID. As with all nonbarrier methods of contraception, patients should be counseled that the intrauterine system does not protect against sexually transmitted infections, and if such a risk is present, condoms should be used.

Perforation is another uncommon risk of IUD insertion, but it is potentially serious. Perforation occurs at the time of insertion, and perforation rates are approximately 1 in 3000 insertions.[20] This risk is due to the blind introduction of the device into the uterus. At any time, if an IUD is found to be outside the uterus, even in asymptomatic patients, it should be removed from the peritoneal cavity. The presence of the copper IUD in the peritoneal cavity has been associated with complications, including severe adhesions and bowel obstruction. Such data are not available for the levonorgestrel intrauterine system, but until there is reason to believe otherwise, this IUD should also be removed, usually via laparoscopic approach.

Pregnancies are rare with an IUD in place given their efficacy. However, if a woman conceives while using an IUD and the device is not subsequently removed, the incidence of spontaneous abortion is about 55%, about three times greater than would occur in pregnancies without an IUD. The current recommendations include removal of an IUD should a woman conceive with the IUD in place and wishes to continue the pregnancy. There is difficulty with removal of the IUD at the time of pregnancy diagnosis. Ultrasound guidance and other techniques may improve the ability to safely remove the IUD without repeated prodding.[20,21]

The overall safety of intrauterine contraceptives demonstrate that they are not associated with an increased risk of endometrial or cervical carcinoma and may actually be associated with a reduced risk in these neoplasms during use and after removal.[22,23] The IUD is a very useful method of contraception for women who have completed their families and do not wish to have permanent sterilization. The LNG-IUS has many noncontraceptive benefits such as a decrease in menstrual symptoms and bleeding, and it is also a treatment for endometrial hyperplasia. Studies have also shown that the LNG-IUS is useful for treatment of women with adenomyosis and endometriosis. Women in the United States who use an IUD have a higher level of satisfaction with their method of contraception than do women using any other method of reversible contraception. IUD use is very common among female gynecologists but is underutilized by a large proportion of candidate women in the United States.

Contraceptive Implants

Implants allow for long-acting reversible contraception without a pelvic exam and regardless of shape and size of the uterus. Subdermal implants were approved by the FDA in 1990. Norplant is a sustained release progestin-only system that consists of six capsules, each measuring 34 mm in length, with a 2.4 mm outer diameter. Each capsule contains 36 mg of levonorgestrel for a total of 216 mg of steroid hormone that remains unchanged within capsules over 9 years of use. Norplant is no longer available on the U.S. market. However, it is widely used in other parts of the world. Implanon/Nexplanon is a progestin-only method that contains 68 mg of 3-ketodesogestrel (etonogestrel) within a single 4-cm flexible rod. The major mechanism of action of subdermal implants is ovulation inhibition via inhibition of luteinizing hormone.[24-26] Insertion is accomplished in the outpatient setting. The capsules are implanted in the subcutaneous tissue through a trocar that is enclosed in the contraceptive implant

kit. As with all progestin-only methods, the cervical mucus is thickened and the endometrial lining becomes decidualized. The effects on the endometrial lining produce the clinical symptoms of initial irregular unscheduled bleeding, followed by scant bleeding or amenorrhea.[25,26] Amenorrhea rates with Implanon in clinical trials run about 50% of women. Frequent and prolonged bleeding occurred in 20%.[25,26]

In one multicenter study in Europe and Canada, the discontinuation of this method for abnormal bleeding reached a rate of 23% within the first 2 years of use.[27] However, in a comparative study of the single implant (Implanon) with the six capsules of levonorgestrel (Norplant), there were fewer bleeding episodes and less blood loss per episode with the single implant. The most common adverse effects with the implant were acne, breast pain, and headache.[26] The etonogestrel implant (Implanon) lasts for 3 years. It releases 60 to 70 mg of etonogestrel per day and this gradually decreases over time.[28] Levels of etonogestrel in the serum are therapeutic within 8 hours of insertion. In clinical use, etonogestrel implant (Implanon) can be inserted within 5 days of the onset of the menstrual cycle in a cycling woman and in the setting of a negative hCG in a noncycling woman. Etonogestrel implant has not yet been FDA approved for postpartum use, but it appears to be safe for immediate postpartum insertion[29-31] with improved long-term pregnancy prevention when compared with other postpartum methods.[32] Implanon, or Nexplanon, is also approved for use immediately after miscarriage and after abortion.

Steroid Contraceptives

Hormonal contraception was initially marketed in the United States in pill form in 1960. The original formulation included 50 μg of estrogen. Such dosing is rarely used today, and the majority of hormonal contraceptives on the U.S. and European markets include doses of 35 μg of estrogen or less, all of which qualify as "low-dose" hormonal contraceptives. The oral contraceptive pill is still the most widely used hormonal contraceptive delivery system. However, steroid contraceptives also take the form of a transdermal patch, a combined hormonal vaginal ring, and progestin-only methods include a 3-month injectable, a subdermal implant, and an intrauterine contraceptive. The oral contraceptive pill is perhaps the most widely studied medication in history. Although it is biologically plausible that other delivery systems, such as the transdermal patch and the vaginal ring, carry with them similar contraceptive benefits, side effects, and contraindications as the combined contraceptive pill, verification of this biological plausibility has not yet been done in large clinical trials. For this reason, we will focus on the combined hormonal contraceptive pill when discussing the details of the mechanism of action, the side effects, the noncontraceptive benefits, and the contraindications to combined hormonal contraceptive use. The specific issues related to the other delivery systems will be addressed in the respective sections.

Hormonal Contraception

The history of hormonal contraception dates back into the early 1900s when it was observed that ovulation is linked to pregnancy and the presence of a corpus luteum. The history of hormonal contraception is not glamorous, but instead exemplifies the dedicated, multidisciplinary efforts required to make scientific advances that may be politically challenging. The chemist Russell Marker purified progesterone from both animal and plant sources. Carl Djerassi, another chemist at the company Syntax, found that the progestational activity of yam-derived progesterone could be enhanced by removing the 19-carbon from this plant progesterone. A reproductive health activist named Margaret Sanger brought the scientist Gregory Pincus together with the philanthropist Catherine McCormick in the 1950s. Pincus, together with other scientists from Boston, worked with the funding supplied by Catherine McCormick to develop a progestational agent in pill form to act as a contraceptive. The clinical trials of the early oral contraceptive pill were conducted in Puerto Rico. The initial compound consisted of 10 to 40 mg of synthetic progestin. The initial products, however, were contaminated with 1% mestranol, a synthetic estrogen. When the mestranol was removed from the compound for a more pure progestational agent, clinical trial results demonstrated more breakthrough bleeding and the decision was made to retain the estrogen for cycle control. This is the history behind the combined hormonal contraceptive as we know it today.

Pharmacology

There are three main formulations for combined hormonal contraception delivered orally. These include monophasic combination pills, multiphasic combination pills, and progestin-only pills. The progestin component of the combined hormonal contraceptive is most commonly a 19-nortestosterone progestin. These progestins more closely resemble testosterone than their alternative, the 21-carbon acetoxyprogesterone derivative. Medroxyprogesterone acetate and megestrol acetate are 21-carbon progestins. The two classes most commonly used are the estranes and gonanes. Those derived from 17α-acetoxyprogesterone are referred to as the pregnanes. 19-Nortestosterone derivatives are orally active, but they do carry some androgenic and progestational effects. The estrane family of progestin, norethindrone derivatives (Fig. 36.1), include norethindrone, norethynodrel, norethindrone acetate, ethynodiol

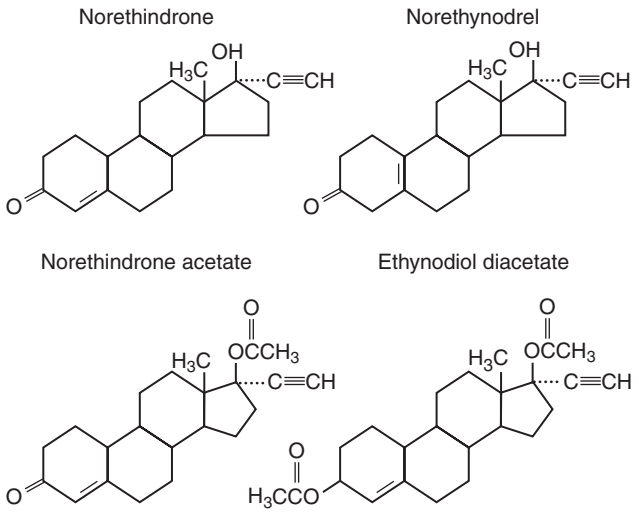

FIGURE 36.1 Chemical structures of the estrane progestins used in oral contraceptives.

diacetate, lynestreneol, norgestrel, norgestimate, desogestrel, and desogen. Regardless of the nomenclature, most estrane progestins are converted to norethindrone when they are metabolized. The norgestrel family of progestins, the gonane progestins (Fig. 36.2), include desogestrel, gestodene, norgestimate, and etonogestrel, and are utilized in the combination vaginal ring. Drospirenone is one progestin that is used in oral combination hormonal contraception but is not a member of the estrane or gonane families. Drospirenone is considered to have less androgenicity than the 19-nortestosterone-derived progestins. Drospirenone is derived from spironolactone and it has anti-androgenic and antimineralcorticoid activity. This formulation has not been shown to have decreased progestin associated side effects in randomized control trials at a population based level. However, it is an option for women using combined hormonal contraception today. Because the progestin component of combined hormonal contraception is what is responsible for the contraceptive efficacy, most dosages of oral contraceptive pills are dependent upon the amount of progestin required to achieve contraceptive efficacy. The gonane class has greater progestational activity per unit weight than the estrane class, which accounts for the smaller amount required in these oral contraceptive formulations.

Combination hormonal contraceptive pills by definition combine the progestin with one of two types of estrogens, most commonly ethinyl estradiol and less commonly ethinyl estradiol 3-methyl ether, which is otherwise known as mestranol (Fig. 36.3). The original oral contraceptive formulations contain mestranol, which was utilized in the 50-μg formulation. These 50-μg formulations are termed first-generation combined hormonal contraceptives. These forms are rarely utilized today, and most oral contraceptives contain estrogen doses of 35 μg or less and are referred to as low-dose estrogen oral contraceptives. Oral contraceptive pills with 20 to 35 μg of ethinyl estradiol are termed second-generation products. The third-generation formulation refers to those with the newer versions of the levonorgestrel derivatives, the newer versions of the gonane progestins, and they include desogestryl, norgestimate, and gestodene. Combination oral contraceptives are given continuously for 3 weeks, and the traditional formulation allows for a placebo, medication-free week, in the fourth week. The withdrawal of the estrogen in the combined hormonal contraceptives results in endometrial sloughing. This sloughing results in a withdrawal bleed that usually lasts 3 to 4 days. Uterine blood loss is about 25 mL and this is less than the average 35 mL that is lost with menses in an ovulatory cycle.

