The WHO classification divides women with anovulation into three major groups: WHO Group I consists of those women with anovulation, low levels of endogenous gonadotropins, and very little endogenous estrogen production (hypogonadotropic hypogonadism). WHO Group II consists of those women with anovulation or oligo-ovulation, a wide variety of menstrual disorders, relatively normal (or elevated) gonadotropin levels, and evidence for significant endogenous estrogen production.[71] Many women in WHO Group II have PCOS. WHO Group III are women with ovarian failure (hypergonadotropic hypogonadism).

Clomiphene is most effective in inducing ovulation in women in WHO Group II. In women with severe hypoestrogenism and hypogonadotropic hypogonadism (WHO Group I), clomiphene is typically ineffective in the induction of ovulation. In contrast, women in WHO Group I respond very well to gonadotropin injections or pulsatile GnRH treatment. Failure to have a withdrawal uterine bleed following the administration of progesterone is presumptive evidence of severe hypoestrogenism in women with anovulation and an anatomically normal uterus.[72] Clomiphene is unlikely to effectively induce ovulation in this setting.[72] The mechanisms responsible for the low rate of ovulation in response to clomiphene in women with hypogonadotropic hypogonadism and low endogenous production of estrogen

are not fully characterized. Maruo and colleagues[73] have reported that clomiphene induction of ovulation has a low chance of success in women with triiodothyronine levels below 80 ng/mL. In preliminary studies, thyroid hormone supplementation appeared to increase the efficacy of clomiphene induction of ovulation in these women.

Clomiphene citrate is also unlikely to be effective in women with a consistently elevated FSH concentration (depletion of oocyte pool). Although clomiphene is relatively contraindicated in women with pituitary tumors, it has been reported to be effective in the induction of ovulation in women with prolactinomas who did not ovulate with bromocriptine treatment alone.[74] Many physicians prefer to document tubal patency and evaluate semen parameters before initiating ovulation induction.

The FDA-approved dosages for clomiphene are 50 or 100 mg daily for a maximum of 5 days per cycle. After spontaneous menses, or the induction of menses with a progestin withdrawal, clomiphene is started on cycle day 3, 4, or 5 at 50 mg daily for 5 days. Starting clomiphene on cycle day 3 or 5 does not appear to influence the per-cycle pregnancy rate.[75] In properly chosen women, approximately 50% will ovulate at the 50 mg daily dosage; another 25% will ovulate if the dose is increased to 100 mg daily.[76] During each cycle, determination of ovulation should be attempted. In most patients, ovulation occurs approximately 5 to 12 days after the last dose of clomiphene. Measurement of the urinary LH surge is often recommended to assist the couple in prospectively determining the periovulatory interval.

Although the FDA has approved maximal clomiphene doses of 100 mg daily, many clinicians have experience prescribing clomiphene at doses of up to 250 mg daily. A woman who does not ovulate with a clomiphene dose below 100 mg daily for 5 days may ovulate if her dose is increased up to 250 mg daily for up to 14 days. Of the women who do not ovulate at doses below 100 mg daily, up to 70% will ovulate at higher doses, but less that 30% become pregnant.[77]

Anovulatory women in WHO Group II have a fecundability of 0.00 without treatment. Over the first three to six cycles of clomiphene treatment, the fecundability is in the range of 0.08 to 0.25. In cases where the only fertility factor is anovulation in the female partner, fecundability with clomiphene treatment is in the range of 0.20 to 0.25 (Fig. 23.4).[78] Women with hyperandrogenemia, markedly elevated BMI, amenorrhea, or advanced age are less likely to ovulate with clomiphene.[79] A unique advantage of clomiphene is that few fertility treatments are available that increase fecundability from 0.00 to 0.20 at a cost in the range of $100. After 3 to 6 months of clomiphene treatment, fecundability appears to decline.

Prior to initiating a clomiphene cycle, many experts obtain a pregnancy test to rule-out an ongoing pregnancy, then prescribe a progestin withdrawal. A commonly used progestin withdrawal is medroxyprogesterone acetate (Provera) 10 mg daily for 5 days. The first day of full withdrawal flow following the cessation of the progestin treatment is Day 1 of the cycle.

During the clomiphene plus dexamethasone treatment cycle, urine LH measurements can be measured by the patient at home to identify the preovulatory LH surge. The LH surge typically occurs 5 to 12 days after the last day of clomiphene medication. The woman's maximal fertile time

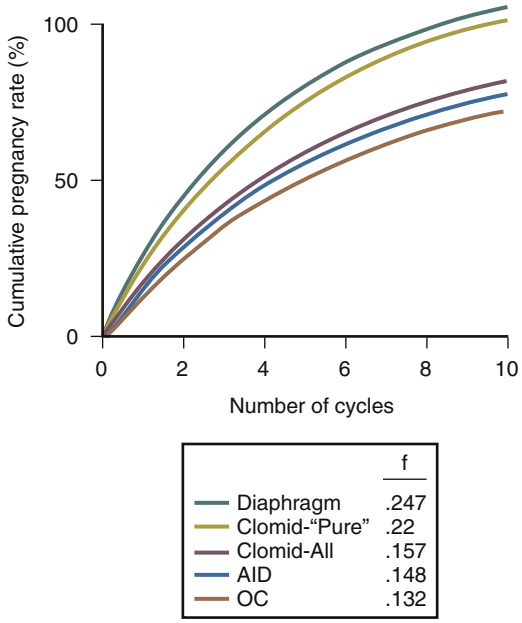

FIGURE 23.4 Cumulative pregnancy rates in women treated with clomiphene for infertility, women discontinuing contraception with the diaphragm or oral contraceptives (OC), and women treated with donor insemination (AID). *(From Hammond MC. Monitoring techniques for improved pregnancy rates during clomiphene ovulation induction.* Fertil Steril *42:503, 1984, with permission.)*

is the day before the urine LH surge, the day of the urine LH surge, and the day following the urine LH surge. Coitus should occur on at least 2 of these 3 days. Alternatively, if the woman prefers not to measure urine LH she can have coitus with her partner every other day for 8 days beginning 5 days after the last clomiphene tablet. Evidence for successful clomiphene induced ovulation is an appropriately drawn serum progesterone level greater than 8 ng/mL. In most clomiphene cycles where successful ovulation has occurred the serum progesterone level is greater than 20 ng/mL. If a menses does not occur within 17 days following the LH surge, a pregnancy test can be obtained.

Preliminary reports suggest that ovulation-inducing medications may be associated with ovarian tumors[80,81] and that the risk may increase with extended use of ovulation-inducing agents. My current view of this data is that nulliparity and infertility are far more important risk factors for ovarian tumors than treatment with an ovulation-inducing medication.[82-84] However, given the reduced fecundability observed in women who do not achieve pregnancy after 6 clomiphene cycles and the risk of ovarian tumors associated with prolonged exposure to clomiphene, limiting clomiphene treatment to fewer than 12 cycles is reasonable. Failure to achieve pregnancy after six clomiphene treatment cycles should prompt a thorough review of the potential causes of the failure and consideration of a new approach to treatment, such as gonadotropin therapy. After four ovulatory cycles induced by clomiphene without achieving a pregnancy, a diagnostic laparoscopy may reveal endometriosis or pelvic adhesions in over 50% of women.[85]

The role of hCG administration in enhancing the pregnancy rate associated with clomiphene treatment is controversial. Some authorities believe that the combination

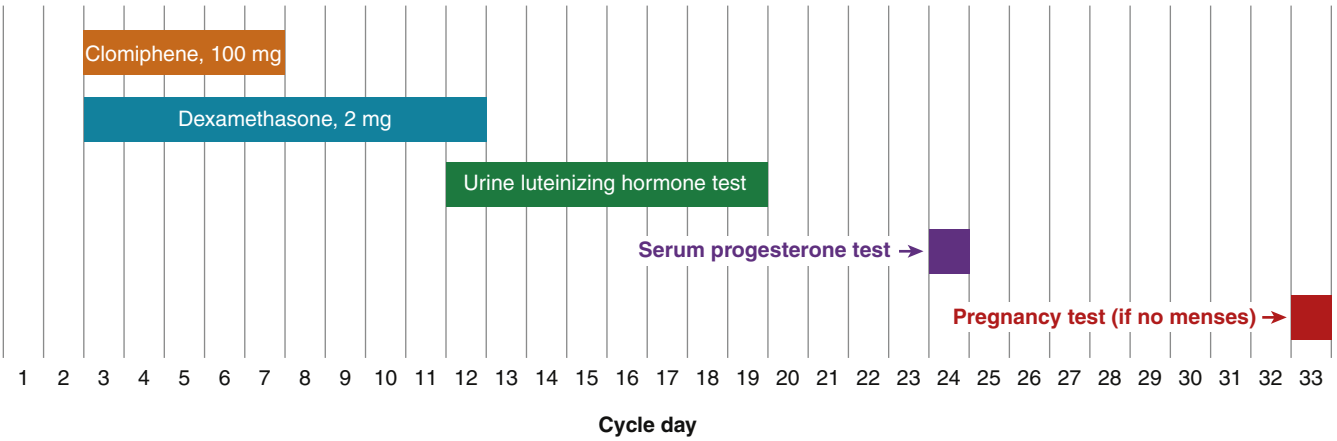

FIGURE 23.5 Schematic outline of a combined clomiphene plus dexamethasone cycle for women who are resistant to ovulation with clomiphene monotherapy.

of clomiphene and a single dose of hCG may increase the efficacy of clomiphene induction of ovulation when women do not ovulate on standard doses of clomiphene.[86] However, in most trials, hCG administration does not consistently improve pregnancy rate compared to women who spontaneously ovulate.[87] After administering clomiphene, sonography can be utilized to monitor follicle size. When mean follicle diameter reaches 18 to 22 mm, hCG can be administered.[88] However, other authorities believe that there is little evidence to support the use of hCG in combination with clomiphene. In one small clinical trial, women receiving clomiphene from cycle days 3 to 7 to induce ovulation were randomized to receive hCG (10,000 IU) to time ovulation, or to monitor the endogenous LH surge using urinary LH testing kits. The pregnancy rate was similar in both groups.[89]

Clomiphene treatment can be associated with adverse changes in the reproductive tract, including induction of a luteal phase defect and the creation of a hostile cervical environment due to low quantity and quality of cervical mucus.[90] Some clinicians recommend endometrial biopsy in a test cycle of clomiphene treatment to assess whether or not clomiphene induces luteal phase deficiency, and many recommend that a postcoital test be performed during the first clomiphene cycle.

In one study of 2369 clomiphene-induced pregnancies, 7% were twins, 0.5% were triplets, 0.3% were quadruplets, and 0.13% were quintuplets.[91] This finding demonstrates that the absolute risk of high-order multiple gestation with clomiphene treatment is quite low. Because clomiphene is a heavily prescribed medication, however, the number of triplets resulting from clomiphene treatment is substantial. In one study that reviewed all the high-order multiple gestations at one tertiary care center, more triplets were conceived after clomiphene treatment than were conceived after treatment with exogenous gonadotropin therapy.[92] The rate of spontaneous abortion after clomiphene-induced ovulation and pregnancy is approximately 15%. The most common symptoms experienced by women taking clomiphene include: vasomotor symptoms (20%), adnexal tenderness (5%), nausea (3%), headache (1%), and, rarely, blurring of vision or scotomata. Most clinicians permanently discontinue clomiphene treatment in women with clomiphene-induced visual changes.

Clomiphene Plus Glucocorticoid Induction of Ovulation

Women with WHO II anovulation who have failed to ovulate using standard doses of clomiphene are referred to as being "clomiphene resistant." A consensus panel of expert fertility specialists recommended that for women with PCOS who are clomiphene resistant the most appropriate next steps in treatment include FSH injections or laparoscopic ovarian drilling.[93] However, for many women these options may be prohibitively expensive. For the clomiphene resistant woman with PCOS, what treatment can be prescribed that is affordable?

Many clomiphene resistant women will ovulate if they are treated with a combination of both clomiphene and dexamethasone. Before initiating combination therapy with clomiphene plus dexamethasone includes the results of the infertility work up should be reviewed to be sure that tubal and male factors are not contributing to the fertility problem. Two randomized clinical trials have reported that, in clomiphene-resistant women, dexamethasone plus clomiphene treatment results in an increase in ovulation and pregnancy rates compared to clomiphene alone.[94,95] One regimen that has been reported to be successful is to treat the clomiphene-resistant woman with clomiphene 100 mg daily for cycle days 3 to 7, and *simultaneously* treat her with dexamethasone 2 mg daily for cycle days 3 to 12 (Fig. 23.5).[94] Treatment with dexamethasone reduces the serum concentration of androgens, thereby increasing the efficacy of the clomiphene. In the randomized trial that used this regimen to treat clomiphene resistant women, the ovulation rate was 75% in the clomiphene plus dexamethasone group and 15% in the clomiphene alone group ($P < 0.001$). The pregnancy rate was 40% in the clomiphene plus dexamethasone group and 5% in the clomiphene alone group ($P < 0.05$). Other investigators have also reported that a glucocorticoid is an effective adjuvant to clomiphene treatment for certain women.[96-98]

Many clinicians instruct their patients to take the dexamethasone at night in order to maximally blunt the early morning corticotropin (ACTH) surge, which stimulates adrenal androgen production. However, experienced clinicians have found that for many women a nighttime dose

of dexamethasone energizes them and causes difficulty in falling and remaining asleep. Some experts recommend that patients take the dexamethasone in the morning. If the combination of clomiphene (100 mg daily for 5 days) plus dexamethasone does not cause ovulation, a cycle with a clomiphene dose of 150 mg daily for cycle days 3 to 7 plus dexamethasone can be prescribed. If this regimen does not cause ovulation, the patient should consider other options for ovulation induction such as weight loss, FSH injections, laparoscopic ovarian drilling, or *in vitro fertilization (IVF)*.

Clomiphene and Estrogen-Progestin Pretreatment

A risk factor for failure to ovulate with clomiphene is an elevated circulating testosterone level. Estrogen-progestin pretreatment prior to a cycle of clomiphene may improve ovulation rates by suppressing circulating testosterone prior to initiation of a clomiphene cycle. In a small case series and a randomized trial, 2 months of continuous estrogen-progestin contraceptive pill prior to treatment with clomiphene was reported to decrease circulating testosterone levels and improve ovulation and pregnancy rates in women with PCOS who had failed to ovulate with clomiphene 150 mg daily for 5 days.[99] In the randomized trial, 48 women who had failed to ovulate with clomiphene 150 mg daily for 5 days were randomized to 42 to 50 days of pretreatment with an estrogen-progestin contraceptive (ethinylestradiol 0.03 mg plus desogestrel 0.15 mg daily with no break) followed by clomiphene 100 mg daily for 5 days, or clomiphene alone.[100] The oral contraceptive regimen (OCP) significantly reduced circulating testosterone prior to initiation of clomiphene. The ovulation rate was 65% and 11% respectively in the OCP-clomiphene citrate (CC) group versus the CC group. Per cycle pregnancy rates were 54% and 4% respectively. A regimen of OCPs followed by clomiphene may be clinically indicated in women who have failed to ovulate with clomiphene or in women known to have an elevated total testosterone. A large-scale randomized trial of this sequential regimen is warranted.

Clomiphene Plus Estrogen and Progesterone Treatment of the Endometrium

In some cases, clomiphene has been reported to adversely affect cervical mucus quality and endometrial morphology.[101] This effect is probably mediated through the anti-estrogenic properties of clomiphene and its metabolites. The anti-estrogenic effects of clomiphene on the cervix and endometrium possibly reduces the pregnancy rate during clomiphene treatment. A number of investigators have reported that the addition of estrogen to clomiphene treatment can increase endometrial growth compared with that observed with clomiphene alone. In a well-designed study, vaginal estradiol (0.1 mg daily) from day 8 to the LH surge and progesterone gel (90 mg daily) starting 3 days after ovulation were demonstrated to improve the number of "in-phase" endometrial biopsies in women taking clomiphene.[102] As of yet, no clinical trial has demonstrated that the combination of clomiphene plus estrogen/progesterone increases pregnancy rates compared with clomiphene without estrogen/progesterone.

An alternative approach to dealing with the anti-estrogenic effects of clomiphene is to start treatment on cycle day 1 rather than cycle days 3, 4, or 5. Conceptually, by treating with clomiphene from cycle days 1 to 4, there are more days for clomiphene to "wash out" of the body prior to ovulation. In one randomized study, 23 women with unexplained infertility were randomized to receive clomiphene (plus intrauterine insemination [IUI]) with treatment from cycle days 1 to 5 or cycle days 5 to 9. The pregnancy rate was reported to be higher in the group that received the clomiphene treatment from cycle days 1 to 4.[103]

Clomiphene and Non-Classical Adrenal Hyperplasia

Many authorities recommend that infertile anovulatory women with non-classical adrenal hyperplasia (NCAH) receive glucocorticoids for induction of ovulation. However, some women with long-standing NCAH also have evidence of ovarian hyperandrogenism and polycystic ovaries by sonographic imaging. Clomiphene alone[104] or clomiphene plus glucocorticoids can be used to induce ovulation and achieve pregnancy in infertile women with NCAH.

Clomiphene Plus Gonadotropin Induction of Ovulation

In women who do not ovulate with standard doses of clomiphene citrate, gonadotropin injections can be added to clomiphene treatment to induce ovulation.[105] The main benefit of this approach to ovulation induction is that it tends to reduce the quantity of gonadotropins needed to induce ovulation during each cycle. The initial rise in LH and FSH induced by clomiphene increases the sensitivity of the follicles to respond to the gonadotropin injections. Typically, clomiphene at doses of 100 to 200 mg daily is administered for 5 days, followed by the initiation of FSH or LH-FSH injections. Investigators have reported that this regimen is associated with a 50% decrease in the dose of gonadotropin required to induce ovulation.[106]

Clomiphene and Metformin

Hyperinsulinemia is a common endocrine abnormality observed in women with PCOS (see Chapter 22). The elevated insulin levels contribute to the reproductive dysfunction by suppressing hepatic sex-hormone-binding globulin production and possibly by acting as a co-gonadotropin with LH in stimulating thecal cell androgen synthesis. Thus, reducing insulin levels is a therapeutic goal in women with PCOS.

Metformin is an oral biguanide antihyperglycemic agent approved for the treatment of type 2 diabetes mellitus. Metformin decreases blood glucose by inhibiting hepatic glucose production and by enhancing peripheral glucose uptake, possibly by interacting with the Peutz-Jegher syndrome tumor suppressor gene *(LKB1)* which activates adenosine-monophosphate-activated protein kinase.[107] It increases insulin sensitivity at the postreceptor level and stimulates insulin-mediated glucose disposal. Generic extended release metformin is available in doses of 500-, 750-, and 1000-mg tablets. The target metformin dose is in the range of 1500 to 2550 mg daily. When using metformin extended-release tablets, the entire daily dose is given at dinner time. To minimize gastrointestinal adverse effects like nausea, many clinicians recommend that metformin should be started at 500 or 750 mg daily for 1 week, followed by an increase in the dose to the target range. Progesterone levels can be measured periodically at appropriate days to determine if

ovulation has occurred, or the patient can keep a basal body temperature record. If ovulation has not occurred after 5 to 10 weeks of metformin treatment, then clomiphene, 50 mg daily for 5 days, can be administered in conjunction with metformin. If the patient becomes pregnant, the metformin therapy can be discontinued. Metformin is a category B drug for pregnant women and has been used by some clinicians to treat diabetes in pregnant women.

The most common adverse effects associated with metformin are gastrointestinal disturbances, including diarrhea, nausea, vomiting, and abdominal bloating. In rare cases, metformin treatment has caused fatal lactic acidosis. In most of these cases, some degree of renal insufficiency was present. Prior to initiating treatment with metformin, the patient's serum creatinine concentration should be measured and demonstrated to be less than 1.4 mg/dL. Other insulin sensitizers may also be effective in induction of ovulation, either alone, or in combination with clomiphene or FSH.

Clinical trials have reported conflicting results concerning the relative efficacy of metformin versus clomiphene. In general, the majority of large-scale clinical trials have reported that both metformin and clomiphene monotherapy are effective at inducing ovulation in women with PCOS, but clomiphene results in a greater per cycle ovulation, conception, and birth rates than metformin.[108] In this study, 626 women with anovulatory infertility caused by PCOS were randomized to receive clomiphene alone, metformin alone, or clomiphene plus metformin. The live birth rate was 27% in the clomiphene-metformin group, 23% in the clomiphene group, and 7% in the metformin group. In contrast, other investigators have reported that single-agent treatment with clomiphene or metformin results in similar pregnancy rates.[109] In some studies, metformin appears to be more effective in inducing ovulation in women with an above average waist to hip ratio, a marker of increased visceral fat.[110]

Clomiphene versus Tamoxifen or Raloxifene for Ovulation Induction

Clomiphene, tamoxifen, and raloxifene are mixed estrogen agonists-antagonists with varying degrees of agonist or antagonist activity in different end organs. In a randomized trial, 371 with anovulatory infertile women with PCOS were randomized to receive clomiphene citrate 100 mg daily or tamoxifen 20 mg daily for 5 days. The ovulation rate was 64% in the clomiphene group and 52% in the tamoxifen group ($P = 0.01$) and the pregnancy rate was 19% and 11% in the clomiphene and tamoxifen groups respectively ($P = 0.04$).[111] Clomiphene at a dose of 100 mg daily appears to be superior to tamoxifen at a dose of 20 mg daily for induction of ovulation in women with PCOS. In a small clinical trial, 5 days of treatment with clomiphene 100 mg daily or raloxifene 100 mg daily resulted in a similar rate of ovulation, but pregnancy rate was not studied in this trial.[112]

Aromatase Inhibitors

Clomiphene is effective in inducing ovulation because of its anti-estrogenic properties. During clomiphene treatment, the hypothalamus and pituitary register a decrease in estradiol feedback, and consequently there is an increase in FSH and LH secretion. Aromatase inhibitors including letrozole and anastrozole block estradiol synthesis, reduce estradiol feedback and increase production of FSH in premenopausal women. Letrozole at doses of 2.5 mg to 7.5 mg daily for 5 days, and anastrozole at a dose of 1 mg daily for 5 days have been demonstrated to induce ovulation in WHO II women. In a clinical trial comparing clomiphene 100 mg daily for 5 days versus letrozole 7.5 mg daily for 5 days in infertile couples undergoing ovarian stimulation plus intrauterine insemination (IUI), the pregnancy rates per cycle were 12% in the letrozole group and 9% per cycle in the clomiphene group.[113] In a clinical trial of letrozole 2.5 mg for 5 days versus anastrozole 1 mg daily for 5 days for ovulation induction in women with PCOS, the per cycle pregnancy rate was 19% in the women treated with letrozole and 10% in the women treated with anastrozole.

In one large randomized clinical trial, clomiphene was demonstrated to be superior to anastrozole for the induction of ovulation in women with WHO II anovulation. In this trial, 271 women with WHO II anovulatory infertility were randomized to receive for 5 days: clomiphene 50 mg, anastrozole 1 mg or 5 mg or 10 mg. The ovulation rates were 65% for clomiphene and 30%, 37%, and 36% for anastrozole 1 mg, 5 mg, and 10 mg, respectively. This study suggests that clomiphene is superior to anastrozole for ovulation induction.[114]

Aromatase inhibitors are not approved by the FDA for ovulation induction. Pregnancy and birth registries indicate that pregnancy outcome following ovulation induction with aromatase inhibitors is good.[115] In one registry, the risk of congenital cardiac malformations was greater with clomiphene induced pregnancy than with letrozole induced pregnancy.[116] However, concern remains about the potential adverse effects of these agents on pregnancy, especially given known adverse effects on rabbit and rodent pregnancy.

Ovulation induction and ovarian stimulation in women with estrogen-sensitive tumors, such as breast cancer may be a special situation that warrants the use of aromatase inhibitors.[117] Aromatase inhibitors increase FSH levels, but block estradiol production resulting in folliculogenesis with relatively reduced levels of circulating estradiol. In women with a history of estrogen-sensitive tumors, inducing folliculogenesis and ovulation while maintaining relatively low levels of circulating estradiol has a theoretical advantage.[118] This effect may be especially advantageous in women with a history of breast cancer planning on undergoing an IVF cycle.[119]

Aromatase inhibitors may be an effective monotherapy option for women who are clomiphene resistant. In one trial, 250 anovulatory women with PCOS who did not ovulate with standard doses of clomiphene were randomized to treatment with letrozole 2.5 mg daily for 5 days or metformin 1500 mg plus clomiphene 150 mg daily for 5 days. The ovulation rate was 65% in the letrozole group and 70% in the metformin-clomiphene group. The pregnancy rate was 15% and 14% in the letrozole and clomiphene groups respectively.[120] Some clinicians believe that aromatase inhibitors are especially effective in inducing ovulation in obese and morbidly obese women who are resistant to clomiphene.[121] In obese and morbidly obese women, aromatase inhibitors may be able to reduce peripheral aromatization of androgens, thereby reducing adipose-dependent estrogen negative feedback on the hypothalamus and pituitary and increasing the rate of ovulation.

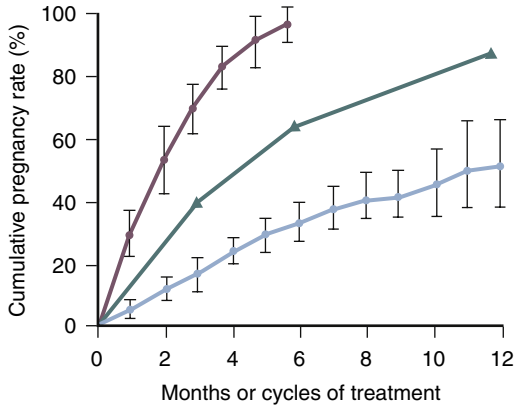

FIGURE 23.6 Cumulative pregnancy rates for infertile anovulatory women treated with gonadotropins for ovulation induction. Solid circles represent the cumulative pregnancy rate in women in World Health Organization WHO Group I. Open circles represent the cumulative pregnancy rate in women in WHO Group II who have failed induction of ovulation with clomiphene. For comparison, the triangles represent cumulative pregnancy rate in normal women. *(From Dor I, Itzkowic D, Mashiach S. Cumulative pregnancy rates following gonadotropin therapy.* Am J Obstet Gynecol *136:102–105, 1980, with permission.)*

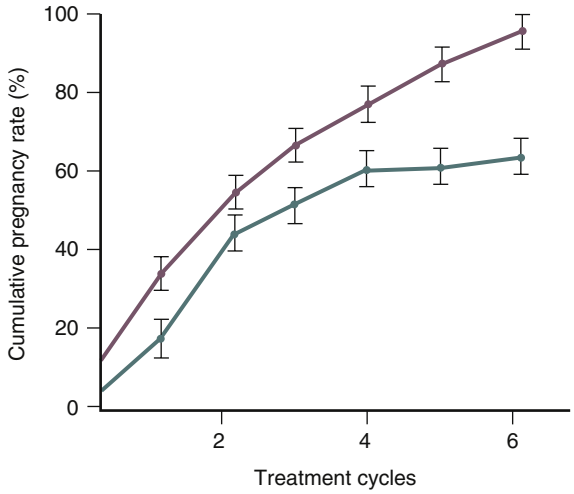

FIGURE 23.7 Cumulative pregnancy rates for hypogonadotropic anovulatory women (World Health Organization WHO Croup I) treated with gonadotropins. Solid circles represent the cumulative pregnancy rate in women less than 35 years old. Open circles represent the cumulative pregnancy rate in women more than 35 years old. *(From Lunenfeld B, Insler V.* Human gonadotropins. *In Wallach EE, Zacur HA [eds].* Reproductive Medicine and Surgery. *St. Louis: Mosby, 1995, p 617.)*

Gonadotropin Induction of Ovulation

The use of gonadotropins, gonadotropins plus GnRH antagonists, and gonadotropins plus growth hormone to treat infertility; and the prevention and treatment ovarian hyperstimulation syndrome are discussed in detail in Chapter 30. Important concepts related to the use of gonadotropins to treat anovulatory infertility is that women with the best prognosis for success have hypogonadotropic hypogonadism (WHO I) (Fig. 23.6) and are younger than 35 years of age (Fig. 23.7 and Fig. 23.8).

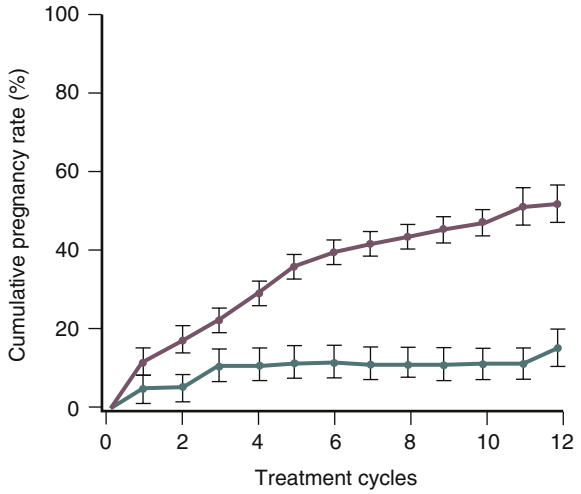

FIGURE 23.8 Cumulative pregnancy rates following gonadotropin treatment for anovulatory women who did not respond to clomiphene induction of ovulation (WHO Croup II). Solid circles represent the cumulative pregnancy rate in women less than 35 years old. Open circles represent the cumulative pregnancy rate in women more than 35 years old. *(From Lunenfeld B, Insler V.* Human gonadotropins. *In Wallach EE, Zacur HA [eds].* Reproductive Medicine and Surgery. *St. Louis: Mosby, 1995, p 617.)*

Ovarian Surgery for Ovulation Induction in PCOS

Ovarian wedge resection was one of the first treatments used to induce ovulation in women with PCOS. However, classical ovarian wedge resection was associated with ovarian and tubal adhesions. Laparoscopic ovarian drilling using insulated needle cautery has been reported to be associated with a 70% rate of ovulation and a 50% pregnancy rate.[122] The procedure can be performed by immobilizing the ovary with a probe and inserting an insulated needle electrode into the ovary. A cutting current of 100 watts can be used to ease the needle into the ovarian cortex. After the needle is inserted into the ovary, a 40-watt coagulating current is applied for 2 seconds at each point of puncture. Each ovary can be treated with 5 to 10 punctures; smaller ovaries should be treated with fewer punctures. In general, one or two punctures are not adequate to ensure ovulation postoperatively.[123] At the completion of the procedure, 1000 mL of crystalloid solution can be left in the pelvis.

In one clinical trial, 88 anovulatory, infertile women with PCOS who had not ovulated with clomiphene were randomized to ovarian surgery, FSH injections, or combination LH-FSH injections. The ovulation rate (70%) and the pregnancy rate (50%) were similar in all three groups. The spontaneous abortion rate was higher in the two groups that received gonadotropins. The investigators concluded that ovarian surgery was as efficacious as gonadotropin injections for ovulation induction in women with PCOS who did not ovulate with clomiphene.[124] In another clinical trial, women with PCOS who failed to ovulate with clomiphene 150 mg daily for 5 days were randomized to gonadotropin injections or laparoscopic ovarian diathermy. Six months after surgery, cumulative spontaneous pregnancy rate was 28%. After three cycles of gonadotropin injections, cumulative pregnancy rate was 33%.[125]

The risks of ovarian surgery for women with hirsutism are greater than the potential benefits. However, for women with PCOS and infertility who have been unable to become pregnant with weight loss, clomiphene and metformin treatment; the option of ovarian surgery for ovulation induction may be warranted prior to induction of ovulation with FSH. Survey data indicate that many patients prefer one surgical intervention compared to ovulation with FSH injections, if the two treatments have comparable success rates.[126] Cost-benefit analyses suggest that laparoscopic surgery for ovulation induction is associated with less healthcare costs than FSH injections.[127] Other authorities believe that the rare serious risks associated with surgery makes FSH injections the preferable option.[128]

Gonadotropin-Releasing Hormone (GnRH) Induction of Ovulation

A key feature of hypothalamic biology is the pulsatile release of the decapeptide GnRH from the arcuate nucleus into the pituitary portal circulation. The pulsatile release of GnRH stimulates the pituitary to produce LH and FSH in a pulsatile manner. In turn, pituitary gonadotropin secretion stimulates follicular development, ovulation, and progesterone secretion in the luteal phase. In women with WHO Group I anovulation (low levels of endogenous gonadotropins and decreased endogenous estrogen production), the pulsatile administration of GnRH is effective in inducing ovulation (Fig. 23.9). The advantages of GnRH induction of ovulation include a reduced need for cycle monitoring and a reduced risk of multiple gestation due, in part, to an intact pituitary feedback system. Unfortunately, GnRH for ovulation induction is currently not available in the United States.

Santoro and colleagues[129] proposed eight criteria for identifying women most likely to safely achieve ovulation with pulsatile GnRH:

1. Primary or secondary amenorrhea for at least 6 months
2. Absence of hirsutism, galactorrhea, or ovarian enlargement
3. Weight not below 90% of ideal body weight
4. No excessive exercise or stress
5. Normal serum prolactin, TSH, dehydroepiandrosterone sulfate (DHEAS), and testosterone concentrations
6. Low gonadotropin concentrations
7. No evidence for a structural central nervous system lesion
8. No recent hormone treatment

GnRH is administered using a computerized pump that delivers one pulse of GnRH every 90 minutes at a dose of 75 to 100 ng/kg per pulse. Interpulse intervals as short as 1 hour[130] or as long as 2 hours[131] have been successfully utilized. GnRH doses as low as 25 ng/kg per pulse can successfully induce ovulation, but are associated with subnormal luteal phase progesterone secretion.[130] Both intravenous and subcutaneous administration of GnRH have been successfully used to induce ovulation. Intravenous administration probably results in more reliable induction of ovulation, but this route is associated with more technical problems (restarting the intravenous catheter) and risk of infection than subcutaneous administration.

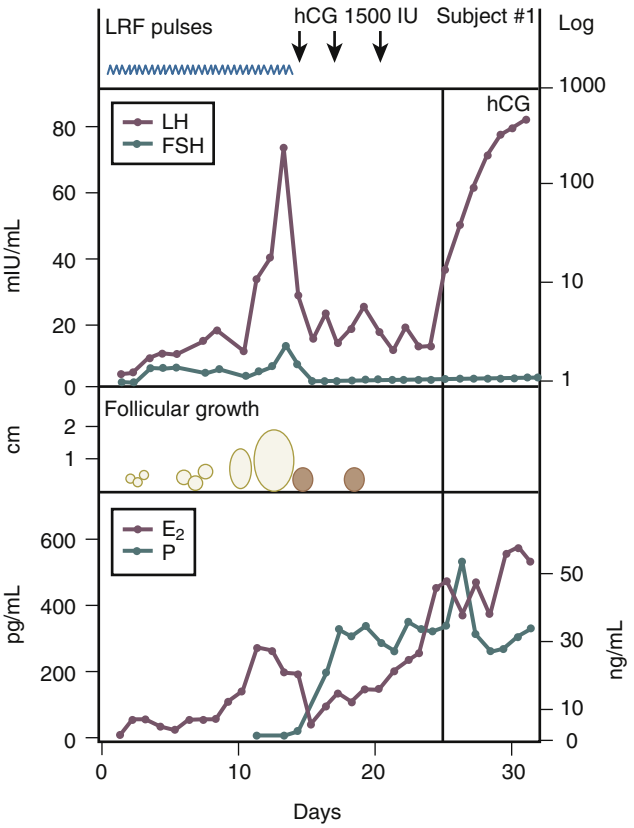

FIGURE 23.9 Endocrine and ovarian follicular response to induction of ovulation with gonadotropin releasing hormone, 5 μg intravenous bolus over 2 hours. LRF, Luteinizing hormone releasing factor, more commonly known as gonadotropin releasing hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; FSH, follicle stimulating hormone; P, progesterone; E_2, estradiol; IU, international units; pg, pictograms; ng, nanograms; mIU, milli-international units; mL, milliliters. *(From Reid RL, Leopold GR, Yen SSC. Induction of ovulation and pregnancy with pulsatile luteinizing hormone releasing factor: dosage and mode of delivery.* Fertil Steril *36:565, 1981, with permission.)*

The intensity of clinical monitoring can range from regular follicle monitoring with sonography and serum estradiol measurements to basal body temperature measurement with use of an ovulation predictor kit. Low-intensity monitoring is acceptable because the risk of multiple pregnancy or ovarian hyperstimulation is low with pulsatile GnRH therapy. If no response is observed after 2 to 3 weeks of treatment, the GnRH dose per pulse can be increased to the range of 10 μg to 20 μg per pulse.[131]

Studies that directly compare the efficacy of gonadotropin versus pulsatile GnRH induction of ovulation report equivalent rates of ovulation and pregnancy. However, the risk of multiple gestation is probably higher with gonadotropin treatment (14%) than with pulsatile GnRH treatment (8%).[132] This increased risk is due to a higher rate of multifollicular development with gonadotropin treatment (48% of cycles) than with pulsatile GnRH treatment (19% of cycles). Pulsatile GnRH results in a decreased risk of high-order multiple gestation when compared with gonadotropin treatment.[133]

Hyperprolactinemia

Infertile women with hyperprolactinemia and anovulation often achieve pregnancy after treatment with a dopamine agonist such as bromocriptine or cabergoline. The treatment of hyperprolactinemia is discussed in Chapter 3.

Luteal Phase Deficiency

Historically, *luteal phase deficiency* has been defined as the delayed maturation of the endometrium determined by histological dating of tissue obtained by endometrial biopsy, which lags appropriate development by at least 2 days (see Chapter 10). However, most recent research indicates that delayed maturation of the endometrium is commonly observed at a similar rate in both fertile and infertile women.[134] In addition, histological "dating the endometrium" probably does not have the accuracy or precision necessary to use it as a guide to infertility treatment.[135] Currently it is believed that competent endometrial maturation occurs over a wide range of progesterone concentrations. In human experiments, a progesterone concentration in the range of 5 ng/mL, approximately 75% below normal luteal progesterone concentration, supports adequate histological and biochemical secretory changes consistent with a competent secretory endometrium.[136] Consequently, the role of luteal phase deficiency in female infertility has diminished.

From an endocrine perspective, follicular or luteal function that is far outside the normative range is likely associated with reduced fertility. In the most extreme example, it is known that resection of the corpus luteum and the associated reduction in progesterone secretion, reduces fertility and causes abortion in women prior to about 49 days of pregnancy.[137] In addition, numerous clinical trials have observed that luteal phase progesterone support improves pregnancy rates following IVF cycles involving controlled ovarian hyperstimulation and ovarian follicle puncture to harvest oocytes.[138] It is probable that an occasional case of infertility may be caused by poor follicle development and inadequate corpus luteal secretion of progesterone or a relative resistance to progesterone effect in the endometrium. It is unlikely that luteal phase deficiency is a common cause of infertility.

The Aging Ovary, the Aging Follicle

An immutable feature of ovarian physiology is that the number of oocytes and follicles, is fixed *in utero* and declines following an exponential curve (mathematically similar to the curve for the decay of radioactive material) from the second trimester, as shown in Figure 23.10 (also see Chapters 9 and 15). At birth, estimates of the number of oocytes and follicles in a pair of human ovaries is approximately 2 million. At the completion of puberty, the number of eggs in a pair of human ovaries is in the range of 250,000. After 35 to 37 years of age, the rate of loss of oocytes and follicles appears to accelerate.[139,140] During adult reproductive life, follicles most sensitive to the growth promoting effects of FSH are apparently first selected to become the dominant follicle. As the ovary and the residual follicular pool ages, the remaining follicles appear to be relatively resistant to FSH. The aging follicles contain oocytes that are less likely to result in a successful pregnancy. The decrease in fecundability

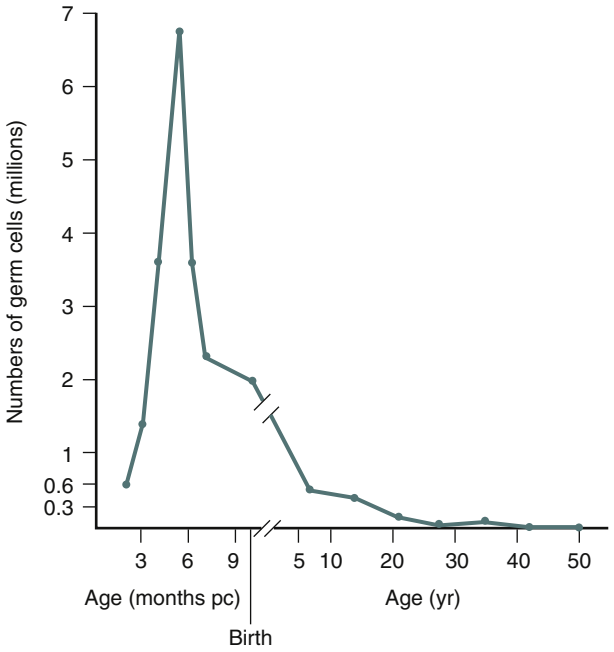

FIGURE 23.10 Changes in the total number of oocytes (and follicles) in human ovaries before and after birth. The number of germ cells in the ovary peaks *in utero* during the second trimester. *(From Baker TC. Radiosensitivity of mammalian oocytes with particular reference to the human female.* Am J Obstet Gynecol *110:746–761, 1971.)*

associated with aging is probably due to a decline in both the quantity and quality of the oocytes. Data to support the concept that the aging oocyte is less likely to result in a successful pregnancy comes from multiple sources (see Fig. 23.7 and Fig. 23.8).

Recent research has called into question some classical tenets of ovarian aging including the potential for renewal of follicles and oocytes in the adult ovary and the mathematical characteristics of the rate of decline of small follicles. Most mammalian species do not have histologically detectable mitotic oogonia or stem-like germ cells in the adult ovary. However, recent studies in rodents and humans have reported that there are rare stem cells in the adult ovary that can be harvested, stimulated to undergo mitotic replication and then be triggered to undergo meiosis to form competent oocytes.[141] The methods used in these experiments are complex, and support of the concept using alternative experimental techniques would be valuable. However, if oogonial stem cells are present in the adult ovary, the discovery opens the possibility of identifying treatment options to premature ovarian failure and menopause. It is clear from multiple studies that the number of small follicles in the ovary decline as a woman ages. Mathematical descriptions of the decline favor one of three models: (1) an exponential rate of decline with a fixed "half-life," similar to models describing the decay of radioactive material; (2) an exponential rate of decline with two distinct rates of decline, a slow rate of decline early in life, and a more rapid rate of decline later in reproductive life; and (3) a power model where the rate of decline accelerates throughout a woman's life.[142] The rate of decline of antimüllerian hormone (AMH), a biochemical marker of ovarian follicle number, and the antral follicle count assessed

by sonography also appear to accelerate with female aging, supporting the power model of decline.[143]

The discovery of interventions that could prevent the decline of oocytes and follicles in the adult ovary is an important priority. In the mouse model, two interventions of caloric restriction or knock-out of the peroxisome proliferator-actived receptor γ coactivator-1α , a component of a metabolical regulatory pathway, were reported to delay the rate of oocyte loss.[144]

For infertile couples where the cause of the infertility is azoospermia in the male partner, the success of donor sperm insemination is directly related to the age of the female partner. In women under 30 years of age, the first three cycles of insemination resulted in a per-cycle pregnancy rate of 0.10. In women older than 35 years of age, the first three cycles of insemination was associated with a per-cycle pregnancy rate of 0.06.148. Data from IVF programs also suggests that the age of the female partner is an important determinant of pregnancy rates. In women younger than 30 years of age, the clinical pregnancy rate per cycle is in the range of 0.25. In women over 40 years of age, the pregnancy rate per cycle is in the range of 0.12 with a high rate of spontaneous abortion.[145]

Changes in both oocyte quantity and oocyte quality (function) account for the relationship between the age of the female partner and fecundability. The poor functional quality of oocytes in the terminal follicle pool is a major cause of the relationship between female aging and diminishing fecundability. The poor functional quality of these oocytes is supported by the observed high rate of trisomic pregnancy that occurs following their fertilization[146] and the poor performance of these oocytes in the process of IVF, including poor fertilization, embryonic growth, low implantation, and pregnancy rates.

Five major methods are in use to assess the size of the ovarian follicle and oocyte pool in infertile women: (1) cycle day 3 FSH concentration, (2) cycle day 3 inhibin B, (3) antimüllerian hormone (AMH) measured at any time in the menstrual cycle,[147] (4) antral follicle count by transvaginal sonography, and (5) the clomiphene challenge test. In the normal menstrual cycle, decreases in estradiol and inhibin A during menses are associated with an increase in FSH production during the first 5 days of the menstrual cycle (see Chapters 8 and 9). The magnitude of the rise in FSH during menses is dependent on the magnitude of negative feedback provided by the circulating inhibin B concentration. During menses, inhibin B is secreted from small follicles. The greater the number of small follicles, the greater the inhibin B concentration during menses and the smaller the rise in FSH during menses because inhibin B has a negative feedback effect on FSH. The increase in FSH during menses stimulates the growth of an ovarian follicle that will be selected to achieve dominance during the cycle. As the selected follicle grows, it secretes increasing quantities of estradiol, inhibin B and inhibin A, thereby suppressing FSH production to low levels. As the follicular pool declines, inhibin B levels during menses decline and the magnitude of the FSH increase during menses increases, resulting in elevated serum FSH concentrations on cycle days 2, 3, and 4. AMH is expressed by small follicles, so as the follicle pool declines, serum AMH decreases. AMH levels are relatively constant throughout the menstrual cycle, increasing the convenience of obtaining a clinical useful AMH measurement compared with the timed measurements required for the interpretation of FSH and inhibin B values. An elevated serum FSH on cycle day 3 or a decreased cycle day 3 inhibin B or decreased AMH at any time during the cycle are good biochemical markers of a depleted follicular pool. A depleted follicle and oocyte pool is associated with decreased fecundability, an increased rate of pregnancy loss and an increased rate of aneuploid pregnancy. Particularly in infertile women older than 35 years of age, measurement of cycle day 3 FSH, inhibin B, or AMH are very helpful in identifying women with a reduced follicular pool. Antral follicle count also provides a clinically useful assessment of the ovarian follicle and oocyte pool.

Antral follicle count (AFC) is the sum of the number of antral follicles 2 to 10 mm in diameter in each ovary assessed in the 2-dimensional ovarian slice with the greatest area by high-resolution transvaginal sonography. AFC is commonly assessed during the early follicular phase of the menstrual cycles, but some authorities report it can be performed at any time in the menstrual cycle.[148] An antral follicle count ≤4 is associated with a poor follicular response to ovarian hyperstimulation, resulting in the development of a low number of large antral follicles and in IVF cycles, the retrieval of a low number of oocytes. However, AFC ≤ 10 are also associated with reduced ovarian response compared to an AFC > 10.[149,150] The AFC count has good inter-observer reliability and the AFC count shows much more variation between women than within the same woman measured in multiple tests.[151]

During menses, negative feedback control of FSH is largely from inhibin B, and to a lesser degree from estradiol. Using an estrogen antagonist such as clomiphene, the estradiol negative feedback is blocked and FSH negative feedback is only from inhibin B, resulting in a greater rise in FSH. This may increase the sensitivity of the measurement of FSH to detect a depleted follicle pool. The clomiphene challenge test is performed by administering clomiphene, 100 mg daily from cycle day 5 to 9. FSH levels are drawn on cycle days 3 and 10. An elevated FSH level on either cycle day 3 or 10 is associated with a diminished ovarian follicular pool and reduced fecundability. In some series, for every 100 women with an elevated day 10 FSH (post-clomiphene challenge), only 40 have an elevated day 3 FSH (pre-clomiphene challenge). Women who may be candidates for the clomiphene challenge test include those over 35 years of age, cigarette smokers, and women with unexplained infertility, stage III or IV endometriosis, previous bilateral ovarian surgery, or history of poor response to FSH stimulation. The clomiphene test is probably effective in detecting women with diminished follicular reserve because it blocks the negative feedback of estrogen, leaving only inhibin B to suppress FSH production. In women with diminished ovarian reserve, inhibin B levels appear to be very low and are incapable, on their own, of suppressing FSH production. Some investigators have reported that the measurement of FSH after a course of clomiphene citrate is more sensitive for identifying women with diminished ovarian reserve than is the cycle day 3 FSH test.[152,153] Other investigators have reported that basal FSH and the clomiphene challenge test have similar performance in identifying women with decreased fecundity due to a depleted follicle pool.[154]

Dozens of studies in IVF have reported that the number of mature follicles stimulated and the number of oocytes retrieved is related to basal FSH, inhibin B, AMH, and antral follicle count.[155] In a classic study of the relationship between cycle day 3 FSH and pregnancy rate in an IVF program, women with a day 3 FSH concentration of less than 10 mIU/mL had an ongoing pregnancy rate of 0.18. In contrast, women with a cycle day 3 FSH level greater than 25 mIU/mL had an ongoing pregnancy rate of 0.00.[156] The cycle day 3 FSH predicts the magnitude of the ovarian response to exogenous gonadotropin stimulation—including the peak estradiol concentration, the number of follicles, and the number of oocytes that are obtained at follicular aspiration. Since measures of the size of the ovarian follicular pool predict the magnitude of the ovarian response to stimulation, these measures can be used to guide the choice of stimulation regimens. For example, using a basal AMH test to guide selection of stimulation regimens, women with low AMH levels (reduced follicle pool) would be stimulated with higher doses of gonadotropins and women with higher levels of AMH (large follicle pool) would be stimulated with lower doses of gonadotropins.[157] Measures of the size of the follicle pool, such as AMH can also be used to assess the magnitude of the decrease in the ovarian follicle pool following ovarian cystectomy for diseases such as endometriosis.[158] It should be noted that although measures of the ovarian follicle pool are good predictors of the number of mature follicles stimulated and the number of oocytes retrieved during ovarian stimulation, they are not as good predictors of pregnancy because they may not adequately assess oocyte *quality* especially in situations where the female partner is older than 40 years of age.[159]

Many genetic and lifestyle factors determine the rate of follicular loss and the age at which serum FSH measured during menses begins to rise. For example, cigarette smoking appears to hasten the pace at which the follicular pool is depleted. Menopause occurs significantly earlier in women who smoke.[160] In women in their mid 30s, cycle day 3 FSH also appears to be approximately 25% higher in cigarette smokers than in non-smokers.[161] In cigarette smokers, the number of oocytes per pair of ovaries appears to be reduced.[162]

Chemotherapy with alkylating agents or pelvic radiation are two important exposures that are associated with a diminished follicular pool. Women who are older than 30 years of age and have completed six courses of chemotherapy for Hodgkin disease typically lose more than 90% of their follicles and many enter menopause immediately after the chemotherapy.[163] Radiation doses as low as 400 rads to the ovary will induce menopause in women over 35 years of age. Girls are much more resistant to the induction of menopause with chemotherapy or pelvic radiation, probably due to their large follicular pool.

Once a diminished ovarian follicular pool has been identified it is often "too late." Fertility treatments at this point have lower success than the same treatments in women with a normal follicular pool.[164] Women with diminished ovarian follicular reserve are probably best counselled to consider oocyte donation or adoption. Consequently, many authorities are recommending that infertility evaluation and treatment be initiated in women older than 35 years of age after only 6 months of failure to conceive. Evaluation of the size of the ovarian follicle pool is probably warranted in infertile women older than 35 years of age. As a simple rule to guide clinicians, advancing age of the female partner is associated with poor oocyte quality, and increasing levels of basal FSH is associated with a reduced ovarian follicle pool and reduced ovarian responsiveness to stimulation.[165]

Cancer Treatment and Infertility

Issues related to fertility preservation and the treatment of infertility in cancer patients is discussed in Chapter 33, Fertility Preservation.

Anatomical Factors in the Female

Tubal Factor Infertility

Tubal or peritoneal disease is identified in approximately 20% of the female partners of infertile couples. Pelvic inflammatory disease (PID), appendicitis, septic abortion, and previous pelvic or tubal surgery are major contributors to tubal disease. Endometriosis commonly causes peritoneal and ovarian adhesions and distorts tubal anatomy, but in almost all women with endometriosis the fallopian tubes are patent. The rate of tubal infertility has been reported to be 12%, 23%, and 54% after one, two, and three episodes of PID, respectively.[166] Subclinical pelvic infections with chlamydia trachomatis is a major cause of tubal disease associated with infertility. Patton and colleagues[167] studied tubal biopsy specimens from 25 women with PID and tubal infertility. *Chlamydia trachomatis* was detected in 3 out of 25 specimens by culture, 12 out of 24 specimens by *in situ* hybridization, 15 out of 22 specimens by immunoperoxidase staining, and 2 out of 10 specimens by transmission electron microscopy. Serum antibodies against chlamydia were detected in 15 out of 21 subjects. In this cohort, chlamydia was identified in 19 out of 24 women with PID and infertility.[167] Many subsequent studies have demonstrated that circulating high-titre chlamydia antibodies are associated with tubal disease as detected at the time of laparoscopy.[168] In one large population study, the presence of chlamydia antibodies was strongly associated with tubal factor infertility.[169] Approximately 1% to 4% of women of 18 to 26 years of age are infected with Chlamydia.[170] A history of a ruptured appendix increases the risk of developing tubal factor infertility. In one case-control study, a history of ruptured appendix was associated with a 4.8-fold increase in the risk of tubal infertility. Appendicitis without rupture was not associated with an increased risk of tubal infertility.[171]

Following pelvic surgery, adhesions develop in approximately 75% of women.[172] The mechanism of postoperative adhesion formation is not fully understood, but it involves invasion of fibroblasts into the postsurgical fibrinous bridges. As a result, adhesive tissue develops, connecting two normally unconnected structures or covering the surface of a structure with *de novo* adhesions (Fig. 23.11). In the normal peritoneal healing process, a serosanginous proteinaceous fluid exudes from the site of injury and coagulates into fibrin bands. In the normal healing process,

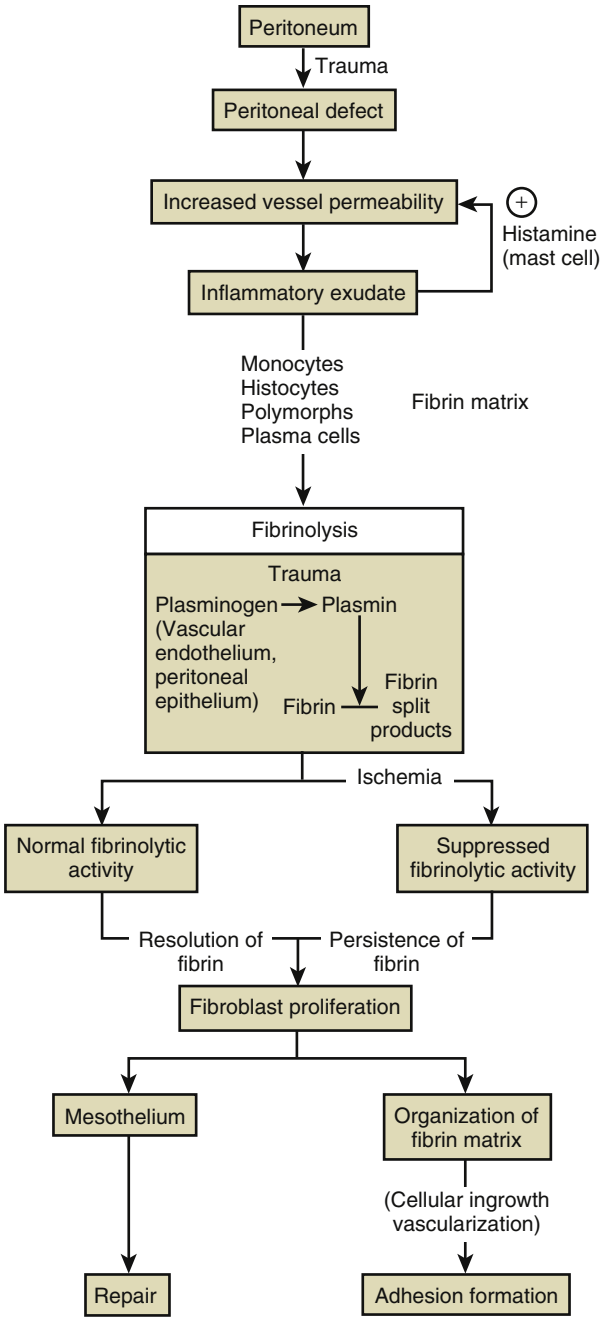

FIGURE 23.11 Schematic of the normal healing response to a surgical injury in the pelvic peritoneum. *(From Montz FJ, Shimanuki J, DiZerega CS. Postsurgical mesothelial re-epitheliazation. In DeCherney AH, Polan ML [eds], Reproductive Surgery. Chicago: Mosby Year Book, 1987.)*

endogenous fibrinolytic activity lyses these fibrin bands within 4 days. If the fibrinous bands are invaded by fibroblasts, angiogenesis occurs and a permanent bridge of tissue (an adhesion) is created. Factors that decrease fibrinolytic activity (ischemia, infection, drying of peritoneal surfaces) or increase fibroblast infiltration of the fibrin clot will increase the chance of developing adhesions.[173] Factors that increase fibrinolytic activity, such as plasmin preparations (plasmin, actase, and fibrinolysin) or plasmin activators (streptokinase, urokinase, and tissue-type plasminogen activator), are efficacious in preventing postsurgical adhesion formation.[174]

Methods reported to minimize postoperative adhesions include the use of dextran, adhesion-prevention barriers like regenerated oxidized cellulose (Interceed) and expanded polytetrafluoroethylene (PTFE, Gore-Tex), heparin, glucocorticoids, fibrinolytic agents, hyaluronic acid-based fluid agents, polyethylene glycol hydrogel, and nonsteroidal anti-inflammatory agents. Most of these agents have been demonstrated to be effective in laboratory models of adhesion formation.[175-177] Little clinical data is available to help guide the clinical use of adhesion prevention agents

Oxidized regenerated cellulose (Interceed), one of the most widely studied adhesion prevention adjuvant agents, becomes a gel shortly after placement on a surgically traumatized pelvic surface. The gel reduces the chance of formation of fibrin bridges between two opposing structures and thereby reduces the chance of adhesion formation. The material is resorbed within 1 week as it is metabolized into glucose and glucuronic acid. Oxidized regenerated cellulose has been demonstrated to reduce adhesion formation in women in well-controlled randomized prospective studies. In one study of 66 women with bilateral adnexal adhesive disease, the use of Interceed on one adnexa resulted in a 39% reduction of postoperative adhesion scores compared with the adnexa that did not receive the Interceed barrier. The use of Interceed resulted in a twofold increase in the number of adnexae without adhesions at the second-look laparoscopy.[178] Similar findings were obtained when oxidized regenerated cellulose was utilized to reduce adhesions after ovarian surgery.[179] A disadvantage of Interceed is that the surgeon must place the material over the area that is thought to be at high risk of adhesion formation. In many surgical cases, adhesions may occur at sites distant from the area where the Interceed is placed.

As noted above, the three most commonly utilized tests of tubal patency are the HSG, the hysterosalpingo contrast sonography (-), and laparoscopy. The advantages of HSG are that it utilizes few resources, produces data concerning the shape of the uterine cavity, and may increase fecundability by altering the peritoneal environment. The major disadvantages of HSG are that it requires a fluoroscopy imaging device, causes pain during the performance of the procedure, and provides no information concerning the presence of peritoneal diseases like endometriosis and ovarian adhesions. In addition, if the HSG demonstrates proximal tubal occlusion, a confirmatory test (selective tubal catheterization or laparoscopy) is required. This additional testing is necessary because about 15% of the cases where HSG demonstrates proximal tubal occlusion are actually due to "tubal spasm" that is spontaneously reversible. HSG is usually performed between cycle days 5 and 12. Many centers prepare women for the procedure with a short course of an antibiotic and an antiprostaglandin agent like ibuprofen immediately before the procedure. The risk of infection following HSG is in the range of 1%.[180]

Many studies report that following an HSG, fecundity is increased in the 12 to 24 months following the procedure. For example, in a clinical trial, women with infertility were randomized to HSG with an oil-based contrast media or with no intervention. After 24 months, pregnancy rates were 58% and 41% in the HSG and no intervention groups,

respectively ($P = 0.03$).[181] The fertility enhancing effects of an HSG appear to occur both with oil-based and water-based contrast agents. In one trial, 175 women were randomized to undergo HSG with either oil-based or water-soluble contrast agents. The oil-based contrast agent gave better resolution of the uterine cavity and the aqueous agent gave better resolution of the tubal mucosa. The post-procedure pregnancy rates were similar in the two groups.[182]

The main diagnostic advantage of laparoscopy over HSG is that it has better sensitivity and specificity for diagnosing tubal and peritoneal disease than HSG. In addition, laparoscopy can diagnose endometriosis and can be used to treat abnormalities observed at the time of the procedure.

HyCoSy is performed by cannulating the cervical os, and under ultrasound imaging injecting an ultrasound contrast media into the uterus. Specialized ultrasound devices that utilize contrast-tuned imaging are available to enhance the interpretation of the finding, but standard ultrasound devices can be used for the procedure.[183] Ultrasound contrast media are microbubbles suspended in a solution. The shell of the microbubble is made of albumin, galactose, lipids, or polymers. The bubble contains a gas that has low solubility in aqueous fluids, such as sulphur hexafluoride or octafluoropropane. The gas in the bubble generates a strong unique signature during ultrasound imaging. The media fills the uterine cavity providing an image of the shape of the cavity and detecting small intracavity filling defects caused by polyps or submucus myomas. If the proximal and distal fallopian tubes are patent, the contrast media flows into the proximal tube and out the distal tube into the peritoneal cavity. HyCoSy is an office-based procedure that is performed in the early follicular phase. HyCoSy is associated with less pain than HSG.[184] HyCoSy has sensitivity to detect tubal disease similar to HSG, but is superior to HSG for the detection of small intracavitary lesions.[19]

As noted above, Chlamydia infection is a common cause of tubal damage. One novel strategy for triaging infertile women into groups at high and low risk for tubal occlusion is the measurement of circulating anti-Chlamydia antibodies. For infertile women with absent or low-titre antibodies to Chlamydia the rate of tubal damage on laparoscopy or HSG is about 5%. For infertile women with high-titre antibodies to Chlamydia the rate of tubal damage on laparoscopy or HSG is about 35%.[185] In women with high titre antibodies to Chlamydia, more severe tubal damage is observed than in women with low titre or absent antibodies.[186] Testing for anti-Chlamydia antibodies as a screening strategy to identify infertile women with tubal disease is limited by false positive tests due to cross-reactivity with Chlamydia pneumoniae. Therefore, HSG or HyCoSy remains the first line test to evaluate tubal patency.[187]

Although Chlamydia is the most common cause of tubal damage in North America and Europe, tuberculosis is a common cause of distal tubal occlusion for women from Northern India and Nepal.[188] In areas with a high prevalence of tuberculosis, evaluation of the female partner for tuberculosis using a polymerase chain reaction test on an endometrial biopsy specimen identified women who would benefit from antimicrobial therapy.[189]

Surgery for the treatment of infertility due to tubal disease is most successful if disease is localized in the distal portion of the tube. *Fimbrioplasty* is the lysis of fimbrial adhesions or dilatation of fimbrial strictures. *Neosalpingostomy* is the creation of a new tubal opening in a fallopian tube with a distal occlusion. Dlugi and colleagues[190] evaluated the success of unilateral versus bilateral fimbrioplasty or neosalpingostomy in 113 women with tubal factor infertility. Overall, these procedures were associated with a postsurgery monthly pregnancy rate of 0.026. Similar monthly pregnancy rates following fimbrioplasty or neosalpingostomy have been reported by Canis and colleagues.[191] Women with major adhesions who had bilateral procedures had the lowest chance of achieving pregnancy. In contrast, *in vitro* fertilization treatment of tubal disease is associated with a per cycle pregnancy rate of approximately 0.30. After tubal surgery, however, couples can attempt to achieve conception naturally over many menstrual cycles. When viewed from a cumulative perspective, approximately 50% to 70% of the good-prognosis patients treated with distal tubal surgery became pregnant, and approximately 10% of the pregnancies achieved are ectopic pregnancies.

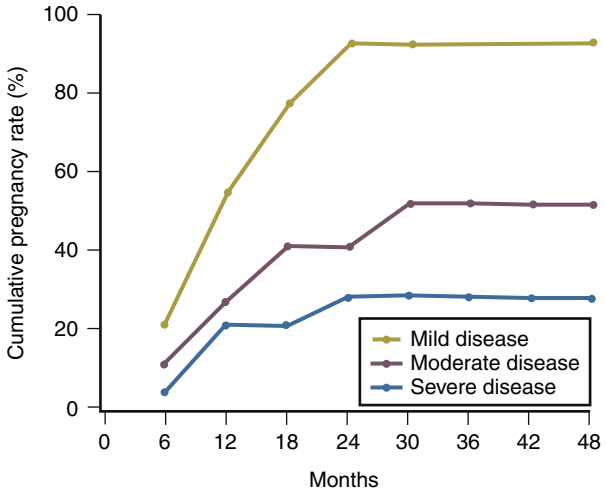

FIGURE 23.12 Life table analysis of pregnancy outcome following neosalpingoneostomy, by extent of disease. *(From Schlaff WE, Dassiakos D, Damewood MD, Rock JA. Neosalpingostomy for distal tubal obstruction: prognostic factors and impact of surgical technique.* Fertil Steril *54:984, 1990, with permission.)*

Poor prognostic factors for successful pregnancy following surgical treatment of distal tubal disease include tubal diameter greater than 30 mm, absence of visible fimbriae, dense pelvic adhesions, ovarian adhesions, advanced age of the female partner, diminished ovarian follicle number, and prolonged duration of the infertility problem (Fig. 23.12).[192] Infertile women with bilateral proximal and distal tubal disease have very low chances of conceiving following surgical treatment.[193] Treatment with IVF is much more successful than surgical treatment in this group of women.

In women with tubal infertility, proximal tubal occlusion accounts for about 20% of cases. Causes of proximal tubal occlusion include mucus debris, spasm at the uterotubal junction, or occlusion. Occlusion is commonly caused by fibrosis associated with salpingitis isthmica nodosa, pelvic inflammatory disease, adenomyosis, fibroids, or endometriosis. A major advance in the treatment of proximal tubal occlusion associated with infertility is the development of flexible tip guidewire techniques to restore patency to the proximal portion of the fallopian tube (Fig. 23.13 and Fig. 23.14).[194]

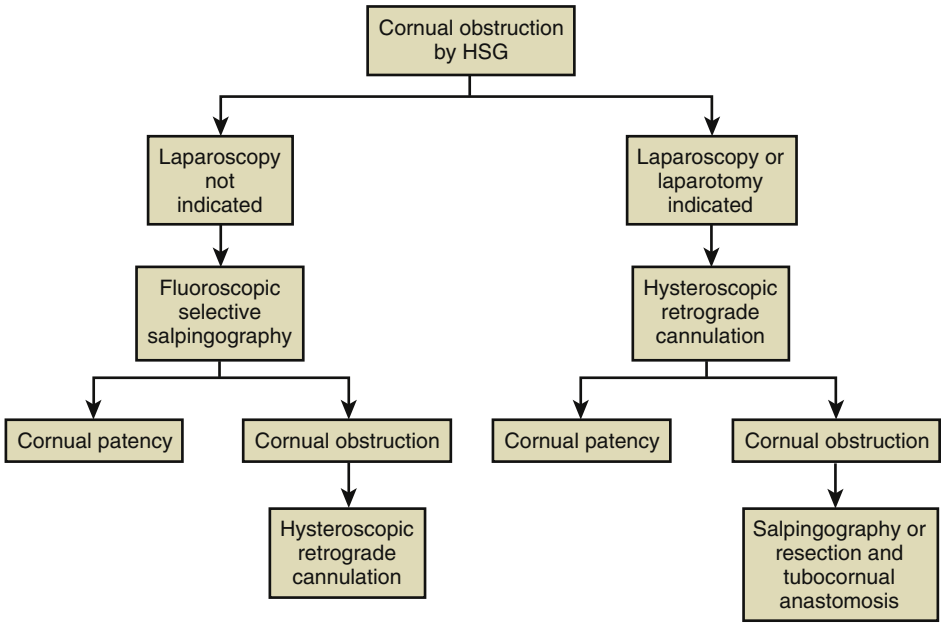

FIGURE 23.13 Schematic algorithm for treatment of women with proximal tubal obstruction. If laparoscopy or laparotomy is planned due to known major pelvic disease, proximal obstruction can be evaluated and treated by a hysteroscopic procedure performed at the same operation. If the patient is not thought to require a surgical procedure for pelvic pathology, proximal tubal obstruction can be evaluated and treated by fluoroscopic selective salpingography and catheter treatment. *(From Novy MI, Thurmond AS, Patton P, et al. Diagnosis of cornual obstruction by transcervical fallopian tube cannulation.* Fertil Steril *50:434, 1988, with permission.)*

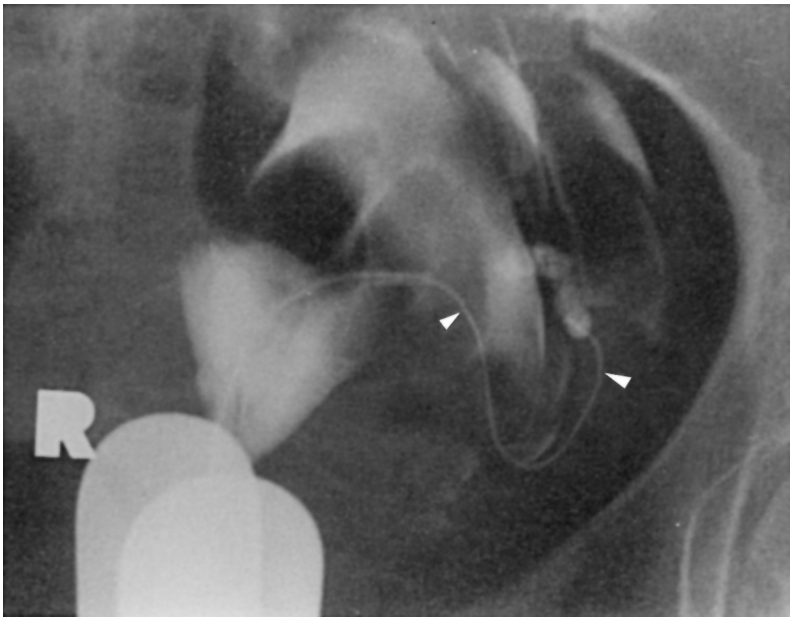

FIGURE 23.14 Transcervical bougie dilatation recanalizes an obstructed right tube. Note residual strictures around arrowheads at the isthmic segment of the tube, suggesting the presence of salpingitis isthmica nodosa. *(From Lang EK, Dunaway HH. Recanalization of obstructed fallopian tube by selective salpingography and transvaginal bougie dilatation: outcome and cost analysis.* Fertil Steril *66:210–215, 1996, with permission.)*

In one study of transcervical fluoroscopic catheter recanalization, successful recanalization was achieved in 47 of 65 tubes treated (72%). Of the 40 women with open tubes following the procedure, 9 achieved live births (23%), 4 had ectopic pregnancies (10%), and 1 woman became pregnant but had an early abortion. In the 11 women in whom tubal recanalization was not successful, there were no pregnancies.[195] In a large meta-analysis, tubal cannulation was successful in 85% of cases and 50% of the successfully treated women conceived.[196] If tubal cannulation cannot be accomplished, IVF is a better treatment option than surgery to reimplant the tubes into the uterus or excise the occlusion and reanastomose the tubes to the uterine cornua.[197]

One of the most successful surgical procedures for infertility is the microsurgical reanastomosis of fallopian tubes that were subjected to surgical sterilization procedures. The clinical characteristics that are associated with a high success rate for surgical reanastomosis include: (1) patient under 40 years of age; (2) tubal length greater than 4 cm; (3) sterilization performed with the Falope ring, clip, or Pomeroy tubal ligation technique; and (4) absence of associated pelvic pathology. Cumulative pregnancy rates in the year following the procedure are in the range of 50% to 80%. In one large case series that studied the impact of the age of the female partner on the postreanastomosis pregnancy rate, the reported cumulative intrauterine pregnancy rates were 81%, 67%, 50%, and 13% for female partners younger than 36, 36 to 40, 40 to 43, and older than 43 years of age.[198] Laparoscopic and robot assisted laparoscopic surgical reanastomosis have largely replaced traditional laparotomy approaches to tubal reanastomosis.[199,200] In a cohort study of the role of IVF or surgical reanastomosis for the

treatment of women with a tubal sterilization who wanted to conceive, for women younger than 37 years of age, surgical reanastomosis and IVF resulted in similar cumulative pregnancy rates, but surgical reanastomosis was reported to be more cost effective than IVF. For women older than or equal to 37 years of age, surgical reanastomosis resulted in fewer pregnancies than IVF.[201]

For infertile women with tubal disease, treatment with IVF is associated with a pregnancy rate of approximately 30% in the first cycle of treatment. Several studies indicate that hydrosalpinges decrease the pregnancy rate in IVF cycles.[202,203] The fluid in the hydrosalpinx may contain toxic factors that decrease the implantation rate of embryos or have direct embryotoxicity.[204] A meta-analysis of three controlled trials reported that laparoscopic salpingectomy for hydrosalpinx prior to IVF increased pregnancy rates by 75% compared with not performing the surgery.[205] In one trial, 204 women were randomized to undergo salpingectomy prior to IVF or to undergo IVF without prior salpingectomy.[206] The live birth rate was 29% in the women who had salpingectomy followed by IVF and 16% in the women who had IVF alone ($P < 0.05$). Laparoscopic salpingectomy should be considerd for all women with hydrosalpinges prior to undergoing IVF. Interestingly, in infertile women with one patent tube of normal caliber, and one blocked tube with a hydrosalpinx, surgical removal of the single blocked tube is associated with a good spontaneous pregnancy rate.[207] An alternative to salpingectomy of hydrosalpinges prior to IVF is to clip the proximal end of the tube to prevent the fluid from the hydrosalpinx to drain into the uterine cavity and disrupt embryo-endometrial interaction.[208,209] Some clinicians advise that if the proximal tube is clipped that the distal end of the hydrosalpinges should be widely fenestrated to prevent fluid from becoming trapped within the tube.

Uterine Factor Infertility

Congenital uterine abnormalities, such as a uterine septum, bicornuate uterus or uterine didelphys are associated with an increased risk of spontaneous abortion and preterm birth.[210,211] These problems are discussed in detail in Chapters 14 and 27.

Cervical Factor Infertility

The cervix is an active participant in shepherding sperm from the vagina to the upper reproductive tract. In the normal cervix, the secreted cervical mucus has physicochemical properties that facilitates the transport of sperm. Congenital malformation and trauma to the cervix may impair the ability of the cervix to produce normal mucus.

The postcoital test is the procedure most frequently utilized to examine the adequacy of the cervical mucus and the sperm-mucus interaction. Late in the follicular phase, the infertile couple is instructed to have sexual intercourse. The female partner is seen after intercourse and a small amount of cervical mucus is obtained using oval forceps with a hollow aperture. The glycoproteins in the mucus support the property of *spinnbarkeit*, or stretchability of the mucus. By allowing the prongs of the forceps to separate the spinnbarkeit, the mucus can be tested. A separate aliquot is dried on a glass slide. Due to the high concentration of salts in the normal mucus in the late follicular phase, the dried mucus will crystallize in a fern-like pattern. A third aliquot is placed on a glass slide overlaid with a cover slip and examined under the high power microscope objective for the presence of sperm.

Two major problems with the postcoital test are that there is little consensus on the normal range, and that the test has poor predictive value for pregnancy. For example, some authorities suggest that a normal test requires more than 20 sperm per high-power field.[212] Other authorities conclude that the presence of a single sperm indicates a normal test.[213] In one study of the relationship between the postcoital test and fecundability, 20% of fertile women were observed to have one sperm or less per high-power field.[212] In another study, fecundability did not seem to be altered by the presence of between 0 and 11 sperm per high-power field.[214] Further reducing the potential validity of the postcoital test is the observation that the inter-observer and intra-observer reproducibility is poor.[215]

Dysplasia of the cervix is a common problem that is often treated with excision of cervical tissue infected with human papilloma virus. Recent epidemiological studies have reported that loop electrosurgical excision (LEEP) of cervical tissue is associated with cervical stenosis,[216] preterm delivery, and low birth weight infants.[217]

Endometriosis

The relationship between endometriosis and infertility and the treatment of infertility caused by endometriosis are reviewed in Chapter 26.

Uterine Leiomyomata

The impact of uterine leiomyomata on fertility is reviewed in Chapter 27.

Immunological Factors and Recurrent Abortion

Recurrent abortion caused by autoimmune diseases, coagulopathies, and infections are discussed in Chapter 14.

Genetic Causes of Infertility

For many decades it has been known that major chromosomal abnormalities are often associated with infertility. For example, women with 45,X (Turner syndrome) have premature depletion of the oocyte pool and are typically sterile. Translocations and interstitial deletions of the X chromosome are associated with premature ovarian failure, although the identity of the genes in these deletions remains to be established. In infertile men, Yq11 microdeletions are observed in about 5% of cases.[218] A major goal of reproductive scientists is to identify individual genes that are associated with infertility. Recently, a few genes in women that influence fecundability have been identified.[219] Genes in which mutations affecting fertility and fecundity have been identified include Galactose-1-phosphate uridyl transferase *(GALT)*,[220] the FSH receptor,[221] the LH receptor,[222] premutations in the *FMR1* (fragile X syndrome) gene,[223] the *FOXL2* transcription factor

gene,[224] the *BMP 15* gene,[225] the *NR5A1* (steroidogenic factor 1) gene,[226] and the ataxia—telangiectasia *(ATM)* gene.[227]

Development of low cost methods for high resolution genetic testing is rapidly changing the approach to genotype-phenotype studies of infertile couples. Comparative genomic hybridization[228] and whole genome multiplex sequencing[229] increase the sensitivity of genetic tests to find "broken genes" that might cause or contribute to infertility.

Unexplained Infertility

Unexplained infertility is diagnosed when a couple has failed to achieve a pregnancy after 12 months of attempting conception and has completed a thorough evaluation without finding a cause for the infertility.[230] The diagnosis of unexplained infertility rests heavily on the definition of what constitutes a thorough fertility evaluation. For many fertility specialists, a thorough evaluation includes documentation of the following normal findings:

- Adequate ovulation, using either a midluteal phase serum progesterone determination of greater than 3 ng/mL
- Tubal patency, as determined by HSG, HyCoSy, or laparoscopy
- Normal semen analysis, demonstrating 15 million sperm per millilitre, greater than 32% motility and greater than 4% normal morphology by strict criteria
- Adequate ovarian oocyte reserve, using either a cycle day 3 FSH determination (below 15 mIU/mL), a clomiphene challenge test (both cycle day 3 and 10 FSH measurements below 15 mIU/mL), or antral follicle count greater than 4.

Many specialists believe that laparoscopy is an important component of a thorough infertility evaluation because it identifies undetected peritoneal adhesions and endometriosis lesions that would otherwise remain undetected. Other specialists believe that laparoscopy is not a necessary component of a thorough infertility evaluation, and should be reserved for use in selected cases.

The benefit of laparoscopy is that it allows a complete evaluation of the pelvis for diseases such as endometriosis and pelvic adhesions and treatment of those lesions at the time of the surgery. On the downside, laparoscopy is an expensive surgical procedure and the presence of endometriosis and pelvic adhesions does not influence the approach to treatment because empiric treatment quickly escalating to IVF is a practical and successful approach.

In one large retrospective study of 495 infertile couples with normal ovulation, normal HSG, and normal semen analysis, laparoscopy was performed on all the female partners and 35% were diagnosed with either major pelvic adhesions and tubal disease (10%) or endometriosis (21%).[231] In a separate study, a cost-benefit analysis concluded that for couples with normal ovulation, HSG and semen analysis, a laparoscopy to detect and treat endometriosis and peritoneal adhesions followed by expectant management was more cost effective than no laparoscopy or no laparoscopy but IUI followed by superovulation IUI followed by IVF.[232] One approach is to limit the use of laparoscopy in the infertility evaluation to those women who have a high likelihood of having endometriosis or pelvic adhesions, such as women with a history of severe dysmenorrhea or dyschezia.

Many cases of unexplained infertility are probably caused by the presence of multiple factors (e.g., female partner 37 years of age or older, male partner with semen parameters in the low end of the normal range). Each of these factors on their own do not substantially reduce fertility; when more than one factor is present, however, the pregnancy rate is reduced. Subtle changes in follicle development, ovulation, oocyte function, the luteal phase, and sperm function have been reported in couples with unexplained infertility.[233] In some couples with unexplained infertility, the male partner has a semen analysis with sperm concentration and motility at the lower end of the normal range.[234]

When couples with unexplained infertility are treated with IVF, they demonstrate reduced oocyte fertilization and embryo cleavage rates compared with couples where tubal factor is the cause of the infertility. For example, in one study, the oocyte fertilization rate for tubal factor infertility and unexplained infertility were 60% and 52%, respectively. When couples with unexplained infertility are treated with IVF, they have a higher rate of complete fertilization failure than couples with tubal factor infertility (6% versus 3%). These results suggest that couples with unexplained infertility probably have subtle functional abnormalities in oocyte and sperm function.[235]

Empirical Treatment of Infertility

The management of couples with unexplained infertility typically starts with treatments that consume few resources (lifestyle changes, timing of the intercourse to the fertile time of the menstrual cycle, expectant management, IUI, clomiphene, clomiphene plus IUI) and moves sequentially to treatments requiring proportionately greater resources (gonadotropin injections plus IUI or IVF), as shown in Figure 23.15.[236] This sequential approach to infertility, utilizing progressively more resource-intensive interventions, can be described as a "staircase" approach to empirical infertility treatment. The rationale underlying this strategy is that treatment is initiated with low-cost, low-risk interventions; and then with each step in the program, interventions are initiated that utilize greater resources and carry more risk. This approach has been demonstrated to be cost-effective in the treatment of unexplained infertility.[237] The pace at which the staircase is climbed is dependent on many factors, including the age of the female partner and the beliefs and values of the clinicians and patients.

Lifestyle changes can enhance the fertility of couples.[238,239] Lifestyle changes that can improve fertility include: normalize body mass index (BMI), stop smoking, reduce the use of caffeine and alcohol, reduce stress, reduce excessive exercise and for some couples, increase the frequency of sexual intercourse at the fertile time of the cycle. Lifestyle changes to enhance fertility have not been tested in high-quality clinical trials. Most of the evidence linking optimizing lifestyle choices and fertility are derived from epidemiological studies. Most epidemiological studies report that the magnitude of the impact of optimizing lifestyle choices on fertility is greater for the female partner than the male partner, but both partners should jointly participate in optimizing their reproductive health. Epidemiological studies

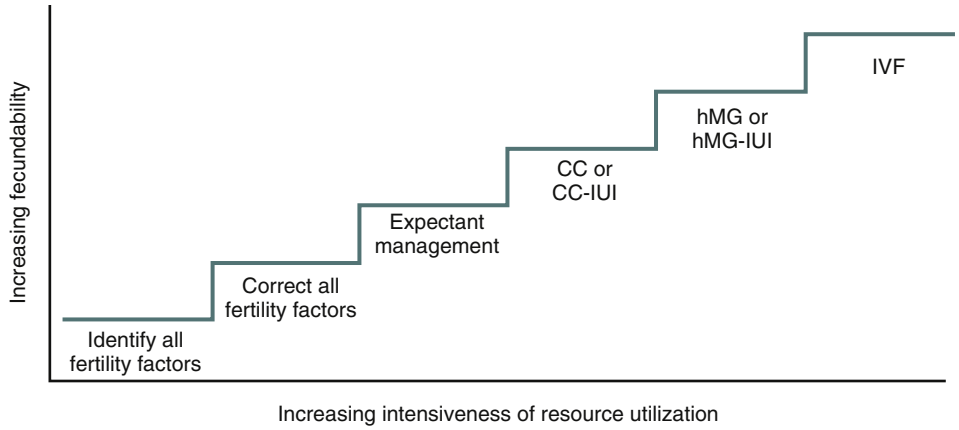

FIGURE 23.15 Staircase approach to empirical infertility treatment. For women over 35 years old, the first three steps in the algorithm should be rapidly completed. In women less than 30 years old, more time can be spent on the first three steps in the staircase. CC, clomiphene; IUI, intrauterine insemination; hMG, human menopausal gonadotropins; IVF, *in vitro* fertilization.

indicate that for the female partner, cigarette smoking and excessive caffeine and alcohol consumption reduce fertility. Couples with unexplained infertility should be counselled to stop smoking cigarettes. The female partner should be counselled to reduce caffeine intake to no more than 250 mg daily (two cups of coffee) and to reduce alcohol intake to no more than four standardized drinks per week. The male and female partner should be guided to try to achieve an optimal body mass index, ranging from 19 to 25 kg/m^2.[240,241] For couples with unexplained infertility and a low frequency of coitus, recommending an increase in coital frequency to at least twice per week may be associated with increased pregnancy rates.[242]

Based on data from observational studies, dietary patterns appear to influence the ovulation rate in women and semen quality in men. In women, an increase in the frequency of normal ovulatory cycles is observed with the following dietary patterns: high intake of low-glycemic index food, low protein intake from animal sources, high protein intake from vegetable sources, high intake of fat from dairy products, and high iron intake.[243] A Mediterranean-type dietary pattern appears to optimize fertility potential.[244] Among men a diet high in saturated fats appears to be associated with a reduction in sperm concentration in an ejaculate and high intake of omega-3 fats was associated with superior sperm morphology.[245]

In the treatment of unexplained infertility, timing intercourse to the portion of the menstrual cycle with the greatest chance for conception is an important and inexpensive intervention that can increase fecundability.[246] Urine LH testing at home is commonly utilized to identify the LH surge which occurs 1 to 2 days before ovulation. The days of the cycle with the greatest probability of pregnancy with one episode of sexual intercourse are the days of ovulation, and the two days before ovulation.[45,247,248] Since the urine LH surge occurs 1 to 2 days before ovulation it identifies in a prospective manner the fertile days of the cycle.

For young couples with unexplained infertility, expectant management is a reasonable and cost-effective approach to treatment.[249-251] When couples with unexplained infertility are followed prospectively without active treatment, approximately 1% to 4% become pregnant each month. For couples with unexplained infertility and a fecundability less than 0.01 (poor prognosis couples), waiting to initiate treatment is not cost effective. For couples with unexplained infertility and a fecundability of 0.04 (good prognosis couples), expectant management with timing of intercourse to the fertile part of the cycle is cost effective. Fertility factors that improve prognosis in couples with unexplained infertility include: female partner younger than 32 years of age, couple with less than 2 years of infertility, couples with a prior pregnancy, and a semen analysis with sperm motility greater than 40%.[252] Effective fertility treatment for unexplained infertility must increase the pregnancy rate above this baseline fecundability of approximately 0.01 to 0.04. The age of the female partner influences the pregnancy rate associated with expectant management.[253] For women over age 37, the pregnancy rate per cycle with expectant management is under 1%. For couples where the female partner is over 37 years of age, the ovarian oocyte pool declines rapidly—inevitably causing ovarian aging to become the cause of the fertility problem. For these women, expectant management is not recommended. Many couples of all ages become frustrated with their inability to conceive. For these couples, active treatment is recommended.

Intrauterine Insemination

The IUI procedure consists of washing an ejaculated semen specimen to remove prostaglandins and other factors and then concentrating the sperm in a small volume of culture media with a high protein concentration to enhance capacitation and the acrosome reaction. The sperm suspension is then injected directly into the upper uterine cavity using a small catheter threaded through the cervix. In one study of various methods used to prepare the sperm for intrauterine insemination, the swim-up and Percoll gradient preparation techniques resulted in superior pregnancy rates than the simple wash, swim-down, or refrigeration/heparin techniques.[253] The intrauterine insemination is timed to take place just prior to ovulation, typically using home urine LH monitoring. In couples reporting male infertility, IUI more than doubles the pregnancy rate compared with intracervical insemination or timed natural cycles (odds ratio 2.2; 95% confidence interval, 1.4 to 3.4).[254] In one study of couples with mild male infertility, the pregnancy rate per cycle was 6.5% for IUI versus 3.1% for intracervical insemination or timed natural intercourse.[255] IUI also appears to be effective for couples with unexplained infertility.

In a large clinical trial sponsored by the National Institutes of Health, 932 infertile couples with unexplained infertility or stage I or II endometriosis were randomized

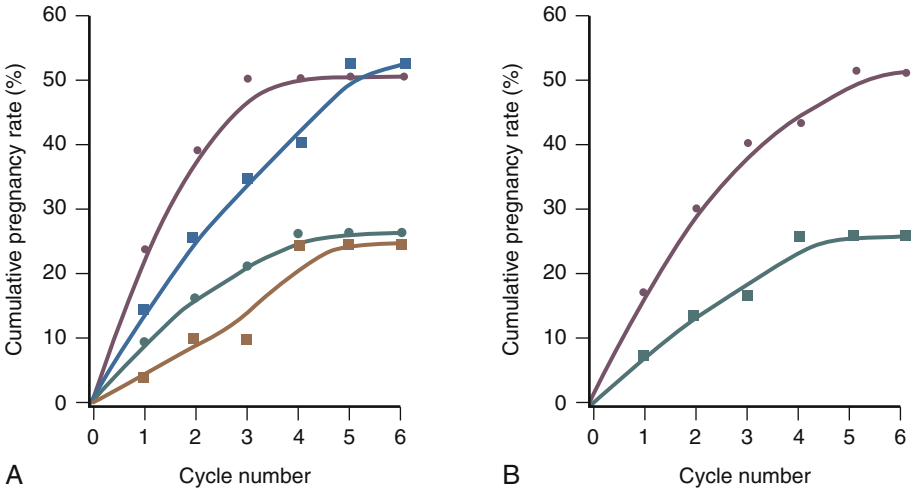

FIGURE 23.16 Cumulative pregnancy rates by Kaplan Meier life-table analysis for 290 infertile couples undergoing clomiphene IUI therapy stratified by the age of the female partner. **A**, Ages of women: purple circles, under 30; blue squares, 31 to 35; green circles, 36 to 40; brown squares, 41 or over. **B**, Ages of women: circles, under 35; squares, over 35. *(From Agarwal SK, Buyalos RP. Clomiphene citrate with intrauterine insemination: is it effective therapy in women above the age of 35 years?* Fertil Steril *65:759–763, 1996, with permission.)*

to one of four treatment groups: intracervical insemination of sperm (ICI); IUI; FSH injections plus ICI; or FSH injections plus IUI.[234] The purpose of the ICI was to be a control treatment that mimicked natural intercourse. The purpose of the IUI was to place a large number of sperm high in the reproductive tract. The purpose of the FSH injections was to stimulate multiple follicular development and ovulation, thereby increasing the number of oocytes available for fertilization in a single cycle (this type of treatment is explained later in this chapter). Most of the women in this study had either unexplained infertility or early stage endometriosis. The investigators reported that the per-cycle pregnancy rate in the group that received the control (ICI treatment) was 2%.[234] This pregnancy rate is similar to expectant management. IUI treatment was associated with a 5% per-cycle pregnancy rate. The per-cycle pregnancy rates in the FSH-ICI and FSH-IUI groups were 4% and 9%, respectively. In this study, IUI was clearly effective for the treatment of unexplained infertility.[234]

Multiple procedure-related factors appear to influence the effectiveness of IUI. Most recent studies report that one IUI per cycle results in a pregnancy rate similar to 2 IUI procedures per cycle.[256,257] In couples with a mild male factor problem, double IUI may increase the pregnancy rate.[258] Resting supine after the IUI procedure may also be associated with higher pregnancy rates than those in patients who ambulated soon afterwards.[259]

Clomiphene Citrate

Clomiphene has been demonstrated to be effective in the treatment of unexplained infertility. In normal ovulatory women, clomiphene treatment often results in the ovulation of two follicles and an increase in luteal phase progesterone production. These treatment-dependent changes probably increase fecundability. A 2000 meta-analysis of 11 prospective trials of clomiphene treatment for women with unexplained infertility demonstrated that clomiphene was superior to placebo or no treatment. The odds ratio for clinical pregnancy per clomiphene treatment cycle was 2.5 (95% confidence interval, 1.35 to 4.62).[260] In one trial where 118 female partners from couples with unexplained infertility were randomized to treatment with placebo or clomiphene citrate (100 mg daily, cycle days 2 to 6), the per-cycle pregnancy rates were 5% and 7%, respectively ($P < 0.05$).[261]

Although the absolute treatment effectiveness is modest, the low cost and low adverse effects of clomiphene make it a useful initial treatment for unexplained infertility. The main complication of clomiphene is an increase in multiple gestation. In one study of 2369 clomiphene-induced pregnancies, 7% were twins, 0.5% were triplets, 0.3% were quadruplets, and 0.13% were quintuplets.[262] The risk of high-order multiple pregnancies with clomiphene treatment is low, but the high volume of clomiphene cycles makes this intervention an important contributor to the total number of high-order pregnancies.[263]

Many normal ovulatory women undergoing empirical treatment of infertility with clomiphene have endometriosis. Many clinicians believe that clomiphene use in this setting may be associated with an increase in estradiol levels and an increase in endometriosis disease activity, including pelvic pain and the growth of ovarian endometriosis cysts.

Clomiphene Plus Intrauterine Insemination

The combination of clomiphene (increases the rate of double ovulation) plus IUI (places a large number of motile sperm high in the female reproductive tract) may simultaneously treat mild abnormalities of ovulation, oocyte function, and sperm function. In one study, 67 couples were randomized to treatment with clomiphene plus IUI or placebo. The pregnancy rate per cycle was 3.3% for control group and 9.5% for clomiphene plus IUI group.[264] For clomiphene-plus-IUI cycles, timing of the IUI is usually based on home urine LH measurement. Timing IUI with home urine LH measurement or exogenously administered hCG is associated with a similar pregnancy rate, but hCG administration is associated with greater cost and an increased risk of OHSS.[265] Advancing age of the female partner is associated with a decrease in success rates for IUI therapy (Fig. 23.16).[266]

Gonadotropin Injections and Gonadotropin Injections plus Intrauterine Insemination

Both gonadotropin injections alone and gonadotropin injections plus IUI increase fecundability in women with unexplained infertility. Gonadotropin injections plus IUI

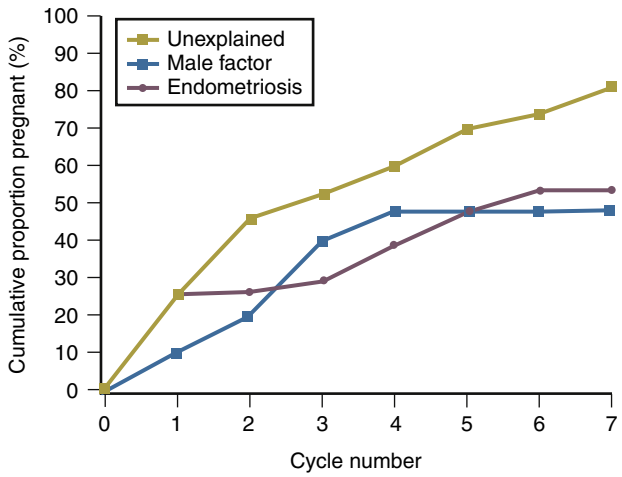

FIGURE 23.17 Cumulative pregnancy rate for gonadotropin-intrauterine insemination treatment for various fertility conditions: Unexplained, early stage endometriosis, and male factor. *(From Nulsen JC, Walsh S, Dumex S, Metzger DA. A randomized and longitudinal study of human menopausal gonadotropin with intrauterine insemination in the treatment of infertility.* Obstet Gynecol *82:780–786, 1993, with permission.)*

also appears to increase fecundability in infertile women with stage I or II endometriosis and in infertile men with semen abnormalities (Fig. 23.17).[267] In one study, 932 infertile couples with unexplained infertility or stage I or II endometriosis were randomized to one of four treatment groups: ICI, IUI, FSH injections plus ICI, or FSH injections plus IUI. The pregnancy rate in the control, the ICI group, was 2% per cycle. In the FSH-plus-ICI and the FSH-plus-IUI groups, the pregnancy rate per cycle was 4% and 9%, respectively.[234] The main complication of the use of FSH injections in the treatment of infertility in women with unexplained infertility is an increase in the rate of multiple gestations and ovarian hyperstimulation. Of the ongoing pregnancies in this study, 3% were quadruplets, 5% were triplets, and 20% were twins.

In another study of gonadotropin injections with or without IUI, Serhal and colleagues[268] randomized 62 couples with unexplained infertility to receive IUI alone, gonadotropin injections alone, or gonadotropin injections plus IUI. The per-cycle pregnancy rate was 2.2% for IUI alone, 6.1% for gonadotropin injections alone, and 26% for gonadotropin injections plus IUI. Similar results have been reported by other investigators.[269,270]

Although there is evidence for the efficacy of gonadotropin with or without IUI for the treatment of unexplained infertility, many authorities highlight the increased risk of multiple gestation with these therapies, and advise that the use of gonadotropin-IUI should be very limited.[271,272] In addition, if good prognosis couples with unexplained infertility can be counselled to continue to try to get pregnant on their own, and not pursue gonadotropin therapy, many will become pregnant spontaneously.[273] In a recent trial comparing the 3 step sequential treatment protocol: clomiphene-IUI, followed by gonadotropin-IUI, followed by IVF versus a 2 step sequential treatment protocol: clomiphene-IUI, followed by IVF, the clinical utility of the gonadotropin-IUI was poor.[274] In this study, the per cycle pregnancy rate for clomiphene-IUI was 7.6%, gonadotropin-IUI 9.8%, and IVF-31%. Since gonadotropin-IUI is expensive, and much less effective than IVF, the most cost-efficient approach was the two-step sequential treatment plan of clomiphene-IUI followed by IVF. The two-step approach was approximately 15% less expensive per live birth than the traditional 3-step approach.

Many authorities strongly caution against the use of FSH-IUI in the empiric treatment of infertility because it increases the risk of high-order multiple gestations and because IVF is a more effective intervention.[275,276] When using FSH-IUI, it is difficult to prevent all high-order multiple pregnancies, but withholding hCG administration in the presence of ≥3 follicles over 15 mm is one intervention that has been reported to reduce the multiple pregnancy rate.[277] Over the past 30 years, the pregnancy rate per cycle of IVF has increased from approximately 5% to 40% per cycle. As the pregnancy rate per cycle of IVF increases, the clinical utility of FSH-IUI decreases because IVF becomes a more cost-effective method of achieving a pregnancy.

In IVF cycles, the addition of a GnRH agonist or antagonist analogue to the gonadotropin injection regimen is known to improve pregnancy rates. However, the addition of a GnRH agonist analogue to a regimen of gonadotropin injections plus IUI does not appear to consistently increase the pregnancy rate in couples with unexplained infertility. In a study of the effect of adding a GnRH agonist to FSH-IUI therapy, 91 couples with unexplained infertility were randomized to receive treatment with gonadotropin injections and IUI or GnRH agonist analogue treatment plus gonadotropin injections and IUI. The pregnancy rate per cycle was 11% and 13%, respectively.[278] In a study of the effect of adding a GnRH antagonist to FSH-IUI treatment, 233 couples with unexplained or male factor infertility were randomized to receive FSH-IUI or a GnRH antagonist plus FSH-IUI. The pregnancy rate per cycle was 12% and 8% in the FSH-IUI and GnRH antagonist-FSH-IUI groups respectively ($P = 0.03$).[279]

In Vitro Fertilization

In Vitro Fertilization (IVF) is effective in the treatment of unexplained infertility.[280] In one randomized trial, 116 couples with unexplained infertility and a poor prognosis for spontaneous pregnancy were randomized to single embryo transfer IVF or FSH-IUI. The live birth rate was 22% and 7% for IVF and one cycle of FSH-IUI respectively. However, when the women in the FSH-IUI group completed 3 cycles of FSH-IUI, the cumulative life birth rate was 21%. The multiple pregnancy rate was 14% in the single embryo transfer IVF group and 25% in the FSH-IUI group.[281] In one cohort study, couples with unexplained infertility were treated for up to 3 cycles with gonadotropin injections plus IUI. The couples who did not become pregnant were then treated with IVF.[282] The per-cycle pregnancy rate was 16% for the couples treated with gonadotropin injections plus IUI, and 37% for the couples treated with IVF. Published cohort studies with no control group report that the treatment of unexplained infertility with IVF results in per-cycle pregnancy rates in the range of 20% to 40%.[283]

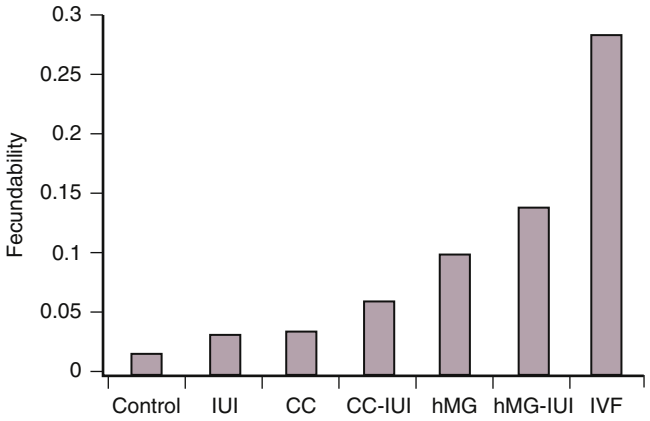

FIGURE 23.18 Fecundability associated with empirical treatment of unexplained infertility. Control, no treatment; IDI, intrauterine insemination; CC, clomiphene citrate; CC-IDI, clomiphene citrate plus intrauterine insemination; hMG, human menopausal gonadotropin; hMG-IUI, human menopausal gonadotropin plus intrauterine insemination; IVF, *in vitro* fertilization and embryo transfer.

Pace of Escalation in the Treatment of Unexplained Infertility

As noted above, couples with unexplained infertility and a good prognosis may be offered expectant management, and if that is not successful proceed slowly from low-resource interventions to resource intensive treatments like FSH-IUI or IVF. For couples with unexplained infertility and a poor prognosis (female age >37 years, >2 years of infertility) it may be preferable to more rapidly move from low-resource interventions to FSH-IUI or IVF. Studies of cohorts of infertility patients report that after 3 cycles of any one treatment, such as IUI, CC-IUI, or FSH-IUI, the pregnancy rate tends to decline. In general, after 3 cycles of any one treatment, it is recommended to consider advancing to the next step in the treatment algorithm (Fig. 23.18).[284]

Environmental Exposures Associated With Infertility

The impact of environmental factors on reproduction is discussed in Chapter 20.

Contraindications to Infertility Treatment

An adage in medicine is "first do no harm." Fertility treatments have the potential to significantly harm women and children born of fertility treatments. Counterbalancing the potential harm caused by fertility treatment is the right of patients to request treatments to achieve an important health goal, even if some risks are involved. There are a limited number of diseases that are an *absolute contraindication* to fertility treatment. In one such disease, Eisenmenger, pregnancy has an approximately 50% likelihood of causing death to the mother.[285] Many authorities strongly caution against fertility treatment in women with Turner syndrome due to an approximately 1% to 2% risk of aortic dissection.[286] However, many high-risk obstetricians will not advise against pregnancy in these women if their aortic root diameter is not dilated. The age of the female partner is a factor that must always be considered when recommending fertility treatment. There must be an age of the female partner where fertility treatment poses too great a risk for mother and child, such as age greater than 55 years. Population studies raise the concern that oocyte donation to older women is associated with an increased maternal mortality rate.[287]

There are many clinical situations where there is a relative contraindication to fertility treatment. Most of these contraindications are due to obstetrical considerations: the pregnancy poses serious risks during the pregnancy or at the time of delivery. For example, a woman with massive pelvic adhesions and a frozen pelvis can achieve a pregnancy with IVF. But at delivery if an emergency caesarean delivery is necessary, a bowel resection may be needed to gain access to the uterus to complete the caesarean delivery. The BMI of the female partner is of particular concern to obstetricians because of the high risk of difficult vaginal delivery. Obstetricians and fertility specialists have not reached a consensus about the wisdom of fertility treatment in women with a BMI greater than 60 kg/m^2. Many fertility specialists believe that delaying fertility treatment in a 40-year-old infertile woman with a BMI greater than 60 kg/m^2 is unethical because her ovarian follicle pool is nearly depleted.[288] Delaying her fertility treatment for additional attempts at weight loss may result in further depletion of her ovarian follicle pool. In contrast, obstetricians counsel that in women with a BMI greater than 60 kg/m^2 the risks of pregnancy, including a high rate of difficult caesarean delivery, make it dangerous to use fertility treatments.[289]

Infertility Treatment and Pregnancy Outcomes

The outcome of pregnancy in infertile women, regardless if the pregnancy arises spontaneously or following fertility treatment, appears to be different than in non-infertile women. For example, in a study from the Danish National Birth Cohort, fetal birth weight was compared in 51,000 singletons born of fertile couples, 5787 born of infertile couples *conceiving naturally* and 4317 born of infertile couples after fertility treatment. Maternal age and body mass index were greater in the infertile couples. After adjusting for these variables and smoking status, both the infertile couples who conceived naturally and those who conceived after fertility treatments had an increased risk of having a baby with a birth weight less than or equal to 5% compared with non-infertile women (6% versus 4.2%).[290] Similar findings have been reported in studies from Finland, subfertile women who conceived spontaneously and those who conceived following fertility treatment had a similar rate of preterm birth, low birth weight, and need for neonatal intensive care.[291] A study from Norway examined the birth outcomes in 2546 women who had 1 child by IVF and 1 child conceived without treatment.[292] Compared to the entire Norwegian population, IVF conceptions were associated with a lower mean birth weight (25 g), shorter duration of gestation (2 days), and increased risk for small for gestational age birth weight (OR 1.26, 95% CI, 1.10 to 1.44). However, when compared to their matched sibling who was conceived without fertility treatment, there was no differences in birth weight, length of gestation, or risk

for small for gestational age birth weight. The biological processes causing infertility may have a larger impact on pregnancy outcome and fetal growth than the infertility therapy itself.[293]

Adoption

A difficult decision in fertility treatments is deciding when to cease active interventions designed to increase fecundability. Throughout the process of fertility treatment, it is prudent to raise the issue of when to cease active intervention and to offer adoption as an alternative method of building a family. It may be useful for couples to simultaneously explore the option of adoption while they are undergoing fertility therapy. If the fertility therapy fails, adoption may help couples cope with the symbolic loss created by their infertility.

Psychosocial Aspects of Infertility

Many observational studies indicate that stress is associated with infertility; in turn, the treatment of infertility can cause stress. Reducing stress prior to initiating intensive fertility treatments may improve the ability of the couple to successfully complete the treatments recommended.[294] For example, in one study, 151 women were given a standardized test to evaluate their moods, sense of optimism, social support networks, self-perceived stress, and methods of coping prior to undergoing IVF. Elevated levels of baseline stress were associated with fewer oocytes retrieved and fertilized and fewer embryos.[295] No definitive clinical trial demonstrates that reducing stress prior to infertility treatment improves pregnancy rates. In one small clinical trial, however, Domar and colleagues reported that treatment of infertile women with a support group or a structured relaxation program was associated with better pregnancy rates with infertility treatment than those observed in a control group.[296]

Infertility and the associated diagnostic and therapeutic procedures can produce substantial stress for both male and female partners and disrupt their relationship with each other. Inherently, diagnostic and therapeutic procedures offer hope for an imminent successful conception, but each subsequent menstrual cycle rekindles the feeling of loss. The repetitive cycles of hope and loss can be very stressful for couples with infertility.[297] Infertility may be perceived by the couple as a loss that is difficult to grieve because the absence of fertility is somewhat intangible. Infertility may be especially stressful for those couples where the cause of the infertility is difficult to identify.[298] The classic progression of emotions related to a loss are often expressed by the infertile couple.[299] These include the feelings of disbelief and surprise, denial, anger, isolation, guilt, grief, and resolution. For many couples, the female partner bears a disproportionate degree of responsibility for the loss symbolically represented by infertility. Although infertility treatment is often perceived as extremely stressful, infertility treatment does not appear to be associated with long-term emotional distress, dysfunction, or *de novo* psychiatric conditions.[300] Recent preliminary findings suggest that effective management of the stress and psychosocial sequelae of infertility might decrease the cost of fertility treatments and increase the fecundability of the couple.

Patients report that it is important that they be treated with respect and dignity and have all treatment options thoroughly and fairly presented. Patients wanted their clinicians to recognize their distress and respond in an empathic manner.[301,302] In most surveys, patients report that they are highly satisfied with the care provided by their fertility clinicians.[303]

Social and Ethical Issues

Medicine is an ethical profession that has long adhered to basic principles of human rights: respect for the dignity of human life, the right of an individual to participate in decisions that affect their health, an unwavering dedication to seek good and to avoid unnecessary harm, and a commitment to treat the patient fairly. Fertility practitioners also have an ethical obligation to protect the security of the human genetic material in their custody. Most ethicists are in agreement that the inviolability of each human precludes any medical intervention without the individual's consent. Free and informed consent is the cornerstone of ethical medical practice. Practices that are deceptive or could have the appearance of being deceptive undermine the credibility of clinicians in the fertility profession. Embryonic development is a continuous biological process. Current law tends to assign gradually increasing rights to the developing fetus. A human does not acquire full legal identity until birth but is offered some legal protection as a fetus *in utero* (e.g., restrictions on legal abortion in the third trimester). Modern society is not unified on the point in the developmental process where the developing embryo or fetus becomes a unique individual with full rights to inviolability and inalienability. This disagreement, which is most obvious in the debate over abortion, will make it difficult to reach consensus on the ethics of certain types of fertility research, such as that performed on discarded embryos. However, most practitioners and ethicists are in agreement that cloning of humans is not ethical.

CHAPTER 24

Male Infertility

Paul J. Turek

Male infertility affects 15% of reproductive age men worldwide and is treatable in many cases. In the United States, 8 million couples are affected.[1] Roughly 50% of couples have causal or associated male factors.[2] In addition, 1% to 10% of male factor infertility is a result of an underlying, often treatable, but possibly life-threatening medical condition.[3] In addition to well-established etiologies, genetic causes of male infertility are now commonly diagnosed. Finally, impaired semen quality has now been linked to an increased risk of later testicular and prostate cancers.[4,5] For these reasons, the male evaluation is conducted systematically to acquire relevant information from the history, physical examination, semen analysis, and hormone assessment. The American Urological Association and the American Society for Reproductive Medicine guidelines recommend that evaluations of male and female partners occur in parallel. Using evidence-based medicine, this chapter outlines diagnostic and treatment algorithms that guide clinical management. Randomized controlled clinical trials, basic scientific studies, meta-analyses, case-controlled cohort studies, best-practice policy recommendations, and reviews from peer-reviewed literature are incorporated into algorithms that provide timely guidelines to the current management of male infertility.

The Male History and Physical Examination

A thorough history reviews past and current attempts at paternity (Fig. 24.1 and Box 24.1). Important medical problems to elucidate include fevers and systemic illnesses such as diabetes, cystic fibrosis, cancer, and infections. Prior surgery, including orchidopexy and herniorraphy; trauma; retroperitoneal, pelvic, and bladder procedures; and prostate surgery may impair fertility. A family history of cryptorchidism, midline defects, or hypogonadism is also important. A developmental history of hypospadias, congenital anomalies, prenatal DES (diethylstilbesterol) exposure, and medication use (Box 24.2) should be reviewed. A social history with the habitual use of the gonadotoxins alcohol, tobacco, recreational drugs, anabolic steroids, and wet heat exposure should be elucidated. Spermicidal lubricants and incorrect patterns of timing intercourse may be noted from a sexual history. Lastly, an occupational history determines exposure to ionizing radiation, chronic heat, benzene-based solvents, dyes, pesticides, herbicides, and heavy minerals.

The physical examination assesses body habitus including obesity, gynecomastia, and secondary sex characteristics. The phallus may reveal hypospadias, chordee, plaques, or venereal lesions. The testes should be evaluated for size, consistency, and contour irregularities suggestive of a mass. At least 80% of testis volume is determined by spermatogenesis; hence, testis atrophy is likely associated with decreased sperm production. The epididymides are palpated for induration, fullness, or nodules, which are indicative of infection or obstruction. Delineation of each vas deferens may reveal agenesis, atresia, or injury. The spermatic cords should be examined for asymmetry suggestive of lipoma or varicocele, lesions that are differentiated by an examination in both the standing and supine positions. Meaningful varicoceles are diagnosed exclusively by physical examination. Lastly, a rectal examination is important in identifying large cysts, infections, or dilated seminal vesicles, all of which can be associated with infertility.

Semen Evaluation

Although not a true measure of fertility, the semen analysis, if abnormal, suggests that the probability of achieving fertility is lower than normal.[6] Two semen analyses, performed after 2 to 3 days of sexual abstinence, are sought owing to the large biological variability in semen quality. Lubricants should be avoided and the specimen kept at body temperature during transport. Normal reference values can be found in Table 24.1 and are based on a recent World Health Organization (WHO) analysis of 1800 new fathers from eight countries and three continents.[7] Recall that human spermatogenesis takes 60 to 80 days to complete (Fig. 24.2), so that an individual semen analysis reflects biological influences occurring 2 to 3 months prior.[8]

The formal evaluation of sperm shape is termed morphological assessment. Several descriptive systems exist to evaluate morphology, and within each system, sperm are designated normal or abnormal based on specific size criteria. It is believed that sperm morphology may correlate with a man's fertility potential as reflected by *in vitro* fertilization (IVF) success, although the reliability of this finding has recently been called into question.[9,10] Specifically, sperm morphology has been correlated with the ability of sperm to successfully penetrate cervical mucus, bind to the zona pellucida, and influence embryo implantation rate. In general, the percentage of sperm with normal morphology has discriminatory power in distinguishing fertile from infertile semen, although no particular value is diagnostic of fertility.[6] However, sperm morphology provides no insight into the chromosomal complement of the cell. Morphology for a given patient can also change depending on stress or toxic insult to the testes. Morphological examination can complement the

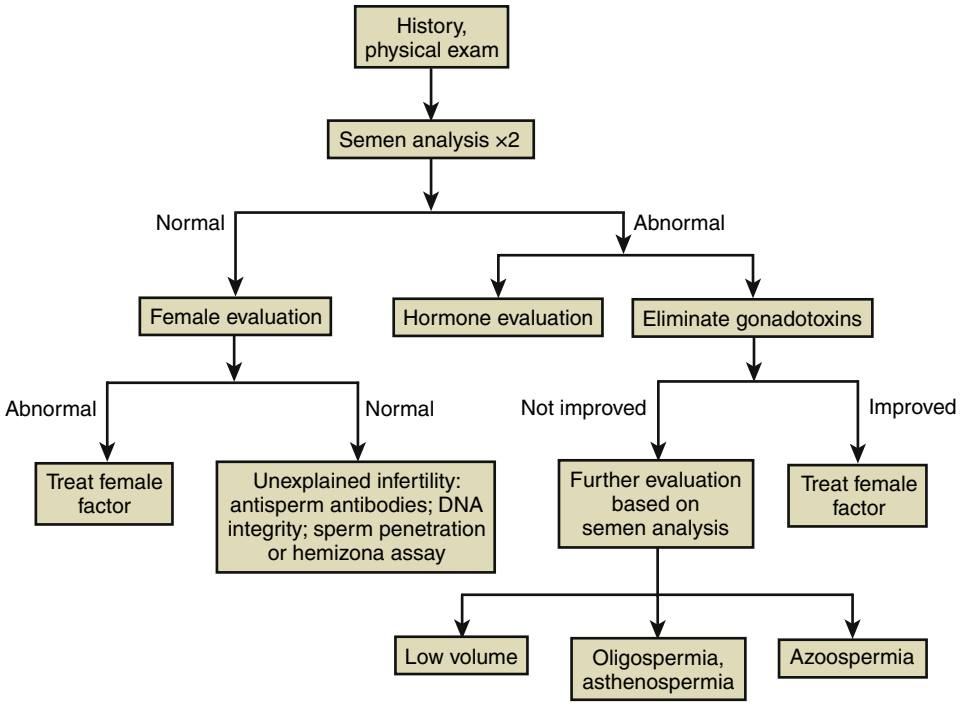

FIGURE 24.1 General algorithm for the diagnostic evaluation of male infertility. *(From Turek PJ. Practical approach to the diagnosis and management of male infertility.* Nature Clin Pract Urol *2:1, 2005.)*

Box 24.1 Components of the Male Infertility History

MEDICAL HISTORY
- Fevers
- Systemic illness—diabetes, cancer, infection, obesity
- Genetic disease—cystic fibrosis, Klinefelter syndrome

SURGICAL HISTORY
- Orchidopexy, cryptorchidism
- Herniorraphy
- Trauma, torsion
- Pelvic, bladder, or retroperitoneal surgery
- Transurethral resection for prostatism
- Pubertal onset

FERTILITY HISTORY
- Previous pregnancies (current and with other partners)
- Duration of infertility
- Previous infertility treatments
- Female evaluation

SEXUAL HISTORY
- Erections
- Timing and frequency
- Lubricants

FAMILY HISTORY
- Cryptorchidism
- Midline defects (Kartagener syndrome)
- Hypospadias
- Exposure to diethylstilbestrol
- Other rare syndromes—prune belly, etc.

MEDICATION HISTORY
- See Table 24.2

SOCIAL HISTORY
- Alcohol
- Smoking/tobacco
- Cocaine
- Anabolical steroids
- Wet heat exposure (hot tubs, baths)

OCCUPATIONAL HISTORY
- Exposure to ionizing radiation
- Chronic heat exposure (cooks, firefighters)
- Aniline dyes
- Pesticides
- Heavy metals

routine semen analysis in the male evaluation but its exact role in the estimation of male fertility is currently unclear.[10]

Results of Initial Male Evaluation

The initial male evaluation may be normal or abnormal (Fig. 24.1). If normal, further consideration should be given to female factor evaluation, including a thorough assessment of ovulation, pelvic anatomy, and age-related fertility issues. If the initial male assessment reveals abnormalities, then further evaluation or treatment is indicated.[11] Clinicians can have a significant impact in reducing male factor infertility by simple counseling regarding coital timing, avoiding wet heat and other exposures, and lifestyle changes. For example, coital lubricants should also be avoided if possible, including Surgilube®, K-Y jelly®, and saliva. If necessary, vegetable oils are safe for sperm.

Likewise, androgenic steroids often taken to increase muscle mass, act as male contraceptives.[12] Excess testosterone inhibits the pituitary-gonadal hormone axis and inhibits sperm production. The routine use of hot tubs, baths, or saunas should be discouraged, as these activities

Box 24.2 Drugs with Potential Adverse Effects on Male Fertility

COMPETITION WITH ANDROGEN RECEPTOR
- Spironolactone
- Cimetidine
- Flutamide
- Nilutamide
- 5 alpha reductase inhibitors

DIRECT TOXIC EFFECT ON LEYDIG CELLS
- Alkylating agents (e.g., cyclophosphamide)
- Alcohol
- Selective serotonin reuptake inhibitors (SSRI)

INHIBITORS OF TESTOSTERONE SYNTHESIS
- Ketoconazole
- Spironolactone
- Cyproterone
- Tetracycline
- Alcohol

STIMULATORS OF ESTRADIOL SYNTHESIS OR ACTIVITY
- DES (diethylstilbestrol)
- Digoxin
- Dibromochloropropane (pesticides)
- Spironolactone
- Medroxyprogesterone
- Bisphenol-A

HEAVY METAL TOXINS
- Lead
- Arsenic
- Cadmium
- Mercury

PITUITARY INHIBITION
- Testosterone
- Marijuana

MITOTIC INHIBITORS
- Allopurinol
- Colchicine
- Sulfasalazine
- Nitrofurantoin

EFFECTS ON FERTILIZATION
- Nicotine
- Calcium channel blockers

EJACULATORY DYSFUNCTION
- Lithium
- Antipsychotics
- Tricyclic antidepressants
- Valproic acid
- Phenytoin

UNCLEAR MECHANISM
- Monoamine oxidase inhibitors
- Cocaine
- Finasteride
- Seritonergic reuptake inhibitors

Table 24.1 Semen Analysis—WHO 5th Centile Reference Values for Fertile Men

Characteristic	5th Centile Value
Ejaculate volume	>1.5 mL
Sperm concentration	>15 × 10^6 sperm/mL
Motility	>40%
Forward progression	2 (scale 1-4)
Morphology	>4% (Strict)
Other features	No agglutination (clumping), white blood cells, or increased viscosity

WHO, World Health Organization.

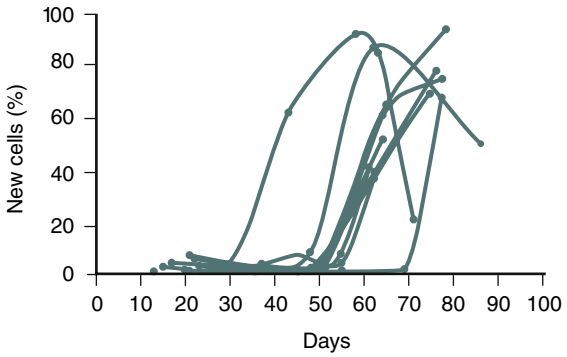

FIGURE 24.2 Timeline to make and ejaculate sperm. Labeling curves for 11 subjects with normal semen analyses. Subjects were given deuterated water daily for 3 weeks and semen was collected regularly for 90 days. Sperm DNA enrichment was measured and percentage of new sperm in the ejaculate was calculated. Overall, the mean time to detection of labeled sperm in the ejaculate was 64 ± 8 days (range 42 to 76), much faster than the 90 days classically ascribed to this process. *(From Misell LM, Holochwost D, Boban D, et al. A stable isotope/mass spectrometric method for measuring the kinetics of human spermatogenesis in vivo.* J Urol *175:242, 2006.)*

elevate intratesticular temperature and may impair sperm production.[13] As obesity is strongly associated with poor semen quality, weight reduction should be considered.[14] Sports such as bicycling are safe unless associated with significant urinary symptoms (prostatitis) or pelvic "numbness" that may predispose to erectile dysfunction.

Further Male Factor Evaluation

If lifestyle changes are unsuccessful, then further evaluation is warranted, following published best-practice policies.[11] This should include an assessment of the pituitary gonadal axis with testosterone and follicle-stimulating hormone (FSH) levels. Hormone testing is indicated in infertile men with sperm densities below 10 × 10^6 sperm/mL, or with evidence of a medical endocrinopathy.[15] The chance of a clinically significant endocrinopathy presenting as infertility is approximately 2%.[15] The more common patterns of hormonal disorders observed in male infertility are found in Table 24.2.

Adjunctive sperm tests are also available to diagnose the cause of male factor infertility and are pursued based upon the predominant semen analysis finding, as discussed later. When the infertility is unexplained, several tests can be considered, the most popular of which is an assessment of sperm deoxyribonucleic acid (DNA) integrity.[16] Evidence suggests that the

Table 24.2 Characteristic Endocrine Profiles in Infertile Men

Condition	T	FSH	LH	PRL
Normal	NL	NL	NL	NL
Primary testis failure	Low	High	NL/high	NL
Hypogonadotropic hypogonadism	Low	Low	Low	NL
Hyperprolactinemia	Low	Low/NL	Low	High
Androgen resistance	High	High	High	NL

FSH, follicle stimulating hormone; LH, luteinizing hormone; NL, normal; PRL, prolactin; T, testosterone.

quality of sperm DNA-chromatin packaging is important for fertility. High levels of reactive oxygen species and oxidative stress are known to cause sperm DNA fragmentation. The structure of sperm chromatin (the DNA-associated proteins) can be measured by several methods, including the single cell gel electrophoresis (comet) and terminal deoxynucleotidyl transferase nick end labeling (TUNEL) assays as well as by flow cytometry after acid exposure and acridine orange staining.[16] These tests measure the degree of DNA fragmentation with chemical stress on the sperm DNA-chromatin complex, and can indirectly reflect the quality of sperm DNA integrity. Abnormally fragmented sperm DNA rarely

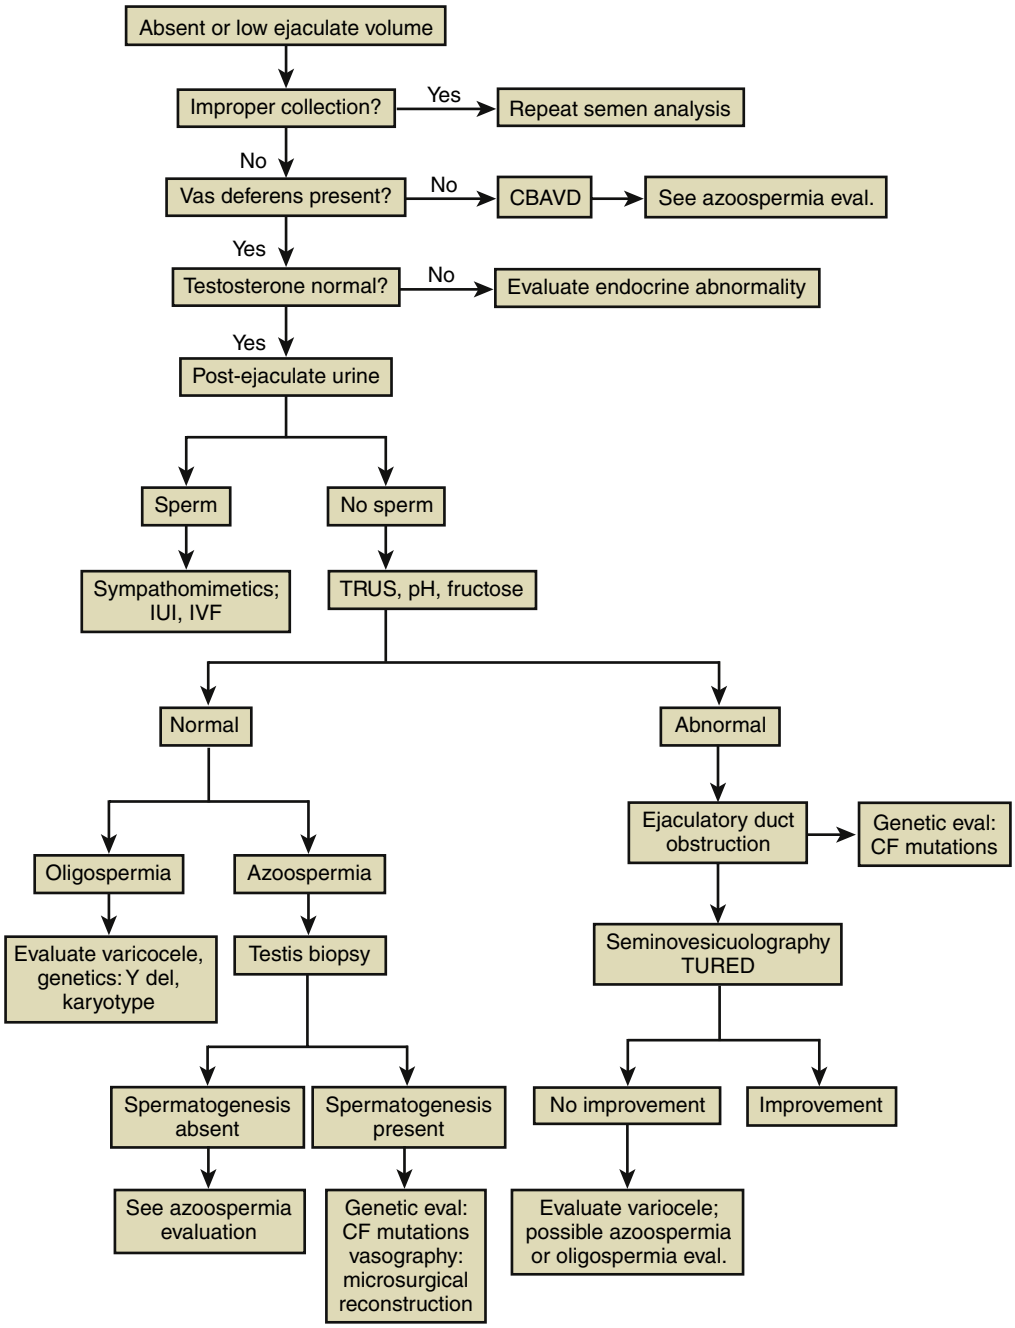

FIGURE 24.3 Algorithm for evaluation of absent or low ejaculate volume. CBAVD, congenital absence of vas deferens; CF, cystic fibrosis; IUI, intrauterine insemination; IVF, *in vitro* fertilization; TRUS, transrectal ultrasound; TURED, transurethral resection of the ejaculatory duct; Y del, Y chromosome deletion. *(From Turek PJ. Practical approach to the diagnosis and management of male infertility.* Nature Clin Pract Urol *2:1, 2005.)*

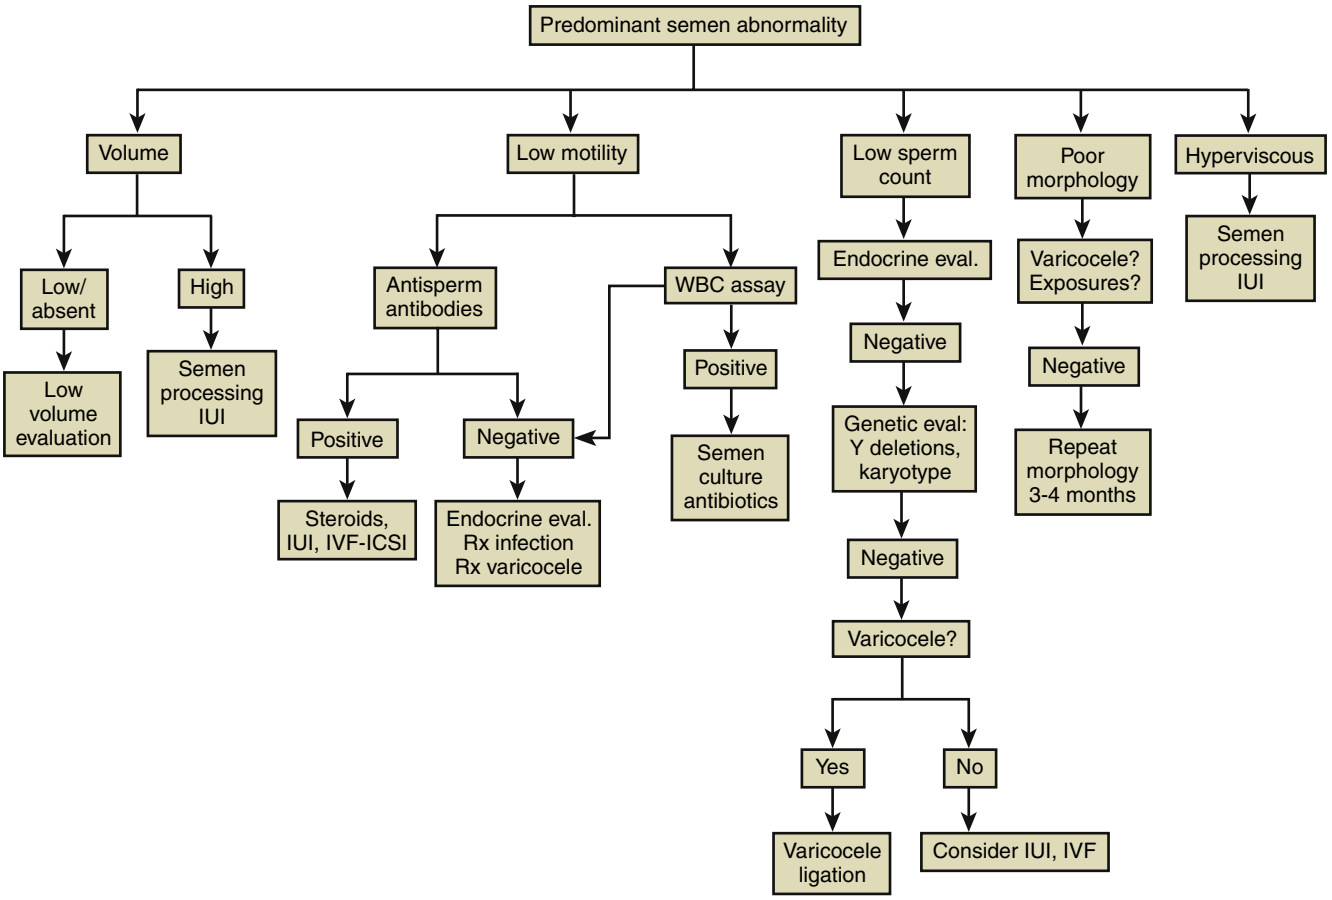

FIGURE 24.4 Algorithm for evaluation of semen analysis abnormalities. ICSI, intracytoplasmic sperm injection; IUI, intrauterine insemination; IVF, *in vitro* fertilization; Rx, treat; WBC, white blood cell. *(From Turek PJ. Practical approach to the diagnosis and management of male infertility.* Nature Clin Pract Urol *2:1, 2005.)*

occurs in fertile men, but can be found in 5% of infertile men with normal semen analyses and 25% of infertile men with abnormal semen analyses.[17] Such testing can detect infertility that is missed on a conventional semen analysis. Often reversible, DNA fragmentation may be caused by tobacco use, medical disease (e.g., cancer), hyperthermia, air pollution, infections (e.g., leukocytospermia), chemotherapy, irradiation, sperm processing, and varicocele.[18]

Low Volume Ejaculate

The evaluation of low ejaculate volume is uniformly informative, as it is generally due to one of five problems: improper sample collection, congenital absence of the vas (and seminal vesicles), a hypoandrogenic state, retrograde ejaculation, or ejaculatory duct obstruction. These conditions can be systematically examined as outlined in Figure 24.3 on page 541. A low seminal pH (<7) can replace semen fructose in this diagnosis. Importantly, transrectal ultrasound criteria to diagnose ejaculatory duct obstruction, including the presence of cysts, calcification, or dilated seminal vesicles or ducts, may "over read" the diagnosis by 50% and should be confirmed with "functional" studies such as vasography or duct chromotubation prior to endoscopic treatment.[19] The response of retrograde ejaculation to alpha-agonist medications is best for nonsurgical nerve damage to the hypogastric plexus (e.g., diabetes mellitus).[20] Bladder harvest of sperm in nonresponders can often be used with intrauterine insemination (IUI) to overcome infertility.

Oligospermia-Asthenospermia

Low sperm motility is observed in 25% of abnormal semen analyses; an isolated low sperm concentration is much less common. Low sperm motility may be due to antisperm antibodies (>50% of sperm bound) or excessive white blood cells in the ejaculate (leukocytospermia), the latter resulting in overproduction of reactive oxygen species that can damage sperm.[21] Because "round cells" in the infertile ejaculate are more commonly immature germ cells (65%) rather than leukocytes,[22] special leukocyte stains are recommended before treatment. Semen cultures are uninformative in asymptomatic infertile men with leukocytospermia as 83% are normally positive with multiple organisms.[23] It is important to evaluate sexually transmitted diseases, penile discharge, prostatitis, or epididymitis. An expressed prostatic secretion is examined for leukocytes, and urethral cultures for *Chlamydia* and *Mycoplasma* can be considered. As a reference, the prevalence rate for PCR-based Chlamydia antigen detection is 0.3% among infertile men in general.[24] Although the findings vary by both methodology and laboratory, in general, more than 50% of sperm bound with antibodies is considered significant and merits treatment.

Low sperm concentration may be due to an endocrinopathy such as prolactinoma, varicocele, or genetic causes, as outlined in Figure 24.4. Although eternally debated, there is substantial evidence to support the role of varicocele in male infertility (Table 24.3). Increasingly, genetic abnormalities

Box 24.3 Current Indications for Genetic Testing of Infertile Men

1. A semen analysis with sperm concentration <5 million sperm/mL in a couple considering *in vitro* fertilization (IVF) and intracytoplasmic sperm injection (ICSI) (Y microdeletion assay and karyotype analysis)
2. A semen analysis showing no sperm with evidence of testis atrophy in a couple considering testis sperm extraction with IVF and ICSI (Y microdeletion assay and karyotype analysis)
3. A semen analysis showing no or low sperm concentration with at least one absent vas deferens on physical examination (cystic fibrosis gene mutations)
4. A semen analysis showing no sperm with evidence of normal spermatogenesis (cystic fibrosis gene mutations)
5. A couple with other syndromes or conditions suggested by personal or family histories (e.g., Kallmann syndrome)

should be considered in men with sperm concentrations less than 5 million/mL.[25] Deletion of regions on the Y chromosome (microdeletions) occur in 6% of men with severely low sperm counts and in 15% of men with no sperm counts. In addition, 2% of men with low counts and 15% to 20% of men with no sperm counts will harbor chromosomal abnormalities detected by cytogenetic analysis (karyotype). These conditions include Klinefelter syndrome and translocations of non-sex chromosomes. Box 24.3 outlines current indications for genetic testing of infertile males. Importantly, varicocele repair for oligospermia in the setting of positive genetic findings is unlikely to improve semen quality or result in natural pregnancy.[26]

Azoospermia (Fig. 24.5)

If sperm are absent in a routine semen analysis, the differential diagnosis is excurrent ductal obstruction or testicular failure. The semen specimen should be centrifuged to assess for very low sperm numbers that effectively rule out complete obstruction.[27] If one or both vasa deferentia are not palpable, then a diagnosis of congenital absence of the vas deferens (CAVD) is made, and appropriate genetic testing for cystic fibrosis gene mutations is recommended prior to sperm retrieval and *in vitro* fertilization (IVF) and intracytoplasmic sperm injection (ICSI). Affected patients exhibit a similar spectrum of wolffian duct defects as those with cystic fibrosis, but generally lack the severe pulmonary, pancreatic, and intestinal problems. Roughly 80% of azoospermic men with CAVD and one third of men with unexplained obstruction will harbor cystic fibrosis gene mutations.[28,29] Based on FSH values and a diagnostic testis biopsy, accurate differentiation of men into nonobstructive (testis failure) or obstructive azoospermia is possible. Genetic testing for nonobstructive azoospermia with Y chromosome microdeletion and karyotype analysis is recommended, as outlined in Box 24.3. The relative frequency of the different Y chromosome microdeletions among azoospermic men is outlined in Figure 24.6. Treatment of prolactinomas with dopamine agonists or transsphenoidal resection is indicated in men with hormonal disorders.

Unexplained Infertility

Infertile couples with an unremarkable female evaluation and normal semen parameters are termed, "unexplained infertility" (Fig. 24.1). In such cases, further evaluation of male factor infertility is warranted, yet a precise clinical care algorithm is lacking. Antisperm antibodies and poor chromatin structure, the latter reflective of increased levels of denatured sperm DNA, are each found in 10% of semen analyses in unexplained infertility.[18,30] Tests of sperm function such as the sperm penetration assay or the hemizona assay may also be considered. Finally, many couples proceed to intrauterine insemination. As our knowledge of the genes that control sperm capacitation, fertilization and egg activation improves, many cases of unexplained infertility will be more clearly defined. For example, the recent identification of the sperm factor phospholipase C zeta (PLCz) as the chemical responsible for calcium flux and egg activation in mammals will likely explain some cases of human pregnancy failure.[31]

Treatment of Male Infertility

Male infertility is associated with a defined cause in half of cases (Fig. 24.7). When associated with life-threatening disease, the disease should be treated (Box 24.4). Because of advances in assisted reproduction (including ICSI), there has been a concerning trend to avoid male factor treatments in favor of assisted reproduction. This is unfortunate, as many male factor treatments help infertile couples conceive without assisted reproduction.[32]

Certainly, maternal reproductive potential should be considered before correctable male factors are treated. This reasoning becomes obvious given that it takes 2 to 3 months to improve spermatogenesis after therapy. Thus, an important guiding principle in the decision to treat male infertility is to first determine whether or not the female partner has more than 1 year of stable reproductive potential. If so, then correcting male infertility is almost always warranted.

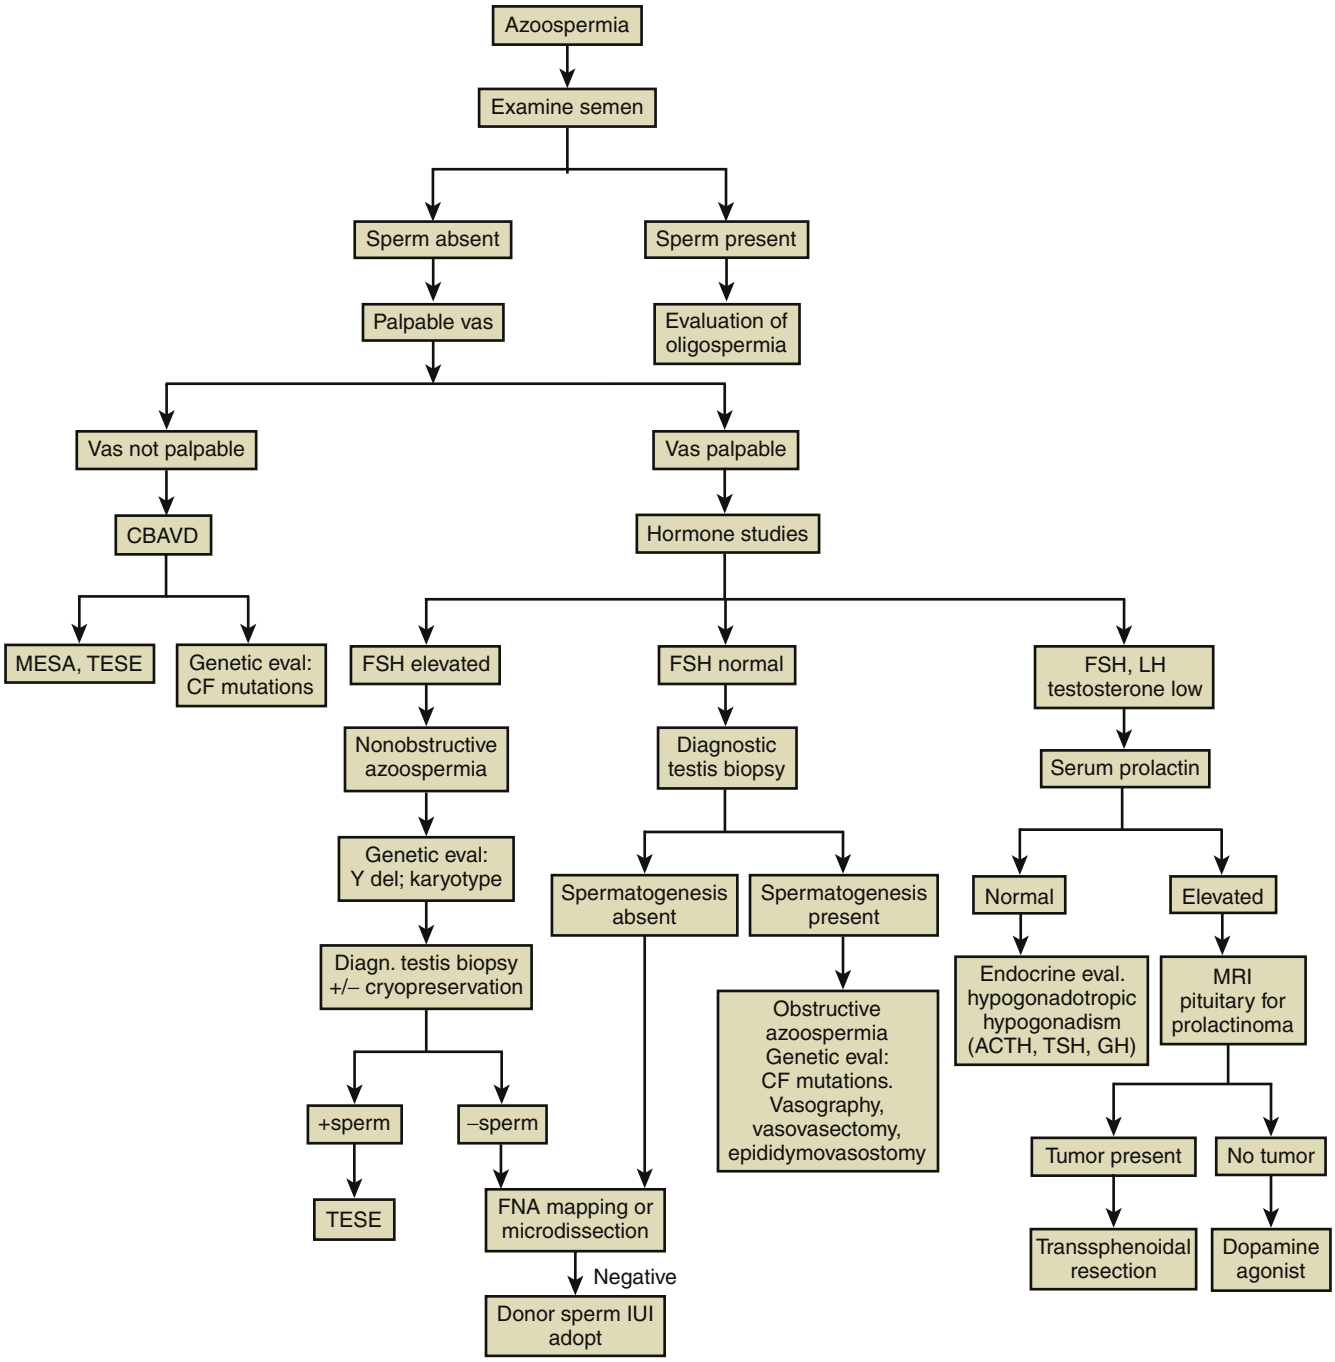

FIGURE 24.5 Algorithm for evaluation of azoospermia or no sperm in the ejaculate. Practical approach to the diagnosis and management of male infertility.* Nature Clin Pract Urol *2:1, 2005.)*

Correctable Male Factor Problems

Coital Therapy

Simple counseling on issues of coital timing, frequency, and gonadotoxin avoidance can improve fertility. Coital lubricants should be avoided. Although scarcely published, hot baths and hot tubs are detrimental to sperm production.[13] Avoidance of tobacco, marijuana, excessive alcohol, and other recreational drugs is important. Maintaining a healthy weight and diet are germane to good fertility. Treating situational erectile dysfunction associated with timed intercourse with oral phosphodiesterase inhibitors is common and safe.

Ejaculatory Dysfunction

Retrograde ejaculation is diagnosed by finding sperm in the postejaculate bladder urine, and is treated with sympathomimetic medications or bladder harvest of sperm with

Rectal probes (foreground) of different sizes are available to accommodate differences in patient anatomy. Ejaculates can be obtained in virtually all anejaculatory patients with this technology.

assisted reproduction. Premature ejaculation occurs when men ejaculate before their partner is ready. Although not an established cause of infertility, it can produce significant relationship stress. Sexual counseling combined with serotoninergic reuptake inhibitors or local anesthetics can be effective treatment. Ejaculatory failure or anejaculation has a variety of causes that include pelvic nerve damage from diabetes mellitus, multiple sclerosis, or abdominal-pelvic surgery; spinal cord injury; and psychosocial issues. Vibratory stimulation and rectal probe electroejaculation are common and effective techniques that help anejaculatory patients to conceive (Fig. 24.8).[20]

Leukocytospermia

Elevated leukocytes in semen (>1 million/mL) is termed pyospermia or leukocytospermia and is associated with (a) subclinical genital tract infection, (b) elevated reactive oxygen species, and (c) poor sperm function and infertility. Sperm are highly susceptible to the effects of oxidative stress induced by leukocytes because they harbor little cytoplasm and therefore little antioxidant activity. The treatment of leukocytospermia is controversial without overt bacteriological infection. When appropriate, the limited use of broad-spectrum antibiotics such as doxycycline and trimethoprim-sulfamethoxazole in combination with frequent ejaculation has been shown in a randomized controlled study to durably reduce seminal leukocyte concentrations.[33] Generally, the female partner is also treated.

Immunological Infertility

Antisperm antibodies are a complex problem for which available treatments include corticosteroid suppression, IUI, or IVF-ICSI. Corticosteroid suppression attempts to weaken an overactive immune system to reduce sperm antibodies and facilitate conception; however, two older, placebo-controlled, double-blind, crossover trials have shown conflicting findings regarding benefit of this treatment.[34,35] In addition, therapy must be undertaken for 6 to 9 months for best results. IUI places more sperm nearer to the ovulated egg to optimize the odds of fertilization. IVF and ICSI are very effective in overcoming infertility due to antisperm antibodies. Because the presence of antibodies is associated with obstruction in the genital tract, such lesions should be sought and corrected.

Varicocele

Although debated, there is substantial evidence to support the value of varicocele repair in male infertility. The outcomes of three controlled clinical trials that have examined treatment of palpable varicoceles generally favor varicocele repair, as summarized in Table 24.3.[36,37] Several meta-analyses have also examined outcomes of varicocele treatment and did not support varicocele repair as effective treatment.[38,39] However, one study has significant design flaws in that it examined trials that included subclinical varicoceles, the clinical relevance of which are unclear.[39] Furthermore, a controlled trial published by Madgar and colleagues[37] showed that a relative 6-fold benefit for varicocele repair was deemed an "outlier" in the meta-analysis, leaving only a single trial evaluable for clinical varicocele. Finally, the large WHO trial (238 patients) was excluded from the analysis.[36] Thus, more prospective trials are needed to prove that varicoceles improve fertility. However, clinically, semen quality will improve in 51% to 78% of men after varicocele repair and the associated pregnancy rate is 24% to 60%, with pregnancies occurring an average of 8 months after surgery.[32,40]

In addition to clinical care arguments that suggest varicocele repair is beneficial for infertility, economic analyses also support this treatment. Cost-benefit arguments demonstrate that varicocelectomy is more cost-effective than assisted reproduction[41] and "shift of care" analyses show that 30% to 50% of couples who begin as candidates for assisted reproduction due to low semen quality can be "rescued" from such procedures and conceive naturally after varicocelectomy.[32] Decision analysis research suggests that varicocele repair may have the greatest value in severe male factor cases that would otherwise require IVF-ICSI.[42] On the contrary, it is also apparent varicocele treatment is not worthwhile in the presence of coexisting genetic infertility.[26]

Several modalities are available for varicocele treatment, including vein ligation through retroperitoneal, inguinal, or subinguinal incisions, percutaneous transvenous embolization, and laparoscopy. Success rates do not differ significantly among approaches. Complication rates range from 1% for the incisional approach to 4% for laparoscopy. The most significant complication with embolization is the 10% to 15% technical failure rate (inability to access and occlude the culprit veins).

Ejaculatory Duct Obstruction

Ejaculatory duct obstruction is observed in 5% of azoospermic men, but is often overlooked in the male evaluation. Partial obstruction is likely more common than currently diagnosed, but is more difficult to diagnose than complete obstruction, as ultrasound findings are not specific for partial obstruction.[19] A 20% to 30% pregnancy rate can be expected from endoscopic treatment of the obstruction, and 70% to 80% of men will achieve significant, early, and durable improvements in semen quality.[19,43] Complications occur in 10% of cases and include hematuria, watery ejaculate, and epididymitis.

Vasovasostomy

Vasectomy reversal success depends on many factors, the most important of which are the surgeon's skill and the findings at surgery. Because of the need for superb tissue technique, experienced surgeons use a microscope. Evidence of inflammation or infection after the vasectomy, and a long interval from vasectomy-to-reversal are both associated with a decrease in surgical success.[44] If sperm are found at the cut edge of the vas during surgery, then 85% to 99% of patients can be expected to have a return of sperm after vasovasostomy.[45] With a healthy female partner, this is associated with a pregnancy rate of 40% to 65%.[45,46] If the vas fluid shows no sperm, the primary procedure involves connecting the vas to the epididymis in a procedure termed epididymovasostomy. In experienced hands, approximately 60% to 80% of men will have sperm in the ejaculate and a 30% to 35% pregnancy rate can be expected.[44,47]

A growing literature suggests that vasectomy reversal may be more cost-effective for pregnancy than IVF and ICSI.[47] Given the difficulty of randomizing patients to vasectomy reversal or sperm-retrieval and ICSI, decision analysis and Markov modeling research has been applied to this issue.[42,48] Decision analytical models are methods of estimating and calculating outcomes by identifying a clinical question, disaggregating the problem into discrete units to include all reasonable choices and consequences, and assigning probabilities and costs to the various events and outcomes. Decision science has revealed that reversal surgery is often more cost-effective than sperm retrieval and ICSI, but threshold values for surgical success are required to maintain its cost-effectiveness (Fig. 24.9).[42] Markov modeling is a form of decision analysis in which hypothetical patients proceed through health states over time based on predefined probabilities and costs. As patients are cycled, outcomes, including incurred costs and events, are tracked. Markov analyses have been used to better understand the relative impact of vasectomy obstructive interval and female partner age on fertility after vasectomy. These analyses have shown that female fertility potential impacts

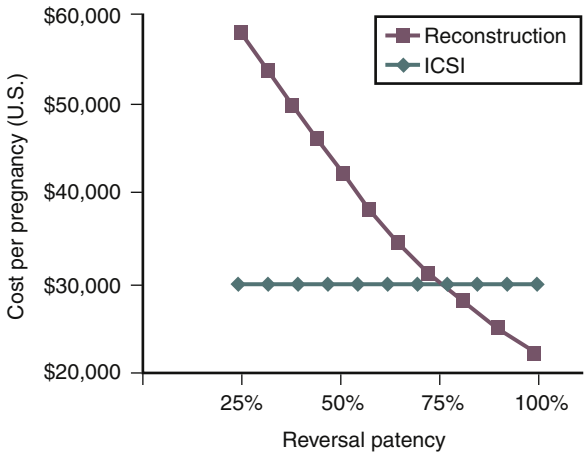

FIGURE 24.9 Sensitivity analysis from decision modeling of vasectomy reversal compared with intracytoplasmic sperm injection (ICSI) and sperm retrieval. This figure shows a cost comparison of both methods over a range of reversal patency rates when the pregnancy rate is held constant at 40%. This demonstrates that a minimum threshold vasectomy reversal patency rate (78%) is important to achieve if vasectomy reversal is to remain more cost-effective than ICSI. *(From Meng M, Greene K, Turek P. Surgery or assisted reproduction? A decision analysis of treatment costs in male infertility.* J Urol *174:1926, 2005.)*

cost-effectiveness more profoundly than does vasectomy obstructive interval (Fig. 24.10).[48] This suggests that, in the absence of randomized data comparing ICSI and sperm retrieval with vasectomy reversal, the primary driver of cost-effective care is the variable of female age and maternal reproductive potential. Even given this, respectable crude pregnancy rates have been reported in vasectomy reversal series in the setting of advanced maternal age.[49,50]

In addition to vasectomy, infertility can also result from idiopathic obstruction. In such cases, 65% of blockages are found within the epididymis, 30% in the vas deferens, and 5% in the ejaculatory duct.[51] In most cases of idiopathic obstruction, the blockage can be pinpointed and corrected with microsurgery. To distinguish obstructive azoospermia from that due to a sperm production problem, a testis biopsy is generally necessary.

Hormonal or Oxidative Dysfunction

Hormone therapy can and should be offered to patients with treatable diseases that predispose to infertility. Less effective treatments are those that seek to overcome ill-understood conditions or those without well-proved treatments. Examples of treatable conditions include hyperprolactinemia, hypothyroidism, congenital adrenal hyperplasia, and testosterone excess or deficiency (e.g., steroids or Kallmann syndrome). Examples of medical treatments that may not work in all men include clomiphene citrate, tamoxifen, human chorionic gonadotropin (hCG) therapy, L-acetylcarnitine, and antioxidant and herbal therapy. When given unselectively to infertile men, these measures should be considered empirical treatments for male infertility.[52] Like with cancer or aging, oxidants are thought to be a fundamental cause of male infertility as they clearly damage DNA and reduce sperm motility. Notably, a recent Cochrane review of 34 randomized controlled trials (2876 subjects) of antioxidant use in men whose partners were undergoing IVF demonstrated fourfold higher rates of conception and live births in the antioxidant arm.[53] The use of aromatase inhibitors in men with elevated estradiol: testosterone ratios have shown some benefit to semen quality in a single study.[54]

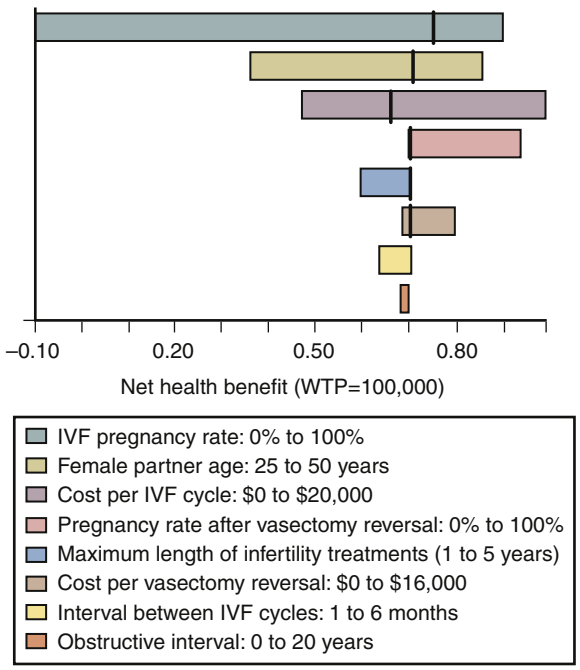

FIGURE 24.10 Tornado diagram from Markov modeling for intracytoplasmic sperm injection compared with vasectomy reversal. This figure shows the relative impact of female partner age, vasectomy obstructive interval, and other clinical parameters on net health benefit (NHB) and demonstrates that female age has the largest effect on cost effectiveness. Widths of horizontal bars indicate magnitude of impact of that parameter on NHB. The wider the bar, the greater the impact on NHB. Thick vertical bars are threshold values at which reversal and assisted reproductive technology switch being more cost-effective. IVF, *in vitro* fertilization; WTP, willingness to pay. *(From Hsieh M, Meng M, Turek PJ. Markov modeling of vasectomy reversal and ART for infertility: how do obstructive interval and female partner age influence cost-effectiveness?* Fertil Steril *88:840, 2007.)*

Assisted Reproduction

If neither surgery nor medical therapy is appropriate treatment for male infertility, assisted reproduction can be initiated. From a male infertility point of view, the choice of technique depends mainly on the degree of impairment in total motile sperm concentration (Fig. 24.11).

Intrauterine Insemination

Intrauterine insemination involves placement of washed ejaculated sperm within the female uterus, beyond the cervix. In this way, more motile sperm can progress to the fallopian tubes where fertilization normally occurs. The principal indication for IUI is a cervical factor, but IUI is also used for low sperm quality, immunological infertility, and in men with mechanical problems of sperm delivery (e.g., hypospadias). There should be at least 5 million to 40 million motile sperm in the ejaculate (volume × concentration × motility) to make this procedure worthwhile. Success rates vary widely and are directly related to female reproductive potential; given this, pregnancy rates of 30% for four cycles can be expected.[55]

In Vitro Fertilization and Intracytoplasmic Sperm Injection

First described in 1978, *in vitro* fertilization (IVF) is more complex than IUI and removes even more obstacles to sperm in the female reproductive tract. Following ovarian hyperstimulation and ultrasound-guided transvaginal egg retrieval, oocytes are fertilized *in vitro* with 500,000 to 5 million motile sperm. After fertilization, embryos are placed into the uterus transcervically. This technology can bypass moderate to severe forms of male infertility in which

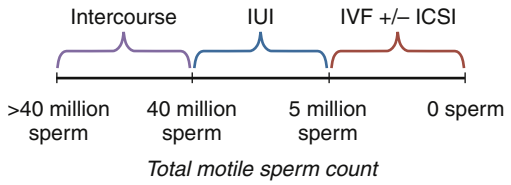

FIGURE 24.11 Level of assisted reproduction needed for conception based on semen quality determined by total motile count (volume × concentration × motile fraction). IUI, intrauterine insemination; IVF, *in vitro* fertilization; ICSI, intracytoplasmic sperm injection. *(From Turek PJ. Practical approach to the diagnosis and management of male infertility.* Nature Clin Pract Urol *2:1, 2005.)*

there are low numbers of motile sperm. A revolutionary addition to IVF was described in 1992 and is referred to as sperm micromanipulation or ICSI, in which a single sperm is microinjected directly into the egg cytoplasm.[56] ICSI has lowered the sperm requirement for egg fertilization from hundreds of thousands to one viable sperm, thus allowing treatment of the most severe forms of male infertility. In a systematic review and meta-analysis, an association was found between the degree of sperm DNA fragmentation and pregnancy rates after IVF and ICSI, but this relationship was not deemed clinically significant.[57] The current indications for IVF and ICSI for male factor diagnoses are listed in Table 24.4.

Genetic Evaluation

High-technology solutions to pregnancy, including ICSI, are now known to be a two-edged sword. On one hand, ICSI is very enabling, allowing men who would otherwise have no chance for paternity the opportunity for fatherhood. However, because man and not nature selects sperm for ICSI, how it alters natural selection is not clear. Genetic evaluation of the infertile couple is important prior to IVF and ICSI for male infertility due to oligospermia or azoospermia that is not due to acquired blockage (Box 24.3). In addition, there is some debate about whether IVF-ICSI is as effective for men with defined genetic infertility, in particular Y chromosome microdeletions, as it is for other male factor indications (Table 24.5).[58-61] Although overall rates of major birth defects associated with ICSI (3.3%) are similar to those associated with intercourse,[62] chromosomal abnormalities are increased in offspring with ICSI[63] and increased rates of conditions such as hypospadias, and syndromes such as Angelman and Beckwith-Wiedemann have been reported.[64-66] In addition, subtle development defects and delays have been detected in children conceived with assisted reproduction.[67] For these reasons, genetic counseling is recommended for all couples considering IVF-ICSI.

Table 24.4 Indications for Assisted Reproduction Technologies with Male Factor Infertility

Male Factor Issue	IVF	IVF-ICSI
Retrieved sperm (testis and epididymis)	—	Yes
Low motile sperm count (<5 million)	Yes	Maybe
Poor sperm morphology (<4% strict or Kruger)	—	Maybe
Failed trial of IUI	Yes	Maybe
Immunological infertility (antisperm antibodies) and failed IUI	—	Yes
Abnormal sperm DNA integrity	?	Maybe
Correctable male factor with limited maternal reproductive potential	Yes	Maybe

ICSI, intracytoplasmic sperm injection; IUI, intrauterine insemination; IVF, *in vitro* fertilization.

Sperm Retrieval Techniques

ICSI has led to the development of aggressive surgical techniques for azoospermic men to provide sperm for egg fertilization. Since 1988, epididymal sperm aspiration has been performed either microsurgically (MESA) or percutaneously (PESA). Since 1995, testis sperm retrieved by needle (TESA) or biopsy (TESE) is routinely performed in men with obstructive azoospermia. Currently, there is insufficient clinical trial evidence to recommend a preferred sperm retrieval technique in azoospermic men.[68]

Although sperm retrieval in obstructive azoospermia is not difficult, there is a failure to obtain sperm for ICSI in 25% to 50% of men with nonobstructive azoospermia (Box 24.5).[69] In addition, clinical features of testicular size, history of ejaculated sperm, serum FSH level, or histological findings at biopsy do not accurately predict whether or not sperm will be recovered on exploration.[69] Because of this, strategies have been developed to more accurately determine which men with failing testes are candidates for ICSI, and surgical techniques have been

Box 24.5 Conditions Associated with Nonobstructive Azoospermia

- Idiopathic primary testicular failure
- Y chromosome microdeletions
- Karyotype disorder
- Sex chromosomes (Klinefelter syndrome)
- Non-sex chromosomes, translocations, aneuploidy
- Secondary testicular failure
- Noonan syndrome
- Kallmann syndrome
- Idiopathic gonadotropin deficiency
- Hypothalamic/pituitary tumor
- Hyperprolactinemia
- Cancer chemotherapy/radiotherapy treatment
- Varicocele effect
- Gonadotropin suppression
- Drug-induced (anabolical steroids, alcohol, glucocorticoids)
- Congenital adrenal hyperplasia
- Severe systemic illness (cancer, uremia)
- Cryptorchidism
- Sperm autoimmunity
- Pesticide/toxin exposure

Table 24.5 Summary of Studies of IVF-ICSI Outcomes in Couples with Yq Deletions

			Normal Fertilization Rate		Pregnancy/Cycle	
Author	Points	Yq deletions	Control	AZF	Control	AZF
Mulhall et al[58]	3	AZFc	45% (n = 25 cycles)	36% (n = 6 cycles)	—	—
Van Golde et al[60]	8	AZFc with oligospermia	71% (n = 107 pts)	55%	25%	16%

ICSI, intracytoplasmic sperm injection; IVF, *in vitro* fertilization.

refined to minimize the invasiveness of sperm harvest procedures. The first of these, the multi-biopsy method, involves taking as many biopsy samples as needed at the time of ICSI.[69] Another approach involves taking testis tissue by biopsy for both diagnosis (histology) and sperm retrieval simultaneously and *in advance* of ICSI to avoid cycle cancellation if sperm harvest fails.[70] Microdissection TESE uses microsurgical exploration of the widely opened testis to search for pockets of sperm.[71] Finally, diagnostic testis fine needle aspiration (FNA) "mapping" under local anesthesia literally maps out the geography of sperm production in the testis to determine patient candidacy for future testis sperm retrieval (Fig. 24.12).[72] Subsequently, at ICSI, needles or biopsies are "directed" to testis locations informed by the map. Most recently, preoperative factors such as FSH, inhibin B, and total testosterone have been used to construct formulas to predict sperm retrieval.[73] Regardless of approach, most men with nonobstructive azoospermia will have usable testis sperm by one of these methods.

Advances in Identifying Genes Involved in Male Infertility

It is widely believed that much of currently unexplained nonsyndromic male infertility will be found to have a genetic basis. And, as a complex disease, it is estimated that 1000 genes could be involved with normal male fertility. Past research aimed at discovering genetic loci responsible for male infertility involved targeting specific genes or gene regions or traditional genetic linkage approaches. These and other methods led to the identification of mutations associated with unique sperm phenotypes in selected populations. These include mutations in the aurora kinase C *(AURKC)*, a serine/threonine kinase, which cause macrozoospermia, characterized by sperm with large heads, increased chromosomal content, and a variable number of tails; and mutations associated with globozoospermia, sperm with round heads (*SPATA16;* spermatogenesis associated 16, a gene encoding a Golgi protein) and (*DPY19L2;* dpy-19-like 2, a gene encoding an inner nuclear membrane protein).

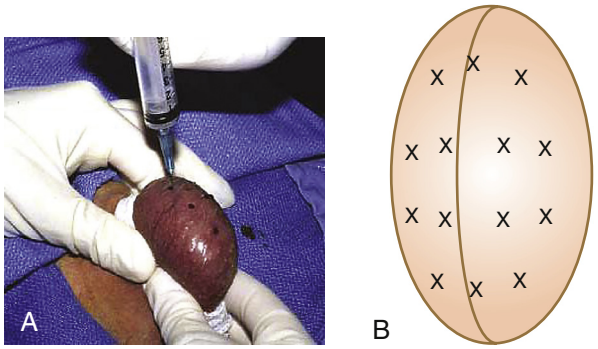

FIGURE 24.12 Technique of percutaneous fine-needle aspiration "mapping" for sperm in the testis. **A,** Samples are taken systematically from the testis for cytological examination for sperm. **B,** A recent sampling template. This is done in advance of assisted reproductive technology procedures. *(From Turek PJ, Cha I, Ljung B-M. Systematic fine needle aspiration of the testis: correlation to biopsy and the results of organ "mapping" for mature sperm in azoospermic men.* Urology *49:743, 1997.)*

The completion of the Human Genome Project in 2003 and the International HapMap Project in 2005 allowed the development of research tools and databases powerful enough to detect mutations using population-based approaches, genome-wide association studies (GWAS). GWAS techniques examine large numbers of genetic variations in a population, and associate variations with a specific trait or disease. To date, more than 1000 human GWAS have been carried out to examine 200 diseases and traits.[74] GWAS focus on small genetic variations termed single nucleotide polymorphisms (SNPs). SNPs are smaller variations in the human genome than are classic genetic deletions, insertions or copy number variants, but can be significant trait-altering events. In contrast to earlier genetic approaches that are able to test one or only a few genetic regions, GWAS investigate the entire genome. Such studies have been particularly useful in finding genetic variations in common, complex diseases such as asthma, cancer, diabetes, heart disease, and mental illnesses.

GWAS compare the DNA from those with a disease and those without a disease. From each person's DNA, millions of small genetic variations are read using SNP-based arrays. SNPs that occur commonly with a disease are "associated" with the disease, and therefore point to areas of the human genome that may influence the risk of that disease. Importantly, GWAS are unable to distinguish whether a genetic variant actually causes a disease. In addition, given the massive number of statistical tests needed to analyze GWA data, there can be an increased potential for false associations with this research.

Three recent GWAS have been reported that examined SNPs associated with male infertility (Table 24.6). In two studies of azoospermic Chinese men, a total of five genetic loci were observed to be associated with this condition, including several within the Human leukoctye antigen (HLA) region.[75,76] In a third study, fertile men were examined to determine associations between the fertility traits of family size and birth rate and potential genetic loci.[77] A total of nine loci were shown to be significantly associated with fertility traits and three were deemed reasonable candidate male fertility genes (Table 24.6). In summary, as a novel gene discovery tool, GWAS have great potential to delineate many of the thousand or so genes presumed to be associated with male fertility.

Table 24.6 Genome Wide Association Studies and Implicated Genetic Loci for Male Infertility

Study	Patient Population	Associated Genetic Loci

Note: OR = Odds ratio.

Conclusions

Evaluation of male factor infertility should be conducted to uncover life-threatening conditions and to detect correctable problems that present as infertility. The semen analysis may be viewed as a "biomarker" of men's health, as male infertility has also been shown to lead to an increased risk of later developing both testis and prostate cancers. Genetic causes of male infertility are assuming a greater role as our understanding of genomic medicine grows. Medical or surgical treatments should be undertaken after consideration of female partner reproductive potential. There is a need for adequately powered and well-controlled clinical trials to better understand both the value of classic male factor treatments, and the role of assisted reproduction in male infertility treatment.