Mechanism of Action

The traditional contraceptive pills are given for 3 out of 4 weeks in the month. Newer formulations have focused on diminishing or eliminating the pill-free week in order to allow for a decreased number of bleeding days or elimination of bleeding days entirely. The progestin component of the combination pills prevents ovulation by inhibiting gonadotropin secretion. This effect comes directly from the progestational agent's suppression of luteinizing hormone (LH) secretion, thereby preventing ovulation. The estrogenic agent suppresses follicle-stimulating hormone (FSH). However, it is important to note that even if follicles do develop, which is commonly seen with combination pills of 20 μg or less, these follicles do not develop sufficiently and the progestational component still inhibits the luteinizing hormone surge that is necessary for ovulation. The progestin component also works by thickening the cervical mucus and altering the endometrium such that it is not receptive to implantation. The endometrium in a progestin-dominant milieu is decidualized and atrophic. These lower genital tract effects are sufficient in and of themselves to afford

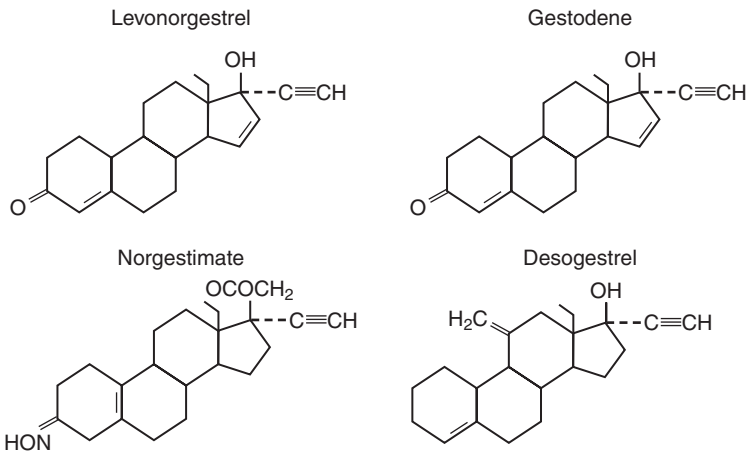

FIGURE 36.2 Chemical structure of the gonane progestins used in oral contraceptives.

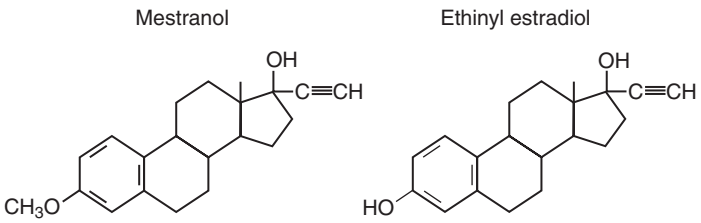

FIGURE 36.3 Structures of the two estrogens used in combination oral contraceptives.

good contraception. In fact, many progestin-only methods work primarily by cervical mucus thickening and endometrial lining decidualization.

The FDA has approved three new contraceptive formulations for continuous use. These methods are called Lybrel, Seasonale, and Seasonique. The efficacy of these regimens appears to be similar to the 21/7-day efficacy period. The clinical trials that were done initially for the approval of these formulations demonstrate that continuous use of hormonal contraception suppresses folliculogenesis at improved rates over the traditional 21/7-day regimens. This choice should be considered in the clinical scenario when patients may have ovarian cysts and are looking for suppression of follicle growth as a noncontraceptive benefit of their hormonal contraceptive. Studies have demonstrated that these new formulations are acceptable to women of reproductive age. They are highly convenient with fewer bleeding days over time. Noncontraceptive benefits include decreased dysmenorrhea, decreased endometriosis pain, and fewer instances of headaches, bloating, and mood swings. Good candidates for continuous hormonal contraceptives are all women but specifically women who have symptoms in their pill-free week. Breakthrough bleeding is, however, more common than during the first 3 months of use in the conventional 21/7-day regimen. Over time, this breakthrough bleeding reaches the usual rate.

Long-term safety data have not yet been amassed with continuous hormonal contraceptives, but markers of safety and pregnancy after discontinuation appear to be similar to the traditional 21/7-day oral contraceptive pill. Lybrel is a 20-μg ethinyl estradiol pill with 0.09 mg of levonorgestrel. It can be taken 365 days per year. There is no placebo or pill-free interval. The Pearl Index for efficacy is 1.55 per 100 user-years.[33] There appears to be no differences in pregnancy rates between Lybrel and a 20-μg ethinyl estradiol per 0.1 mg levonorgestrel pill.[34] Sixty percent of women are amenorrheic by the year's end. Breakthrough bleeding is common, with 40% of women complaining of breakthrough bleeding at the third pack, decreasing over time to 21% at pack 13.[33] So, a large percentage of women on Lybrel are amenorrheic, and those who are not will likely have unscheduled bleeding. Once Lybrel is discontinued, 99% of women will resume regular menses within 90 days.

Seasonale was FDA approved in 2003 as a 30-μg ethinyl estradiol and 0.15 mg levonorgestrel 84-day pill regimen with 7 days of placebo every 3 months. Patients have four withdrawal bleeds per year with 91-day cycles. A randomized control trial[35] comparing Nordette, which is the same hormonal dosing but in a traditional 21/7-day regimen, to Seasonale showed that Nordette had a higher continuation rate at 1 year, and an improved acceptability of bleeding patterns. Both have high compliance, however, and the Pearl Index is 0.6 for Seasonale and 1.78 for Nordette, rendering Seasonale a more effective contraceptive. Total number of bleeding days is decreased with Seasonale but there is increased breakthrough bleeding in the first 3 months. Its safety profile approximates that of other hormonal contraceptive pills with no unexpected laboratory changes, no lipid changes, and no thromboembolic events in greater than 1000 cycles of Seasonale use. Seasonique[36] is a 30-μg ethinyl estradiol pill with 0.15 mg of levonorgestrel for 84 days, followed by 7 days of 10 μg of ethinyl estradiol. This pill allows for four withdrawal bleeds per year and has a Pearl Index of 0.78. Unscheduled bleeding decreased with time in clinical trials, and scheduled bleeding occurs for about 2 to 3 days in duration. The reasoning behind these newer formulations is to increase efficacy and theoretically decrease side effects associated with the pill-free period. Shorter hormone-free intervals suppress the hypothalamic-pituitary axis more consistently.[37] Studies have demonstrated less folliculogenesis in the extended cycle regimen.[38] A randomized control trial[39] was done to compare a 21/7-day pill consisting of 20 μg of ethinyl estradiol and 100 μg of levonorgestrel versus a 20-μg ethinyl estradiol per 150-μg desogestrel regimen, followed by two placebo pills, followed by five pills of 20 μg of ethinyl estradiol versus 28 solid days of 20 μg ethinyl estradiol and 150 μg desogestrel. This trial had three arms and examined the traditional pill-free interval versus estrogen alone in place of a pill-free interval and demonstrated a statistically significant decrease in folliculogenesis on ultrasound and lower FSH and LH levels during the pill-free interval. A Cochrane review[40] of traditional 21/7-day administration versus continuous administration showed no difference in efficacy, no difference in safety profiles, high compliance rate, and high satisfaction rate. Continuous administration was in this review associated with a decrease in headaches, genital irritation, feelings of fatigue, bloating, and menstrual pain. Mood, headache, and pelvic pain scores improved with continuous hormonal contraception. In women who had undergone ablation for endometriosis and then failed traditional 21/7-day low-dose monophasic contraception for suppression of pain, there was significantly reduced frequency and severity of pain on continuous low-dose monophasic contraceptives for up to 24 months. Continuous oral contraceptive pills (OCPs) suppress both the ovary and the endometrium to a greater extent than cyclic OCPs and have been shown to have beneficial effects on both pain and mood symptoms related to menstruation.[41] It is important to note that although the FDA has approved these three formulations for extended use, many physicians have been using extended cycle regimens for their patients for years. Most monophasic hormonal contraceptive pills will produce acceptable results when used continuously.

Side Effects of Continuous Cycle Oral Contraceptives

There are limited long-term data to answer the question of adverse outcomes in continuous hormonal contraception. The longest study is a 2-year study on Seasonale.[42] What these data do show are that unexpected bleeding and spotting decrease with length of use: this is an important counseling point for any woman considering use of extended cycle OCPs. The incidence of thromboembolism is not well known. There has only been one reported case.[35] No endometrial hyperplasia or cancers were reported in these clinical trials.[35,42] In terms of lipid profiles, triglycerides and low-density lipoproteins (LDLs) were similar in range for women on continuous hormonal contraception as those who were cycling.[35,36] In one study, there were five cases of women with cholecystitis or cholelithiasis, but it is unclear if this was due to other risk factors.[38] Return to fertility appears to be fairly prompt after continuous hormonal oral contraception is discontinued.[34,38,42] The study of Lybrel[34] demonstrated that 99% of women were ovulating within

90 days of discontinuing the 365-day per year pill. Ninety-two percent ovulated within 60 days, and 38.5% ovulated within 30 days of discontinuing the oral contraceptive.

Metabolical Effects

The use of synthetic steroids and combination hormonal contraceptive formulations has multiple metabolical effects. The vast majority of these effects, including effects on lipids, carbohydrate metabolism, and other hormonally responsive organs, such as the breasts, are generally transient and self-limited and minor. Rarely, however, these other effects can result in serious consequences. The majority of the serious side effects associated with hormonal contraception are cardiovascular events that are related to the effects that estrogen has on the coagulation system.

Venous Thromoembolism

The increased cardiovascular events including venous thromboembolism and arterial thromboembolism appear to be due to coagulation-mediated effects, not atherosclerosis. Epidemiological data have shown us that the risk of venous thromboembolism (VTE) is dose-dependent with the amount of estrogen in the oral contraceptive formulation.[43] The background rate of venous thromboembolism in women of reproductive age is thought to be about 0.8 per 10,000 women-years. Recent data,[44] however, have demonstrated that the true prevalence of VTE in the population of women is difficult to elucidate. Deep venous thromboembolism (DVT) in particular is often silent and self-limited. Given that symptomatic venous thromboembolism is clearly a rare event, but potentially also asymptomatic and therefore underreported, background risk is hard to discern. This should be kept in mind at all times given the reporting bias that may be present when venous thromboembolism is attributed to the use of oral contraceptives.