CHAPTER 25

Endocrine Disturbances Affecting Reproduction

Alice Y. Chang
Richard J. Auchus

The reproductive systems are vulnerable to disruption by internal and external forces including disease, malnutrition, and various forms of stress. The male and female axes are both susceptible to dysfunction from the same processes, although the female axis tends to be more sensitive. This chapter will review the influence of endocrine disorders of the pituitary, adrenal, and thyroid on reproduction. Each section will discuss the most important and relevant disorders of the specific gland and its effects on female reproduction first. Features specific for male reproduction will be discussed where relevant in each disease subsection. The reader is directed to chapters 3, 18, and 21 for review of neuroendocrine disorders; chapters 4, 17, and 18 for further discussion of congenital adrenal hyperplasia; chapter 21 for a review of Cushing disease; and chapter 28 for a review of endocrine disorders in pregnancy.

Pituitary Disorders

Overview

As the "master gland," the anterior pituitary gland controls the secretion of several essential hormones from other major endocrine glands, including the thyroid (releasing thyroxine and triiodothyronine), adrenal cortex (cortisol, dehydroepiandrosterone sulfate), and gonads (predominantly estradiol in females and testosterone in males). The anterior pituitary gland also produces growth hormone and prolactin, which act directly on target organs. The actions of growth hormone are largely exerted via the local or systemic production of insulin-like growth factor-1 (IGF1). The posterior pituitary regulates water metabolism via the production of vasopressin and induces milk letdown via the production of oxytocin. Disorders of the pituitary can be partial or complete, isolated to one hormone or multiple, and related to hormone deficiency or hormone excess. The axes controlled by the pituitary gland share the following basic principles:

1. Input from higher brain centers to the hypothalamus
2. Releasing and inhibitory factors influencing pituitary hormone secretion
3. Hypothalamic factor pulsatility, leading to pulsing of pituitary and target gland hormones
4. Feedback inhibition at both the hypothalamus and pituitary by active target gland hormones
5. Peripheral metabolism of target gland products
6. Influence of diurnal rhythm

The relative importance of these regulatory components varies for each axis and is described below in more detail. These axes are shown schematically in Figure 25.1.

Of the pituitary axes, the thyroid axis is the simplest for several reasons. The primary product of the thyroid is thyroxine (T_4), which is a precursor of the active hormone triiodothyroinine (T_3). Since T_4 is heavily protein-bound, T_4 has a long half-life (7 days), and T_4 is slowly metabolized to T_3. This scenario provides steady, well-dampened feedback, and the thyroid axis therefore shows high stability and low pulsatility. Hypothalamic thyrotropin-releasing hormone (TRH) pulses stimulate release of thyroid stimulating hormone (TSH); however, negative feedback by T_3 directly on the pituitary tightly regulates TSH biosynthesis and primarily regulates the thyroid axis. Thus the thyroid axis is a model endocrine feedback system due to its stability and simplicity.

In contrast, the adrenal axis is characterized by a strong diurnal rhythm, with the shorter half-life of cortisol (1 hour) leading to greater pulsatility. The adrenal axis is also more sensitive to factors beyond hypothalamic corticotropin-releasing hormone (CRH) and negative feedback by cortisol. Both vasopressin and various cytokines increase production of corticotropin (ACTH) in response to stress or illness. As a consequence, this intricate feedback system provides a more responsive axis to physiological changes and needs. However, this level of sophistication complicates clinical testing.

The growth hormone (somatotropin, GH) axis is primarily a two-component axis regulated by the hypothalamus. Growth-hormone releasing hormone (GHRH) serves as the major positive stimulus and somatostatin (SS) as the major negative stimulus. GH stimulates the production of IGF1 in the liver and locally in other tissues. Circulating IGF1 derives from the liver and exerts some negative feedback on the axis, but this influence is small relative to SS. Numerous hormonal and metabolical factors, however, also alter GH secretion by modulating the release of GHRH and SS. While the two hypothalamic hormones regulate GH pulsatility throughout the

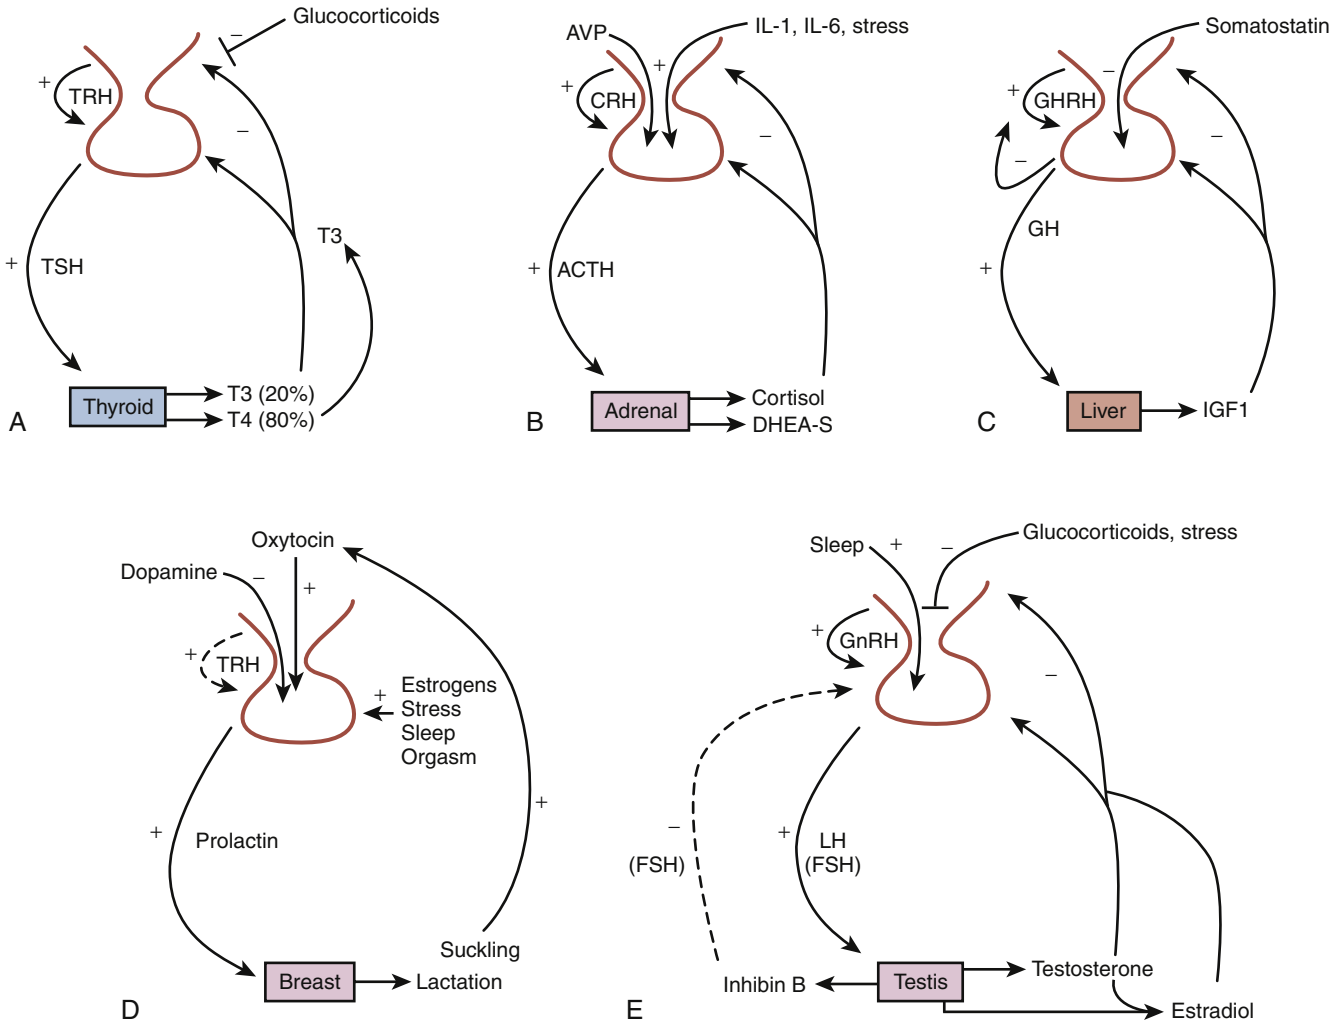

FIGURE 25.1 The major factors regulating the anterior pituitary axes. **A**, thyroid axis; **B**, adrenal axis; **C**, growth-hormone (GH)-insulin-like growth factor-1 (IGF1) axis; **D**, prolactin axis; **E**, gonadal axis. The male gonadal axis is shown here; the corresponding female axis is discussed at length in Chapter 8.

day, the greatest GH pulses are produced in deep sleep. Significant physical stressors, including hypoglycemia, also increase GH secretion.

Prolactin is the only anterior pituitary hormone that is primarily under negative control, mediated by dopamine (DA). For this reason, prolactin rises whenever blood flow to the pituitary from the hypothalamus is impaired. Therefore, hyperprolactinemia can result from a large pituitary tumor, which does not itself secrete prolactin, by blocking blood flow from the stalk. Prolactin is also increased by stress, nipple stimulation, and TRH, so prolactin rises transiently for several reasons and persistently for several others (Table 25.1). Prolactin acts on the breast to enable lactation, but there is no known hormonal product from the breast that exerts feedback on prolactin secretion. Estrogens also stimulate lactotrope growth.

The gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and their regulation by gonadotropin-releasing hormone (GnRH) are discussed in detail for the male and female in other chapters. Here, we simply emphasize that pulsatile GnRH secretion every 90 to 120 minutes is critical to LH and FSH production.

Table 25.1 Causes of Hyperprolactinemia

Cause	Characteristic features(s)
Prolactinoma	Mass effects if macroadenoma
Acromegaly	Headaches, heavy perspiration, acral changes
Macroadenoma (not prolactin secreting)	Peripheral vision loss, anterior pituitary defects
Other infiltrative or hypothalamic diseases	Anterior pituitary defects, maybe diabetes insipidus
Drugs	Other specific side-effects of drug
Pregnancy	Positive hCG, amenorrhea
Renal failure	Comorbidities of renal failure
Chest wall stimulation	Variable prolactin
Stress	Including phlebotomy
Primary hypothyroidism	See Table 25.4

hCG, human chorionic gonadotropin.

While this principle is true for both males and females, the influence on fertility and symptoms differs in other respects. The reproductive axis is particularly sensitive to disorders and disruptions of the pituitary-hypothalamic axes as discussed in further detail below.

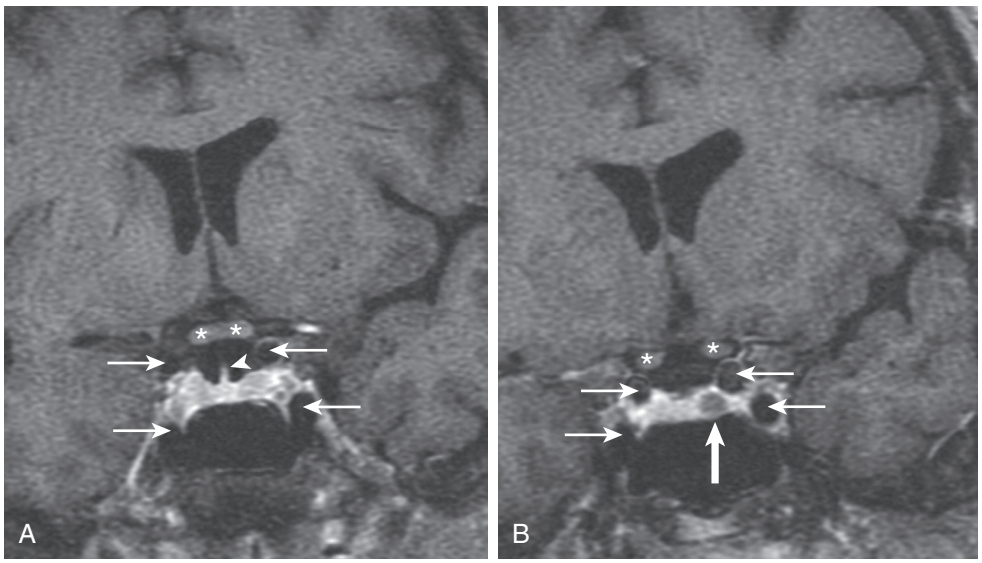

FIGURE 25.2 **A,** Normal pituitary. In this T1-weighted coronal image after gadolinium contrast, the pituitary gland is seen in the area of high-signal below the pituitary stalk *(indicated by chevron arrowhead)*. The carotid arteries are indicated by *thin arrows*, and the optic nerves are labeled with *asterisks (*)*. **B,** Pituitary microadenoma. The *thick arrow* shows the tumor as a hypointensity within the high-signal pituitary gland.

Loss of pituitary function is most commonly caused by drugs, exogenous hormones, or tumors. Tumors affect pituitary function by overproduction of hormones, including interference with the above axes (such as prolactin impairing gonadotropin secretion) or by mass effect. Any pituitary tumor >1 cm in maximal diameter is defined as a macroadenoma. The acquisition of pituitary hormone deficiencies due to tumors tends to follow the order GH first, then LH+FSH, then TSH, and finally ACTH.[1] Consequently, the reproductive axis is fairly vulnerable to disruption by macroadenomas of any cell type. Decompression by transsphenoidal surgery can restore pituitary function, particularly for the ACTH and TSH axes,[2,3] but iatrogenic hypopituitarism is a common risk of surgery. Radiotherapy tends to cause hypopituitarism over a period of 2 to 15 years and for this reason should be used judiciously in women of reproductive age.[4] In the following discussion, both the nature of the pituitary disorder and its treatment are addressed as they affect strategies for restoring reproductive function.

Pituitary Disorders that Affect Reproduction

Prolactinoma and Hyperprolactinemia

The combination of amenorrhea and galactorrhea in a young woman is a classic presentation of prolactinoma; however, these two symptoms may occur individually or not at all.[5] Hyperprolactinemia has many potential etiologies (Table 25.1). The mechanisms of reproductive dysfunction in hyperprolactinemia vary somewhat with etiology, but prolactin disrupts the pulses of GnRH and also directly reduces the production of LH and FSH.[6-8]

The diagnosis of hyperprolactinemia is established by measuring a serum prolactin at any time of day without dynamic testing, although the stress of phlebotomy can cause slight elevations.[9] Falsely elevated prolactin measurements can be caused by the presence of macroprolactin, also known as "big-big prolactin,"[10] which is a complex of prolactin and IgG detected variably in different immunoassays but lacking normal biological activity.[11,12] If the prolactin is clearly elevated and causes other than pituitary tumors are excluded, a dedicated MRI of the sella with gadolinium contrast agent should be performed.

Microprolactinomas (tumors <1 cm in greatest diameter) are found in about 1% of women age 20 to 40 years old.[13] The degree of prolactin elevation is roughly proportional to the size of the tumor.[14] A tumor not secreting prolactin might cause hyperprolactinemia via stalk compression and impaired dopamine delivery, but the prolactin rarely if ever rises above 250 ng/mL.[15] For example, a patient with a 3 cm pituitary mass and a prolactin of 150 ng/mL probably does not have a prolactinoma. In cases of large pituitary tumors with mild prolactin elevations, however, the prolactin measurement should be repeated with dilutions to identify the "high-dose hook effect," which artifactually lowers the assayed value.[16] GH is a full prolactogen in humans; consequently, galactorrhea with mildly elevated prolactin and a pituitary tumor could be secondary to a somatotropinoma rather than prolactinoma.[17] On T1-weighted MRI, microprolactinomas tend to be hypointense relative to the normally bright pituitary and usually do not distort the architecture of the gland (Fig. 25.2). Although the larger macroprolactinomas tend to enhance with gadolinium, the pattern is quite variable, and macroprolactinomas tend to distort the architecture of the gland (Fig. 25.3) with the inferior portion of the pituitary stalk often deviating away from the tumor.

Prolactinomas are generally very responsive to medical therapy with dopamine agonists (bromocriptine and cabergoline).[18] Even for large and invasive macroprolactinomas with visual changes, tumor shrinkage by dopamine agonists can be immediate and effective (Fig. 25.3). Treatment options are selected based on symptoms, tumor size, and patient goals. Indications for treatment include infertility, amenorrhea, galactorrhea (particularly if spontaneous and bothersome), hypopituitarism, and mass effect. A woman with a 5 mm microprolactinoma, serum prolactin of 60 ng/mL, regular menses, and only trace expressible galactorrhea does not require treatment, because these tumors rarely grow.[19] In contrast, the same woman with infertility would be treated if she desires pregnancy. Cyclic estrogen and progestin for endometrial and bone protection or symptoms of estrogen deficiency is an option for patients with

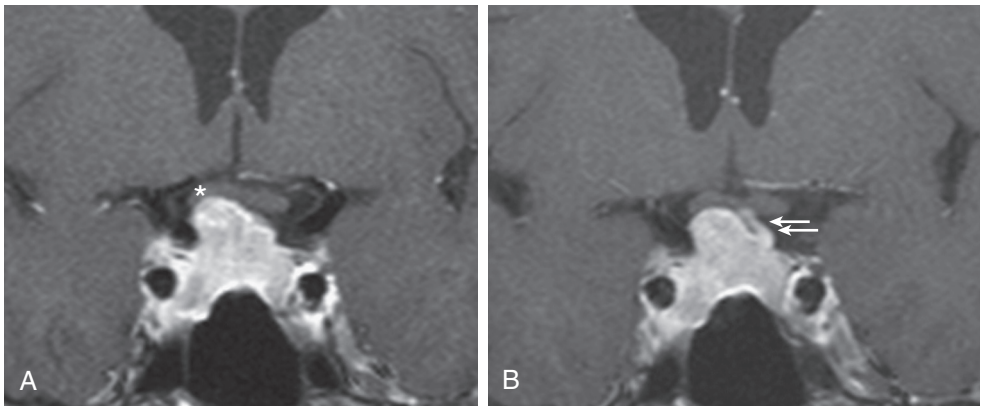

FIGURE 25.3 Macroprolactinoma and response to cabergoline. **A**, T1-weighted coronal image after gadolinium contrast at diagnosis with a serum prolactin of 350 ng/mL. The tumor is pressing against the optic nerve on the left (*). **B**, After 3 months of treatment with cabergoline at 0.5 mg twice weekly, the serum prolactin had fallen to 10 ng/mL. The stalk is now visible *(arrows),* and the tumor no longer abuts the optic nerve *(black rim separating the tumor from the optic nerve)*.

microprolactinomas and irregular menses but without galactorrhea and who do not desire pregnancy, with low risk of tumor growth.[20-22]

Bromocriptine is administered in 2 to 3 divided doses with a total of 2.5-40 mg/d. The main side effects of bromocriptine are nausea, lightheadedness, and nasal stuffiness. The dose is slowly advanced every 4 to 10 days as tolerated until the serum prolactin is normalized and the symptoms are relieved. Cabergoline, administered at 0.25-2 mg once or twice weekly, is much more potent and better tolerated than bromocriptine.[23] Bromocriptine is generally preferred if pregnancy is desired, stopping the medication upon confirming conception.[24] Cabergoline use early in pregnancy was not found to increase the risk for miscarriage or fetal malformations and is generally considered safe also.[25] Visual fields and serum prolactin should be monitored throughout pregnancy and during lactation, more closely for macroprolactinomas. MRI without contrast is performed if tumor growth is suspected, and cabergoline restarted to prevent vision compromise and/or hypopituitarism during pregnancy.

In some cases, particularly those without visible tumor on MRI scan, cabergoline can be discontinued after 2 to 5 years without recurrence of hyperprolactinemia.[26] Chronic treatment with high doses of cabergoline for Parkinson's disease has been rarely associated with cardiac valve disease[27,28] due to the serotonin receptor agonism by cabergoline but not bromocriptine. In one study, asymptomatic moderate tricuspid regurgitation was detected echocardiographically in 54% of cabergoline-treated prolactinoma patients versus 18% of controls.[29] Consequently, periodic cardiac exam is necessary in patients treated with cabergoline, and echocardiography is indicated if a murmur is appreciated or if high doses are required.

Surgery and radiotherapy are reserved primarily for rare tumors unresponsive to dopamine agonists and for patients intolerant to these drugs.[30] Surgery is most effective for microadenomas, with success rates approaching 90% for microadenomas but only about 60% for macroprolactinomas.[30,31] An immediate postoperative prolactin of less than 2 ng/mL is reliable evidence of cure. Radiotherapy takes at least a year to lower the prolactin significantly and to stop tumor growth.

Occasionally, patients present with normoprolactinemic galactorrhea and regular menses. If the galactorrhea is bothersome, treatment with bromocriptine or cabergoline to lower the prolactin to less than 2 ng/mL is effective in stopping the galactorrhea.[32] The duration of therapy required is roughly proportional to the duration of time that the galactorrhea has been present. Patients should be counseled to wear a tight bra or breast binder and to avoid both nipple stimulation and checking for expressible milk production during the course of therapy.

In men, the majority of patients with prolactinoma come to medical attention with macroprolactinomas and markedly elevated prolactin values.[33] Men present with symptoms attributable either to mass effect, such as vision loss and diplopia, or to hypogonadism, including fatigue, loss of libido, and erectile dysfunction.[33] Galactorrhea is rare but seen if gynecomastia is present and hyperprolactinemia is severe. Sperm count is usually reduced only after many years of hyperprolactinemia. Indications for treatment include mass effects and hypopituitarism. The hypogonadism associated with prolactinomas in men often responds well to dopamine agonist therapy, unless the duration of hypogonadism is prolonged. The erectile dysfunction of hyperprolactinemia does not always improve with testosterone replacement unless the prolactin is normalized.[34] Sperm count is not immediately restored by dopamine agonist therapy and may not return to normal after several months of therapy.

Acromegaly

Acromegaly results from overproduction of GH and IGF-1 accompanied by acral bone and soft tissue growth. Because symptoms are subtle and gradual in onset, the diagnosis may be delayed for several years. Additional symptoms and complications include fatigue, sleep apnea, hyperhydrosis, headache, and carpal tunnel syndrome. The majority of patients with acromegaly have a GH-secreting pituitary tumor (somatotropinomas), less than 10% have GHRH-producing tumors, usually pancreatic neuroendocrine tumors. Menstrual abnormalities are observed when tumor mass effect impairs delivery of hypothalamic releasing factors to the anterior pituitary or when hyperprolactinemia occurs. The direct action of GH can cause galactorrhea; however, tumors

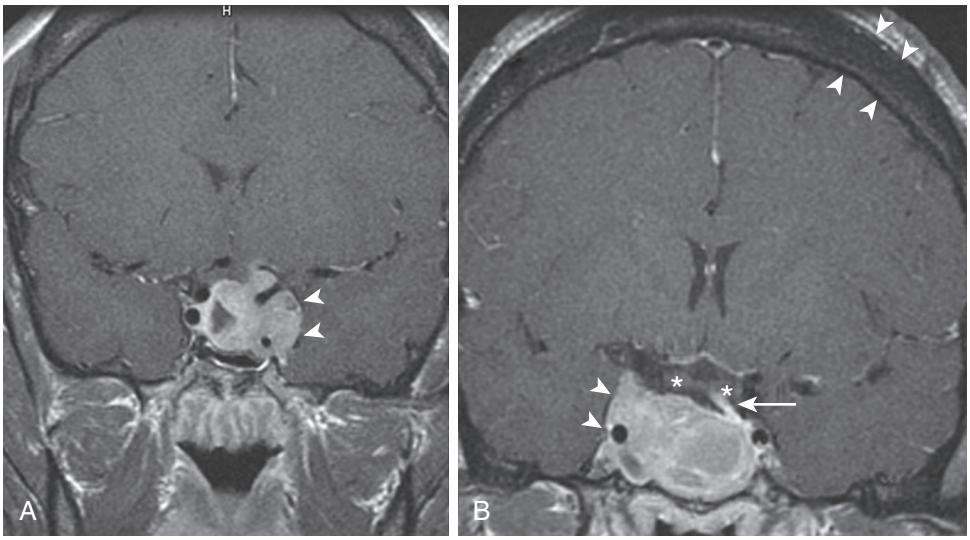

FIGURE 25.4 Magnetic resonance image (MRI) of invasive somatotropinomas. The tumor on the left **(A)** invades the carotid sinus on the right *(chevron arrowheads)* and obliterates the optic nerve on that side. The tumor on the right **(B)** has heterogeneous intensity from internal hemorrhage, and this tumor invades the carotid sinus on the left *(chevron arrowheads)*. The stalk *(arrow)* is visible on the right, but the normal pituitary is not discernable. The optic nerves (*) are not compromised, and diplöic space on the right *(between arrowheads)* is expanded.

that co-secrete GH and prolactin also exist, which complicates the evaluation.[35] Prolactin co-secretion does not predict an improved response to dopamine agonist therapy.[36]

A serum IGF1, corrected for gender and age or Tanner stage, is the best screening test for acromegaly. An elevated IGF1 plus acral changes in a patient with a pituitary tumor are usually sufficient to make the diagnosis. Formal GH suppression testing with 100 grams glucose (normal GH <0.1 ng/mL in males or <1 ng/mL in females[37]) is used mainly to gauge response to therapy. Gigantism occurs when the tumor forms prior to closure of the epiphyses. Genetic causes of acromegaly and gigantism include multiple endocrine neoplasia type 1 (MEN 1, *MEN1* gene), Carney complex (*PRKA1A* gene), and familial isolated pituitary adenoma (FIPA, *AIP* gene).[38]

Combined modality therapy is the norm for the typical invasive somatotropinoma (Fig. 25.4). Large tumors often require both transsphenoidal surgery and craniotomy to debulk the tumor sufficiently for drug or radiotherapy,[39] whereas for microadenomas, cure rates are high and hypopituitarism infrequent for experienced pituitary neurosurgeons.[40] Pure somatotropinomas occasionally respond to dopamine agonists with reduced GH secretion and/or tumor shrinkage, but at high doses.[41] Many somatotropinomas express somatostatin receptors, primarily type 2 (sst2) and remain responsive to somatostatin agonists such as octreotide or lanreotide, given as monthly long-acting intramuscular or deep subcutaneous injections of 10-40 mg or 60-120 mg, respectively. Although earlier reports suggested GH and IGF1 normalization in 70% of patients, more recent studies indicate that less than 40% of patients normalize on somatostatin agonist therapy.[42,43] Some tumor shrinkage occurs in over half of somatotropinomas treated with somatostatin analogs, but the degree of regression is not as dramatic as for prolactinomas treated with dopamine agonists. Pegvisomant, a growth-hormone receptor antagonist that is modified with polyethylene glycol, normalizes IGF1 in up to 95% of patients during the initial trials,[44] but long-term studies indicate that the success rate is 60% to 65%.[45] The drug is given by subcutaneous injection of 40 mg as loading dose, followed by 10-30 mg/day, and it is generally well-tolerated except for transaminase elevation in rare cases. Pasireotide, which binds to sst5 with higher affinity than octreotide, appears promising for the treatment of acromegaly[46] but causes more hyperglycemia than octreotide. GH normally rises in pregnancy due to the secretion of placental GH, which is the product of a separate gene from pituitary GH. Consequently, medical treatment is normally withheld during pregnancy.

Cushing Disease

Hypercortisolism from ACTH-producing pituitary tumors causes infertility both from the effects of glucocorticoids on the hypothalamic-pituitary-gonadal axis and from mass effect if it is caused by a macroadenoma. This topic will be covered in the adrenal section below, and the principles of hypopituitarism from macroadenomas are the same as discussed earlier.

Other Macroadenomas

Many pituitary adenomas are "nonfunctional," meaning that they do not produce significant amounts of biologically active hormones. Most of these tumors, however, derive from the glycoprotein hormone cell lineage and express mRNA for the common alpha subunit and/or the beta subunits of LH, FSH, or TSH,[47] but the glycoprotein products are biologically inactive due to improper glycosylation, dimerization and assembly.[48] In general, these tumors present with symptoms due to mass effect (vision loss, headache) or hypopituitarism. Unlike prolactinomas, these tumors tend to be resistant to medical therapy. Indications for surgery include vision compromise or other mass effect and severe hypopituitarism, such as ACTH deficiency or panhypopituitarism. For the woman with panhypopituitarism and infertility, ovulation induction with gonadotropins is required, as discussed in other chapters. For men, fertility is restored with human chorionic gonadotropins (hCG)

1000-2000 units 2 to 3 times weekly to normalize testosterone, with recombinant FSH 25 to 75 IU three times a week added if necessary.[49]

Lymphocytic Hypophysitis

Lymphocytic infiltration of the pituitary is a rare disorder, which most commonly occurs in postpartum women.[50] Common presentations are headache with inability to lactate postpartum due to impaired prolactin production or polyuria and polydipsia from diabetes insipidus.[51] Some women are relatively asymptomatic but develop amenorrhea or non-specific symptoms of hypopituitarism over time. The pattern of pituitary deficiencies is highly variable and often follows a pattern much different from that observed with macroadenomas, such as ACTH and TSH deficiency with diabetes insipidus but preserved GH and gonadotropins. During the active phase, MRI shows a symmetrically enlarged pituitary and stalk that enhances markedly with gadolinium. After the damage has occurred and the disease has subsided, the MRI can show a partial empty sella. Methylprednisolone in the acute phase is sometimes effective,[52] but pituitary function, when lost, rarely recovers.

Other Disorders Affecting the Pituitary

Granulomatous diseases such as sarcoidosis[53] and tuberculosis can involve the hypothalamus and pituitary, also causing central hypogonadism. Hypopituitarism can be the initial manifestation of sarcoidosis, while others have neurosarcoidosis with manifestations such as optic neuritis. MRI shows brisk enhancement of the meninges with or without hypothalamic and pituitary abnormalities. Other tumors also arise in the hypothalamus and pituitary, including germinomas and lymphomas. Carcinomas metastasize to the pituitary, primarily to the stalk. Diabetes insipidus is often a presenting manifestation, and hypogonadism is one of the most frequent manifestations of hypopituitarism in these neoplastic disorders.

Hemochromatosis (primary or secondary) and amyloidosis are infiltrative diseases that cause hypopituitarism.[54] The classic triad includes liver dysfunction, skin bronzing, and diabetes mellitus ("bronze diabetes"), but arthropathy, cardiomyopathy, and various endocrinopathies including adrenal insufficiency[55] and hypogonadotropic hypogonadism[56] are common as well. Iron deposition in the hypothalamus has predilection for impairing GnRH production among the releasing hormones. Hemochromatosis is one of the few disorders in which the male reproductive axis is more vulnerable to disruption than in the female, due to monthly menses in women.

Adrenal Disorders

Overview

The adrenal consists of a cortex, with three distinct zones, and a medulla. The medulla is an extension of the sympathetic nervous system and produces epinephrine. The steroid-producing cells of the cortex are arranged into the outermost zona glomerulosa, which produces aldosterone; the zona fasciculata, which produces cortisol, and the zona reticularis, which produces the androgen precursor dehydroepiandrosterone sulfate (DHEAS). DHEA and DHEAS are metabolized to testosterone in peripheral tissues. Cortisol and DHEAS production is regulated primarily by ACTH (Fig. 25.1), whereas aldosterone synthesis is mainly stimulated by the renin-angiotensin system and by potassium.

Diseases of the adrenal gland causing hormone deficiency rarely interfere with reproduction, but certain hormone excess states contribute to infertility, particularly for women. In the male, the contribution of adrenal DHEAS and other 19-carbon steroids to circulating testosterone concentrations is normally small, but in women, the majority of testosterone normally derives from adrenal-derived precursors. Consequently, disorders that increase adrenal DHEAS production cause hyperandrogenemia in women, which can impair fertility. Hypercortisolism may suppress gonadotropin production in women and, to a lesser extent, in men. We will not discuss primary aldosteronism, adrenal insufficiency, or pheochromocytomas in this chapter, because these disorders rarely impair fertility in isolation.

Adrenal Disorders that Affect Reproduction

Cushing Syndrome

The Cushing syndrome is categorized as iatrogenic or endogenous, and endogenous Cushing syndrome is dichotomized as being ACTH-dependent or ACTH-independent (Table 25.2). The majority of Cushing syndrome is ACTH-dependent, the most common cause being ACTH-producing pituitary tumors, which is called Cushing disease. The differential diagnosis of ACTH-dependent Cushing syndrome also includes ectopic production of ACTH or CRH by carcinomas, neuroendocrine tumors, and bronchial carcinoids.[57] ACTH-independent Cushing syndrome is caused by unilateral adenomas or carcinomas and by bilateral micronodular or macronodular hyperplasia. Cushing disease occurs most commonly in young women, and DHEAS production is more commonly elevated in ACTH-dependent forms of Cushing syndrome than in ACTH-independent forms. Consequently, Cushing disease in women is the most relevant form of hypercortisolism that impairs reproduction.

The clinical manifestations of cortisol excess can be subtle in the early stage when the diagnosis is most difficult but the benefits of treatment and potential for full recovery the greatest. Cortisol is a catabolical hormone that causes lipolysis and fat redistribution, as well as breakdown of body tissues such as muscle, skin, and bone. Central obesity is a prominent and common feature, with disproportionate fat accumulation around the face and neck. The dorsocervical fat pad ("buffalo hump") is a well-known feature of Cushing syndrome, but

Table 25.2 Etiologies of Endogenous Cushing Syndrome

ACTH-Independent	Adrenocortical adenoma
	Adrenocortical carcinoma
	Macronodular hyperplasia
	Micronodular hyperplasia
ACTH-Dependent	Corticotrope tumor (Cushing disease)
	Corticotrope hyperplasia
	Ectopic ACTH syndrome
	Ectopic CRH syndrome

supraclavicular fat pads are more specific for this disorder, especially in an otherwise nonobese individual (Fig. 25.5). Facial and upper chest plethora is observed (Fig. 25.5), and women often develop hirsutism.

Proximal muscle weakness and skin thinning are two very specific features of Cushing syndrome, and osteoporosis in an obese individual should raise suspicion as well.[57] Patients endorse difficulty arising from a chair and walking up stairs or getting out of a car, combing their hair, or changing an overhead light bulb. Skin thinning and capillary fragility cause easy bruising, and if weight gain is rapid, the striae formed are violaceous and non-blanching, reflecting hemorrhage into the new skin by fragile blood vessels. These striae are found on the abdomen and flanks, near the axillae, and on the thighs and breasts. If greater than 1 cm, purple striae are very specific for hypercortisolism; however, these findings develop late and only in severe disease.

The most important scenario in which Cushing syndrome should be considered is in the young woman with oligomenorrhea and hirsutism who could be mistaken for simple polycystic ovary syndrome (PCOS). A history of hirsutism onset after age 25 or specific findings for hypercortisolism, such as easy bruising, thin skin, proximal muscle weakness, and osteoporosis, should prompt screening for Cushing syndrome.

The diagnosis of hypercortisolism can be difficult early in the disease because of the large overlap with normals. Testing is based on the principles that the cortisol production rate is increased,[58] that the normal diurnal rhythm is disrupted, and that cortisol is not suppressible.[59] These principles are employed by the 24 hour urinary free cortisol,[60] late-night saliva[61] or serum cortisol measurements,[62] and overnight dexamethasone suppression testing,[63] respectively. The caveats of testing are beyond the scope of the chapter, but the reader should be aware that both false-positive and false-negative results are common. Consequently, tests often must be repeated several times before a diagnosis can be made or excluded.

Once hypercortisolism is confirmed, an ACTH measurement will determine if the disease is ACTH-dependent or ACTH-independent. If ACTH-independent (ACTH <5 pg/mL), an abdominal computed tomography scan of the adrenal glands is obtained. Patients with early ACTH-independent Cushing syndrome will have low but not suppressed ACTH (5-15 pg/mL), and these patients should have serial testing until the diagnosis is clarified.[64] If the ACTH is normal or elevated, the next step is magnetic resonance imaging of the pituitary with gadolinium contrast. The caveat of pituitary imaging is that small abnormalities of the pituitary are common, and about half of patients with Cushing's disease do not have a visible tumor by MRI. To conclusively exclude the ectopic ACTH syndrome, inferior petrosal sinus sampling is performed.[65] Blood draining both sides of the pituitary is sampled from the inferior petrosal sinuses under ovine CRH stimulation (100 μg bolus), and the ACTH values in these specimens are compared with those obtained in peripheral blood drawn simultaneously. An ACTH step-up greater than 3 from peripheral blood to the inferior petrosal sinus is reliable evidence for a pituitary source of ACTH.

Treatment of Cushing syndrome is primarily surgical. Cushing disease is treated with transsphenoidal pituitary adenomectomy, yet even in the hands of experienced surgeons, long-term cure rates are not above 80%. Repeat surgery, radiotherapy, and even bilateral adrenalectomy may be recommended if disease persists. Medical management with metyrapone, ketoconazole, and triolstane has been employed but are seldom very effective in severe disease. Mifepristone at high doses blocks the glucocorticoid receptor and improves the catabolical and metabolical features of all forms of Cushing syndrome,[66] but the renal and hemodynamic manifestations of hypertension and hypokalemia must be managed independently. Cabergoline is effective in reducing hypercortisolism for a subset of pituitary tumors that express dopamine type 2 receptors.[67] Furthermore, many corticotrope tumors express sst5 but not sst2, so while octreotide is rarely effective in reducing ACTH secretion, pasireotide reduces ACTH and cortisol production in the majority of cases.[68] In contrast, ACTH-independent Cushing syndrome is normally cured by unilateral or bilateral adrenalectomy, except in the case of adrenocortical carcinomas with inoperable or metastatic disease.

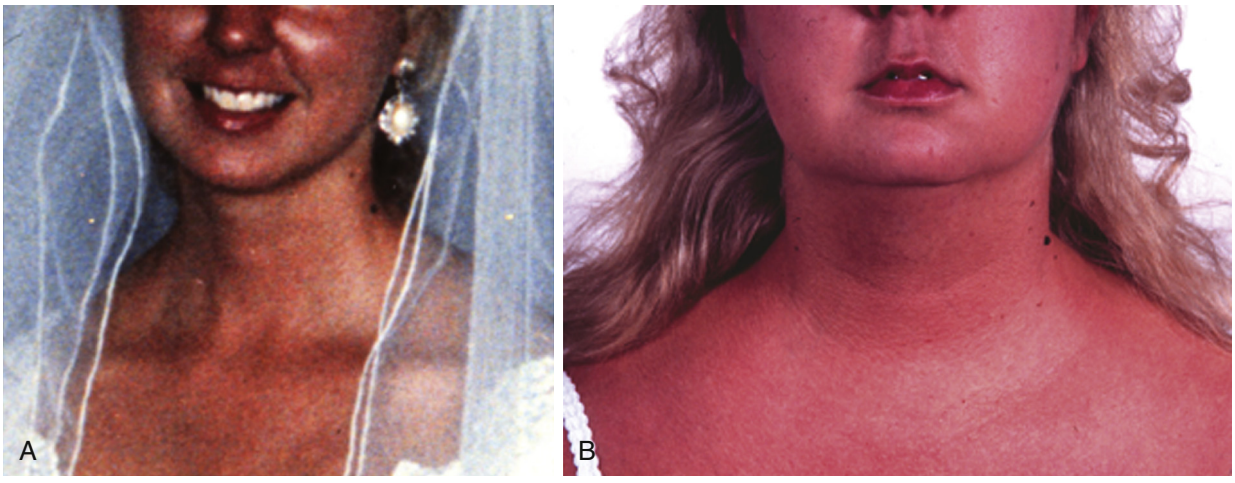

FIGURE 25.5 Subtle clinical signs of Cushing syndrome. This woman is shown 4 years before diagnosis **(A)** and at the time of diagnosis **(B)**. In part **B**, she demonstrates facial plethora and loss of clavicular silhouettes due to supraclavicular fat.

Congenital Adrenal Hyperplasia (CAH): 21-Hydroxylase Deficiency

The manifestations of 21-hydroxylase deficiency (21OHD) in the infant as an intersex disorder were discussed elsewhere, so this discussion will be restricted to adults with classical and non-classical forms of 21OHD. Among the forms of congenital adrenal hyperplasia (CAH), 21OHD is by far the most common form, accounting for >90% of cases.[69] Classical 21OHD is caused by mutations in the *CYP21A2* gene, which severely impair the activity of the encoded P450c21 enzyme to <2% of wild-type activity.[70] Nearly all of these patients have clinical manifestations and require therapy with glucocorticoid and mineralocorticoid replacement. Milder mutations, particularly the V281L allele, cause non-classical 21OHD (Table 25.3).[71] Males with non-classical 21OHD are rarely ascertained unless evaluation for premature pubertal features (body hair, acne, growth spurt) is sought. Females with non-classical 21OHD present with hyperandrogenism, which manifests with hirsutism, acne, and irregular menses,[72] but not all patients are symptomatic or require treatment. Similarly, patients with intermediate severity are often not diagnosed until adulthood, particularly males (Fig. 25.6). In many countries, 21OHD testing is part of newborn screening procedures, so most newborns are identified before adrenal crisis occurs, even if not ascertained by genital ambiguity.

The diagnosis of 21OHD is based on elevated circulating concentrations of 21-deoxysteroids, in particular 17-hydroxyprogesterone (17OHP). A random serum 17OHP > 10,000 ng/dL with serum cortisol <5 μg/dL establishes the diagnosis of classical 21OHD in males and females, and dynamic testing is rarely required.[73] In the case of non-classical disease, a morning serum 17OHP >800 ng/dL should prompt repeat measurement of cortisol and 17OHP 30 to 60 minutes after cosyntropin administration (250 mcg I.V. or I.M.). Postcosyntropin 17OHP values in the 1500-10,000 ng/dL range are typical of non-classical 21OHD.[74-76] If laboratory data are equivocal, genetic testing for mutations in the *CYP21A2* gene on DNA from peripheral blood cells is available.

The repertoire of mutations commonly found in 21OHD is limited due to the molecular mechanism responsible for most cases. The *CYP21A2* gene is located in a duplicated locus within the HLA region on chromosome 6p that includes the genes for the fourth component of complement. In the duplicated region, the DNA corresponding to the *CYP21A2* gene is replaced by the *CYP21A1P* pseudogene.[77,78] This pseudogene contains several mutations that render the cognate mRNA and protein non-functional. Most cases of 21OHD derive from gene conversion events, in which some or all of the *CYP21A2* gene is replaced by the corresponding region of the *CYP21A1P* pseudogene.[79] Consequently, the spectrum of mutations and the worldwide prevalence of 21OHD is fairly consistent, but certain mutations are particularly common in specific populations, such as V281L in Yupik Eskimos.[80] Occasionally, true point mutations are found instead.[81] Heterozygous carriers are identified with confidence by genetic testing, whereas 17OHP values, even after cosyntropin stimulation, show broad overlap with normal individuals of either gender.

The mechanisms of reduced fertility in women with classical 21OHD are complex, although affected women have given birth to normal female infants.[82] Chronic hyperandrogenemia, even though largely adrenal in origin, causes chronic oligo-anovulation. In addition, many women with 21OHD develop a secondary PCOS, with characteristic ovarian morphology, thecal hyperplasia, and ovarian androgen excess as well.[83] The block in 17OHP metabolism causes accumulation of adrenal-derived progesterone as well, and high circulating progesterone concentrations impair endometrial maturation and implantation.[84] Overtreatment with synthetic glucocorticoids, however, can suppress gonadotropins and cause glucose intolerance with its attendant reproductive disturbances.[85]

Women with virilization of the external genitalia face additional impediments to fertility related to anatomical considerations. Vaginal stenosis, either prior to reconstruction surgery or following suboptimal surgery and/or dilation, is known to cause dyspareunia,[86,87] which discourages coitus.[88,89] Vaginal anomalies also comprise sperm

Table 25.3 21-Hydroxylase Deficiency

Form	Common Mutations
Classical	
Salt-wasting	Large deletions, 656A/C-G*, G110del8nt, Q318X R356W*, R483P, I236N+V237E+M239K
Simple virilizing†	656A/C-G*, I172N, R356W*
Non-classical	P30L, V281L, R339H, P453S

*Can be associated with either salt-wasting or simple virilizing disease.
†All patients with classical 21-hydroxylase deficiency are prone to salt wasting with physiological stress, but the most severely affected experience spontaneous salt-wasting crises in infancy.

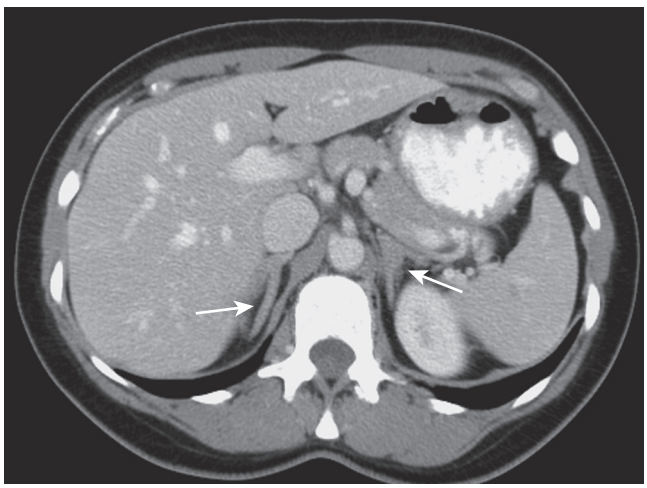

FIGURE 25.6 Computed tomography of adrenal glands in a woman with non-classical 21OHD diagnosed at age 50. She had both severe hirsutism and rapid somatic growth in childhood with normal external genitalia. She menstruated regularly during her reproductive years and gave birth to three children without glucocorticoid or ovulation therapies. Screening laboratory values included a testosterone of 179 ng/dL, SHBG of 52 nmol/L, DHEAS of 427 μg/dL, ACTH of 16 pg/mL, and 17OHP of 1100-2500 ng/dL. The 17OHP rose to >17,000 ng/dL with cosyntropin stimulation, establishing the diagnosis of 21OHD. The enlarged but normally-shaped adrenal glands are indicated by *arrows*.

deposition, and high circulating progesterone concentrations inhibit sperm penetration and fertilization. Psychosocial influences should not be underestimated. The fact that 21OHD is a genetic disorder associated with masculinization contributes to difficulties finding a partner and has been associated with preference for relationships with female partners in some but not all studies.[90]

Women with non-classical 21OHD are most commonly identified during an evaluation of hirsutism, oligomenorrhea, or infertility mimicking PCOS. It is difficult to distinguish non-classical 21OHD from idiopathic PCOS on clinical grounds.[72,91] More careful studies suggest that the frequency of PCOS in women with non-classical 21OHD is not much higher than in the general population. Nevertheless, if infertility and chronic anovulation are present in a woman with non-classical 21OHD, these women often benefit from glucocorticoid replacement. Curiously, about 70% of women with non-classical 21OHD in one large series are compound heterozygotes for one non-classical and one classical allele,[92] whereas the majority should be homozygous for non-classical allele given population estimates of carrier frequencies. This result suggests that primarily the less severely affected non-classical 21OHD patients do not come to medical attention. Furthermore, cryptic and largely asymptomatic non-classical 21OHD was found in 4% of parents with children affected by classical 21OHD,[93] all of whom were heterozygous carriers of classical alleles.

Little data exist to guide the optimal management of adults with 21OHD, either for long-term glucocorticoid replacement or for improving fertility.[85] A range of treatment regimens are used without obvious rationale, although the convenience of once-daily dosing favors use of the more potent glucocorticoids including prednisone, prednisolone, and dexamethasone.[94,95] In a large audit of 21OHD patients in England, many were short and obese, with poor health metrics and quality of life, and overtreatment with glucocorticoids appeared to be common.[96] Consequently, the minimum amount of glucocorticoid replacement to maintain testosterone in an acceptable range is recommended for chronic therapy in women, although this dose and target steroid values will vary among individuals. Serum 17OHP should not be normalized, as occurs with over-treatment, but dose adjustments should be based on serum testosterone and androstenedione values. Hydrocortisone is preferable for chronic therapy but must be given in at least two divided doses, although sustained-release preparations are in development.[97,98] Prednisolone and dexamethasone lower androgen production more effectively than hydrocortisone, particularly for the morning rise in ACTH and adrenal-derived steroids, where even bedtime hydrocortisone is not very effective. Fludrocortisone acetate, in doses sufficient to normalize plasma renin activity and serum potassium, eliminate orthostasis, and maintain fluid balance, should be maintained throughout life with rare exceptions.

Despite the many barriers to achieving pregnancy in women with 21OHD, fecundity rates in those women who attempt pregnancy are greater than 90%, equivalent to the general population.[99] The most critical parameter favoring conception appears to be follicular-phase serum progesterone, which should be lowered to less than 0.6 ng/mL (2 nmol/L) with multiple doses of hydrocortisone and/or prednisolone. A bedtime dose of 0.5-2 mg prednisolone, which is combined with either daytime hydrocortisone (two doses) or one dose of prednisolone, appears to be particularly important for achieving pregnancy. Ovulation induction with standard methods and agents might be necessary despite optimal adrenal replacement regimens. Despite clinical features of PCOS shared with 21OHD, metformin and other insulin sensitizers have not been studied adequately in women with 21OHD. Prenatal treatment with dexamethasone has been shown to reduce fetal virilization in couples who have one or more children with 21OHD,[100] but this treatment is considered experimental due to the paucity of long-term outcomes data in treated children with or without 21OHD.[73]

Almost all men with non-classical 21OHD are asymptomatic and can be identified only with genetic testing. Men with classical 21OHD, in contrast, frequently develop infertility, particularly if poorly controlled. Severe adrenal androgen excess rarely causes gonadotropin suppression with subsequent Leydig cell atrophy, reduced testicular testosterone production, and impaired spermatogenesis.[101,102] Glucocorticoid replacement often normalizes testicular function, although high doses are often required initially. More commonly, adrenal rests are the cause of male infertility in 21OHD.[103] The steroid-producing cells of the adrenal cortex and the gonads derive from the same pool of precursors during embryogenesis. The migration of adrenal cells to the suprarenal space can be imperfect, and adrenal cortex cells or progenitors appear to reside in the testis or within the groin and abdomen. ACTH is trophic for these adrenal rest cells as well, and when ACTH is high as in poorly controlled 21OHD, these cells will form masses, most often in the testis itself. These tumors are present in most men with 21OHD, and their size correlates better with adrenal volume than with single steroid measurements.[104] Testicular ultrasonography is the most sensitive method of diagnosis, although many are palpable.[105] Because the testis is confined to a rigid capsule, the growth of intra-testicular adrenal rests impairs testicular blood flow and efflux of sperm into the ejaculate. Treatment of adrenal rests requires potent glucocorticoids, such as dexamethasone, 1-2 mg at night, although even this therapy is not always successful in reducing tumor size and restoring fertility. Combination therapy with daytime hydrocortisone and low-dose (0.1 mg) bedtime dexamethasone also appears effective and less toxic than dexamethasone monotherapy at higher doses.[106] Surgical resection of the adrenal rests by a competent urologist is associated with a low risk of recurrence but with little improvement in spermatogenesis.[107] This result, however, could reflect a selection bias in reserving surgery for the most severely affected men.

Other CAH

The other forms of CAH associated with androgen excess in women are 11-hydroxylase deficiency (11OHD) and 3β-hydroxysteroid dehydrogenase/isomerase deficiency (3βHSDD). In 11OHD, caused by mutations in the *CYP11B1* gene, the 11-deoxysteroids 11-deoxycorticosterone (DOC) and 11-deoxycortisol are markedly elevated, and excess DOC causes hypertension and hypokalemia unlike 21OHD.[108] Serum 17OHP may be elevated in 11OHD, but much less than in 21OHD with similar hyperandrogenemia. In 3βHSDD, caused by mutations in the *HSD3B2*

gene, the diagnostic steroid ratios are those of delta-5 to delta-4 steroids, such as 17-hydroxypregnenolone/cortisol ratios greater than 6 standard deviations above normal.[109] Note that circulating testosterone concentrations are paradoxically elevated in women with 3βHSDD. The delta-5 steroids DHEA and DHEAS are metabolized to active androgens in the periphery and converted to delta-4 steroids by 3βHSD type 1, which is abundant in liver and skin, explaining this phenomenon.

The mechanisms responsible for infertility in men and women with 11OHD are similar to those in 21OHD. Treatments are similar, except that mineralocorticoid receptor antagonists (spironolactone, eplerenone) are useful to control hypertension during chronic therapy. Note that spironolactone is also an androgen receptor antagonist and is contraindicated in women who have unprotected intercourse. Women with 3βHSDD, even in the most severe cases, have mild clitoromegaly and little labioscrotal fusion, so anatomical impediments to pregnancy are less important, and high progesterone is less of a negative factor for reproduction than in 21OHD and 11OHD.[109]

Forms of CAH that impair both androgen and estrogen production include combined 17-hydroxylase/17,20-lyase deficiency,[110] caused by mutations in the *CYP17A1* gene encoding P450c17,[111] and isolated 17,20-lyase deficiency,[112] due to mutations in *CYP17A1*[113,114] or its redox partner proteins cytochrome P450-oxidoreductase (*POR* mutation G539R)[115] and cytochrome b_5.[116,117] Lipoid CAH, due to mutations in the *STAR* gene encoding the steroidogenic acute regulatory protein (StAR)[118] or rarely the *CYP11A1* gene encoding P450scc,[119] abrogates all steroid production, although a non-classic form with partial StAR deficiency mainly impairs cortisol production.[120] POR deficiency manifests as a spectrum of phenotypes with disordered steroidogenesis,[121] from primary amenorrhea in phenotypically normal women to the Antley-Bixler syndrome, with skeletal dysmorphologies.[122,123] The discussion of these diseases is beyond the scope of this chapter, and fertility is very rare in these patients despite the optimal therapy.

Thyroid Disorders

Overview

Before discussing the specific effects of thyroid disorders on reproductive function, it is important to understand some basic principles and potential areas of interaction between elements of thyroid hormone physiology and reproductive function.

Within the thyroid gland, millions of follicles are the factories and storage silos for all of the circulating T_4 and 20% of the active T_3 thyroid hormone. The thyroid follicle is composed of simple secretory epithelial cells surrounding a lumen containing colloid—a gelatinous substance composed primarily of thyroglobulin and T_4 (Fig. 25.7). The unique aspect of the thyroid gland is its ability to store enormous quantities of thyroid hormone in the follicular colloid. Iodide imported from the circulation and concentrated in colloid is used for iodination of the thyroglobulin backbone by thyroid peroxidase (TPO) (Fig. 25.8) to produce inactive precursor mono- and diiodotyrosines. Synthesis of T_4 and T_3 using these precursors is also catalyzed by TPO. Reuptake

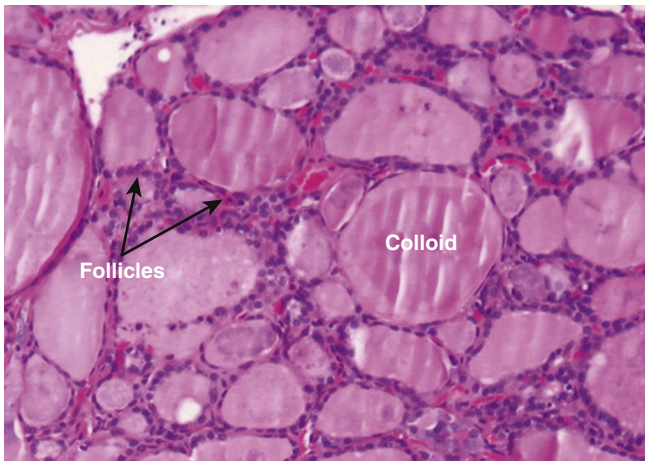

FIGURE 25.7 Histology of a normal thyroid gland. Shown is a 100× magnification of a hematoxylin and eosin-stained section of normal thyroid. Single-layer, epithelial-lined follicles of variable sizes are filled with pink colloid where thyroglobulin, T_3, and T_4 are stored.

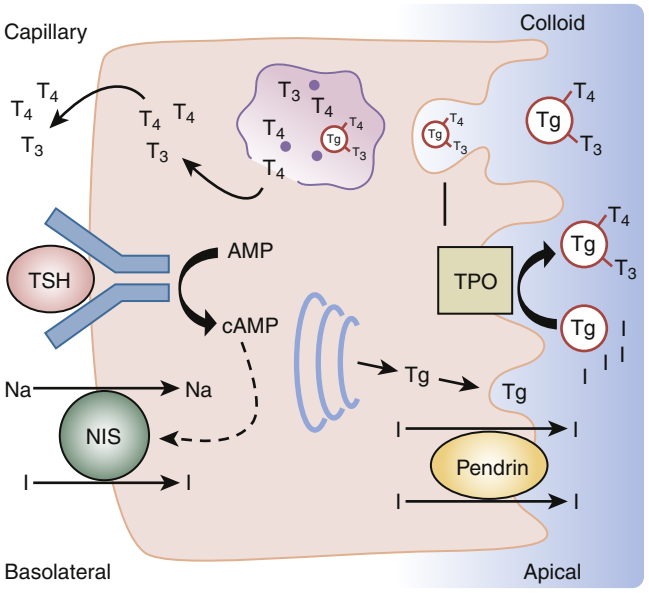

FIGURE 25.8 Production of thyroid hormone in the follicular epithelial cell. This schematic illustrates the variety of functions carried out in the follicular epithelial cell from iodine (I) transport via the sodium iodide symporter (NIS), thyroglobulin (Tg) synthesis, iodination, and T_4 production by thyroid peroxidase (TPO) at the apical membrane where Tg and Tg complexed with T_3 and T_4 are stored. Reuptake and Tg digestion from the complexes allows for secretion of T_3 and T_4 through the basolateral membrane into the abundant capillary network. Stimulation by thyrotropin (TSH) of the TSH receptor results in cyclic AMP (cAMP) production, which augments hormone production by stimulating many cellular functions.

and Tg digestion off of the stored T_3 and T_4 from the colloid allows for secretion through the basolateral membrane into the abundant capillary network.

As described in the pituitary section overview, the hypothalamic-pituitary-thyroid axis is a straightforward model of an endocrine feedback system. The anterior pituitary secretes TSH, which regulates multiple steps in thyroid hormone production: (1) growth of the follicles, (2) iodine uptake, and (3) iodinaton of thyroid hormone by

the secretory epithelial cells. Control of TSH secretion, and therefore, ultimate control of all elements required for thyroid hormone production, is tightly regulated by negative feedback of circulating T_4 and T_3, suppressing production of both TRH from the hypothalamus and TSH by the anterior pituitary (Fig. 25.1A).

Outside of the hypothalamic-pituitary-thyroid axis, the major regulator of thyroid hormone production is the concentration of thyroid hormone globulin (TBG). Circulating T_4 is almost entirely (99%) bound to plasma proteins—approximately 70% bound to TBG, 20% to transthyretin (prealbumin), and 10% to albumin. In women, significant changes in TBG glycosylation in the liver are induced by rises in estradiol during pregnancy or exogenous estrogens, prolonging TBG half-life, and increasing circulating TBG concentrations.[124] The rise in TBG can transiently decrease free T_4 concentrations, leading to an increase in the TSH and total T_4 to maintain normal free T_4. During pregnancy, this may also lead to a visible enlargement of the thyroid gland or goiter. Peripheral conversion of T_4 to T_3 is mediated by deiodinases, types 1 and 2 located in different locations both at the tissue and cellular level. Interestingly, type 3 deiodinase is almost exclusively expressed in the placenta where it is tightly regulated by thyroid hormone concentrations.

Thyroid Disorders that Affect Reproduction

Diseases of the thyroid are more common in women than men. The most common conditions are Hashimoto's thyroiditis and Graves disease, both autoimmune diseases of the thyroid. Despite the importance of thyroid hormone in maintaining normal organ and endocrine function throughout the body, the exact mechanisms for thyroid hormone's effects are not well understood. Notably, it is the absence of thyroid hormone (hypothyroidism) and the multitude of accompanying symptoms that demonstrates its importance throughout the body. Similarly, for reproduction, hypothyroidism has more significant effects on menstrual cycles and fertility than hyperthyroidism, or more generally, thyrotoxicosis. Hypothyroidism may exert more of an effect on reproduction through a decrease feedback to the hypothalamic-pituitary axis, subsequent hyperprolactinemia, and interference with GnRH pulsatility and ovulation. The effect of low and high thyroid hormone concentrations on reproduction may also be mediated indirectly by effects on sex hormone binding globulin (SHBG) function and production as well as directly on steroidogenesis and sperm morphology, production, or function.[125] Subclinical hypothyroidism and autoimmune thyroid disease have been associated with decreased fertility and miscarriage, although the mechanism and benefit from treatment with thyroid hormone replacement are still not clear.[126-128]

Hypothyroidism

The overall prevalence of hypothyroidism is 3.1% in reproductive age women.[129] Women with hypothyroidism present with any of numerous symptoms and signs (Table 25.4). The reproductive age woman may experience irregular menses, anovulatory cycles, menorrhagia, or present only with infertility.[125] A significant mechanism for alterations in the reproductive system is through the hypothalamic-pituitary axes. While basal gonadotropins are normal, elevated TRH can stimulate lactotrophs to produce prolactin, which interferes with GnRH pulsatility as described earlier in the pituitary section. In women and men, hypothyroidism reduces SHBG binding affinity through altered sialic acid content, which reduces total and often free fractions of estrogens and androgens[130]; conversely, hyperthyroidism increases SHBG production.[131] Hypothyroidism may also interfere with ovarian function. Experimentally, T_4 has been shown to stimulate ovarian steroidogenesis in granulosa cells cultured *in vitro*.[132] In men, hypothyroidism has been associated with decreased libido, erectile dysfunction, and abnormalities of sperm morphology or motility.[125] As opposed to women, the hypogonadotropic hypogonadism associated with hypothyroidism is not associated with hyperprolactinemia, but the hypogonadism can correct after thyroxine replacement.[133] Abnormalities of sperm count, motility, and morphology as well as erectile dysfunction and poor testosterone response to hCG injections also improve after T_4 replacement.[134,135]

Table 25.4 Common Clinical Presentations of Thyroid Disorders

Hypothyroidism	Hyperthyroidism
Weight gain	Weight loss
Fatigue	Fatigue
Constipation	Increased frequency of bowel movements
Cold intolerance	Heat intolerance
Hair loss	Anxiety
Menorrhagia	Dyspnea on exertion
Infertility	Palpitations
Dry skin	Diaphoresis
Periorbital edema	Lid lag or "stare"
Hoarseness	Tremor
Delayed reflexes	Hyperreflexia
Anemia	Supraventricular arrhythmias

Subclinical Hypothyroidism and Autoimmune Thyroid Disease

While more severe hypothyroidism clearly interferes with successful ovulation and fertility, more subtle abnormalities of the pituitary-thyroid axis or the underlying autoimmune disease may also affect fertility. In one study of women presenting to an infertility clinic with normal thyroid function tests, women with lower or higher than normal responses to TRH stimulation had lower pregnancy rates than women with normal responses.[136] Few studies have investigating the role of subclinical hypothyroidism in male reproduction. In one study, men with subclinical hypothyroidism had the same hypogonadotropic hypogonadal profile as hypothyroidism, but there was no association with changes in sperm quality.[137] Treatment of subclinical hypothyroidism with T_4 replacement has only been shown to improve pregnancy outcomes in women positive for anti-TPO antibodies.[138]

Multiple studies have reported an association of antithyroid antibodies and miscarriage and preterm birth in euthyroid women.[127,139] However, it is not clear whether this association represents a more generalized autoimmunity or a need for thyroid hormone replacement. There are only two small studies with T_4 replacement in euthyroid women with antithyroid antibodies with two meta-analyses in disagreement

whether there is a significant risk reduction of miscarriage and preterm delivery with treatment.[127,128,140,141] Until a large, randomized placebo-controlled trial provides stronger evidence of a treatment effect, T_4 replacement is not recommended to prevent miscarriage in women with anti-TPO antibodies if they are euthyroid. T_4 treatment should only be considered in women with anti-TPO antibodies who have subclinical or clinical hypothyroidism.[126]

The most common cause of hypothyroidism is chronic autoimmune thyroiditis (Hashimoto thyroiditis). In addition to Hashimoto thyroiditis, hypothyroidism may also be seen in patients with acute (silent) and subacute thyroiditis (Table 25.5). Postpartum thyroiditis is an acute thyroiditis that occurs within 6 months of delivery and is usually self-limited. Thyroiditis typically has an acute thyrotoxic phase followed by a hypothyroid recovery phase and eventually a euthyroid phase. Postpartum thyroiditis typically presents with symptoms in the hypothyroid phase, whereas subacute thyroiditis presents with pain during the hyperthyroid phase. Although most return to a euthyroid state in the short-term, 20% to 64% of these women will develop chronic hypothyroidism over the next few years.[142] An important secondary cause of hypothyroidism is radioactive iodine ablation or thyroidectomy for definitive treatment of Graves disease, thyroid nodules, or thyroid cancer.

The diagnosis of hypothyroidism itself is easily made with modern immunoassays. Clinical hypothyroidism is defined by both higher than normal TSH and lower than normal free T_4 concentrations. An elevated TSH greater than 10 mIU/L is a clear indicator of hypothyroidism with very rare exceptions (Fig. 25.9). Subclinical hypothyroidism describes the mild or early changes when the TSH rises before the free T_4 falls below normal. The mild elevation in TSH compensates for the early decline in T_4 production by the thyroid gland. During pregnancy, trimester-specific and lab-specific reference ranges should be used to determine the optimal TSH range and the diagnosis of clinical hypothyroidism.[126] Although not necessary for the diagnosis of hypothyroidism, additional tests of anti-TPO and anti-thyroglobulin antibodies may influence treatment decisions by establishing underlying Hashimoto's thyroiditis. The presence of anti-TPO antibodies increases the risk for developing clinical hypothyroidism from 2.1% to 4.3% per year.[143] Age and female gender also increase the risk of progression to overt hypothyroidism.

The treatment of hypothyroidism involves replacement of thyroid hormone with synthetic T_4 (levothyroxine). A general guide for replacement is a weight-based dose of 1.6 μg/kg once daily, but actual requirements may vary. After initiation or dose adjustment, follow-up tests should be ordered after at least 6 to 8 weeks. To minimize problems with absorption, levothyroxine should be taken without other drugs, especially calcium or iron-containing tablets.

For the woman known to have hypothyroidism prior to pregnancy, very close monitoring of the TSH is required to maintain a euthyroid state given the increase in TBG and therefore total T_4 requirements. This dose increase is particularly important for the fetus, with strong evidence that maternal hypothyroidism may affect fetal intellectual development during the first trimester when the fetus is dependent on maternal thyroid hormone.[144] Maternal hypothyroidism and subclinical hypothyroidism are associated with a higher risk for miscarriage, hypertension in pregnancy, low birth weight from premature delivery,[145,146] and gestational diabetes.[147] Guidelines suggest achieving a target of TSH less than 2.5 μU/mL before pregnancy to lower the risk for maternal hypothyroidism in the first trimester.[126,148] The T_4 dose usually needs to be increased by anywhere from 10% to 20% to as high as 30% to 50% within the first month of gestation, and therapy should be monitored at least every 4 weeks in the first trimester after any adjustment.[126,149]

Table 25.5 Common Causes of Thyroid Disorders

Primary Hypothyroidism	Primary Hyperthyroidism
Chronic autoimmune thyroiditis (Hashimoto)	Graves disease
Radioiodine ablation	Toxic multinodular goiter
Thyroidectomy	Solitary toxic nodule
Silent/postpartum thyroiditis (hypothyroid phase)	Silent/postpartum thyroiditis (lymphocytic)
Subacute thyroiditis (hypothyroid phase)	Subacute thyroiditis (granulomatous)
Iodine deficiency	Iodine-induced (e.g., amiodarone)
Drugs (thionamides, lithium)	Exogenous thyroid hormone ingestion

Hyperthyroidism

Women and men with hyperthyroidism present with typical findings of weight loss, palpitations, anxiety, and increased frequency of bowel movements. For women, although oligomenorrhea and amenorrhea may be more common in women with hyperthyroidism than euthyroid women, there is less evidence of ovulatory dysfunction and infertility in hyperthyroidism than hypothyroidism. Fewer studies have

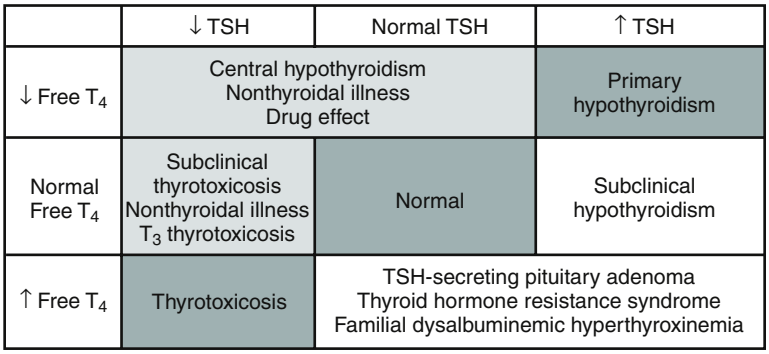

FIGURE 25.9 Differential diagnosis of thyroid disorders based on TSH and free T_4 results.

evaluated reproductive function in hyperthyroid women. Hyperthyroidism is associated with increased SHBG and estrogen concentrations. Abnormalities in basal and stimulated gonadotropins have been observed in women with hyperthyroidism, which reverses after treatment for hyperthyroidism.[125] During pregnancy, there can be subtleties to the diagnosis of thyrotoxicosis and distinguishing hyperthyroidism from normal physiological changes, hyperemesis gravidarum, and gestational trophoblastic disease. As opposed to association of antithyroid antibodies with fertility and miscarriage rates, the thyroid receptor stimulating antibodies of Graves disease have more of an impact on the fetus and the risk for neonatal thyrotoxicosis.[126]

In men with Graves disease, symptomatic hypogonadism and bioavailable testosterone lower than normal controls have been observed despite the overall increase in total testosterone and SHBG. These findings have been associated with impaired gonadotropin response to hCG and significant abnormalities in semen quality. Changes in semen parameters could be reversed with anti-thyroid treatment.[150] Older men are more likely to be clinically affected because of a lower gonadal reserve to compensate for the increases in SHBG. Elevated estradiol may result in gynecomastia and also likely explains the normal gonadotropin concentrations with low free testosterone.[125]

Graves disease is the most common cause of hyperthyroidism. In addition to the symptoms of thyrotoxicosis and goiter, patients may present with the typical stare and extraocular muscle paralysis resulting from infiltrative orbitopathy and opthalmopathy. Graves disease is an autoimmune disease with the thyroid stimulating immunoglobulin or anti-TSH receptor antibody driving unregulated stimulation of thyroid hormone production.

Thyroiditis refers to any inflammatory state of the thyroid. The thyrotoxicosis of thyroiditis results from release of stored thyroid hormone, which may persist for up to 2 months. As discussed above, the usual course is then transient hypothyroidism followed by recovery of thyroid function, although chronic hypothyroidism may also develop. Subacute (de Quervain's) thyroiditis is distinguishable by a history of neck pain and recent viral infection and physical findings of fever and exquisitely tender thyroid. The serum thyroglobulin is often elevated in thyroiditis, and the erythrocyte sedimentation rate is particularly elevated in subacute but not silent thyroiditis.

Other potential causes of thyrotoxicosis include an autonomous thyroid nodule and multi-nodular goiter. Toxic adenoma, which is less common than Graves' disease or toxic multinodular goiter, is usually a benign, solitary tumor with autonomous T_4 and T_3 production. In a large proportion of toxic adenomas, a somatic or germline mutation in the genes encoding the TSH receptor or G protein subunits results in constitutive activation of TSH receptor signaling.[151] Multi-nodular goiter is less likely to cause hyperthyroidism in reproductive age women and is more common in older patients. Growth and the development of autonomous function take years to manifest as hyperthyroidism, and most toxic adenomas are greater than 3 cm in diameter.

The diagnosis of thyrotoxicosis is clear with an elevated free T_4 and low TSH. However, a low TSH with a low or normal free T4 has several additional diagnoses to consider other than subclinical hyperthyroidism (Fig. 25.9). Diagnosis of thyrotoxicosis during pregnancy should be made more cautiously than hypothyroidism, because the TSH level can be low in the first trimester due to hCG-mediated thyroid stimulation. Because total T_4 is elevated due to the increased TBG during a normal pregnancy, pregnancy-specific ranges for total T4 should be used. Alternatively, free T4 concentration can be measured and will only be elevated above non-pregnant ranges in overt hyperthyroidism.

Radioactive iodine scans are not necessary to make the diagnosis of hyperthyroidism but are most useful for distinguishing Graves disease from toxic adenoma (Fig. 25.10), thyroiditis, and factitious disorder. Usually, clinical factors obviate the need for diagnostic scans. Especially since radioactive iodine scans are contraindicated during pregnancy, another useful test is the thyroid stimulating immunoglobulin (TSI) or thyroid receptor antibody (TRAB). Elevated TSI or TRAB supports the diagnosis of Graves disease and is recommended for measurement in the week 20 to

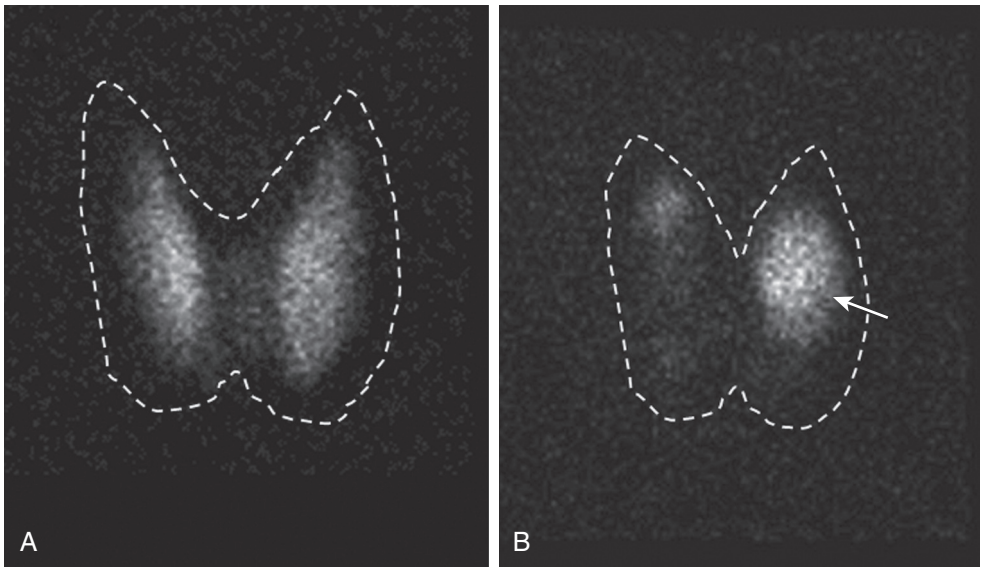

FIGURE 25.10 Radioactive iodine-123 scans to distinguish Graves disease from toxic adenoma. **A**, Increased radioactive iodine uptake seen symmetrically throughout a thyroid gland with Graves disease. **B**, Increased uptake by a toxic adenoma, indicated by *arrow*, with little uptake elsewhere. The dotted lines approximate the outline of the thyroid gland with minimal uptake in comparison to the adenoma.

24 of pregnancy to determine the need for increased fetal monitoring. In pregnancy, breastfeeding, or women trying to conceive, ultrasonography with Doppler blood flow may be useful for distinguishing Graves disease from thyroiditis. The need for experienced technicians and radiologists, however, limits the ability to recommend the general use of ultrasonography for this purpose.[126]

The pharmacological treatment of Graves disease is antithyroid treatment with a thionamide—typically propylthiouracil from 50 mg tid to 100 mg qid or methimazole 5 to 40 mg per day in one or two divided doses, although thionamide doses twice as high are used for the first few days or weeks in severe or life-threatening thyrotoxicosis. The goal of therapy initially is a T_4 in the normal range, as the TSH rise may lag behind. Patients may experience a sustained remission after 12 to 18 months of therapy. Elevated T_4 from thyroiditis is both transient and will not respond to anti-thyroid treatment. Symptoms of palpitations, anxiety, and tremor can be managed with a beta-blocker such as propranolol or metoprolol. In the case of subacute painful thyroiditis, pain responds to non-steroidal anti-inflammatory drugs or a course of corticosteroid therapy. Thionamides are useful for restoration of euthyroidism in patients with toxic adenomas and multi-nodular goiters, but usually definitive therapy (below) is required.

Radioactive iodine-131 ablation is an alternative to antithyroid agents for hyperthyroidism (aside from thyroiditis). When counseling reproductive age women and men about ablation, there is no evidence that previous radioactive iodine ablation at low doses used for hyperthyroidism will affect subsequent fertility in women or men or increase the risk for congenital abnormalities.[125,126,152] In higher doses used for thyroid cancer remnant ablation, radioactive iodine may be associated with azospermia, and sperm cryopreservation should be discussed with young men to preserve fertility for the first few months to years after therapy.[125] Otherwise, guidelines suggest women wait at least 6 months after ablation to ensure that target TSH values are obtained on T_4 replacement therapy.[126]

Methimazole is the preferred anti-thyroid treatment for hyperthyroidism over propylthiouracil due to concerns of hepatotoxicity. One important exception is the first trimester of pregnancy because of the rare association of methimazole with congenital abnormalities. After the first trimester of pregnancy, it is recommended that pregnant women are switched to methimazole for the remainder of the pregnancy.[126,153] In practice, methimazole is often used throughout pregnancy if unable to successfully control T_4 concentrations with PTU due to tolerability and efficacy issues. The goal for therapy in hyperthyroidism prior to conception or while pregnant is a free T_4 at or slightly above the upper limit of the normal range to avoid hypothyroidism.[126]

Surgery—thyroidectomy or resection of a toxic adenoma—is generally reserved for treating hyperthyroidism in disease refractory to medical therapy, for glands that are producing obstructive symptoms, for large nodules, and when radioactive iodine is contraindicated or refused. In pregnancy, surgery is reserved for cases when disease is severe and refractory to medical therapy, or when antithyroid agents cannot be used due to the side effect of agranulocytosis or liver damage.

CHAPTER 26

Endometriosis

Robert Taylor
Dan I. Lebovic

Endometriosis is a chronic condition characterized by the growth of hormone-responsive endometrial tissue outside the uterine cavity. Typically, ectopic endometriotic implants are found on the peritoneal surface, within the ovary or invading the rectovaginal septum; however, many examples of more widely distributed lesions have been described. Several studies suggest that the overall prevalence of endometriosis among reproductive-age women is around 11%.[1] This disease is accompanied by pelvic pain or infertility in up to 90 million women worldwide. Its symptoms are associated with work absenteeism, social isolation, and high costs of therapy. In addition, endometriosis is the third most common indication for hysterectomy in the United States.[2] This outcome can be particularly devastating in women who undergo hysterectomy for endometriosis before the age of 30, because they are likely to have residual somatic symptoms and a psychological sense of loss.[3] Careful estimates of healthcare costs for 2002 in the United States were $22 million.[4] Furthermore, in a cohort study of more than 1.4 million births in Sweden, women with endometriosis were associated with an increased risk of cesarean section, preterm delivery, preeclampsia and antepartum hemorrhage.[5]

History and Histogenesis

Classical Theories of the Origins of Endometriosis

Scholars of this disease have traced original sources that describe the pathological features of endometriosis in Dutch and Belgian women of the late 1600s.[6] Curiously, the prevalence of endometriosis remains high in that part of the world.[7] The great German pathologists von Rokitansky and Meyer wrote extensively about this disorder in the latter part of the 19th century. In the United States, the first clear pathological description of an ovarian endometrioma was reported to the Johns Hopkins Medical Society in 1899.[8] Dr. John A. Sampson graduated from Johns Hopkins that same year. After more than 25 years in the practice of gynecological surgery, he put forward the hypothesis that endometriosis lesions arose from endometrial tissue that escaped through the fallopian tubes at the time of menstruation. This tissue, he postulated, implanted on peritoneal surfaces and regenerated an endometrial epithelial lining.[9] Contemporaneously, Halban proposed that viable endometrial cells might travel via hematogenous or lymphatogenous vascular transport.[10] Although this metastatic theory explains rare manifestations of distant, extraperitoneal lesions (e.g., endometriosis in the brain[11] or nose[12]) it does not explain the gravity-dependent, intraperitoneal location of most foci of endometriosis.

Retrograde Menstruation and Implantation

Even today, the prevailing theory concerning the etiology of endometriosis is the implantation hypothesis set forth by Sampson.[9] This theory has been supported by the documentation of reflux menstruation[13] and intraperitoneal spillage of viable endometrial cells[14] in ovulating women (Fig. 26.1).[15] Furthermore, the incidence is increased in cases of menstrual outflow obstruction; in women with known endometriosis, ablation of the eutopic endometrium dramatically reduced the risk of recurrence.[16] Interestingly, the recurrence rate of endometriosis was lower in women who had vaginal deliveries than in nulliparous women or those undergoing cesarean section suggesting cervical dilatation following vaginal parturition reduces resistance to menstruum.[17] That more than 60% of unilateral lesions occur in the left hemipelvis also is consistent with accumulation of refluxed cells in this location, due to the position of the mesentery of the sigmoid colon.[18]

The adhesion of shed endometrial cells to peritoneal and subperitoneal surfaces involves the expression of extracellular membrane adhesion molecules and their coreceptors. Although some researchers have argued that implants of endometrium have never been clearly visualized microscopically in the process of attaching to the peritoneum,[19] the *in vitro* findings of Witz and colleagues[20] indicate that the process of implant invasion into the subperitoneal space is so rapid that one would not expect to observe adherent fragments of endometrium (Fig. 26.2).[21] This origin has been proposed by Nisolle and Donnez[22] to be the most likely source of intraperitoneal lesions *in vivo*.

Coelomic Metaplasia

An alternative hypothesis, historically attributed to Meyer,[23] suggests that metaplasia of the coelomic epithelium is the origin of endometriosis. This theory is logical, because cells from both the peritoneum and endometrium derive from a common embryologic precursor: the coelomic cell. However, this theory has been difficult to support scientifically.