Several observational studies have been performed to determine the occurrence of VTE in users of oral contraceptive containing formulations with less than 50 μg of estrogen[45-47] These studies were consistent and showed that the risk of DVT was increased approximately three- to fourfold among women using oral contraceptives compared with women not using oral contraceptives. Thus, the use of oral contraceptives with less than 50 μg of estrogen is still associated with about a threefold to fourfold increased risk of VTE compared with a nonpregnant population who are not taking oral contraceptives, but about a 50% reduction in risk of VTE compared with a pregnant or recently postpartum population.[47]

Several epidemiological papers have similarly considered the impact of the different progestin preparations on VTE risk.[48-52] Many of these use insurance-claims databases to address the questions, and one used a prospective study design. In young healthy women overall, the risk of VTE is low at 1 to 13 events per 10,000 women. When compared with pregnancy and the postpartum period, the benefits of combined oral contraceptive (COCs) outweigh the risks. In the 1980s, disproportionate concern about the risk of VTE associated with COCs caused many women in the United Kingdom to discontinue their COCs and was associated with an increase in unintended pregnancy and induced abortions. While there may be debates about the very small potential differences in risk among hormonal contraceptive preparations, the clear message should be that as a class, hormonal contraception is safe and promotes health.[53]

Stroke and Myocardial Infarction

The use of 50-μg oral contraceptive pills did appear to have an impact on the coagulation system. This was due to an increase in clotting factors, such as factors V, VIII, X, and fibrinogen. Studies that addressed this question in the group taking COCs of 35 μg and less have not demonstrated clearly an increased risk of clotting related events in women using pills at this dose.[54,55] The incidence of a cardiovascular event is not associated with duration of oral contraceptive (OC) use.[56] There is no increased risk of cardiovascular morbidity among past-users of OCs.[57] Most of the studies that have shown an increased risk of myocardial infarction have been observational studies in which the women at risk for myocardial infarction (MI) also had other risk factors that cause arterial narrowing, such as preexisting hypercholesterolemia, hypertension, diabetes mellitus, or smoking more than 15 cigarettes per day. Smoking is clearly thrombogenic in and of itself,[58] and smoking is an independent risk factor for MI.[54] It appears, however, that the use of low-dose oral contraceptives by heavy cigarette smokers significantly enhances their risk of experiencing an MI because these two factors act synergistically.[54] Prior oral contraceptive use in a smoker and prior smoking in an oral contraceptive user does not seem to be associated with an increased risk of MI. Both the Royal College and the WHO studies report that the risk of MI in oral contraceptive users was severalfold greater if they had hypertension than if they did not. Two large case control studies in the United States have shown no significantly increased risk of MI in oral contraceptive users.[55,59] A recent World Health Organization (WHO) technical report stated that women who do not smoke and have their blood pressure checked and who do not have hypertension or diabetes have no increased risk of MI if they use combined oral contraceptives, regardless of their age.[60]

Exogenous estrogen does increase the synthesis of several coagulation factors that promote thrombosis in a dose-dependent manner. The small increased risk of VTE exists in all women using combined oral contraceptives (COCs). The risk of MI or stroke in nonsmoking, normotensive women is not increased with COC users. However, in women with preexisting medical problems, the risk of thrombosis may be further increased by simultaneous use of combined hormonal contraceptives. The potential risk of stroke with combined hormonal contraceptives is even more difficult to assess than the risk of MI or DVT. Early studies in the 1970s of higher dose (50 μg) combined hormonal contraceptives did suggest a potential relationship between this dose of pill and stroke. However, even these data were conflicting. Data on early formulations of pills do not apply to the contemporary pills. Women without other risk factors do not appear to have an increased risk of stroke while on oral contraceptive pills.[61,62] The safety of pills with doses under 35 μg of estrogen in women who smoke or have other thrombogenic medical problems, such as hypertension with end-organ disease, is not known because women with these risk factors are rarely on combined hormonal contraceptives today.

Other Metabolical Effects

Although combined hormonal contraceptives do have metabolical effects that are detected at the laboratory level, such effects are very rarely associated with statistically significant or concerning outcomes. Table 36.3 shows the chemical and clinical effects that estrogens and progestins have on the human metabolical system.

Mood Changes

The 19-nortestosterone derivatives do have central nervous system effects and estrogen does as well. It was postulated that high doses of synthetic estrogens would replace changes in luteal depression. No study to date has demonstrated an increase in depression due to estrogen at the dosing currently used in combined oral contraceptives.[63,64] However, the progestin component may be associated with an increase in irritability, fatigue, and depression.

Hepatic Proteins

Synthetic estrogens in oral contraceptives cause an increase in hepatic production of several proteins and these include sex hormone–binding globulin (SHBG) and globulins that are part of the coagulation cascade, such as factors V, VIII, and X and fibrinogen.[65] Progesterone and progestins decrease the synthesis of SHBG. The balance between these effects make one pill more appropriate for, for example, a woman with hyperandrogenicity due to polycystic ovary syndrome over another.

Increased angiotensin may be the mechanism by which blood pressure can become elevated. This seems to be an estrogen-driven effect, because there an increase in mean blood pressure in women who ingest oral contraceptive pills levels, but this is lower in women who ingest formulations with 30 to 35 μg of ethinyl estradiol. Women who use oral contraceptive pills are slightly more likely to develop hypertension and about 0.4% of current low-dose oral contraceptive users became hypertensive in one study. Women who receive progestins without an estrogen component do not have an increase in blood pressure over time.[66]

Obesity

Obesity and its accompanying comorbidities are rapidly increasing worldwide. Obesity alone does not appear to be protective against unintended pregnancy. Furthermore, pregnancy in obese women increases risks for obstetrical and neonatal complications. For this reason, appropriate contraception is important in the obese population in order to help reduce unnecessary risk of stillbirth neonatal death, cesarean delivery, endometritis, and thromboembolism—all of which appear to be increased in pregnancy in obese women.

Obesity may decrease the effectiveness of some contraceptives. It has been shown that obesity can affect how a person metabolizes any medication, including hormonal contraceptives.[67-69] It remains unclear if these pharmacokinetic differences are substantial enough to result in unwanted pregnancies from contraceptive failure. A recent systematic review demonstrated that there was a higher failure rate among women with increased body weight and/or increased BMI using the following methods: certain combined oral formulations, the transdermal patch, a progestin-only vaginal ring, and the six-rod levonorgestrel implant.[70]

A case control study of 454 patients age 15 to 45 with a first episode of venous thromboembolism (VTE) revealed that the combined effect of obesity and oral contraceptive pills incurred a tenfold increased risk of VTE among women with a BMI greater than 25 kg/M^2. This risk increase was 2 to 4.6 times higher than in patients with only one risk

factor. On these data, some organizations, specifically the Royal College of Obstetricians and Gynecologists, advised that the risk of oral contraceptives generally outweigh the benefits for women with BMI of 35 to 39 kg/M^2 and that oral contraceptive pills that are combined should not be used in women with a BMI of 40 kg/M^2 or more.[71,72]

Oral Contraceptives and Malignancies

Given the extensive history now of oral contraceptive pills and our ability to follow populations of women who used these pharmaceuticals in their reproductive years, both prospective cohort and retrospective case control designs have been used to assess the relationship between OCs and cancer risk. In general, hormones are considered promoters but not initiators of cancer, so the oncological effects, if any, of steroids should be seen as a dose response and may or may not be related to duration of use.

A study examining cancer incidence in relation to OC use in the Oxford Family Planning Association contraceptive study included 17,032 women recruited at family planning clinics ages 25 to 39 years old between 1968 and 1974, who were using OCs, a diaphragm, or an intrauterine device. Breast cancer findings (844 cases) were very reassuring (relative risk ratio [RR][45] comparing women ever using OCs with those never doing so 1.0, 95% confidence interval [CI] 0.8 to 1.1). There was a strong positive relationship between cervical cancer incidence (59 cases) and duration of OC use (RR comparing users for 97+ months with nonusers 6.1, 95% CI 2.5 to 17.9). Uterine body cancer (77 cases) and ovarian cancer (106 cases) showed strong negative associations with duration of OC use: RRs for 97+ months of use were 0.1 (95% CI 0 to 0.4) and 0.3 (95% CI 0.1 to 0.5), respectively. This apparent protective effect for both cancers persisted more than 20 years after stopping OCs.[73]

Ovarian Cancer and Benign Ovarian Neoplasms

Over 20 reports of oral contraceptives and the subsequent evolvement of ovarian cancer have been published. Eighteen of these have found a reduction in risk in the most common of epithelial ovarian cancers (Fig. 36.4). The magnitude of the risk reduction appears to be linked to the duration of time of use of the oral contraceptive pill.[74] A large case control study has demonstrated that not only is the duration of oral contraceptive use related to the protective effect, but that this risk reduction lasts for years after the cessation of oral contraceptive use.[73] Oral contraceptives appear to also significantly reduce the incidence of benign ovarian neoplasms, including serous and mucinous cystadenomas, benign cystic teratomas, fibromas, and endometriomas.[75] Endometrial cancer has similarly been well studied in relation to oral contraceptive use. Twelve retrospective studies have suggested an association between oral contraceptive use and endometrial cancer risk reduction.[76] One study has shown that oral contraceptive users have one-third the risk of endometrial cancers as nonusers and this likewise persists after cessation of use, and the duration of oral contraceptive use seems to correlate with the amount of risk reduction found.

Breast Cancer

Multiple studies have tried to address the concern that estrogen might stimulate the growth of neoplastic breast tissue. One study of over 53,000[77] women did show that there is a slightly increased risk (RR 1.24, 95% CI 1.15 to 1.3) of women who are actively using oral contraceptives developing breast cancer. This association appears to decline after stopping OCs and was no longer present after 10 years of use. These cancers appear to be less advanced clinically than the cancers that occur in non-OC users. It is possible that breast cancer is diagnosed earlier in OC users than in nonusers, but this could also be due to a biological effect of the OCs in terms of tumor promotion. New data demonstrate that OCs do not further increase risk for women with a family history of breast cancer and may be associated with a reduction in risk of breast cancer.[78,79]

A quantitative assessment of oral contraceptive use and risk of ovarian cancer.* Obstet Gynecol *80:708–714, 1992.)*

Postcoital Contraception

Postcoital contraception, also known as emergency contraception or the "morning after pill," is the use of a contraceptive method after unprotected acts of intercourse. For women who have had known unprotected intercourse, meaning they were not using a primary method of contraception or in whom a barrier method may have failed, postcoital contraception provides a second opportunity to decrease the risk of pregnancy from a midcycle act of intercourse. Both hormonal methods and the ParaGard IUD can be used as effective postcoital contraception. The original methods of emergency or postcoital contraception were developed by using high doses of estrogen compounds. Examples of such compounds include diethylstilbestrol 25 to 50 mg per day, ethinyl estradiol 5 mg per day, or conjugated estrogens 30 mg per day. With these agents, treatment was continued for 5 days. If treatment was initiated within 72 hours of an isolated midcycle act of intercourse, the efficacy was estimated at 75%.[80] If more than one act of intercourse had occurred, or if the treatment was delayed, the efficacy was decreased.

The side effects associated with these high doses of estrogenic compounds led to the development of an alternative approach tested in Canada in the 1970s and now known as the Yuzpe method. This is a combination oral contraceptive method of postcoital contraception that initially consisted of using the Ovral oral contraceptive pill, using a total of four tablets of ethanyl estradiol (0.05 mg) and DL-norgestrel (0.5 mg). These are given in two doses of two pills each, 12 hours apart. Studies[81,82] demonstrated that this regimen had a similar degree of efficacy and decreased adverse side effects when compared with the 5 day estrogen regimens. Pooled data from studies on the Yuzpe method from 1977 until 1993 that include 5226 women demonstrated a failure rate of about 1.5%.[83] Demographers estimated that the Yuzpe regimen prevents about 75% of expected pregnancies when used within 72 hours of unprotected intercourse. A combined method of estrogen and progestins called Preven was then FDA approved as a dedicated product for postcoital contraception. This product, however, is no longer on the market in the United States.

More recently, a progestin-only method of postcoital contraception has been developed and is now available in a dedicated product called Plan B. The initial Plan B product consisted of two tablets of 0.75 mg of levonorgestrel. The product labeling indicates that the first pill should be taken at time 0 and the second 12 hours later. The use of levonorgestrel alone has been compared directly to levonorgestrel plus estradiol in a randomized control trial.[81] Failure rates were similar when these two regimens were ingested within 48 hours of unprotected intercourse, each about 2%. Substantially less nausea and vomiting was noted with the levonorgestrel-alone method.[82,84] Given the comparable efficacy and improved side effect profile, progestin-only methods of postcoital contraception are now preferable. A randomized control trial performed by the World Health Organization[84] that included 2000 women in 21 centers evaluated the efficacy of levonorgestrel alone within 72 hours after a single act of unprotected intercourse. In this trial, the 1.1% pregnancy rate demonstrated superior efficacy over the Yuzpe method, which was associated with a 3.2% pregnancy rate. The estimates calculated by the authors demonstrated that 85% of pregnancies were prevented with levonorgestrel alone compared to 57% of pregnancies prevented with the combined regimen. Decreased nausea and vomiting were once again demonstrated with levonorgestrel alone.

Effectiveness is greatest with any method of postcoital contraception when it is given within 24 hours of sexual intercourse than in the subsequent 48 hours. Randomized trials have shown that taking both the 0.75 mg tablets of levonorgestrel as a single dose offers the same efficacy without increasing side effects as taking each 12 hours apart. Thus, Plan B One-Step was developed and marketed as a dedicated product containing 1.5 mg of levonorgestrel in a single pill. In addition, though original studies all tested the efficacy of emergency contraceptive regimens within 72 hours of unprotected intercourse, more recent studies have demonstrated efficacy up to 120 hours after intercourse.[85,86] As stated above, the efficacy declines with increasing time from the unprotected intercourse event. Patients should thus be counseled that emergency contraception can be taken within 120 hours of unprotected intercourse but that it is a time-sensitive drug with maximum efficacy resulting when the intervention is used as early as possible.

Advanced prescription or advanced supply of Plan B has been shown to increase its use among various subgroups of women, including adolescents, and has not been shown to decrease use of the primary method of contraception.[87] Advance prescription of Plan B should be standard of care given its potential to help prevent unintended pregnancy as a backup method. Multiple studies have found no adverse effects in terms of either increased risk taking or decreased contraceptive use. In the United States, Plan B was first made available over the counter for women above the age of 18 in August 2006. In April of 2009, the over the counter access was expanded to include women above the age of 17. There is no reason to suspect that levonorgestrel is unsafe for women younger than the age of 17.[88] As teens are at particularly high risk for unintended pregnancy, advance prescription of emergency contraception should be encouraged for all young women using barrier method contraception or daily methods of contraception. Reproductive health care providers should discuss the availability of postcoital contraception with all patients seeking pregnancy prevention as its use may be necessary in any woman not using a long-term method of contraception (intrauterine device, implant, or sterilization).

The exact mode of action of emergency contraception has not yet been established. Initially it was thought that the estrogen and progestin combination alter the endometrium to prevent implantation of the fertilized ovum.[89,90] More recent studies, however, have suggested that emergency contraception may work through delaying ovulation, or, if taken post ovulation, through the interference of ovum transport or through impairment of corpus luteum function.[91,92] However, the data to support any single mechanism of action with postcoital contraception is inadequate at this point; thus, it is likely a combination of effects that accounts for its efficacy.

The most recent addition to the postcoital contraception armamentarium is ulipristal acetate, marketed in the United States as Ella. Ulipristal is a selective progesterone receptor modulator with primarily antiprogestin activity that is highly effective for use as emergency contraception. Antiprogestins may be more effective than progestins due to their ability to both delay ovulation and inhibit implantation.[93] Ulipristal can delay ovulation by as much as 5 days; of note, ulipristal appears to be effective in the advanced follicular phase even after LH levels have begun to rise, a period when levonorgestrel is no longer effective in inhibiting ovulation. A meta-analysis of two trials of ulipristal versus levonorgestrel for emergency contraception found that ulipristal was at least or more effective at all time intervals (0 to 24 hours, 0 to 72 hours, and 0 to 120 hours).[94] For each time interval, the rate of pregnancy in patients receiving ulipristal ranged from 0.9% to 1.4% versus 2.2% to 2.5% in patients receiving levonorgestrel; these differences were statistically significant. There was no difference in the side effect profile of the two drugs. Ella is given as a single dose of 30 mg ulipristal acetate and can be taken within 120 hours of unprotected intercourse. Currently, Ella is only available by prescription in the United States.

Several studies have found that the insertion of a copper IUD within 5 to 10 days of midcycle unprotected

intercourse is an effective method to prevent pregnancy.[95,96] One such study included nine different trials involving almost 900 women who had received an IUD in the postcoital midcycle. Only one pregnancy occurred in this aggregated group, for a pregnancy rate of approximately 0.1%. Thus, based on studies to date, the insertion of a copper IUD is the most efficacious method of postcoital contraception. Benefit can occur up to 10 days after unprotected midcycle intercourse. The copper IUD is a good option for women who also desire an IUD for long-term contraception after an episode of unprotected intercourse.

Transdermal Contraceptive System

Approved for use in the United States in 2001, the transdermal contraceptive system (TCS) consists of a 20-cm^2, beige-colored, three-layered matrix patch that releases 150 μg of norelgestromin (the active metabolite of norgestimate) and 20 μg of ethinyl estradiol at a constant rate each day into the systemic circulation.[97] The three layers of the thin matrix consist of an outer protective layer of polyester, a medicated adhesive middle layer, and a polyester inner liner that is removed just prior to application to the skin.

Circulating blood levels of each steroid remain relatively constant during the 7 days the patch is scheduled to be in place, as well as for an additional 2 days, in contrast to the peaks and troughs that occur after ingestion of an oral contraceptive pill (Figs. 36.5 and 36.6).[98] In a pharmacokinetic study,[97] steady-state conditions of each steroid were achieved in the serum of women using the patch for three cycles. Steady-state serum concentrations increased only slightly from the first week of the first treatment cycle until the third week of the third treatment cycle, indicating minimal accumulation. The circulating levels of norelgestromin are sufficient to inhibit ovulation while the patch is in place.

The patches are applied to the skin of the abdomen, buttocks, upper arm, or upper torso (except for the breasts) for 1 week and then removed. A patch is applied to a different site for 3 consecutive weeks; no patch is applied during the fourth week to allow withdrawal bleeding to occur. Withdrawal bleeding similar in duration to that which occurs with OC use usually begins 2 to 3 days after the last patch is removed.

Contraceptive effectiveness of the TCS is similar to that for OCs. In a pooled analysis from three large clinical studies, the overall pregnancy rate from more than 22,000 treatment cycles was 0.88 pregnancies per 100 woman-years.[99] In these studies the pregnancies were uniformly distributed among the 3236 subjects with body weight less than 198 pounds, but 5 pregnancies occurred among the 83 subjects weighing 198 pounds or more. Thus, the TCS appears to have a lower level of effectiveness in women with body weight of 198 pounds or more.

A randomized trial demonstrated that the incidence of perfect compliance with the TCS, 88.2% of cycles, was significantly better than with the OC, 77.7% of cycles.[100] The convenient dosing schedule of the patch likely enhances compliance and may result in greater effectiveness than the OC in actual use. In the clinical trials during which 70,552 patches were worn, the rate of replacement for complete detachment of the patch was 1.8%, and for partial detachment was 2.9%.[101] Various conditions of exercise, heat, and humidity did not increase the incidence of detachment or the force required to remove the patch.[102]

Adverse effects were analyzed in the comparative study with the OC. The patch had a higher incidence of intermenstrual spotting and breast tenderness than the OC in the first two cycles of use but not thereafter.[100] About 20% of women using the TCS noted intermenstrual spotting and breast discomfort in the first cycle of use. Application site reaction also occurred in 20% of the subjects using the TCS. Other adverse effects, such as headache and nausea, were similar with these two methods of steroid contraception.[100] Thus, the TCS is an effective reversible alternative method of steroid contraceptive.

Venous Thromboembolism Risk

In 2006, the U.S. product labeling for the TCS was revised to include a warning that the TCS provides a higher steady-state concentration of ethinyl estradiol than OCs and lower peak concentrations. Pharmacokinetic studies reveal that steady-state levels are approximately 60% higher than an OC containing 35 μg of ethinyl estradiol while the peak concentration on the TCS is 25% less than that in women taking OCs (Ortho Evra [norelgestromin/ethinyl estradiol transdermal system], Raritan, NJ; Ortho-McNeil Pharmaceuticals, Inc, 2006).

It is not clear whether this difference in pharmacokinetics translates to a change in the risk of serious adverse events, such as venous thromboembolism. Two studies on this subject have been reported to date. The first was a case-control study with data abstracted from a managed-care database; 68 new cases of idiopathic VTE in TCS users were identified, and when compared to control subjects, the odds ratio (OR) was 0.9 (95% CI 0.5 to 1.6), demonstrating a similar risk for both methods.[103] A second study performed from insurance claim outcomes from a major national health insurer reported a more than twofold increase in the VTE rate (adjusted incidence rate ratio 2.2, 95% CI 1.3 to 3.8) among TCS users compared to norgestimate-containing OC users. Acute myocardial infarction and ischemic stroke were also investigated in this study, but each had too few outcomes to provide conclusive results.[104] The story here is similar to that of the studies on VTE risk with differing progestins. The counselor should keep in mind that the risk of VTE on either TCS or OCs remains lower than the risk of VTE during pregnancy, and if the patient and health care provider believe that the TCS is the best way to prevent pregnancy, it use is certainly warranted.

Continuous Regimens or Extended Use

The TCS had also been studied to evaluate for extended use to delay or prevent menses. A study performed to evaluate the bleeding profile and satisfaction on a continuous regimen compared 158 women using an extended regimen (weekly application for 12 weeks, followed by 1 week off, then 3 more weeks) to 81 women using the usual cyclic regimen (weekly application for 3 weeks followed by 1 week off, continued for four cycles). Extended use resulted in fewer bleeding days overall, with delayed median time to bleeding of 54 days. Women were equally satisfied with both regimens.[105] Recent data suggest that continuous use may result in fewer contraceptive failures that traditional 21 to 7 day use.[106]

Contraceptive Vaginal Ring

The vaginal contraceptive ring contains ethinyl vinyl acetate that releases ethinyl estradiol and the third-generation progestin, etonorgestrel. The ring currently on the market has an outer diameter of 54 mm and a cross-sectional diameter of 4 mm. It was approved by the FDA in 2001. The vaginal contraceptive ring is highly efficacious with a Pearl Index of 1.18 and an efficacy of 99.1%. The vaginal ring is a flexible, soft device and is available in one size only and does not need to be fitted. If desired, the ring can be removed for up to 3 hours without altering the contraceptive effectiveness. In a review of 12 randomized controlled trials comparing the contraceptive vaginal ring and combined oral contraceptives, both forms achieved the same contraceptive efficacy and adequate ovarian suppression with comparable incidence of adverse effects, such as breast tenderness, headache, and nausea. Vaginal administration was associated with higher local adverse events such as leukorrhea, vaginal discomfort, vaginitis, foreign body sensation, expulsions, and coital problems, leading to higher discontinuation rates. Overall, both contraceptives improved overall sexual function and were highly acceptable. Advantages to the ring included lower systemic estradiol exposure (50% compared to a 30-μg ethinyl estradiol pill) with a lower incidence of irregular bleeding and spotting.[107]

Injectable Contraceptives

Injectable contraceptives are used throughout the world. These include depo-medroxyprogesterone acetate (DMPA), norethisterone enanthate (NET-EN), and combined injectable contraceptives of different combinations of estrogens and progestins that are given monthly. DMPA is the only currently available injectable contraceptive in the United States. It is used by approximately 3% of women of reproductive age.