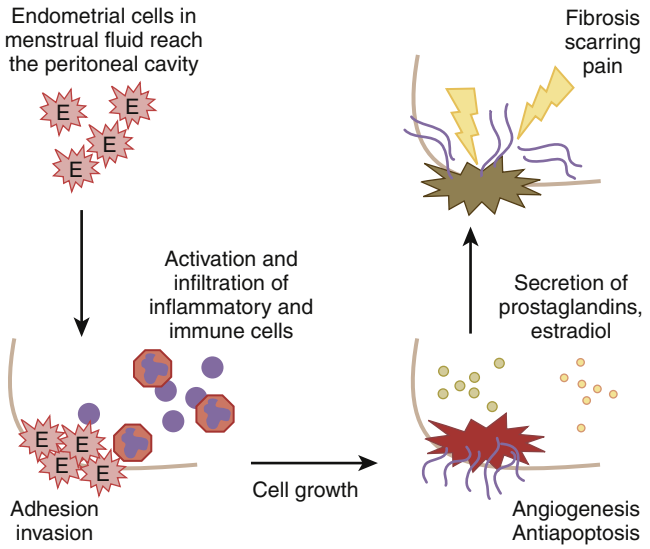

FIGURE 26.1 Proposed establishment of peritoneal endometriotic implants via retrograde menstruation, attachment, proliferation, migration, neovascularization, inflammation, and fibrosis. E, endometrial cell. *(From Flores I, Rivera E, Ruiz LA, et al. Molecular profiling of experimental endometriosis identified gene expression patterns in common with human disease.* Fertil Steril *87:1180–1199, 2007.)*

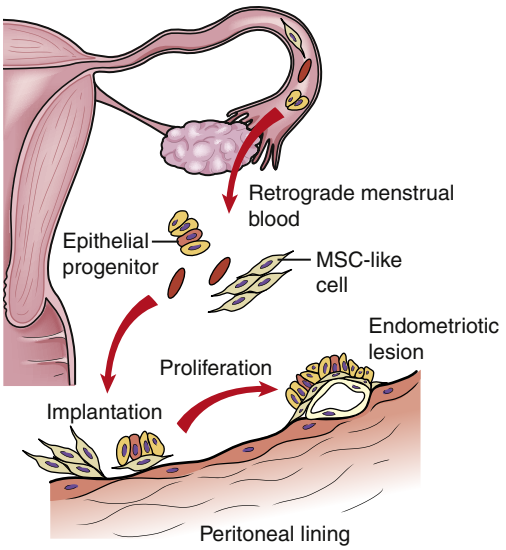

FIGURE 26.3 Role of endometrial stem cells in the pathogenesis of endometriosis. Endometrial epithelial progenitor cells and mesenchymal stem-like cells (MSC) enter the peritoneal cavity via retrograde menstruation wherein they establish endometriotic lesions. *(Adapted from Gargett CE, Masuda H. Adult stem cells in the endometrium.* Mol Hum Reprod *16:818–834, 2010.)*

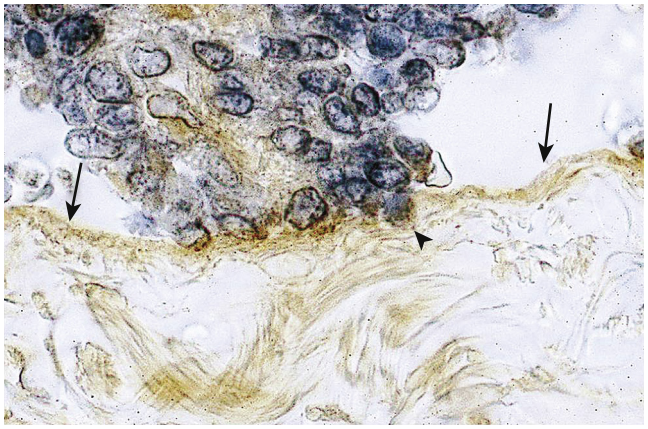

FIGURE 26.2 Early invasion of an endometrial implant through the mesothelium. The mesothelium is labeled with monoclonal antibody to cytokeratin and stained with diaminobenzidine *(arrows)*. An endometrial stromal cell *(arrowhead)* passing through the mesothelium is thought to represent the initial step of invasion into the stroma of the peritoneum. Original magnification, ×31,000. Counterstained with hematoxylin. *(From Witz CA, Monotoya-Rodriguez IA, Schenken RS. Whole explants of peritoneum and endometrium: a novel model of the early endometriosis lesion.* Fertil Steril *71:56–60, 1999.)*

If the postulate were correct, one would expect much higher rates of pleural endometriosis because that mesothelium is the same as that which lines the abdominal cavity. Furthermore, investigators have been unable to show that peritoneal cells can be experimentally differentiated into endometrial cell types. Lastly, metaplasia is an age-related process. Endometriosis occurs early in reproductive-aged women, and its incidence peaks in the third decade. This pattern would not be predicted by a linear, progressive likelihood of metaplasia. Nevertheless, this has been postulated as the most likely source of deep, adenomyotic nodules of endometriosis in the rectovaginal septum[22] and in some cases of endometrioma.[24] A related theory, that is more straightforward in pathophysiology, is the embryogenetic theory: atypical locations of müllerian duct cells deposited during migration at the time of embryogenesis. With the onset of menarche and stimulation with estradiol, these ectopic cells may then grow into classic endometriotic lesions. Signorile and colleagues buttressed this theory when they found 9% of 101 human female fetuses possessed primitive endometrium outside the uterine cavity.[25]

Neoclassical Theories of Endometriosis Histogenesis

In the past decade, scholars of endometriosis have considered integrated models for the etiology of this disorder. We currently recognize that genetic, anatomical, endocrine, immunological, and possibly environmental factors influence the risk of developing endometriosis. Hence, the neoclassical view of this syndrome requires a broader conceptualization of its etiology and the mechanisms whereby endometriosis produces its clinical symptoms. Based on histological and biochemical similarities of endometriosis lesions with the basalis layer of the endometrium, Leyendecker and colleagues suggested that endometriosis is derived from the subendometrial zone that they refer to as *archimetra*.[26] More recently, authors have posited that endometriosis may arise from rare adult stem cells residing within the uterus.[27-29] Endometrial mesenchymal stem cells have been isolated in both the basalis and functionalis; these appear to have a predominant perivascular localization (Fig. 26.3).[30]

Epidemiology

Endometriosis has been found in women between the ages of 12 years old and 80 years old, with the average age being

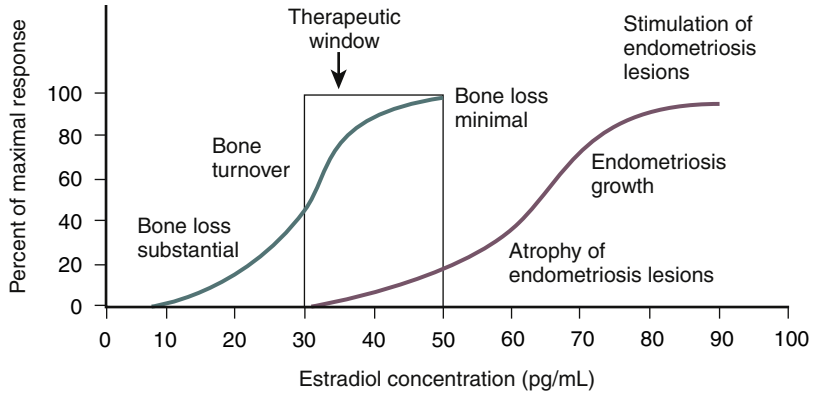

FIGURE 26.4 The estrogen threshold hypothesis postulates that different estrogen target tissues have differential hormone sensitivity. In this model, a therapeutic window of serum estradiol concentration, between 30 and 50 pg/mL, should protect against bone mineral loss and prevent stimulation of endometriosis lesion growth. *(From Barbieri R. Hormone treatment of endometriosis: the estrogen threshold hypothesis.* Am J Obstet Gynecol *166:740–745, 1992.)*

approximately 28 years old. Exposure to ovarian hormones appears to be essential to fostering lesion growth, with the vast majority of the cases found in women aged 20 years old to 50 years old. The estrogen dependency of this condition led Barbieri to propose the hypothesis that concentrations of estradiol over 50 pg/mL were needed to support the growth of endometriosis lesions (Fig. 26.4).[31] This hypothesis will be discussed in more detail when the medical treatment of endometriosis is considered later in this chapter.

In severe disease there seems to be a familial correlation; however, no clear mendelian genetic trait has been identified and most researchers believe it to be complex and multifactorial.[32] These points will be discussed more fully later in this chapter. Retrograde menstruation and increased exposure to menstrual flow (reduced parity, longer duration of menstrual periods, and shorter cycle length) have been identified as risk factors for endometriosis.[33] Recently, environmental factors, such as dioxin[34,35] and other presumed endocrine disrupters have been implicated.[36]

When adolescent girls present with chronic pelvic pain, endometriosis may be found in up to 38% and nearly 70% for those with recalcitrant symptoms.[37,38] In contrast to adults who often present with cyclic pain, these adolescents have a greater prevalence of acyclic pain. Initial surgery usually reveals stage I (77% to 92%) or II disease (8% to 23%) with a preponderance of red lesions (75%) as opposed to that normally seen in adults (25%).[39] Since the disease is progressive,[40] treatment ought to be initiated with oral contraceptives or a progestin regimen in order to impede disease progression as well as preserve fertility.

Demography

The prevalence of endometriosis ranges from 2% to 50% of reproductive-aged women. Unfortunately, this number is widely disparate depending upon the study. In women with infertility, the prevalence ranges from 21% to 47%. This high frequency may be due to the fact that endometriosis plays a causative role in infertility, but it also may be due to a diagnostic selection bias. Women with infertility are more likely to undergo laparoscopy as part of their clinical evaluation, thereby confirming the diagnosis. Childhood and early adulthood body size inversely influence the risk of endometriosis such that a lower body mass index (BMI) is associated with a lower risk.[41] This may be related to the finding that in adolescents, a lower BMI is associated with a later age of menarche and a lower incidence of the disease (OR, 0.3; 95% CI, 0.1-0.6).[42] Asian women have a ninefold greater risk of developing endometriosis compared to white women.[43]

Observations of a high prevalence of endometriosis in primate colonies exposed to dioxin,[44] a particularly potent polychlorinated biphenyl (PCB) industrial contaminant, have suggested that this compound might influence the risk of endometriosis in women. Recent case-control studies revealed increased adjusted odds ratios for endometriosis in women exposed to dioxins and other PCB chemicals of this type.[45,46] *In utero* exposure to PCBs was shown to induce an endometriosis-like uterine phenotype (e.g., reduced progesterone receptor levels) in females of the F1 generation.[47]

Genomics, Genetics, and Epigenetics

Genes seem to influence susceptibility for endometriosis[48]; however, as previously noted, the mode of hereditary transmission appears to be polygenic and likely to involve multiple loci.[32] Several lines of evidence implicate genetics as a risk factor. In one study, first-degree female relatives (mothers and sisters) of women with severe endometriosis had a 7% incidence, whereas primary female relatives of their partners (who typically have similar ethnic and socioeconomic status) had less than 1% incidence of endometriosis.[49] Consistent with this observation is the finding of Kennedy and colleagues that familial cases of endometriosis tend to be more severe and have an earlier onset of symptoms than sporadic cases.[50] Large population studies based in Iceland and Australia and the United Kingdom identified loci on chromosome 9q and 10q, respectively, significantly associated with endometriosis, but retrospective sib-pair analyses of this type can be complicated by diagnostic misclassification.[51,52]

Over the past several years, complementary DNA (cDNA) microrray methods have been used to identify endometriosis-related genes. Giudice and colleagues[53] were among the first to use Affymetrix chips with arrayed oligonucleotides and observed that many progesterone-regulated genes are relatively downregulated in eutopic (intrauterine) endometrium of women with endometriosis. This effect appears to be most dramatic for gene expression in the early secretory phase of the cycle.[54] Genes involved in oxidative stress, and the wingless-related integration site (WNT) and mitogen-activated protein (MAP) kinase signalling pathways have been consistently reported.[55] Our group[56] focused on the reduced expression of glycodelin mRNA, which encodes

a progesterone-regulated, secreted glycoprotein associated with immunological tolerance of the semiallogeneic blastocyst. These findings are consistent with a comprehensive meta-analysis showing lower embryonic implantation rates in women with advanced endometriosis undergoing *in vitro* fertilization. This study is discussed in more detail later in the chapter.

Another powerful genomic screening technique was introduced by Liang and Pardee in 1992.[57] Differential display–polymerase chain reaction (dd-PCR), in a fashion akin to subtraction hybridization, employs random sets of oligonucleotide primers and PCR to amplify fragments of differentially expressed cDNAs from two different tissues. Endometriotic implants and biopsies of eutopic endometrium from normal and endometriosis cases were obtained in the midproliferative phase of the ovulatory cycle and analyzed by Lundeen and colleagues[58] using this technique. One interesting PCR product was observed to be consistently up-regulated in ectopic and eutopic endometriotic tissue relative to normal eutopic endometrium. The cDNA was shown to correspond to the zinc-finger transcription factor, early growth response-1 (EGR-1). EGR-1 is an interesting candidate because it can be activated by a variety of upstream signaling molecules that are known to be associated with endometriosis, including estradiol, interleukin (IL)-lβ, IL-6, and TNF-α.[56]

Lebovic and colleagues[59] compared cDNAs expressed in normal endometrial stromal cells with those derived from endometriotic implants, with and without pretreatment with the inflammatory cytokine IL-lβ. Endometriotic stromal cells substantially down-regulated a tumor suppressor gene *(TOB1)* in response to IL-1β treatment, whereas normal endometrial stromal cells showed no effect of IL-1β. *TOB1* is an endogenous inhibitor of the *ERBB2* receptor, a member of the epidermal growth factor receptor family that is overexpressed in many human cancers. Monoclonal antibodies directed against this receptor, such as trastuzumab, and other inhibitors of *ERBB2* have been shown to reduce the progression of metastatic breast cancer.[60] In a similar study of normal endometrial stromal cells, Rossi and colleagues found angiogenic and extracellular matrix remodeling genes were upregulated by IL-1β.[61] The significance of these findings in endometriosis is that endometriotic stromal cells appear to have a growth advantage in an inflammatory environment, mediated by the attenuation of a natural inhibitor of mitotic activity induced through the *ERBB2* receptor pathway.

A new development in the genetics of endometriosis is the identification of micro-ribonucleic acid (miRNA) expression. These small RNAs hybridize with mRNA transcripts and induce their degradation, functionally repressing gene actions. MiRNAs have been identified that would be expected to reduce production of steroid receptors known to be down-regulated in endometriosis. These may become interesting new targets for endometriosis therapeutics.[62-65]

Cytogenetics of Endometriosis

Cytogenetic methods that assess gene content in intact or microdissected endometriotic tissues include chromosome satellite painting and comparative genomic hybridization. Kosugi and colleagues[66] used fluorescence *in situ* hybridization (FISH) to find substantially increased aneuploidy and loss of heterozygosity of chromosome 17 in endometriotic lesions. Interestingly, this chromosomal region is the location of several tumor suppressor genes important in the normal regulation of the mitotic cell cycle. Among these is the *p53* locus, which is lost in cases of severe endometriosis,[67] and the *TOB1* tumor suppressor, noted to be preferentially down-regulated in endometriotic cells treated with IL-1β.[59] A 50% loss of heterozygosity (LoH) for chromosomes 1p and 22q was noted by Gogusev and colleagues[68] in endometriotic implants. Lower levels of LoH also have been reported for chromosomes 9p and 11q.[69] These findings suggest that genomic instability is a feature of endometriosis.

Comparative genomic hybridization is a technique based on the competitive *in situ* hybridization of differentially labeled DNA from endometriosis and normal endometrial tissue to human metaphase spreads. Regions of gain of DNA sequences are seen as an increased color ratio of the two fluorochromes labeling the respective DNAs. Using this method, Gogusev and colleagues in Paris identified chromosomal regions in which gene copy numbers are altered in endometriosis.[68] In an established endometriosis cell line (FbEM-1), these investigators observed that the *c-ERBB2* protooncogene was overexpressed.[70] This result complements the finding that *TOB1* is reduced in endometriosis and suggests that *ERBB2* signalling is important in endometriosis.

Genetic Polymorphisms and Endometriosis Risk

Several candidate gene polymorphisms have been evaluated in women with endometriosis. In general, these have fallen into three major classes, each representing presumed pathogenetic abnormalities:

1. Genes involved in xenobiotic metabolism
2. Genes that mediate inflammatory responses
3. Genes regulating steroid action

An N-acetyltransferase 2 allele *(NAT2*4/*6)* was significantly more common among affected women (35.2%) than population control subjects (8.1%) or unaffected women (4.2%; $P = 0.02$). More affected women (57.4%) were found to be "fast acetylators" than were population control subjects (32.3%) or unaffected women (33.3%; $P < 0.05$). Altered N-acetyltransferase 2 *(NAT2)* enzyme activity, which would enhance the rate of xenobiotic acetylation, may be a predisposing factor in endometriosis.[71]

Based on the observation that women with vaginal agenesis carried N314D mutations in the galactose-1-phosphate uridyl transferase *(GALT)* gene regulating galactose metabolism,[72] Cramer et al.[72] speculated that this defect also might be associated with increased retrograde menstruation and may predispose to endometriosis.

A proteomic analysis of plasma proteins from 56 endometriosis cases and 20 unaffected controls identified elevated concentrations of vitamin D binding protein among the cases. Based on trypsin digestion patterns it was discerned that the guanine-cytosine (GC)*2 allele was over represented in women with endometriosis.[73] This allele has been associated with impaired macrophage phagocytosis, as postulated in the impaired immunosurveillance of endometriosis, reviewed below.

Viganò and colleagues reported a polymorphism of the intercellular adhesion molecule-1 *(ICAM-1)* in women with severe endometriosis.[74] The implication of such a protein, where abnormal cellular adhesion is suspected, deserves further investigation. Despite the hypothesis that dioxins and other environmental toxicants might play an etiological role in endometriosis,[44] Japanese women with this condition were not observed to have an increased incidence of polymorphisms in the aryl hydrocarbon receptor gene or associated factors studied to date.[44] Variants in the glutathione S-transferase genes were reported by Baranova and colleagues[75] in a group of French and Slavic women with endometriosis, but the same polymorphisms were not identified in subjects from the United Kingdom.[76] A polymorphism in the 5′ untranslated region of the human *VEGF* (vascular endothelial growth factor) gene (+405G>C) also has been correlated with an increased risk of endometriosis development in Italian Caucasian, South Indian, and Korean populations.[77]

Several genome wide association studies (GWAS) have been published. The first included 1907 cases and 5292 controls from Japan and identified polymorphisms on chromosome 9p21 (located within the intron of a gene encoding a cyclin-dependent kinase inhibitor antisense RNA) and chromosome 1p36 (near the *WNT* locus).[78] Another study[79] of 3194 cases and 7060 controls, drawn from a population of women from Australia, the UK and the US, reported a locus on chromosome 7p15.2. The latter site is located 1.35 megabases upstream from the plausible candidate genes homeobox A *(HOXA)10* and *HOXA11*. Yet another GWAS study and meta-analysis confirmed an association with an SNP on chromosome 7p15.2, and an SNP near the *WNT4* gene. Several other new loci were also discovered. There was a significant overlap in Japanese and European ancestry populations suggesting that risk alleles contribute to endometriosis across populations. It should be noted that the variants associated with endometriosis in these GWAS studies had relatively low odds ratios (≤1.44).

Inconsistencies among these reports reflect some of the inherent methodological problems with GWAS. In particular, the recruitment of pre-existing cases and the willingness of these subjects to participate in research can bias the results. There also are pitfalls in control recruitment, including the use of patients who have other diseases as control subjects. Failure to replicate findings in a different racial or ethnic group, as noted above, may not mean that the original study was flawed, but could reflect differences in allele frequency between populations. Finally, if gene–environment interactions affect the magnitude of a genetic risk factor, another population may not be exposed to the same environmental factor as in the original study.

Nuclear Receptor Genes as Biomarkers of Endometriosis Risk

Homozygosity for a *Pvu II* polymorphism in the estrogen receptor *(ER)-α* gene was found less frequently in women with endometriosis when compared with a disease-free group.[80] A variant progesterone receptor *(PR)* allele, called *PROGINS*, is characterized by an *Alu* insertion in intron G and two additional mutations in exons 4 and 5. The *PROGINS* allele codes for a progesterone receptor with increased stability and augmented hormone-induced transcriptional activity. Homozygosity for this allele was present in 3.2% of women with endometriosis and 0.9% of control subjects.[81] This result is at odds with the evidence that progesterone action is decreased in endometriotic tissue, due to a relative decrease in the ratio of PR-B (which generally activates gene transcription) to PR-A (which generally suppresses transcription) isoforms.[82]

Bulun and colleagues observed that ERβ mRNA is overexpressed approximately fortyfold and PR-B is underexpressed by 88% in endometriotic tissue. The apparent mechanism in the former case involves hypomethylation of cytosine and guanine-rich (CpG) islands in the ERβ gene promoter, indicating that epigenetic regulation may, in part, explain this observation.[83]

Familial aggregation of endometriosis also could be attributed to epigenetic factors, and although sparse, recent evidence supports this interesting hypothesis. Another pertinent gene that was found to be hypomethylated in endometriosis is the homeobox transcription factor HOXA10. This protein also is expressed in midsecretory phase endometrium and its expression is reduced in clinical endometriosis and in an induced baboon model of the disorder.[84-86]

Clinical Presentation

Symptoms and Signs

The most common symptom in women with endometriosis is progressive, secondary dysmenorrhea. The pain usually begins before menses and continues throughout the duration of menstrual flow. It may be accompanied by dyspareunia, dysuria, or dyschezia. The pain also may be referred to musculoskeletal regions, such as the flank or low back. Cyclic *in situ* menstruation at the site of an endometriotic lesion is believed to result in a chronic inflammatory nidus. Cytokine release and activation of prostaglandin-mediated pain perception, or direct infiltration of endometriotic cells into afferent nerves have been proposed.[87] Furthermore, the enhanced inflammatory milieu may result in sensitization of nociceptors and central neurons.[88] New hypotheses suggest that coordinated neural and vascular growth, "neuroangiogenesis," and secondary central neuropathic sequelae contribute to pelvic pain.[89]

The second most common symptom is infertility with monthly fecundity rates similar to unexplained infertility patients at 0.02 to 0.10. It has long been accepted that women with moderate and severe endometriosis have fertility problems due to the mechanical interference with sperm-egg union or zygote transport, as a result of pelvic adhesions and disruption of normal anatomy. Interestingly, women with minimal or mild endometriosis also have decreased fertility outcomes when compared with those patients without clinical evidence of disease. The exact causes remain elusive to date, but several postulated mechanisms are addressed later in this chapter.

Unfortunately, due to the diffuse and pusillanimous nature of endometriotic lesions, the physical examination is commonly unrevealing. The bimanual examination is of limited precision in either localization or diagnosis of endometriosis. However, the astute clinician can appreciate pain or induration in the vicinity of otherwise nonpalpable lesions, most commonly in the cul-de-sac or rectovaginal septum.

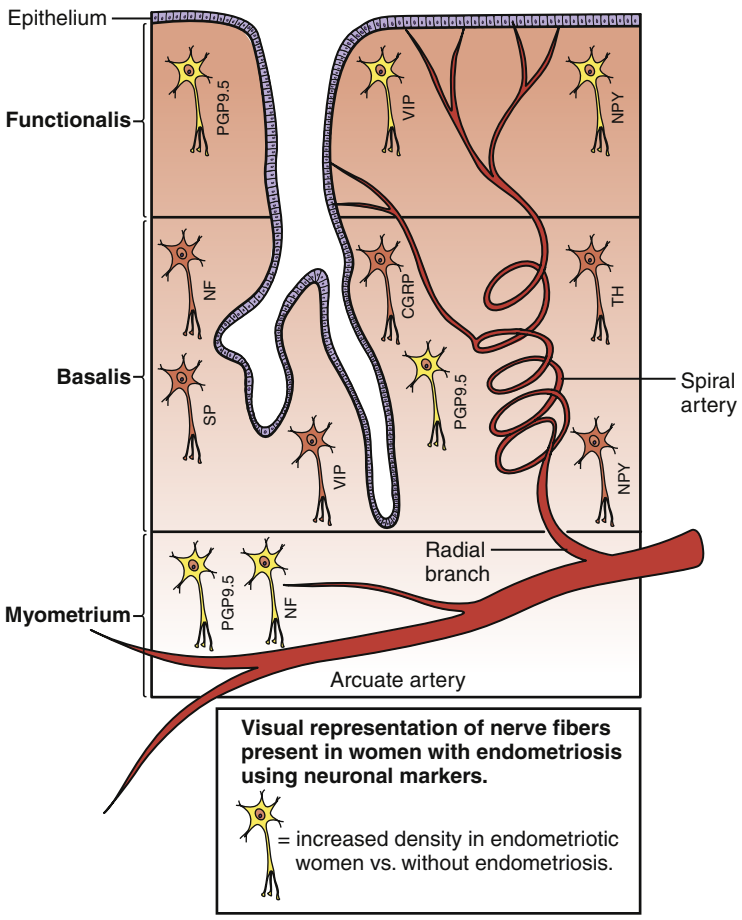

FIGURE 26.5 Neuronal markers denoting which nerve fibers are present in the various layers of the endometrium. *(Adapted from Medina MG, Lebovic DI. Endometriosis-associated nerve fibers and pain.* Acta Obstet Gynecol Scand *88:968–975, 2009.)*

Tender nodules may be palpable along the uterosacral ligaments or within the cul-de-sac, especially if the examination is done just before the menses. Rarely, impaired renal function and azotemia can develop in women with retroperitoneal ureteric fibrosis.

Ectopic endometrium within the uterine corpus is termed adenomyosis, and although this entity is not covered in this chapter, there seems to be an association between adenomyosis and endometriosis. Utilizing junctional zone measurements from magnetic resonance imaging (MRI) to diagnose adenomyosis in patients with endometriosis, the prevalence of adenomyosis was 90% in one recent study.[90] Interstitial cystitis is another comorbidity in at least 60% of women with endometriosis.[91]

Diagnosis

Direct visualization of endometriotic implants is the current gold standard for diagnosis. Although endometriosis is associated with certain biochemical characteristics (described later in this section), none of these features have adequate sensitivity or specificity for clinical application. Hence, laparoscopy, and rarely laparotomy, is the most common means to establish a firm diagnosis. The histopathological confirmation of endometriosis is established on the microscopic identification of ectopic endometrial epithelium and stroma, often with fibrosis and the infiltration of hemosiderin-laden macrophages. These pathognomonic features are documented in only approximately 70% of clinically suspicious cases.

Radiological imaging techniques have been evaluated as noninvasive approaches to endometriosis diagnosis, but these methods have not replaced surgical verification of lesions. The diagnostic sensitivity and specificity of imaging modalities are reviewed later in this chapter. With the discovery that a greater density of nerve fibers is present in the functionalis layer of eutopic endometrium in endometriosis than those without endometriosis (Fig. 26.5), a minimally invasive endometrial biopsy may help reduce the delay in diagnosis and subsequent treatment of endometriosis.[84,92,93]

Because disease is found in the dependent areas of the pelvis, performance of a systematic rectovaginal examination is critical. Some authors have advocated the use of needle biopsy to confirm the histological features of the nodular rectovaginal lesion.[94]

Variable Lesion Appearance

Visually, peritoneal endometriosis can take on a variety of appearances. Classically, physicians were taught that endometriosis implants were blue-black "powder burns" or "mulberry lesions" of the peritoneum. In recent years, several stages of implant development have been appreciated, each with a corresponding appearance. Early, active lesions can appear as papular excrescences or vesicles, and can range in color from clear to bright red.[95] About one third of lesions are in phase with the eutopic endometrium and have a tendency to spontaneously grow and regress. This characteristic suggests a fluctuating proliferation in association with hormone production during the menstrual cycle.[96]

L/S, laparoscopy; NR, not reported.

Advanced, active lesions are associated with inflammation, fibrosis, and hemorrhage, and they take on the more classic pigmented appearance (Fig. 26.6). These lesions can express myriad colors—black, brown, purple, red, or green—due to the presence of heme degradation products as the foci undergo periodic hemorrhage and fibrosis. Dormant and healing lesions appear white or calcified, reflecting remnants of glands embedded in fibrous tissue.[95] In a histological study, visually white and mixed-color lesions were more likely to contain histological evidence of endometriosis than were black or red lesions.[97]

Although difficult to prove in cross-sectional clinical studies, endometriosis appears to be a progressive disease, as evidenced by longitudinal laparoscopies in female baboons.[98] At least eight studies were reported of repeat laparoscopy in women assigned placebo treatment.[99-106] Combining these placebo participants yields a total of 162 women that confirm that endometriosis is a disease in flux. There was a nearly equal distribution among women whose disease stage deteriorated (31%), was unchanged (32%), or improved (38%). In fact, all but one study noted that 23% of placebo patients had complete regression of disease over intervals of 4 to 39 months (Table 26.1). Regrettably, this means for over two thirds of women the disease will either persist or progress, and this situation must be addressed with postoperative medical management.

An evolution of the visual appearance of the lesions from clear to red to black to white has been suggested to correlate with the subject's age.[107] This observation implies that the appearance of endometriotic lesions may correlate with their biology. Deeply invasive lesions of the rectovaginal septum have the histological characteristic of smooth muscle hyperplasia, so-called *adenomyotic nodular endometriosis*. Some argue that this reflects a unique histogenesis from müllerian remnants,[22] but other authors accept that these lesions also may be manifestations of retrograde menstruation and implantation.[108,109]

A specific manifestation is the *endometrioma*, or *chocolate cyst* (Fig. 26.6). These ovarian cysts gained their moniker by the characteristic chocolate syrup appearance of

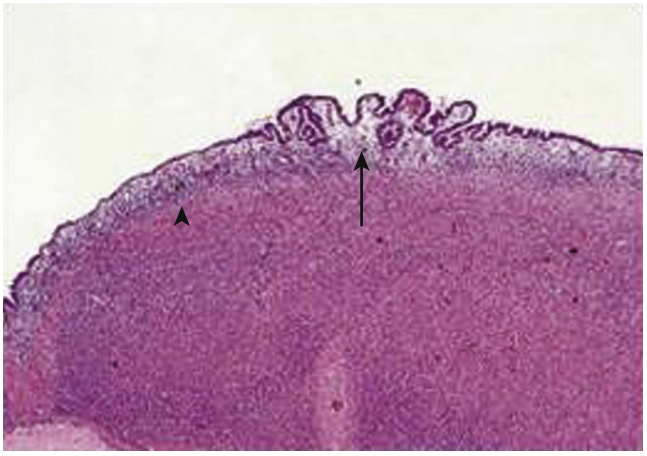

FIGURE 26.7 Presumptive development of ovarian endometrioma via surface epithelial metaplasia. Low-power view of an endometriotic lesion arising in ovarian surface epithelium. The typical or well-developed area of endometriosis is seen in the center of the lesion *(arrow)*, with transition from minimal epithelial and stromal changes from normal ovarian surface epithelium on the sides of the focal lesion *(arrowhead)*. *(From Zheng W, Li N, Wang J, et al. Initial endometriosis showing direct morphologic evidence of metaplasia in the pathogenesis of ovarian endometriosis.* Int J Gynecol Pathol *24:164–172, 2005.)*

their contents, often seen at rupture. These cysts arise after implantation of ectopic endometrial tissue and subsequent invasion into the ovarian cortex or alternatively as a result of metaplasia (Fig. 26.7).[24] The cell types present in these cysts include endometrial epithelium (both as glands and flattened cells), endometrial stroma, and hemosiderin-laden macrophages. In some cases, ciliated cells, similar to those of oviduct epithelium, have been observed.[110] It is reported that pelvic pain associated with endometrioma is positively correlated with ovarian blood flow and microvascular density, suggesting that enhanced angiogenesis may relate to symptoms.[111] Techniques to culture the endometriotic lining of these cysts[112] have been widely adapted and allow a reliable and reproducible source of primary endometriosis cells for *in vitro* research.

Under scanning electron microscopy, microscopic lesions have been found in the normal-appearing peritoneum of women with and without endometriosis.[113] The clinical significance of these findings is a matter of controversy at present, but researchers argue that the prevalence of histological endometriosis may be underestimated.

Classification

The system most widely used to classify the extent of endometriosis was promulgated by the American Fertility Society in 1985.[114] This scheme designates disease extent based upon total three-dimensional volume of endometriosis. Importance is placed upon depth of invasion, bilaterality, and ovarian involvement, as well as density of associated adhesions and extent of cul-de-sac involvement. Using this classification, scores are tallied to objectify and compare natural history and treatment outcomes among different centers and surgeons. Scores of 1 to 15 reflect minimal or mild disease; 16 to 40, moderate; and over 40, severe. It is important to note that this staging system has not been shown to correlate with predicting pregnancy or the more common symptom of pelvic pain.[115] New classifications are being promoted to try to correct inadequacies of the current schema, but their complexity and lack of sensitivity have hindered adoption.[116-118] Some authors have suggested the incorporation of objective biochemical markers of inflammation as a means to assess disease parameters beyond laparoscopically visible lesions.[119,120] Future studies will evaluate the utility of the latter recommendations.

Radiological Imaging

Economic pressures and perioperative risks associated with surgical staging have stimulated attempts to develop noninvasive tests for endometriosis. Radiological evaluation by MRI and ultrasonography show some promise.

Compared with other imaging modalities, MRI is the best technique to identify endometriosis. It lacks, however, sufficient sensitivity and specificity, especially in the detection of small implants and adhesions. MRI also may have a role in evaluating treatment response with endometriosis patients receiving medical therapies such as danazol, progestins, or gonadotropin-releasing hormone analogs.[121,122]

Overall sensitivity of MRI in the detection of endometrial implants is 77%, with a specificity of 78%.[99] MRI identification of endometriomas is more satisfactory and has high sensitivity (90% to 92%) and specificity (91% to 98%) rates.[121] MRI scans of endometriomas are characteristically identified by "shading," with homogeneous hyperintensity on T1-weighted images and relative hypointensity on T2-weighted images. The signal intensity pattern is consistent with the presence of intracellular methemoglobin (Fig. 26.8). Endometriomas may have a complex appearance, usually related to the presence of blood clots or debris within the cyst, and in this setting use of intravenous contrast material may be helpful in distinguishing these products from more worrisome ovarian neoplasms.

Ultrasonography

Endometriomas may be difficult to differentiate from ovarian neoplasms by ultrasonographic features alone. Recurrent episodes of bleeding and surrounding inflammation sometimes result in a heterogeneous internal appearance (suggesting solid components), a thickened wall, or apparent septations. Apparent septations may be particularly misleading because they can reflect compressed ovarian parenchyma intervening between the endometrioma and a satellite cyst. Endometriomas tend to be well vascularized and Doppler blood flow may erroneously suggest a neoplastic mass.

Although endometriomas may mimic neoplasms, they typically demonstrate a characteristic sonographic appearance. Because of ease of use, cost-effectiveness, and accessibility, transvaginal ultrasonography has become the imaging modality of choice when evaluating the ovary for an endometrioma.[123] The classic endometrioma has diffuse low-amplitude internal echoes, enhanced sound transmission, and a visible uniform wall, sometimes containing bright reflectors (Fig. 26.8).[124,125] The reflectors have been postulated to represent red blood cell breakdown products. About 50% of ovarian masses that are histologically

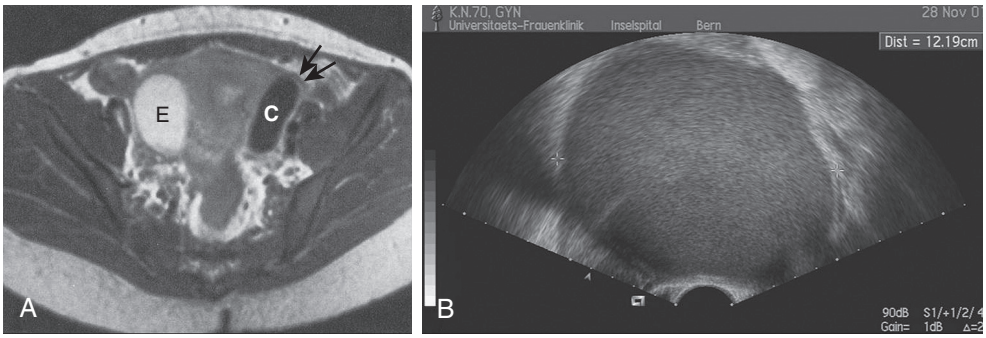

FIGURE 26.8 **A,** Magnetic resonance imaging of the pelvis reveals characteristic high signal intensity in the right ovarian lesion suggesting an endometrioma *(E)*. The low signal intensity lesion of the left ovary is consistent with a simple ovarian cyst *(C)*. Note enhancement of the periphery of the cyst *(arrows)*. **B,** Transvaginal ultrasonography reveals a cystic adnexal mass with diffuse, homogenous moderate-level echoes consistent with an endometrioma. *(**A** from Jaffe R, Pierson RA, Abramowicz JS (eds). Imaging in Infertility and Reproductive Endocrinology. Philadelphia, Lippincott, 1994; **B** courtesy of Dr. Michael D. Mueller, University of Bern, Switzerland.)*

confirmed endometriomas demonstrate this characteristic sonographic appearance.[126] Although the same appearance may occur in an acutely hemorrhagic cyst, the latter will evolve or resolve over time but an endometrioma usually remains stable or enlarges. Serial sonograms are often necessary before the physician may reliably assume that a mass is an endometrioma.

Serum Markers of Endometriosis

Although they might provide great clinical value, serum markers of endometriosis have proved to be elusive.[127] The best studied of these is the tumor marker cancer antigen (CA)-125. This transmembrane glycoprotein, initially identified in serous ovarian carcinomas, was noted by Barbieri and colleagues to circulate at elevated concentrations in women with endometriosis.[128] The CA-125 gene has yet to be fully characterized, but it encodes a 4-megadalton product with repetitive peptide motifs and O-linked polysaccharides, which is synthesized and secreted by cells of coelomic origin.[129] Some authors have found this marker to be a better correlate of active endometriotic lesions than peritoneal adhesions, and it may have utility in monitoring the progression of disease or recurrence during therapy.[130] Although the sensitivity of preoperative CA-125 for the detection of endometriosis is too low for a screening test, high concentrations may be predictive of advanced disease.[131] The addition of serum soluble ICAM-1 only modestly improved the sensitivity of concomitant CA-125 screening for endometriosis.[132]

Two recent papers have addressed the use of serum biomarkers in the identification of women with endometriosis. Othman and colleagues reported significantly elevated levels of IL-6, monocyte chemoattractant protein-1 (MCP-1), and interferon-γ (IFN-γ) in the serum of women with endometriosis relative to infertile controls without laparoscopic evidence of endometriosis.[133] Among these, IL-6 was the most predictive biomarker. An algorithm including several of the same cytokines was found to perform better than any individual analyte in separating endometriosis and control subjects in a similar study.[134] Fassbender and colleagues used plasma proteomic analysis to identify five unique proteins in cases of endometriosis.[135] This unbiased strategy may be a fruitful approach to discover new biomarkers.

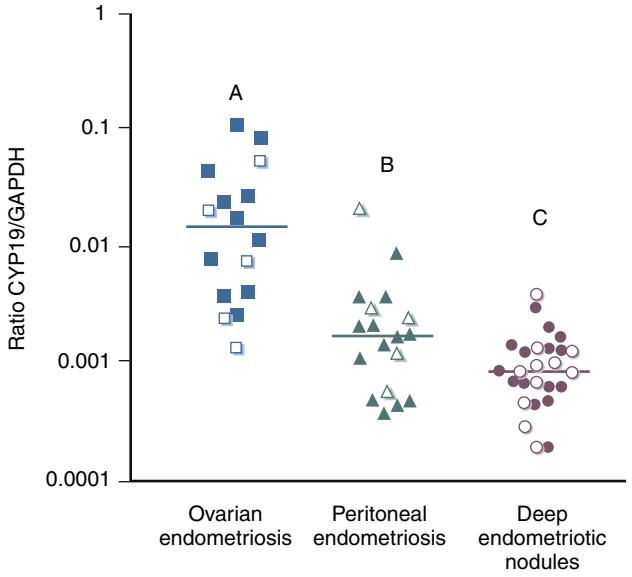

FIGURE 26.9 CYP19 (P450 aromatase) expression in ovarian endometriosis *(A)*, peritoneal endometriosis *(B)*, and deeply invasive endometriosis *(C)* of the rectovaginal septum. Data are expressed relative to glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA. Expression of aromatase [P450 aromatase/CYP19] in peritoneal and ovarian endometriotic tissues and deep endometriotic [adenomyotic] nodules of the rectovaginal septum.* Fertil Steril *85:1516–1518, 2006.)*

Pathogenesis

Hormone Responsiveness (Steroids and Nuclear Receptors)

One of the defining characteristics of endometriosis is its endocrine responsiveness. Typically endometriosis only becomes symptomatic after the onset of menses[136] and, in the majority of cases, resolves spontaneously with menopause. An unusual case of persistent postmenopausal endometriosis led investigators to the discovery that aromatase expression and estradiol biosynthesis occurred within the endometriotic implant itself.[137] Aromatase activity is particularly high in ovarian endometrioma (Fig. 26.9).[138] Relative

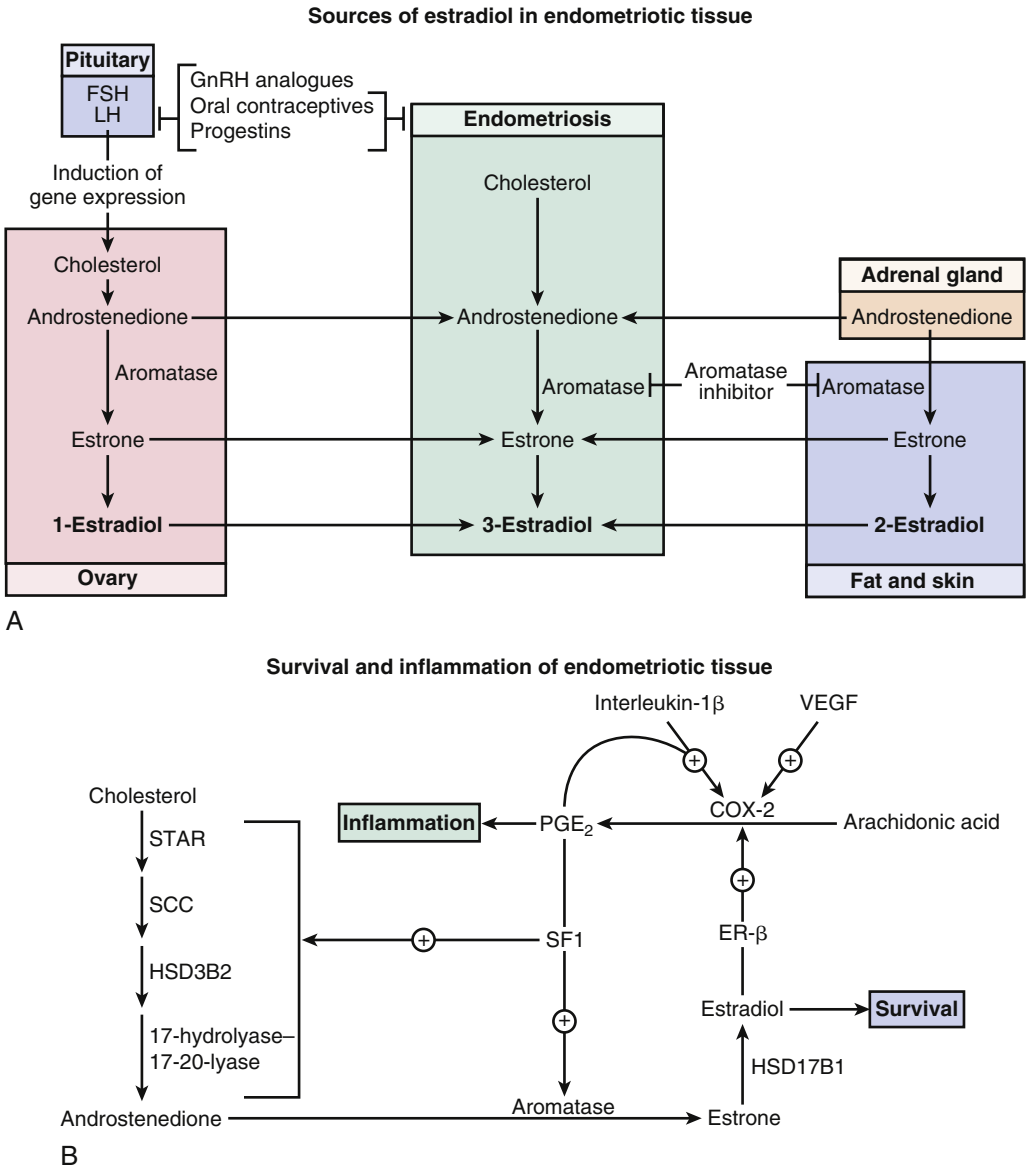

FIGURE 26.10 **A**, There are multiple sources of estradiol in endometriotic tissue. One source is via the pituitary follicle-stimulating hormone (FSH) and luteinizing horomone (LH), which induce ovarian biosynthesis of estradiol. The additional sources are from aromatase activity in fat, skin, and local production within endometriotic tissue. **B**, High levels of estradiol and prostaglandin E_2 (PGE_2) are produced by a feedforward loop. All the enzymes necessary for *de novo* steroid biosynthesis from cholesterol are expressed in stromal cells isolated from endometriotic implants. Among these, the steroid acute regulatory (StAR) protein, aromatase P450, and 17β-HSD type 1 appear to be the most highly regulated in this cell type. StAR and aromatase activities are modulated via the cAMP pathway and the transcription of these genes is activated by the aberrant expression of steroidogenic factor-1 (SF-1), resulting in estradiol synthesis and lesion proliferation. Prostaglandin synthesis is regulated by cyclooxygenase-2 (COX-2), which in turn is controlled by estradiol, cytokines, and vascular endothelial growth hormone (VEGF), contributing to inflammation and a feedforward effect on local estradiol production. *(Adapted from Bulun SE. Endometriosis.* New Engl J Med *360:268–279, 2009.)*

overexpression of the orphan nuclear receptor SF-1 in endometriotic cells appears to be a major reason for increased aromatase activity in these lesions.[139] Steroid biosynthesis and metabolism are clearly intrinsic activities within these lesions. Also identified in ectopic endometrial tissues were messenger RNA transcripts encoding steroid acute regulatory (StAR) protein,[140] which controls the delivery of cholesterol to the inner membrane of mitochondria, cholesterol P450 side chain cleavage (SCC) enzyme, 3β-hydroxysteroid dehydrogenase type 2, and 17α-hydroxylase. Further, oxidative metabolism of estradiol to the less biologically active estrone by 17β-hydroxysteroid dehydrogenase type 2 is decreased in endometriosis, aggravating local estrogen action.[141] Thus, endometriotic lesions appear to have co-opted the ability to generate their own estrogenic milieu (Fig. 26.10).

Like their derivative eutopic endometrium, endometriotic lesions express estrogen and progesterone receptors. Over the years, however, several authors have indicated that concentrations of these steroid receptor proteins may be altered in endometriotic implants.[142-144] In cultured stromal cells from these lesions, both estrogen[145] and progesterone receptor[82] isoform expression appear to differ from those

in normal endometrium. These differences may impart a growth advantage to endometriotic implant cells. Estrogen receptor β is highly expressed in endometriosis and is an emerging target for new therapeutics.[146] The roles of androgen action in endometriosis are as yet poorly defined; however, androgen receptors are expressed in normal endometrium and endometriosis lesions,[147] and clinical evidence supports the efficacy of danazol therapy for relief of pain associated with endometriosis.[148]

Lesion Establishment (Adhesion, Proteolysis, Invasion)

As discussed previously, the Sampson hypothesis[149] posits that viable endometrial cells spill into the peritoneal cavity apposing the peritoneal surface and adhere to the mesothelial monolayer. Although some controversy exists as to whether or not such invasion requires an *a priori* breach in the mesothelial surface[150] or if the cells are capable of invading intact mesothelium,[151] this is a necessary step in lesion establishment. The expression of hyaluronic acid (on peritoneal cells) and its receptor, cluster determination (CD)44 (on endometrial cells), have been proposed to play a role in this early attachment step.[152] Enhanced cytokine (e.g., IL-lβ, IL-6, and TNF-α) expression and action in the eutopic endometrium of women with endometriosis,[153] may predispose the adhesion of shed endometrial fragments in these cases. The ability of endometriotic cells to invade the peritoneal surface has stimulated extensive research into their cancer-like proteolytic properties.[154] The identification of specific matrix metalloproteinases (MMPs), which themselves are regulated by cytokines and ovarian steroid hormones, has been a particularly active area of investigation.[155,156] In the eutopic endometrium, these enzymes and their endogenous inhibitors (tissue inhibitor of metalloproteinases-[TIMPs]), are activated and repressed, respectively, following hormone withdrawal in the late luteal phase of the cycle. Implications of this work suggest that hormonal medications, particularly progestins, may inhibit invasive behavior. However, relative steroid hormone insensitivity and increased cytokine activity observed in endometriotic tissues may enhance MMP action in endometriosis, facilitating peritoneal invasion.

Proliferation and Apoptosis

A variety of human growth factors stimulate endometrial cell mitogenic activity. Many of these factors also have been identified in endometriotic tissues and in the peritoneal fluid of women with endometriosis. Although their precise roles in endometriosis are not well known, these factors are potential regulators of endometriosis implant proliferation. Table 26.2 summarizes the principal mitogens detected in the pelvic fluid of women with endometriosis and compares their concentrations with women without evidence of this disorder. The table provides reference sources for more detailed information.

Programmed cell death (apoptosis) is also an important mechanism for the cyclical remodeling of the endometrium.[157] Eutopic endometrial apoptosis was found to be decreased in women with endometriosis[158] and in endometriotic epithelium.[159,160] These findings indicate another potential selective advantage for the persistence of endometriotic lesions within the peritoneal cavity.[161]

IL-1RA	Zhang et al, 2007[214]

Angiogenic Factors

Given the ubiquity of retrograde menstruation, it is not clear why endometriosis only develops in a subset of women. Using the analogy of tumor metastasis[162,163] some authors have postulated that the angiogenic potential of the intraperitoneal environment may predict the likelihood that lesions become established.[164,165] Indeed, on visualization, endometriotic implants are often surrounded by exaggerated vascularity (Fig. 26.11); extrapelvic endometriosis, while rare, typically occurs in well-vascularized sites.[166] This concept is consistent with other analogous aspects of endometriosis pathogenesis and cancer biology. In addition to increased angiogenesis, endometriotic lesions manifest enhanced proliferative, adhesive, and invasive capacity; more LoH and genomic instability; and decreased apoptosis.

The sprouting of new blood vessels from preexisting vessels is complex and includes the proteolytic degradation of extracellular matrix, proliferation and migration of endothelial cells, and ultimately the formation of patent capillary tubules supplying the angiogenic stimulus. Many different growth factors and cytokines have been shown to exert chemotactic, mitogenic, or inhibitory activities on endothelial cells, smooth muscle cells, and pericytes. Increased IL-1β sensitivity increases the angiogenic potential of endometriosis lesions.[167] An attractive interpretation of this finding (assuming the Sampson hypothesis is accepted) is that

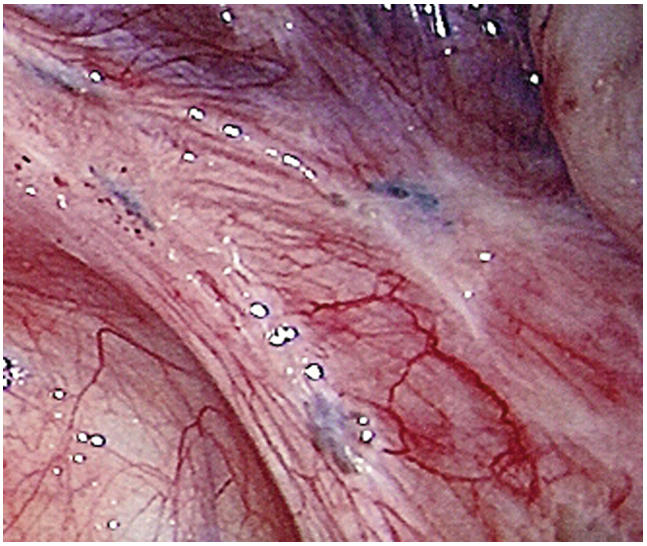

FIGURE 26.11 Laparoscopic photograph of endometriotic implants on the peritoneum overlying the uterosacral ligament. *(From Taylor RN, Yu J, Torres PB, et al. Mechanistic and therapeutic implications of angiogenesis in endometriosis.* Reprod Sci *16:140–146, 2009.)*

the endometrial lining of women destined to develop endometriosis already manifests an "activated" angiogenic phenotype. As an analogy to Knudson's "two-hit" hypothesis of oncogenesis,[168] women susceptible to the development of endometriosis may carry a "first hit" genetic trait that enhances endometrial cell angiogenic factor production. This proposal is in keeping with the familial trends observed in cases of endometriosis.[49,169,170] Angiogenic activity within advanced stage endometriomas appears to be particularly robust.[171]

Although pelvic fluid is a complex medium containing and influenced by multiple cell types, we and other investigators have found this to be a useful biological medium to define intercellular mediators of the local reactions associated with endometriosis.[172-174] Peritoneal fluid seems to play an important role in the process of neovascularization. Oosterlynck and colleagues[174] used the chick chorioallantoic membrane bioassay to show that pelvic fluid from women with endometriosis had more angiogenic activity than pelvic fluid from healthy control subjects. We confirmed this observation using an *in vitro* model of human endothelial cell proliferation. Thymidine incorporation into nascent cellular DNA demonstrated that peritoneal fluid from women with endometriosis contains substantially more angiogenic activity than pelvic fluid from normal control subjects.[164]

A vast array of angiogenic principles are synthesized by human endometrium and endometriosis. Among these are basic fibroblast growth factor, IL-6, IL-8, macrophage migration inhibitory factor, platelet-derived growth factor, prokineticin 1, and vascular endothelial growth factor (VEGF), which is the most potent of these (Table 26.2). We initially reported that endometrial VEGF levels were expressed highest in the mid-secretory phase of the cycle, a time when estradiol and progesterone levels were elevated, and confirmed VEGF expression in endometriotic implants.[175] Other studies using immunohistochemistry and endometrial cultures corroborate these findings.[176] These two ovarian steroid hormones have direct transcriptional effects on the human VEGF gene promoter.[177,178] VEGF, IL-6, and IL-8 mRNA were noted to be substantially up-regulated in endometriomas in relation to normal ovarian tissue.[179,180] In totality, these findings suggest that the local expression of angiogenic cytokines in endometriosis implants contributes to implant neovascularization and may correlate with symptoms.[111]

Fibrosis

Biochemical principles secreted by endometriotic lesions (perhaps in response to apoptosis) or their neighboring cells may contribute to the fibrosis and adhesions that classically surround the implants and adjoining pelvic organs.[181,182] Indeed, TGF-β, a growth factor associated with other types of intraperitoneal adhesion formation,[183] was noted to be elevated in peritoneal fluid of women with endometriosis.[184]

Oxidative Stress and Endometriosis

The role of oxygen free radicals as mediators of the cellular pathology associated with endometriosis has been postulated in recent years. *Free radicals* are highly reactive molecules that transiently contain one or two unpaired electrons. The transfer of electrons to other structural or regulatory molecules can induce cell damage. Most free radicals of biological significance are referred to as *reactive oxygen species* (ROS), such as hydroxyl (HO•), peroxyl (ROO•), or superoxide ($O2^{\bullet -}$) radicals. Oxidative stress implies a homeostatic deviation, wherein the pro-oxidant environment exceeds the defensive ability of antioxidant vitamins and enzymes in a physiological system. Endometrial stromal cells *in vitro* have a mitogenic response to oxidative stress[185] and free radicals may contribute to lesion proliferation and invasion.

Murphy and colleagues found that peritoneal fluid levels of the antioxidant vitamin E were decreased and the ratio of lysophosphatidylcholine to phosphatidylcholine increased in women with endometriosis.[186] These findings were interpreted to reflect increased lipid peroxidation in endometriosis. However, attempts by others to directly assay lipid peroxidation by measurements of malondialdehyde[187] or 2,2′-azino-di-3-ethylbenzthiazoline sulfonate reduction[188] failed to detect differences between endometriosis subjects and control subjects. Nevertheless, this novel hypothesis is an excellent focus of further investigation.[189]

Inflammation (Immune Cells, Chemokines, Cytokines, Prostaglandins)

The accumulation of immune cells within the peritoneal cavity and endometriotic lesions has been recognized in women with this disorder for over 15 years.[190-192] This phenomenon is thought to be initiated via the innate immune system, which is not antigen-specific and has no memory. Granulocytes, natural killer (NK) cells, and macrophages are the major cells providing this type of defense and they are recruited into tissues via the expression of soluble chemoattractant proteins referred to as *chemokines* (Fig. 26.12), demonstrates the elaborate interplay between the nervous, endocrine, and immune systems. Given the predominant monocytic inflammatory response in endometriosis, chemokines specific for this cell lineage have been

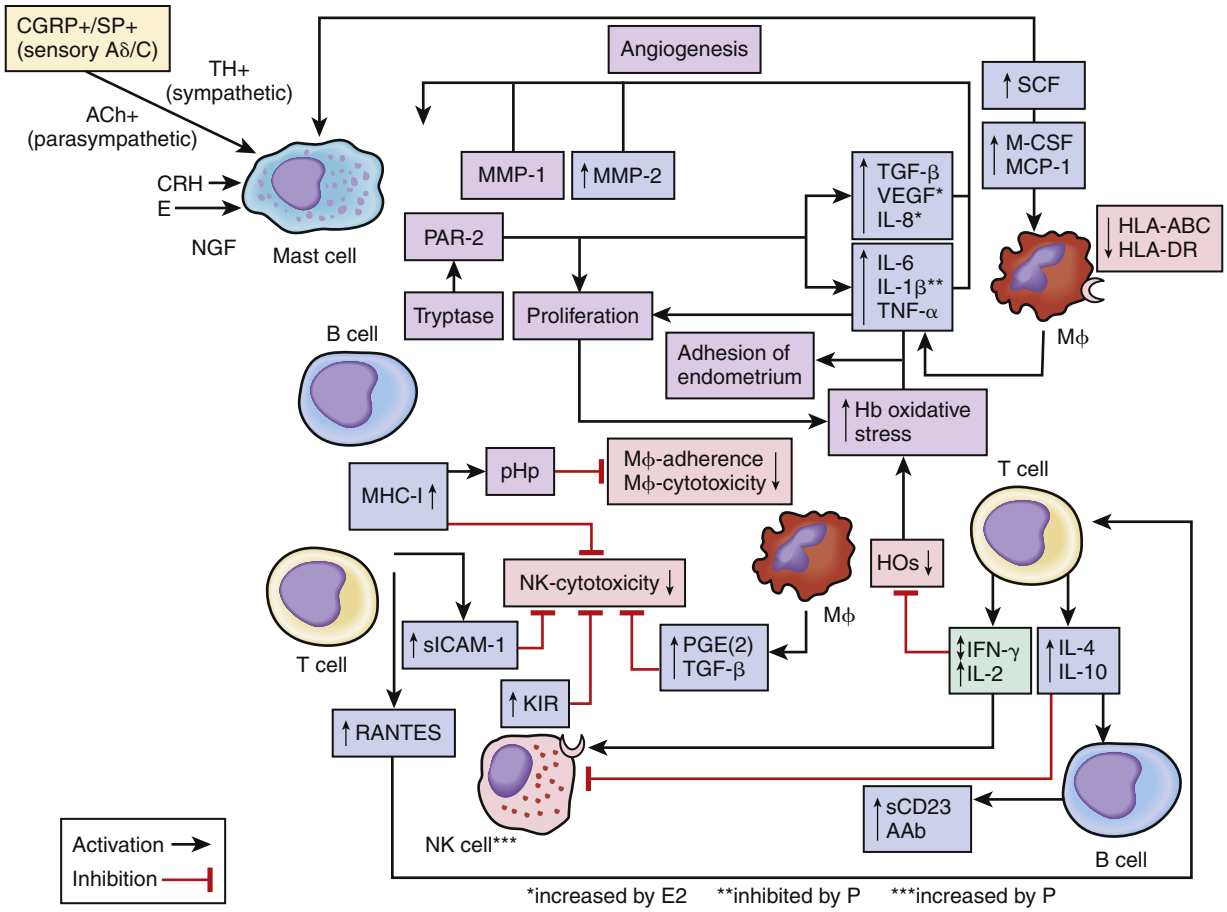

FIGURE 26.12 Neuroendocrine-immune disequilibrium in endometriosis. In endometriosis, elevated levels of M-CSF, MCP-1, RANTES, and SCF in peritoneal fluid may lead to increased recruitment of macrophages, T cells, and mast cells. Although markers of antigen presentation on macrophages such as HLA-ABC and HLA-DR are decreased in endometriosis, macrophage-derived IL-6, IL-1β, TNF-α, TGF-β, VEGF, and IL-8 are increased in peritoneal fluid, together with MMP-1 and MMP-2, stimulating angiogenesis. IL-6, IL-1β, and TNF-α support adhesion of endometrial cells to the peritoneum, and TNF-α stimulates the proliferation of ectopic tissue, resulting in high levels of Hb. T cell-derived IL-2 and IFN-γ decrease HO, leading to oxidative stress. IFN-γ has been inconsistently described as increased or decreased. Increased T-cell-derived IL-4 and IL-10 inhibit cellular immunity and stimulate B cells to AAb production. sCD23 is increased in peritoneal fluid in endometriosis and might derive from activated B cells. Lymphocytes are increased in peritoneal fluid and abundantly present in ectopic tissue. Decreased NK cell cytotoxicity might be due to high anti-inflammatory T cytokines, increased KIR, high macrophage-derived PGE_2 and TGF-β, high MHC-I expression on ectopic cells, and high sICAM-1 levels in peritoneal fluid. Nerve fibers found within lesions are positive for CGRP, SP, TH, and Ach, and NGF and CRH were demonstrated. CRH and accumulated E can activate mast cells to release tryptase, activating PAR-2, which leads to increased secretion of VEGF, IL-8, and IL-6 and proliferation of ectopic tissue. pHp, expressed by ectopic tissue, decreases adherence and, in stage III and IV, cytotoxicity of peritoneal macrophages. E2 further increases RANTES, IL-8, and VEGF, whereas P inhibits IL-1β secretion from peritoneal macrophages and increases NK cell numbers. AAb, autoantibodies; Ach, acetylcholine; CGRP, calcitonin-gene-related peptide; CRH, corticotropin-releasing hormone; E, estrogen; E2, estradiol; Hb, hemoglobin; HO, heme oxygenases; IL, interleukin; HLA, human leukocyte antigen; IFN-γ, interferon-γ; KIR, killer cell inhibitory receptor; M-CSF, macrophage colony stimulating factor; MCP-1, monocyte chemotactic protein-1; MHC-I, major histocompatibility complex class-I; MMP, matrix metalloproteinase; NGF, nerve growth factor; NK, natural killer; P, progesterone; PAR-2, protease-activated receptor-2; PGE_2, prostaglandin E_2; pHp, peritoneal haptoglobin; RANTES, regulated upon activation normal T cell expressed and secreted; sCD23, soluble CD23;, SCF, stem cell factor; sICAM-1, soluble intercellular adhesion molecule-1; SP, substance P; TGF-β, transforming growth factor-β; TH, tyrosine hydroxylase; TNF-α, tumor necrosis factor-α; VEGF, vascular endothelial growth factor. *(Adapted from Tariverdian N, Theoharides TC, Siedentopf F, et al. Neuroendocrine-immune disequilibrium and endometriosis: an interdisciplinary approach.* Semin Immunopathol *29:193–210. 2007.)*

evaluated and identified in peritoneal fluid and endometriotic lesions. In particular, IL-8, MCP-1, and regulated upon activation normal T cell expressed and secreted (RANTES) have been studied intensively. Specific references to these important chemokines are provided in Table 26.2, and the general topic of peritoneal chemokines has been reviewed in recent literature in detail.[193]

We have postulated that the accumulation of peritoneal macrophages initiates a rather complex network of chemokines, cytokines, and growth factors that contribute to the pathophysiology of endometriosis.[194] This hypothesis is summarized in Figure 26.13. The activation of autoregulatory loops may contribute to a feedforward amplification of local inflammation within endometriotic implants.

Adaptive immunity, by contrast, refers to that "learned" by experience and induces an enhanced anamnestic response with repeated antigen exposure. Thymus and bursa-dervied (T and B) lymphocytes and antibody-producing plasma cells

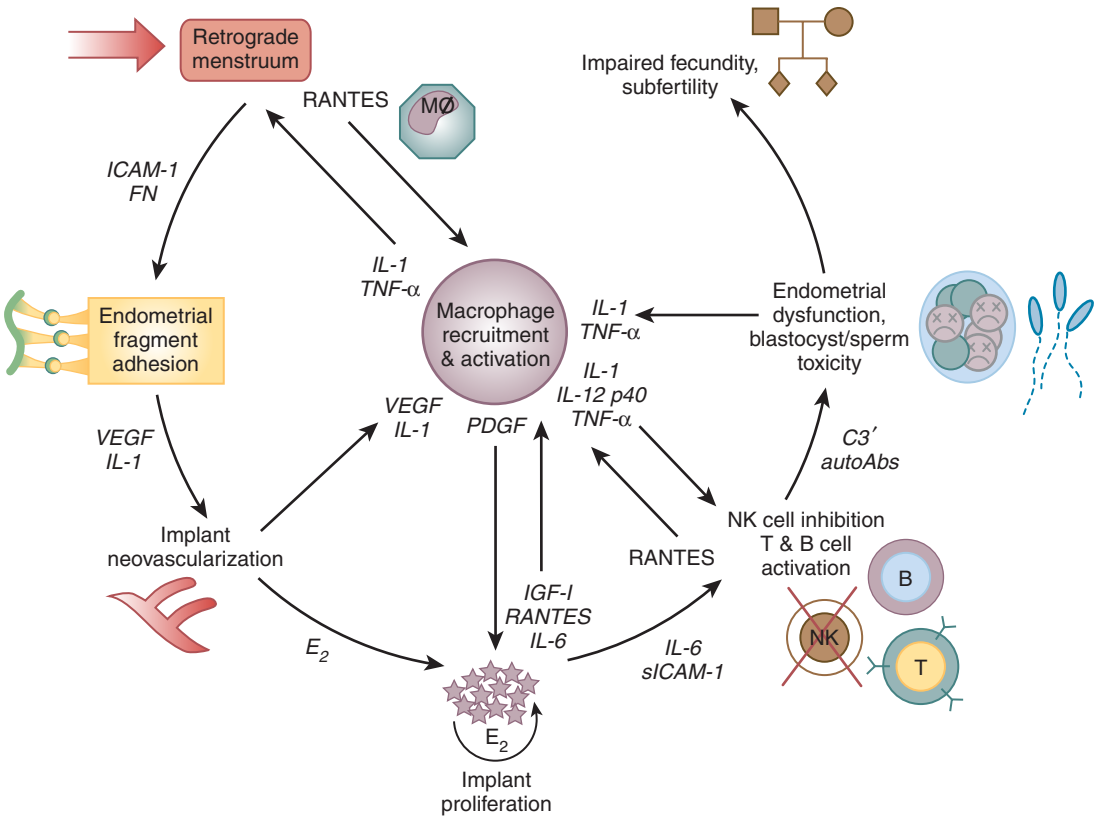

FIGURE 26.13 Schematogram depicting the network of chemokines, cytokines, and growth factors in the pathophysiology of endometriosis. autoAbs, autoantibodies; C3′, complement 3; E_2, estradiol; FN, fibronectin; sICAM, soluble intercellular adhesion molecule; IGF-1, insulin-like growth factor-1; IL, interleukin; MØ, macrophage; NK cell, natural killer cell; PDGF, platelet-derived growth factor; RANTES, regulated on activation, normal T cell expressed and secreted; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

are the primary cell types providing adaptive immunity. Weed and Arquembourg[195] first observed immunoglobulin G (IgG) and complement deposits in the eutopic endometrium of women with endometriosis and proposed that development of endometrial autoantibodies might explain poor reproductive outcomes in some women with this syndrome. Elevated levels of complement component C3 also were noted in peritoneal fluid of women with endometriosis.[337] Increased concentrations of T cells were observed in baboons with spontaneous endometriosis but not in those with surgically induced disease. This observation led the authors to suggest that an underlying immunocyte abnormality might precede, rather than reflect a response to, intraperitoneal endometrial implants.[196]

In the 1980s, serum of women with endometriosis was used to identify endometrial autoantigens by Western blotting methods. Similar findings were confirmed with enzyme-linked immunosorption assays against solubilized endometrial antigens and endometrial cell monolayers.[197] It has been suggested that a generalized adaptive immune response, manifested by polyclonal B-cell activation, occurs in some cases of endometriosis.[198]

Leukocytes recruited and activated by endometriosis-derived chemokines secrete a variety of soluble inflammatory mediators. Particularly potent among these are proinflammatory cytokines (reviewed in Table 26.2) and prostaglandins. These mediators also have intrinsic vasoactive and pain-activating properties and are thought to lie along a critical common pathway involved in the symptoms of endometriosis.[194]

Although no clear associations were found in early genotyping studies assessing the major histocompatibility type I and II loci human leukocyte antigen (HLA)-A, -B, and -DR),[199,200] more recent immunohistochemical analyses of tissues from women with endometriosis suggest an increased expression of HLA-DR antigen in endometrial and endometriotic epithelial cells than what is seen in other infertile control subjects.[201] Moreover, the coincidence of surgically confirmed endometriosis with other autoimmune disorders, including systemic lupus erythematosus, Sjögren syndrome, rheumatoid arthritis, and multiple sclerosis, was documented in a self-reported, cross-sectional survey of more than 3500 members of the North American Endometriosis Association.[202] In a recent histochemical and microarray study of ovarian endometriosis, macrophages, plasma cells, complement proteins, and a B-lymphocyte stimulating cytokine (BLyS), all were found to be markedly upregulated relative to matched eutopic endometrium. These same markers are elevated in other autoimmune diseases, including systemic lupus erythematosus, Sjögren syndrome, and rheumatoid arthritis.[203]

Immunosurveillance

An intriguing concept in the etiology of endometriosis is defective immunosurveillance in susceptible women. If

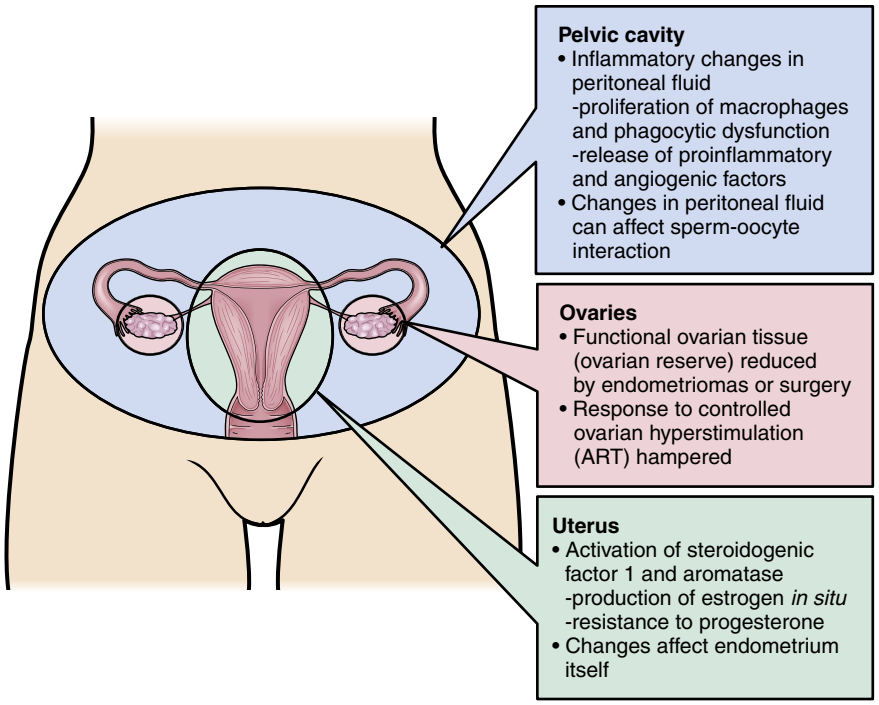

FIGURE 26.14 Mechanisms of endometriosis-associated infertility. ART, assisted reproductive technologies. *(Adapted from de Ziegler D, Borghese B, Chapron C. Endometriosis and infertility: pathophysiology and management.* Lancet *376:730–738, 2010.)*

normal eutopic endometrium elicited an immune response, antiendometrial autoantibodies would be prevalent in all women rather than a subset of cases with endometriosis.[204] Hence, adaptive immunity toward these cells seems to occur as a result of their ectopic location. As an overwhelming majority of cycling women regurgitate menstrual endometrium into the peritoneal cavity, why does endometriosis occur in only 10% to 15% of these individuals?

In normal women, intraperitoneal menstrual debris appears to be eliminated without loss of immune tolerance, presumably mediated by $CD8^+$ T cells and immunosuppressive cytokines (e.g., IL-13, IL-1RA). However, as noted in other autoimmune disorders, immune tolerance might break down in endometriosis, resulting in the recognition of ectopic implants by a chronic inflammatory response. Induction of so-called "blocking antibodies" or tolerance to endometrial antigens[205] have been postulated but never confirmed. Nevertheless, defects in NK cell activity and reduced production of immunosuppressive cytokines have been reported in cases of endometriosis. For example, ICAM-1 may interfere with peritoneal immunosurveillance and allow refluxed endometrium to escape clearance from the peritoneal cavity.[206] Increased concentrations of this protein have been noted in pelvic fluid of women with endometriosis.[207] Endometrial cells also are inherently resistant to apoptosis and phagocytosis,[208] yet endometriosis only occurs in a minority of menstruating women, as previously noted. Some researchers have suggested that mediators of the innate immune system, particularly macrophages and NK cells, clear regurgitated endometrial cells from the peritoneal cavity. Oosterlynck and colleagues first described decreased NK cell cytotoxicity against endometrial and hematopoietic cells in women with endometriosis.[209] The same group showed that peritoneal fluid from women with endometriosis contained more soluble NK cell suppressive activity than peritoneal fluid from fertile control subjects. In addition, the phagocytic ability of endometriotic peritoneal macrophages is reduced by suppressed expression of the scavenger receptor CD36.[210]

Hornung and colleagues postulated that expression or secretion of the non-classical major histocompatibility antigen HLA-G by endometriotic cells might inhibit NK cell function in this setting, but were unable to detect this protein in ectopic or eutopic endometrial stromal cells or tissues by Western blotting, and no soluble HLA-G protein was detectable in peritoneal fluid.[211] However, using *in situ* methods, Barrier and colleagues observed HLA-G in endometriotic glands.[212] Interestingly, reduced expression of other anti-inflammatory cytokines (i.e., IL-13 and IL-1RA) was reported in the peritoneal fluid of women with endometriosis.[213,214]

Possible Mechanisms of Endometriosis-Associated Infertility

How mild to moderate endometriosis reduces fertility is among the most controversial aspects of research in this field (Fig. 26.14). A case-control study found a significantly lower serum level of the ovarian reserve marker anti-müllerian hormone (AMH) in 87 women with moderate-to-severe endometriosis compared to 306 without the disease.[215] In addition to mechanical effects of lesions and adhesions on the adnexa, evidence supports the hypothesis that endometriosis causes an immunologically hostile environment within the pelvis. Evidence from oocyte donor programs indicates that egg or early embryonic development are disturbed in women with endometriosis[216,217] and specific chemokine concentrations are elevated in the follicular fluid of affected women undergoing *in vitro* fertilization (IVF).[218] The resolution of this critical issue will advance our understanding of endometriosis-associated infertility and should pave the way to improved therapies.

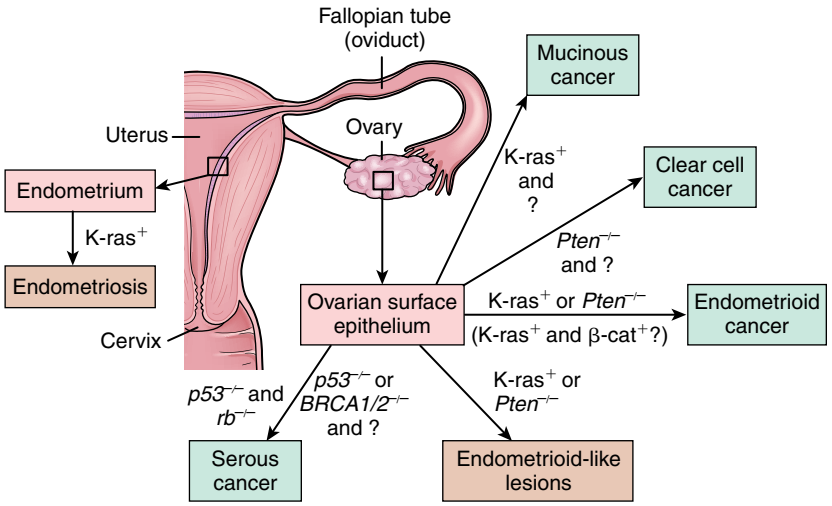

FIGURE 26.15 Proposed genetic alterations in the development of endometriosis and epithelial ovarian cancers. *Pink rectangle*, normal tissue; *brown rectangle*, benign disease; *green rectangle*, cancerous lesions; +, activating mutations in oncogenes; –/–, inactivating mutations in tumor suppressor genes; ?, indicates that the second genetic hit is unknown. *(Adapted from Matzuk MM. Gynecologic diseases get their genes.* Nat Med *11:24–26, 2005.)*

In general, inflammatory responses in the vicinity of the ectopic endometrial implants are thought to impair sperm transport,[219] tubal motility,[220] and oocyte development.[221] *In situ* menstruation within endometriotic lesions has been proposed to cause adhesion formation, fibrosis, and proximal tubal obstruction.[222,223] Moreover, the eutopic endometrium of women with endometriosis manifests a variety of histological and biochemical perturbations, including increased immune cell infiltration[224] and increased cytokine and chemokine expression.[153,225,226] Increased concentrations of complement component C3,[162] E-cadherin, total β-catenin and decreased αvβ3 integrin,[227] glycodelin,[228] HOXA10, and HOXA11[84] have been reported. Based on our current knowledge of their functions, dysregulation of these gene products would be predicted to cause impaired implantation. Altered αvβ3 integrin expression may be corrected by aromatase inhibitor therapy.[229]

High peritoneal fluid concentrations of prostaglandins have been noted by some authors but not by others. As these are rapidly acting autocrine and paracrine substances, circulating levels may not be revealing. Prostanoids offer an attractive mechanism for endometriosis-associated pain and also may affect fertility via interference with tubal motility and ovum pick-up.[230] When sperm were incubated with peritoneal fluid from healthy controls compared to those with endometriosis the latter samples significantly induced sperm DNA fragmentation.[231] There is some evidence that women with endometriosis have abnormal[17] or suppressed uterine peristalsis which may have a negative impact on sperm or oocyte transport.[232]

Some data indicate that the spontaneous abortion rate is increased in women with endometriosis,[233] although this finding has been disputed in other studies.[234] In a meta-analysis of IVF outcomes, women with advanced endometriosis had substantially lower fertilization and implantation rates compared with other indications.[235] These observations are discussed in further detail later in this chapter.

Endometriosis and Genital Tract Carcinoma

Endometriosis is identified concurrently in approximately 17% of ovarian carcinoma cases. In a recent pooled analysis of case-control studies involving more than 23,000 participants (7911 with ovarian cancer) a history of endometriosis was associated with a 1.5% life-time risk of developing ovarian cancer (endometrioid, clear-cell, and low-grade serous).[236] A murine model that combined an oncogenic Kirsten rat sarcoma *(K-ras)* allele activation with a tissue-specific conditional knock-out of the tumor suppressor phosphatase and tensin *(Pten)* resulted in aggressive and widely metastatic endometrioid ovarian adenocarcinoma, recapitulating the histomorphological appearance seen in the human disease (Fig. 26.15).[237] Using an intact immunocompetent murine model of endometriosis, Cheng and colleagues were able to activate *K-ras* in donor endometrial tissue to promote endometriotic lesion development.[238] Recently, *K-ras* variant alleles were identified in 31% of endometriosis cases, compared to 5% of controls.[239]

A rare but serious complication of cervical endometriosis is the misclassification of cervicovaginal cytologic smears as harboring a high-grade intraepithelial lesion, atypical glandular cells of undetermined significance, or even an adenocarcinoma *in situ*.[240]

Treatment

Surgical Therapy for Pain Associated with Endometriosis

Owing to their peritoneal location, most endometriotic lesions are amenable to laparoscopic extirpation. Techniques involving aggressive implant excision, electrofulguration, or laser vaporization have been adapted through endoscopic ports and these procedures have been taught widely to gynecological surgeons. It is relatively rare that laparotomy or hysterectomy is necessary in the treatment of women who wish to preserve their uterus.

One of the first evidence-based evaluations of laparoscopic treatment of endometriosis-associated pelvic pain was carried out in the United Kingdom in the early 1990s. Sutton and colleagues conducted a randomized, prospective, double-blind trial in 63 patients with minimal to moderate endometriosis. Half of the subjects underwent laser ablation of endometriotic deposits and laparoscopic uterine nerve ablation, and the others received a diagnostic laparoscopy

and expectant management. Pain symptoms quantified by a visual analog scale were significantly improved in 62.5% of those receiving laser ablation, compared with 22.6% in the expectant group at 6 months after surgery.[241] In a long-term follow-up study of the laser-treated cohort (approximately 72 months after surgery), continued symptom relief was reported in 55.3% of the respondents.[242] Laparoscopic uterosacral nerve ablation does not add any further relief of pain beyond ablative surgery alone.[243,244] In a randomized, blinded, crossover pain study, Abbott and colleagues demonstrated an 80% success rate in excisional endometriosis surgery compared to an approximately 30% response to sham surgery. The effects were independent of extent of disease.[106] These reports substantiate a therapeutic role for laser laparoscopy in the management of endometriosis pain and indicate that the median time to pain recurrence after surgical treatment was 20 months. Future innovations in endoscopic surgery for endometriosis may include targeted energy absorption, such as photosensitization of the lesions using hematoporphyrin derivatives[245] or autofluorescence to detect nonpigmented endometriotic lesions.[246] Tissue staining with either indigo carmine or methylene blue at the time of laparoscopy can help accentuate the identification of subtle lesions.[247]

Treatment of ovarian endometriomas (chocolate cysts) can be particularly challenging. These respond very poorly to medical therapy, and hence, operative extirpation is the preferred approach. Jones and colleagues treated 73 consecutive cases of endometrioma larger than 2 cm by laser or bipolar diathermy. After 1 year, 16.4% of subjects had recurrences. This prognosis was noted to be particularly more likely if the cysts were bilateral.[248] According to a recent Cochrane Review, excision was better than drainage and ablation for (1) recurrence of the endometrioma, (2) recurrence of symptoms, and (3) fertility outcome.[249] Recurrence after surgical intervention can be decreased with the use of postoperative suppressive medical therapy such as hormonal contraceptives.[250]

Definitive treatment for endometriosis consisting of a hysterectomy with removal of both ovaries leads to the dilemma of postoperative hormonal therapy (for hypo-estrogenemia) in the face of exacerbating residual endometriosis.[251] The recurrence rate with hormonal therapy is 3.5% or 0.9% per year and there is no greater risk of recurrence of pain if estrogen is started immediately after surgery compared with a 6-month delay.[252] If hysterectomy with ovarian cryopreservation has been performed in a premenopausal woman, no postoperative suppressive medical therapy is warranted as the recurrence rate is small.[253]

Medical Therapy for Pain Associated with Endometriosis

Hormonal treatments approved for endometriosis treatment by the U.S. Food and Drug Administration (FDA) include gonadotropin-releasing hormone analogue (GnRHa), depot medroxyprogesterone acetate, and the androgen danazol. In addition, continuous oral contraceptives have been evaluated and are widely used.[254] An alternate progestin approved for endometriosis use in Europe, dienogest, is actually a component of the FDA-approved oral contraceptive Natazia™.[255] When used continuously following surgery for endometriomas, oral contraceptives significantly reduced recurrence when compared to nonusers.[256,257] The majority of evidence supporting medical therapy for endometriosis is observational; however, some randomized clinical trials have been evaluated.[258] An evidence-based assessment of treatment of endometriosis-associated pelvic pain in two randomized, placebo-controlled trials indicated that medroxyprogesterone acetate, danazol, or GnRHa were all more effective than placebo. Pain relief of more than 6 months' duration was noted in 40% to 70% of women.[259]

Although highly effective in the management of chronic pain with endometriosis, GnRHa treatment has been limited to 6 months by the FDA because of the hypoestrogenic effects induced by ovarian suppression. The previously mentioned principle of an estrogen threshold (Fig. 26.4)[260] has been used to overcome this limitation. Suppression of the hypothalamic-pituitary axis with GnRHa is now accompanied with "add-back" of exogenous ovarian steroids. Dose-seeking trials have identified "add-back" regimens that reverse vasomotor symptoms and bone mineral loss. Add-back regimens consisting of norethindrone acetate combined with low-dose estrogen can safely extend pain relief and bone preservation for at least 1 year, and one trial with a limited number of participants found no ill effect after 10 years of add-back therapy.[261,262] Three months of the nasal spray formulation of GnRHa seemed to be as effective as a 6-month course.[263] Another option is subcutaneous depot medroxy-progesterone. Two randomized, clinical trials demonstrated that the 6 months of subcutaneous progestin was as effective as leuprolide acetate in diminishing endometriosis-associated pain.[264,265] Drop-out rates were significant for both groups, however. The purported benefits of the subcutaneous progestin are decreased cost, easier administration, and more favorable effect on bone mineral density.

In a double-blind, placebo-controlled, crossover study, a nonsteroidal anti-inflammatory drug (naproxen) was twice as effective as placebo in relief of secondary dysmenorrhea associated with endometriosis.[266] High levels of cyclooxygenase-2 (COX-2) are expressed in endometriotic lesions,[267] implying that selective COX-2 inhibitors might also be of clinical benefit. Although this class of drugs is effective in the treatment of primary dysmenorrhea,[268] the limited data available from endometriosis trials were inconclusive.[269]

Experimental Medical Therapy

Like COX-2 inhibitors, a variety of evolving new medical treatments hold theoretical promise for the treatment of endometriosis-associated pain and inflammation. GnRH antagonists, which induce an immediate suppression of gonadotropin production without the initial "flare" effect of the GnRH superagonists,[270] may be advantageous in this setting.[271] Selective estrogen receptor modulators (SERMs) also may be of theoretical benefit. Due to its partial agonist activity within the endometrium, tamoxifen can exacerbate endometriosis.[272] Although raloxifene was shown to reduce endometriosis in murine and rhesus models of this disease,[273] a preliminary clinical trial unexpectedly showed exacerbation of this SERM on pain symptoms.[274] Through their effects on estrogen production and action, aromatase inhibitors[137] have been proposed as new therapeutics in endometriosis.[275] Aromatase inhibitors have been proposed

as new therapeutics in endometriosis.[276] Acceptance must await larger clinical trials. Although there is no randomized controlled trial, an early open-label, nonrandomized proof-of-concept study suggests a benefit in the treatment of rectovaginal endometriosis.[277] Endometriosis in this anatomical location also expresses the aromatase enzyme (Fig. 26.9).[138]

Progesterone receptor modulators have also been investigated.[278] Early experiences with high and low doses of the antiprogestin mifepristone showed an improvement in pelvic pain without ostensible regression of peritoneal implants.[279,280] The antiglucocorticoid effects of this class of compounds, and their ability to create a hyperestrogenic endometrial milieu,[281] are likely to limit clinical applicability. Interesting recent *in vitro* studies suggest that part of the effectiveness of mifepristone might be due to its antioxidant properties.[282] Ligands for another nuclear receptor, peroxisome proliferator-activated receptor (PPAR)-γ, were shown to reduce RANTES and IL-8 secretion and the proliferation of endometriotic stromal cells; inhibit macrophage activation and migration in *in vitro* and murine models of endometriosis[283-285]; and to reduce endometriotic lesion volume in rat and baboon models of the disease.[286-289]

Therapeutic agents that target cytokine production and action also are under investigation as possible clinical adjuncts for endometriosis treatment. Using a rat model of endometriosis there was efficacy shown with imiquimod (toll-like receptor agonist), recombinant human INF-α-2b, leflunomide, thiazolidinedione, and levamisole.[288,290-292] Administration of thiazolidediones or recombinant TNF-binding protein-1 or anti-TNF-α monoclonal antibody c5N inhibited the development of endometriosis in a baboon model[293-295] and blockade of VEGF action in mouse endometrium can be achieved using soluble VEGF-R1 (sflt-1).[296] Future applications of the same strategies may possibly be useful in clinical endometriosis.