Medroxyprogesterone Acetate

Medroxyprogesterone acetate (MPA) is a 17-acetoxyprogesterone compound. Unlike most other synthetic progestins, MPA is structurally most closely related to progesterone, instead of testosterone, and possesses less androgenic activity. MPA is rapidly metabolized in humans to progesterone. The 3-month injectable dosage is 150 mg. The drug is delivered by intramuscular injection into the deltoid or gluteus muscle and is released slowly into the circulation.

MPA is an extremely effective contraceptive with a 1-year pregnancy rate of 0.1% and a 2-year accumulative pregnancy rate of 0.4%. Its primary mechanism of contraceptive action is ovulation inhibition, but it works by increasing the cervical mucus viscosity and creating progestational changes in the endometrium as well.

Mechanisms of Action

With consistent use, DMPA is highly effective, with a failure rate of approximately 0.4% per WHO clinical trial.[108] DMPA requires re-dosing every 3 months intramuscularly. The contraceptive levels are maintained for at least 14 weeks and may be metabolized differently in different women. There is a margin of safety built into the dosing regimen of intramuscular DMPA. Unlike other lower dose progestin-only methods, DMPA works primarily by blocking the LH surge and ovulation. FSH is not systematically suppressed with progestin-only methods. In addition to LH blockade, the progestin-dominant hormonal milieu results in thickening of the cervical mucus and alteration of the endometrium. Estrogen levels are comparable to those in early follicular phase of noncontracepting women. Because of this, symptoms of estrogen deficiency, such as vasomotor symptoms or vaginal atrophy, are not present with this method of contraception. In order to obtain suppression of ovulation in the initial injection cycle, DMPA must be administered within several days after the onset of menses.[109] Studies show that if DMPA is administered as late as

9 days after the onset of menses, 2 out of 13 women showed evidence of ovulation.[110] It is recommended in the package labeling that the first dose be given within the first 5 days of the onset of menses and evidence supports giving DMPA no later than 7 days after the onset of menses.

Pharmacokinetics

DMPA reaches therapeutic levels within 20 minutes of intramuscular injection.[111] Effective blood levels are found at greater than 0.5 ng/mL and this occurs within 24 hours after injection. MPA appears to be cleared slightly differently depending on the assay used in the study. MPA levels plateau at about 1 to 1.5 ng/mL and remain at that level for approximately 3 months, after which they begin to decline. In some subjects it appears that MPA levels remain detectable in the circulation for 7 to 9 months after initial injection. Estradiol levels in these subjects are found to be in the range of the early follicular phase during these times. However, other studies demonstrated that MPA levels decreased to less than 0.5 ng/mL after 4 to 6 months of use and one study demonstrated a decrease in circulating levels at 13 weeks of use.[112]

The pharmacodynamics of MPA may be variable based on individual metabolism or based on the study assay used, and further studies are needed to improve our understanding of this. However, no study has shown metabolical clearance of therapeutic levels of the drug before 12 weeks after the initial dose, and this supports the current product labeling.

Return to Fertility

The lag time in the clearing of MPA from the circulation results in delayed resumption of ovulation for women in the population.[113] This quality is a by-product of the injectable delivery system. Women who use MPA should be counseled that there will be a delay in the resumption of fertility. This, however, is not a permanent effect. Ninety percent of MPA users become pregnant by 18 months after the last injection.

Disadvantages of MPA Use

Women who use MPA will experience unscheduled bleeding during the early months of use. Perhaps most important, women who experience breakthrough bleeding on MPA should be reassured that this is a well-understood side effect of use of MPA. Weight changes are another disadvantage of MPA use. Other studies have shown longitudinally that MPA users may gain between 3.3 and 8.8 lbs (1.5 and 4 kg) in the first year of use.[24] The weight gain associated with MPA may also have some individual risk factors such as tendency to gain weight and ethnic background. One study demonstrated a statistically significant increase in weight gain among Navajo women randomized to MPA versus combined hormonal contraceptives. The metabolical effects of MPA on body weight are unclear, and weight and exercise should be evaluated in all women who are concerned about weight gain on MPA before the method is discontinued.

There have been no randomized control trials to assess the effects of DMPA on mood. There have, however, been several observational studies that demonstrate that the clinically significant difference in mood is rare with MPA.[114]

Headaches are the most common reason cited for discontinuation of MPA in the first year. There is no conclusive evidence to suggest that the use of DMPA increases the severity of tension of migraine headaches and the presence of headaches is not a contraindication to initiation or continuation of MPA use. However, if women find that their headache incidence increases while on this method, counseling regarding the benefits of perhaps changing to another method should be initiated.

Metabolical Effects of DMPA

DMPA does not increase liver production of proteins as the estrogen component of combined hormonal contraception does. Therefore, there is no evidence to suggest that clotting factors are increased with DMPA use. A WHO study also reported that blood pressure measurements are unchanged with DMPA users over 2 years.[115] Injectable progestins do not appear to be associated with increased risk of VTE, MI, or stroke. This makes DMPA a very desirable method of contraception in women with comorbidities, in an aging cohort, or in potentially obese women because these women may all have other risk factors for venous or arterial thromboembolic events.

Bone Mineral Density

The FDA recently placed a black box warning on MPA labeling which stated that MPA has been shown to be associated with a decrease in bone mineral density in women with long-term use. Many studies have demonstrated that bone mineral density is decreased in women on MPA.[116-118] No studies, however, demonstrated that MPA users are at increased risk of a fracture.[117,119] Furthermore, the use of a DEXA (dual energy x-ray absorptiometry) scan, the test used to assess bone mineral density, may not be a valid test in the premenopausal population. Studies also suggest that the loss in bone density is likely to be entirely reversible with discontinuation of MPA. This biological effect of a progestin-dominant hormonal milieu on bone mineral density can be likened to that of a breastfeeding woman, who also will experience a transient loss in bone mineral density while breastfeeding, which appears to be reversible after breastfeeding is discontinued. For women who do well on MPA as their long-term contraceptive method, we encourage continued use for the duration of time that contraception is required. We do not recommend discontinuing the use of MPA based on concerns of bone mineral density alone. Women and adolescents who use MPA for contraception or control of menorrhagia should be encouraged to have a calcium-rich diet, or perhaps to supplement with calcium if necessary during this time. DEXA scan should not be used routinely in women who are using DMPA for contraception.

Recommendations for Initiating MPA Use

Women should be counseled about the importance of repeat dosing every 3 months of MPA, as well as about the primary side effect experience: abnormal bleeding for the first one to two injections followed by a high likelihood of amenorrhea. If these bleeding patterns are acceptable to the patient, then MPA is a reasonable method. Women who are cycling can be dosed within the first 5 days of the onset of their menses and do not require backup contraception after this point. Women can also receive MPA within the first 5 days postpartum. MPA can be used immediately after abortion or miscarriage. Women who are using lactational amenorrhea as their contraceptive method can institute

MPA at any time so long as hCG value is negative. For a woman seeking a repeat dose of DMPA beyond the 13-week period, if she is still amenorrheic and her hCG value is negative, it is appropriate to re-dose at this time. Concerns about new pregnancy should always be balanced with the understanding that pregnancies that have occurred with DMPA during DMPA use have not demonstrated any evidence of increase risk of teratogenicity in this population or on adverse pregnancy outcomes.

Combined Estrogen-Progestin Injectable Contraception

A combined method of injectable contraception is no longer on the U.S. market. However, in other parts of the world this method is available and it is a highly discreet method of contraception. Because of the combined estrogen and progestin in the injectable formulation, the bleeding irregularities that are associated with progestin-only injection (DMPA) are not experienced with this combined method. Progestin and estrogen combined injectables contain a low-dose of a long-acting progestin and a low-dose of an estradiol. The most widely used method contains 17α-hydroxyprogesterone caproate (250 mg) and estradiol valerate (5 mg). This is a commonly used method in Asia and in Latin America. Previously in the United States, a combined injection of medroxyprogesterone acetate, 25 mg, and estradiol cypionate (E_2C), 5 mg, was available under the name Lunelle, but this is not currently the case.

MPA-E_2C is a well-tolerated method of contraception with a reasonable side effect profile.[120] The amount of pregnancy data is sparse owing to the short amount of time that it was on the market. However, in clinical trials, no pregnancies occurred in 782 women over 8008 cycles.[83] Side effects and clinical effects of the injectable combined hormonal contraceptive are similar to those of oral contraceptive pills.

Spermicides and Barrier Methods

Spermicides are a nonprescription barrier method of reversible contraception. All spermicidal agents contain a surfactant, usually 1000 mg nonoxynol-9 (N-9), that immobilizes or kills sperm on contact. They also provide a mechanical barrier and can be used with barrier methods of contraception such as condoms or diaphragms; therefore they need to be placed into the vagina before each coital act. Spermicides used alone, are 75% to 85% effective in preventing pregnancy.[121] The effectiveness of these agents increases with increasing age of the woman and is similar to that of the diaphragm in all age and income groups.

There was a great deal of hope invested in the possibility that N-9 might act as an anti-infective agent as well as a spermicide, and prevent against Human Immunodeficiency Virus (HIV) and other sexually-transmitted infections (STIs). While initial *in vitro* studies were promising, clinical trials have demonstrated that N-9 containing spermicides do not provide protection against HIV or STI. According to a recent study by the WHO, N-9 appears to increase HIV transmission in high-risk women, perhaps by causing lesions and ulcerations in the genital mucosa. These effects were also found to be dose-related, so at lower doses, the gel did not have a protective or promotive effect on HIV transmission or disruptions in the vaginal ecology.[122] N-9 does not appear to effect transmission of other STIs, such as gonorrhea or chlamydia.

Microbicides

Microbicides are products in development designed to protect against HIV and other STIs. Many of the candidate microbicides may also be effective contraceptives. The development of microbicides is urgent as the incidence of transmission of HIV and STIs is greatest in women of reproductive age.[123] Currently, the only proven way to protect against the sexual transmission of HIV is with the male condom, which is not always available and may not be a viable option for all women because it requires male cooperation. Many microbicidal compounds are currently under development, and they will provide additional protection when used with condoms, but may be used as primary protection for those who are unable or unwilling to use condoms consistently.

The pharmacological action of microbicides is based on several different mechanisms: (1) kills or immobilizes pathogens, (2) prevents the infective agent from entering target cells, (3) prevents a pathogen from replicating once it has entered cells, (4) boosts the vagina's or rectum's own defense system, and (5) acts like an invisible condom that forms a barrier between the pathogen and vaginal tissues. The focus is on developing such products that can be applied in advance before sexual intercourse, and spread evenly over the vagina, cervix, or rectum.

Many potential microbicides are in various phases of development, but most are in early phases of clinical trial or in preclinical stages. A recent study in several African nations demonstrated the effectiveness of a Tenovifir gel (9-[(R)-2-phosphonomethoxypropyl]) adenine monohydrate (PMPA). Overall, these researchers reported an estimated 39% reduction in HIV transmission.[124] Currently, studies are underway to test different methods of administration including applying the microbicide gel at different intervals to study whether or not that improves the effectiveness of the gel. Furthermore there is hope that the antiretroviral medications may also be effective against other STIs including: herpes simplex, bacteria, yeast, fungi, and other viruses.

Some of the groups of compounds that are being developed as microbicides are noted in Table 36.4.

Barrier Methods

Diaphragm

Diaphragms are soft latex or silicone barriers that cover the cervix. They provide contraception by blocking the entrance to the uterus and preventing the sperm from fertilizing the egg. They may also be used in conjunction with spermicides or microbicides that immobilize the sperm, and therefore, lead to better contraception. Diaphragms provide no protection against HIV or sexually transmitted infections, however may be combined with mircrobicides in the future to provide dual protection against pregnancy and STIs.

Currently, available diaphragms must be fitted by a healthcare provider. The largest size that does not cause

Table 36.4 Microbicide Compounds Under Development

Microbicide Group	Mode of Action	Examples
Surface active agents (detergents)	Penetrate cervical mucus, disrupt viral envelopes, cover the surface of viral STDs	Nonoxynol 9, octoxynol 9, benzalkonium chloride, menfegol, and *n*-docosanol
Sulfated compounds	Bind to virus or host cell receptors and block viral uptake	Dextrin sulfate, Dextran 2 sulfate, carageenan, polystyrene sulfonate, heparin sulfate: cholic acid, cellulose sulfate, PC-515, and naphthalene sulfonate (PRO 2000)
Anti-HIV compounds	Antiretroviral agents that prevent virus replication	Tenofovir (adenine antiretroviral drug), serine proteinase inhibitor, novel aryl phosphate derivatives of azidothymidine (AZT), nevirapine gel or cream, and cyanovirn N
Natural defense compounds	Increase host natural defenses against STIs by maintaining the normal acidic pH of the vagina in the presence of semen, contain lactobacillis which produces hydrogen peroxide killing HIV and STDs	Lactobacillus suppositories, buffer gel, and acid gel (ACIDFORM)

discomfort or undue pressure on the vaginal epithelium should be used. After the fitting, the woman should remove the diaphragm and reinsert it herself. She should then be examined to make sure the diaphragm is covering the cervix. The diaphragm should be used with a spermicide and be left in place for at least 8 hours after the last coital act. If repeated intercourse takes place or coitus occurs more than 8 hours after insertion of the diaphragm, additional spermicide should be used. Although spermicide use with the diaphragm is advised, it has not been conclusively demonstrated that pregnancy rates are lower when a spermicide is used with a diaphragm than when the diaphragm is used alone. The number of urinary tract infections in women who use diaphragms is significantly higher than in nonusers, probably because of the mechanical obstruction of the outflow of urine by the diaphragm. A one-size-fits-most nonlatex diaphragm is currently being studied, and, if approved for use, has the potential to simplify this method of contraception significantly.

Advantages

- Not easily felt by either partner (reasonably discrete)
- Immediately effective
- Immediately reversible
- Female-controlled
- Nonhormonal

Disadvantages

- Requires personalized fitting by healthcare professional
- Difficulty in insertion may be experienced
- May need to be refitting after full term pregnancy, pelvic or abdominal surgery
- Must be used with every coital act
- Moderately effective

Cervical Cap

The *cervical cap* is a cup-shaped plastic or rubber device that fits around the cervix. It may be either a cavity rim cap (Prentif and Oves), a cap that fits the vaginal walls around the cervix. (Femcap, Dumas, Vimule) or a large cap-like device (Lea's shield). Femcap is the only cervical cap Food and Drug Administration (FDA)-approved for use in the United States. These barrier methods can be left in place longer than the diaphragm. The various types of caps are manufactured in different sizes and should be fitted to the cervix by a healthcare provider.

The cap should be left on the cervix for no more than 48 hours, and a spermicide should always be placed inside the cap before use.[125] Failure rates with the cervical cap for nulliparous women are similar to those observed with the diaphragm, but for parous women failure rates are twice as high.

Constraints of Fitting of a Cervical Cap

- Fitting is to be done by a healthcare professional
- Vaginal delivery may lead to a scarred or irregularly shaped cervix
- Antiflexed uterus is necessary for cavity rim caps
- All sizes are not available
- Refitting may be needed after child birth

Male Condom

The male condom is the only method of contraception that has been shown to prevent transmission of sexually transmitted infections (STIs) including HIV, so its use by individuals at risk for infection should be encouraged. The male condom should not be applied tightly against the tip of the penis, but rather the condom tip should extend beyond the end of the penis by about half an inch to collect the ejaculate. Care must be taken on withdrawal not to spill the ejaculate. When used by strongly motivated couples, the male condom is very effective. The male condom has a 'typical use' failure rate of 14%. Recent studies have shown that teens were most likely to use condoms for birth control and 68% to 80% used a condom when they became sexually active.[5,126] The male condoms provide a physical barrier that prevents sperm and egg interaction. They are intended for one time use only.

Female Condom

A female condom was approved for marketing in the United States in 1994. It consists of a soft, loose-fitting sheath and two flexible polyurethane rings. One ring lies inside the vagina at the closed end of the sheath and serves as an insertion mechanism and internal anchor.

The outer ring forms the external edge of the device and remains outside the vagina after insertion, thus providing protection to the labia and the base of the penis during intercourse. The condom is pre-lubricated and is intended for one-time use only. Fitting by a health professional is not required. In comparison to the male condom, the female condom has the advantage of being able to be inserted before beginning sexual activity and to be left in place for a longer time after ejaculation occurs. Because the female condom also covers the external genitalia, it should offer greater protection against the transfer of certain sexually transmitted organisms, particularly genital herpes. Because polyurethane is stronger than the latex used in male condoms, the female condom is less likely to rupture.

In a multicenter clinical trial, the cumulative pregnancy rate in U.S. centers at 6 months was 12.4%. The 6-month pregnancy rate with perfect use was 2.6%. However the typical 1-year failure rate is 21%.[2] At the end of 6 months in the U.S. study, about one-third of the women had discontinued use of this method. Clinical trials with the female condom have not directly compared its use with other barrier techniques. Trussell and colleagues,[127] using the data of other studies, concluded that the efficacy rate of the female condom with perfect use would be similar to that of the diaphragm and cervical cap, but the failure rate of the female condom with typical use would be higher than that of the diaphragm. Because of the lack of prospective clinical trials with the male condom, no statistical comparison of the effectiveness of the two types of condoms can be made. Moreover, the effectiveness of the female condom for reducing sexual infection transmission has not been evaluated. However, because polyurethane does not allow virus transmission, it should reduce a woman's risk of acquiring human immunodeficiency virus infection.

Contraception in Women of Special Subpopulations

Given the overall safety of hormonal contraception, especially in young healthy women, and when compared to the risk that pregnancy conveys, there are few instances when the risks of providing contraception outweigh the benefits. Overall mortality in the general population is not increased by OC use.[128] However, there are occasions when special consideration to contraceptive method must be given due to a woman's comorbidities or health circumstances.

Noncontraceptive Benefits of Hormonal Contraception

The noncontraceptive health benefits of hormonal contraception are derived from a variety of epidemiological studies that have been conducted since combined hormonal contraceptive pills were initially marketed in the 1960s. A study of combined hormonal contraceptive pills containing less than 35 μg of ethinyl estradiol (those that are routinely in clinical use today) estimate that use of these oral contraceptive pills allows for a 70% reduction in ovarian cancer (Fig. 36.4), 50% reduction in endometrial cancer, 45% reduction in uterine blood loss, 50% reduction in dysmenorrhea, 65% reduction in premenstrual symptoms, 50% reduction in acne, 20% reduction in benign ovarian tumors, and 80% reduction in ectopic pregnancy.[129] Twelve case-control studies and three cohort studies have examined the relation between OCs and endometrial cancer, and all but two of these studies have indicated that the use of these agents has a protective effect against endometrial cancer, the third most common cancer among U.S. women.[130,131] Women who use OCs for at least 1 year have an age-adjusted relative risk of 0.5 for diagnosis of endometrial cancer between the ages of 40 and 55 years compared with nonusers. This protective effect is related to duration of use, increasing from a 20% risk reduction with 1 year of use to a 40% reduction within 2 years of use, to about a 60% reduction with 4 years of use. A prospective study of almost 30 years showed that OC users had one-third the risk of endometrial cancer as nonusers (RR, 0.34; CI, 0.17 to 0.66) and one-third the risk of dying of uterine cancer (RR, 0.3), compared with age-matched non-OC users.[132,133]

Eighteen studies on ovarian cancer and oral contraceptives have found a reduction in risk (Fig. 36.4).[74] The relative risk of ovarian cancer among ever-users of OCs was 0.64, a 36% reduction. The magnitude of the decrease in risk is directly related to the duration of OC use, increasing from about a 40% reduction with 4 years of use to a 53% reduction with 8 years of use and a 60% reduction with 12 years of use. Beyond 1 year, there is about an 11% reduction in ovarian cancer risk for each of the first 5 years of use. The protective effect begins within 10 years of first use and continues for at least 20 years after the use of OCs ends. In the 1968 to 1995 analyses of the RCGP data,[133] OC users were half as likely to develop ovarian cancer as nonusers (RR, 0.49; CI, 0.3 to 0.8) and had a 40% decreased risk of death due to ovarian cancer (RR, 0.5). In a large case-control study, OC users had a 40% decrease in risk of ovarian cancer that increased to 70% reduction with 10 or more years of use.[134]

With the advent of the ability to test for hereditary predispositions to breast and ovarian cancer, the potential value for chemoprophylaxis with hormonal contraceptive regimens has become more important. Results from three studies indicate that women with *BRCA1* and *BRCA2* mutations who use combined hormonal contraceptive pills have a decreased risk for developing ovarian cancer.[79] It is important to counsel women who are at increased risk for ovarian cancer due to hereditary reasons that chemoprophylaxis can offer a safe and effective way to reduce their risk of developing ovarian cancer. Furthermore, the use of combined hormonal contraception does not increase a woman's risk of developing breast cancer.[73,77] In a large study by the Centers for Disease Control, current or past use of combined hormonal contraceptive pills did not increase the risk for developing breast cancer in women who were 35 to 64 years of age.[135] Women who are at increased risk of breast cancer due to genetic or family history were not at increased risk if they used combined hormonal contraceptives. Most studies show a similar pattern of risk with hormonal contraceptive use regardless of a woman's reproductive history or her family history of breast cancer when it comes to her personal risk for breast cancer development.

Recent studies have shown that OCP use is not associated with an increase in breast cancer incidence, even in those who carry the *BRCA1* and *BRCA2* mutations.[79]

The odds ratio for developing breast cancer with COC use was 0.74 (CI 0.55 to 0.99) for women with neither mutation; 0.18 (CI 0.08 to 0.42) for women with *BRCA1* mutation; and 0.92 (CI 0.3 to 2.84) with the *BRCA2* mutation. Therefore, it is evident that the use of the low-dose hormonal contraceptive pills that are currently in clinical practice today do not increase the risk for breast cancer in women who are genetically predisposed to developing this disease and afford a risk reduction for ovarian cancer in this same population.[78,79]

Given the overall safety of hormonal contraception, especially in young healthy women, and when compared to the risk that pregnancy conveys, there are few instances when the risks of providing contraception outweigh the benefits. Overall mortality rate in the general population is not increased by OC use.[128] However, there are occasions when special consideration to contraceptive method must be given due to a woman's co-morbidities or health circumstances.