A novel approach to the treatment of pain associated with deep, rectovaginal endometriosis was introduced[297] in a prospective, self-controlled trial of 11 symptomatic patients with rectovaginal endometriosis. Use of a levonorgestrel-releasing intrauterine device for 12 months resulted in significant improvement in dysmenorrhea, pelvic pain, and deep dyspareunia, and objective resolution of the size of rectovaginal endometriotic lesions by ultrasonography was noted. Another trial found similar pain relief after 6 months of therapy comparing the levonorgestrel intrauterine device with GnRHa.[298] Other agents that may have some potential if confirmed in larger clinical trials include, etonogestrel nonbiodegradable contraceptive implant, bufalin, BAY 11-7085, (a soluble inhibitor of NK-κB activation), dopamine agonists, French maritime pine bark extract, yiweining, rapamycin, metformin, oral gonadotropin releasing hormone antagonist, human chorionic gonadotropins, doxycycline, melatonin, genistein, atorvastatin, trichostatin A, and vaginal danazol.[299-310]

Evidence is accumulating to suggest that medicinal botanicals with anti-inflammatory and pain-alleviating properties hold promise for treatment of endometriosis.[311] Although their safety remains untested formally, in general these additives are not thought to impair ovulation or fertilization and hence may be taken by women attempting conception. Medicinal herbs and their active components exhibit cytokine-suppressive, COX-2-inhibiting, antioxidant, sedative, and pain-alleviating properties, which would be predicted to have salutary effects in endometriosis. Although controlled, randomized clinical trials are rare, phytotherapies with a long tradition of safe use (e.g., curcumin and its analogs) have multiple beneficial characteristics and should be evaluated more thoroughly (Table 26.3).[312]

Surgical Therapy for Infertility Associated with Endometriosis

The role of laparoscopic surgery in the amelioration of infertility in women with minimal to mild endometriosis has long

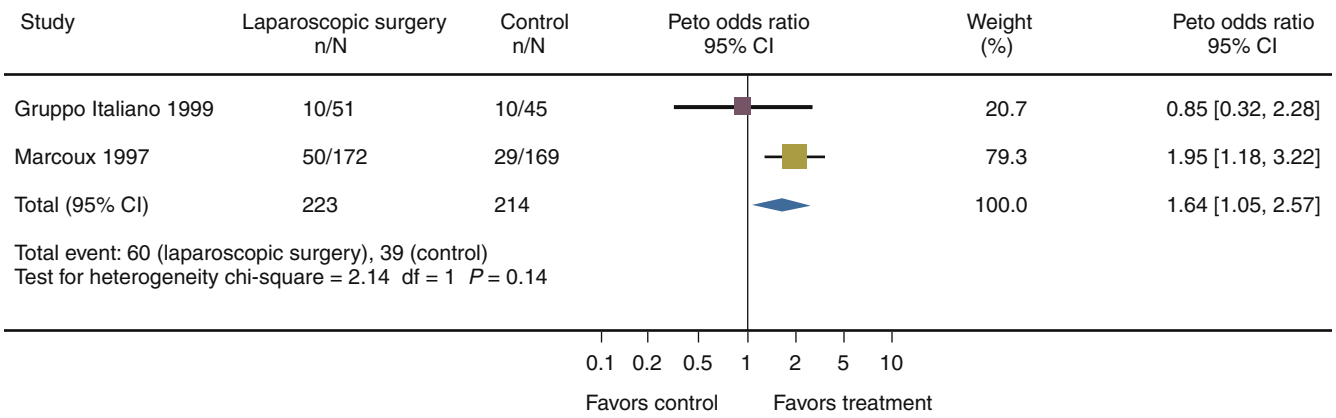

FIGURE 26.16 Meta-analysis of the two randomized trials assessing the efficacy of laparoscopic surgery in the treatment of subfertility associated with minimal-to-mild endometriosis. Combining live birth and ongoing pregnancy data from the two studies shows an improvement with laparoscopic surgical treatment (OR 1.64, 95%; CI 1.05-2.57). df, degrees of freedom *(From Jacobson TZ, Barlow DH, Koninckx PR, et al. Laparoscopic surgery for subfertility associated with endometriosis.* Cochrane Database Syst Rev *4:CD001398, 2002.)*

been an accepted dictum. This question was objectively addressed in a recent meta-analysis of two randomized controlled trials: the multicenter Canadian trial[313] and a smaller Italian study.[314] In this analysis, destruction of lesions—even in early-stage disease with infertility—led to improved pregnancy rates in women attempting spontaneous conception. One of the criticisms of the Canadian study is that adhesiolysis was performed preferentially in the surgical treatment group and that this intervention, rather than lesion ablation per se, may have accounted for the higher pregnancy rate. Based upon the larger (and more positive) of the two studies,[313] an additional pregnancy was achieved for every eight operative laparoscopies performed (Fig. 26.16). Given an estimated prevalence of 30% endometriosis in an otherwise undiagnosed infertile population, the total number of laparoscopic cases to yield a single additional pregnancy would jump to 4 (Table 26.4). Hence, although a place exists for surgical treatment of endometriosis-associated infertility, it carries a relatively high cost. There is some evidence that ablation of lesions in minimal-to-mild disease prior to IVF results in a higher live-birth rate.[315]

No published controlled trial compares surgical treatment versus no treatment in women with moderate to severe endometriosis; however, many publications cite a near-zero pregnancy rate for women with extensive disease. Uncontrolled trials show increased pregnancy rates for these women if normal pelvic anatomy is restored.[316]

When considering surgical extirpation of endometriomas, the data are limited and conflicting. Some studies indicate that cystectomy may be deleterious to residual oocyte and hormone function,[317-319] whereas another showed no differences in fertility outcomes between those women with resected endometriomas, those with endometriosis, and those with tubal infertility.[320] Ovarian cystectomy for endometriomas has been associated with significantly diminished AMH after surgery.[321,322] Beretta and colleagues[323] demonstrated better pain and spontaneous fertility outcomes after cystectomy compared with drainage and coagulation. A recent Cochrane review of the published literature supports this recommendation.[249] Further studies will be needed to clarify the risk-to-benefit ratio of endometrioma excision in women with endometriosis-associated infertility.[324] Prospective trials are needed prior to recommending transvaginal ultrasound needle-guided aspiration of endometriomas prior to IVF.[325]

In cases of infertility due to moderate-to-severe endometriosis, some authors have advocated combined medical and surgical therapy.[326] The current medical treatments are described later in this section, but due to their anovulatory side effects, these treatments impair fertility in the short term.

Medical Therapy for Infertility Associated with Endometriosis

Most established medical therapies are aimed at inhibition of ovulation as a means of interrupting hormonal stimulation of endometriotic implants. Therefore, these approaches are used only for short periods of time to decrease the size or activation state of endometriotic lesions prior to attempted conception. Five trials using six different treatments were compared with placebo or no treatment. Another eight randomized trials were performed in which danazol was compared with a second medication. A meta-analysis[327] of several trials showed no differences between the treatment and control arms with respect to fertility outcomes

(odds ratio = 0.85; 95% confidence interval, 0.45-1.22). However, when one considers the time from diagnosis, commencement of medical treatment, and interruption of ovulation versus no treatment, patients undergoing medical treatment had a substantially lower monthly fecundity rate than control subjects because of the loss of opportunities for conception.[314] Conventional hormonal regimens, therefore, have no place in the treatment of endometriosis-associated infertility.

Superovulation has been studied in three randomized trials and led to an improved clinical pregnancy rate in women with endometriosis.[328-330] Whether or not intrauterine insemination is of any added benefit remains to be determined.

Use of gonadotropin releasing hormone agonist, or possibly oral contraceptives, for 3 months prior to IVF increases the clinical pregnancy rate by fourfold.[331,332]

Assisted Reproductive Technology

Three randomized trials have been done comparing ovulation induction[330] and ovulation induction combined with intrauterine insemination in women with endometriosis.[328] It was clearly shown in these studies that these treatments enhanced fertility relative to timed coitus alone.

A single randomized controlled IVF trial was reported, but only 15 patients underwent IVF and 6 had no treatment. These numbers are too small to derive meaningful conclusions.[333] In a retrospective study, no differences were found in women undergoing IVF versus expectant management over a 3-year period.[334] Although it seems that IVF may reduce the time to pregnancy, it is unknown whether it actually increases the absolute pregnancy rate. Further trials will be needed before recommendations can be made. It is comforting to note that IVF is not a risk factor for endometriosis recurrence.[335]

In a meta-analysis of 22 independent studies, Barnhart and colleagues[235] determined that the overall likelihood of achieving pregnancy was significantly lower for stage III-IV endometriosis patients (adjusted odds ratio, 0.56; 95% confidence interval, 0.44-0.70) compared with tubal factor control subjects. Multivariate analysis demonstrated a decrease in fertilization and implantation rates and fewer oocytes in the endometriosis subjects. This would be consistent with the lower AMH levels in moderate-to-severe endometriosis.[215]

Summary

Although recognized for centuries, the etiology and pathogenesis of endometriosis remain topics of intense debate and investigation. The classical theories of histogenesis have been replaced by a neoclassical concept that this is a complex, multigenic disorder influenced by epigenetic and environmental factors. Definitive establishment of a clinical diagnosis requires direct observation, and ideally histopathological confirmation of ectopic endometriotic implants. However, a presumptive clinical impression (supported by physical findings and confirmatory radiological imaging) is adequate for most clinicians to initiate therapy.[336] Future confirmatory biochemical tests, based on endometrial biopsy findings, and possibly by serum analytes may reduce the necessity of laparoscopic evaluation for diagnosis. However, surgical treatment of endometriosis, perhaps with improved means of endoscopic lesion ablation, will likely retain a prominent place in endometriosis therapy.

The development of new medical treatments for endometriosis will parallel our further understanding of its underlying pathophysiology. Increased concentrations of activated pelvic macrophages and lymphocytes and elevated levels of specific cytokines and growth factors support the hypothesis that the immune response is activated in endometriosis. Angiogenesis inhibitors may play a more prominent therapeutic role in the future, but care must be taken to avoid the potential teratogenic side effects of this drug class. Medicinal herbs, despite millennia of clinical use, remain untested formally and potentially harbor untoward effects on ovulation, fertilization, or embryonic development. Whether components of the innate and adaptive immune systems play primary, causative roles, or merely reflect a reaction to the presence of ectopic implants, is unknown at present. A complex network of locally produced chemokines, cytokines, and prostaglandins is proposed to modulate the growth and inflammatory behavior of endometriosis—affecting implant proliferation and invasion, the recruitment of capillaries to the growing lesions, and further attraction of leukocytes to foci of peritoneal inflammation. Future endometriosis therapeutics will need to exploit our identification of relatively specific targets within pathways that regulate the growth and invasion of endometriotic lesions, ideally sparing or correcting the function of a woman's eutopic endometrium.

CHAPTER 27

Benign Uterine Diseases

Zaraq Khan
Elizabeth A. Stewart

The traditional concept of the uterus is that the endometrium is the dynamic tissue, providing an intricate set of functions throughout the menstrual cycle that rarely culminates in implantation and pregnancy. The myometrium has been viewed as an inert tissue, chiefly important during pregnancy and when abnormal, providing the surgical livelihood of clinical gynecologists.

However, to understand both the physiology of menstruation and the pathophysiology of abnormal uterine bleeding, both the myometrial and the endometrial layers of the uterus are important. First, both myometrial processes (adenomyosis and leiomyomas) and endometrial processes (polyps) can result in abnormal uterine bleeding. Secondly, on the molecular level, since the mass of the myometrial layer is so much greater than that of the endometrial layer, the myometrium can act as a reservoir of growth factors or immune cells that then may act on the endometrium in a paracrine or local endocrine fashion.

The study of uterine molecular mechanisms is in its infancy. Study of the human uterus is difficult since all of the surgical specimens available for *in vitro* study are by definition abnormal. Additionally, many of the disorders that cause abnormal uterine bleeding (such as leiomyomas) appear to be heterogeneous in their molecular mechanisms. Just as the clinical phenotype of polycystic ovaries can result from various molecular defects, leiomyomas likely have many underlying genetic etiologies and environmental stimuli.

Nevertheless, basic investigation is beginning to reveal that a number of common molecular mechanisms are shared by phenotypically different diseases such as leiomyomas, adenomyosis, and endometrial polyps. We can speculate that in the future these diseases may be classified on the basis of molecular defects rather than on microscopy. This would allow us to understand the genotype-phenotype relationships that we currently find puzzling: for example, why some women have profound heavy menstrual bleeding with these diseases and others are asymptomatic. Understanding new elements of the biology of these diseases will lead to innovative therapy.[1]

Our lack of understanding of molecular physiology and pathophysiology has left us with extirpative surgical treatment as our therapeutic mainstay. While we have become more elegant in our surgical approach, the high risk of recurrent disease following conservative surgeries indicates that understanding the underlying mechanism and moving toward prevention is likely to be more successful.

The fact that modern women spend a larger percentage of their lifespan menstruating compared with women in previous centuries and females of other species may also contribute to many pathological conditions. Many genes are differentially regulated at specific parts of the menstrual cycle. Thus, constantly turning the same molecular switches on and off may have the same effect as constantly turning a light switch on and off: the system becomes disrupted.[2] This fact, as well as species differences, has made it difficult to use animal models to study the function of uterine tissue.

Finally, the economic implications of these diseases are significant. The cost of leiomyomas alone in the U.S. has been estimated at $5.9 to 34.4 billion annually.[3] Lost productivity due to clinically significant leiomyomas are also a substantial cost, accounting for over 40% of total costs which average in excess of $4800 per woman per year in a commercially-insured population.[4] Neither of these figures takes into account the cost of sanitary protection, alternative and complementary remedies or the costs of women who are symptomatic but not seeking care.

Uterine Leiomyomata

Epidemiology

Uterine leiomyomas, frequently termed myomas or fibroids, are benign clonal smooth muscle-cell tumors ranging in size from several millimeters to many centimeters (Fig. 27.1). Clinically, fibroids are appreciated in approximately 25% of all women and in African American women they appear to have a threefold increased incidence and relative risk.[5] Careful pathological study of surgical specimens suggests more than 80% of African American and 70% of Caucasian women have detectable leiomyomas which parallels the lifetime incidence of the clinical disease.[6,7] Thus, in African American women, it appears there is little occult disease. This suggests that in this group, growth acceleration of transformed myocytes into clinical fibroids may be ubiquitous.[7,8] African American women are not only significantly more likely to have leiomyomas than Caucasian women but to be younger at the time of diagnosis and hysterectomy.[5,9-11] They also have more severe diseases,[9,11,12] and are two to three times more likely to have hysterectomy for leiomyomas and six-fold more likely to have a myomectomy (Table 27.1).[13,14]

Known risk factors don't adequately explain this racial disparity.[15,16] Newly discovered genetic polymorphisms

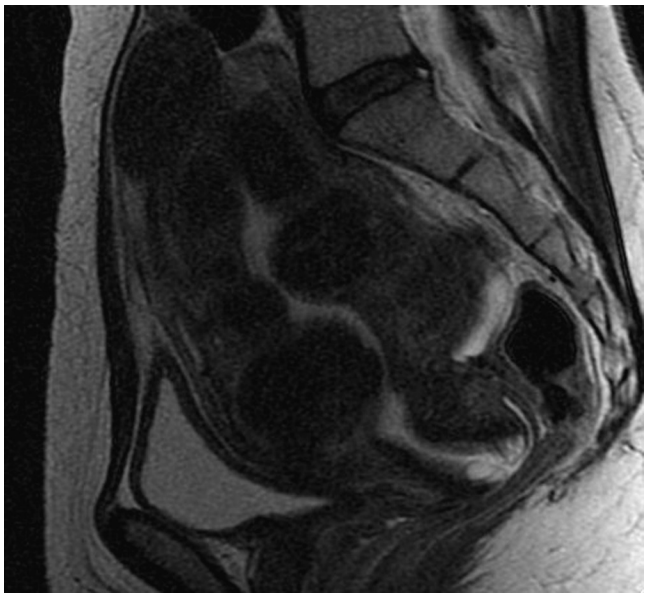

FIGURE 27.1 A T_2-weighted fast-spin echo (FSE) sagittal image of a leiomyomatous uterus with multiple type 2 submucosal fibroids. This sagittal image allows the endometrial cavity to be visualized from the fundus to the cervix, indicating that these fibroids are not displacing the cavity laterally. This series of images is typically best to visualize clinically important submucous fibroids. Visualization of the sacrum and coccyx, bladder and rectum allows assessment of bulk effects of the fibroid in the pelvis.

Table 27.1 Table Depicting Increased Burden of Fibroid Disease in African American Population

Fibroid Characteristic	African American vs. Caucasian Women	Reference Number
Incidence of uterine fibroids	Threefold increase	5
Relative risk	Threefold increase	5
Age at diagnosis	3-5 years younger	11
Severity of disease	Fivefold increase	11
Fibroid growth at older age (≥45 years)	Sevenfold-eightfold increase	53
Myomectomy risk	Sixfold increase	13
Hysterectomy risk	Twofold-threefold increase	14

that include abnormal transcriptional factors, increased aromatase activity and signal transduction genes may dictate a more severe phenotype of the disease in African American women.[17,18] Polymorphism of *catechol-O-methyltransferase (COMT)*, an essential enzyme for estrogen metabolism, has been shown to be linked to fibroid formation and is more common in African American women.[19] Vitamin D has been shown to inhibit fibroid proliferation via COMT pathway[20] and also reduces fibrosis caused by *transforming growth factor-β3 (TGFβ3)*.[21] Role of vitamin D has been reproduced in the Eker mouse model,[22] where supplementation with 1,25 dihydroxyvitamin D3 at 0.5 μg/kg per day for 3 weeks, lead to reduced myoma size compared to controls.[22] There have seen studies on African American women that correlate fibroid risk to polycystic ovarian syndrome[23] and self-reported experience of racism.[24] Understanding the unique genetic and environmental factors leading to increased risk for African American women is a key research agenda for leiomyomas. There is mixed data regarding fibroid risk in Latina women.[5,14,25]

Reproductive factors affect the risk of leiomyomas. Numerous studies have shown that parity is associated with decreased fibroid risk.[16,26,27] One hypothesis is that the remodeling of the postpartum uterus can clear nascent fibroids.[28] Support for this hypothesis came from recent studies.[29,30] In one of these reports of women beginning with pregnancy, 36% of them had no identifiable lesion on ultrasonography postpartum and 79% of the remaining fibroids had decreased in size.[31] Progestin use in the postpartum period was the only significant risk factor for limited regression of fibroids postpartum.[30] The fact that this study contrasts with previous reports, that progestin only injectable contraceptives are associated with decreased fibroid risk[32,33] and progestin only contraceptives are widely used in breastfeeding women make it critical to further explore this area. Although clinical dogma traditionally suggested that oral contraceptive pills (OCPs) were contraindicated for women with myomas, OCPs instead appear to protect against clinically evident fibroids with the caveat that timing of use may be important.[16,26,27] Exposure to OCPs between ages 13 and 16 for women in the Nurses' Health Study led to an increased relative risk of leiomyomas, while later OCP use was protective in direct proportion to duration of use.[16] Postmenopausal hormone replacement therapy (HRT) has been associated with a higher likelihood of having fibroids on pathology after surgery in one report, although this may have been due to bias, since HRT may have inhibited normal postmenopausal fibroid regression.[25] Early menarche is also associated with increased risk of developing fibroids,[11] and may explain earlier disease in African American women in whom menarche is earlier than Caucasian women.[34]

Environmental and dietary habits also appear to influence risk of myoma formation. Decreased vegetable and fruit intake, especially citrus fruits[35] and significant consumption of red meats was associated with an increased relative risk of fibroids and consumption of green vegetables with a decreased risk of myomas.[36] Reduced dairy consumption,[37] use of hair relaxer,[38] and increased intake of alcohol, especially beer, appears to increase risk in African American women.[39] Association of fibroid risk with high alcohol intake has also been reported in Japanese women.[40] No one has however, demonstrated that dietary intervention leads to changes in fibroid incidence, symptomatology, or fibroid regression. Major life events and stress,[41] as well as a history of abuse in childhood[42] have been linked to presence of uterine fibroids. *In utero* exposure to diethylstilbestrol (DES) in animals[43] and humans[44] as well as consumption of soy formula in infancy, low childhood socioeconomic status, early gestational age at birth and maternal pre-pregnancy or gestational diabetes status have all been associated to increase fibroid development risk.[15,44] Caffeine consumption was not noted to be a risk factor[39] and smoking is considered protective through an unknown mechanism.[26,45] Dietary Vitamin A from animal sources appears protective.[35]

Increased body mass index (BMI) or weight gain since age 18 also appears to influence myoma risk in some cohorts.[10,46-48] High dietary glycemic index and glycemic load[49] and decreased physical activity[50] are also risk factors. Finally, women with leiomyomas appear to be more

likely to have hypertensive disease than control women.[51] It is unclear whether this commonality is due to a common underlying mechanism since leiomyomas have been shown to share pathogenic features with development of metabolical syndrome.[52]

Pathophysiology

Leiomyomas have a median of 9% change in volume in a 6-month period.[53] Growth appears to be race related. African American and Caucasian women had similar growth till 35 years of age, after which growth rates declined for Caucasian women.[53] It is also shown that growth in fibroids is not dependent on position of the fibroid in the uterus.[54] Size of fibroids may be important as greater than 5 cm diameter lesions have less short-term change.[54]

Gonadal Steroids: Estrogen and Progesterone

There are substantial *in vitro* data supporting major roles for both estrogen and progesterone in the biology of uterine leiomyomas. The role of progesterone on myoma growth has moved beyond the simplistic concept of increasing mitosis to include inhibiting the apoptosis pathway via *B-cell lymphoma 2 (Bcl 2)* induction.[55-57] The apoptotic inhibitor *Bcl2* is present in leiomyomas but is largely undetectable in myometrium. Recently the role of *Kruppel-like transcription factor 11 (KLF11)* in integrating progesterone mediated myoma cell signaling and proliferation has been shown.[58,59] Likewise, regarding estrogen action, local action is likely key via an up-regulation of the enzyme *aromatase P450* and its gene *CYP19*.[60-62] Other elements of estrogenic response in myomas can also come into play as myoma cells have a modest increase in type I isotype of *17β hydroxysteroid dehydrogenase*.[63]

Modulation of steroid receptors is also important. Leiomyomas have increased amounts of both estrogen and progesterone receptor (ER and PR) messenger ribonucleic acid (mRNA) compared with normal myometrial tissue.[64-66] Both the A- and the N-terminally truncated B-isoforms of the PR appear to be present in both leiomyomas and myometrium, however, the A-isoform predominates.[67] Similarly, ER-α rather than ER-β appears to be the predominant form in leiomyomas.[68] In addition to the direct action of ovarian steroids on the uterus, it is possible that the reproductive axis may also influence uterine metabolism through the direct action of pituitary gonadotropins on the uterus. Gonadotropin-releasing hormone (GnRH), which is clinically used to reduce myoma size, abolishes gene expression differences between normal myometrium and myomas.[69] The placental glycoprotein chorionic gonadotropin (hCG) has been shown by several laboratories to have direct actions on myometrial metabolism.[70-72] Additionally, work has shown that follicle stimulating hormone (FSH), luteinizing hormone (LH), thyroid stimulating hormone (TSH), and their common α-subunit can all have stimulatory effects on uterine prolactin production.[71,73] There appears to be a variant LH/hCG receptor present in human uterine tissue that may modulate this action.[74,75] LH has also been associated with myoma formation but not growth independent of the patient's age.[76] Finally genome wide microarray studies have shown a strong role of glucocorticoids in pathogenesis of fibroids.[77]

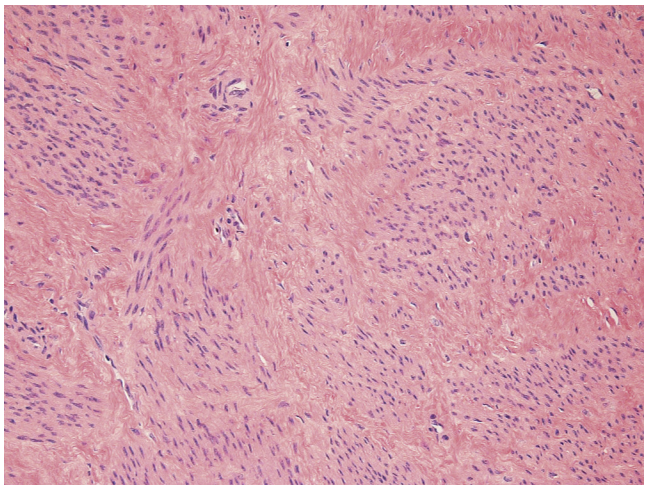

FIGURE 27.2 Histological evaluation of fibroid using hematoxylin and eosin staining highlights both cellular bundles and the acellular extracellular matrix. The extracellular matrix not only contains significant amounts of collagen type I and III but can also act as a reservoir for growth factors such as basic fibroblast growth factor (bFGF).

Fibrotic Factors

Leiomyomas can also be viewed as fibrotic tumors with a dynamic extracellular matrix (ECM) playing an important role in pathophysiology (Fig. 27.2).[78] This hypothesis dates back to the 1990s where experiments demonstrated that the ECM characterizing fibroids contains significant amounts of collagen types I and III protein, and up-regulation of mRNA levels occurs during the proliferative phase of the menstrual cycle in leiomyomas but not myometrium.[79] Other matrix components including *matrix metalloprotease stromelysin 3 (MMP 11)* and *dermatopontin* (a collagen binding protein, also having decreased expression in keloid scars) have also been shown to be dysregulated in leiomyomas.[80,81] Morphological arrangement of extracellular proteins is also abnormal in myomas.[82]

The *transforming growth factor-β (TGF-β)* system also appears to be involved in the pathophysiology of leiomyomas, as in other fibrotic processes. A complete review of this topic is beyond the scope of this chapter. Leiomyomas appear to have higher levels of *TGF-β* and particularly *TGF-β3* mRNA and protein and this in turn affects cellular proliferation.[1,83,84] Vitamin D supplementation has recently shown reversal of *TGF-β3* induced fibrosis in fibroids.[85] Additionally, *Granulocyte macrophage colony-stimulating factor (GM-CSF), connective tissue growth factor (CTGF), TGF-β4* (also known as *lefty* or *ebaf, endometrial bleeding-associated factor*), the sma and mad related (SMAD) family of transcriptions factors and the mitogen-activated protein kinase (MAPK) signaling pathway appear to be part of the fibrotic pathway dysregulated in myomas, or the myometrium or endometrium of the uterus in women with leiomyomas or abnormal uterine bleeding.[86-92] Alterations in ECM can modify mechanical stress on cells, leading to activation of Rho-dependent signaling. Activation of this solid state signaling and altered state of stress may also contribute to fibroid growth.[93,94]

Angiogenesis

Angiogenesis, the formation of new blood vessels, is physiological in the female reproductive tract as opposed to most other tissues where it is pathological. Abnormalities in uterine

blood vessels and angiogenic growth factors also appear to play a role in the pathobiology of myomas. The myomatous uterus shows increased numbers of arterioles and venules as well as venule ectasia.[95] These changes are not confined to the leiomyoma itself but also involve the myometrium and the endometrium.[96,97] Although such venous abnormalities were originally postulated to be the result of physical compression of the vascular structures by bulky myomas,[1] it is likely that molecular alterations are actually responsible for increased vessel number or abnormal function.[1,98]

The process of angiogenesis involves interactions with specific components of the ECM that are dysregulated in fibroids such as collagens type I and III.[99] There is also conflicting data regarding whether the resident immune cells (especially mast cells) contribute to myoma physiology by modulating angiogenesis.[100]

The *basic fibroblast growth factor (bFGF)* receptor-ligand system appears to be a significant factor in leiomyoma pathophysiology. In addition to promoting angiogenesis, *bFGF* is a smooth muscle-cell mitogen and acts similarly to estradiol on leiomyoma smooth-muscle cells.[101-103] Leiomyomas have increased levels of *bFGF* mRNA compared to matched myometrium, a reservoir of *bFGF* protein in the ECM and dysregulation of the endometrial type I *bFGF* receptor.[104,105]

Genetic Influences: Clinical

There are several lines of evidence that suggest that fibroids have a genetic component. First, monozygotic twins have twice the rate of concordance for hysterectomy of dizygotic twins.[106,107] There is also familial clustering; with a two-fold to sixfold increased risk of a woman having fibroids if a woman has an affected first-degree relative.[108,109] Finally, there are also specific syndromes that have a demonstrated genetic component and whose phenotype includes uterine leiomyomas in association with other specific lesions:

*Hereditary Leiomyomatosis and Renal Cell Cancer (HLRCC, MIM 605839)**

This syndrome is autosomal dominant, and affected families manifest cutaneous leiomyomas and papillary renal cell carcinoma (RCC).[110-112] Affected women can have uterine leiomyomas as well as uterine leiomyosarcomas.[110] Both malignancies (sarcomas and RCC) are atypical in their presentation compared to their sporadic counterparts; uterine sarcomas can appear in young premenopausal women, and the papillary RCC is often metastatic at presentation and more likely to be seen in women.[110] Two other syndromes had described only the association of cutaneous and uterine leiomyomas, but lessons form molecular genetics suggest these are incomplete forms of the HLRCC syndrome and should be of historical interest only (Reed Syndrome or Multiple Cutaneous and Uterine Leiomyomas [MCUL], Mendelian Inheritance in Man [MIM] 150800).[113,114]

Fumarate hydratase (FH), an enzyme that is part of the Krebs tricarboxylic acid cycle, is the gene mutation at 1q 42-43 responsible for hereditary leiomyomatosis and renal cell cancer (HLRCC) syndrome.[110,111,115,116] Germline mutations appear to result in absent or nonfunctional proteins, and thus, *FH* appears to act as a tumor suppressor.[112,117,118] *FH* appears to play a role in a small percentage of nonsyndromic leiomyomas and in Caucasian women.[119,120]

Although work on elucidating the pathogenesis of HLRCC syndrome continues, *FH* mutations appear to induce a change toward a hypoxic phenotype.[120,121] Thus, the hypothesized relationship between hypoxia and myoma pathogenesis appear linked for this subset of leiomyomas.[122]

Currently identifying women at higher risk of malignancy due to HLRCC syndrome is an important clinical task, just as identifying women whose families carry the breast cancer gene (BRCA) mutations.[123] However, in the future, individualized therapy will likely be possible based on genotype and underlying predisposition genes.[123]

Cowden Disease (MIM 158350)

This disease is a type of hamartomatous polyposis syndrome characterized by leiomyomas as well as other benign tumors, including lipomas and hamartomas. It is autosomal dominant in inheritance and has involvement of the candidate gene, *phosphatase and tensin homologue (PTEN)*.[124-128] Patients with Cowden disease have increased risk of endometrial, thyroid, kidney, and colorectal cancers. Around 40% of women with Cowden disease are reported to have fibroids.[129]

Cytogenetic and Molecular Genetics

There is also cytogenetic and molecular genetic evidence for the role of genetics in leiomyomas. Leiomyomas are monoclonal, and each tumor is an independent clonal event. Although this fact was originally investigated using G6PD polymorphisms, androgen receptor polymorphism studies concur.[130,131]

Secondly, certain cytogenetic rearrangements characterize leiomyomas. Although 40% of fibroids are 46,XX,[132] there are specific karyotypic abnormalities that have been consistent in a number of studies: t(12;14)—Translocations between chromosomes 12 and 14, Trisomy 12, rearrangements of 6p, 10q, and 13q, and Deletion of 3q and 7q.[123,132,133] There is evidence that karyotypic evolution is a late event in the pathogenesis of leiomyomas.[131] There is also some evidence that genotype is related to both fibroid size and location and that specific karyotypic groups have specific gene expression profiles.[132,134,135] Thus, many of the characteristics we attribute to submucous fibroids, as an example, may be related to genotype and thus, the clinical heterogeneity we see may be more intelligible when genotypic information is available.[136]

Many candidate genes identified for uterine fibroids map to the regions involved in these karyotypic groups. *High mobility group protein A2* (*HMGA2*, formerly called *HMGI-C*) is an architectural transcription factor located on chromosome 12 that is involved in the pathogenesis of fibroids with t(12;14).[137,138] The *HMGA2* gene is very large (13 kb with 5 exons) and most translocations involving leiomyomas map to the 5′ region of the gene.[137,139] However, recent evidence suggests that unique transcripts from the opposite deoxyribonucleic acid (DNA) strand may also play a role in pathogenesis.[140] Diminished stature, early age at menarche and higher risk of formation of fibroids has been linked to *HMGA2*.[141] *HMGA1 (HMGI[Y])* codes for a related gene on chromosome 6p.[142,143] Interestingly, abnormalities in expression of *HMGA2* in a

*The Web site: http://www3.ncbi.nlm.nih.gov/omim/contains the full online catalog of these genetic disorders.

murine model produce abnormalities of fat deposition and metabolism.[144,145] Abnormal expression of *HMGA2* could therefore potentially explain the correlation of metabolical syndrome in patients with fibroids.[52]

A genome wide association study (GWAS) from Japan, determined significant associations with uterine fibroids in three chromosomes 10q24.33, 22q13.1, and 11p15.5.[146] Subgroup analyses revealed strong association of marker single-nucleotide polymorphisms (SNPs) with uterine fibroids regardless of presence or absence of heavy or painful menstrual bleeding suggesting these SNPs are associated with predisposition genes.[146]

Finally the role of *mediator complex subunit 12 (MED12)* transcriptional factor, a mediator of both global and specific gene transcription located on chromosome Xq13.1 has also been described in the pathogenesis of uterine fibroids.[147] *MED12* was altered in 70% of tumors from 80 patients studied in this report from Scandinavia and pathway analysis suggested that ECM receptor interaction, Wingless family *(Wnt)* signaling and focal adhesion pathways were altered by this change. [147] Whole genome sequencing has recently shown *MED12* mutations to be present frequently in fibroids in racially and ethnically diverse American women confirming its importance as a key molecule in fibroid pathobiology.[148]

Rad51L1, (hREC2) encodes an enzyme which repairs double-stranded DNA breaks and is the only gene where a fusion transcript appears to play a role in fibroid biology. *Rad51L1* is on chromosome 14, and there are reports that in rare myomas with t(12;14) it forms a fusion transcript with 5′ *HMGA2*.[149-151] Inactivation of a tumor suppressor gene, *cut-like homeobox gene (CUTL1)*, acts in some myomas to suppress transcription of the C-*Myc* oncogene.[152]

Finally, the Eker Rat model for leiomyomas has a germline defect in the *tuberous sclerosis complex 2 (Tsc-2)* tumor suppressor gene.[153] In this model, recent work suggests that there is a developmental window where the expression of disease is modulated by the effect of interaction of the tumor suppressor and the steroidal milieu.[153] This animal model and especially cell lines that have been created from it have been a major asset for fibroid research. However, there are some facets of the Eker rat model that suggest it may be a better model for syndromic fibroids such as those seen in HLRCC syndrome rather than sporadic fibroids. New murine models are under development that may also aid researchers and also give insights into fibroid pathogenesis.[154] The high incidence of myomas may be explained in part by the predominance of tumor suppressor mechanisms.

A significant limitation of genetic studies is that they have largely been conducted in areas where Caucasians predominate and may not accurately reflect the karyotypes seen in African American women. Given the different clinical behavior of myomas in African American women, it is reasonable to believe that unique genes may be contributing to this risk. Association of a polymorphism in the *catechol-O-methyltransferase (COMT)* gene seen more frequently in African-American women was linked to leiomyoma risk.[19] *In vitro* work also suggests there may be differences in growth factor regulation in leiomyomas from African American women.[155] Linkage analysis for *FH* in non-syndromic leiomyomas demonstrated a significant effect of race with linkage only seen in Caucasian women and a negative relation in African American patients.[120]

Other Influences

Epidermal growth factor (EFG) is a growth factor mitogenic for smooth-muscle cells and EGF mRNA is up-regulated in leiomyomas only in the secretory phase of the cycle.[156,157] Receptor levels appear to be similar in leiomyomas and myometrium.[158] Latest work concentrates on the role of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase derived *reactive oxygen species (ROS)* for signaling EGF and platelet derived growth factor (PDGF) signaling pathway, leading to myoma cell proliferation.[159]

Heparin-binding growth factors are important biological regulators in leiomyomas since they can be secreted and bound to the reservoir of heparin sulfate proteoglycans filling the leiomyomatous ECM. *Heparin-binding epidermal growth factor (HBEGF), vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), hepatoma-derived growth factor (HDGF),* and the previously described *basic FGF* are all found in myomas.[104,160] Many have also been documented to be stored in the ECM.

Insulin-like growth factors (IGFs) can act as smooth muscle-cell mitogens and were originally shown to have increased binding to leiomyomas compared to myometrium.[158] However, assessment of mRNA levels suggests that gene expression differed among studies.[161-163] Later studies suggested specific modulation of the IGF-binding proteins.[164] Recent work has shown the role of activation of tyrosine kinases and especially the *IGF-1* signaling pathway in fibroids.[165] Regulation of these factors following GnRH-agonist treatment has also been reported.[166] There may also be increased prevalence of leiomyomas in women with acromegaly.[167]

Prolactin also appears to play an important role in myoma pathogenesis. *In vitro* studies suggest that it is mitogenic for leiomyoma and myometrial smooth-muscle cells and that the prolactin receptor is present in these tissues, setting up an autocrine or local endocrine system.[168] Additionally, agents that appear to cause clinical regression of uterine leiomyoma also appear to decrease prolactin production *in vitro*.[67,73]

The resident immune cells also appear to influence leiomyoma biology. Mast cells have been implicated in leiomyoma pathobiology given that they are generally uniformly distributed in myometrium but highly variable in leiomyomas.[73] Recent work has suggested a correlation of mast cell number with vasculature.[169] A number of cytokines have also been shown to be differentially regulated in leiomyomas and myometrium. *Interleukin 8 (IL8)* has decreased expression of both the ligand and its receptor in myometrium compared to leiomyomas.[170] The functional significance of this is shown by the fact that neutralizing antibody to *IL8* decreases cellular proliferation *in vitro*.[170] *Monocyte chemotactic protein-1 (mcp1)* is largely undetectable in normal samples of leiomyoma and myometrium but is increased significantly following GnRH-agonist therapy.[171]

Wnt 7a, the human homolog of the wingless Drosophila genes involved in anteroposterior (AP) axis formation and smooth muscle-cell patterning, appears to be suppressed in leiomyomas compared to normal myometrium and to be inversely related to ER-α expression.[172] In contrast, *secreted*

frizzled related protein 1 (sFRP1), a modulator of *Wnt* signaling, is increased in leiomyomas (particularly in the late proliferative phase) and increased by estradiol treatment and hypoxia.[173] *HOX* gene expression does not appear to differ between leiomyomas and myometrium.[174] The mRNA for proto-oncogenes *cfos* and *cjun* are also overexpressed in leiomyomas compared to normal myometrium.[175]

Parathyroid hormone-related peptide (PTHrP) mRNA is also overexpressed in leiomyomas compared with normal myometrium.[176] Serum overexpression of this protein originating from a fibroid simulating the hypercalcemia of malignancy has been reported in the literature.[177-180]

Micro RNAs (miRNAs) are small noncoding RNAs which generally inhibit gene expression and appear to have a key role in leiomyoma pathogenesis. While early studies showed there was differential expression of specific miRNAs between leiomyomas and normal myometrium and association of key miRNAs with leiomyoma size and patient race, more recent studies have started to define the key regulatory pathways they influence.[181-184] In particular, dysregulated miRNAs appear to be involved in multiple adhesion pathways and multiple signally pathways including MAPK, calcium, and insulin.[183]

Principles of Treatment

Uterine leiomyomas do not always necessitate treatment. Generally, expectant management is appropriate until the woman develops enough symptoms that she requests treatment. The U.S. Agency for Healthcare Research and Quality on comparative management of fibroids has noted the lack of published data that examines the effectiveness of treatment strategies.[185] There are two important caveats to this generalization. First, although bleeding symptoms are usually evident, bulk symptoms can be insidious in their onset and often attributed to other processes such as aging. An initial assessment of whether bleeding, bulk-related symptoms, or both are prompting therapy helps to guide appropriate therapeutic options.[2] Women not electing therapy cannot reflexively be termed asymptomatic; they may have substantial symptoms but view the therapies they are offered as worse than the disease.[2] As a second step, assessing the patient's desire regarding reproduction helps refine the available options. In general, women with complaints of heavy menstrual bleeding alone tend to have more options for therapy (e.g., endometrial ablation, hysteroscopic myomectomy and hormonal therapy including progestin containing intrauterine device (IUD) than women with concurrent bulk-related symptomatology.

Finally, menopause can be a cure for women with myomas. Clearly, heavy menstrual bleeding ceases with the onset of menopause. However, not all women have enough volume reduction to alleviate their symptoms. In addition, bleeding symptoms may continue for women who elect postmenopausal hormone replacement therapy (HRT), and studies have suggested growth of myomas in women who take HRT.[25,186]

Surgical Therapies

Hysterectomy provides the only cure for fibroids and will remain a viable treatment option for the near term. Additionally, short-term outcome studies suggest that women with myomas experience improved quality of life following hysterectomy, and hysterectomy also eliminates concomitant conditions including adenomyosis, endometrial polyps, and abnormal pap smears.[2,187,188] Unlike the case in hysterectomy for endometriosis, the ovaries can be retained without losing therapeutic efficacy. Generally, women weigh the risk of menopausal symptoms against the risk of ovarian tumors in making this decision. The attention paid to the ovary's production of androgens postmenopausally and their possible importance in mood and libido appears to be leading to an increase in number of women who retain their ovaries even if they are perimenopausal.[189] The fact that hysterectomy, even without oophorectomy, decreases the risk of ovarian cancer may also affect decision-making on this issue.[190,191] Laparoscopic, rather than open hysterectomy if possible should be a goal if this treatment modality is chosen. As robot-assistance has shown reduction in likelihood of conversion to laparotomy at time of hysterectomy, there may be hidden potential in this new modality compared to traditional aggressive surgery.[192] Despite definitive treatment, hysterectomy alone (without oophorectomy) has been linked to increased incidence of cardiovascular morbidity,[193,194] prolapse,[195] and worsening cognitive function including Alzheimer and Parkinson disease.[196] These long-term adverse outcomes should be kept in mind when recommending hysterectomy as a surgical therapy.

Finally, the use of supracervical or subtotal hysterectomy in women with leiomyomas is debated. The fact that 7% of women in an unselected population have cyclic bleeding following this type of hysterectomy deserves further study to see whether these women had bleeding complaints or fibroids prior to hysterectomy.[197] Women may also run the theoretical risk of the formation of cervical fibroids following supracervical hysterectomy. Finally, accumulating data suggests that, at least in the short term, sexual functioning is not improved with supracervical hysterectomy.[198,199]

Nonetheless, as women seek less invasive and the healthcare system seeks less costly options, alternatives to hysterectomy will become more widely used. All surgical alternatives to hysterectomy, however, share the risk of new myoma formation what is commonly but incorrectly termed fibroid "recurrence." Unlike the similar phenomenon after surgery in malignant disease, this is unlikely to be persistence of the same tumor but instead growth of additional tumors that may have been missed, not treated, resistant to treatment, or not yet present at the time of initial therapy. Thus, following a variety of techniques, including abdominal myomectomy and uterine artery embolization, the risk of subsequent procedures is significant.[200,201]

Since the 1930s, abdominal myomectomy has been the traditional alternative to hysterectomy, because it preserves the uterus and allows childbearing.[202] However, open myomectomy does have morbidity similar to that of hysterectomy and has significant risk of subsequent surgery.[203-205] Myomectomies are now increasingly being performed laparoscopically, with or without robot-assistance. Rates of conversion to laparotomy have been reported as low as 2% after laparoscopic myomectomy[206] and it has shown fewer complications when compared to open myomectomy.[207,208] Patients undergoing traditional myomectomy via laparotomy, when compared to robot-assisted myomectomy, had more estimated blood loss and a longer length of stay in

the hospital.[209,210] When outcomes from robot-assisted laparoscopic myomectomy, standard laparoscopic myomectomy and open myomectomy were compared, patients with laparoscopic and robot-assisted procedures had similar blood loss and length of stay, both of which were reduced compared to the open procedure.[211] Short-term surgical outcomes are similar after robot-assisted myomectomy and standard laparoscopic myomectomy.[212] Reports have shown increased operating time with robotic procedures, however rate of complications are low compared to open surgery.[211,213,214] Using single port laparoscopy or laparoendoscopic single-site surgery (LESS) has led to success for myomas; however, since this is the newest form of laparoscopic innovation, data is limited.[215-217]

Abdominal myomectomy permits healthy pregnancies after surgery and pregnancy rates have been reported to be in the 50% to 60% range.[218] Uterine rupture following myomectomy is very rare at 0.5% to 1% and is suggested that it may be related to surgical technique.[219] The common clinical practice of counseling women who have had a myomectomy with a transmural uterine incision to undergo an elective cesarean section is based on this risk of uterine rupture following classical cesarean delivery. However, there is no evidence they are analogous situations.[220] There is enough evidence to question the rationale for the conventional practice and recommendation of cesarean delivery after myomectomy, even if the endometrial cavity has been breached.[221-225]

Though laparoscopic myomectomy involves much smaller incisions and a quicker recovery time, it does require a surgeon skilled in laparoscopic suturing and not all women have the size and number of fibroids amenable to this technique. While updated series suggest that the risk of uterine rupture is low following laparoscopic myomectomy, rare cases continue to be reported.[226-230] Because these uterine ruptures typically occur remote from term, appropriate counseling for patients contemplating pregnancy is important, especially if devascularization with cautery occurs intraoperatively. Data is very limited on obstetrical outcomes following robot-assisted myomectomy, but the few reports have been reassuring.[231,232]

Myolysis is a variation on the technique of laparoscopic myomectomy in which the leiomyoma tissue is coagulated rather than removed.[233] While this technique is easier to master than laparoscopic morcellation or suturing, localized destruction without repair may also increase the chance of uterine rupture and adhesion formation.[234]

For women with submucous myomas, the use of hysteroscopic myomectomy has distinct advantages. With their accessible location, type 0 and I (European Society of Hysteroscopy Classification) myomas can be resected with an intrauterine operative endoscope with good long-term results.[235] Although this procedure requires highly skilled practitioners, it can be done as outpatient surgery, often with a regional or local anesthetic and sedation that eases recuperation. Symptomatic relief is good with fewer than 16% of women in one large series who were treated for menorrhagia reporting second surgeries after 9 years.[235-237] Fertility rates appear excellent after hysteroscopic myomectomy, and there have been no case reports of uterine rupture after uncomplicated hysteroscopic myomectomy.[238]

For women who have completed childbearing and for whom bleeding is the primary problem, endometrial ablation, either alone or in combination with hysteroscopic myomectomy, may give relief with minimal invasiveness.[239] Increasingly, a levonorgestrel IUD can be used for a "reversible endometrial ablation."[240,241] In addition to providing effective control of bleeding, it provides contraception for women in this premenopausal age group, in contrast to surgical endometrial ablation which leaves women at risk for tubal and cervical and cervical ectopic pregnancies.

Uterine Artery Embolization (UAE)

Transcatheter arterial embolization has long been an effective percutaneous technique for controlling bleeding in a wide variety of disorders. Its use for the treatment of leiomyomas was first reported in 1995.[242] Although initially used as an alternative for patients who were felt to be poor surgical candidates, the resolution of symptoms in the initial cohort encouraged the use of this technique as a primary therapy.

UAE is increasingly the first line alternative to hysterectomy for women with bulk-related symptoms and no desire for future pregnancy,[243,244] and has been recommended by the American Congress of Obstetrics & Gynecology (ACOG) as a safe and effective form of uterine preserving treatment for fibroids.[220] It provides a decrease in heavy menstrual bleeding and bulk-related symptoms in 75% to 85% of women and a volume reduction of 30% to 46% over up to 5 years of follow-up.[244] Need for a second form of intervention after UAE is noted to be somewhere between 9% and 32%.[245-248] Previously thought of as a contraindication, fibroids greater than 10 cm diameter in size, have been shown to be treated successfully with UAE.[249,250]

A series of randomized clinical trials (RCT), mostly conducted in Europe, have compared outcomes of up to 5 years for women undergoing UAE and surgery (which included hysterectomy and/or myomectomy). These studies show women undergoing UAE have less pain, shorter hospital stay, a quicker return to work, equal post treatment symptom scores (based on standardized and validated questionnaires), no difference in health-related quality of life years and less healthcare costs when compared to surgery.[245,246,248,251-253]

It is relatively common for submucous myomas to be expelled vaginally after treatment[244] and thus, most hysteroscopically-resectable fibroids are still approached surgically. Similarly, the presence of pedunculated subserosal fibroids has historically been considered a relative contraindication to UAE therapy although no cases have been reported of intraperitoneal expulsion. There is some data that suggests that UAE can still be performed in these cases of pedunculated fibroids.[254,255] A laparoscopic approach can also be considered in such patients. Studies also suggest that high T2 signals predict greater volume reduction and complete devascularization predicts outcome at 5 years.[256-258]

Most patients develop significant pain and some vaginal discharge following the procedure and usually require intravenous narcotics for pain control. "Postembolization syndrome," defined as the combination of diffuse abdominal pain, mild fever, and mild leukocytosis is common and can occur in 30% to 40% of patients and gradually improves over a week.

It is important to assess the effects of UAE on the ability of women to become pregnant subsequently or to carry a pregnancy to term. Thus far, there are a number of reported patients who became pregnant following UAE.[259-265] Although no difference in intrapartum adverse outcomes was noted when patients after UAE were compared to patients after myomectomy, cesarean delivery rate was increased in both groups.[260,263] Pregnancy clearly can and does occur following UAE with success rates reported from 20% to 60%,[263,265] however, the risk of spontaneous miscarriage in these women has been noted to be higher compared to women with fibroids that have not undergone UAE treatment.[266] There are two major areas of caution for women wishing to optimize their fertility potential: effects on ovarian function and myometrial wall integrity.

Due to increased placental implantation issues after UAE, close monitoring of the placental status has been recommended.[264] Around 13% of women in one series, who were nulliparous and had no other risk factors, had some form of placenta previa or accreta in one series.[264] The early data on ovarian damage used amenorrhea as the indicator of perturbed ovarian function.[267,268] It is clear that amenorrhea risk is age related with women under 40 having a 3% risk and women over 50, a 41% risk.[267] Newer studies evaluate follicle stimulating hormone (FSH) and antimüllerian hormone (AMH) levels to detect more subtle damage.[269-272] While studies with short-term outcome may not show impact,[270] most have shown an age dependent risk, with risk increasing more so after 45 years of age.[269,271] Compared to hysterectomy, UAE causes more of a decrement in AMH levels after a 2-year follow-up following UAE treatment.[272] However, it is often overlooked that surgery also has an adverse impact on ovarian reserve. A putative mechanism is suggested in another report that indicated significantly increased FSH levels following UAE in patients with utero-ovarian vascular anastomoses.[271]

Focused Ultrasound: Non-Invasive Treatment

MRI guided focused ultrasound surgery (MRgFUS) provides a noninvasive ablation method that is FDA-approved for the treatment of uterine fibroids since 2004. While pioneered for the treatment of uterine fibroids, this modality can be used to treat multiple diseases and may prove to be the next step in surgical innovation from open to minimally invasive to noninvasive approaches.

Just as a laser amplifies and collates light into a therapeutic modality, FUS can deliver a large amount of energy to target tissues in a noninvasive way. Treatment is accomplished by placing a transducer against the abdomen, targeting an intraabdominal myoma without breaching the skin. The intensity of FUS used for treatment is significantly higher than that used in diagnostic ultrasound and can rapidly increase temperature at the focal point in excess of 70° C. At this temperature, coagulative necrosis will occur.[273] The procedure is performed under conscious sedation. After T2-weighted images are obtained (to develop a treatment plan), FUS sonications are targeted at the fibroid while MRI provides continuous thermal feedback.

The strongest predictor of MRgFUS success is the nonperfused volume (NPV) or the area devascularized by treatment that is nonperfusing in post treatment gadolinium imaging in the fibroid achieved after treatment.[274-280] Seventy one percent of women reached a target symptom reduction score on the uterine fibroid symptom and quality of life (UFS-QOL) questionnaire[281] at 6 months and 51% maintained this at 12 months in one of the pivotal trials.[276] In newer studies as higher NPV rates were achieved, quality of life improved.[282] Volume reduction is again proportional to NPV achieved after treatment. Up to 40% reduction in volume has been noted in fibroids after MRgFUS treatment.[280] When low NPV (of around 26%) was achieved, 28% of patients ended up with an alternative form of treatment at 12 months after MRgFUS.[282] Newer reports with higher NPV achieved (around 60%) led to failure of treatment in only 8% of women.[283]

Complications from MRgFUS are very rare. The most common complication is skin burns. These can occur because of poor coupling or abdominal scars on the patient that are encountered within the FUS bean pathway. An early trial reported around 5% risk of burns.[276] Only one case of extensive skin burns has been reported.[284] Use of acoustic reflectors (like cork or foam) and an energy-blocking patch on scars has shown success in prevention of burns.[285,286]

A parallel enrollment trial compared MRgFUS to abdominal hysterectomy, and recorded significant clinical complications and short form health survey (SF-36) at 1, 3, and 6 months. Clinically significant complications were lower in MRgFUS group, with SF-36 scores improved in both arms at 6 months, however, they were significantly better in the hysterectomy group.[287] There is currently an NIH funded randomized clinical trial comparing MRgFUS to UAE (NCT00995878, clinicaltials.gov) which should provide important information. Studies have also shown MRgFUS to be in the range of currently accepted criteria for cost effectiveness.[288,289]

Subsequent pregnancy related complications after MRgFUS treatment are minimal. Forty five pregnancies in 51 women were reported in the only published series.[290] Live birth rate of 41%, mean birth weight of 3.3 Kg, spontaneous abortion rate of 28%, and term delivery rate of 93% was noted.[290] At least one patient with a fibroid impinging on the cavity and unexplained infertility, conceived spontaneously after MRgFUS treatment.[291]

Ultrasound-guided focused ultrasound (typically referred to as high intensity focused ultrasound, HIFU) has been used to treat several solid tumors outside the United States.[292] Since feasibility studies showed promising results for use of ultrasound guided-HIFU for uterine fibroids[293,294] larger studies have been reported. These reports have not only demonstrated safety and efficacy of ultrasound guided-HIFU for treatment of uterine fibroids,[295-297] but also shown safety of pregnancy within 1 year of treatment in one report.[298]

Medical Therapies

There is a lack of randomized trials to demonstrate effectiveness of medical management of fibroids.[299] Oral contraceptive pills, progestins, nonsteroidal antiinflammatory drugs, antifibrinolytic agents, androgenic compounds, and progestin loaded intrauterine devices, all of which are useful in the treatment of idiopathic heavy menstrual bleeding, have not been studied with leiomyoma–related bleeding. Nonetheless, they are widely used and are likely effective in at least a subset of women with fibroids. A systematic

review suggested that in trials when women were assigned to medical therapy at least 60% of them had undergone surgery by 2 years.[240]

GnRH-Agonists

Since the action of native GnRH depends on its pulsatile release, the effects of GnRH-agonists depend upon their continuous presence. They first cause a time-limited increase in gonadotropin release, termed the flare. This subsequently leads to receptor downregulation, followed 1 to 3 weeks later by a hypogonadotropic hypogonadal state. It is this down-regulated phase that is useful clinically in the treatment of myomas. Alterations of the GnRH molecule, typically at the two glycine (G) residue positions 6 and 10, produce a longer half-life and are more useful for clinical purposes.

Many studies have focused on the efficacy and benefits of GnRH-agonist treatment for women with fibroids. Most women experience a substantial reduction in mean uterine volume of 30% to 60% over 3 to 6 months of therapy.[300,301] However, there is a wide range of responsiveness with rare individuals achieving no volume reduction. Both the estradiol levels at week 12 and the weight of the woman are correlated with the degree of uterine shrinkage.[301]

The other primary benefit of GnRH-agonist treatment is the induction of amenorrhea. Menses typically return 4 to 10 weeks following the end of GnRH-agonist treatment. Fibroid and uterine volume usually returns to pretreatment size within 3 to 4 months. The rapid return of ovarian steroidogenesis, coupled with an increase in the concentration of estrogen receptors in fibroids recently treated with GnRH-agonists, may contribute to the rapid regrowth of these tumors.[302]

GnRH-agonists can have significant adverse effects, the most important of which is bone loss. Six months of GnRH-agonist treatment can cause a 6% loss in trabecular bone, not all of which is reversible on discontinuation of therapy.[300] Symptomatic side effects of GnRH-agonist therapy are common. Hot flashes are universal in women undergoing treatment. Other less common side effects include sleep disturbance, irregular vaginal bleeding, vaginal dryness, headache, depression, hair loss, and musculoskeletal symptoms.[300]

Because of the concerns regarding bone loss with GnRH-agonists, clinical use of these drugs is typically confined to use as preoperative therapy or in women for whom a short period of treatment will be effective. The GnRH-agonist, Lupron® is FDA-approved for the presurgical treatment of uterine fibroids to correct anemia in conjunction with iron administration.[303] This is the only medical treatment FDA approved for treatment of this disease.

Administration prior to either hysterectomy or myomectomy is the most common current use of these agents. Length of therapy varies from 1 to 6 months depending on the surgical and hematological goals and the planned procedure. The amenorrhea induced by GnRH therapy leads to improved hemoglobin concentrations, which permits women who are anemic to correct this problem and potentially to donate their own blood for transfusion. Preoperative GnRH therapy also has been shown to reduce intraoperative blood loss significantly.[303] Although current guidelines from ACOG suggest that use of GnRH-agonists is beneficial preoperatively, they also state that for each individual the benefit must be weighed against the cost and the side effects.[220]

GnRH-Agonist Therapy with Estrogen and Progestin Add-Back Regimens

For many women, 3 to 6 months of symptomatic relief from leiomyomas does not allow them to avoid surgery but does afford them the opportunity to prepare themselves optimally for an operation. Therefore, the concept of adding additional therapy to minimize the side effects of prolonged therapy was developed, the so-called add-back regimens.[304-306] The goal of add-back regimens was to achieve a window of therapeutic efficacy during which side effects would be lessened or eliminated, yet no regrowth of the myomas would occur.

Studies have utilized one of two treatment strategies: simultaneous and sequential administration. With simultaneous treatment regimens, both the GnRH-agonist and the add-back regimens are started at the same time. In sequential treatment regimens, the GnRH-agonist is given alone for up to 6 months before steroid hormone treatment is added reducing a period of hypoestrogenism before steroid add-back therapy is started. Studies have suggested that sequential treatment is superior for therapeutic efficacy in the treatment of fibroids.[305]

Innovative GnRH-Agonist Add-Back Therapies

The estrogen receptor antagonists, tamoxifen and raloxifene, have been used in randomized prospective 6-month studies in a simultaneous add-back study design with the GnRH agonist.[307,308] Results were conflicting. No change in myoma size was noted when 20 mg of tamoxifen was used;[308] whereas, when 60 mg of tamoxifen was used a reduction in myoma size, but not symptoms, was noted.[307] Studies using raloxifene (60 mg/day) therapy in postmenopausal women with leiomyomas were able to cause a reduction in size.[309] Tibolone, a synthetic steroid, has been used as a single agent for menopausal HRT for its combination of estrogenic and progestational actions in the same molecule.[310] This medication has been studied in premenopausal women receiving GnRH-agonists for the treatment of myomas.[311] There was no inhibition of uterine shrinkage with tibolone, and patients showed preservation of bone density as well as symptomatic improvement. Thus, tibolone may be used as a single-agent add-back in the future.[312] Ipriflavone, an isoflavone that is a weak estrogen modulator, has been studied in add-back regimens.[313] Although originally studied to determine its effect on bone, it appears effective in slowing bone loss and decreasing symptoms without impeding the volume reduction of GnRH-agonist therapy.

GnRH-Antagonists

GnRH-antagonists have also been studied in the treatment of uterine leiomyomas.[314-317] The lack of flare effect and rapid onset of action give them an advantage over GnRH-agonists. Although they are not Food and Drug Administration (FDA)-approved for this indication, they have several significant advantages over GnRH-agonists. However, in the United States, these agents are marketed for use of ovulation induction and long-term preparations are not available. This could make treatment of fibroids cumbersome.

Progesterone Modulators

Clinical data regarding the efficacy of progesterone modulators has conformed the importance of progesterone in myoma biology. A concern of paramount importance while using progesterone receptor modulators (PRMs) is the potential of increased risk of endometrial hyperplasia or cancer. Pathologists have however shown a unique histological pattern in patients on these medications.[318] These PRM-associated endometrial changes do not have typical molecular signatures of malignant progression,[319] however, long-term data is still lacking.

Mifepristone (RU486) is a steroidal derivative of norethindrone, which acts primarily as an antiprogestin. It has, in high doses (50 mg/day), shown reduction in myoma size comparable to GnRH-agonists.[319] Thus, the clinical benefit was equivalent to that seen with GnRH-agonists, yet follicular levels of estradiol were maintained to support bone mass and provide symptomatic relief. Identical results were found with a reduction in dose to 25 mg/day; however, with a 5 mg/day dose, although acyclicity was maintained, volume reduction was reduced to 30%.[319-325] More recent studies suggest that doses of 5 and 10 mg produce volume reduction equivalent to those elicited by the higher doses, but produced amenorrhea in only 60% to 65% of women but did result in decreased menstrual blood loss.[320,324] Nonetheless, this provides significant symptomatic improvement. Mifepristone has mild side effects compared with GnRH-agonists. Adverse effects included mild and infrequent hot flashes in approximately 20% of patients during the first month of treatment only with higher doses; however, more persistent symptoms appeared in another study. Mifepristone is not approved for use by the United States FDA. A major impediment to off-label use is that the current available dose of RU486 is not appropriate (200 mg once for pregnancy termination versus 5 to 10 mg/day for fibroid treatment for 6 months).[326]

Ulipristal acetate, another PRM, was recently compared with placebo at 5 or 10 mg once daily for 13 weeks in a randomized control trial.[327] The medication resulted in resolution of heavy menstrual bleeding and significant reduction in fibroid volume, in women with uteri of less than 16 weeks gestational size.[327] There were also no findings of endometrial hyperplasia with its use. In another noninferiority trial, ulipristal was compared to GnRH-agonists, at 5 or 10 mg a day for 13 weeks.[328] Both arms had comparable rates of resolution of heavy menstrual bleeding, however, ulipristal resulted in less myoma size reduction compared to GnRH-agonist but a more rapid induction of amenorrhea.[328] Data from the supplementary appendix of these studies suggests that PRMs provide more prolonged volume reduction after treatment is discontinued compared to GnRH agonists.[328] Endometrial biopsies from women on ulipristal revealed a carryover effect of this medication after 3 months of therapy that lasted up to 6 months.[327] Women with symptomatic fibroids thus may have the option of a unique intermittent therapy with this medication.[329] Like Mifepristone however, the available FDA approved formulation (30 mg tablet) makes off-label use for fibroids problematic.

Other PRMs are being studied for the treatment of uterine leiomyomas.[330] These drugs appear to have efficacy similar to mifepristone but decreased side effects and increased specificity when interacting with the progesterone receptor.

Aromatase Inhibitors

Aromatase inhibitors have shown to decrease symptoms from fibroids and shrinkage in size when given to women that were pre- or peri-menopausal.[331-334] A randomized trial compared letrozole at 2.5 mg/day to triptorelin (3.75 mg/month) for 12 weeks in 70 women with a single fibroid ≥5 cm size. A statistically significant volume reduction in myoma size was noted in the letrozole group vs. the triptorelin arm (45% versus 33%).[334] Serum hormone levels were also significantly reduced in the triptorelin arm vs. the letrozole group.[334] Extensive data regarding the safety, efficacy, and cost-effectiveness of this class of medications as medical therapy for uterine fibroids is still lacking.

Serum Estrogen Receptor Modulators

Selective estrogen-receptor modulators (SERMs), which exhibit tissue-specific agonist or antagonist activity, appear to work better in animal models of myomas than in clinical trials. Studies have examined both tamoxifen and raloxifene. Clomiphene has not been studied and has been reported to cause growth of a myoma in a single case report.[335] Despite promising results in animal models,[336,337] clinical studies have had less impressive results.[309] However, in premenopausal women, raloxifene alone or when combined with GnRH agonists demonstrated little efficacy despite use at three times the conventional dose.[307,338]

Androgens

Danazol, an androgenic steroid most commonly used for the medical treatment of endometriosis, can be used to induce amenorrhea in order to control anemia due to fibroid-related heavy menstrual bleeding. A second androgenic steroid, gestrinone, has been shown to cause volume reduction and amenorrhea in women with myomas.[339] A great advantage of this drug is that, after it is discontinued, there is a carryover effect like those of PRMs; in one study, 89% of the women maintained a decreased uterine volume 18 months after cessation of therapy.[339] Unfortunately, gestrinone is not available in the United States. However, androgenic side effects including acne, hirsutism, and irreversible deepening of the voice have limited its clinical use.

Growth Factor-Directed Treatments

Particular factors which appear to be relevant to leiomyoma biology include the angiogenic factor basic fibroblast growth factor (bFGF), the fibrotic growth factor transforming growth factor-beta (TGF-β), and insulin-like growth factors I and II (IGF I and II), which mediate the effects of growth hormone (GH).[1,122] These molecules, as well as other growth factors, are likely to be targets for leiomyoma treatment in the future.

GH-Directed and IGF-Directed Therapy

Both *growth hormone (GH)* and the *IGFs* appear to have metabolical effects on uterine leiomyomas and the surrounding myometrium.[164] Because women with acromegaly (an excess of growth hormone) have a high incidence of leiomyomas, researchers decided to test the hypothesis that interfering with the growth hormone axis might work as a treatment for leiomyomas.[167] Lanreotide (a long-acting somatostatin analogue) has been used in seven premenopausal women with uterine myomas in a pilot

study in Italy.[340] Over the 3 months of treatment, both uterine volume and the volume of the largest leiomyoma were significantly reduced by 24% and 42%, respectively. Three months following the discontinuation of therapy there was some regrowth, but a significant reduction in uterine volume persisted at 17% and 29%, respectively. Levels of estradiol were not affected by this treatment, though both plasma *GH* and *IGF-I* levels were significantly reduced and additional pathological modulators may be effective.[341]

Anti-Angiogenic Therapies

There is significant evidence that the angiogenic factor *bFGF* and its type I receptor are important in the pathogenesis of leiomyoma-related bleeding.[104,105] In a variety of systems, *interferons (INF) IFN-α* or *INF-β* antagonize the effects of *bFGF* and have proven clinically useful in the treatment of a variety of vascular tumors. *In vitro* studies of leiomyomas demonstrate that *IFN-α* is an effective inhibitor of serum-stimulated and *bFGF*-stimulated DNA synthesis in both leiomyoma and normal myometrial cells, as well as in endometrial cells.[103] A case report also raises the possibility that *IFNs* may provide effective treatment for fibroids. A premenopausal woman who was treated with *IFN-α* for hepatitis C was noted to have significant shrinkage of a leiomyoma after 7 months of interferon therapy.[342] Tranilast [N-(3′4′-dimethoxycinnamonyl) anthranilic acid (N-5′)], a drug currently used in the treatment of a variety of allergic conditions, has been shown *in vitro* to decrease leiomyoma cellular proliferation by arresting cells at the transition from G0 to G1 phase.[343] While it acts as an angiogenesis inhibitor, it also works as a mast-cell stabilizer and a fibrosis inhibitor, which may have relevance for leiomyomas.[343]

Current research also involves work on the role of retinoic acid,[344,345] Vitamin D,[346,347] and green tea components[348] in preventing fibroid formation.

Adenomyosis

Adenomyosis, formerly termed endometriosis interna, is another benign uterine disease characterized by the presence of ectopic endometrial glands and stroma within the myometrium (Fig. 27.3). Furthermore, the surrounding myometrium is usually altered to produce hypertrophy. Disease ranges from grossly visible nodules termed adenomyomas, which can clinically resemble leiomyomas, to disease that is only detectable by microscopy. Definitions vary for the abnormal presence of gland within the stroma, with most settling on a definition of glands found one to three low-power fields from the endomyometrial junction. Clearly, differences in definition will lead to differences in perceived rates.

Classically, an adenomyotic uterus is termed *boggy, globular,* and *symmetrically enlarged*. However, this disease coexists with many other uterine conditions. One study has argued that adenomyosis is not indeed a true disease but a variant of the norm as women had similar symptoms for hysterectomy with and without adenomyosis.[349] Most women in this study were perimenopausal which could have been a major selection bias.

Adenomyosis can affect around 20% to 65% of women,[350] though the accuracy of these numbers can be questioned since diagnosis can only be made with certainty by microscopic examination of the uterus typically after a hysterectomy. In another series of hysterectomies, adenomyosis appears in about one quarter of all uterine specimens but is no more likely to coexist with symptomatic leiomyomas (23.3%) than with endometrial cancer (28.2%) or ovarian cancer (28.1%).[351]

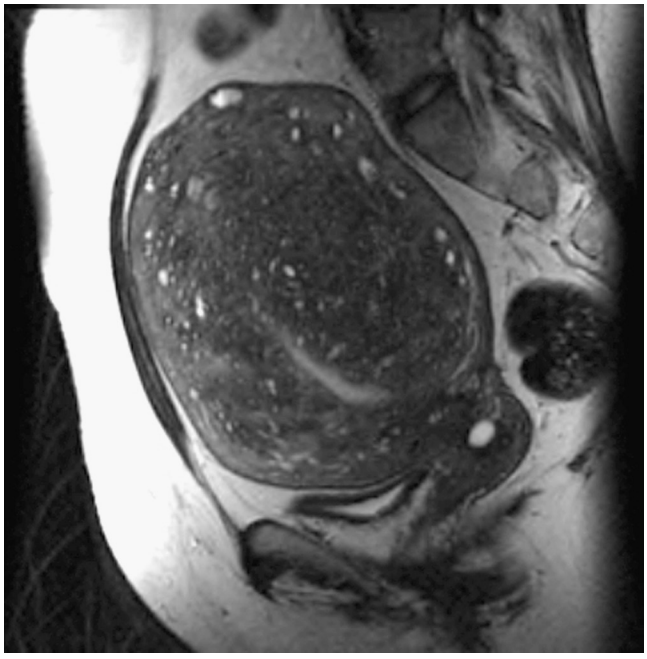

FIGURE 27.3 A T_2-weighted fast-spin echo (FSE) image of the adenomyotic uterus. Adenomyosis is characterized by proliferation of glandular elements of the uterus so that bright (white) areas similar in intensity to the endometrial cavity are seen deep into the uterine wall. The uterine walls can be asymmetric in this disease, and in this image the posterior wall is markedly thicker than the anterior wall. Thickening of the junctional zone, another characteristic of adenomyosis is not seen in this image.

Unlike leiomyomas, adenomyosis is associated with increasing parity.[351-356] It is estimated that at least 80% of women with this disorder are parous. However, this may be a confounding variable since women with a history of multiple pregnancies may simply have had more indications and/or inclination to proceed to hysterectomy during which the diagnosis could be made. Studies that suggest the presence of adenomyosis with imaging modalities rather than histopathology have suggested the presence of this disease process in adolescents as well.[357,358] The California Teachers Study noted clinical differences in women with endometriosis and adenomyosis.[354] Women with adenomyosis were older, had higher parity, early menarche, shorter menstrual cycles and were more obese compared to women with endometriosis.[354] Another study compared women with presence of fibroids and adenomyosis to women with fibroids only.[359] Women with both fibroids and adenomyosis had more pelvic pain and dysmenorrhea, higher parity, a history of previous uterine surgery and had more clinical depression compared to women with fibroids only.[359] Women with histopathology proven adenomyosis were more likely to have a history of previous uterine surgery in several reports.[355,359,360] Data regarding smoking as a risk factor for adenomyosis is controversial.[353,356]

Clinically, adenomyosis has similarities to leiomyomas in that its peak incidence is in women ages 40 to 50 years old with approximately 60% of women reporting abnormal uterine bleeding, chiefly heavy menstrual bleeding. Abnormal distribution of thick and dilated vessels in the endometrium, particularly in the secretory phase of the menstrual cycle, is one explanation for heavy menstrual flow in such women.[361,362] Dysmenorrhea is the other frequent symptom of adenomyosis, occurring in approximately one quarter of all cases.[350] Dysmenorrhea has been correlated with deep penetration and/or a high density of endometrial glands within the myometrium.[363] Abnormal uterine bleeding in the presence of adenomyosis is now classified as FIGO class AUB-A type of bleeding (see the section on abnormal bleeding later in this chapter).[364]

The most widely quoted hypothesis regarding the pathogenesis of adenomyosis is that invasion of the myometrium by the endometrium induces hypertrophy and hyperplasia of the myometrium. Proponents of this theory often quote the association of parity with adenomyosis to suggest that disruption of the layers of the uterus at the time of pregnancy and cesarean delivery may predispose to this condition. However, experimental evidence indicates instead that adenomyosis can be metaplastic process or a developmental defect. First, adenomyosis has been diagnosed in a woman with Rokitansky-Kuster-Hauser syndrome, who lacked eutopic endometrium.[365] Additionally, studies comparing the molecular expression of growth factors show distinct differences between ectopic and eutopic endometrium.[89,366-369] Factors that appear common to the pathogenesis of leiomyomas and adenomyosis include angiogenic factors such as *bFGF*, fibrotic factors including *GM-CSF*, the gonadotropin receptor LH, and resident immune cells.[89,368,370-374] The efficacy of some conventional and investigational therapies may be mediated through these systems.[375,376]

Gonadal steroid hormones also play a role in pathophysiology of adenomyosis. Adenomyotic implants express higher aromatase and estrone sulfatase activity,[377,378] and also have polymorphisms in estrogen receptors (ER).[379] *In vitro* studies have shown normalization of aromatase activity by gonadotropin releasing hormone agonists (GnRH) and danazol, but there is lack of data to show these effects *in vivo*.[375,377] The role of estrogen and ER in adenomyotic implants is further supported by the fact that endometrial hyperplasia was more prevalent in women with adenomyosis in one report.[380] A murine model of adenomyosis also supports this, as early tamoxifen exposure in these mice lead to development of adenomyosis and abnormal myometrium.[381]

Interestingly, another murine model of adenomyosis has been developed by placing a graft of pituitary tissue in a uterine horn.[382,383] Prolactin appears to be the key pathogenic agent in this model: the mice have elevated levels of plasma prolactin, and administration of bromocriptine prevents the development of adenomyosis.[382,384] In this model, there does appear to be endometrial cell invasion due to degeneration of myometrial cells.[383] Indirect exposure of the uterus due to hyperprolactinemia secondary to selective serotonin reuptake inhibitor (SSRI) medications can also induce adenomyosis.[385] This theory is further strengthened by recent work that showed both clinical depression and antidepressant use to be increased in women with adenomyosis.[359] A second model using the FORKO (follitropin receptor knockout mouse) suggests that the rising levels of FSH seen with aging may also play an important pathogenic role in this disease.[386]

Although definitive diagnosis of adenomyosis requires histology, imaging techniques are increasingly able to suggest the appropriate diagnosis. Both transvaginal ultrasonography (TVS) and magnetic resonance imaging (MRI) are used for this purpose. MRI is a better imaging modality for adenomyosis but is expensive. It can also differentiate very well, between an adenomyoma and a fibroid.[387] TVS is a less expensive imaging technique but is known to be operator dependent. A review of 23 articles comparing sensitivity and specificity MRI and TVS revealed both techniques to have similar sensitivity (0.72 for TVS and 0.77 for MRI) and specificity (0.81 for TVS and 0.89 for MRI).[388] Computed tomography has no role in diagnosis of adenomyosis[389] and needle biopsy should be reserved for cases where malignancy needs to be ruled out.[390]

The only definitive treatment for adenomyosis is total hysterectomy. GnRH-agonist treatment has been shown to produce amenorrhea, a transient decrease in uterine size and even in the ability to conceive.[391-393] Other medical therapies include use of levonorgestrel-releasing intrauterine device,[394-397] and a single case report of danazol containing intrauterine device.[398] Unfortunately, resumption of pretreatment uterine size and recurrence of symptoms are usually documented within 6 months of cessation of therapy.[396]

Data regarding conservative surgery (if adenomyoma present) are scarce. Adenomyomectomy has been reported to improve symptoms of adenomyosis,[399,400] and one study reports conservative surgery and GnRH medical therapy following treatment to be superior to surgery alone.[401] Other reported techniques include endomyometrial ablation and laparoscopic myometrial electrocoagulation which appear to decrease symptoms in more than half of patients with 3 years of follow-up data.[402,403]

Both UAE and MRgFUS have been reported for the treatment of adenomyosis. UAE can achieve success rates of approximately 50% over a 36-month follow-up.[404] In a recent report after a median follow-up of 58 months around 18% women ended with a hysterectomy, however, 73% of women were completely asymptomatic.[405] For MRgFUS, the largest study to date included 20 patients with a 6-month follow-up and indicated safe and effective MRgFUS therapy in all subjects enrolled.[406] Another MRgFUS case reports a spontaneous pregnancy with full term delivery after treatment.[407] Ultrasound-guided high-intensity focused ultrasound ablation has also been studied in one report.[297] Seventy eight patients with adenomyosis were enrolled and after a mean follow-up of 24 months around 90% of the patients had complete relief of symptoms.[297]

As imaging techniques get better, adenomyosis is being diagnosed with increasing frequency in women of reproductive age. Data on these women is limited to small case series. Indirect evidence shows a link between adenomyosis and infertility,[408] however, there is no direct link.[409] Increased risk of preterm birth and preterm premature rupture of membranes in women with adenomyosis (diagnosed with TVS or MRI) was noted in one epidemiological study.[410]

Endometrial Polyps

Endometrial polyps, as their name suggests, arise from the endometrial layer of the uterus. They are characterized by glandular proliferation surrounding a central core of prominent blood vessels in the stroma. Polyps are associated with abnormal uterine bleeding, particularly spotting and irregular bleeding, but the underlying mechanism has not been articulated. Several mechanisms are thought to play a role in development of endometrial polyps. These include overexpression of endometrial aromatase activity,[411,412] monoclonal endometrial hyperplasia,[413] genetic factors, particularly cytogenetic rearrangements of chromosome 6p,12q and 7q,[414,415] and alterations in endometrial levels of matrix metalloproteinases and cytokines.[416] Recent work has also shown the role of increased *TGF-β*, *VEGF*,[417] and *bcl-2*[418] in the pathogenesis of endometrial polyps. Historically polyps have been known to have estrogen receptors, though current literature suggests the presence of both estrogen and progesterone receptors (ER and PR).[419,420] It is suggested that both estrogen and progesterone contribute to the elongation of endometrial glands, stroma, and blood vessels to give them a characteristic appearance.[421] Progestins also have an antiproliferative function on polyps[422] as do androgens, however, data suggest that testosterone does not substitute for progestational activity for endometrial polyps.[423]

The estimated prevalence of polyps varies widely from 7.8% to 34.9% depending on the definition and diagnostic modality used.[424-427] The reported prevalence of polyps is as low as 0.9% in women less than 30 years old,[425] and increases with age. Risk factors for development of endometrial polyps include obesity,[428,429] hypertension,[428] diabetes,[428,430] and advancing age, especially postmenopausal status.[428] At least one paper has challenged these classical risk factors and has shown only age to be statistically significant risk factor.[431]

Tamoxifen use in postmenopausal women can lead to development of polyps in around 2% to 36% of women.[432] Tamoxifen induced polyps may be large in number and size and also show unique molecular alterations.[432-435] The levonorgestrel loaded IUD has shown to reduce tamoxifen induced polyp development in patients being treated for breast cancer when followed for a year.[436] Data regarding a relationship between endometrial polyps and postmenopausal hormone therapy are contradictory.[425,437-440]

The most frequent symptom in women with endometrial polyps is abnormal uterine bleeding (AUB-P) in the updated Federation Internationale de Gynecologie et d'Obstetrique (FIGO) classification[441] and is reported in 50% of symptomatic cases.[442] Conversely of women who have abnormal bleeding, approximately 30% have evidence of endometrial polyps.[443] Although abnormal bleeding is the most common clinical representation most polyps may remain symptom free and are an incidental finding on imaging.[444] The size, number, and location of polyps do not correlate with clinical symptomatology.[445]

Most polyps are benign and malignant transformation can occur in 0% to 12.9% of polyps.[446-448] Microsatellite instability has been noted in patients with multiple polyps or polyps with hyperplasia.[449] A recent meta-analysis revealed that the prevalence of malignant polyps was higher in postmenopausal women compared to women in their reproductive years (5.42% versus 1.7%) and that malignant polyps were more likely to bleed than non-malignant ones.[450] Risk factors associated with malignant endometrial polyps include an age greater than 60 years, polyp size greater than 1.5 cm in length, menopausal status, and abnormal bleeding.[432,451,452]

Endometrial polyps are still diagnosed following dilation and curettage (D&C) or hysterectomy, though new methods of diagnosis and treatment are being utilized more frequently.[453] Increasingly, the use of saline-infusion sonography (SIS), also termed sonohysterograms, or less commonly, office hysteroscopy diagnose polyps (Fig. 27.4). Polyps can also be diagnosed by hysterosalpingogram if the uterine cavity is also visualized. Newer 3-D ultrasound probes provide more accurate visualization between the endometrium and myometrium at the fundus and the cornual angles, hence improving the diagnostic accuracy compared to standard ultrasound.[454] A recent review reported a similar performance of transvaginal ultrasound (TVS), saline infusion sonography and hysteroscopy for detection of endometrial polyps.[455] Both hysteroscopy and SIS give a better sense of the endometrial cavity than TVS, however, SIS has an added advantage of providing the examiner with information regarding the adnexa and myometrium as well.