Hormonal Contraceptive Implants

The current etonogestrel implant now available cannot be assessed yet for differential efficacy in obese and nonobese populations. The number of pregnancies thus far has been too low for such conclusions to be drawn. However, the previously used six-rod levonorgestrel implant was associated with a fivefold increase in risk of pregnancy in women who weighed more than 70 kg or 154 pounds. These women are also at increased risk for endometrial cancer; progestin-only methods, specifically the progestin-only intrauterine contraceptive device, may be an appropriate choice in obese women because efficacy does not appear to be decreased in this population and it provides protection against endometrial hyperplasia.

Women with Cardiovascular Disease

A meta-analysis of 10 studies found the odds ratio (OR) for myocardial infarction (MI) and ischemic stroke in OC users versus nonusers was 2.01 (95% CI 1.63 to 2.48). Second-generation OCs were associated with a significant increased risk of both MI and ischemic stroke events (OR 1.85, 95% CI 1.03 to 3.32; and 2.54, 95% CI 1.96 to 3.28, respectively) and third-generation OCs, for ischemic stroke outcome only (OR 2.03, 95% CI 1.15, 3.57).[135] Another meta-analysis found that current OC users have an overall adjusted OR for MI of 2.48 (95% CI 1.91 to 3.22) compared to never-users. The risk of MI for past OC users is not significantly different from that for never-users, overall OR 1.15 (95% CI 0.98 to 1.35; $P = 0.096$).[136]

There is an emerging population of women who are adult survivors of congenital heart disease. This population represents a challenge as pregnancy may either be contraindicated or certainly impose increased risk. Careful assessment of the independent risk of thrombosis in these women, based on the specific heart defect and the degree of correction, must be made when evaluating such patients for appropriate contraception. In general, using progestin-only methods or intrauterine devices is probably the safest mode in these patients. Barrier methods will likely not give sufficient efficacy, and although estrogen-containing methods may be appropriate in some subsets of this population, this choice may require careful attention and thought. Progestin-only methods, however, are safe in women who are at increased risk of MI or thrombosis and therefore can be used in this population.

Hereditary Thrombophilia

In a retrospective family cohort study, women with hereditary deficiencies of protein S, protein C, or antithrombin, who were taking an oral contraceptive had an annual incidence of venous thromboembolism of 3.5%, increasing to 12% in women with more than one type of hereditary thrombophilia.[137] A systematic review found a total of 10 studies together that provided "good" evidence of a greater risk of VTE (risk ratios of 1.3 to 25.1) and cerebral vein or cerebral sinus thrombosis among COC users with factor V Leiden mutation when compared with nonusers who have the mutation.[71] The evidence for prothrombin and other thrombogenic mutations was not as strong as for factor V Leiden mutation. It is unclear whether the type of COC or duration of use modifies the risk of VTE among women with thrombogenic mutations.[43] However, one study found that women with factor V Leiden polymorphisms may remain asymptomatic after prolonged use of OCs. Some authors support the use of SHBG levels and activated protein C resistance as markers of thromboembolic risk with OCPs.[128] The WHO discourages use of OCs in women with either an underlying thrombophilia or a history of a previous VTE.[45] These women are good candidates for progestin-only contraceptives or intrauterine contraceptives.

types of, 27
Gonadotropin inhibitory hormone
description of, 143
gonadotropin-releasing hormone secretion modulation by, 143
Gonadotropin receptors, 35–39
amino acid sequences of, 35–38, 36f
cognate hormones and, 37f
expression of
in extragonadal tissues, 43
post-transcriptional regulation of, 42
post-translational regulation of, 42–43
regulation of, 42–43
transcriptional regulation of, 42
extracellular domain of, 35
genes
description of, 39
naturally occurring mutations of, 39, 40f
polymorphisms of, 42
hormone-induced internalization of, 43
intracellular domain of, 38
proteins, 35–39
serpentine domain of, 38
signaling pathways activated by, 43–44
three-dimensional structures, 35–38, 36f
transcripts, 39–40
α-Gonadotropin subunit, 27–28, 28f, 30
Gonadotropin surge attenuating factor, 147
Gonadotropin surge inhibiting factor, 147
Gonadotropin-inhibitory hormone, 15
Gonadotropin-releasing hormone, 7–13
administration of, 524
agonists
down-regulation regimens, 747–748
flare regimens, 748
hyperandrogenism evaluations, 838
leiomyomas treated with, 594
ovarian stimulation using, 704–705, 747–748, 747f–749f
ovulation induction using, 717
short-course regimen, 748
amino acid structure of, 7, 8f, 142t
antagonists
"estradiol priming" protocols, 750
in vitro fertilization and, 723–725, 725b
leiomyomas treated with, 594
ovarian stimulation using, 748–750
progesterone levels affected by, 182
regimens, 748–750
cell bodies, 4, 7f
congenital deficiency of, 149
definition of, 141
delayed puberty caused by deficiency of, 403–407
dynorphin effects on, 14–15
fertility affected by, 7

Gonadotropin-releasing hormone *(Continued)*
fetal
description of, 16–17
hypothalamus production, 258
follicle-stimulating hormone secretion affected by, 145, 145f
follistatin affected by, 146
functions of, 3–4
gene mutations that affect function of
GNRH1, 406
KISS1, 406–407
KISS1R, 406–407
TAC3, 407
TACR3, 407
gonadotrope cells stimulated by, 10–13
gonadotropin-releasing hormone receptor binding of, 32–33
I, 141–142, 142t, 382–383
II, 141–142, 142t, 383
III, 141–142, 142t
luteinizing hormone and, 12, 145, 145f, 149, 493–494
male gonadal axis role of, 272
mid-cycle surge of, 19
ovulation induction using, 524, 524f
pituitary gonadotroph response to, 51
placental production of, 249
precocious puberty and, 392–401, 392b
prolactin release stimulated by, 50
pubertal secretion of, 422
pulsatile secretion of
amplification of, 431
conditions that affect, 383
description of, 10, 11f, 12–13, 272, 524
estradiol effects on, 18
frequency of, 149, 422, 440
generator of, 15–16, 383–384, 452, 455–456
hyperprolactinemia effects on, 25
kisspeptin, neurokinin B, dynorphin neurons in, 16, 383
luteinizing hormone pulsatile secretion affected by, 272–273, 280
ovulation induction, 524, 715–716
patterns of, 17–18
postnatal development of, 384–386, 385f–386f
progesterone effects on, 147
suppression of, 422
pulse frequency of
in follicular phase of menstrual cycle, 149
luteinizing hormone as marker of, 149
secretion of
abnormalities in, 141
breastfeeding-related inhibition of, 238–239
circadian effects on, 25, 143–144
conditions caused by absence of, 7
continuous, 10, 11f
corticotropin-releasing hormone effects on, 24
developmental changes in, 16–17
dynorphin effects on, 143
ectopic, 472
endogenous opioids effect on, 143
energy availability effects on, 463
estrogen negative feedback on, 146–147
factors that affect, 7
feedback regulation, 18–21, 21f
gonadotropin inhibitory hormone effects on, 143
gonadotropin-releasing hormone receptor antagonists used to estimate, 19
kisspeptin-mediated feedback regulation of, 21f, 142–143, 422
Gonadotropin-releasing hormone *(Continued)*
lactation-related decreases in, 24, 238–239
in menstrual cycle, 149, 153
negative feedback regulation of, 18–20, 146–147
neurokinin B effects on, 143
neuromodulators involved in, 142–144
neuropeptide Y effects on, 439
neurotransmitters that affect, 13
pheromones effect on, 26
physiological influences on, 25–26
positive feedback regulation of, 19
progesterone effects on, 18–19, 147
pulsatile, 10, 11f, 12–13
regulation of, 7, 439
sex steroid effects on, 274
sleep effects on, 25, 143–144
suckling-related inhibition of, 238–239
in women, 18, 143–144
structure of, 7–8, 8f, 705f
synthesis of, 7
Gonadotropin-releasing hormone 2, 7–8
Gonadotropin-releasing hormone neurons
anatomy of, 8
cell bodies of, 10
differentiation of, 383–384
embryological development of, 8–10, 440
energy availability effects on, 463
fetal ontogeny of, 383
firing of, 10
gene mutations that affect development and migration of
CHD7, 406
FGF8, 406
FGFR1, 406
HS6SFT1, 406
KAL1, 405–406
NELF, 406
PROK2, 406
PROKR2, 406
SEMA3A, 406
WDR11, 406
kisspeptin, neurokinin B, dynorphin neuron signaling in, 20f
migration of, during embryogenesis, 8–10, 9f
neuronal inputs into, 13–15
endogenous opiate peptides, 14–15
kisspeptin, 13–14, 13f
neurokinin B, 14
nonsteroidal regulators of, 248t
olfactory placode differentiation of, 141
olfactory system development and, 8–10
Gonadotropin-releasing hormone peptides, 274
Gonadotropin-releasing hormone receptors
antagonists of
description of, 10
gonadotropin-releasing hormone secretion estimations using, 19
progressive precocious gonadarche treated with, 394
structure of, 11f
density of, 10–11
gonadotropin-releasing hormone binding to, 32–33
in male gonadal axis, 274–275
mutations of
description of, 407–408
idiopathic hypogonadotropic hypogonadism associated with, 443
types of, 274–275
Gonadotropin-releasing hormone test, 830
Gonadotropin-releasing hormone type 1 receptor, 7–8, 10–11
Gonadotropin-releasing hormone-associated protein, 48–49
Gonadotropin-releasing hormone-luteinizing hormone-testosterone axis, 285–286
Gonads
development of, 159
feedback signals from, 3
human chorionic gonadotropin functions in, 34
sex steroids produced by, 93
streak, 356
Gonanes, 66
Gordon-Holmes syndrome, 406
GPA2, 29–30
GPB5, 29–30
GPR30, 106, 199
Graafian follicle
description of, 796
formation of, 171
histology of, 160f
Granulocyte macrophage colony-stimulating factor, 588
Granulosa cells, 163–166
A disintegrin and metalloproteinase and thrombospondin motif inducement in, 178
androgen receptors in, 174–175
anti-müllerian hormone produced by, 190, 744, 805–806, 833
antral follicles, 872
apoptosis of, 180–181, 181f
aromatase induction in, 171–172
cuboidal, 169
cyclic GMP production by, 163
description of, 126–127
endocrine activity of, 164–165, 164f
estradiol production by, 164
flattened, 169
follicle-stimulating hormone effects on, 67, 171, 175
follicle-stimulating hormone receptor expression in, 43
follicular growth effects on, 169
gap junctions, 163
inhibin production by, 164, 833
luteinized, 165–166
luteinizing receptors on, 175
mural, 165, 165f
oligoclonal origin of, 163
oocyte and, intercellular communication between, 163–164
phenotypic heterogeneity of, 165–166, 165f
in polycystic ovary syndrome, 498–501, 499f–500f
pregnancy-associated plasma protein A secretion by, 174
progesterone receptor induction in, 177
signaling pathways of, 164
Graves disease, 454, 563–564, 563f, 627–629
Gremlin, 166–167
GR-interacting protein 1, 103
Growth differentiation factor-9
granulosa cell proliferation affected by, 170
oocyte expression of, 162–163, 166
synthesis of, 163
Growth factors
assisted reproductive technology and, 139
endometrial expression of, 223–227
leiomyomas treated with, 595
male reproduction role of, 139
at maternal-fetal interface, 138t
ovary specification affected by, 124–126
oviduct expression of, 201
primordial germ cell formation and development affected by, 124
uterine receptivity regulated by, 135–136