Medical management of polyps has limited role. There is some data regarding prevention of polyp formation in women being treated for breast cancer with tamoxifen,

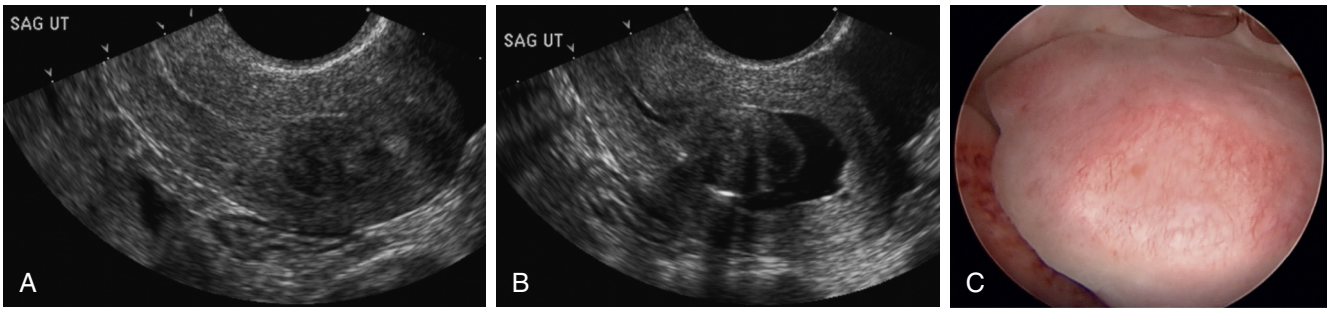

FIGURE 27.4 Comparison of imaging modalities for diagnosis of endometrial polyps. **A,** A sagittal view of a retroverted uterus obtained by a transvaginal ultrasound. A thickened endometrial stripe is appreciated, though the thickness is not well defined. **B,** A saline-infusion sonogram of the same patient. After infusion of saline into the endometrial cavity, the endometrial polyp is visualized protruding into the endometrial cavity and a thin endometrium is seen. **C,** A photograph taken during hysteroscopy reveals a well-defined polyp in the endometrial cavity. Polyps tend to blood vessels that are not as coarse as seen in submucosal fibroids and they have softer edges. *(Images courtesy of Dr. Mary Frates, Department of Radiology, Brigham and Women's Hospital and Harvard Medical School, Boston.)*

its use is limited to research protocols only.[436] Observing asymptomatic polyps can be an option in low risk individuals. When left untreated, asymptomatic polyps can regress spontaneously. In one trial, 27% of lesions resolved within 1 year of follow-up in premenopausal patients.[456] Polyps with mean length of 1.5 cm or more were less likely to resolve.[456] Other studies have shown complete resolution of polyps less than 1 cm.[426,457] The majority of cases of endometrial polyps are however, treated with hysteroscopic resection or hysteroscopically-guided D&C rather than the traditional D&C. Visualization and direct removal with this technique is reported to be more effective in reducing recurrence rates.[458] It has been reported that the volume of menstrual loss in women that underwent polypectomy did not differ from women who did not undergo polypectomy, but intermenstrual bleeding was significantly improved by polypectomy.[459]

There are little data on the effects of polyps on infertility. There are many theories of how polyps can effect implantation. These include mechanical obstruction hindering ostium function and affecting sperm migration[460] and decreased endometrial receptivity due to cytokines and cellular adhesion molecules.[461-464] The only randomized trial showed an improvement of pregnancy rates after polypectomy in women undergoing intrauterine insemination (IUI).[465] Other retrospective data have shown no difference in pregnancy rates, especially if the polyp was less than 1.5 cm in length.[466,467] In light of conflicting data, expert opinion recommends removal of polyps when diagnosed prior to *in vitro* fertilization (IVF) treatment. When lesions are seen during stimulation the treatment decision is made best on an individual basis.[468]

Abnormal Uterine Bleeding

Abnormal uterine bleeding (AUB) affects up to one third of reproductive age women and can occur in conjunction with the pathological processes we have discussed or in their absence. AUB also accounts for around one third of all outpatient gynecological visits.[469] In the United States, AUB (previously called dysfunctional uterine bleeding) is commonly equated with anovulatory bleeding, whereas in Europe it is a diagnosis of exclusion of excessive bleeding not due to demonstrable pelvic disease, complications of pregnancy, or systemic disease. Heavy menstrual bleeding (HMB) may occur in 10% to 30% of women and in up to 50% of women in the perimenopause.[470,471] However, the self-reporting of menstrual regularity and flow is highly variable. Change in pattern of flow is probably the most important sign of pathology. HMB is the type of abnormal bleeding frequently associated with benign uterine pathology, including leiomyomata and adenomyosis. Fragile, large thin-walled vessels and an aglandular endometrium appear to underlie the menorrhagia associated with some submucous myomas.[472] These vessels may arise from abnormalities in angiogenesis associated with growth factors released by myomata (e.g., basic fibroblast growth factor, vascular endothelial growth factor).[1]

There has been a recent push towards changing and standardizing terminology for AUB as confused terminology has made research collaborations and interpretation of clinical trials difficult.[473,474] Terms like *menorrhagia*, *metrorrhagia*, and *dysfunctional uterine bleeding* should be abolished.[474] To standardize communication, FIGO created a universal classification of causes of abnormal uterine bleeding for women in their reproductive years.[364,475-477] The "PALM-COEIN" nomenclature has four categories that are defined by structural criteria. These are: PALM; bleeding due to Polyps, Adenomyosis, Leiomyomas, and Malignancy or hyperplasia. The other four are unrelated to structural abnormalities and include: COEIN; bleeding due to Coagulopathy, Ovulatory disorders, Endometrial causes, Iatrogenic and pathologies Not classified. It is hoped that this classification system should facilitate collaborations to study AUB, however, the ease of use has to be demonstrated. The four structural causes of AUB, excluding bleeding due to malignancy have been discussed in the chapter. Previously classified true dysfunctional uterine bleeding equates to the four nonstructural causes of bleeding in the FIGO classification.

Around 13% of women with HMB have some form of coagulopathic disorder.[478] Systemic disease as a cause of HMB should be suspected in adolescents where coagulopathies including thrombocytopenia, von Willebrand disease, or other coagulopathies may be the underlying cause.[479]

Ovulatory disorders include both ovulatory and anovulatory dysfunction leading to AUB. Anovulatory dysfunctional uterine bleeding is characterized by irregular and prolonged bleeding secondary to disturbances in the hypothalamic-pituitary-ovarian axis. It is most common in the extremes of reproductive life[480] and in association with polycystic ovary syndrome. The unopposed action of estrogen on the uterus, resulting in dilated veins and the lack of suppression of spiral arteriole development, may represent the underlying pathophysiology.[470,471,481] Large, thin walled tortuous vessels can be demonstrated on the surface of the hyperplastic endometrium. Unopposed estrogen reduces vascular tone either through direct effects of estrogen on vascular smooth muscle cells or increased production of nitric oxide, leading to vasodilatation. The endometrium often breaks down unevenly in these circumstances. Scattered patches of thrombotic foci and necrotic degeneration are found adjacent to abnormally proliferated endometrium.

Ovulatory dysfunctional uterine bleeding is characterized by regular episodes of heavy menstrual flow, usually with the heaviest loss during the first 3 days of menstruation. Though many ovulatory disorders can be traced back to endocrinopathies, the underlying abnormality appears to be defects in processes that regulate loss of blood during menstruation, primarily angiogenesis, vasoconstriction, and hemostasis. In contrast to anovulatory dysfunctional uterine bleeding, the surface vessels of the endometrium appear to be grossly normal and only minor abnormalities have been described in endometrial and myometrial veins like venule ectasia.[1]

Endometrial causes of AUB are similar in pathogenesis to ovulatory disorders. In HMB the local endometrial hemostasis process is disrupted. This can be due to deficient production of vasoconstrictors like endothelin-1 and prostaglandin F2α, increased production of vasodilators such as prostaglandin E2 and prostacyclin, and excessive breakdown of clot in the endometrium by abnormal production of plasminogen activator.[482-484] In addition, vascular smooth muscle cell proliferation is reduced in the spiral arterioles in the midsecretory and late secretory stages in women

with menorrhagia, possibly contributing to vessel instability. *Endometrial bleeding associated factor (EBAF)* (a.k.a. *TGF-β4*) a member of the *TGF-β* family of growth factors suppresses production of collagen and promotes expression of collagenolytic and elastinolytic enzymes by antagonizing the normal signaling pathway activated by *TGF-β* growth factors. Abnormal expression of *EBAF*, which in a normal cycle occurs only in the late secretory and menstrual phases, has been reported in the endometrium of women with HMB.[86] *Angiopoietin 1 & 2* (*Ang-1* and *Ang-2*) may also be involved in the pathogenesis of HMB. *Ang-1* promotes vascular maturation, while *Ang-2* destabilizes vessels and initiates neovascularization.[485] An altered ratio of *Ang-1* to *Ang-2* in the endometrium due to down-regulation of Ang-1 expression is also associated with HMB.[485,486]

AUB due to iatrogenic causes (AUB-I) usually include the use of exogenous steroid therapy in form of combined estrogen and progestin pill, patch or ring, and levonorgestrel-releasing intrauterine device. The *not classified* category (AUB-N) includes a number of entities that do not fall into any group, for example AUB due to uterine arteriovenous malformation. Furthermore, this category has been left for new entities that may cause AUB that have not yet been discovered. It is important to note that a woman can have AUB due to more than one cause, for example a woman with HMB due to submucosal fibroid (AUB-L) can also have concomitant anovulation if she has PCOS and would have AUB-O type of bleeding as well.

These pathophysiological mechanisms proposed to underlie dysfunctional uterine bleeding are targets for novel therapeutic interventions (Fig. 27.5). The use of nonhormonal oral anti-fibrinolytic medication called tranexamic acid has shown a 66% response rate for HMB[487] and has shown to be extremely helpful in patients with AUB.[488,489] While tranexamic acid has been widely used internationally for many years, its recent FDA approval is leading to increasing use in the United States. Other options would include the use of antiprogestins or selective progesterone receptor modulators to suppress endometrial growth and stabilize the endometrial vasculature; MMP inhibitors to prevent extracellular matrix catabolism, including the matrix of the vessel walls; and non-steroidal anti-inflammatory drugs (NSAIDs) or selective cyclooxygenase-2 (COX-2) inhibitors to suppress prostanoid synthesis. Even though their use is not novel, combined estrogen and progestin formulation in form of patch, ring or pill, cyclical oral progestins, progestin-releasing intrauterine devices, are still unfortunately being used as the primary therapy for such patients.[490-493] Surgical destruction or removal of endometrium via endometrial ablation with newer nonresectoscopic, operator friendly devices has shown impressive success rates[239,494,495] and are also shown to be safe.[496] Hysterectomy is a definitive but less desirable option for AUB patients that are not concerned about fertility preservation.

Intrauterine Adhesions

The formation of intracavitary synechiae in an organ that routinely undergoes sloughing and regrowth without scarring is not well understood.[497] The clinical literature consistently reports that pregnancy frequently precedes the formation of intrauterine adhesions. The relationship between intrauterine adhesions and pregnancy is thought to be the result of defects in the regeneration of the

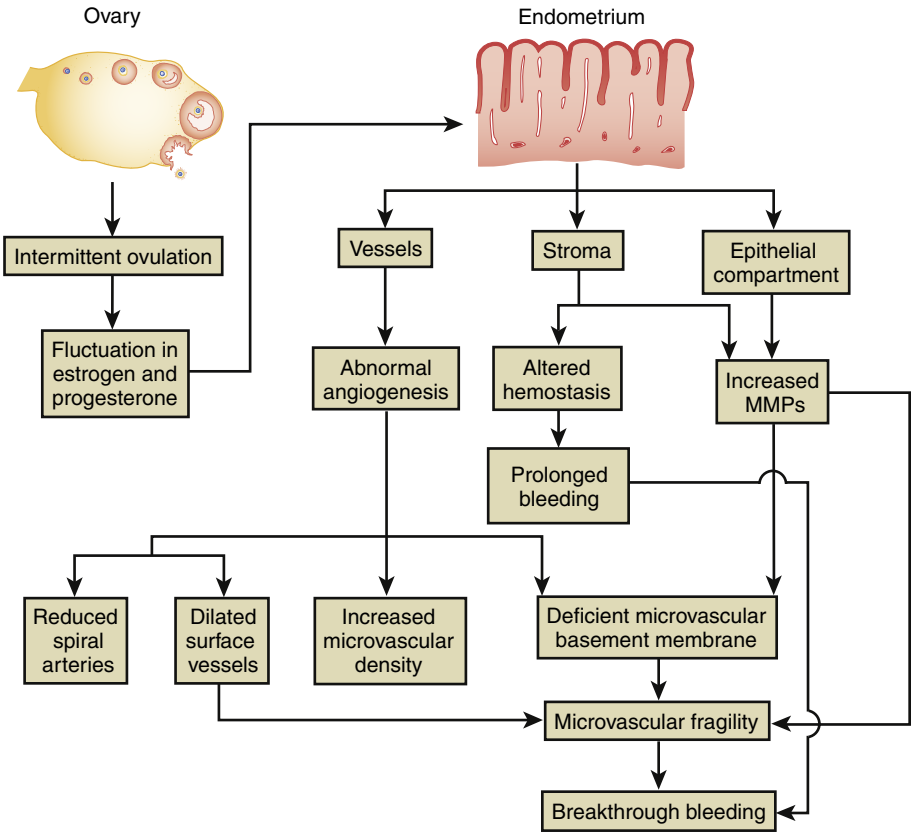

FIGURE 27.5 Ovarian and uterine mechanisms underlying breakthrough bleeding. A schematic drawing detailing the interaction between ovarian steroids and local endometrial factors leading to abnormal uterine bleeding. MMPs, matrix metalloproteinases.

endometrium after delivery, especially the area underlying the placenta. The placental site takes up to 6 weeks to repair with the thrombosed vessels and superficial necrotic tissue exfoliated as growing endometrium undermines the area. Trauma to the regenerating endometrium involved in restoring stroma and epithelium at this site, for example as a consequence of curettage performed 1 to 4 weeks after delivery and may result in a permanent scar with adhesions. This is considered the primary reason for intrauterine adhesions in the industrialized world. A review of 1856 women with intrauterine adhesions revealed 67% had undergone D&C for spontaneous or induced abortion and 22% had a postpartum D&C.[498] In another study, women were either randomized to nonsurgical treatment or D&C after incomplete abortion. Of the women that underwent D&C, 7.7% had some form of intrauterine adhesions compared to no adhesions in the nonsurgical group.[499] Curettage in the first 48 hours postpartum seems to cause fewer adhesions than when they are done later than that.[500] Not only D&C, but any sort of intrauterine instrumentation can lead to development of intrauterine synechiae. The average incidence of adhesion formation after hysteroscopic myomectomy for example has been reported around 10% at second look hysteroscopy after surgery.[501] In another study the rate of adhesion formation was noted at 6.7% after uterine septum take down, 31.3% after myoma resection, and as high as 45.5% after multiple myoma resection.[502] Even though there is need for larger randomized trials there is some evidence that highlights the use of adhesion barriers after hysteroscopic procedures.[503,504] The role of infection after abortion or delivery in formation of uterine synanche is controversial.[505,506] A comparison of uterine cavities of women that delivered via cesarean with and without endometritis at the time, did not show any differences when it came to intrauterine adhesions.[507]

In the developing world, infection of the endometrium particularly with mycobacterium tuberculi is an important cause of uterine synanche. With the human immunodeficiency virus-acquired immune deficiency syndrome (HIV-AIDS) epidemic and ease of air travel, genital tuberculosis should not be considered a threat to the developing world only. It is also important to note that most African studies have still attributed the major cause for intrauterine adhesions to be previous cavitary instrumentation.[508-510] Estimated prevalence of genital tuberculosis varies widely between 2% to 25% in infertile women, depending on diagnostic criteria used and the geographical location.[511,512] Tuberculous adhesions can be in as high as 35% of women with the infection[513] and have a poor prognosis for future fertility.[498,514] A characteristic *pipe stem* or *beaded* appearance on hysterosalpingogram and culture with acid fast stains on endometrial biopsy is helpful but, both tests have poor sensitivity. Newer tests like interferon-gamma release assays are more useful currently.[515]

Women with intrauterine adhesions may have no symptoms or a variety of menstrual disorders including hypomenorrhea, oligomenorrhea, amenorrhea, dysmenorrhea, and very rarely heavy menstrual bleeding.[498] Infertility, amenorrhea, and hypomenorrhea are the most common presenting complaints with infertility rates reported as high as 43%.[498] A number of classification systems have been proposed for women with intrauterine adhesions.[516] All systems require a thorough evaluation of the endometrial cavity to note the consistency, extent, and location of the adhesions. There is paucity of data from comparison of these classification systems.[516]

Hysterosalpingography is performed to view the cavity, and hysteroscopy reveals the intrauterine lesions. Ultrasonography, sonohysterography, and magnetic resonance[517,518] imaging can also be valuable in certain cases (Fig. 27.6). One group compared hysterosalpingography, sonohysterography, and transvaginal ultrasonography in patients with infertility and found both hysterosalpingography and sonohysterography imaging to have similar sensitivities of around 75% in detecting intrauterine adhesions. There was very limited use of transvaginal sonography in detection of synechiae in this study.[519] The gold standard for diagnosis of intrauterine adhesions is by diagnostic hysteroscopy.[520]

There is no consensus regarding the optimal methods to treat and prevent intrauterine adhesions. Since asymptomatic adhesions do not interfere with a woman's general well being, expectant management in such women has lead to resumption of regular menses in 1 to 7 years in up to 78% of women in one report.[498] There is no role of medical therapy for treatment of intrauterine adhesions. Before wide spread use of hysteroscope, blind D&C was used. Schenker and Margalioth reported an 84% rate of resumption of normal menses in women after D&C. Fifty one percent of these women conceived and 55% had term deliveries.[498] Surgical removal of adhesions hysteroscopically with blunt dissection, scissors, electrocautery, or laser ablation is now recommended. Return of normal menses after hysteroscopic resection varies between 92% to 96%.[521] The primary goal of surgery is to restore normal volume and shape of the uterine cavity.[521] In the nonindustrialized part of the world where hysteroscopic resection may not be feasible, there have been reports to show D&C to be equivalent to hysteroscopic resection, which is reassuring.[510] Post operative management is focused upon reducing the risk of reformation of adhesions, the rate of which can be as high as one in three women with mild to moderate and two in three women with severe adhesions.[516,522-525] Insertion of an intrauterine device or balloon catheter after lysis of adhesions is commonly employed to prevent recurrence.[526]

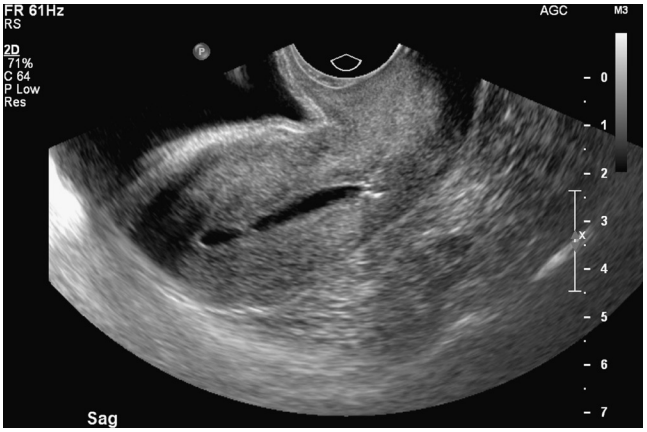

FIGURE 27.6 A sagittal view of an anteverted uterus obtained during saline-infusion sonography. An adhesion can be appreciated in this patient with a history of dilation and curettage (D&C) to treat a first trimester pregnancy loss.

Stimulation of endometrial proliferation with exogenous estrogens alone or in combination with a progestin has been advocated although there is debate as to the efficacy of this treatment as well as the administration of antibiotics and anti-inflammatory steroids.

Successful pregnancy rates after hysteroscopic resection of adhesion can be up to 63%,[521] with issues of placentation being most serious complication of pregnancy. Of 696 births reported in a recent review,[521]17 pregnancies had placenta accreta. Preterm delivery rate was 40% to 50% in this group of patients.[521]

Dysmenorrhea

Primary dysmenorrhea, menstrual pain not associated with recognizable pelvic disease, is due to intrinsic uterine dysfunction. Occurring only in ovulatory cycles, the symptoms of dysmenorrhea usually commence a few hours before the onset of the menstrual flow. Pain is greatest when the endometrium is shedding rapidly, approximately 12 hours after flow begins. The diagnosis of primary dysmenorrhea is established when secondary causes of dysmenorrhea are ruled out and based on medical history and normal findings on pelvic and rectovaginal examination and imaging.

The prevalence of dysmenorrhea in women varies between 50% to 90% in most studies.[527-536] Under 30 years old, smoking, irregular or heavy menstrual flow, body mass index (BMI) less than 20 kg/m^2, menarche before age 12, history of sexual assault, and a strong family history of dysmenorrhea are a few of the many risk factors known for primary dysmenorrhea.[537,538]

The painful cramps of dysmenorrhea are associated with uterine contractions; in women with dysmenorrhea, uterine contractile activity is heightened during menses, and basal myometrial tone and amplitude of contractions are increased.[539] During intense contractions, there is a reduction in blood flow to the endometrium suggesting that ischemia, in part, causes the pain of dysmenorrhea. There is also evidence from Doppler studies to show higher resistance in uterine vessels in women with primary dysmenorrhea, which can reduce blood flow to the endometrium.[540,541] The uterine contractions are prompted by prostaglandins, which are potent uterotonic agents both *in vitro* and *in vivo* acting through cell surface prostaglandin receptors.[542] Prostanoids may also directly sensitize uterine pain fibers. The notion that prostanoids are central to the pathogenesis of dysmenorrhea is supported by the observations that eicosanoids, most prominently prostaglandin F2-alpha ($PGF_2\alpha$), are found in high concentrations in menstrual fluid and that $PGF_2\alpha$ levels are higher in the endometrium and menstrual fluid of women complaining of dysmenorrhea than in women with pain-free menses.[543] This high concentration of prostaglandins has been shown not only in the endometrium but also in saliva of women during attacks of menstrual migraine associated with dysmenorrhea.[544] More recently patients with primary dysmenorrhea have also been hypothesized to have endothelial dysfunction.[545]

Treatment of primary dysmenorrhea is individualized to each patient's severity of symptoms. All drugs effective in inhibiting prostaglandin synthesis, including the potent nonsteroidal anti-inflammatory drugs (NSAIDs) ibuprofen, naproxen, and mefenamic acid alleviate symptoms of dysmenorrhea.[546] A Cochrane database review included 73 randomized trials to compare NSAID therapy to placebo and paracetamol. NSAIDs were significantly more effective in reducing pain symptoms compared to placebo or acetaminophen.[547] A combination of NSAID and paracetamol may also be helpful in relieving pain of primary dysmenorrhea.[548] Choosing an appropriate NSAID for treatment may be difficult. It is not clear whether some NSAIDs work better than others.[547] Some studies suggest that fenamates (class that includes mefenamic acid, flufenamic acid, tolfenamic acid, etc.) may have better pain relieving propensities than phenylpropionic acid derivatives (class that includes ibuprofen and naproxen).[549,550] Though there may not be sufficient data to prove the superiority of medications from the fenamates class, a reasonable option would be to start with NSAIDs from phenylpropionic acid derivative group and move onto fenamate class of medications if insufficient relief is noted.

Combined oral contraceptive pills (OCPs) are second line medications after NSAIDs for relief of pain from primary dysmenorrhea. No randomized trials have compared the efficacy of NSAIDs with OCPs. A systematic review compared OCPs to placebo and evaluated 10 randomized trials. A treatment benefit with OCPs was noted (pooled OR 2.99, 95% CI 1.76-5.07).[551] Continuous rather than cyclical administration of OCPs has shown more success in treating patients with primary dysmenorrhea.[552,553] Contraceptive ring users have similar results to OCP users for dysmenorrhea,[554] where as contraceptive patches have not shown comparable results to OCPs.[555] The use of levonorgestrel releasing intrauterine device for primary dysmenorrhea has been limited to case reports.[556] Commonly if treatment with NSAIDs is not successful after 3 months, OCPs are tried for another 3 months. If no relief is noted, reasons for secondary dysmenorrhea should be explored.

A long list of complementary and alternative medicines has been used for treatment of primary dysmenorrhea. Most of them have shown similar efficacy to the conventional nonsteroidal anti-inflammatory medications. Heat applied to the lower abdomen,[557,558] aerobic exercise,[559] yoga,[560,561] acupuncture,[562] aromatic essential oil massage,[563] and the use of far infrared emitting belts[564] are one of the few nonpharmacological agents tested for dysmenorrhea in randomized clinical trials and have shown promising results. Data on diet supplements are limited to a few small studies. A low fat vegetarian diet,[565] diet rich in dairy,[566] omega-3 fatty acids,[567] and vitamin E supplementation[568,569] have been effective in pain management from primary dysmenorrhea.

Newer medications that include calcium antagonists like nifedipine are also effective because they prevent uterine contraction.[570-572] Magnesium[573] and glyceryl trinitrate[574] have also been used for primary dysmenorrhea. In addition to prostanoids, other uterotonic substances including lipoxygenase products, vasopressin, and oxytocin may have a role in dysmenorrhea. Thus, antagonists of the V_1 receptor and oxytocin receptor have a therapeutic effect in dysmenorrheic subjects. Reductions in nitric oxide (NO), which relaxes uterine smooth muscle, may also contribute to the intensified contractions associated with dysmenorrhea.[575]

CHAPTER 28

Endocrine Diseases of Pregnancy

Andrea G. Edlow
Errol R. Norwitz

Physiological and endocrine adaptations occur in the mother in response to the demands of pregnancy. These demands include support of the fetus (volume support, nutritional and oxygen supply, and clearance of fetal waste), protection of the fetus (from starvation, drugs, toxins), preparation of the uterus for labor, and protection of the mother from potential cardiovascular injury at delivery. The presence of a preexisting endocrine disorder is likely to affect the ability of the mother to adapt to the demands of pregnancy and, as a result, may influence fetal growth and development. Drugs used to treat such disorders may also affect perinatal outcome. The most common preexisting endocrine disorders that can complicate pregnancy are diabetes mellitus, thyroid dysfunction, and obesity. Less common preexisting maternal endocrine disorders include pituitary tumors, diabetes insipidus, and hyperparathyroidism.

The physiological and endocrine adaptations that characterize pregnancy can also lead to the development of pregnancy-specific diseases in previously healthy women, the most common of which are gestational diabetes and disorders of the endocrine and sympathetic nervous systems associated with preeclampsia and preterm labor. This chapter is designed to review in detail the underlying pathophysiology of these pregnancy-specific diseases, as well as the effects of pregnancy on pre-existing endocrine disorders. A better understanding of these conditions will improve the ability of clinicians to optimize maternal and perinatal outcome in such pregnancies.

Diabetes Mellitus

Effects of Pregnancy on Maternal Glucose Metabolism

Normal pregnancy can be regarded as a diabetogenic (prodiabetic) state with evidence of insulin resistance, maternal hyperinsulinism, and reduced peripheral uptake of glucose. These endocrine alterations, which result primarily from the production of anti-insulin hormones from the placenta (see Chapter 12), are designed to ensure a continuous supply of glucose for the developing and growing fetus. Therefore, in pregnancy, the control of maternal glucose metabolism is shared by the mother and the fetoplacental unit. The endocrine and molecular mechanisms by which the fetoplacental unit is able to reset the carbohydrate homeostatic equilibrium in the mother are not clear, but likely involve the action of several placental hormones. These hormones include growth hormone (GH), human chorionic somatomammotropins (hCS, placental lactogens), corticotropin-releasing hormone (CRH), cortisol, and progesterone.

Insulin Production and Action Changes during Pregnancy

Major functional changes occur in insulin production and action during pregnancy. β-cells in the islets of Langerhans within the pancreas—the cells responsible for insulin production—undergo hyperplasia, leading to insulin hypersecretion and an increase in circulating insulin levels throughout pregnancy.[1-3] It is this mechanism, along with the hemodilution of pregnancy and the initial enhanced responsiveness of cells to circulating levels of insulin,[4-6] that is likely responsible for the fasting hypoglycemia seen in early pregnancy. However, as pregnancy progresses, peripheral resistance to insulin increases.[4-7] In an attempt to overcome this resistance, the pancreas further increases insulin secretion. This compensatory response serves to return circulating maternal glucose levels to the normal range, but results also in chronically elevated insulin levels (both in the fasting and fed state), in the postprandial hyperglycemia that characterizes normal pregnancy,[8] and in islet cell hyperplasia.

Beta cell hyperplasia and expansion are controlled, in part, by prolactin and hCS, which both cause an increase in the number of pancreatic β-cells in pregnancy. Recent data from mice have provided some insights into the mechanisms regulating β-cell hyperplasia. Kim and colleagues found that serotonin acts downstream of lactogenic hormone signalling via the prolactin receptor to stimulate β-cell proliferation.[9] Karnik and colleagues reported that repression of menin—the protein product of the MEN1 gene—is necessary for normal β-cell proliferation, and that prolactin represses menin levels in pancreatic islets.[10]

Insulin resistance refers to a decrease in the ability of a fixed concentration of circulating insulin to stimulate peripheral glucose uptake in adipocytes and muscle cells. The condition can be demonstrated either by the insulin tolerance test or by glucose loading tests. An insulin tolerance test involves the injection of a standard dose of insulin followed by serial blood glucose measurements. The clearance

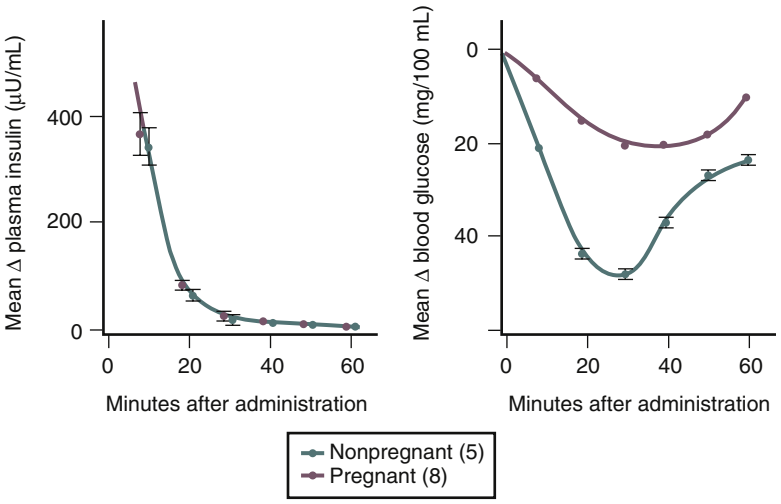

FIGURE 28.1 Effect of pregnancy on insulin clearance and insulin sensitivity. *Left,* Intravenous injection of insulin (0.1 unit/kg) results in identical clearance curves for circulating insulin in nonpregnant *(open circles)* and pregnant subjects *(closed circles). Right,* In pregnant subjects *(closed circles),* the intravenous injection of insulin results in a smaller decline in circulating glucose than that seen in nonpregnant subjects. The blunted biological effect of insulin in pregnancy suggests that pregnancy is a state of insulin resistance. *(From Burt RL, Davidson WF. Insulin half-life and utilization in normal pregnancy.* Obstet Gynecol *43:161, 1974, with permission from The American College of Obstetricians and Gynecologists.)*

of insulin from the circulation is not altered by pregnancy (Fig. 28.1).[11] The half-life of insulin is approximately 7 minutes both before and during pregnancy.[11] However, in pregnant subjects, the administration of insulin results in a smaller decline in circulating glucose than that seen in nonpregnant subjects (Fig. 28.1). Furthermore, in pregnancy, intravenous (Fig. 28.2) or oral (Fig. 28.3) administration of glucose causes significant hyperinsulinemia as compared with the nonpregnant state,[4] resulting in relative hyperinsulinemia after meals. Taken together, these data provide evidence in support of pregnancy being an insulin-resistant state.

The molecular mechanisms responsible for the insulin resistance in pregnancy are not well understood, but several factors are likely involved. Although insulin receptor kinase activity does not appear to be affected by pregnancy, the numbers of high-affinity insulin receptors on the surface of adipocytes are threefold lower in pregnancy than in nonpregnant women.[2,12] The glucose transport system also appears to be perturbed in pregnancy, with a threefold reduction in insulin-stimulated glucose transport as compared with nonpregnant controls.[12]

The movement of glucose into adipocytes and skeletal muscle cells is mediated by the glucose transport proteins, GLUT-1 and GLUT-4. GLUT-1 is responsible for basal glucose transport and is not responsive to insulin. Insulin increases glucose uptake in cells by stimulating the translocation of GLUT-4 from intracellular sites to the cell surface.[13,14] Up to 75% of insulin-dependent glucose disposal occurs in skeletal muscle, whereas adipose tissue accounts for only a small fraction.[15] In some pregnancies complicated by gestational diabetes, GLUT-4 is markedly reduced and fails to translocate to the cell surface with insulin stimulation, leading to a reduction in glucose transport in both the basal and insulin-stimulated states.[16] Taken together, these data suggest that the peripheral insulin resistance that characterizes pregnancy likely results from several integrated mechanisms, including a decrease in insulin receptor number, a "postreceptor" defect in insulin action, and alterations in glucose transport systems.[15-18] The postreceptor mechanisms that contribute to insulin resistance in late pregnancy occur in skeletal muscle at the β-subunit of the insulin receptor, at the level of insulin receptor substrate-1 (IRS-1), and in the cytoplasm, where increased free intracytoplasmic p85α regulatory subunit of phosphatidylinositol 3-kinase leading to decreased ability of insulin to stimulate the association of catalytic proteins with IRS-1.[19,20] Together, these alterations in insulin signaling likely result in less glucose uptake in skeletal muscle.

Impaired suppression of nonesterified fatty acids (NEFAs) in pregnant women suggests another mechanism for insulin resistance in pregnancy. NEFAs have been demonstrated to impair insulin-stimulated hepatic glucose uptake and whole body glucose disposal.[21] Impaired NEFA suppression to endogenous insulin has been observed in a pregnant population subjected to a hyperinsulinemic clamp.[22] Thus, inappropriately elevated NEFA levels may play a role in the insulin resistance observed in pregnancy. Dysregulation of NEFA has been implicated in both insulin resistance in normal pregnancy and decreased insulin secretion in gestational diabetes, and has been posited as a pathophysiological link between gestational diabetes and the subsequent development of type 2 diabetes (DM2).[23-25]

Fetoplacental Counterregulatory Hormones

Although the molecular mechanisms have yet to be fully elucidated, the fetoplacental unit is clearly responsible for the pregnancy-induced insulin resistance, exerting its effect largely through the production of counterregulatory (anti-insulin) hormones. Insulin promotes the uptake of glucose by adipocytes and muscle cells. Counterregulatory hormones inhibit insulin-mediated glucose uptake by adipocytes and muscle cells, acting largely at a postreceptor level. Such hormones include, among others, GH, hCS, cortisol, and progesterone.

Placental GH and hCS

Placental GH differs from pituitary GH by 13 amino acid (191 nucleotide) substitutions[26] and circulates in at least three isoforms: 22-, 24-, and 26-kDa.[27] Human chorionic somatomammotropins are single-chain proteins produced largely by the syncytiotrophoblast with a high degree of sequence homology to both GH and prolactin. In primates, hCS genes appear to have evolved from a precursor GH gene; in nonprimate species, on the other hand, the placental lactogens appear to have evolved from a precursor

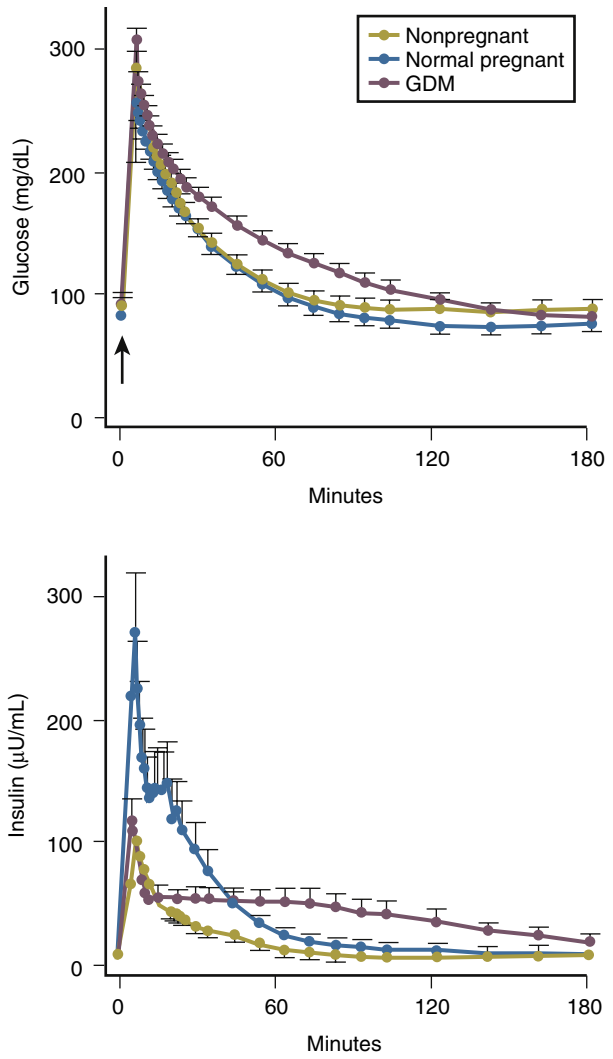

FIGURE 28.2 Insulin and glucose response to an intravenous glucose challenge. Comparison of insulin and glucose responses to a rapid intravenous infusion of glucose (300 mg/kg) in nonpregnant women, pregnant women, and pregnant women with gestational diabetes mellitus (GDM). In GDM, there are both elevated glucose and insulin concentrations, suggesting that the condition is an insulin-resistant state. The *arrow* indicates injection of glucose. *(From Buchanan TA, Metzger BE, Freinkel N, Bergman B. Insulin sensitivity and B-cell responsiveness to glucose during late pregnancy in lean and moderately obese women with normal glucose tolerance or mild gestational diabetes.* Am J Obstet Gynecol *162:1008, 1990.)*

prolactin gene. Because of these differences in evolution, we have chosen to use the term "human chorionic somatomammotropins" to refer to these genes collectively.[28] The dominant isoform of hCS is 191 amino acids in length, with a molecular mass of 23 kDa.[26,29] hCS binds with high affinity to prolactin (PRL) receptors, but with low affinity to GH receptors, suggesting that it functions largely as a lactogen rather than as a somatogen in pregnancy. Conversely, placental GH binds with high affinity to GH receptors but with low affinity to PRL receptors.[30] Thus, by midgestation, the endocrinological mileu is one of high levels of two lactogenic hormones (PRL and hCS), and placental GH, which is acting almost exclusively as a somatogen. hCS is also secreted directly into the fetal circulation, but is present in much lower levels than fetal PRL. Placental GH, however, is detectable only in maternal blood.[31,32]

The factors that regulate GH and hCS synthesis and secretion are not fully understood, but somatostatin and GH-releasing hormone produced by the cytotrophoblast may play inhibitory and stimulatory roles, respectively.[33-35] Additional regulation of hCS may be provided by insulin and angiotensin II, which both stimulate hCS release,[36,37] as well as by dynorphin (Fig. 28.4).[38] This placental endocrine and paracrine-autocrine regulatory system is similar to that observed in the hypothalamic-pituitary axis, which has led Dr. Samuel Yen to refer to the placenta as *the third brain*.[39]

The genes coding for GH and hCS are clustered together in a single region of chromosome 17 in the following order (5′ to 3′): *hGH-N* (pituitary GH gene), *hCSL*, *hCS-A*, *hGH-V* (placental GH gene), and *hCS-B*.[40] The pattern of expression of these genes is tissue-specific and changes throughout gestation. For example, the placenta does not express the *hGH-N* (pituitary GH) gene. Pituitary GH is secreted in a pulsatile fashion from the maternal anterior pituitary, and can be measured in the maternal serum throughout the first trimester of pregnancy.[41] Thereafter, however, pituitary GH secretion progressively declines. By the third trimester of pregnancy, pituitary GH secretion is effectively suppressed and cannot be rescued by induction of a hypoglycemic stimulus or by amino acid infusions (which will be discussed later in this chapter).[42,43] In contrast, circulating concentrations of placental GH—encoded by the *hGH-V* (placental GH) gene and expressed exclusively in the placenta—increase progressively throughout the second and third trimesters of pregnancy.[41,44] Similar differences are seen in the expression of the *hCS* genes. For example, at 8 weeks' gestation, the *hCS-A* and *hCS-B* genes are expressed equally in the placenta; however, at term, expression of *hCS-A* is five times greater than that of *hCS-B*. Results of radioreceptor assay studies suggest that the relative contributions to circulating GH-like activity in pregnancy at term are 85% from *hGH-V* (placental GH), 12% from hCS, and less than 3% from *hGH-N* (pituitary GH).[45] Multiple genes, multiple mRNA species (as in the *hCS-L* and *hGH-V* genes, which generate two distinct mRNA transcripts on the basis of alternative splice-acceptor sites for each gene[46]), and heterogeneity in posttranslational processing result in many isoforms of these key placental hormones. The potential teleological advantages of having multiple placental GH-like genes are to ensure that the placenta can generate sufficient quantities of GH-like hormone to regulate maternal and fetal metabolism, and to minimize the risk of pregnancy failure due to a functional "knockout" of any single gene.

During pregnancy, there is a major transition in the locus of control of the GH axis from the maternal hypothalamic-pituitary unit to the placenta. Circulating levels of placental GH and hCS increase throughout pregnancy. These proteins act through cell surface receptors (GH and prolactin receptors belong to a superfamily of cytokine receptors that share a high degree of sequence homology[28]) to stimulate the production of insulin-like growth factor-1 (IGF-1). Circulating concentrations of IGF-1 in the maternal serum increase throughout pregnancy, reaching a peak near term.[47,48] This increase in IGF-1 has also been observed in a pregnant dwarf with complete pituitary GH deficiency,[42] suggesting

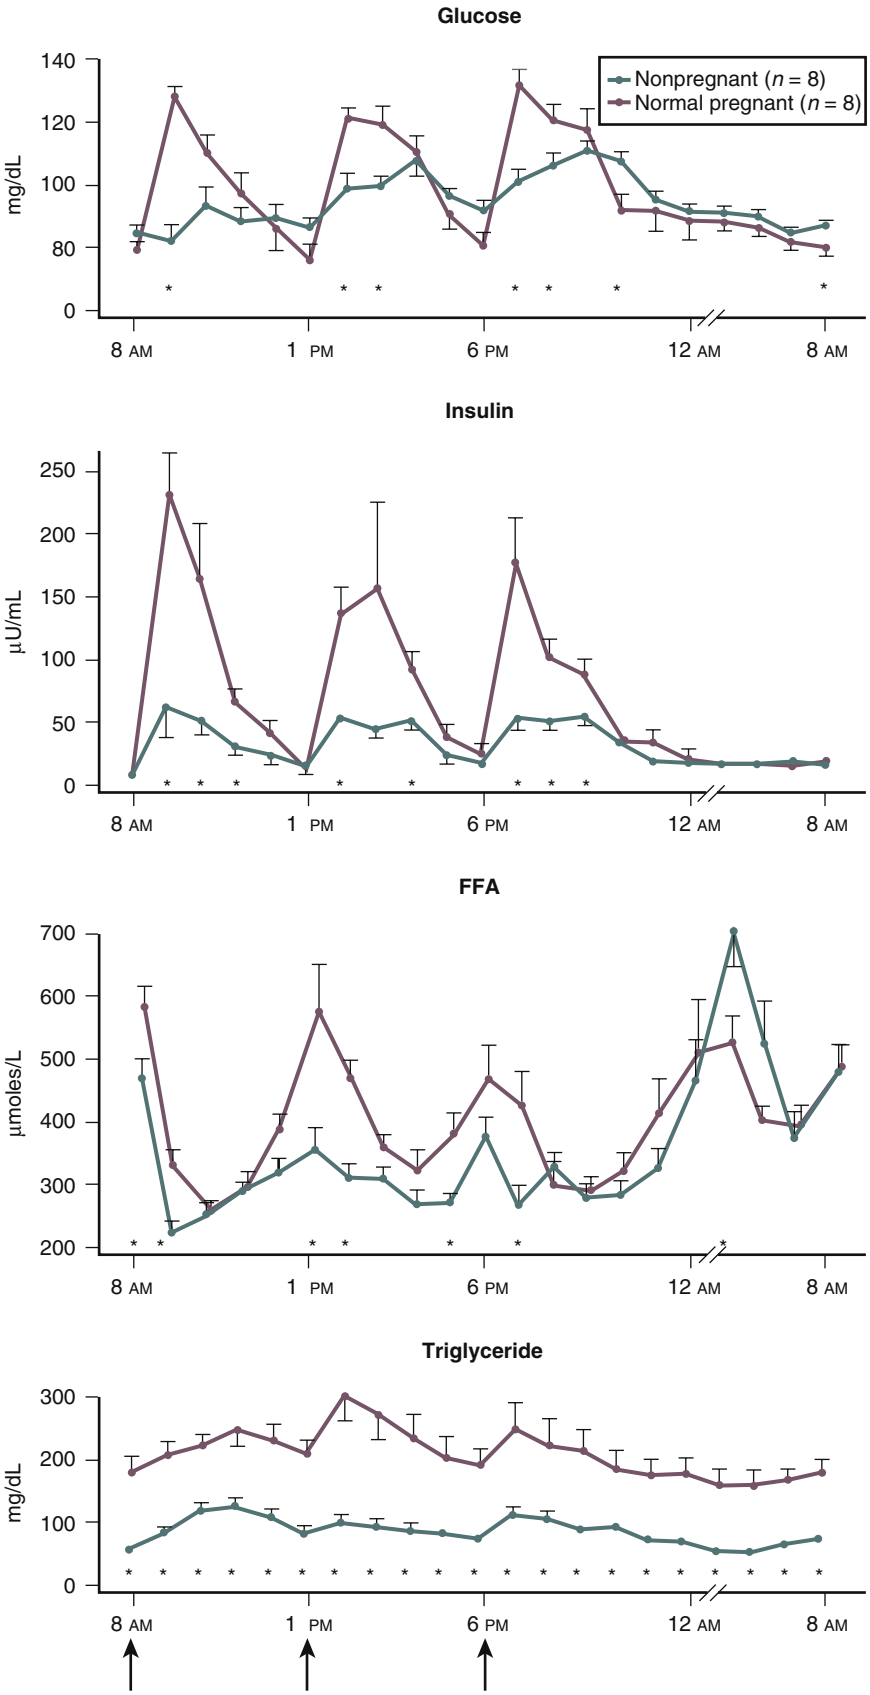

FIGURE 28.3 Effect of pregnancy on carbohydrate and lipid metabolism in the fed and fasting state. Comparison of glucose, insulin, free fatty acid, and triglyceride responses to 24 hours of feeding and fasting in nonpregnant *(open circles)* and normal pregnant women in the third trimester *(closed circles)*. In the fed state *(asterisk)*, pregnancy is associated with elevated levels of circulating glucose and insulin. In the fasting state, pregnancy is associated with decreases in glucose below those that are seen in the nonpregnant state. The *arrows* indicate timing of meals. FFA, free fatty acids. *(From Phelps RL, Metzger BE, Freinkel N. Carbohydrate metabolism in pregnancy.* Am J Obstet Gynecol *140:730, 1981.)*

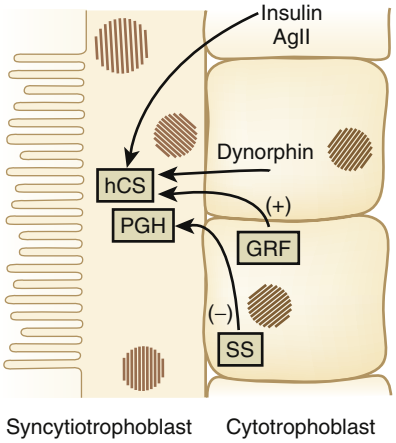

FIGURE 28.4 Regulation of placental counterregulatory hormones. Diagrammatic depiction of a potential placental regulatory system involving growth hormone-releasing factor (CRF), somatostatin (SS), human chorionic somatomammotropin (hCS), and placental growth hormone (PGH). The modulating roles of dynorphin, insulin, and angiotensin II (AgII) are also shown. The placenta has endocrine regulatory systems that parallel those in the maternal and fetal hypothalamic-pituitary units. Yen has proposed that the placenta is a "third brain."

that placental hormones may mediate this effect. Concentrations of IGF-binding protein-1 (IGFBP-1) rise in the first trimester, reach a peak at approximately 12 to 14 weeks of gestation, and thereafter remain stable for the remainder of pregnancy.[49] The level of unbound (bioavailable) IGF-1 therefore increases as pregnancy progresses, and likely contributes to the suppression of *hGH-N* (pituitary GH) gene expression in the latter half of gestation.

In the circulation, GH can exist in a free form or bound to a GH-binding protein (GHBP). Approximately 30% of circulating GH is bound to GHBP and therefore not biologically active.[50] Veldhuis and colleagues[51] proposed that GHBP may serve as a buffer to prevent the level of free (bioavailable) GH from falling too low between secretory pulses. GHBP is the ectodomain of a larger cellular GH receptor and is released into the circulation after proteolytic cleavage of the parent molecule. It is likely, therefore, that circulating concentrations of GHBP parallel that of the cellular GH receptor in important target organs like the liver. This relationship allows for a balance between GH action (mediated through the GH receptor) and inactivation (by binding to the GHBP). The greater the levels of circulating GHBP, the greater the concentration of cellular GH receptors and the greater the sensitivity of cells to the actions of GH. GHBP concentrations tend to decline as gestation advances,[52] although the reason for this change and its physiological significance remain unclear.

This system is not a prerequisite for pregnancy success, because a normal pregnancy is possible in women with Laron dwarfism in which both the GH receptor and GHBP are absent.[53] However, aberrations in this system may be associated with pregnancy-related complications. For example, GHBP levels have been shown to be significantly higher in women with gestational diabetes compared with nondiabetic pregnant women.[54] This observation suggests that the concentration of GH receptors is also increased in women with gestational diabetes, leading to a degree of sensitization to the effects of GH and hCS. An increased sensitivity to the effects of circulating GH could explain many of the endocrine changes observed in gestational diabetes, including insulin resistance, higher serum glucose levels, and an increased incidence of fetal macrosomia.

Differential levels of placental GH and hCS have been noted in normal and pathological pregnancies. Low maternal levels of placental GH and hCS have been noted in pregnancies complicated by hypertension, preeclampsia, and intrauterine growth retardation.[55,56] Conversely, high levels of hCS have been noted in the blood of pregnant mothers with gestational diabetes.[57,58] Placental gene expression profiling has demonstrated different mRNA expression profiles of placental GH and hCS in pregnancies affected by preeclampsia and GDM, compared to normal pregnancies.[59] The same investigators also demonstrated downregulation of the entire GH/hCS cluster in the placenta in pregnancies with small-for-gestational-age newborns, with significantly increased expression of hCS mRNA placental transcripts in pregnancies resulting in large-for-gestational-age newborns.[60] Uteroplacental insufficiency, as seen in preeclampsia and other maternal hypertensive disorders, may lead directly to decreased placental GH expression, resulting in decreased maternal lipolysis and decreased maternal IGF-I.[31]

Circulating levels of placental GH, IGF-1, and the IGFBPs appear to correlate with birth weight. For example, a decrease in both placental GH and IGF-1 levels has been associated with intrauterine growth restriction (IUGR).[61] The decrease in placental GH levels is due both to a decrease in placental mass and a decrease in the density of placental GH-secreting cells.[62] There is also a strong inverse correlation between maternal IGFBP-1 concentrations and birth weight in both term and preterm pregnancies.[63,64] The higher the IGFBP-1 concentration, the lower the circulating level of unbound (bioavailable) IGF-1 and the lower the birth weight. Moreover, several investigators have reported a positive correlation between birth weight and circulating concentrations of IGF-1 in the fetus and neonate.[65,66] Reece and colleagues[66] reported that IGF-1 concentrations were significantly lower in neonates below the mean birth weight for gestational age than levels in neonates above the mean (mean ± SEM: 40 ± 11 versus 86 ± 6 ng/mL, respectively), with no differences in IGF-2 concentrations. Similar findings were reported by Lassarre and colleagues.[65] Conversely, maternal hyperglycemia may increase placental and fetal weight via induction of IGF-2 and fetal hyperinsulinemia.[67] Increased maternal fat stores may reduce plasma adiponectin, and thus increase hCS expression via decreased adiponectin suppression.[68] Increased hCS in the fetal circulation may promote fetal hyperinsulinemia via induction of β-cell replication, increasing fetal weight gain.[31,69,70] Taken together, these data suggest that GH, hCS, IGF-1, as well as their binding proteins (GHBP and the IGFBPs) may play an important role in governing fetal growth and pregnancy outcome, and that these endocrine factors may be regulated by both the mother and the fetoplacental unit.

Cortisol

Cortisol is a potent diabetogenic hormone. It promotes lipolysis in adipocytes and protein breakdown in muscle, leading to an increase in circulating free fatty acids and amino

Table 28.1 Fasting Maternal Glucose, Insulin, Glucagon, Amino Acid, Alanine, Free Fatty Acid, and Cholesterol Concentrations in Late Pregnancy Compared with the Nonpregnant State

	Measurement (mean ± SEM)	
	Nonpregnant State	Late Pregnancy
Glucose (mg/dL)	79 ±2.4	68 ± 1.5*
Insulin (μ/mL)	9.8 ± 1.1	16.2 ± 2.0*
Glucagon (pg/mL)	126 ± 6.1	130 ± 5.2
Amino acids (μM)	3.82 ± 0.13	3.18 ± 0.11*
Alanine (μM)	286 ± 15	225 ± 9*
Free fatty acids (mg/dL)	76 ± 7	181 ± 10*
Cholesterol (mg/dL)	163 ± 8.7	205 ± 5.7*

Data from Freinkel N, Metzger BE, Nitzan M, et al. Facilitated anabolism in late pregnancy: some novel maternal compensations for accelerated starvation. In Malaisse WJ, Pirart J (eds). Diabetes International Series 312. Amsterdam: Excerpta Medica, 1973, p 474.

acids.[71] Levels of adrenocorticotropic hormone (ACTH) and cortisol increase in pregnancy.[72] The increase in ACTH is due, at least in part, to an increase in CRH production by the placenta (discussed later in this chapter). Much of the increase in total cortisol concentration in pregnancy is due to the excessive production of corticosteroid-binding globulin by the liver under the influence of estrogen. However, there is also a significant increase in urinary free cortisol excretion during pregnancy, suggesting that circulating levels of free cortisol may also be increased.[73] The relative contribution of an increase in circulating free cortisol to the insulin resistance of pregnancy is unclear.

Progesterone

High concentrations of progesterone have been shown to cause insulin resistance in cells in culture and in laboratory animals by decreasing insulin receptor number and causing a postreceptor defect in insulin action, which has yet to be fully elucidated.[74-76] High circulating concentrations of progesterone may likely contribute to the pregnancy-related insulin resistance.

Fasting State

In nonpregnant women, there is a constant need to maintain circulating glucose concentrations for use by the brain. During an overnight fast, glucose is released from the liver by both glycogenolysis (breakdown of glycogen stores [75%]) and gluconeogenesis (production of glucose from circulating metabolical precursors [25%]). The precursors for gluconeogenesis include pyruvate, alanine (from muscle), glycerol (from the breakdown of triglycerides in adipose tissue), and lactate (from anaerobic metabolism).

Pregnancy is associated with an increased demand for glucose and alanine, both of which are required by the developing fetus. As such, the fasting state in pregnancy is characterized by a rapid and often severe decrease in maternal serum glucose and alanine concentrations. Associated with these changes is an increase in the circulating levels of free fatty acids (derived from triglyceride breakdown in adipose cells) and ketone bodies (Fig. 28.3; Table 28.1).[77,78] The hyperketonemia that characterizes late pregnancy is the result of enhanced lipolysis, which is likely due, in turn, to the insulin resistance in adipocytes caused primarily by the placental counterregulatory hormones.

In pregnancy, the acceleration of lipid catabolism during fasting helps the mother to rely on fat as a major energy source, thereby minimizing protein catabolism (preserving muscle mass) and allowing both glucose and amino acids to be used preferentially by the fetus.[8] These metabolical adaptations have been termed "accelerated starvation" by Freinkel.[79] Although a useful descriptive term, this characterization of pregnancy is largely inaccurate because fat mass is known to increase significantly during pregnancy.[80]

Fed State

The fetus is a thief! Many of the metabolical and endocrine adaptations associated with pregnancy are designed to maintain a preferential and uninterrupted supply of metabolical fuel from mother to fetus as dictated by the progressively increasing demands of the growing fetus. The placenta is relatively impermeable to fat, but readily transports glucose, amino acids, and ketone bodies from the maternal to the fetal circulation.

Pregnancy is associated with hyperlipemia, both in the fasting and the fed states. Total plasma lipid concentrations increase progressively after 24 weeks of gestation. Increases in triglycerides, cholesterol, and free fatty acids are significant (Fig. 28.5 and Fig. 28.6; Table 28.1).[8,78,81,82] High-density lipoprotein cholesterol levels rise during early pregnancy, and low-density lipoprotein cholesterol concentrations increase in later pregnancy.[81,82]

In pregnancy, an oral glucose load is associated with a greater increase in circulating glucose concentration, a smaller decline in free fatty acids, and a larger increase in serum triglycerides than that seen in the nonpregnant state (Fig. 28.5).[8,78] A similar effect has been observed in pregnancy after meals (Fig. 28.3).[8] These adaptations allow the mother to use primarily available triglycerides, glycerol, and free fatty acids for metabolical fuel after meals, and to preserve glucose and amino acids for preferential use by the fetus (Fig. 28.7). The cause of these metabolical changes is likely the lipolytic action of the placental counterregulatory hormones (GH, hCS, cortisol, and progesterone), which serve to promote lipolysis during fasting and hypertriglyceridemia in the fed state.

Pancreatic β-Cells: The Missing Link

To a point, pancreatic β-cells will respond to insulin resistance with increased insulin secretion. Bergman and colleagues first characterized a predictable hyperbolic relationship between the quantity of insulin produced by β-cells and tissue sensitivity to insulin.[83] The disposition index, or the "hyperbolic correction," is a measure of insulin secretion corrected for insulin resistance.[84] A left-shifted curve, representing decreased compensatory insulin secretion for a given level of insulin resistance, may be seen in women who develop both gestational diabetes (GDM) and type 2 diabetes mellitus (DM2). Buchanan posits that insulin resistance actually causes the β-cell dysfunction observed in GDM, and that chronic insulin resistance leading to β-cell failure may be the mechanism by which women with GDM progress to DM2.[85]

Gestational Diabetes

Depending on the patients screened and the diagnostic criteria used, GDM complicates approximately 7% of all pregnancies, resulting in at least 200,000 cases annually in the United States alone.[86] The American Diabetes Association (ADA) classification of diabetes mellitus is summarized in Box 28.1.[86] Gestational diabetes mellitus (GDM)

Maternal metabolism relies on triglycerides and fatty acids.

has previously been defined as any degree of carbohydrate intolerance with the onset of pregnancy or first recognized during pregnancy.[19] The American Congress of Obstetricians and Gynecologists (ACOG) still endorses this terminology.[87] Due in part to the increasing prevalence of obesity among young women, an increasing proportion of women will have unrecognized type 2 diabetes at the time of screening for gestational diabetes. To address this increased potential for prepregnancy diabetes, in 2010 the International Association of Diabetes and Pregnancy Study Group (IADPSG) recommended changing the classification of diabetes diagnosed during pregnancy to overt or gestational.[88]

Box 28.1 American Diabetes Association (ADA) Classification of Diabetes Mellitus

TYPE 1 DIABETES MELLITUS
Caused by β-cell dysfunction, usually leading to absolute insulin deficiency

TYPE 2 DIABETES MELLITUS
Typically associated with peripheral insulin resistance and varying degrees of abnormalities in insulin secretion

GESTATIONAL DIABETES MELLITUS
Characterized by peripheral insulin resistance resulting from counterregulatory (anti-insulin) hormones produced by the placenta

OTHER TYPES
Genetic defects in carbohydrate metabolism
Diseases of the exocrine pancreas
Endocrinopathies
Drug-induced or chemical-induced diabetes
Infections
Uncommon forms of immune-mediated diabetes
Genetic syndromes sometimes associated with diabetes

The American Diabetes Association (ADA) endorsed this recommendation.[86] Overt diabetes would be diagnosed at the initial prenatal visit in women who met any of the following criteria: (1) fasting plasma glucose ≥126 mg/dL [7.0 mmol/L], (2) hemoglobin A1C ≥6.5%, or (3) random plasma glucose ≥200 mg/dL [11.1 mmol/L], followed by a confirmatory elevated fasting plasma glucose or A1C as previously described.

Screening for Gestational Diabetes

Patients with GDM are typically asymptomatic. Some experts and organizations have recommended screening all pregnant women for GDM.[89-93] The World Health Organization has recommended universal screening and utilizing a 75-g, 2-hour oral glucose tolerance test (OGTT) for screening and diagnosis.[91] The United Kingdom has also adopted the 2-hour OGTT for screening and diagnosis, but does not recommend universal screening.[94] ACOG has endorsed a selective risk-based approach to screening, utilizing a 50-g 1-hour glucose challenge test (GCT), followed by a 100-g 3-hour OGTT for diagnosis if GCT is positive.[87,95] The United States Preventive Services Task Force and the Canadian Task Force on Preventive Health Care both concluded there is insufficient evidence to recommend universal screening for gestational diabetes.[96,97] The most recent IADPSG study group recommendations recommend universal screening at 24 to 28 weeks' gestation with the 75-g, 2-hour OGTT, and screening high-risk women for pregestational diabetes with fasting or random plasma glucose, or hemoglobin A1C at the first prenatal visit.[19] The low-risk category that some recommend excluding from GDM screening includes women under age 25 who have normal body mass index (BMI), who have no first-degree relatives with the condition, and who are not members of ethnic or racial groups with a high prevalence of diabetes (Hispanic, Native American, Asian, or African American). Identifying and deferring screening in these low-risk women will decrease the overall number of patients screened by approximately 10% and will only overlook 3% of all women with GDM.[98]

Table 28.2 Glucose Screening for Gestational Diabetes with the 50-g Oral Glucose Load Test

Glucose Cutoff	Proportion of Women with a Positive Test	Sensitivity for Gestational Diabetes Mellitus
≥140 mg/dL (≥7.8 mmol/L)	14%-18%	≈80%
≥130 mg/dL (≥7.2 mmol/L)	20%-25%	≈90%

Data from Kjos SL, Buchanan TA. Gestational diabetes mellitus. *N Engl J Med* 341:1749, 1999.

Screening traditionally has been performed at 24 to 28 weeks of gestation.[99,100] For women at risk for undiagnosed type 2 diabetes (women with a history of gestational diabetes or polycystic ovarian syndrome, a high BMI, persistent glycosuria, a strong family history of diabetes, a prior macrosomic infant, or a prior unexplained late fetal demise), early screening for GDM should be performed at the first prenatal visit.[86] If the early screen is negative, the screen should be repeated at 24 to 28 weeks.

The Two-Step Approach

At this time, there is no universal accepted standard for screening and diagnosis of diabetes in pregnancy. Screening for diabetes in pregnancy has traditionally been performed as a two-step approach. The first step utilizes the *glucose load test* (GLT), also known as the *glucose challenge test* (GCT). First proposed as a screening test for GDM by O'Sullivan and colleagues in 1973,[101] the GLT is a nonfasting 50-g oral glucose challenge followed by a venous plasma glucose measurement at 1 hour.[99,102-104] The GLT is considered positive if the 1-hour glucose measurement is greater than a previously agreed threshold. Both 130 mg/dL and 140 mg/dL have been suggested.[99,105] Use of a lower cutoff will increase the detection rate of women with GDM, but will result in a substantial increase in the false-positive rate (Table 28.2).[105,106] There is no absolute GLT cutoff that should be regarded as diagnostic of GDM.[99,105-108]

The second step of the two-step approach requires a three-hour *glucose tolerance test* (GTT), which is only performed if the GLT is positive. A fasting glucose measurement of at least 105 mg/dL in the setting of a positive GLT is highly predictive of an abnormal GTT.[108] In pregnancy, the GTT involves an overnight fast and subsequent 100-g oral glucose challenge. Venous plasma glucose is measured fasting and at 1 hour, 2 hours, and 3 hours after the glucose load.

Although there is general agreement that two or more abnormal values are required to confirm the diagnosis,[99,105] there is little consensus about the glucose values that define the upper range of normal in pregnancy and no threshold that perfectly predicts adverse pregnancy outcome. Even one elevated value has been associated with an increased incidence of macrosomia and birth injury. A secondary analysis of a treatment trial for mild gestational diabetes found that elevations in fasting glucose and 3-hour GTT levels were associated with adverse pregnancy and neonatal

Table 28.3 Diagnostic Thresholds for Gestational Diabetes During 100-g Glucose Tolerance Test

	Plasma Glucose Values mg/dL (mmol/L)		
	National Diabetes Data Group*	Sacks et al#	Carpenter and Coustan§
Fasting	105 (5.8)	96 (5.3)	95 (5.2)
1-hour	190 (10.6)	172 (9.4)	180 (9.9)
2-hour	165 (9.2)	152 (8.3)	155 (8.6)
3-hour	145 (8.1)	131 (7.2)	140 (7.7)

*National Diabetes Data Group. Classification and diagnosis of diabetes and other categories of glucose intolerance. *Diabetes* 28:1039, 1979; #Sacks DA, Abu-Fadil S, Greenspoon JS, Fotheringham N. Do the current standards for glucose tolerance testing in pregnancy represent a valid conversion of O'Sullivan's original criteria? *Am J Obstet Gynecol* 161:638, 1989; §Carpenter MW, Coustan DR. Criteria for screening tests for gestational diabetes. *Am J Obstet Gynecol* 144:768, 1982.

outcomes.[109] The same study found that fasting glucose of 90 mg/dL or greater and 1-hour value of 165 mg/dL or greater were associated with an increased risk for adverse neonatal outcomes, while a 1-hour value of 150 mg/dL or greater was associated with an increased risk for large for gestational age neonates. Two- and 3-hour glucose levels were not associated with an increased risk for adverse outcomes until far beyond current diagnostic thresholds, however, suggesting a need to reevaluate current diagnostic cutoffs for the 3-hour GTT (Table 28.3).

The One-Step Approach

In 2010, the one-step approach to diagnosing diabetes in pregnancy was proposed by IADPSG.[88] This approach was subsequently endorsed by the ADA,[86] but not by ACOG.[87] The IADPSG approach advocates diagnosing gestational diabetes in women who meet either of the following criteria: (1) fasting plasma glucose ≥92 mg/dL (5.1 mmol/L), but less than 126 mg/dL (7.0 mmol/L) at any gestational age, or (2) at least one abnormal result on a 75 gram 2-hour oral glucose tolerance test, which could be administered at 24 to 28 weeks of gestation. Abnormal values are defined as: (1) fasting plasma glucose ≥92 mg/dL (5.1 mmol/L), but less than 126 mg/dL (7.0 mmol/L) or (2) 1-hour value ≥180 mg/dL (10.0 mmol/L) or (3) 2-hour value ≥153 mg/dL (8.5 mmol/L) (Box 28.2).[88] This interpretation of the 2-hour OGTT results marks a departure from both the WHO criteria (in which only an abnormal fasting or 2-hour plasma glucose can be used for diagnosis), and the current ADA criteria (which require two abnormal values for the diagnosis of gestational diabetes). To reflect the continuous association between maternal glycemic concentrations and adverse perinatal outcomes seen in the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study data, the IADPSG-selected thresholds for the 2-hour OGTT represent the average glucose values at which there were 1.75 times the odds of infant birth weight, cord blood C-peptide (a proxy for fetal hyperinsulinemia), and percent neonatal body fat greater than the 90th percentile.[110] Women with one or more values above the thresholds above had a two-fold higher frequency of preeclampsia and large for gestational age infants, and more than a 45% increase in preterm delivery and primary cesarean delivery. The algorithm for screening and diagnosis of GDM proposed by IADPSG is outlined in Box 28.2.

Box 28.2 Strategy for the Detection and Diagnosis of Hyperglycemic Disorders in Pregnancy

FIRST PRENATAL VISIT

- Measure FPG, A1C, or random plasma glucose on all or only high-risk women†
- If results indicate overt diabetes (FPG ≥ 7.0 mmol/L [126 mg/dL], A1C ≥ 6.5%, random plasma glucose ≥11.1 mmol/L [200 mg/dL] with confirmation):
  - Treat and follow-up as for preexisting diabetes
- If results not diagnostic of overt diabetes and FPG ≥ 5.1 mmol/L (92 mg/dL) but <7.0 mmol/L (126 mg/dL):
  - Diagnose as GDM
- If results not diagnostic of overt diabetes and FPG < 5.1 mmol/L (92 mg/dL):
  - Test for GDM from 24 to 28 weeks' gestation with a 75-g OGTT‡

24-28 WEEKS' GESTATION: DIAGNOSIS OF GDM

- 2-hour, 75-gram OGTT: perform after overnight fast on all women not previously found to have overt diabetes or GDM during testing earlier in this pregnancy:
  - Diagnose overt diabetes if FPG ≥ 7.0 mmol/L (126 mg/dL)
  - Diagnose GDM if one or more value equals or exceeds the following thresholds:
    - FPG ≥5.1 mmol/L or 92 mg/dL
    - 1-hour plasma glucose ≥10.0 mmol/L or 180 mg/dL
    - 2-hour plasma glucose ≥8.5 mmol/L or 153 mg/dL
- OGTT is normal if all values are less than above thresholds

Data and format adapted from Metzger, BE et al. for the International Association of Diabetes and Pregnancy Study Groups Consensus Panel. International Association of Diabetes and Pregnancy Study Groups Recommendations on the Diagnosis and Classification of Hyperglycemia in Pregnancy. *Diabetes Care* 2010;33(3):676-682.[88]

Guidelines are to be applied to women without known diabetes antedating pregnancy. Postpartum glucose testing should be performed for all women diagnosed with overt diabetes during pregnancy or GDM.

†Decision to perform evaluation for glycemia on all pregnant women at first prenatal visit or only on women with characteristics indicating a high risk for diabetes is to be made on the basis of the background frequency of abnormal glucose metabolism in the population and on local circumstances.

‡The IADPSG panel concluded there is insufficient evidence to know whether there is a benefit of generalized testing to diagnose and treat GDM before the usual 24-28 weeks' gestation.

FPG, fasting plasma glucose; GDM, gestational diabetes mellitus; OGTT, oral glucose tolerance test.

The utilization of IADPSG diagnostic criteria for overt and gestational diabetes would result in 18% of women being diagnosed with diabetes in pregnancy.[88] The potential long-term economic impact of implementing the IADPSG guidelines is unknown at this time, but in the short-term, healthcare costs would likely be increased. Including the costs of long-term health intervention with diet and exercise, a recent cost-effectiveness analysis estimated that for every 100,000 pregnancies, the IADPSG approach would increase costs by over $125,600,000.[111] This analysis concluded that the IADPSG screening recommendations are cost effective only if post-delivery care reduces diabetes incidence.

Identification of overt diabetes early in pregnancy is important due to the associated increased risk of congenital

anomalies, and maternal complications such as nephropathy and retinopathy. In contrast, GDM poses little immediate risk to the mother. Such women are not at risk of diabetic ketoacidosis (DKA), which is primarily a disease of absolute insulin deficiency, but are at increased risk for developing hypertensive disorders of pregnancy compared to women without GDM.[112,113] GDM has been associated with a variety of perinatal and neonatal complications, including increased risk of macrosomia, operative delivery, shoulder dystocia, birth trauma, hypoglycemia, hyperbilirubinemia, hypocalcemia, and perinatal mortality.[99,114] In 2008, the Hyperglycemia and Adverse Pregnancy Outcome (HAPO) Study Cooperative Research Group reported the results of a multinational, multicenter study that examined the relationship between maternal hyperglycemia and adverse pregnancy outcomes.[110] The study demonstrated a continuous relationship between maternal hyperglycemia and large-for-gestational-age infants, cord blood C-peptide, neonatal hypoglycemia, and cesarean delivery. The risk of these adverse outcomes increased continuously as fasting plasma glucose levels increased from 75-mg/dL range, and as the 1- and 2-hour oral GTT values increased.

Transplacental glucose transport is a facilitated process that is mediated by the glucose transporter isoform GLUT-1.[115,116] Some researchers have hypothesized that maternal hyperglycemia in diabetes increases placental glucose transfer, resulting in fetal hyperglycemia and increased fetal insulin concentration that in turn stimulates fetal growth.[117] However, even in diabetic pregnancies with evidence of strict glycemic control, fetal macrosomia (defined as an estimated fetal weight of at least 4500 g[118]) is not uncommon,[119-121] which suggests a complex relationship between metabolical derangement and fetal growth in diabetes.[122] Other factors that may contribute to fetal macrosomia include obesity and high circulating levels of amino acids and lipids.[105]

Many of the complications of GDM are due to fetal macrosomia. Increased birth weight is associated with an increased risk of cesarean delivery, operative vaginal delivery, and birth injury to both the mother (vaginal, perineal, and rectal trauma) and fetus (including orthopedic and neurological injury).[99,101,105,114,123-125] Shoulder dystocia with resultant brachial plexus injury are serious consequences of fetal macrosomia, and are further increased in the setting of GDM because the macrosomia of diabetes is associated with increased diameters in the upper thorax of the fetus. Recent data also suggest that offspring of mothers with both gestational and prepregnancy diabetes may be predisposed to develop obesity, diabetes, and hypertension, via intrauterine programming/epigenetic modification.[126-130] For example, a study of 9439 children aged 5 to 7 years old evaluated the prevalence of childhood obesity relative to maternal glycemia in pregnancy.[130] This study found that maternal fasting glucose level of at least 95 mg/dL on a 3-hour 100-gram oral glucose tolerance test, gestational diabetes by Carpenter and Coustan criteria, and a top quartile 50-g, 1-hour glucose challenge test result were all associated with childhood obesity. Treatment of GDM reduced the rates of childhood obesity to rates similar to that of offspring born to women with normal glucose challenge tests, but this effect was only observed among offspring with birthweight of 4000 g or less. The authors concluded that maternal hyperglycemia resulted in metabolical imprinting for childhood obesity in offspring.

Interventions that definitively decrease the risk of macrosomia and subsequent adverse outcomes are limited. Two multicenter randomized clinical trials have demonstrated that the treatment of mild hyperglycemia in pregnancy reduces neonatal morbidity and macrosomia.[131,132] The Australian Carbohydrate Intolerance Study in Pregnant Women Trial (ACHOIS) demonstrated that treating pregnant women with impaired glucose tolerance on a 75-g OGTT resulted in a significant reduction in a composite perinatal outcome including perinatal death, shoulder dystocia, orthopedic injury and nerve palsy.[131] In the ACHOIS trial, glycemic control was achieved through a combination of dietary counseling, four times daily home blood glucose monitoring (maintaining fasting glucose levels less than 99 mg/dL and 2-hour postprandial levels less than 126 mg/dL), and insulin for persistent hyperglycemia. There was a reduction in the diagnosis of macrosomia (21% to 10%), but an increase in intensive care unit (ICU) admissions (61% to 71%). Induction of labor was increased in the intervention groups (from 29% to 39%) with no increase in the cesarean delivery rate, which was stable at 31% to 32%. In 2009, a second randomized controlled trial also demonstrated improved outcomes in women with glucose intolerance on a 100-g OGTT.[132] Landon and colleagues reported that glycemic control achieved through a combination of dietary counseling, four times daily home blood glucose monitoring (maintaining fasting glucose levels less than 95 mg/dL and 2-hour postprandial levels less than120 mg/dL), and insulin for persistent hyperglycemia did not result in a significant reduction in combined neonatal morbidity and mortality—a composite outcome including stillbirth, perinatal death, neonatal hyperbilirubinemia, hypoglycemia, hyperinsulinemia, and birth trauma. Treatment of glucose intolerance did, however, result in significant reductions in mean neonatal birth weight and fat mass, reduced frequency of large for gestational age neonates (14.5% to 7%), birth weight greater than 4000 g (14% to 6%), shoulder dystocia (4% to 1.5%) cesarean delivery (34% to 27%), and pregnancy-induced hypertension (14% to 9%), compared to usual care.

GDM cannot be prevented. The goal of antepartum management is to prevent fetal macrosomia and its resultant complications by maintaining maternal blood glucose at desirable levels throughout gestation (fasting, below 95 mg/dL; 1-hour postprandial, below 140 mg/dL or 2-hours postprandial, below 120 mg/dL).[99] Initial recommendations should include a diabetic diet consisting of 30 to 35 kcal/kg of ideal body weight given as 40% to 50% carbohydrate, 20% protein, and 30% to 40% fat to avoid protein catabolism. Daily home glucose monitoring and weekly antepartum visits to monitor glycemic control should also be instituted. If diet alone does not maintain blood glucose at desirable levels, insulin administration may be required.[133] If initial fasting glucose levels are consistently greater than 95 mg/dL and 2-hour postprandial values over 120 mg/dL, insulin therapy can be started right away with every effort made to avoid iatrogenic hypoglycemia.[134,135] The Fifth International Workshop on Gestational Diabetes[19] recommended exercise as an adjunct to diet for the treatment of GDM, although randomized studies have failed to demonstrate a beneficial effect of exercise on glycemic control in women with GDM.[136]

In the United States, oral hypoglycemic agents (sulfonylureas in particular) have not traditionally been recommended for use during pregnancy because of the possibility of fetal teratogenesis and prolonged neonatal hypoglycemia. This class of drugs works by stimulating pancreatic β-cells to synthesize and release insulin. Because the adverse fetal consequences of GDM are likely related to fetal hyperinsulinemia, any agent that could cross the placenta and increase fetal insulin production should be used with caution in pregnancy. First-generation sulfonylureas have been shown to cross the placenta and, as such, are contraindicated in pregnancy. There are conflicting data regarding the transplacental passage of second-generation sulfonylurea agents (glyburide and glipizide). The majority of human studies to date have demonstrated minimal fetal exposure,[137-139] likely secondary to high protein binding[140] and possibly active transport of glyburide from the fetal to the maternal circulation.[141,142] One study reported umbilical cord blood concentrations of glyburide as high as 70% of maternal serum concentrations,[143] but the majority of studies have found that cord blood concentrations of glyburide range from undetectable,[144] to 1% to 2% of maternal serum concentrations.[145,146]

Congenital malformations associated with the use of oral sulfonylurea drugs in pregnancy have been described,[147] but most of these reports failed to take into account maternal glycemic control. More recent studies have shown that the risk of malformations correlates strongly with the degree of glycemic control at the time of conception and is unrelated to the type of anti-diabetic therapy.[148] Moreover, such reports refer to oral hypoglycemic treatment in early pregnancy, whereas treatment for GDM only begins after the period of fetal organogenesis thereby eliminating any concern regarding malformations due to treatment alone.

Between 1974 and 1983, Coetzee and Jackson[149] treated 423 women with a new diagnosis of diabetes in pregnancy with oral hypoglycemic agents, and found no cases of serious neonatal hypoglycemia and no increase in perinatal mortality. A clinical trial by Langer and colleagues[144] randomized 404 women with singleton pregnancies and GDM requiring treatment to either glyburide or insulin therapy. Results showed no difference in glycemic control or neonatal outcome (including congenital malformations, macrosomia, neonatal hypoglycemia, or admission to neonatal intensive care). Eight women (4%) in the glyburide group required insulin therapy. Glyburide was not detected in the cord blood of any of the infants in the glyburide group. Jacobsen and colleagues performed a retrospective analysis comparing 236 women taking glyburide to 268 women taking insulin for control of gestational diabetes unresponsive to diet therapy.[150] Women in the insulin group had a higher mean BMI and higher mean fasting value on GTT, suggesting these women may have had a greater predisposition to poor glycemic control. The study reported no significant differences between groups in birth weight, macrosomia, or cesarean delivery. More women in the glyburide group achieved mean fasting and postprandial goals (86% versus 63%), and their neonates were less likely to be admitted to the neonatal intensive care unit (NICU) compared to women taking insulin (15% versus 24%). Women treated with glyburide, however, had a higher incidence of preeclampsia (12% versus 65%) and their neonates were more likely to receive phototherapy (9% versus 5%). From the standpoint of maternal safety, hypoglycemia is the most commonly reported maternal side effect. Langer and colleagues reported that 2% of patients taking glyburide had blood glucose measurements less than 40 mg/dL, compared with 20% of patients taking insulin.[144] Other studies reported no significant difference in rates of maternal hypoglycemia between women taking glyburide compared to insulin.[151,152] While the limited data currently available do not permit firm conclusions to be drawn about the efficacy and safety of oral hypoglycemic drugs in pregnancy, these agents are being used more frequently by obstetric care providers.[153]

Unlike glyburide, metformin is known to cross the human placenta,[154] which has reduced enthusiasm for its use during pregnancy. Metformin is a biguanide agent that acts by reducing peripheral insulin resistance and inhibiting gluconeogenesis. Since insulin acts as a potent growth factor, there is a theoretical concern that metformin passage across the placenta may lead to excessive fetal growth. Despite these concerns, metformin is now commonly being used by reproductive endocrinologists to achieve pregnancy in women with polycystic ovarian syndrome (PCOS).[155] Although *in vitro* models[156,157] and *in vivo* studies[154] have shown that metformin does cross from the maternal to the fetal compartment, multiple small retrospective studies have failed to show any significant adverse outcome with first trimester metformin exposure.[155,158,159]

The largest randomized clinical trial to date investigating the efficacy of metformin compared to insulin for treatment of gestational diabetes is the Metformin in Gestational Diabetes Trial (MiG).[160] In this randomized, open-label trial, 363 women were randomized to metformin and 370 to insulin, with 46% of women on metformin requiring supplemental insulin. There was no significant difference in perinatal complications between treatment groups. The primary composite outcome of neonatal hypoglycemia, respiratory distress, need for phototherapy, birth trauma, 5-minute Apgar score less than 7, or prematurity was 32% in both the metformin and the insulin group. Women preferred metformin to insulin therapy (77% versus 27%), and there were no serious adverse events associated with the use of metformin. Rowan and colleagues also followed the infants from the MiG study to the age of 2 years old in the offspring follow-up (TOFU) study, and found that children born to women taking metformin had larger measures of subcutaneous fat, but overall body fat was the same as in children whose mothers were treated with insulin alone.[161] The authors concluded that further follow-up is needed to determine whether children exposed to metformin will develop less visceral fat and therefore be more insulin sensitive than children exposed to insulin alone. A smaller open-label study randomized 100 women with GDM to therapy with insulin or metformin, finding no significant differences in the incidence of large for gestational age, mean birthweight, or neonatal morbidity.[162] Thirty-two percent of women randomized to metformin required supplemental insulin; these women tended to have higher BMIs, higher fasting blood glucose levels, and required medical therapy for GDM earlier than those women who achieved adequate glycemic control with metformin alone. Thus, metformin may provide a reasonable alternative to insulin in the

Table 28.4 White Classification of Diabetes in Pregnancy

White Class	Age of Onset (yr)	Duration (yr)	Vascular Disease	Therapy
A	Only in pregnancy	Only in pregnancy	No	A1: diet controlled A2: insulin requiring
B	>20 or	<10	No	Insulin
C	10-19 or	10-19	No	Insulin
D	<10 or	>20	Benign retinopathy hypertension	Insulin
F	Any	Any	Nephropathy	Insulin
R	Any	Any	Proliferative retinopathy	Insulin
H	Any	Any	Atherosclerotic heart disease	Insulin
T	Any	Any	Renal transplant	Insulin

treatment of gestational diabetes, particularly in lean or moderately overweight women who develop GDM later in gestation.

A recent randomized trial comparing metformin to glyburide in 149 patients with GDM found that use of glyburide was more likely to result in adequate glycemic control.[163] Insulin was required to achieve adequate glycemic control in 35% of patients taking metformin but only 16% of those randomized to glyburide. A systematic review concluded that maternal glucose levels did not differ substantially between pregnant women treated with oral diabetes agents versus insulin, and that the use of glyburide or metformin was not associated with an increase in adverse maternal or neonatal outcomes compared to the use of insulin.[164] The ADA and ACOG currently do not endorse the use of oral anti-hyperglycemic agents during pregnancy.[95,165]

The risk of stillbirth is increased in women with poorly-controlled GDM,[99,105,125] although it is not clear whether this is true also of pregnancies with mild disease.[166,167] For this reason, many centers recommend weekly fetal testing starting at 32 weeks and early delivery (typically at 38 to 40 weeks) for women with GDM who require oral or insulin therapy and those with a pregnancy complication (macrosomia, polyhydramnios, or hypertension). Whether weekly fetal testing and early delivery is necessary in pregnancies complicated only by diet-controlled GDM is not clear. Sonographic estimation of fetal weight should be considered at 36 to 38 weeks' gestation. The use of prophylactic elective cesarean delivery to reduce the risk of maternal and fetal birth injury in the setting of fetal macrosomia remains controversial.[99] It is clear, however, that induction of labor for so-called "impending macrosomia" does not decrease the risk of cesarean delivery or intrapartum complications.[168,169] In labor, maternal glucose levels in pregnancies complicated by GDM should be maintained at 100 to 120 mg/dL to minimize the risk of fetal hypoxic injury. For the same reason, neonatal blood glucose levels should be measured within 1 hour of birth, and early feeding should be encouraged. Delivery of the fetus and placenta effectively removes the source of the anti-insulin hormones that cause GDM. As such, no further management is required in the immediate postpartum period.

GDM frequently indicates underlying insulin resistance. Fifty percent of women with GDM will experience GDM in subsequent pregnancies, and 30% to 65% will develop type 2 diabetes later in life.[105,170-172] All women with GDM should, therefore, have a standard (nonpregnant) 75-g GTT approximately 6 weeks postpartum and should consider preventative and early diagnostic strategies like weight reduction, increased exercise, and regular screening for diabetes.

Pregnancy in Women with Type 1 or Type 2 Diabetes Mellitus

Pregestational diabetes, which affects approximately 1% of women of childbearing age, can be due either to absolute insulin deficiency (type 1, insulin-dependent diabetes mellitus [IDDM]) or to increased peripheral resistance to insulin action (type 2, noninsulin-dependent diabetes mellitus [NIDDM]), as shown in Box 28.1. The fasting glucose cutoff for diagnosing pregestational diabetes was reduced from 140 to 126 mg/dL in 1997.[173] On the basis of this change, there are approximately 21 million people with pregestational diabetes in the United States alone.[174]

The White classification of diabetes in pregnancy (Table 28.4) was developed by Dr. Priscilla White at the Joslin Diabetic Center in Boston, Massachusetts, in an attempt to correlate severity of diabetes with pregnancy outcome.[175] Although this classification is commonly used, any direct correlation between White class and prognosis remains unclear. Features known to be associated with poor pregnancy outcome include DKA, poor compliance, hypertension, pyelonephritis, and vasculopathy.

In contrast to GDM, pregestational diabetes is associated with significant maternal and perinatal mortality and morbidity (Box 28.3).[176,177] One of the more important complications is the increased risk of congenital malformations associated with hyperglycemia at the time of fertilization and embryo development. The incidence of congenital anomalies and spontaneous abortions in such patients correlates directly with the degree of glycemic control at conception, as measured by circulating maternal glycosylated hemoglobin levels.[178-180] Overall, approximately 30% to 50% of the perinatal mortality in diabetic pregnancy is due to fetal malformations.[181] Structural anomalies commonly seen in association with diabetes include cardiac defects (ventricular septal defects, transposition of the great vessels), renal agenesis, and neural tube defects (anencephaly, open spina bifida).[182] Some congenital defects—specifically sacral agenesis and caudal dysplasia—are as much as 400 times more common in the offspring of women with diabetes than in women with normal glucose metabolism[183] and, as such, are considered pathognomonic. The overall prevalence of these anomalies, however, is low.

Box 28.3 Pregnancy-Related Complications of Pregestational Diabetes

MATERNAL
- Spontaneous abortion
- Diabetic ketoacidosis
- Hypertension
- Preeclampsia/eclampsia
- Preterm birth
- Cesarean delivery
- Severe perineal injury
- Infectious morbidity (chorioamnionitis, endometritis, wound infection)

FETAL
- Congenital anomalies
- Macrosomia
- Intrauterine growth restriction
- Late fetal demise
- Non-reassuring fetal testing (previously referred to as "fetal distress")

NEONATAL
- Birth trauma (e.g., hypoxic ischemic cerebral injury; skull, clavicular, and long bone fractures; shoulder dystocia and brachial plexus injury)
- Hypoglycemia
- Neonatal sepsis
- Delayed organ maturation (respiratory distress syndrome, hyperbilirubinemia)

The factors responsible for diabetic embryopathy are not well defined, but glucose[184,185] and ketone bodies such as β-hydroxybutyrate[186,187] have both been implicated. Recently, oxidative stress[188,189] and apoptosis dysregulation[190,191] have been identified as potential mechanisms for diabetic embryopathy in animal models. Moreover, in a rat model of oxidative stress-induced diabetic embryopathy, the abnormal phenotype can be rescued by the use of antioxidants.[192,193] Several prospective randomized studies have shown that strict glycemic control around the time of conception is effective in reducing the risk of congenital malformations in women with established diabetes.[177,182,194-198] In one trial, intensive preconception management of diabetic women with vascular disease reduced the malformation rate from 19% to 8.5% [198] Unfortunately, most women with diabetes do not seek care prior to conception.[199,200] Maternal serum α-fetoprotein estimation at 15 to 20 weeks' gestation and a detailed sonographic fetal anatomical survey (with or without a fetal echocardiogram) at 18 to 22 weeks can be useful in screening for fetal malformations.

Intensive antepartum management should be initiated as early as possible and continued throughout gestation with a view to maintaining maternal blood glucose at desirable levels (fasting, below 95 mg/dL; premeal, below 100 mg/dL; 1 hour postprandial, below 140 mg/dL or 2 hours postprandial, below 120 mg/dL; during the night, not below 60 mg/dL; with an overall goal of mean capillary glucose levels of 100 mg/dL, corresponding to a glycated A1C ≤6%). Although the frequency of self-glucose monitoring recommended in pregnancy varies by organization, glucose should be monitored a minimum of four times daily (fasting, and 1 or 2 hours postprandial), and could be monitored as many as nine times daily (fasting, premeal, 1 or 2 hours postprandial, before bedtime, and at 3 AM if nocturnal hypoglycemia is suspected).[201] ACOG and the ADA provide recommendations for not only postprandial but premeal blood glucose levels.[176,202] If compliance with frequent fingersticks is in question, postprandial blood glucose levels have been shown to correlate more closely with adverse pregnancy and neonatal outcomes than do fasting or premeal blood glucose levels.[135,203,204] Initial recommendations for management of pregestational diabetes include a strict diabetic diet, regular exercise, daily home glucose monitoring, insulin treatment, and weekly antepartum visits to monitor glycemic control.[176] Such an approach has been shown to decrease perinatal mortality from a baseline of 20% to 30% to approximately 3% to 5%.[120,177,194,196,198]

Insulin, rather than oral agents, has been the mainstay of therapy in pregestational diabetics. To date, there are no randomized clinical trials to establish efficacy of oral agents in the management of pregestational diabetes in pregnancy. Insulin should be administered subcutaneously at 0.7 to 1.0 units/kg per day in divided doses. Traditional recommendations have been to administer two-thirds of the total daily dose in the morning (60% Neutral Protamine Hagedorn [NPH], 40% regular or rapid acting) and one-third in the evening (50% NPH, 50% regular/rapid acting). Rapid-acting insulin, namely lispro or aspart, achieves better glycemic control with fewer hypoglycemic episodes compared to regular insulin.[205-207] Lispro or aspart has the additional benefit of convenience, as these rapid-acting insulins can be administered immediately premeal, while regular insulin has to be administered 20 to 30 minutes before a meal. Alternative regimens may include dividing the total daily insulin requirement into 50% basal and 50% prandial, with either half or two-thirds of the basal administered as NPH in the morning, and the other half or one-third of basal insulin administered as NPH before bedtime. The remaining 50% of total daily insulin requirement may be divided in thirds and administered as lispro or aspart before meals. Insulin doses should be adjusted by approximately 20% up or down in response to the results of capillary blood glucose monitoring. Care should be taken to avoid iatrogenic hypoglycemia due to excessive insulin administration.[134]

Assessment of thyroid function is recommended (6% of diabetic women have coexisting thyroid disease), and baseline liver and renal function tests (including 24-hour urinary protein quantification and creatinine clearance determination) should be performed at the first prenatal visit. An ophthalmological examination should also be carried out every trimester. Glycosylated hemoglobin levels should be determined every 4 to 6 weeks throughout gestation.[176,178,179] At any one time, approximately 5% of maternal hemoglobin is glycosylated, known as hemoglobin Al (HbA1). HbAlc refers to the 80% to 85% of HbA1 that is irreversibly glycosylated and is therefore a more accurate measure of glycemic control. Because red blood cells have a life span of around 120 days, HbAlc measurements reflect the degree of glycemic control over the past 3 months.

Hypertension, prematurity, and late fetal demise are the most common complications of pregnancy in diabetic women.[120,176,181,208] Approximately 30% of diabetic women will develop hypertension in the third trimester. Pregnancy-induced hypertension often results in labor induction and is a major contributor to premature delivery in diabetic

women. Sustained maternal hyperglycemia results in fetal hyperglycemia that leads, in turn, to fetal hyperinsulinemia and increased oxygen demand. As such, fetuses of diabetic mothers are at increased risk of antepartum hypoxic ischemic cerebral injury and late fetal demise.[208,209] For this reason, weekly antepartum fetal testing (fetal cardiotocography) is usually recommended starting at 32 weeks' gestation.[210] After 36 weeks, testing is usually performed twice weekly. If the fetal heart rate tracing is abnormal, further testing (either a biophysical profile or contraction stress test) is mandatory.

A major issue in the care of the pregnant diabetic woman is the proper timing of delivery. No pregnant diabetic woman should be delivered after 40 weeks because of the increased risk of late fetal demise. If metabolical control is good, spontaneous labor at term should be awaited. Women with poorly controlled diabetes or with complications (worsening hypertension, intrauterine growth restriction [IUGR], oligohydramnios), on the other hand, should probably be delivered at around 37 to 38 weeks. Early delivery in pregnancies complicated by pregestational diabetes is associated with an increased risk of fetal respiratory distress syndrome, and consideration should be given to validation of fetal lung maturity prior to elective induction. Fetal lung maturation is inhibited by insulin and testosterone, and enhanced by endogenous cortisol, thyroxine, prolactin, and estradiol-17β. In infants of diabetic mothers, hyperinsulinemia and hyperandrogenemia are common findings and may contribute to the delay in lung maturation observed in diabetic pregnancies.[211-213] The increased testosterone observed in male infants of diabetic mothers may be due to elevated concentrations of human chorionic gonadotropin (hCG), which stimulates testosterone synthesis in fetal Leydig cells.

As many as 25% of infants of diabetic mothers are macrosomic.[176,214] If the estimated fetal weight is at least 4500 g, many authorities would recommend elective cesarean delivery at or beyond 39 weeks to minimize the risk of birth trauma, primarily shoulder dystocia and resultant brachial plexus injury. Elective cesarean delivery in women with pregestational diabetes should always be scheduled early in the morning, the patient's morning prandial insulin dose should be withheld and basal insulin dose can be halved.

During labor, patients are starved. Intravenous glucose should therefore be administered (typically 5% dextrose at a rate of 75 to 100 mL/hour) to all women with pregestational diabetes, and blood glucose levels should be checked every 1 to 2 hours. Regular insulin should be given as needed either by intravenous infusion (starting at 0.5 to 1 units/hour) or subcutaneous injection to maintain maternal glucose levels at around 100 to 120 mg/dL. Strict maternal glycemic control in labor is critical to preventing fetal hyperglycemia and hyperinsulinemia, both of which increase fetal oxygen demand and thereby predispose to fetal cerebral hypoxic ischemic injury.[208]

During the first 48 hours postpartum, women may have a "honeymoon period" during which their insulin requirement is decreased. Moreover, the need for strict glycemic control is reduced, and circulating glucose levels of 150 to 200 mg/dL can be comfortably tolerated during this period pending discharge from the hospital and regulation of glucose levels in the home environment. Once a woman is able to eat, she can return to her prepregnancy insulin regimen.

Obesity and Pregnancy

Obesity is one of the greatest public health challenges in the United States.[215] The prevalence of obesity has steadily risen since the 1980s.[216] In 2003 to 2004, 61.8% of U.S. women were overweight and 33.2% were obese.[217] From 2000 to 2005, the prevalence of obesity increased by 24%, with the prevalence of morbid obesity increasing by 50%.[218] Even more concerning, U.S. female children and adolescents (younger than 20 years old) had a 16% overweight prevalence suggesting that this public health issue will worsen rather than improve in the near future. As expected, the increased obesity prevalence is now evident also in the obstetric population.[219,220]

The preferred method of weight assessment is the body mass index (BMI). BMI is calculated as the body weight in kilograms divided by the square of the height in meters. Normal weight is defined as a BMI between 18.5 and 24.9 kg/m^2. Overweight refers to a BMI between 25 and 29.9 kg/m^2. Obesity is a BMI greater than 30 kg/m^2. Obesity is further divided into class I (30 to 34.9 kg/m^2), class II (35 to 39.9 kg/m^2), and class III (BMI greater than 40 kg/m^2) also known as *morbid obesity* or *extreme obesity*. The advantage of using BMI for defining obesity is that no adjustments need to be made for gender or height, and no tables are required for determining the normal range.[221]

Obesity is a complex neuroendocrine and metabolical disorder that has been implicated in a large number of fetal and maternal complications, including spontaneous abortion, congenital malformations, stillbirth, preeclampsia, GDM, fetal macrosomia, cesarean delivery, venous thromboembolic disease, surgical complications, and urinary tract infections.

Congenital malformations classically associated with obesity include neural tube defects, ventral wall defects, and abnormalities of the great vessels.[222-224] There is some evidence suggesting an increased risk for other anomalies in offspring of obese women, including hypospadias, isolated hydrocephalus, and orofacial clefts.[225-229] In one study, obese women weighing more than 110 kg had a four-fold increased risk of having a fetus with a neural tube defect as compared with a control population weighing 50 to 59 kg. For women weighing 80 to 89 kg, the risk was increased 1.9-fold.[224] Interestingly, folic acid supplementation (0.4 mg daily) did not appear to reduce the risk of neural tube defects in this cohort of obese women.[224] These data are consistent with other studies showing that a BMI greater than 29 kg/m^2 is associated with a 1.9-fold increase in the risk for neural tube defects.[222] The mechanism by which obesity causes congenital anomalies is not known. It is conceivable that, in obese women, subtle abnormalities in glucose metabolism contribute to the increased risk of congenital malformations, similar to that of pregestational diabetes.

Perinatal mortality is increased with progressive obesity.[230-232] In a cohort of 167,750 Swedish women,[230-232] Cnattingius and colleagues (1998) demonstrated a 1.7-fold increased risk in late fetal death for overweight women (BMI 25 to 29.9 kg/m^2) and a 2.7-fold increase for obese

women (BMI greater than 30 kg/m^2) when compared to women with a prepregnancy BMI less than 20 kg/m^2.[231,233]

Obesity has consistently been associated with hypertensive disorders of pregnancy.[234,235] For example, one large prospective multicenter cohort study of more than 20,000 women demonstrated that obese women with a BMI between 30 to 34.9 kg/m^2 had a 2.5- and 1.6-fold relative risk for gestational non-proteinuric hypertension and preeclampsia, respectively. For obese women with a BMI greater than 35 kg/m^2, a similar association was found with a relative risk of 3.0- and 3.3-fold, respectively.[236] In a systematic review of 13 studies including over 1.4 million women, O'Brien colleagues (2003) calculated a twofold increased risk of developing preeclampsia with every 5-7 kg/m^2 increase in BMI.[237]

Other well-documented risks of obesity include an increased incidence of GDM and fetal macrosomia,[220,236,238] birth injury, maternal perineal trauma, and cesarean delivery.[220,236,238] In a study of 20,130 births, a BMI greater than 39 kg/m^2 was associated with a 46% cesarean delivery rate compared with 20% in a control group of women with a BMI less than 29 kg/m^2.[239] In obese women, limiting total pregnancy weight gain to no more than 15 to 25 pounds appears to decrease the risk of fetal macrosomia without increasing the risk of low birth weight or IUGR.[240] Randomized controlled trials seeking to establish the optimum gestational weight gain in obese women are ongoing.[241,242] The increased cesarean delivery rate is associated also with increased surgical morbidity in obese women, including anesthestic complications, wound separation and infection, and venous thromboembolic events.[243-245] Maternal obesity also appears to be protective against spontaneous preterm birth. The risk of spontaneous preterm birth decreases with increasing maternal BMI, perhaps due to decreased uterine activity in these women compared to normal BMI controls.[246-248]

Obstetric management of the obese patient should include calculation of BMI, careful attention to blood pressure, a nutrition consultation, institution of a daily exercise program, and early screening for GDM. A careful sonographic anatomy survey (with or without fetal echocardiogram) at 18 to 22 weeks' gestation is indicated in obese women given the increased risk of fetal structural anomalies, although body habitus may result in suboptimal imaging. Serial growth scans should also be considered given the limitations of other methods of fetal growth assessment. Anesthesia consultation in the third trimester should also be considered prior to the onset of labor. If cesarean section is required, every effort should be made to reduce the risk of wound separation and infection, including prophylactic antibiotics, and closure of the subcutaneous layer.[249]

For women in developed countries, obesity has become one of the leading endocrine causes of morbidity and mortality. Effective treatments for obesity have so far eluded medical science. Bariatric surgery, which includes a multitude of procedures to reduce gastric capacity or bypass the stomach, has been shown to promote weight loss and reduce long-term mortality.[250,251] Its use as a weight loss tool has increased in popularity,[252] and the resultant weight loss often leads to improved fertility. The safety of pregnancy after these procedures is unclear. Early case reports suggested an increased risk of adverse pregnancy outcomes.[253-255] However, more recent studies have suggested no significant increased risks during pregnancy, but a number of potential benefits, including reduced risks of diabetes and hypertension.[256-259] Such women should all be given vitamin and mineral supplementation, especially iron, folate, and vitamin B12.[249]

Leptin is a hormone secreted primarily by adipocytes and acts to suppress appetite while increasing energy expenditure, thereby regulating body weight. Mice lacking the leptin gene (*ob/ob* mice) are obese and anovulatory. Administration of human leptin to *ob/ob* mice increases energy expenditure, reduces weight and fat mass, and restores ovulation and fertility.[260,261] In humans, absolute leptin deficiency is rare and supplemental recombinant leptin has not been shown to promote weight loss. During pregnancy, leptin is produced by maternal and fetal adipocytes as well as syncytiotrophoblast cells.[262] Circulating leptin levels rise rapidly in the first trimester, maintain high levels throughout pregnancy, and drop precipitously after delivery, suggesting a major contribution from the placenta.[263,264] Leptin levels in the maternal circulation correlate with maternal body mass, but not with levels in umbilical cord blood at birth or birth weight. However, leptin levels in umbilical cord blood do correlate directly with both birth weight[265,266] and fetal adiposity.[267] The significance of the increased leptin levels in the maternal circulation during pregnancy are unclear, although it has been suggested that leptin may act to mobilize maternal fat stores and increase the availability of substrate to the fetus.[268] In diabetic pregnancies, alterations in maternal and fetal leptin levels have not been particularly informative.[267] In pregnancies complicated by preeclampsia, umbilical cord leptin levels are decreased and reflect the reduction in fetal growth and fat stores.[269] Interestingly, maternal leptin levels are increased in preeclampsia and appear to correlate with the severity of the disease.[270,271] The significance of this observation remains unclear. Although the regulation and mechanisms of action of leptin are not fully understood, it is possible that manipulation of the leptin-leptin receptor system may ultimately prove to be a safe and effective treatment for adult obesity and fetal macrosomia.

The developmental origins of health and disease hypothesis posits that the *in-utero* environment induces fetal adaptive responses to facilitate offspring health and survival.[272] The metabolical and hormonal changes that result from these responses lead to altered homeostatic set points, which ultimately may prove maladaptive in other environments. Fetal adaptation is likely mediated by epigenetic phenomena, including DNA methylation and histone modification.[273] There is growing evidence that maternal obesity and overnutrition may induce fetal adaptive responses that predispose to obesity, diabetes, metabolical derangements, and increased cardiovascular risk later in life.[274-278] Maternal hyperglycemia, an inflammatory intrauterine mileu, and leptin dysregulation all may contribute to the increased cardiometabolical risk for offspring born to obese gravidas.[130,279-282] Sheep and rat models suggest that *in-utero* overnutrition may predispose to childhood and adult obesity via increased leptin exposure *in utero*, with subsequent inhibited leptin receptor development in the hypothalamus, and thus decreased sensitivity to leptin-mediated appetite suppression.[283-285] Indeed, increased leptin and insulin concentrations have been described in human offspring of obese

mothers, suggesting that fetal programming of appetite and satiety pathways may be an important determinant of adult disease states.[286,287]

Hypothalamic-Pituitary Diseases

Pregnancy-Associated Changes in Pituitary Structure and Function

The pituitary gland is composed of three parts: the anterior lobe (adenohypophysis), the intermediate lobe (prominent in the fetus but attenuated in the adult), and a posterior lobe (neurohypophysis). During pregnancy, the structure and function of the pituitary gland are significantly altered.[288] In the nonpregnant state, the pituitary gland weighs between 0.5 and 1.0 g. One autopsy study of 118 pregnant women demonstrated a 30% increase in the weight of the pituitary gland compared with nonpregnant controls (1070 mg versus 820 mg, respectively).[289] This increase in weight is associated also with an increase in volume (Table 28.5)[290,291] and a change in shape. In pregnancy, the pituitary gland develops a convex, dome-shaped superior surface,[292] which may impinge on the optic chiasm and account, in part, for the bitemporal hemianopia observed in some apparently healthy pregnant women.[293,294] Pregnancy is *not* associated with an increased incidence of pituitary adenoma.

On the basis of the hormones they produce, the adenohypophysis contains at least five different cell types: lactotropes (that primarily secrete prolactin), corticotropes (adrenocorticotropic hormone [ACTH]), somatotropes (GH), gonadotropes (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]), and thyrotropes (thyroid-stimulating hormone [TSH]). The cellular composition of the adenohypophysis, however, changes throughout pregnancy. This is especially true of the lactotrope cell population. Immunohistochemical studies have shown that, in the nonpregnant state, approximately 20% of cells in the adenohypophysis are lactotropes.[295,296] This number increases in pregnancy such that, by the third trimester, approximately 60% are lactotropes. Moreover, the increase in lactotropes is most pronounced in the lateral portions of the adenohypophysis. By 1 month postpartum, the number of lactotropes in the anterior pituitary of nonlactating women is decreased. However, postpartum resolution of lactotrope hyperplasia is incomplete, and nonpregnant multiparas have on average more lactotrope cells than do nulligravid women.

In contrast to lactotropes, the numbers of somatotropes, gonadotropes, and α-subunit—secreting cells in the adenohypophysis decrease in pregnancy and the number of thyrotropes do not change. These changes in cellular composition are associated with changes in circulating hormone levels.

Table 28.5 Volume of the Pituitary Gland Throughout Pregnancy as Determined by Magnetic Resonance Imaging

Gestational Age (Weeks)	Subject Number	Pituitary Volume (mm^3) Mean ± SEM
Nonpregnant	20	300 ± 60
9	10	437 ± 90
21	11	534 ± 124
37	11	708 ± 123

Data from Gonzalez JG, Elizondo G, Saldivar D, et al. Pituitary gland growth during normal pregnancy: an in vivo study using magnetic resonance imaging. Am J Med 85:217, 1988.

Prolactin

Levels of prolactin in the maternal circulation increase throughout pregnancy, reaching concentrations of approximately 140 ng/mL at term (Fig. 28.8).[297] Although the maternal decidua is a major site of prolactin production during pregnancy, prolactin in the maternal circulation originates primarily from the maternal pituitary with small contributions from the maternal decidua and fetal pituitary. The observation that circulating levels of prolactin in pregnant women with pre-existing hypopituitarism remain low throughout pregnancy supports the hypothesis that very little decidual prolactin enters the maternal circulation.[298,299] Decidual production of prolactin leads to elevated levels in the amniotic fluid, which peaks at approximately 6000 ng/mL at the end of the second trimester.[296]

The hyperprolactinemia of pregnancy is likely due to increased circulating levels of estradiol-17β. Aside from this increase in basal levels, prolactin secretion by the maternal pituitary is stimulated by thyrotropin-releasing hormone (TRH),[300] arginine,[301] meals,[301] and sleep[302] in a manner similar to that seen in nonpregnant women. After delivery, maternal prolactin concentrations in nonlactating women decrease to prepregnancy levels within 3 months.[303] In

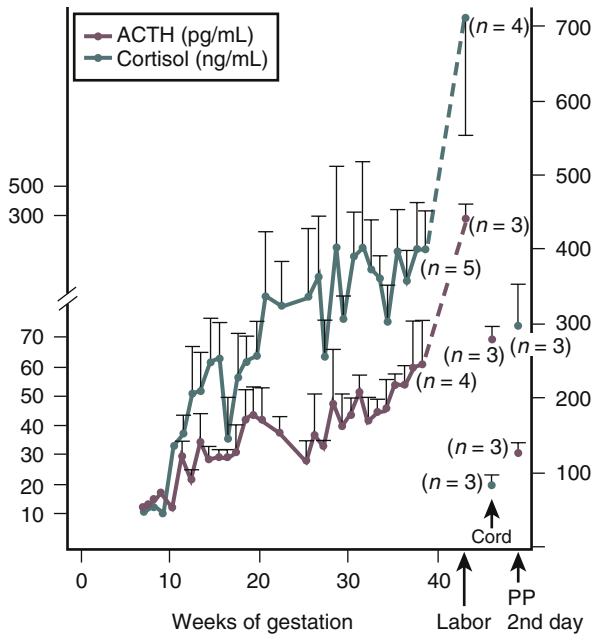

FIGURE 28.9 ACTH and total cortisol concentration in the maternal circulation throughout gestation. *(From Carr BR, Parker CR, Madden J D, et al. Maternal plasma adrenocorticotropin and cortisol relationships throughout human pregnancy.* Am J Obstet Gynecol *139:416, 1981.)*

lactating women, basal circulating prolactin levels decrease slowly to nonpregnant levels over a period of several months with intermittent episodes of hyperprolactinemia in conjunction with nursing.

Pregnancy is also associated with a shift in prolactin isoforms. In the nonpregnant state, the N-linked glycosylated isoform of prolactin (G-PRL) predominates in the circulation. As pregnancy progresses, increasing amounts of nonglycosylated prolactin appear in the circulation.[304] In the third trimester, the concentration of circulating nonglycosylated prolactin exceeds that of GPRL. Nonglycosylated prolactin appears to be more biologically active than G-PRL.[305] The precise function of the elevated circulating levels of prolactin in pregnancy is not clear, but it appears to be important in preparing breast tissue for lactation by stimulating glandular epithelial cell mitosis and increasing production of lactose, lipids, and certain proteins.[304-306] The role of prolactin in amniotic fluid is not known.

Pregnancy produces changes in prolactin secretion that persist long after delivery. Musey and colleagues[307] reported that the basal serum prolactin level and the prolactin response to perphenazine stimulation was lower after pregnancy than before pregnancy. They also found that the serum prolactin concentration was significantly lower in the parous women (mean, 4.8 ng/mL) than in the nulliparous women (8.9 ng/mL).[307] These and other studies[308,309] suggest that pregnancy permanently suppresses the secretion of prolactin by the maternal pituitary.

Adrenocorticotropic Hormone

ACTH levels in the maternal circulation increase from approximately 10 pg/mL in the non-pregnant state to 50 pg/mL at term,[72] and increase further to approximately 300 pg/mL in labor (Fig. 28.9).[72] Although the placenta can produce ACTH,[310] the majority of circulating ACTH appears to come from the maternal pituitary.[311] Placental production of corticotropin-releasing hormone (CRH) may be a major cause of the elevated levels of ACTH in the maternal circulation.[312-314] In nonpregnant women, serum CRH levels range from approximately 10 to 100 pg/mL. In the third trimester of pregnancy, these concentrations increase to 500 to 3000 pg/mL but then decrease precipitously after delivery.[314,315]

In addition to increasing pituitary ACTH secretion, chronically elevated levels of CRH in the maternal circulation reduce the ability of exogenous glucocorticoids to suppress the maternal ACTH–cortisol axis,[316-318] enhance the ability of vasopressin to induce an ACTH response, and diminish the effect of exogenous CRH.[312,313] CRH binding protein (CRH-BP) inactivates CRH, thereby preventing its action on the maternal or fetal pituitary. CRH-BP levels in the maternal circulation decrease during the last few weeks of pregnancy, resulting in an increase in free (biologically active) CRH.[319]

Although the maternal adrenal glands do not change in size, pregnancy is associated with significant changes in the circulating concentrations of adrenal hormones. For example, serum cortisol levels increase substantially in pregnancy. The majority of circulating cortisol is bound to cortisol-binding globulin (CBG), which is produced by the liver. Circulating levels of CBG increase during pregnancy in response to elevated levels of estrogen, and CBG may retard the clearance of these hormones. It is not surprising, therefore, that total cortisol levels increase in pregnancy. However, levels *of free* cortisol in the circulation[316,317]—as well as in saliva[320] and urine[73,316,317]—are also increased, which is likely due to the increased levels of ACTH in the maternal circulation. Maternal hypercortisolemia is also observed in complete molar pregnancy, suggesting that the increased cortisol is not derived from a fetal source. Other changes in adrenal hormone levels that occur in association with pregnancy include an increase in circulating levels of aldosterone[321] and adrenal androgens, primarily androstenedione and testosterone.

Growth Hormone

Maternal serum GH levels begin to increase at around 10 weeks' gestation, plateau at approximately 28 weeks, and can remain elevated for several months postpartum.[322] The majority of this GH is derived from the placenta (GHV), with a marked reduction in basal somatotropin (GH–N) production by the maternal pituitary.[45] Moreover, the release of GH-N in response to either insulin-induced hypoglycemia (Fig. 28.10)[43] or arginine stimulation[323] is markedly attenuated, suggesting that maternal pituitary GH secretory reserve is diminished in pregnancy.

Thyroid-Stimulating Hormone

In general, the concentration of TSH (thyrotropin) in the maternal circulation remains within the normal range during pregnancy.[324,325] Normative data from pregnant women suggest the upper reference range for TSH in pregnancy may be 2.5 to 3.0 mIU/L, rather than 4.0 mIU/L, the upper limit of normal in healthy, nonpregnant individuals.[326,327] At 9 to 13 weeks of gestation, there is a modest decline in circulating TSH levels (Fig. 28.11).[328,329] This coincides with the peak placental production of hCG, and some authorities

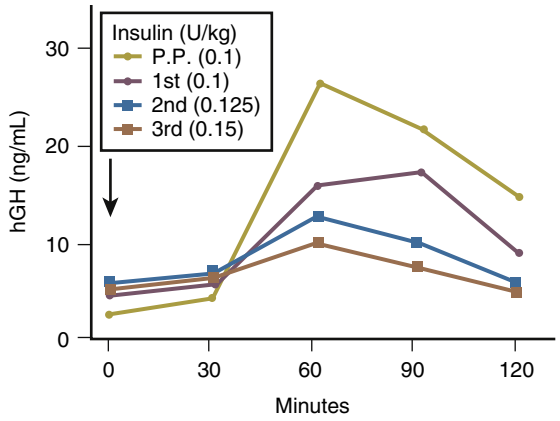

FIGURE 28.10 Human pituitary growth hormone response to insulin hypoglycemia in pregnancy. In pregnancy, pituitary growth hormone response to hypoglycemia is blunted. *(Adapted from Yen SSC, Vela P, Tsai CC. Impairment of growth hormone secretion in response to hypoglycemia during early and late pregnancy.* J Clin Endocrinol Metab *31:29, 1970.)*

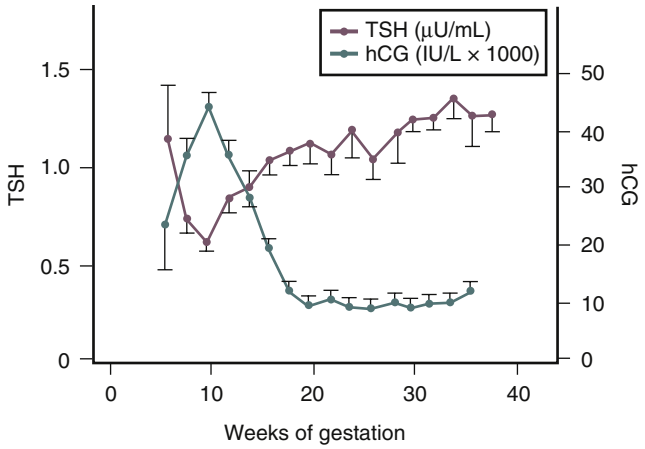

FIGURE 28.11 Maternal concentration of serum TSH and hCG as a function of gestational age. The decrease in serum TSH at approximately 10 weeks' gestation may be due to thyrotropic effects of hCG. *(Adapted from Glinoer D, de Nayer P, Bourdoux P, et al. Regulation of maternal thyroid during pregnancy.* J Clin Endocrinol Metab *71:276, 1990.)*

have suggested that the decrease in TSH may be due to the weak thyrotropic properties of hCG.[330-332] An alternative hypothesis is that the placenta may secrete a hormone with TRH or TSH-like properties, but this hypothesis is not supported by most data.[333]

Enlargement of the thyroid gland is a common finding during pregnancy. This growth is not due to any deficiency in the hypothalamic-pituitary-thyroid axis, but rather a result of relative iodide deficiency and increased demand for thyroid hormone secondary to elevated levels of thyroid-binding globulin (TBG).[328] Increased TBG concentrations result in the need for increased production of thyroxine (T_4) and triiodothyronine (T_3) to maintain adequate concentrations of free hormone. The thyroid responds to the need for increased production with increased vascularity, cellular hyperplasia, and ultimately glandular hypertrophy.[328] Indeed, the TSH response to exogenous TRH stimulation remains normal throughout pregnancy.[324,325] An appreciation of the physiological changes in thyroid hormone levels is important to accurately assess thyroid status in pregnancy. Total T_4 and T_3 levels are elevated due to TBG excess, and therefore have not typically been utilized to evaluate thyroid status during pregnancy. The most appropriate test to detect thyroid dysfunction during pregnancy is the TSH assay. If this is abnormal, classically free T_4 and free T_3 levels have been measured. However, more recent uncertainty about the accuracy of free T_4 immunoassays in pregnancy has led some to reconsider the use of adjusted total T_4 in pregnancy in select situations (see section on "Maternal Thyroid Function in Pregnancy" later in this chapter).[334,335]

Gonadotropins

Maternal serum LH and FSH levels are decreased by 6 to 7 weeks of pregnancy and are below the limits of detection of many radioimmunoassays by the second trimester.[336-338] The marked decrease in gonadotropin immunoreactivity in the pituitary glands of pregnant women[296,339] coupled with the blunted LH and FSH response to exogenous gonadotropin-releasing hormone (GnRH) stimulation (Fig. 28.12)[336-338] suggests that this effect is localized primarily to the pituitary. The suppression of pituitary LH and FSH synthesis and secretion likely results from elevated circulating levels of sex steroids (estradiol-17β, progesterone) and regulatory peptides (such as inhibin) during pregnancy.

Pituitary Tumors in Pregnancy

Mutations are the primary cause of pituitary tumors. Most pituitary tumors are monoclonal, indicating that a somatic mutation in a single progenitor cell is the cause of the tumor. In one study, 100% of GH-producing tumors and 75% of ACTH-producing tumors were found to be monoclonal.[340] In one series of GH-secreting tumors, mutations in the gene coding for the Gs protein were reported in 10 of 25 tumors, resulting in a constitutively active mutant Gs protein.[341] Other endocrine factors (such as the levels of estradiol-17β, progesterone, and dopamine) can influence tumor phenotype, and changes in these hormones during pregnancy may affect tumor growth. In general, pituitary tumors are benign and slow growing.

Pituitary tumors are commonly classified according to size as either microadenomas (less than 10 mm in diameter) or macroadenomas (larger than 10 mm). The clinical behavior of microadenomas and macroadenomas vary considerably during pregnancy. Macroadenomas may be associated with extrasellar extension, local invasion, or compression of the optic chiasm with resultant bitemporal hemianopia, and such conditions may become exacerbated in pregnancy. In one series of 60 pregnant women with macroadenomas, for example, 20% showed evidence of worsening visual field defects, significant enlargement on serial imaging studies, or neurological signs.[288] Urgent neurosurgical decompression may be required during pregnancy if the tumor enlarges markedly or causes neurological sequelae.

In contrast, microadenomas tend to behave in a relatively benign manner in pregnancy, with no evidence of functional

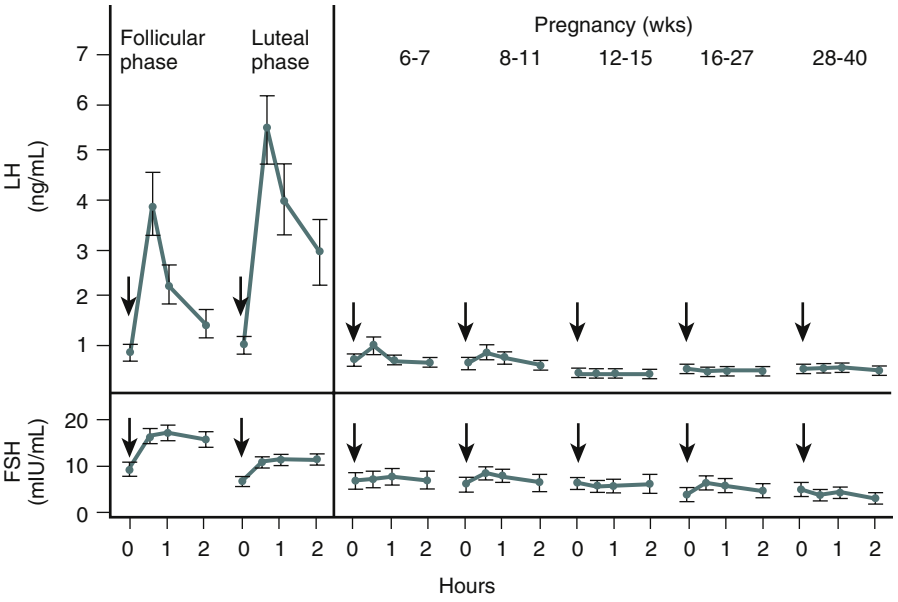

FIGURE 28.12 Effect of pregnancy on GnRH stimulation test. Serum levels of LH and FSH before and after a 100-μg bolus of GnRH *(arrow)* in pregnant women and normal menstruating women. During pregnancy, LH and FSH levels are markedly suppressed. *(From Miyake A, Tanizawa O, Aono T, Kurachi K. Pituitary responses in LH secretion to GnRH during pregnancy.* Obstet Gynecol *49:549–551, 1977, with permission from The American College of Obstetricians and Gynecologists.)*

pituitary deficiency and a low risk of neurological complications. In a longitudinal observational study of 215 pregnant women with microadenomas, for example, approximately 5% of women developed headaches, and less than 1% experienced worsening of visual field defects or demonstrated neurological signs.[288]

Prolactinoma

Prolactinoma refers to a tumor of prolactin-secreting lactotrope cells, and is typically associated with elevated levels of prolactin in the maternal circulation (see Chapter 3). In the initial evaluation of a suspected prolactinoma, measurement of circulating levels of thyroxine, TSH, and IGF-1 is important. This evaluation will exclude secondary causes of hyperprolactinemia, specifically hypothyroidism (thyroxine, TSH) and acromegaly (IGF-1). An imaging study of the hypothalamus and pituitary is also indicated, and computerized evaluation of the visual fields via automated perimetry is recommended if compression of the optic chiasm is suspected.[342]

Women with marked hyperprolactinemia are usually anovulatory and, as such, infertile. If such a patient does not desire pregnancy, treatment with combination estrogen–progestin therapy will reduce the risk of osteoporosis and regulate the menstrual cycle. This approach appears to be safe and is associated with few tumor-related complications, including minimal risk of tumor growth.[343] For infertile women with significant hyperprolactinemia who wish to conceive, treatment is usually required to induce ovulation. Controversy continues as to whether surgery or dopamine-agonist treatment represents the best first-line therapy for such women. Some authorities would recommend surgical treatment prior to conception to reduce both the need for dopamine-agonist treatment and the incidence of neurological complications during pregnancy.[344] However, microsurgical resection of a prolactinoma can result in death (in 0.3% of cases) or serious morbidity, such as a cerebrospinal fluid leak (0.4%).[345] Moreover, a long-term cure can be expected in only approximately 60% of women treated surgically. For these reasons, the weight of evidence in the literature suggests that medical treatment should be regarded as the best first-line therapy for infertile women with significant hyperprolactinemia.[346,347]

Having confirmed the diagnosis of a pituitary microprolactinoma, the goals of treatment are four-fold:

1. Suppress prolactin production and induce ovulation
2. Decrease tumor size
3. Preserve pituitary reserve
4. Prevent tumor recurrence

Treatment with a dopamine agonist can normalize circulating prolactin levels, establish regular ovulation, decrease tumor size, and preserve pituitary reserve.[348,349] A disadvantage of dopamine-agonist treatment is that it is not effective in preventing tumor recurrence once treatment is discontinued. Four dopamine agonists have been demonstrated to be effective in the treatment of hyperprolactinemia: bromocriptine, pergolide, quinagolide, and cabergoline. Cabergoline is administered once weekly and may be more effective than bromocriptine in the treatment of microadenomas.[350]

Little information is available concerning the effects of pergolide, quinagolide, and cabergoline on pregnancy, though increasing experience with cabergoline suggests that it is safe.[351,352] In contrast, there is substantial experience that bromocriptine is safe in pregnancy, with no significant increase in the overall rate of fetal congenital abnormalities.[353,354] The most common adverse effects associated with bromocriptine therapy are nausea, vomiting, and postural hypotension. Starting with low-dose therapy (0.625 mg daily) and increasing the dose slowly over a period of a few weeks can minimize these side effects. In some patients, doses as low as 2.5 mg daily may be effective. Prolactin levels should initially be checked every month for 3 months and thereafter every 3 months until the levels have returned to normal.

In women with microprolactinomas, bromocriptine can be discontinued once pregnancy is established. The majority of such women will have no further complications during

pregnancy. For those women who do experience neurological sequelae such as headache or cranial nerve dysfunction, bromocriptine therapy can be immediately reinstituted. Marked enlargement of a microprolactinoma or persistence of neurological sequelae despite medical treatment may be an indication for urgent neurosurgical intervention, but such complications are rare. In contrast, pituitary insufficiency and neurosurgical complications are far more common in women with macroadenomas. Such women should therefore be evaluated for panhypopituitarism before dopamine-agonist treatment is initiated. Women with macroprolactinomas are also more likely to develop complications in pregnancy.[288] One approach to the management of such women is to discontinue bromocriptine treatment once pregnancy is established, and to re-institute therapy if symptoms or signs of increasing tumor volume develop.[355] An alternative plan, which is equally appropriate, is to continue bromocriptine treatment throughout pregnancy.[356,357] Lactation does not appear to worsen the clinical course of women with prolactinomas, and such women should be encouraged to breastfeed.[358]

Cushing Disease

Cushing disease refers to the clinical syndrome resulting from excessive pituitary ACTH production. It is typically associated with depressed gonadotropin secretion, and spontaneous pregnancy is rare in women with untreated Cushing disease. Most cases of Cushing disease are due to pituitary microadenomas. As such, neurosurgical complications are rarely seen in pregnancy. However, the metabolical derangements associated with Cushing disease have been implicated as the cause of the observed increases in pregnancy-related complications, including premature labor, pregnancy-induced hypertension, and GDM.

Acromegaly

Acromegaly refers to the clinical syndrome associated with elevated circulating levels of GH. Acromegaly is often associated with anovulation, but spontaneous pregnancy can occur.[359,360] Except for complications associated with pituitary enlargement, acromegaly does not appear to adversely effect pregnancy outcome.[361] Since GH is an insulin antagonist, pregnancies complicated by excess circulating GH are at increased risk of hyperglycemia and diabetes.[362] In most women, definitive treatment for acromegaly can be deferred until after delivery. Bromocriptine, transsphenoidal surgery, and more recently octreotide, a somatostatin agonist, have been used successfully to treat acromegaly during pregnancy.[361]

Pituitary Insufficiency

Sheehan Syndrome

Sheehan syndrome (pituitary apoplexy) refers to the onset of acute hypothalamic–pituitary dysfunction that typically occurs after severe obstetric hemorrhage and resultant maternal hypotension at delivery. It is the most common cause of hypopituitarism worldwide, though not commonly seen in the United States.[363] During pregnancy, the pituitary volume increases by approximately 100%. This increase in pituitary size, coupled with the low-flow, low-pressure nature of the portal circulation, appears to make the pituitary and parts of the hypothalamus particularly susceptible to ischemia caused by obstetric hemorrhage and hypotension. The majority of cases of Sheehan syndrome occur in developing countries where deliveries are not performed in healthcare facilities by skilled attendants, increasing the risk of complications from obstetrical hemorrhage.

The hallmark of this syndrome is a loss of anterior pituitary hormone reserve, which may be complete or partial. Prolactin and GH deficiency are the most common abnormalities observed in Sheehan syndrome, but every imaginable pattern of pituitary hormone deficiency has been described. In a study of 10 African women with Sheehan syndrome, Jialal and co-workers[364] described the pituitary hormone response to a combined intravenous insulin (0.1 unit/kg), TRH (200 mg), and GnRH (100 mg) challenge test. The pattern of pituitary hormone response revealed the following loss of secretory reserve: 100% of these women had both prolactin and GH deficiency, 90% had cortisol deficiency, 80% had TSH deficiency, 70% had LH deficiency, and 40% had FSH deficiency.

The initial clinical manifestations of Sheehan syndrome include failure of lactation, failure of hair growth over areas shaved for delivery, poor wound healing after cesarean delivery, and generalized weakness. The best single test to confirm the diagnosis of Sheehan syndrome is to administer intravenous TRH (100 mg) and measure serum prolactin levels at 0 and 30 minutes. The ratio of prolactin measured at 30 minutes to that before TRH treatment (time 0) should be greater than 3.0.[365] If the ratio is abnormal, a complete evaluation for panhypopituitarism should be initiated.

In addition to loss of anterior pituitary hormone reserve, mild hypothalamic and posterior pituitary dysfunction is also frequently seen in women with Sheehan syndrome. Detailed neuropathological reports of autopsy specimens by Sheehan and Whitehead[366] have shown that 90% of women with postpartum hypopituitarism have evidence of atrophy and scarring of the neurohypophysis. Subsequent studies have also demonstrated atrophy of the supraoptic and paraventricular nuclei in such patients.[367] These observations have been confirmed in several clinical studies demonstrating that most women with Sheehan syndrome have mild functional defects in both vasopressin secretion and maximal urinary concentrating capability.[368,369]

Lymphocytic Hypophysitis

Lymphocytic hypophysitis is a rare disorder caused by infiltration of the adenohypophysis with lymphocytes and plasma cells. Most cases of lymphocytic hypophysitis occur in women in the third trimester of pregnancy or immediately postpartum.[370] In some cases, circulating antipituitary antinuclear or antimitochondrial antibodies have been detected. Pituitary enlargement can result in neurological complications (headache, visual field defects, cranial nerve palsy) requiring surgical intervention,[371] while pituitary cell damage may result in hyperprolactinemia, hypothyroidism, or adrenal insufficiency.[372] High-dose glucocorticoid therapy may be effective in treating some cases of lymphocytic hypophysitis when neurological sequelae are present.[373]

Diabetes Insipidus

Arginine vasopressin-antidiuretic hormone (AVP-ADH) is a cyclic nonapeptide secreted by the axonal terminals of the

neurohypophysis emanating from neurosecretory neurons located in the supraoptic and paraventricular nuclei of the hypothalamus. Blood osmolality is carefully monitored by sensitive osmoreceptors in the anterior hypothalamus. AVP-ADH is released in response to increasing osmotic pressures or decreasing hydrostatic pressures and act on the kidney to increase water retention. This system is designed to adjust blood osmolality over a relatively narrow range (±1.8%) with a mean of 285 mOsm/kg in nonpregnant women.[374] Pregnancy is associated with a decrease in plasma osmolality of approximately 9 to 10 mOsm/kg, which is evident early in the first trimester and persists throughout gestation[375] and appears to mirror changes in maternal hCG levels.[376] However, circulating AVP-ADH levels do not change in pregnancy.[377] These data suggest that pregnancy is associated with a modest resetting of the osmostat, leading to a 9 to 10 mOsm/kg decrease in the osmotic threshold for AVP-ADH release.

Diabetes insipidus (DI) involves the inappropriate loss of water resulting from failure of adequate tubular reabsorption by the kidney. The condition is characterized by polyuria (defined as more than 3 L of urine in 24 hours), polydipsia, and plasma hyperosmolarity. The causes of DI can be divided into two groups: central and peripheral.

Central (hypothalamic) DI refers to lesions of the hypothalamus or posterior pituitary that lead to inadequate production of AVP-ADH. The differential diagnosis of central DI includes pituitary surgery, trauma, infection, and infiltration of the neurohypophysis by tumors or inflammatory cells. Central DI is typically characterized by the acute onset of massive polyuria of 4 to 15 L per day. *Peripheral (nephrogenic) DI* refers to peripheral resistance to AVP-ADH action. Measurement of plasma AVP-ADH levels may be able to distinguish these two groups (levels are low in central DI and elevated in nephrogenic DI).

Transient nephrogenic DI can occur in pregnancy, usually in association with preeclampsia, HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome, or acute fatty liver of pregnancy.[378] High levels of placental vasopressinase may contribute to pregnancy-associated DI by degrading endogenous AVP-ADH. This increase in vasopressinase activity may also cause women with partial hypothalamic AVP-ADH deficiency to develop overt DI in pregnancy. D-arginine vasopressin (DDAVP) is resistant to degradation by placental vasopressinase. As such, DDAVP may be more effective than native AVP-ADH in the treatment of women with DI. In most cases, DI improves after delivery.[379]

DI is a rare disease in pregnancy. If suspected, the diagnosis of DI should be confirmed by performing a water-deprivation test. After an overnight fast, the patient is denied water until 3% of body weight is lost or urine osmolarity shows no increment in three successive hourly specimens. In women with DI, urine osmolarity remains low while plasma osmolarity increases significantly. This test is best performed by an endocrinologist because of the risks associated with dehydration and hypernatremia.[380] To help identify the cause, 10 μg of DDAVP can be administered immediately after the completion of the water-deprivation test. In women with central DI, there will be a decrease in urine output and an increase in urine osmolarity. In women with nephrogenic DI, on the other hand, there will be only a minimal change in urine output and osmolarity.[381]

Disorders of Thyroid Function

For reasons that are not fully understood, thyroid disease is 5 to 10 times more common in females than in males at all ages. Moreover, many of these conditions are autoimmune in nature with a peak incidence during the childbearing years. For these reasons, thyroid disease is one of the most common endocrine diseases affecting women of reproductive age and—despite the adverse effect of thyroid disease on fertility—such disorders are commonly encountered in pregnancy. Thyroid disease may also present for the first time during pregnancy. Pregnancy may complicate the management of functional thyroid disorders by affecting their clinical manifestations and limiting the approaches commonly used for diagnosis and treatment. The approach to other thyroid conditions like nodular disease must also be modified during pregnancy because of concern for the safety of the fetus.

Thyroid Physiology

Normal Thyroid Function

Thyroid hormone production is dependent in large part on the supply of iodine, which is derived solely from dietary sources and actively transported into the thyroid gland. The functional unit of the thyroid gland is the thyroid follicle, which is composed of a spherical alignment of cuboid epithelial cells surrounding a core of colloid. Colloid consists primarily of thyroglobulin, which provides tyrosine residues for serial iodination that results, through a complex series of biochemical and biophysical alterations, in the production of the thyroid hormones T_4 and T_3.[382] The thyroid gland is responsible for the production of all circulating T_4 and approximately 20% of T_3. Most of the body's supply of T_3 results from peripheral conversion of T_4 through a variety of tissue-specific deiodinase enzymes.

The thyroid hormones, T_4 and T_3—whose total serum concentrations in nonpregnant women are approximately 4 to 12 (μg/dL and 90 to 200 ng/mL, respectively) (Table 28.6)—circulate in a mostly bound form, such that less than 1% circulates as free hormone.[383] Thyroid hormone is bound primarily to a specific serum-binding protein known as thyroid-binding globulin (TBG), with lesser amounts bound to albumin and pre-albumin. As in most endocrine systems, it is the *free* fraction of these hormones, not the total concentration, that are physiologically important.

Regulation of Thyroid Hormone Secretion

Under normal circumstances, the circulating concentration of T_4, the most abundant and commonly measured thyroid hormone, is maintained within a narrow range that varies little from day to day. The follicular cell within the thyroid gland is responsible for the uptake of inorganic iodide from the circulation, its organification into iodinated thyronine compounds, storage of thyroid prohormone in the form of thyroglobulin, and re-uptake of formed thyroid hormone and its ultimate release into the systemic circulation.

Follicular cell activity is under the direct control of the hypothalamic-pituitary-thyroid axis (Fig. 28.13). The

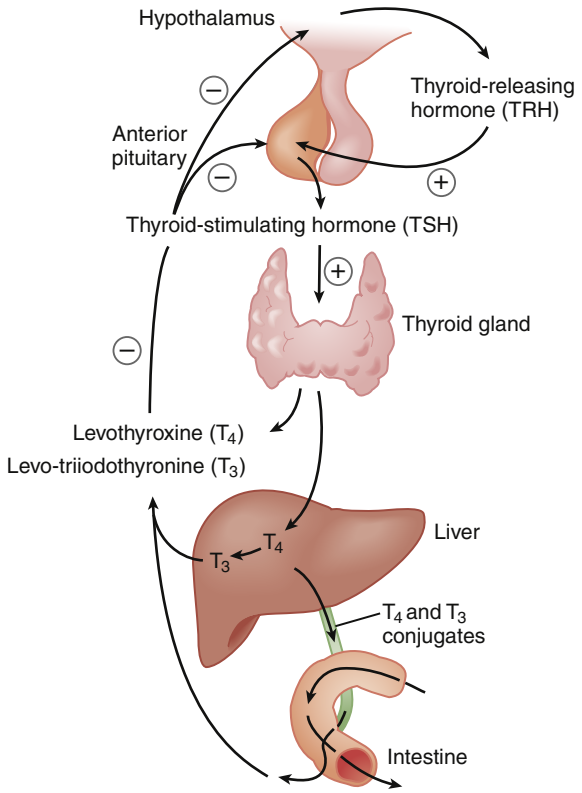

FIGURE 28.13 Diagrammatic representation of the hypothalamic-pituitary-thyroid axis. The hypothalamic-pituitary-thyroid axis and factors responsible for the regulation of thyroid hormone production and metabolism are shown.

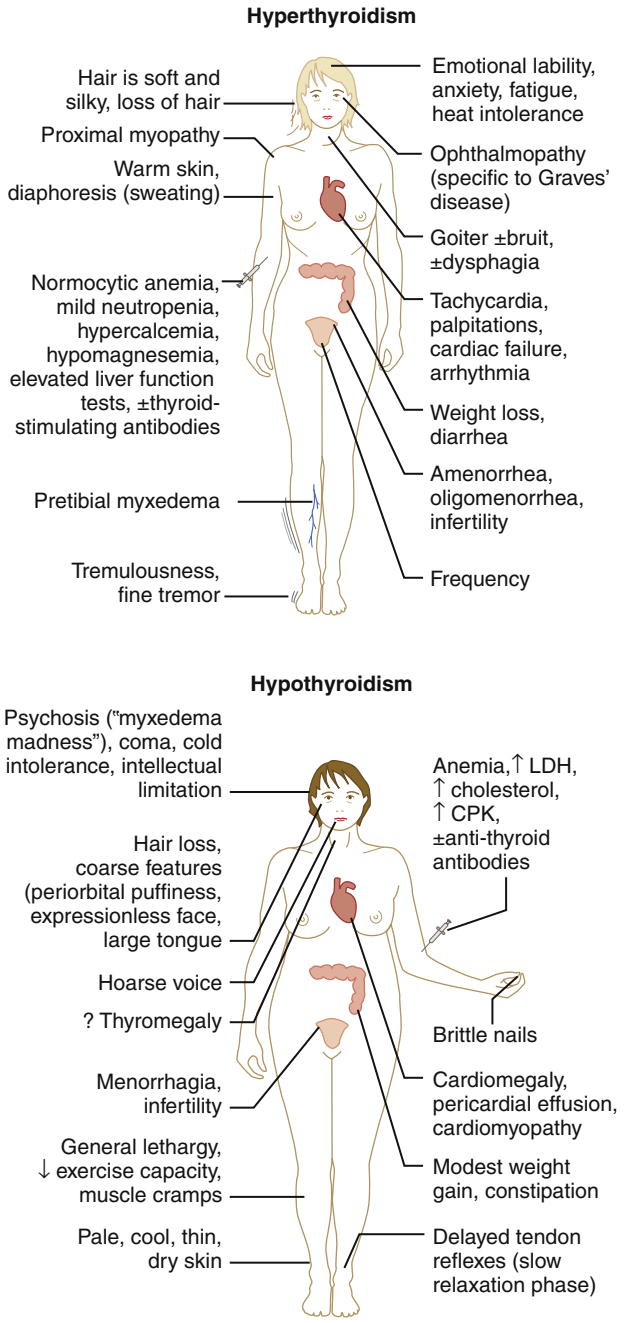

FIGURE 28.14 Diagnosis of maternal thyroid dysfunction in pregnancy. Common symptoms and signs associated with maternal hyperthyroidism and hypothyroidism. CPK, creatine phosphokinase; LDH, lactate dehydrogenase. *(From Norwitz ER, Schorge JO. Obstetrics and Gynecology at a Glance. Oxford: Blackwell Science Ltd, 2001, p 96, with permission.)*

hypothalamus produces the tripeptide TRH, which enters the portal circulation of the infundibular stalk and travels to the anterior lobe of the pituitary where it stimulates specific cells (thyrotropes) to produce TSH. TSH secretion varies diurnally with a peak secretion occurring between 11 PM and 4 AM.[384] TSH enters the systemic circulation and interacts with specific heptahelical, G-protein-coupled receptors on the surface of thyroid follicular cells, which triggers a series of signal transduction cascades culminating in the synthesis and release of thyroid hormones. Through a classical endocrine negative feedback loop, decreased circulating levels of thyroid hormones lead to an increase in TRH and TSH secretion (Fig. 28.13), which in turn leads to increased thyroid growth and activity.

Physiological Role of Thyroid Hormone

The precise role of thyroid hormone remains incompletely understood, although it clearly interacts with numerous biological systems. This fact is underscored by the complex series of symptoms and signs that are evident in patients with thyroid dysfunction (Fig. 28.14). At a cellular level, the active hormone (T_3) is transported into cells where it interacts with specific nuclear receptors. The T_3-receptor complex binds to specific thyroid hormone response elements within the promoter sequences of target genes and functions as a transcription factor, working along with other nuclear proteins to regulate gene expression.[385] In addition to these genomic effects, thyroid hormone also appears to have important extranuclear actions. These actions include regulation of deiodinase activity and, possibly, mitochondrial function.

Effect of Pregnancy on Thyroid Function

Maternal Thyroid Function in Pregnancy

In pregnancy, renal clearance of iodide increases (because of an increase in the glomerular filtration rate) and substantial amounts of iodide and iodothyronines are transferred to the fetus. As pregnancy progresses and fetal thyroid hormone

production increases, the fetus needs increasing amounts of iodide.[386,387] To meet this demand, the placenta is able to rapidly and efficiently transport available iodide from the maternal to the fetal circulation. The placenta is also capable of monodeiodination of iodothyronines, thereby making more iodide available for transport. The net result of these pregnancy-related physiological alterations is a decrease in the circulating concentration of inorganic iodide during pregnancy and a resultant increase in volume of the thyroid gland by 10% to 20% during pregnancy.[328] In light of this relative iodide deficiency during pregnancy, the recommended daily intake of iodine is increased from a baseline of 100 to 150 μg/day to approximately 250 μg/day. To achieve this daily dose, the American Thyroid Association (ATA) recommends that pregnant and lactating women supplement dietary iodine intake with a prenatal vitamin including 150 μg/day of iodine; this is the dose included in the majority of prenatal vitamins in the United States.[388,389]

Serum concentrations of TBG increase in pregnant women by 75% to 100% (the T_4 resin uptake decreases proportionally). Moreover, much of the increase in circulating TBG levels occurs during the first trimester and results from the effects of the hyperestrogenemic state on hepatocytes, with stimulation of TBG synthesis and reduced hepatic clearance due to estrogen-induced TBG sialylation.[390,391] The concentration of TBG plateaus at around 12 to 14 weeks' gestation and is associated with a concomitant increase in circulating total thyroid hormone concentrations (Fig. 28.15).

Indeed, mean concentrations of both total T_4 and T_3 in the maternal circulation increase by 10% to 30% in most longitudinal studies,[328,392,393] usually into a range that is considered elevated in the general population. In the first trimester, the increase in total T_4 exceeds the rise in TBG resulting in a slight increase in free T_4, although free hormone levels typically return to normal by the early second trimester (Fig. 28.15). However, these changes are so subtle that serum free T_4 concentrations in most pregnant women remain within the normal range for nonpregnant women.[328,391-394] While some studies report a substantial decrease in serum free T_4 with progression of gestation,[335,388,395-398] some report no change in T_4 concentrations as gestation progresses.[397] The negative-feedback control system of the hypothalamic—pituitary—thyroid axis functions normally in pregnant women.[391]

Recent data suggest that some free T_4 (and possibly T_3) immunoassays are unreliable in pregnancy, due to an increase in TBG concentration and lower albumin concentrations.[335] While the International Federation of Clinical Chemistry and Laboratory Medicine recommends using an isotope dilution-liquid chromatography/tandem mass spectrometry (LC/MS/MS) method for measuring T_4 in the dialysate from equilibrium dialysis of serum to obtain a reference measurement for serum free T_4,[399] this assay technology is not currently widely available due to high cost. The ATA thus recommends the use of on-line extraction/LC/MS/MS to measure FT_4 in the dialysate or ultrafiltrate of serum samples. If this method is unavailable, they recommend method-specific and trimester-specific reference ranges for serum free T_4.[388] If these adjusted reference ranges are unavailable, or if free T_4 measurements are discordant with TSH measurements, consideration can be given to using adjusted serum total T_4 measurements to assess thyroid function.[335] Total T_4 and T_3 levels in pregnancy are typically 1.5-fold higher than in nonpregnant women, so an adjusted reference range should be used.

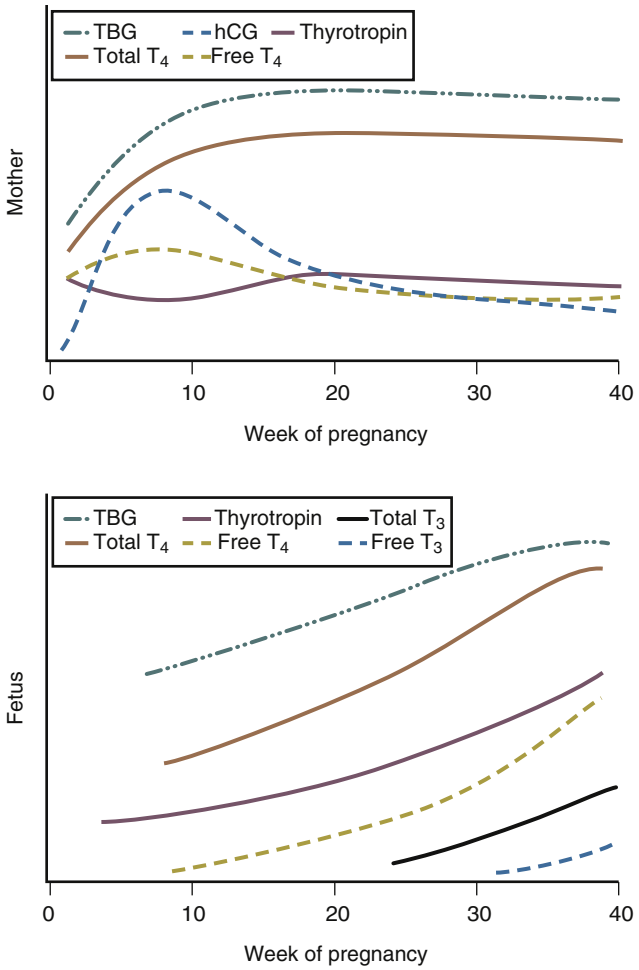

FIGURE 28.15 Relative changes in maternal and fetal thyroid function during pregnancy. The effects of pregnancy on the mother include a marked and early increase in hepatic production of thyroxine-binding globulin (TBG) and placental production of human chorionic gonadotropin (hCG). The increase in serum TBG, in turn, increases serum T_4 concentrations; hCG has thyrotropin-like activity and stimulates T_4 secretion. The transient hCG-induced increase in serum free T_4 inhibits maternal secretion of thyrotropin. *(Adapted from Burrow CN, Fisher DA, Larsen PR. Maternal and fetal thyroid function.* N Engl J Med *331:1072, 1994, with permission.)*

The pregnancy-specific glycoprotein hormone hCG is structurally similar to TSH and has some weak thyrotropic activity, which is estimated at approximately 0.025% that of TSH.[332,400] The production of hCG begins during the first week after fertilization and is highest near the end of the first trimester, after which it declines. This increase causes a transient increase in serum free T_4 concentrations, which in turn decreases serum TSH concentrations during the first trimester (Fig. 28.15).[327,332] Because hCG concentrations are higher in multiple gestations compared to singleton pregnancies, suppression of serum TSH concentrations is more marked in multiple gestations.[327] This cross-reactivity only becomes clinically significant if circulating levels of

hCG are markedly elevated, such as those seen in complete molar pregnancies.

Fetal Thyroid Function in Pregnancy

The fetal thyroid gland and pituitary-thyroid axis becomes functional late in the first trimester. Before that time, any thyroid hormone in the fetus must come from the maternal circulation. By 9 to 10 weeks of gestation, the fetal thyroid begins to concentrate iodine, thyroid follicles become visible, and T_4 synthesis can be demonstrated. TBG and T_4 are first detected in fetal serum at approximately 10 to 12 weeks of gestation, although the majority of fetal thyroid hormone synthesis occurs after the 18th to 20th week of gestation.[391] From this point forward, fetal thyroid secretion increases gradually, reaching a plateau at 35 to 37 weeks.[391,401] At term, fetal serum TSH concentrations are higher, free T_4 concentrations are slightly lower, and T_3 concentrations are one-half those in the maternal circulation.[391,401-405] The progressive increase in serum TBG concentrations with increasing gestational age presumably reflects maturation of the fetal liver and its responsiveness to estrogen stimulation. Increases in pituitary and serum concentrations of TSH during the second trimester coincide with the development of the hypothalamic-pituitary portal circulation, which facilitates the regulation of pituitary TSH secretion by hypothalamic TRH. The increased secretion of TRH despite higher serum free T_4 concentrations implies immaturity of the negative-feedback system that regulates the secretion of TSH and TRH *in utero*.[391,404,405]

Transplacental passage of thyroid hormones (T_4 and T_3) from the mother to the fetus does occur but is minimal, estimated at less than 0.1. This is likely due to the large amount of type III deiodinase enzyme in the placenta, which serves to maintain low serum T_3 concentrations in the fetus while protecting decidual cells from hypothyroidism.[391,404-407] As such, tests of fetal thyroid function—although rarely, if ever, indicated in clinical practice—accurately reflect functioning of the fetal thyroid and are largely unrelated to maternal thyroid status.[391] That said, however, in neonates with congenital hypothyroidism, enough maternal thyroid hormone is able to cross the placenta to prevent the overt stigmata of hypothyroidism at birth and maintain cord blood thyroid hormone levels at approximately 25% to 50% of normal.[408] Iodine, TRH, and TSH receptor immunoglobulins do cross the placenta[409] as does TSH, but to a far lesser extent.[410] Fetal thyroid function is completely dependent on the supply of iodine from the mother. Normal levels of thyroid hormone are critical for neuronal migration and myelination of the fetal brain. Thus, maternal and fetal iodine deficiency in pregnancy has adverse effects on neurocognitive function of offspring.[411-413] Children born to severely iodine-deficient mothers may exhibit profound mental retardation, deafmutism, and motor rigidity, a constellation of symptoms known as cretinism.[388]

Thyroid hormone is also present in measurable quantities in amniotic fluid. At term, total T_4 concentrations in the amniotic fluid are about 0.6 μg/dL, much lower than in maternal or fetal serum. Because protein and TBG concentrations are low in amniotic fluid, however, the free T_4 and T_3 concentrations are slightly higher than in maternal or fetal serum.[414] The source of this thyroid hormone is not known, but studies in fetuses with congenital hypothyroidism suggest that it may come from the maternal circulation.[415] Late in gestation, fetal swallowing appears to allow for the transfer of thyroid hormones from amniotic fluid to the fetal circulation. The physiological role of thyroid hormone in the amniotic fluid is not known.

Functional Thyroid Disorders in Pregnancy

Screening for Thyroid Disorders in Pregnancy

Data from the United States population suggest that 2% to 3% of pregnant women will have an elevated TSH level at the time of routine screening. Of screened women, 0.3% to 0.5% will have overt hypothyroidism (elevated TSH and low free T4, or a TSH level of 10 mIU/L or greater, regardless of free T4 levels), and 2% to 2.5% will have subclinical hypothyroidism (TSH levels above the 97.5th percentile for gestational age with normal free T4 concentration).[416,417] Hyperthyroidism is less common, and occurs in only 0.1% to 0.4% of pregnant women.[418] Overt thyroid dysfunction in pregnancy has consistently been associated with increased risk of adverse pregnancy outcomes and detrimental effects on fetal neurocognitive development (see sections on "Maternal Thyrotoxicosis" and "Maternal Hypothyroidism" later in this chapter). To date, there is no consistent evidence that screening and treatment for asymptomatic hypothyroidism will abrogate the posited association between subclinical hypothyroidism and neurocognitive impairment in offspring. Subclinical hyperthyroidism has not been associated with adverse maternal or fetal outcomes.[419]

While two decision analyses found that universal screening for thyroid dysfunction in pregnancy is cost-effective, both models assumed that treatment of subclinical hypothyroidism in pregnancy would increase offspring IQ, which has not been demonstrated in large randomized clinical trials.[420,421]Although large studies of a targeted case-finding strategy versus universal screening to identify women with hypothyroidism in pregnancy have demonstrated that a targeted case-finding approach may miss as many as 30% to 55% of women with thyroid abnormalities,[422,423] universal screening has not been shown to result in improved population outcomes.[424] Given these data, ACOG, the ATA, and the Endocrine Society recommend a targeted case-finding approach, rather than universal first-trimester screening of all pregnant women for subclinical hypothyroidism.[388,402,425,426] The ATA's suggested criteria for whom to screen for thyroid dysfunction in pregnancy are summarized in Box 28.4.[388] TSH measurement in the first trimester should be performed in these women, with free T_4 measurement if TSH is greater than 2.5 mIU/L. Screening is not indicated in asymptomatic pregnant women who have a mildly enlarged thyroid, in the absence of goiter.[402]

Maternal Thyrotoxicosis

Thyrotoxicosis is the clinical and biochemical state that results from an excess production of and exposure to thyroid hormone from any cause. In contrast, *hyperthyroidism* refers to thyrotoxicosis caused by hyperfunctioning of the thyroid gland.[402] Hyperthyroidism occurs in 0.05% to 0.2% of pregnancies. Graves disease is the most common cause of maternal hyperthyroidism in pregnancy, accounting for 95% of cases.[401,402,406-408,414,415,427] Other causes of thyrotoxicosis in pregnancy are summarized in Box 28.5.

Box 28.4 Women to Screen for Thyroid Dysfunction in Pregnancy

Family or personal history of thyroid disease
Symptoms suggestive of thyroid dysfunction (Fig. 28.14)
From an area with known moderate to severe iodine insufficiency
Type 1 diabetes or other autoimmune disorders frequently associated with autoimmune thyroid dysfunction (vitiligo, adrenal insufficiency, hypoparathyroidism, atrophic gastritis, pernicious anemia, systemic sclerosis, systemic lupus erythematosus, Sjogren's syndrome)
Known thyroid peroxidase antibodies
History of head or neck radiation
History of preterm delivery or recurrent miscarriage
Morbid obesity (BMI ≥ 40 kg/m^2)
Infertility
Age >30 years
Use of amiodarone or lithium
Recent administration of iodinated radiological contrast

Box 28.5 Etiology of Thyrotoxicosis in Pregnancy

- Graves disease: The most common cause of maternal thyrotoxicosis in pregnancy (95%). Results from the circulating thyroid-stimulating IgG autoantibodies, which can cross the placenta leading to fetal thyroid dysfunction.
- Thyroiditis (silent/postpartum [lymphocytic]; subacute [granulomatous]; suppurative [bacterial]): Characterized by hyperthyroidism and the presence of a large, palpable thyroid gland. An acute enlarged, painful, and tender thyroid is suggestive of subacute (De Quervain's) thyroiditis.
- Toxic multinodular goiter
- Solitary toxic nodule (also referred to as a hyperfunctioning thyroid adenoma)
- Gestational trophoblastic neoplasia: Including hydatidiform mole and choriocarcinoma. Probably secondary to elevated levels of hCG.
- Struma ovarii: Refers to thyroid tissue in a mature ovarian teratoma
- Exogenous thyroid hormone: Most commonly due to inadvertent ingestion of thyroid hormone
- Iodine-induced thyrotoxicosis
- TSH-secreting pituitary adenoma
- Gestational hyperthyroidism: Transient hyperthyroidism limited to the first half of pregnancy, frequently associated with elevated levels of hCG. Hyperemesis gravidarum is often coexistent. Typically self-limited, supportive care is indicated.
- Hyperemesis gravidarum: Characteristic symptoms and signs of hyperthyroidism are often absent.
- Familial gestational hyperthyroidism: TSH receptor mutation leading to functional hypersensitivity to hCG.

Of note, gestational hyperthyroidism, defined as "transient hyperthyroidism limited to the first half of pregnancy [and] characterized by elevated free T_4 or adjusted total T_4 and suppressed or undetectable serum TSH, in the absence of serum markers of thyroid autoimmunity"[428] is a frequent cause of thyrotoxicosis in pregnancy. Gestational hyperthyroidism occurs in 1% to 3% of pregnancies, and may be associated with hyperemesis gravidarum. Appropriate management includes supportive therapy and management of dehydration, if necessary. Anti-thyroid medications are not recommended as part of the standard management of gestational hyperthyroidism.[388] While gestational hyperthyroidism occurs in 1% to 3% of pregnancies, hyperemesis gravidarum, a syndrome of nausea and vomiting associated with weight loss of 5% or more in early pregnancy, occurs in 0.5 to 10 per 1000 pregnancies.[429,430] Hyperemesis gravidarum is characterized by higher serum hCG and estradiol concentrations than in nonaffected pregnant women,[428] and hCG has more thyroid-stimulating activity in women with hyperemesis gravidarum.[431,432]

Box 28.6 Effects of Drugs on Thyroid Hormone Synthesis and Metabolism

INHIBITION OF THYROID HORMONE SYNTHESIS BY THYROID GLAND
Iodine, sulfonylureas, lithium

INCREASE IN TSH
Iodine, cimetidine, dopamine agonists, lithium

DECREASE IN TSH
Glucocorticoids, dopamine agonists, somatostatin

INHIBITION OF THYROID HORMONE BINDING TO THYROID-BINDING GLOBULIN (TBG)
Phenytoin, diazepam, sulfonylureas, furosemide, salicylates

INHIBITION OF CONVERSION OF T4 TO T3 IN PERIPHERAL TISSUES (LIVER)
Glucocorticoids, propylthiouracil (PTU), ipodate, propranolol, amiodarone

INHIBITION OF GASTROINTESTINAL RESORPTION OF THYROID HORMONES
Cholestyramine, cholestipol, ferrous sulfate

Numerous drugs are known to interfere with thyroid hormone synthesis and metabolism (Box 28.6). Symptoms and signs may suggest the etiology of thyrotoxicosis in pregnancy (Fig. 28.14). For example, endocrine ophthalmopathy (lid lag, lid retraction) and dermopathy (localized or pretibial edema) are clinical signs that are specific to Graves disease. However, as in nonpregnant patients, confirmation of maternal hyperthyroidism in pregnancy requires thyroid function testing (Table 28.6). Measurement of TSH receptor antibodies and total T_3 may be helpful in trying to distinguish between Graves disease and gestational hyperthyroidism. Radioactive iodine scanning or radioiodine uptake determination should not be performed in pregnancy. There is not sufficient evidence to recommend for or against the use of thyroid ultrasound in distinguishing between possible etiologies of hyperthyroidism in pregnancy.[388]

As compared with well-controlled disease, inadequately treated maternal hyperthyroidism is associated with infertility and adverse perinatal outcome. Maternal complications in pregnancy include an increased risk of preeclampsia, cardiac failure, thyroid storm, and possibly spontaneous pregnancy loss.[401,402,406-408,414,415,427,433,434] Fetal and neonatal risks that are increased in the setting of poorly-controlled hyperthyroidism include preterm delivery, low birth weight, IUGR, stillbirth, central hypothyroidism, and increased perinatal mortality.[433,435-439] Because a large proportion of hyperthyroidism in pregnancy is mediated by IgG antibodies that cross the placenta (Graves disease and chronic

Table 28.6 Changes in Thyroid Function Test Results in Normal Pregnancy and Thyroid Disease

Thyroid Function Test	Units	Normal Non-pregnant Values	Normal Pregnant Values	Comparison to Nonpregnant Values	Hyperthyroidism	Hypothyroidism
Thyroid-stimulating hormone (TSH)	mIU/L	0.4-4.0	1st trimester: 0.1-2.5* 2nd trimester: 0.2-3.0* 3rd trimester: 0.3-3.0*	Decreased (largest decrease in 1st trimester)	Markedly decreased	Markedly increased
Thyroid-binding globulin (TBG)	mg/L	11-21	23-25	Increased	No change	No change
Total levothyroxine (T_4)	μg/dL	3.9-11.6	10.7-11.5	Increased	Increased	Decreased
Free levothyroxine (T_4)	ng/dL	0.8-2.0	Trimester-specific and method-specific ranges should be used	Decreased or no change	Increased	Decreased
Total L-triiodothyronine (T_3)	ng/dL	91-208	205-233	Increased	Normal to increased	Normal to decreased
Free L-triiodothyronine (T_3)	pg/dL	190-710	250-330	No change	Increased	Decreased

*For use if trimester-specific ranges for TSH are not available from the laboratory.

autoimmune thyroiditis), the fetus is at risk of immune-mediated thyroid dysfunction. This is true also of women with a history of Graves disease treated with thyroidectomy or radioactive iodine. Fetal sinus tachycardia (greater than 160 beats per minute persistent for over 10 minutes) is a sensitive index of fetal hyperthyroidism.[388] Only 1% to 5% of neonates born to women with poorly-controlled thyrotoxicosis will develop transient hyperthyroidism or neonatal Graves disease caused by the transplacental passage of maternal antithyroid antibodies.[436,440] In addition to fetal tachycardia, other signs of fetal hyperthyroidism include intrauterine growth restriction, presence of fetal goiter, and craniosynostosis or accelerated bone maturation.[441,442] Congestive heart failure and fetal hydrops may occur in severe cases. Fetuses of women with Graves disease are at risk not only for fetal and neonatal hyperthyroidism, but also for fetal and neonatal hypothyroidism due to overtreatment with antithyroid drugs,[443] and central hypothyroidism.[437-439] High titers of serum thyroid receptor antibodies between 22 and 26 weeks' gestation are a risk factor for fetal or neonatal hyperthyroidism, and thus determination of maternal serum thyroid receptor antibodies is recommended at 20 to 24 weeks' gestation in women with a history of Graves disease.[388,441,444-446] Fetal surveillance with serial ultrasounds is recommended in pregnant women with Graves disease, uncontrolled hyperthyroidism, or those with thyroid receptor antibody levels greater than two to three times the upper limit of normal.[388,402,441,447]

In order to minimize complications, hyperthyroidism is best diagnosed and treated prior to conception, and the use of contraception is advisable until a euthyroid state is achieved. If a patient has high TSH receptor antibody titers and is planning pregnancy in the next 2 years, surgical therapy may be considered. TSH receptor antibody titers tend to increase and remain elevated for many months after radioactive iodine (^{131}I) therapy.[448] If ^{131}I ablative therapy is performed, pregnancy should be delayed for 6 months after thyroid ablation.

The goal of therapy during pregnancy is to control thyrotoxicosis while avoiding fetal and transient neonatal hypothyroidism. The mainstay of treatment for hyperthyroidism in pregnancy is thioamide drugs, specifically propylthiouracil (PTU) and methimazole (the active metabolite of carbimazole), which decrease thyroid hormone synthesis by blocking the organification of iodide.[449,450] PTU also reduces the peripheral conversion of T_4 to T_3, and may therefore have a quicker suppressive effect than methimazole.

Traditionally, PTU has been preferred in pregnant patients because methimazole was believed to pass the placenta more easily and was associated with methimazole embryopathy (including choanal or esophageal atresia, tracheo-esophageal fistula, patent vitellointestinal duct and dysmorphic facies) and fetal aplasia cutis congenita, a rare congenital skin defect of the scalp.[401,402,406-408,414,415,427,433,440,451] Recent data, however, called these associations into question. No difference in free T_4 and TSH concentrations has been demonstrated in the umbilical cord blood of fetuses delivered to women treated with PTU or methimazole,[452] and no definitive increase in the incidence of aplasia cutis or structural anomalies over healthy controls has been shown in women treated with methimazole in pregnancy.[451-454] A recent study including all birth defects related to maternal treatment with carbimazole or PTU over nearly 50 years in the United Kingdom did suggest an elevated risk of structural anomalies in women taking carbimazole in pregnancy compared to those taking PTU,[455] but these data should be interpreted with caution given that carbimazole was historically prescribed far more frequently in the UK than was PTU.

Despite concern about theoretical risk of methimazole embryopathy and fetal aplasia cutis, PTU treatment is associated with an increased risk for fulminant hepatotoxicity and agranulocytosis.[456-459] Hepatotoxicity may occur at any time during PTU treatment and there are no data that monitoring of liver function tests is effective in preventing fulminant hepatotoxicity. Thus, an advisory committee to

the United States Food and Drug Administration recommended limiting the use of PTU to the first trimester of pregnancy.[460] PTU treatment is usually initiated at 50 to 300 mg daily in divided doses (the lowest dose is preferable to minimize the risk of fetal hypothyroidism). Following the first trimester, consideration should be given to transitioning to methimazole, usually initiated at 5 to 15 mg daily. Methimazole is approximately 10 to 15 times as potent as PTU; thus 100 milligrams of PTU is equivalent to 7.5 to 10 mg of methimazole.[388] The goal is to utilize the least amount of drug to maintain maternal free T_4 at the upper limits of normal.[402] TSH and T_4 levels should be checked monthly and treatment adjusted accordingly. Clinicians should remember that stored hormone may not be depleted for 3 to 4 weeks, therefore delaying a clinical response. Complete blood counts should be monitored monthly because of the risk of drug-induced agranulocytosis.[402]

Radioactive iodine administration to ablate the thyroid gland is absolutely contraindicated in pregnancy. Moreover, breastfeeding should be avoided for at least 120 days after ^{131}I treatment.[461] Surgery is best avoided, but may be performed in the second trimester if indicated for failed medical therapy.

Subclinical hyperthyroidism, defined as low TSH with normal free T_4 and T_3 in an asymptomatic patient, is not associated with adverse perinatal outcome.[419] Long-term subclinical hyperthyroidism is associated with osteoporosis, atrial fibrillation, and increased mortality and, as such, should be treated. However, there is little data on the appropriate course of action during pregnancy. Many cases resolve spontaneously. The presence of suppressed serum TSH in the first trimester (TSH less than 0.1 mIU/L) should be investigated with a history and physical examination, as well as free T_4 measurements in all patients.[388]

Thyroid Storm

Thyroid storm (thyrotoxic crisis) is a medical emergency characterized by a severe acute exacerbation of the signs and symptoms of hyperthyroidism. It is a rare complication, occurring in approximately 1% of pregnant patients with hyperthyroidism, but is associated with a high rate of maternal mortality and morbidity.[99] Thyroid storm is diagnosed by a combination of the following symptoms and signs in patients with thyrotoxicosis: fever, tachycardia out of proportion to the fever, altered mental status (restlessness, nervousness, confusion, seizures), diarrhea, vomiting, and cardiac arrythmia.[99] An inciting event (infection, surgery, labor and delivery) can be identified in many instances. The diagnosis can be difficult to make, however, and requires expeditious treatment to avoid severe consequences like shock, stupor, coma, and death.

If thyroid storm is suspected, serum TSH and free T_4 and T_3 levels should be evaluated to help confirm the diagnosis. If the clinical index of suspicion is high, however, *treatment should not be withheld pending the results of the biochemical tests*. The treatment of thyroid storm is summarized in Box 28.7. The goals of treatment are to:

- Reduce synthesis and release of hormone from the thyroid gland (using thioamides like PTU or methimazole, supplemental iodide, and glucocorticoids)
- Block the peripheral actions of thyroid hormones (using glucocorticoids, PTU, and high-dose beta blockers)
- Treat complications and support physiological functions (supplemental oxygen, fluid and caloric replacement)
- Identify and treat precipitating events (such as hypoglycemia, thromboembolic events, and diabetic ketoacidosis)

As with other acute maternal illnesses, fetal well-being should be evaluated and consideration given to delivery, if appropriate.

Box 28.7 Treatment of Thyroid Storm in Pregnant Women

- **Propylthiouracil (PTU),** 600-800 mg orally stat, then 150-200 mg orally every 4-6 hours. If oral administration is not possible, use methimazole rectal suppositories.
- Starting 1-2 hours after PTU, administer **saturated solution of potassium iodide (SSKI),** 2-5 drops orally every 8 hours, or **sodium iodide**, 0.5-1.0 g intravenously every 8 hours, or **Lugol solution**, 8 drops every 6 hours, or **lithium carbonate**, 300 mg orally every 6 hours.
- **Dexamethazone**, 2 mg intravenously or intramuscularly every 6 hours for four doses.
- **Propranolol**, 20-80 mg orally every 4-6 hours or 1-2 mg intravenously every 5 minutes for a total of 6 mg, then 1-10 mg intravenously every 4 hours. If the patient has a history of severe bronchospasm, **reserpine** (1-5 mg intramuscularly every 4-6 hours), **guanethidine** (1 mg/kg orally every 12 hours), or **diltiazem** (60 mg orally every 6-8 hours) should be given.
- **Phenobarbital**, 30-60 mg orally every 6-8 hours as needed for extreme restlessness.

Data from Ecker JL, Musci TJ. Thyroid function and disease in pregnancy. *Curr Probl Obstet Cynecol Fertil* 23:109, 2000.

Maternal Hypothyroidism

Hypothyroidism is caused by inadequate thyroid hormone production. It complicates 0.3% to 0.5% of all pregnancies but is more common in women with other autoimmune diseases, such as type 1 diabetes.[462] The classic signs and symptoms of hypothyroidism (Fig. 28.14) may suggest the diagnosis. Again, however, thyroid function testing is required for a definitive diagnosis (Table 28.6). The causes of hypothyroidism in pregnancy are summarized in Box 28.8. In developed countries, chronic autoimmune thyroiditis (Hashimoto disease) is the most common cause.[401,402,406-408,414,415,427,433,440,451-453,461-463] Worldwide, however, the most common cause of hypothyroidism is iodine deficiency.[401,402,406-408,414,415,427,463] Women previously treated for Graves disease (by radioactive iodine or surgery) may manifest with posttherapy hypothyroidism. Although such women may themselves be asymptomatic, their fetuses remain at risk for thyroid dysfunction as circulating antithyroid antibodies are still present. In women with preexisting Hashimoto disease, pregnancy may actually result in a transient improvement of symptoms.