Growth hormone
aging-related declines in, 338
deficiency of, 451, 842
fetal pituitary gland production and secretion of, 262
gonadotropins and, 760
hypersecretion of, 842
in vitro fertilization and, 760–761
leiomyomas treated with, 595–596
measurement of, 842–843
placental, 605–608
pregnancy levels of, 620
secretion of
after gonadarche, 389
dynamic tests for, 842–843
pulsatile, 472
Turner syndrome treated with, 412
Growth hormone receptor antagonists, for growth hormone-secreting pituitary adenomas, 474
Growth hormone secretagogue receptor-1a, 389
Growth hormone-binding protein, 608
Growth hormone-releasing hormone
description of, 843
fetal hypothalamus production of, 258
functions of, 551–552
prolactin release affected by, 49
Growth hormone-secreting pituitary adenomas, 472–474
Guanosine triphosphate-binding protein, 11–12
Guttmacher syndrome, 194
Gynecomastia, 417

Steroid receptor(s)
  ancestral, gene duplication of, 96
  conformation of, 101–103
  divergence of, 96–97
  DNA interactions, 104
  endometrial immune responses regulated by, 214
  endometriosis, 573–575
  expression of, 101, 102f
  function of, 93–97
  functional domains of, 95f
  hormone binding in, 101–103
  as ligand-dependent transcription factors, 93
  mechanism of action, 94f
  myometrium expression of, 214
  phosphorylation of, 103–104
  structure of, 93–97, 95f
  transcription factors and, interaction between, 105
Steroid receptor coactivator-1, 105, 197
Steroid receptor coactivator-2, 197
Steroid receptor coactivator-3, 197
Steroid sulfatase, 84
Steroid-binding proteins, 90
Steroidogenesis
  adrenal, 363f
  disorders of
    androgen-secreting tumors, 400–401
    apparent cortisone reductase deficiency, 399–400
    aromatase deficiency, 415
    Cushing syndrome, 401
    delayed puberty caused by, 414–416
    familial male-limited precocious puberty, 400
    human chorionic gonadotropin-secreting tumors, 401
    11β-hydroxylase deficiency, 398–399
    21-hydroxylase deficiency, 398
    3β-hydroxysteroid dehydrogenase deficiency, 398
    17β-hydroxysteroid dehydrogenase deficiency, 415–416
    inherited glucocorticoid resistance, 400
    oxidoreductase deficiency, 399
    virilizing congenital adrenal hyperplasia, 397–399
  enzymes involved in, 380
  expression of genes involved in, 86–88
  extraglandular, 88
  fetal adrenal, 260
  gonadal, 277
  hilar cells as site of, 191
  human chorionic gonadotropin effects on, 249
  overview of, 70–84
  pubertal, 380–382
  testicular, 275–277
  tumor necrosis factor-α in, 184–185
Steroidogenic acute regulatory protein
  cholesterol movement affected by, 72–73
  co-expression of, 71–72
  deficiency of, 360t–361t, 364
  description of, 69–70
  expression of, 71
  follicular cysts in women with, 174
  luteinizing hormone effects on, 276
  N-62, 72–73
  in steroidogenic cells, 72
  structure of, 75f
  tissues that express, 72

Steroidogenic acute regulatory protein-related lipid transfer, 67–68
Steroidogenic cells
  cholesterol acquisition, storage, and trafficking in, 67–70, 68f
  corpus luteum, 182
  cytoplasmic lipid droplets, 69
  mitochondria of, 70
  progesterone created by, 80
  steroidogenic acute regulatory protein in, 72
Steroidogenic enzyme inhibitors, 90–92
Steroidogenic factor 1
  description of, 70, 358–359, 444
  mutations of, 410
Steroidogenic organs, 67
Sterol binding proteins, 67–68
Sterol O-acyltransferase 1, 69
Sterol regulatory element-binding proteins, 70
Stra8, 126
Streak gonads, 356
Stress
  functional hypothalamic amenorrhea caused by, 466–469
  human placental lactogen levels affected by, 250
  hyperprolactinemia caused by, 54
  infertility and, 537
  prolactin secretion affected by, 48
  reproductive function affected by, 22–24, 99–100
Stressors, 23–24
Stromal cells
  decidualized, 212f
  endometrial, 224–225
  of late secretory phase of menstrual cycle, 205
  of midsecretory phase of menstrual cycle, 205
  ovarian, gremlin secretion by, 166–167
  tissue factor production by, 210
Stromelysin-1, 178
Stromelysin-3, 178, 588
Subclinical hyperthyroidism, 630
Subclinical hypothyroidism, 303, 561–562, 631
Subendometrial halo, 852
Subendometrial peristalsis, 214
Subzonal insemination, 774
Sulfotransferases, 83–84
SULT2B1 gene, 83
SULT1E1 gene, 83
Superior hypophyseal artery, 5
Supernumerary nipples, 237
Suppressor of cytokine signaling-3, 224
Suppressor T cells, 289t
Supraoptic nuclei, 6f, 7
Surfactant protein-A, 268
Surgery
  bariatric, reproductive function affected by, 429–430
  genital, for disorders of sex development, 372–373
  prolactinomas treated with, 59, 62
Surrogacy, 819
Swyer syndrome, 358
Syncytiotrophoblasts
  description of, 84, 246, 248, 298
  proopiomelanocortin expression by, 252
Systemic lupus erythematosus, 306

T

T cell receptor, 292–293
T cells, 288–289
  CD3+, 296–297
  CD4+, 288–289, 296–297
  CD8+, 296–297
T cells *(Continued)*
  characteristics of, 288–289, 289t
  education of, 292–293
  natural killer, 297–298
  prolactin production by, 51
T helper 1 response, 291, 291f
T helper 2 response, 291, 291f
T regulatory cells, 214–215
TAC3 gene, 14, 143, 407, 443
TACR3 gene, 407
Tamoxifen
  aromatase inhibitors versus, 670, 671t
  breast cancer treated with, 662–663, 667–674, 669f
  clomiphene citrate versus, 522, 709–710
  cyclical mastalgia treated with, 241
  description of, 102–103, 155
  endometrial polyps caused by, 598
  endometriosis affected by, 581–582
  gonadotropin-releasing hormone agonists used with, 594
  metabolism of, 668
Tandem mass spectrometry, 828
Tanycytes, 5
Telomerase, 207
Telophase II, 739
Temozolomide, 481
Terbutaline sulfate, 648t
Testes
  age-related changes in, 340
  anatomy of, 281
  androgen receptor in, 278–279
  aromatase distribution in, 277
  failure of, 413
  feedback control of, 383
  fetal, 261
  formation of, 282f
  intraabdominal development of, 281
  organogenesis of, 353
  percutaneous fine-needle aspiration mapping for sperm in, 549f
  in prepubertal males, 796–797
  prolactin effects on, 52–53
  pubertal development of, 379
  sex determination, 354–359
  steroidogenesis, 275–277
  testosterone production by, 275
Testicular adrenal rest tumors, 400
Testicular biopsy, 777
Testicular regression syndrome, 362, 374t, 414
Testicular sperm extraction combined with intracytoplasmic sperm injection, 413–414
Testicular tissue
  cryopreservation of, 805
  transplantation of, 809
Testis-determining factor, 126–127, 352
Testis-specific protein Y, 375
Testosterone
  age-related declines in, 275, 315, 340–341
  amplification of, 252f
  aromatization of, 277–278, 281
  bioavailable, 836, 839
  biosynthesis of, in Leydig cells, 250f
  decreases in, consequences of
    body composition, 342–343, 345
    bone mineral density, 342, 344–345
    cardiovascular risks, 343
    cognition, 344, 346
    energy, 343, 346
    lean muscle mass, 342–343, 345f
    metabolical risks, 343
    muscle strength, 343, 345–346
    physical function, 343, 346
    sexual function, 344, 346
Testosterone *(Continued)*
  deficiency of, 272
  dihydrotestosterone conversion of, 252f, 277, 353, 365
  erythropoiesis stimulation by, 346
  follicle-stimulating hormone effects on production of, 273–274
  free, 836
  human chorionic gonadotropin effects on, 52–53, 191
  immunoassays of, 836
  inactivation of, 252f, 277–278
  Leydig cell production of, 99, 276
  lifetime secretion pattern, 249f
  luteinizing hormone inhibition affected by, 281
  metabolical clearance rate of, 89t
  negative feedback action of, 383
  phospholipase C activation by, 381–382
  physical function and, 343, 346
  postmenopausal ovary as source of, 190
  production rate of, 89t
  5α-reduction of, 277–278
  secretion rate of, 89t
  sex hormone-binding globulin binding by, 279
  synthesis of, from cholesterol, 276
  testes production of, 275
  total, 836, 839
Testosterone cypionate, 344t
Testosterone enanthate, 344t, 346, 373–374
Testosterone therapy
  adverse effects caused by, 346–347
  body composition changes with, 343, 345
  bone mineral density treated with, 344–345, 345f
  cardiovascular risks with, 346–347
  delayed puberty treated with, 420
  erythrocytosis caused by, 346
  hypogonadism treated with, 342
  muscle strength improvements with, 345–346
  physical function improvements with, 346
  preparations, 344, 344t
  prostate events caused by, 346
  transdermal administration, 342–343
Testosterone undecanoate, 344t
Tetrahydrocannabinol, 227

Windows of susceptibility, 436
Wnt4, 125–126, 134–135
Wnt 7α, 590–591
Wnt family
in female reproductive tract development, 192–194
signaling pathways of, in menstrual cycle, 203f
Wnt4 gene, 193
WNT7A, 203–204
Wnt7a, 135
Wnt5a gene, 193
Wolffian ducts, 132–133, 281
Wolman's disease, 67–68
Women. *See also* Girls
androgen levels in, 837
androgen precursors in, 837
fertility preservation options for, 797–804, 799t–801t
functional hypothalamic amenorrhea in, 24
gonadotropin-releasing hormone secretion in
circadian effects on, 143–144
description of, 18
negative feedback regulation of, 18–19
sleep effects on, 143–144
obesity in, 428–429
prolactinomas in, 58
Women's Health Initiative trial, 325–327, 326t, 656–659

X

X chromosome
defects of, 309
pseudoautosomal region of, 354–356
Xenotransplantation, 809
X-linked alpha-thalassemia/mental retardation, 355t–356t
X-linked Kallmann syndrome, 9–10, 405–406
XO/XY mosaicism, 359f
XX gonadal dysgenesis, 360t–361t

Y

Yuzpe method, 900

Z

Zar1, 162
Zfx, 160, 188
Zinc, 180
Zinc-finger transcription factors, 180
Zona fasciculata, 67, 380
Zona glomerulosa, 67, 380
Zona pellucida
description of, 160f, 161, 735–736, 738
laser-assisted drilling of, 783
ZP1, 161
ZP2, 161
ZP3, 161
Zygote, 135
Zygote intrafallopian tube transfer, 734