Untreated or inadequately treated maternal hypothyroidism in pregnancy is associated with an increased risk of adverse pregnancy outcome, including preeclampsia, low birth weight, placental abruption, preterm birth, and stillbirth.[401,402,406-408,414,415,427,463] It is not clear whether untreated hypothyroidism is a risk factor for IUGR

Box 28.8 Etiology of Hypothyroidism in Pregnancy

PRIMARY HYPOTHYROIDISM

- Iodine deficiency (the most common cause of hypothyroidism worldwide)
- Chronic autoimmune thyroiditis (Hashimoto): Characterized by hypothyroidism, a firm goiter, and the presence of circulating antithyroglobulin and/or antimicrosomal autoantibodies
- Silent/postpartum thyroiditis (hypothyroid phase)
- Prior treatment for hyperthyroidism (includes women previously treated with radioactive iodine or surgery [thyroidectomy] leading to post-therapy hypothyroidism)
- Prior high-dose external beam neck irradiation
- Infectious (suppurative) thyroiditis: Characterized by fever and a painful, swollen thyroid gland. Common infections include *Staphylococcus aureus, S. hemolyticus,* and fungi.
- Subacute thyroiditis (hypothyroid phase): Similar to suppurative thyroiditis, but it is usually the result of a viral infection and is self-limiting
- Thyroid agenesis/dysgenesis
- Drug-induced hypothyroidism
- Dietary goitrogens (includes such drugs as thioamides and lithium)
- Organification enzyme defects

SECONDARY HYPOTHYROIDISM

- Pituitary adenoma
- Pituitary necrosis/hemorrhage
- Lymphocytic hypophysitis
- Central nervous system sarcoidosis
- Prior hypophysectomy
- Cranial irradiation
- Suprasellar/parasellar
- Traumatic injury to pituitary/hypothalamus

independent of other complications. Thyroid hormones also have important roles in embryogenesis and fetal maturation. Maternal hypothyroxinemia is associated with neonatal hypothyroidism and with defects in IQ and long-term neurological function in the offspring.[402,464,465] Women with iodine-deficient hypothyroidism are at particularly high risk of having a child with congenital cretinism (growth failure, mental retardation, and other neuropsychological deficits).

Early diagnosis and treatment of maternal hypothyroidism is essential to avoid antepartum pregnancy complications and impaired neonatal and childhood development. Indeed, in an iodine-deficient population, treatment with iodine in the first and second trimesters of pregnancy has been shown to significantly reduce the incidence of congenital cretinism.[466] With the advent of routine newborn screening for congenital hypothyroidism, it has become clear that size, weight, appearance, behavior, extrauterine adaptation, and immediate postnatal development are usually normal in infants with hypothyroidism, even those with thyroid agenesis.[467]

Although untreated hypothyroidism is associated with adverse perinatal outcome, the maternal and fetal consequences of isolated maternal hypothyroxinemia (normal TSH in conjunction with free T4 concentration in the lower 5th or 10th percentile of the reference range), and subclinical hypothyroidism (SCH) during pregnancy are not as clear. One study utilizing stored serum samples of nearly 17,300 pregnant women reported that isolated maternal hypothyroxinemia was not associated with adverse pregnancy outcomes.[468] However, another study utilizing nearly 11,000 stored serum samples from the multicenter, prospective First- and Second-Trimester Evaluation of Risk (FASTER) trial found that women with hypothyroxinemia and normal TSH had 1.6 times the odds of preterm labor, nearly twice the odds of macrosomia, and 1.7 times the odds of gestational diabetes.[469]

The majority of studies suggest that SCH is associated with increased perinatal risk.[402,464,465,470,471] A retrospective cohort study of over 17,000 women demonstrated that untreated subclinical hypothyroidism was associated with a threefold risk of placental abruption and a 1.8-fold risk of preterm birth before 34 weeks, compared to euthyroid controls.[471] Subclinical hypothyroidism in pregnancy has also been associated with a fourfold risk of fetal death,[416] an increased risk for severe preeclampsia,[472] and an increased miscarriage rate even in thyroid peroxidase antibody (TPOAb)-negative women.[473-475] However, other large studies have failed to demonstrate an association between SCH and adverse obstetrical outcomes.[469,476,477] The only trial to directly address the impact of treatment for SCH randomized over 4500 pregnant women to either a case-finding group or universal thyroid screening strategy.[424] Negro and colleagues found that the universal screening approach did not result in an overall decrease in adverse perinatal outcomes, but TPOAb-positive women with SCH (TSH greater than 2.5 mIU/L) who were treated with levothyroxine had a lower risk of adverse obstetrical outcomes, including miscarriage, hypertension, preeclampsia, gestational diabetes, placental abruption, cesarean delivery, congestive heart failure, preterm labor, respiratory distress, neonatal intensive care unit admission, low and high birth weight, preterm or very preterm delivery, low Apgar score, and perinatal death.[424] This finding failed to reach statistical significance, however, due to the broad range of outcomes identified as adverse events and the high proportion of adverse outcomes in euthyroid women.

Most controversial is the association between subclinical hypothyroidism, isolated maternal hypothyroxinemia, and neurological impairment in the offspring.[463,478,479] A large case-control study reported a 7-point reduction in IQ scores in children born to mothers with untreated TSH elevations in pregnancy, compared to children born to euthyroid mothers.[463] Pop and colleagues reported impaired psychomotor development in offspring born to women with isolated hypothyroxinemia.[478] Similarly, a retrospective cohort study of Chinese women found that SCH, hypothyroxinemia, and elevated TPOAb titers were associated with lower intelligence scores and impaired motor development of offspring at 25 to 30 months.[480] The Generation R study, a prospective, nonrandomized population-based cohort from the Netherlands, found that while SCH was not significantly associated with cognitive outcomes in offspring, both mild (OR 1.44) and severe (OR 1.8) hypothyroxinemia were associated with expressive language delay, and severe maternal hypothyroxinemia predicted a higher risk of nonverbal cognitive delays (OR 2.03).[481]

Other studies, however, have failed to find an association between maternal subclinical hypothyroidism and cognitive performance in offspring.[481-483] To date, only one randomized controlled trial has investigated whether levothyroxine

therapy for women with either overt or subclinical hypothyroidism is associated with an improvement in childhood intellectual development.[483] The Controlled Antenatal Thyroid Screening (CATS) study enrolled nearly 22,000 women with singleton pregnancies, and randomized them before 16 weeks' gestation to screening and treatment for TSH greater than the 97.5th percentile and/or free T_4 less than the 2.5th percentile, or storage of serum samples until after completion of pregnancy. The CATS study found no significant difference in mean IQ or in the proportion of children with IQ less than 85 at 3 years of age, in children born to 390 treated mothers compared to 404 untreated mothers.[483] The Maternal Fetal Medicine Unit of the National Institutes of Health is currently conducting a multicenter randomized controlled trial to evaluate the effects of levothyroxine therapy for pregnant women with SCH. The primary outcome of this study is child IQ at age 5; the results are anticipated in 2015.[388] Thus, while an association between maternal SCH-isolated hypothyroxinemia and adverse fetal neurocognitive outcomes is biologically plausible, such an association has not been clearly demonstrated in prospective, randomized controlled trials. The most recent guidelines of the ATA therefore recommend levothyroxine therapy for pregnant women with SCH and anti-TPO antibodies, but conclude there is insufficient evidence to recommend for or against treating women with SCH in the absence of TPO antibodies, and do not recommend therapy for isolated hypothyroxinemia in pregnancy.[388]

Levothyroxine is the treatment of choice for pregnant and nonpregnant women with overt hypothyroidism. Treatment should be initiated at an oral dose of 100 to 150 μg daily. TSH levels should be measured serially every 4 weeks, and the dose of levothyroxine adjusted to maintain TSH levels within trimester-specific ranges. As thyroid hormone production is increased during pregnancy, most women will need an increase in their daily dose by approximately 30% to 50% during pregnancy.[484,485]

Postpartum Thyroiditis

Postpartum thyroiditis is an autoimmune inflammation of the thyroid gland that presents as new-onset, painless hypothyroidism, transient thyrotoxicosis, or thyrotoxicosis followed by hypothyroidism within 1 year postpartum. The condition occurs in approximately 5% (range 4% to 10%) of women without preexisting thyroid disease and may also occur after early pregnancy loss.[486-488] Thirty-three percent to 50% of women with antithyroid antibodies in the first trimester will develop postpartum thyroiditis, with higher titers conferring a greater risk.[488] The classic form begins with transient thyrotoxicosis, followed by transient hypothyroidism, with a return to euthyroid state by the end of the first postpartum year.[488] Studies have found that the classic presentation of postpartum thyroiditis is seen in approximately 20% of cases, while the majority of women (44% to 48%) with postpartum thyroiditis have isolated hypothyroidism (with fatigue, weight gain, and depression), and approximately 30% experience isolated thyrotoxicosis (characterized by dizziness, fatigue, weight loss, and palpitations).[486,488,489]

The diagnosis of postpartum thyroiditis requires a high clinical index of suspicion. The diagnosis is confirmed by documenting abnormal serum levels of TSH and T_4 in a previously euthyroid patient. Differentiating postpartum thyroiditis from Graves disease can be challenging. Thyroid receptor antibodies are often positive in Graves disease but usually are negative in postpartum thyroiditis, and radioiodine uptake is elevated or normal in Graves disease and low in postpartum thyroiditis. ^{123}I or technetium scans are preferable to ^{131}I scans in breastfeeding women, due to the shorter half-life.[488] The need for treatment in women with postpartum thyroiditis is not clear, although it may be warranted to control symptoms.[402,489] In one prospective study of 605 asymptomatic pregnant and postpartum women, none of the women with thyrotoxicosis and only 40% of women with hypothyroidism required treatment.[489] If treatment is required, it can usually be tapered within 1 year. The majority of studies examining the impact of postpartum thyroiditis on long-term thyroid function have found that between 10% and 20% of women with postpartum thyroiditis will require long-term treatment.[489-495] A recent prospective study of 169 women with postpartum thyroiditis, however, reported a much higher rate of 54% of women with persistent hypothyroidism after 1 year.[496] Women with the highest levels of TSH, high TPO antibody titers, multiparous women, older women, and those with a history of miscarriage have the highest risk for developing permanent hypothyroidism.[402,488,489] Both levothyroxine and iodine treatment during pregnancy have been investigated as a potential strategy to prevent postpartum thyroiditis in women with antithyroid antibodies, but neither intervention was effective.[497,498] A more recent prospective placebo-controlled study evaluating the efficacy of selenium in preventing postpartum thyroiditis in TPOAb-positive women found that selenium decreased both the incidence of postpartum thyroiditis and permanent hypothyroidism.[499] Selenium administration was also associated with a significant decrease in postpartum TPOAb titers. Given that only one trial has demonstrated this benefit, there is insufficient evidence at this time to recommend selenium supplementation during pregnancy in TPOAb-positive women. Even in women whose thyroid function returns to normal, the risk of recurrent postpartum thyroiditis in a subsequent pregnancy is approximately 70%.[500,501] Women with a prior history of postpartum thyroiditis should have annual TSH screening to evaluate for permanent hypothyroidism.[388]

Structural Thyroid Disorders in Pregnancy

Goiter

Goiter refers to enlargement of the entire thyroid gland. Goiters can be classified into several categories according to the functional status of the gland (hypothyroid, hyperthyroid, or euthyroid) or to its clinical or scintigraphic appearance (diffuse or multinodular). The most common causes of goiter are summarized in Box 28.9.

Treatment is rarely necessary for diffuse goiter if the patient is asymptomatic and thyroid function testing is normal. With time, however, diffuse enlargement of the thyroid gland typically evolves into multinodular goiter, with progressive autonomous functioning of one or more follicles and occasional progression to thyrotoxicosis. This progression is seen most often in the largest goiters, those with nodules greater than 2.5 cm in size, and in older patients.[502] Large, dominant nodules should undergo fine-needle aspiration because malignant neoplasms can coexist with this typically benign condition. A trial of thyroid hormone

Box 28.9 Most Common Causes of Goiter

- Endemic goiter (iodine deficiency)
- Sporadic goiter (diffuse non-toxic goiter; multinodular goiter)
- Diffuse toxic goiter (Graves disease)
- Thyroiditis (chronic autoimmune [Hashimoto disease]; subacute; silent/postpartum; suppurative)
- Drugs (thioamides, iodides, lithium)
- Dietary/environmental goitrogens
- Organification enzyme defects
- Diffuse malignant disease (lymphoma, anaplastic carcinoma)
- Infiltrative diseases (Riedel thyroiditis, sarcoidosis, amyloidosis)

suppression is reasonable in most patients, although less than 50% of nodules will respond to medical therapy by decreasing in size.[503] The approach to therapy in the patient with a toxic multinodular goiter includes thyroid ablation with radioactive iodine, thioamides, or thyroidectomy.

Thyroid Nodules

Nodules of the thyroid are common; they are palpable in 5% of the general population and may be even more common in areas of relative iodine deficiency. Careful attention must be taken to examination of the thyroid nodule and surrounding tissues because of the small but real potential of malignancy. Malignant transformation is more common in the largest nodules, in those with progressive growth, in older women, and in women with other risk factors for malignancy (such as prior neck irradiation).

The majority of thyroid nodules are found on pathological examination to be either hyperplastic or adenomatous in origin. Benign and malignant neoplasms of the thyroid are listed in Box 28.10. Papillary and follicular carcinomas represent the majority of the cancers. The incidence of thyroid cancer in pregnancy is 1/1000.[504] Pregnancy itself does not appear to increase the risk of malignant transformation[461-465] or alter the course of thyroid cancer.[504,505] Moreover, treatment for thyroid cancer does not appear to increase the risk of congenital anomalies, low birth weight, or stillbirths.[506]

Any thyroid nodule discovered during pregnancy should be further evaluated, because malignancy may be found in up to 40% of these nodules.[502,504-507] Fine-needle aspiration coupled with careful cytopathological examination of the aspirate is the technique of choice for evaluation of a thyroid nodule. Ultrasound examination may be helpful in distinguishing simple cysts from solitary nodules, in the evaluation of a multinodular goiter, or in the follow-up of known thyroid lesions. However, ultrasonography is a purely anatomical study and does not provide any functional or histological information. Similarly, scintigraphy (with either technetium or radioiodine) can provide functional information that may be important, because functional ("hot") nodules are rarely malignant and almost all carcinomas are non-functional ("cold"). However, such testing cannot definitively exclude malignancy. As such, neither of these diagnostic tests can replace fine-needle aspiration for the initial evaluation of a thyroid nodule.

If a diagnosis of thyroid cancer is made, a multidisciplinary treatment plan should be established. Management options include pregnancy termination, treatment during pregnancy, and preterm or term delivery with definitive treatment after pregnancy. The decision will be affected by the gestational age at diagnosis and by the tumor characteristics.[402] Definitive treatment for thyroid cancer is thyroidectomy and radiation. If necessary, thyroidectomy can be performed during pregnancy, preferably in the second trimester. However, given the slow progression of most thyroid cancers, surgery can often be delayed until after delivery.[504] Radiation is best deferred until after pregnancy.

Box 28.10 Most Common Causes of Thyroid Nodules

BENIGN

- Follicular adenoma
- Colloid nodule
- Hiirthle cell adenoma
- Multinodular goiter
- Simple cyst
- Nodular autoimmune thyroiditis
- Marine-Lenhart nodule (in Graves disease)

MALIGNANT

- Papillary carcinoma
- Follicular carcinoma
- Hürthle cell carcinoma
- Medullary carcinoma
- Anaplastic carcinoma
- Lymphoma
- Metastases to the thyroid

Disorders of Calcium Metabolism

Total calcium stores in the mother are distributed between a large skeletal pool of "inert" calcium (1 kg) and a small extracellular pool of bioavailable calcium. These two pools of calcium are maintained in a state of dynamic equilibrium, controlled on the one hand by parathyroid hormone (PTH) and by calcitonin on the other. PTH stimulates release of calcium from bone and promotes calcium uptake from the gastrointestinal tract, while calcitonin suppresses calcium release from bone. Calcium uptake from the gastrointestinal tract is also regulated by vitamin D metabolites. Calcium is excreted by the kidneys and is sequestered by the fetoplacental unit to build the fetal skeleton.

Pregnancy is associated with a net accumulation of calcium. At term, the total accumulation of calcium in the mother is approximately 25 to 30 g, most of which is sequestered in the fetal skeleton. This is due primarily to elevated circulating levels of biologically active 1,25-hydroxyvitamin D (cholecalciferol) leading to an increase in calcium absorption from the gastrointestinal tract.[508-510] The decidua may be a major source of 1,25-hydroxyvitamin D in pregnancy.[511] Calcitonin levels do not change in pregnancy. Although initial studies suggested that serum PTH levels increase during pregnancy[512] subsequent studies using more sensitive dual-antibody assays have shown that PTH levels are lower throughout gestation.[513,514] Urinary excretion of calcium increases during pregnancy,[515] but the ratio of urinary calcium to creatinine decreases,[516] suggesting an attempt by the kidneys to reabsorb and conserve calcium even in the face of an increased glomerular filtration rate. In general, bone density

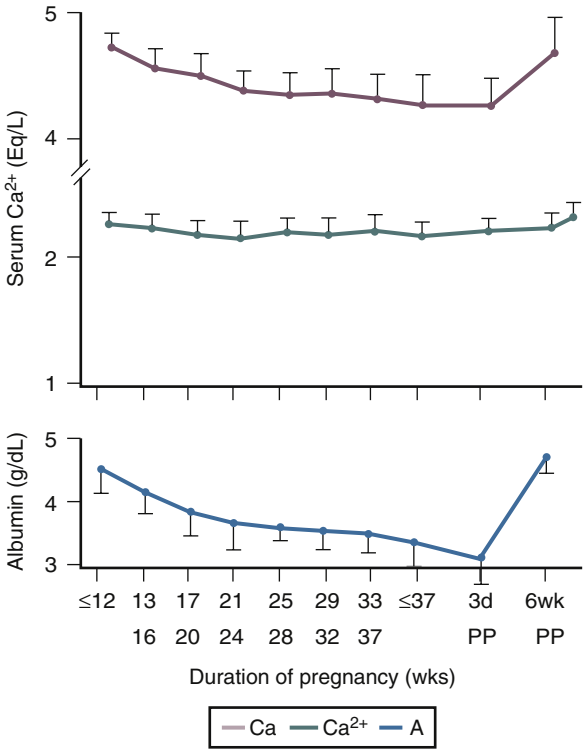

FIGURE 28.16 Serum calcium, ionized calcium, and albumin concentrations during pregnancy. During pregnancy, there is a marked decrease in circulating albumin concentration; this results in a decrease in total calcium. There is no change in ionized calcium. A, albumin. *(From Pitkin RM, Reynolds WA, Williams CA, Hargis CK. Calcium metabolism in normal pregnancy: A longitudinal study.* Am J Obstet Gynecol *133:781, 1979.)*

remains relatively constant during pregnancy, although some investigators have reported a slight decrease in bone density in the third trimester.[517] Pregnancy is also associated with a decrease in serum albumin and a concomitant decrease in total calcium concentrations (Fig. 28.16).[512,513] The upper limit of normal for total serum calcium in pregnancy is approximately 9.5 mg/dL. However, ionized calcium concentrations do not change significantly during pregnancy.[513]

Calcium from the maternal compartment is actively transported across the placenta against a concentration gradient to the fetal compartment. This process is regulated, at least in part, by the production of PTH-related protein (PTHrP), a PTH homolog, by the fetal parathyroid glands.[518] PTHrP levels rise in maternal serum throughout gestation.[514,519] In mice lacking the gene coding for PTH-related protein, calcium transport from the maternal to the fetal compartment is markedly impaired but can be rescued completely by administration of exogenous PTH-related protein.[520] Compared with the mother, the human fetus is relatively hypercalcemic, hypercalcitonemic, and hypoparathyroid. Separation of the fetus from the mother is associated with a fall in serum calcium and a compensatory rise in serum PTH and a fall in calcitonin levels.

Hyperparathyroidism

Primary hyperparathyroidism in pregnancy is rare; only a few hundred cases have been reported. Causes of hyperparathyroidism include a solitary parathyroid adenoma (80 of cases), generalized hyperplasia (15), multiple adenomas (3%), and carcinoma (less than 2%). Maternal complications of untreated or poorly controlled hyperparathyroidism include hyperemesis gravidarum, generalized weakness, headache, confusion, emotional lability, nephrolithiasis, pancreatitis, and hypertension.[521] Spontaneous abortion and perinatal mortality rates are also increased in pregnancies complicated by hyperparathyroidism[522]; however, improved diagnosis and treatment have led to a substantial decrease in perinatal mortality.[523] Most authorities recommend surgical excision of the parathyroid adenoma in symptomatic women,[521,524,525] but controversy persists as to the optimal management for asymptomatic women and women with mild hyperparathyroidism. At birth, neonatal hypocalcemic tetany is common and typically occurs in the first 2 weeks of life.[526,527]

Unusual causes of hypercalcemia in pregnancy include familial hypocalciuric hypercalcemia (FHH) and sporadic cases of inappropriate secretion of PTH-related protein.[528] Women with FHH typically present with mild hypercalcemia, mild elevations in circulating PTH concentrations, and low urinary calcium. Because of the autosomal-dominant nature of the disease and high penetrance, infants can present with either hypercalcemia (if the neonate has FHH) or hypocalcemia (if the neonate does not have FHH but is responding to maternal hypercalcemia).[528]

Hypoparathyroidism

The most common cause of maternal hypoparathyroidism is incidental resection of the parathyroid glands at the time of thyroidectomy. This complication occurs in approximately 1% of thyroidectomy cases. Symptoms of hypocalcemia include numbness and tingling of the fingers and orofacial area. Chvostek sign (twitching of the facial muscles when the facial nerve is tapped) and Trousseau sign (induction of carpopedal spasm by applying pressure to the upper arm with a blood pressure cuff) are often present.

If untreated, maternal hypocalcemia can lead to compensatory hyperparathyroidism in the fetus leading to bone demineralization. The treatment of maternal hypoparathyroidism is calcium (1.2 g daily) and either vitamin D (50,000 to 150,000 IU daily) or the active metabolite, calcitriol (0.25 to 3 μg daily).[529] If circulating calcium levels can be maintained at or near the normal range, pregnancy outcome will not be adversely affected.[530] In women with hypocalcemia, labor may be complicated by generalized tetany that requires intravenous calcium administration. Vitamin D is secreted into breast milk and may lead to hypercalcemia in the newborn.[531] As such, breastfeeding may not be advisable in women receiving high-dose vitamin D therapy.

Adrenal Diseases

Adrenal Insufficiency

Adrenal insufficiency may be either primary or secondary. *Primary adrenal insufficiency* (Addison's disease) results from destruction of both adrenal cortices. The most common cause of primary adrenal insufficiency is autoimmune destruction of the adrenal glands, which can occur

Box 28.11 Autoimmune Polyglandular Syndromes

COMMON TYPE 1*
- Addison disease
- Hypoparathyroidism
- Mucocutaneous candidiasis

LESS COMMON TYPE 1
- Hypogonadism
- Malabsorption
- Vitiligo
- Pernicious anemia
- Alopecia
- Hypothyroidism

COMMON TYPE 2
- Addison disease
- Thyroid dysfunction
- Type 1 diabetes mellitus

LESS COMMON TYPE 2
- Hypogonadism
- Myasthenia gravis
- Vitiligo
- Pernicious anemia
- Alopecia

*Type 1 is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome.

Data from Neufeld M, MacLaren NK, Blizzard RM. Two types of autoimmune Addison's disease associated with different polyglandular autoimmune syndromes. *Medicine (Baltimore)* 60:355, 1981.

in isolation or in association with other autoimmune endocrinopathies like autoimmune polyglandular diseases, type I and type II (Box 28.11).[532] The presence of circulating antibodies against cytochrome P450 monooxygenases involved in steroidogenesis may suggest the diagnosis of autoimmune adrenal insufficiency.[533] Other causes of primary adrenal insufficiency include human immunodeficiency virus (HIV) disease, tuberculosis, sarcoidosis, and adrenal leukodystrophy.

Secondary adrenal insufficiency, on the other hand, results from an abnormality in the hypothalamic-pituitary-adrenal axis that leads to ACTH deficiency and resultant adrenocortical atrophy. In secondary adrenal insufficiency, the zona glomerulosa of the adrenal gland (and thus mineralocorticoid production) are preserved, because they are under the control of the renin-angiotensin system.[534,535]

Regardless of the cause, the most common symptoms of adrenal insufficiency are generalized weakness, fatigue, nausea, anorexia, diarrhea, and weight loss. Pigmentation in the creases of the palms of the hands, knuckles, and knees can be seen in some patients with primary adrenal insufficiency (Addison disease) due to an increase in secretion of melanocyte-stimulating hormone from an overactive adenohypophysis. Laboratory features of Addison disease include hyponatremia, hyperkalemia, and an increase in plasma blood urea nitrogen. The diagnosis of Addison disease can be confirmed using the ACTH stimulation test, in which a serum cortisol level is measured 60 minutes after an intravenous bolus of 0.25 mg synthetic[1,24] ACTH (cosyntropin). A normal ACTH stimulation test result is associated with a serum cortisol measurement of greater than 18 μg/dL.[535] The absence of an adequate cortisol response is highly suggestive of primary adrenal insufficiency. Secondary adrenal insufficiency should be suspected if there is a suboptimal cortisol response to the ACTH stimulation test, but a normal serum aldosterone concentration.[536]

Adrenal insufficiency in pregnancy has been described, and initial reports suggested a high perinatal mortality rate. More recent experience suggests good outcomes with the use of glucocorticoid therapy,[537,538] although fetal growth restriction has been described.[539]

Treatment of Addison disease should include physiological replacement of cortisol as well as mineralocorticoid, if necessary. Endogenous cortisol production rates are typically in the range of 20 to 30 mg daily, but may be as high as 300 mg daily. Hydrocortisone (cortisol) at a dose of 20 to 30 mg daily (two thirds in the morning and one third in the late afternoon or early evening) is typically prescribed as replacement for both pregnant and nonpregnant women. An alternative is oral prednisone at 2.5 to 7.5 mg daily. Fluorohydrocortisone (Florinef) at a dose of 0.1 mg daily should adequately treat mineralocorticoid deficiency. Mineralocorticoid therapy is not necessary for secondary adrenal insufficiency.

Addisonian crisis (adrenal crisis) refers to a state of acute adrenal insufficiency. This condition is rarely seen during pregnancy but frequently develops in the immediate postpartum period.[540] This is likely because, in pregnancy, the kidney synthesizes large amounts of deoxycorticosterone (a weak glucocorticoid and mineralocorticoid) from progesterone.[541] The immediate treatment of adrenal crisis should include intravenous hydration with normal saline, glucose replacement, and high doses of cortisol given either intramuscularly or intravenously (100 mg bolus every 6 to 8 hours for the first 24 hours).

Women with Addison disease undergoing surgery should be given stress doses of cortisol. On the day of surgery, 100 mg of cortisol can be administered either intramuscularly or intravenously and repeated every 6 to 8 hours during surgery and in the immediate postoperative period. This dose can be reduced by 50 mg daily until oral glucocorticoid replacement can be reinstated. Consideration should also be given to administering stress doses of cortisol in labor. By the second trimester, very little cortisol crosses the placenta intact due to high placental type 2 11β-hydroxysteroid dehydrogenase activity that converts cortisol to cortisone. As such, the fetus is highly resistant to adrenal suppression caused by maternal ingestion of glucocorticoids.[542]

Cushing Syndrome

Cushing syndrome results from exposure to excessive circulating levels of cortisol. The condition may be ACTH-dependent, as in ACTH-secreting pituitary adenoma (Cushing disease) and ACTH- or CRH-secreting tumors like bronchial carcinoids. Cushing syndrome can also be ACTH-independent, resulting from exogenous glucocorticoids, adrenal adenoma, or carcinoma. In nonpregnant women, Cushing disease is threefold more common than adrenal adenomas. In pregnancy, however, adrenal adenomas are the most common cause of Cushing syndrome (Table 28.7).[543]

The most common clinical features of Cushing disease include proximal muscle weakness, centripetal obesity

Table 28.7 Etiology of Cushing Syndrome in Nonpregnant and Pregnant Populations

Etiology	Nonpregnant (n = 108)	Pregnant (n = 58)
ACTH-secreting pituitary tumor leading to bilateral adrenal hyperplasia	64 (59%)	19 (33%)
Adrenal adenoma	17 (16%)	29 (50%)
Adrenal carcinoma	10 (9%)	6 (10%)
Ectopic ACTH	17 (16%)	1 (2%)
Unknown	0 (0%)	3 (5%)

Data from Buescher MA, McClamrock HD, Adashi EY. Cushing's syndrome in pregnancy. *Obstet Gynecol* 79:130, 1992. Reprinted with permission from The American College of Obstetricians and Gynecologists.

("potato stick" person with thick trunk and thin limbs), facial plethora, supraclavicular and dorsal ("buffalo hump") fat pads, violaceous striae, hirsutism, personality changes, and hypokalemia. In nonpregnant women, significant and persistent elevation in urinary free cortisol excretion (greater than 200 μg/day) confirms the diagnosis.

Cushing syndrome can be difficult to recognize and diagnose during pregnancy, however, because normal pregnancy is associated with physiological hypercortisolism and increased urinary free cortisol excretion. Initial studies suggested that urinary free cortisol excretion was significantly increased in pregnancy, with a mean of 130 (range, 60 to 250) μg/day.[544] However, more recent studies using high-performance liquid chromatography have shown that normal pregnant subjects have a 24-hour urinary free cortisol excretion of approximately 23 μg, which is increased to 165 to 3360 μg daily in the setting of Cushing syndrome.[545] As such, urinary free cortisone and cortisol as determined by high-performance chromatography may have greater sensitivity and specificity in the diagnosis of Cushing syndrome than does the measurement of urinary free cortisol by standard assay techniques.[546]

Once diagnosis has been confirmed, every effort should be made to identify the cause. Given the high incidence of adrenal adenomas and carcinomas in pregnant women with Cushing syndrome (Table 28.7), it may be appropriate to first perform a high-resolution imaging study of the adrenal glands, either with computed tomography or magnetic resonance imaging. If the imaging study is negative, then tests should be performed to identify an ACTH-secreting pituitary tumor (CRH stimulation followed by petrosal sinus sampling for ACTH) or an extrapituitary source of ACTH or CRH (computed tomography of the chest).[547]

Cushing syndrome is associated with an increased risk of pregnancy-related complications, including hypertension (65%), diabetes (325), preeclampsia (10%), congestive heart failure, and maternal death.[548] Perinatal morbidity and mortality are also increased in such pregnancies. Adverse perinatal outcomes include an increased risk of prematurity (65% t), IUGR (26%), and perinatal death (16%).[548]

Cushing syndrome is a rare condition in pregnancy due to the high frequency of ovulation dysfunction. As such, it has not been possible to systematically examine and compare treatment strategies for this condition. Given the high maternal and perinatal morbidity associated with this condition, aggressive antepartum and intrapartum management is indicated. Surgery (unilateral adrenalectomy) should be considered if a functional adrenal adenoma is identified. In the case of an ACTH-secreting pituitary tumor, transsphenoidal resection can be performed during pregnancy.[549] Medical treatment options include antiglucocorticoids and inhibitors of adrenal steroidogenesis. Metyrapone,[550,551] aminoglutethimide,[552] and ketoconazole[548,553] have all been used to treat Cushing syndrome in pregnancy. However, the efficacy or safety of these agents during pregnancy has yet to be established.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) refers to a group of genetic disorders of steroidogenesis. It occurs in approximately 1 in 14,000 live births but is more common in certain populations. In the Yupik Inuit, for example, CAH occurs at a frequency of 1 in 300 live births.[554] The most common cause of CAH is a deficiency of 21-hydroxylase enzyme activity, which leads, in turn, to a decrease in circulating cortisol levels, a compensatory increase in ACTH production, and an increase in adrenal androgen production.

The exposure of a female fetus to high levels of androgens during early embryonic development can lead to clitorimegaly, labioscrotal fusion, ambiguous genitalia, abnormal course of the urethra, and virilization. In severe forms of 21-hydroxylase deficiency, the conversion of progesterone to mineralocorticoids (deoxycorticosterone, corticosterone, and aldosterone) is reduced, resulting in "salt wasting." If undetected and untreated, the saltwasting form of the disease may be associated with neonatal hyponatremia, hyperkalemia, and death. In CAH due to 21-hydroxylase deficiency, 75% of cases are associated with salt wasting and 25% present with virilization but no salt wasting. For the obstetrician evaluating a newborn with ambiguous genitalia, the most important disease to exclude is 21-hydroxylase deficiency associated with salt wasting. Failure to recognize this condition can lead to discharge of the newborn resulting in neonatal dehydration and death.

If a mother has previously delivered a child with CAH, or if either she or the father has CAH, then appropriate recommendations include antenatal genetic counseling, prenatal glucocorticoid treatment, and genetic testing of the neonate after delivery. Women with non-classical 21-hydroxylase deficiency who have not previously delivered a child with CAH do not require prenatal intervention because the probability that the fetus is severely affected is low (less than 1%) in most cases.

For parents wishing to pursue glucocorticoid therapy to reduce the risk of virilisation of a female fetus, the suggested management of these pregnancies is summarized in Figure 28.17.[555] In such cases, the mother should be treated with dexamethasone (20 μg/kg daily in three divided doses) as soon as the pregnancy is confirmed. This dose has been shown to normalize 17-hydroxyprogesterone levels in the amniotic fluid of affected fetuses.[556] Chorionic villus sampling should be offered at 9 to 11 weeks' gestation. If a male fetus is identified, steroid therapy can be discontinued. If the fetus is a female, prenatal diagnosis can be achieved

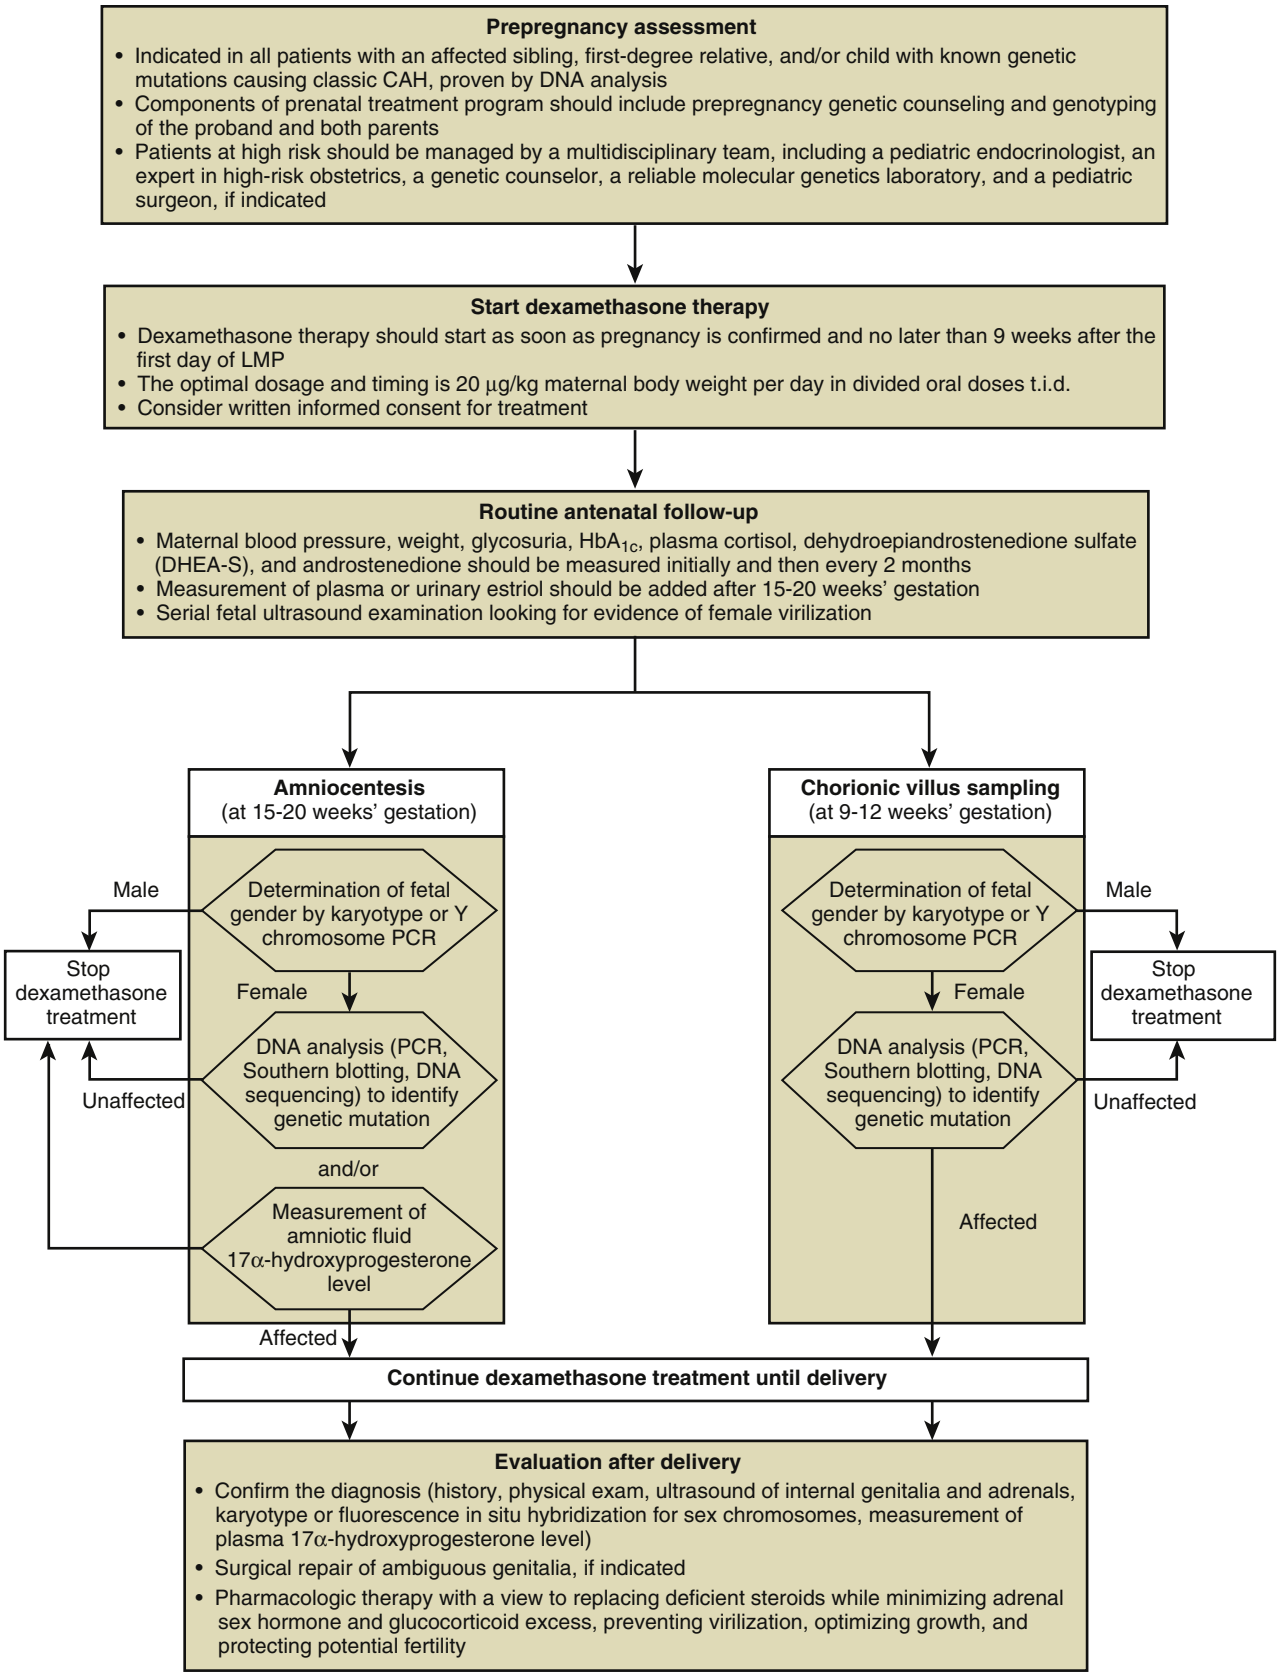

FIGURE 28.17 Proposed algorithm for the management of pregnant women at risk for congenital adrenal hyperplasia. CVS, chorionic villus sampling. *(From LWPES/ESPE CAH Working Croup. Consensus statement on 21-hydroxylase deficiency from The Lawson Wilkins Pediatric Endocrine Society and The European Society for Pediatric Endocrinology.* J Clin Endocrinol Metab *87:4048, 2002.)*

by CYP2 genotyping. If an affected female fetus is identified, glucocorticoid treatment should be continued for the entire pregnancy. The goal of this protocol is to suppress endogenous androgen production by the fetal adrenal and thereby prevent virilization of an affected female fetus. If dexamethasone therapy is initiated too late in gestation (typically regarded as later than 9 weeks' gestation), clitoromegaly and labioscrotal fusion may already have occurred.

Because estriol in the maternal circulation is derived almost exclusively from placental metabolism of fetal androgens (primarily 16-hydroxy dehydroepiandrosterone sulfate [16-OH DHEAS]), estriol levels can be used to monitor the efficacy of maternal glucocorticoid therapy to suppress fetal adrenal steroidogenesis. An estriol level of less than 0.2 nM in the maternal circulation is associated with marked suppression of fetal adrenal steroidogenesis, whereas a level of greater than 10 nM is associated with inadequate suppression of the fetal adrenal.[557]

Exactly how effective this protocol is in preventing virilization is not clear. In one study, implication of this protocol in 14 pregnancies at risk resulted in the treatment of two affected female fetuses, one of whom was virilized.[558] A subsequent report described the effects of antenatal glucocorticoid treatment on 15 female fetuses found to have CAH on the basis of antepartum genetic testing. Of the 15 female infants, 5 responded completely and 10 responded partially.[558] In the largest experience to date of 61 affected female fetuses, New and colleagues demonstrated that, for affected females, the average Prader score (an objective scoring system of virilisation graded on a scale from 1 [mild] to 5 [severe]) for those treated prenatally at or before 9 weeks' gestation was 0.96, whereas those with no prenatal treatment had an average Prader score of 3.75.[559] Taken together, these data suggest that approximately 85% of affected female fetuses who receive glucocorticoid therapy will have either no virilization or mild virilization.[555]

Potential complications of long-term antepartum dexamethasone treatment include the development of iatrogenic Cushing syndrome in the mother[557] and subtle cognitive and motor deficits in the child,[560,561] although not all studies have confirmed this association.[562]

Pheochromocytoma

Pheochromocytomas are catecholamine-secreting tumors that arise from chromaffin cells. Although the majority (90%) occur in the adrenal gland, these tumors can also be found outside of the adrenal, primarily at the base of the bladder and at the aortic bifurcation (organ of Zuckerkandl). Of all cases, 10% are bilateral and 10% are malignant. In a minority of cases (10%), pheochromocytomas may occur in association with other systemic disorders like neurofibromatosis (von Recklinghausen disease), multiple endocrine neoplasia type IIA (Sipple syndrome), and von Hippel-Lindau syndrome.

Pheochromocytomas account for 0.1% of hypertension in adults. These tumors are rare in pregnancy, and only a few hundred cases have been reported in the literature. However, they pose a very high risk for both mother and fetus. Anesthesia, vaginal delivery, uterine contractions, or even vigorous fetal movements can precipitate fatal maternal hypertension. Fetal growth restriction is a common finding due primarily to uteroplacental insufficiency. If untreated, the overall maternal mortality rate ranges from 4% to 17%, with a fetal loss rate of 11% to 26%.[563-565] Antenatal diagnosis reduces the maternal mortality rate to 0% to 2% and the fetal loss rate to 1% to 15% [563-565]; however, only half of such cases are diagnosed prior to conception.[563] Delay in diagnosis is, therefore, associated with considerable morbidity and mortality. Any pregnant woman with paroxysms ("spells") of labile hypertension, headaches, palpitations, sweating, flushing, blurred vision, anxiety, emesis, dyspnea, or convulsions should prompt an investigation to exclude the diagnosis. It should be remembered, however, that 50% of women with pheochromocytoma will present with sustained hypertension.

Maternal and fetal survival depends on early diagnosis, aggressive medical therapy, and correct timing of delivery and surgery. Confirmation of the diagnosis requires documentation of elevated circulating levels of metanephrines and catecholamines in either urine or blood. Although testing for fractionated plasma free metanephrines appears to be the most sensitive, it is not as specific as the standard 24-hour urine catecholamines and metanephrines measurements.[566] Given the ease of a random plasma test over a 24-hour urine collection, some authorities have advocated the former as a first line test, especially in women with a high clinical suspicion for pheochromocytoma.[567] Plasma catecholamines and urinary vanillylmandelic acid (VMA) are used less commonly because of their poor accuracy.[567] Catecholamine levels are not affected by pregnancy. Localization of the tumor can be achieved by radiological imaging (magnetic resonance imaging is the modality of choice) or, rarely, by selective sampling of the adrenal veins. Scintigraphy (^{131}I) is contraindicated in pregnancy.

Initial treatment should include pharmacological control of hypertension and tachycardia. Alpha-adrenergic blockage should be initiated immediately, preferably with phenoxybenzamine (starting at 10 mg every 8 hours and increasing gradually until orthostatic hypotension is achieved). Alternative agents include prazosin or labetalol. Beta-blockade should be reserved for women with persistent tachycardia or arrhythmias and selective and short-acting agents are preferred (such as metoprolol or atenolol). Optimal management of a pregnant patient with pheochromocytoma involves collaboration between obstetricians, endocrinologists, anesthesiologists, and general surgeons. The decision of whether or not to proceed with surgical resection depends on the success of medical treatment, the size of the tumor, estimated risk of malignancy, and gestational age.[563-565] In the first and second trimesters, surgical resection of the tumor is associated with good fetal outcome. More recently, laparoscopic tumor resection has been described in pregnancy.[568] In later pregnancy, delivery by elective cesarean followed by tumor resection is commonly recommended

Ovarian Endocrine Tumors

The precise incidence of adnexal masses in pregnancy is not known. Increasing use of ultrasonography during pregnancy suggests that sizable adnexal masses complicate as many as 1 in 200 pregnancies.[569-571] These data are consistent with a large retrospective study that showed significant adnexal

neoplasms were identified in 1 of 197 cesarean deliveries.[572] The majority of adnexal masses occurring in pregnant women are simple cysts less than 5 cm in diameter, which carry a small risk of complications such as malignancy (less than 5%), torsion, rupture, or hemorrhage.[570,571,573] Some of these adnexal masses will be functional endocrine tumors of the ovary.

The major risk of an ovarian endocrine tumor during pregnancy is virilization of a female fetus. Levels of testosterone[574,575] and androstenedione[575] increase in the maternal circulation throughout gestation, peaking in the third trimester. However, circulating levels of free testosterone remain relatively unchanged prior to 28 weeks' gestation, suggesting that the increase in total testosterone is due in large part to increases in sex hormone–binding globulin.[576] These data are consistent with the observation that the clearance of testosterone decreases during pregnancy.[577] After 28 weeks, however, levels of both total and free testosterone appear to increase in the maternal circulation. In contrast, DHEA and DHEAS concentrations decrease precipitously in pregnancy.[578] This decrease occurs despite an increase in maternal DHEAS production[579] and is likely due to increased metabolical clearance by the placenta.[578,579]

These endocrine changes serve to protect a female fetus from virilization. Other protective mechanisms include a high capacity of the placenta to aromatize androgens such as testosterone and androstenedione to estrogens (estrone, estradiol-17β, and estriol).[580] In this way, the placenta is able, at least in part, to protect a female fetus from exposure to excessive concentrations of testosterone and androstenedione. Dihydrotestosterone, on the other hand, is not a substrate for aromatization. As such, the placenta may be less effective in preventing this steroid from crossing into the fetal compartment and causing virilization. Some female fetuses appear to be uniquely resistant to the virilizing effects of androgens, especially in the second and third trimesters of pregnancy. Although the mechanism is not clear, there are several cases in which markedly elevated levels of androgens have been demonstrated in the umbilical cord blood of female infants without evidence of virilization.[581]

Three ovarian endocrine tumors can cause virilization: luteomas, gestational theca-lutein cysts (hyperreactio luteinalis), and Sertoli-Leydig cell tumors (arrhenoblastomas),[582] all of which are associated with markedly elevated levels of testosterone, dihydrotestosterone, and androstenedione. Luteomas are derived from luteinization and hyperplasia of theca interna cells,[583,584] and are bilateral in approximately 45% of cases.[582] Maternal virilization or hirsutism occurs in approximately 35% of such women, and the risk of virilization of a female fetus is high.

In contrast, theca-lutein cysts are associated with a lower risk of virilization of a female fetus. This disorder occurs typically in conditions with elevated circulating levels of hCG (such as gestational trophoblastic tumors, diabetes, and Rh isoimmunization), which directly stimulates ovarian steroid production. In the majority of cases, the cysts are bilateral.

The risk of both maternal and fetal virilization is highest with Sertoli-Leydig cell tumors. These tumors are usually unilateral. Fortunately, such tumors are usually associated with chronic anovulation and infertility, and are therefore rarely seen in pregnancy.

Preeclampsia

Preeclampsia (gestational proteinuric hypertension) complicates 6% to 8% of all pregnancies.[585,586] The second most common cause of maternal mortality in the United States (after thromboembolic disease), preeclampsia accounts for 12% to 18% of all pregnancy-related maternal deaths (around 70 maternal deaths per year in the United States and an estimated 50,000 maternal deaths per year worldwide).[586-589] It is also associated with a high perinatal mortality and morbidity, due primarily to iatrogenic prematurity.[590]

Preeclampsia is an idiopathic multisystem disorder specific to human pregnancy and the puerperium.[585] More precisely, it is a disease of the placenta because it has also been described in pregnancies where there is trophoblast but no fetal tissue (complete molar pregnancies).[591] Similarly, in the rare situation of an advanced extrauterine intraabdominal ectopic pregnancy complicated by preeclampsia, removal of the placenta is not possible at the time of delivery of the fetus and, as such, preeclampsia persists postpartum instead of resolving.[592]

Despite aggressive research efforts, the pathogenesis of preeclampsia remains poorly understood. Pathological and physiological observations as well as examination of epidemiological studies and biochemical aberrations (Table 28.8) have led to a number of theories to explain preeclampsia. At present, four major hypotheses are the subject of intense investigation:

1. Genetic imprinting
2. Immune maladaptation
3. Placental ischemia
4. Generalized endothelial dysfunction[593,594]

The data in support of each theory are summarized in Box 28.12.[595,596] In addition to endocrine changes, preeclampsia is also associated with abnormalities in the nervous system. For example, Schobel and colleagues[597] have shown that postganglionic sympathetic nerve activity is increased in women with preeclampsia compared with pregnant women without hypertension. This finding suggests that the increase in peripheral vascular resistance and blood pressure that characterize preeclampsia may be due, at least in part, to increased firing of sympathetic neurons. Interestingly, heart rate was not increased in the women with preeclampsia, implying either that increased vagal tone suppressed sympathetic activity in the heart or that the increase in peripheral sympathetic activity is a secondary compensation to plasma volume contraction.

Despite a plethora of hypotheses, there is as yet no single unifying theory that can account for all of the findings in preeclampsia. It is clear, however, that the blueprint for its development is laid down early in pregnancy. Researchers have suggested that the pathological hallmark of preeclampsia is a complete or partial failure of the second wave of trophoblast invasion from 16 to 20 weeks' gestation, which is responsible in normal pregnancies for destruction of the muscularis layer of the spiral arterioles.[598-602] As pregnancy progresses, the metabolical demands of the fetoplacental unit increase. Because of the abnormally shallow invasion of the placenta, however, the spiral arterioles are unable to

Box 28.12 Theories of Etiology of Preeclampsia and Their Supportive Evidence

GENETIC
- Familial inheritance pattern (increased incidence in women with a positive family history of preeclampsia[595] and in pregnancies conceived by men born themselves of preeclamptic pregnancies[792])
- Increased incidence in African-American race[793]
- Increased incidence in women with a prior history of preeclampsia[612]
- Association with Factor V Leiden mutation[613]
- Association with angiotensinogen gene variant[794]
- Association with protein C and/or protein S deficiency[795]
- Association between fetal 3-hydroxyacyl-coenzyme A dehydrogenase deficiency and HELLP syndrome[796]

IMMUNOLOGICAL MALADAPTATION
- Increased incidence in first pregnancies (nulliparity)[797]
- Increased incidence with changed paternity (new partner)[798,799]
- Advanced maternal age >40 years)[611]
- Association with maternal-fetal HLA-DR discordance[614]
- Association with reduced *in vitro* lymphocyte activity[800]
- Lower plasma levels of T lymphocytes[801]
- Higher plasma levels of immune complexes and complement[802,803]
- Lower level of HLA-G mRNA expression in chorionic tissue[804]
- Elevated end-organ deposition of immune complexes and immunoglobulins[805,806]
- Lower incidence of preeclampsia in women who have received a blood transfusion[807]
- Lower incidence of preeclampsia with an extended duration of sexual cohabitation prior to conception[799]
- Higher incidence of preeclampsia in women using contraception that prevent exposure to sperm[808]
- Higher incidence of preeclampsia in women impregnated by men from a different racial group[809]
- Association with autoimmune disease (such as systemic lupus erythematosis)[598]

PLACENTAL ISCHEMIA
- Association with abnormal placentation[599-601]
- Association with excessive placental mass (increased incidence with increasing gestational age, in molar and multifetal pregnancies,[609] in nonimmune hydrops fetalis,[810] and in women with malaria[811]
- Association with intrauterine fetal growth restriction[812]
- Pathological evidence of placental thrombosis and infarction

GENERALIZED ENDOTHELIAL INJURY
- Increased incidence in women with chronic hypertension[615,616]
- Increased incidence in women with chronic renal disease[617]
- Increased incidence in women with antiphospholipid antibody syndrome[618]
- Increased incidence in women with diabetes mellitus[619]
- Association with imbalance in prostaglandin synthesis (elevated thromboxane A2/prostacyclin ratio)[813]
- Association with coagulopathy
- Association with abnormalities in free fatty acid, lipoprotein, and lipid peroxidase metabolism[596]

dilate to accommodate the required increase in blood flow resulting in "placental dysfunction" that manifests clinically as preeclampsia.

A number of recent studies have provided an improved understanding of the pathophysiology of preeclampsia, suggesting that aberrant expression of placentally-derived circulating anti-angiogenic factors may lead to widespread maternal endothelial injury.[603] Vascular endothelial growth factor (VEGF) is an important mitogen involved in angiogenesis and the maintenance of vascular integrity. VEGF acts by binding to two cell surface receptors, VEGF receptors type 1 (flt1) and type 2 (KDR). The flt1 receptor exists in two major isoforms: a functional transmembrane isoform and a soluble truncated isoform known as soluble fms-like tyrosine kinase-1 (sFlt-l). sFlt-1 lacks a membrane binding domain and thus exists free in the maternal circulation where it binds and functionally inactivates VEGF and placental growth factor (PlGF) leading to increased vascular permeability.[604] Levels of sFlt-1 in the maternal circulation increase during pregnancy, but increase earlier and to higher levels in pregnancies destined to develop preeclampsia as compared with normotensive controls. The source and molecular mechanisms responsible for the increase in circulating sFlt-1 levels in preeclampsia remain unclear. Interestingly, anti-VEGF antibodies have been used as pharmacological therapy in nonpregnant individuals for conditions resulting from inappropriate or excessive angiogenesis, such as neoplastic disorders and macular degenerative disease. Common side effects associated with this therapy include hypertension and proteinuria.[605]

More recently, another anti-angiogenic factor—known as soluble endoglin (sEng)—has been implicated in the

Table 28.9 Epidemiological Risk Factors for Preeclampsia

Factor	Risk Ratio
Nulliparity[797]	2.9:1

Box 28.13 Features of Severe Preeclampsia

SYMPTOMS
- Symptoms of central nervous system dysfunction (headache, blurred vision, scotomata, altered mental status)
- Symptoms of liver capsule distention or rupture (right upper quadrant and/or epigastric pain)

SIGNS
- Severe elevation in blood pressure (defined as >160/110 mm Hg on two separate occasions at least 6 hours apart)
- Pulmonary edema
- Eclampsia (generalized seizures and/or unexplained coma in the setting of preeclampsia and in the absence of other neurological conditions)
- Cerebrovascular accident
- Cortical blindness
- Fetal intrauterine growth restriction (IUGR)

LABORATORY FINDINGS
- Proteinuria (>5 g/24 hours)
- Renal failure (rise in serum creatinine concentration by 1 mg/dL over baseline) or oliguria (<500 mL per 24 hours)
- Hepatocellular injury (serum transaminase levels ≥2 × normal)
- Thrombocytopenia (<100,000 platelets/mm^3)
- Coagulopathy
- HELLP syndrome (Hemolysis, Elevated Liver enzymes, Low Platelets)

pathogenesis of preeclampsia. This factor serves as a coreceptor for transforming growth factor-β (TGF-β), and its use in rats leads to a syndrome similar to severe preeclampsia.[606] Like sFlt-1, levels of sEng are elevated in the circulation of women with preeclampsia several weeks before the disease becomes evident clinically.[607]

Although an attractive hypothesis, the role of the antiangiogenic factors (sFlt-1 and sEng) in the pathogenesis of preeclampsia and the ability to use these factors to predict, diagnose, and potentially treat this disorder require further study. It is likely that preeclampsia is not a single disease entity, but rather a clinical syndrome encompassing three distinct elements:

1. New-onset hypertension (defined as a sustained sitting blood pressure of at least 140/90 mm Hg in a previously normotensive woman)
2. New-onset proteinuria (defined as greater than 300 mg/24 hours or at least 1+ on a clean-catch urinalysis in the absence of urinary infection)
3. New-onset significant nondependent edema,[585] although more recent consensus reports have eliminated edema as a criterion for the diagnosis[608]

The diagnosis of preeclampsia can only reliably be made after 20 weeks' gestation. Evidence of proteinuric hypertension prior to 20 weeks' gestation should raise the possibility of an underlying molar pregnancy,[591] multiple pregnancy,[609] drug withdrawal, antiphospholipid antibody syndrome, uniparental disomy in the placenta, or, rarely, a chromosomal abnormality (trisomy) in the fetus.[610]

Although numerous risk factors for the development of preeclampsia have now been defined (Table 28.9),[585,609,611-620] it is not possible to predict with any certainty which pregnancies are going to be complicated by this disease.[621,622] Moreover, despite intensive research efforts, there is no effective way at this juncture in time to prevent the development of preeclampsia in women at high risk.[622,623] As such, the current focus of obstetric care providers is regular prenatal visits with routine blood pressure and urinary protein screening with a view to early identification of preeclampsia followed by aggressive and gestational age-appropriate management.

Preeclampsia is classified as either *mild* or *severe*. A diagnosis of severe preeclampsia should be entertained in women with new-onset proteinuric hypertension accompanied by one or more of a series of complications (Box 28.13). It should be emphasized that only *one* such criterion is required for the diagnosis of severe preeclampsia. Fetal IUGR was excluded from the criteria in 2000 by the National High Blood Pressure in Pregnancy Working Group[608] because of inconsistencies in its definition, but was still included as a criterion for the diagnosis of severe preeclampsia by ACOG in 2002.[585] Mild preeclampsia includes all women with preeclampsia who do not have any features of severe disease.

The only definitive treatment of preeclampsia is delivery of the fetus and placenta to prevent potential maternal complications. Delivery is recommended for women with mild preeclampsia at or near term. In contrast, delivery should be recommended for all women with severe preeclampsia, regardless of gestational age.[585] That said, there are three situations in which expectant management of women with severe preeclampsia may be appropriate:

1. Severe proteinuria (greater than 5 g in 24 hours), because this finding alone is not associated with serious maternal or fetal sequelae[624]
2. Mild IUGR (fifth to tenth percentile) remote from term, as long as antepartum fetal testing remains

reassuring, oligohydramnios is not severe, umbilical artery diastolic flow is not reversed on Doppler velocimetry, and there is progressive fetal growth

3. Severe preeclampsia by blood pressure criteria alone before 32 weeks' gestation that is managed with antihypertensive therapy[625,626]

The rationale for delaying delivery in these pregnancies is to reduce perinatal morbidity and mortality by delivery of a more mature fetus and, to a lesser degree, to achieve a more favorable cervix for vaginal birth. The risk of prolonging pregnancy is continued poor perfusion of major organs in both the mother and fetus, with the potential for severe end organ damage to the brain, liver, kidneys, placenta and fetus, and hematological and vascular systems. Delivery should be initiated—after a course of antenatal corticosteroid therapy, if possible—when there is poorly controlled severe hypertension, thrombocytopenia, eclampsia, elevated liver function tests with epigastric or right upper quadrant pain, pulmonary edema, renal insufficiency, placental abruption, or persistent symptoms (severe headache or visual changes) (Box 28.13). Fetal indications for immediate delivery include nonreassuring fetal testing *(fetal distress)*, severe oligohydramnios, or severe fetal growth restriction (less than the fifth percentile).[585]

Delivery is usually by the vaginal route, with cesarean delivery reserved for appropriate obstetrical indications. Severe preeclampsia does not mandate immediate cesarean birth.[627] The decision to proceed with cesarean or induction of labor and attempted vaginal delivery should be individualized based on such factors as parity, gestational age, cervical examination (Bishop score), maternal desire for vaginal delivery, and fetal status and presentation. Cervical ripening agents may be used if the cervix is not favorable prior to induction, but prolonged inductions should be avoided.[585] The rate of vaginal delivery after labor induction decreases to about 33% at less than 34 weeks, primarily because of nonreassuring fetal testing and failure to progress in labor.[628,629]

The use of antihypertensive agents to control mildly elevated blood pressure in the setting of preeclampsia has not been shown to alter the course of the disease or diminish perinatal morbidity or mortality.[630] Indeed, such therapy may adversely affect uteroplacental perfusion, leading to reduced birth weight.[631] Moreover, the use of antihypertensive agents in preeclampsia may provide a false sense of security by masking an increase in blood pressure as a sensitive measure of worsening disease, and is therefore not generally recommended. These studies serve to confirm that hypertension is a clinical feature, and not the underlying cause, of preeclampsia.

The cause of the blood pressure elevation in preeclampsia is not clear. It has been suggested that it may represent an attempt of the body to maintain perfusion through an underperfused (ischemic) placenta, and may be triggered by a distress signal from the fetoplacental unit.[632] Although treatment of mild to moderate hypertension has not been shown to improve maternal or perinatal outcome, antihypertensive agents should be administered to prevent a maternal cerebrovascular accident from severe hypertension, which accounts for 15% to 20% of deaths from preeclampsia. The risk of hemorrhagic stroke correlates directly with the degree of elevation in systolic blood pressure (and is less related to the diastolic pressure), but there is no clear threshold systolic pressure above which emergent therapy should be instituted.[633] The National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy has recommended initiating therapy when systolic blood pressure exceeds 150 to 160 mm Hg and diastolic pressure exceeds 100 to 110 mm Hg.[608] However, this threshold has not been tested prospectively and the cerebral vasculature of women with underlying chronic hypertension can probably tolerate higher systolic pressures without injury.

The traditional drug of choice for the antepartum management of chronic hypertension is the central acting agent, methyldopa, primarily because of the extensive experience with its use during pregnancy. However, other agents have been increasing in popularity including β-blockers (primarily labetalol) and calcium channel blockers (nifedipine). Hydralazine, labetalol, and nifedipine have all been used for the management of acute hypertensive episodes in pregnancy.[585,608,630]

In term nulliparous women, the duration of labor is not affected by either preeclampsia or magnesium sulphate seizure prophylaxis.[585,634] Close and continuous monitoring of both the mother and fetus is indicated during labor to identify worsening hypertension, deteriorating maternal hepatic, renal, cardiopulmonary, and/or hematological function, as well as uteroplacental insufficiency with evidence of nonreassuring fetal testing. Anticonvulsant therapy is generally initiated during labor or while administering corticosteroids or prostaglandins prior to a planned delivery and continued until 24 to 48 hours postpartum, when the risk of seizures is decreased.

Magnesium sulfate is the drug of choice for seizure prevention.[585,632,634-637] The safety and efficacy of magnesium sulfate seizure prophylaxis was illustrated in the largest study performed on preeclamptic women, the Magpie (Magnesium Sulfate for Prevention of Eclampsia) Trial.[637] The trial followed over 10,000 pregnant women with preeclampsia (defined as blood pressures of at least 140/90 mm Hg on two occasions and proteinuria of 1+ or more) in whom the obstetric care provider was uncertain about the benefit of starting magnesium sulfate therapy. The women were randomly assigned to receive magnesium sulfate (4 g intravenous loading dose then 1 g/hour, or 5 g intramuscularly into each buttock followed by 5 g intramuscularly every 4 hours) or placebo for 24 hours. The maintenance dose was given only if a patellar reflex was present (loss of reflexes being the first manifestation of symptomatic hypermagnesemia), respirations exceeded 12 per minute, and the urine output exceeded 100 mL per 4 hours. Approximately 25% of patients met criteria for severe preeclampsia.

The major finding from this trial was that magnesium sulfate significantly reduced the risk of eclampsia as compared with normotensive controls (0.8% vs 1.9%, respectively). This reduction in eclamptic seizures was observed regardless of the severity of preeclampsia, gestational age, or parity. The data also demonstrated a reduction in maternal mortality (0.2% vs 0.4%, respectively), but no difference in maternal morbidity, perinatal mortality, and neonatal morbidity (except for a lower rate of abruption in treated women [2% vs 3.2%, respectively]). The study concludes that, to prevent one convulsion, 63 women with severe

preeclampsia or 109 women with mild preeclampsia would need to be treated. Magnesium sulfate therapy should therefore be considered for prevention of eclampsia in all women with preeclampsia, including those with mild disease.[637-639] However, some authors have questioned the value of treating all preeclamptic women to prevent seizures in only 0.6% to 3.2% of patients.[640] The incidence of seizures is much lower (approximately 0.1%) in women with nonproteinuric hypertension.[636] For this reason, it may be safe to withhold seizure prophylaxis in such women.

Hypertension due to preeclampsia resolves postpartum, often within a few days, but sometimes takes a few weeks. Elevated blood pressures that persist beyond 12 weeks postpartum are unlikely to be related to preeclampsia. Population-based retrospective cohort studies and large case-control studies have demonstrated that a history of preeclampsia confers an increased risk for future premature cardiovascular disease, and a lifetime increased risk of maternal mortality from cardiovascular causes.[641-651] The relative risk of cardiovascular disease is comparable for women with a history of preeclampsia, and women with known conventional cardiovascular risk factors such as hypertension, obesity, diabetes mellitus, and dyslipidemia, leading some to conclude that preeclampsia or gestational hypertension should be considered a known risk factor for cardiovascular disease in women.[641] Irgens and colleagues reported that women with severe preterm preeclampsia were eight times more likely to die from cardiovascular causes than women without the disease or those with mild preeclampsia, suggesting that preterm preeclampsia may be the most significant mediator of long-term morbidity and mortality.[642]

The underlying mechanisms of future cardiovascular risk in women with preeclampsia are not well understood. Similar biological mechanisms for preeclampsia and cardiovascular disease have been suggested, including inflammation, hypercoagulability, and insulin dysregulation.[652-658] Whether pregnancy acts as a "stress test," unmasking a predisposition to hypertension and cardiovascular disease that would otherwise not have been apparent until a later age,[659,660] or whether a cause-effect relationship exists between preeclampsia and the subsequent development of cardiovascular disease, remains unclear. The finding that women with preeclampsia have a higher prevalence of chronic hypertension as early as 6 months postpartum suggests that early-onset hypertension may be one of the mechanisms by which preeclampsia increases the risk for long-term cardiovascular sequelae.[661] Studies have demonstrated that levels of sFLT-1 remain elevated an average of 18 months postpartum in women with a history of preeclampsia, and markers of endothelial activation may remain elevated for over 15 years after preeclampsia.[658,662] The persistence of an anti-angiogenic milieu long after pregnancy may contribute to these women's predisposition to develop cardiovascular disease.[663]

Parturition

Labor is the physiological process by which the products of conception are passed from the uterus to the outside world (see also Chapter 12). The definition of labor includes an increase in myometrial activity or, more precisely, a switch in the myometrial contractility pattern from irregular *contractures* (long-lasting, low-frequency activity) to regular *contractions* (high-intensity, high-frequency activity)[664] leading to effacement and dilatation of the uterine cervix. An initial cervical examination of at least 2 cm dilatation or at least 80% effacement in the setting of regular phasic uterine contractions is also accepted as being sufficient for the diagnosis of labor in nulliparous women. A bloody discharge ("show") is often included in the description of labor, but is not a prerequisite for the diagnosis.

Considerable evidence suggests that, in most viviparous animals, the fetus is in control of the timing of labor.[665-672] Horse-donkey crossbreeding experiments performed in the 1950s, for example, resulted in a gestational length intermediate between that of horses (340 days) and that of donkeys (365 days), suggesting a role for the fetal genotype in the initiation of labor.[667,670] However, the factors responsible for the initiation and maintenance of labor in humans remain poorly defined. The slow progress in our understanding of the biochemical mechanisms involved in the process of labor in humans reflects, in large part, the difficulty in extrapolating from the endocrine control mechanisms in various animals to the paracrine and autocrine mechanisms of parturition in humans—processes which, in humans, preclude direct investigation.

Regardless of whether the trigger for labor begins within the fetus or outside the fetus, the final common pathway for labor ends in the maternal tissues of the uterus and is characterized by the development of regular phasic uterine contractions. As in other smooth muscles, myometrial contractions are mediated through the ATP-dependent binding of myosin to actin. This process is dependent in large part on the phosphorylation of myosin light chain by a calcium-dependent enzyme, myosin light chain kinase. In contrast to vascular smooth muscle, however, myometrial cells have a sparse innervation that is further reduced during pregnancy.[673] The regulation of the contractile mechanism of the uterus is therefore largely humoral and dependent on intrinsic factors within myometrial cells.

A "parturition cascade" likely exists in the human (Fig. 28.18), responsible for the removal of mechanisms maintaining uterine quiescence and for the recruitment of factors acting to promote uterine activity.[672] Given its teleological importance, such a cascade would likely have multiple redundant loops to ensure a fail-safe system of securing pregnancy success and ultimately the preservation of the species. In such a model, each element is connected to the next in a sequential fashion, and many of the elements demonstrate positive feed-forward characteristics typical of a cascade mechanism. A comprehensive analysis of each of the individual paracrine and autocrine pathways implicated in the process of labor has been reviewed in detail elsewhere.[665,667-669,672,674]

In brief, human labor is a multifactorial physiological event involving an integrated set of changes within the maternal tissues of the uterus (myometrium, decidua, and uterine cervix) that occur gradually over a period of days to weeks. Such changes include, but are not limited to, an increase in prostaglandin synthesis and release within the uterus, an increase in myometrial gap junction formation, and upregulation of myometrial oxytocin receptors (uterine activation). Once the myometrium and cervix are prepared, endocrine or paracrine and autocrine factors from

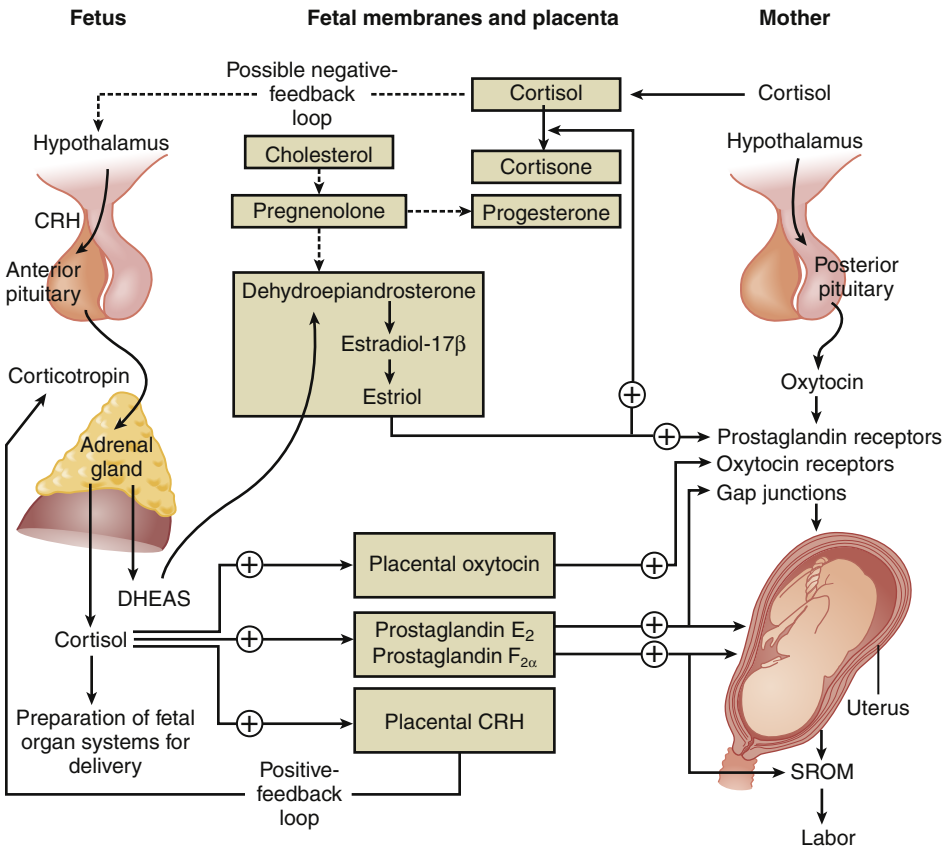

FIGURE 28.18 Proposed mechanism of labor induction at term. The major hormones and paracrine/autocrine factors responsible for promoting uterine contractions at term in an integrated parturition cascade are shown. Plus signs indicate activation or up-regulation. CRH, corticotropin-releasing hormone; DHEAS, dehydroepiandrosterone sulfate; SROM, spontaneous rupture of fetal membranes. *(Adapted from Norwitz ER, Robinson JN, Challis JRC. The control of labor.* N Engl J Med *341:660, 1999.)*

the fetoplacental unit bring about a switch in the pattern of myometrial activity from irregular contractures to regular contractions (uterine stimulation). The fetus may coordinate this switch in myometrial activity through its influence on placental steroid hormone production, through mechanical distention of the uterus, and through secretion of neurohypophyseal hormones and other stimulators of prostaglandin synthesis.

The final common pathway for the initiation of labor appears to be activation of the fetal hypothalamic-pituitary-adrenal axis, resulting in an increase in C-19 steroid (DHEA) production from the intermediate (fetal) zone of the fetal adrenal, the primary substrate for estrogen synthesis in the placenta. This activity is necessary because the human placenta is an incomplete steroidogenic organ, and estrogen synthesis by the placenta has an obligate need for C-19 steroid precursor from the fetus.[669] In the rhesus monkey, infusion of C19 precursor (androstenedione) leads to preterm delivery.[675] This effect is blocked by concurrent infusion of an aromatase inhibitor,[676] demonstrating that conversion to estrogen is important. However, systemic infusion of estrogen failed to induce delivery, suggesting that the action of estrogen is likely paracrine-autocrine.[675,677,678]

In humans, activation of the fetal HPA axis results in increased estrogen production, which is responsible for upregulating myometrial gap junctions and preparing the myometrium for contractions and labor.[679] The major estrogen produced in the human placenta is estriol, which is found in concentrations 10 to 20 times higher than other estrogens. Unlike other estrogens that are made primarily by maternal tissues, estriol is produced almost exclusively by fetal and placental tissues. Because estriol passes easily from the placenta to the maternal circulation, its relative concentrations in serum and saliva have been used as a direct marker of the activity of the fetal HPA axis.[680] Estriol is detectable as early as 9 weeks' gestation, and increases gradually after 30 weeks with a rapid rise prior to the onset of labor.[681,682] This surge in circulating estriol levels occurs approximately 3 to 5 weeks prior to the onset of labor, both at term and preterm,[682,683] but does not occur in patients requiring induction of labor or whose pregnancies are complicated by premature rupture of membranes in the absence of labor.[684] Although critical for the maintenance of early pregnancy, the role of progesterone in the latter half of pregnancy and in labor is less clear. Unlike most other mammalian species, systemic progesterone withdrawal is not a prerequisite for labor in humans[685] and the administration of a progesterone antagonist at term does not result in labor.[686,687]

The exact mechanism responsible for activation of the fetal HPA axis at term remains unclear although changes in corticotropin releasing hormone (CRH) seem to be important. McLean and colleagues suggested that CRH may serve as a "placental clock" that controls the length of gestation, and that elevated levels of CRH in the maternal circulation may predict the timing of labor and delivery.[688] Unlike total CRH levels, CRH bioactivity does not increase throughout gestation due to increased production of CRH binding protein (CRH-BP) by the liver. Approximately 3 to 5 weeks before the onset of labor, levels of CRH-BP in the maternal circulation fall precipitously leading to an increase in free (biologically active) circulating CRH.[688]

The CRH gene is expressed in the human placenta. CRH is found in low concentrations in nonpregnant women, rises in the 2nd and 3rd trimesters of pregnancy, and rises exponentially in the last 3 to 5 weeks of pregnancy for both term and preterm births.[314,689,690] Fetal and maternal glucocorticoids, such as cortisol, stimulate placental CRH production.[691,692] In response, CRH stimulates the production of corticotropin (ACTH) in the mother and fetus resulting in further cortisol release. Thus, a positive feed forward system is initiated that results ultimately in the onset of labor.[693]

The mean duration of human singleton pregnancy is 280 days (40 weeks), dated from the first day of the last normal menstrual period. A term pregnancy is defined as the period from 37 weeks (259 days) to 41 weeks, 6 days (293 days). Preterm (premature) labor is defined as labor occurring prior to 37 weeks of gestation.

Preterm Labor

Preterm birth occurs in 7% to 12% of all deliveries, but accounts for over 85% of all perinatal morbidity and mortality.[694,695] Preterm labor likely represents a syndrome rather than a diagnosis because the etiologies are varied. Approximately 20% of preterm deliveries are iatrogenic and are performed for maternal or fetal indications, including IUGR, preeclampsia, placenta previa, and nonreassuring fetal testing.[696] Of the remaining cases, approximately 30% occur in the setting of preterm premature rupture of the membranes, 20% to 25% result from intraamniotic inflammation and/or infection, and the remaining 25% to 30% are due to spontaneous (unexplained) preterm labor.

Spontaneous preterm labor may reflect a breakdown in the normal mechanisms responsible for maintaining uterine quiescence[665] or a short-circuiting or overwhelming of the normal parturition cascade.[672] The demonstration of endocrine differences, sequence divergence in pregnancy-related genes, and distinctive physiological changes of pregnancy in different mammalian species suggest that human parturition is unique.[697] Evolutionary adaptations associated with human pregnancy may at times provide protection against, and at times promote, preterm birth.[697] Human gestation is relatively long compared to other species, and in the setting of an infected or compromised gestation, preterm birth may provide an evolutionary advantage. An important feature of the proposed parturition cascade would be the ability of the fetoplacental unit to trigger labor prematurely if the intrauterine environment became hostile and threatened the well-being of the fetus. For example, up to 25% of preterm births are thought to result from intraamniotic infection.[696,698,699] In many patients with infection, elevated levels of lipoxygenase and cyclooxygenase pathway products can be demonstrated.[698,700,701] There are also increased concentrations of cytokines in the amniotic fluid of such women. Cytokines and eicosanoids appear to interact and to accelerate each other's production in a cascade-like fashion, which may act to overwhelm the normal parturition cascade and result in preterm labor. Recently, thrombin has been shown to be a powerful uterotonic agent,[702,703] providing a physiological mechanism for preterm labor secondary to placental abruption.

Numerous risk factors for preterm birth have been identified (Box 28.14), and several tests have been developed in an attempt to predict women at risk of preterm delivery (Box 28.15).[247,688,704-718] Prevention of preterm labor, however, has been largely unsuccessful (Box 28.16).[719-722] Improvements in perinatal outcome during this same time period have resulted primarily from antepartum corticosteroid administration and from advances in neonatal care.

Box 28.14 Risk Factors for Preterm Delivery

NONMODIFIABLE RISK FACTORS

- Prior preterm birth
- African-American race
- Social stress
- Age <18 years or >40 years
- Poor nutrition
- Low prepregnancy weight
- Low socioeconomic status
- Absent prenatal care
- Cervical injury or anomaly
- Uterine anomaly or fibroid
- Excessive uterine activity
- Premature cervical dilatation (>2 cm) or effacement (>80%)
- Overdistended uterus (twins, polyhydramnios)
- Vaginal bleeding

MODIFIABLE RISK FACTORS

- Cigarette smoking
- Illicit drug use
- Anemia
- Bacteriuria/urinary tract infection
- Lower genital tract infections (including bacterial vaginosis, *Neisseria gonorrhoea, Chlamydia trachomatis*, Group B streptococcus, *Ureaplasma urealyticum*, and *Trichomonas vaginalis*)
- Gingival disease
- Strenuous work
- High personal stress

Guidelines for the management of preterm labor are summarized in Box 28.17. In many instances, premature labor represents a necessary escape of the fetus from a hostile intrauterine environment and, as such, aggressive intervention to stop labor may be counterproductive. Every effort should be made to exclude contraindications to expectant management and tocolysis, including, among others, intrauterine infection, unexplained vaginal bleeding, non-reassuring fetal testing, and intrauterine fetal demise. Bed-rest and hydration are commonly recommended for the treatment of preterm labor, but without confirmed efficacy.[719,723] Although there is substantial data that broad-spectrum antibiotic therapy can prolong latency in the setting of preterm premature rupture of the membranes remote from term, there is no consistent evidence that such an approach can delay delivery in women with preterm labor and intact membranes.[724]

Pharmacological tocolytic therapy remains the cornerstone of management for acute preterm labor. Although a number of alternative agents are now available (Table 28.10),[672,725-728] there are no reliable data to suggest that any of these agents are able to delay delivery in women presenting with preterm labor for longer than 48 hours. Because no single agent has a clear therapeutic advantage, the adverse effect profile of each of the drugs will often determine which to use in a given clinical setting.

Box 28.15 Efficacy of Screening Tests Used to Identify Women at High Risk for Preterm Delivery

RISK FACTOR SCORING

Risk factor scoring systems based on historical factors, epidemiological factors, and daily habits have been developed in an attempt to predict women at risk of preterm birth. However, reliance on risk factor-based screening protocols alone will fail to identify over 50% of pregnancies that deliver preterm (low sensitivity) and the majority of women who screen positive will ultimately deliver at term (low positive predictive value).[247,704]

HOME UTERINE ACTIVITY MONITORING (HUAM)

HUAM of women at high risk of preterm delivery has not been shown to reduce the incidence of pre-term birth.[710] Such an approach, however, does increase antepartum visits, obstetric intervention, and the cost of antepartum care.[710] There is no role for HUAM to prevent preterm birth.

CERVICAL ASSESSMENT (DIGITAL AND SONOGRAPHIC EXAMS)

Serial digital evaluation of the cervix in women at risk for preterm delivery is useful if the exam remains normal. However, an abnormal cervical exam (shortening and/or dilatation) is associated with preterm delivery in only 4% of low-risk women and 12% to 20% of high-risk women.[714]

Ultrasound has demonstrated a strong inverse correlation between cervical length and pre-term birth.[706,709] If the cervical length is below the 10th percentile for gestational age, the pregnancy is at a sixfold increased risk of delivery prior to 35 weeks.[709] A cervical length of <15 mm at 23 weeks occurs in under 2% of low-risk women, but is predictive of delivery prior to 28 weeks and 32 weeks in 60% and 90% of cases, respectively.[706]

BIOCHEMICAL MARKERS (FETAL FIBRONECTIN)

Elevated level of fetal fibronectin (fFN) in cervicovaginal secretions is associated with preterm delivery.[712]

However, in a low-risk population, the positive predictive value of a positive fFN test at 22 to 24 weeks' gestation for spontaneous preterm delivery prior to 28 weeks and 37 weeks is only 13% and 36%, respectively.[705] The value of this test lies in its negative predictive value (99% of patients with a negative fFN test will not deliver within 7 days[708]), which may prevent unnecessary hospitalization.

ENDOCRINE MARKERS (SALIVARY ESTRIOL, CORTICOTROPIN-RELEASING HORMONE)

Salivary estriol accurately mirrors the level of biologically active (unconjugated) estriol in the maternal circulation.[680] Elevated levels of estriol in maternal saliva (>2.1 ng/mL) is predictive of delivery prior to 37 weeks in a high-risk population with a sensitivity of 68% to 87%, a specificity of 77%, and a false-positive rate of 23%.[707,713]

Corticotropin-releasing hormone (CRH) can stimulate prostaglandin production from the decidua and fetal membranes,[711] and can potentiate the contractile effects of oxytocin and prostaglandins on the myometrium.[715] Maternal plasma CRH levels increase and CRH-BP levels decrease prior to the onset of labor, both at term and preterm, resulting in a marked increase in bioactive CRH. Some authorities have proposed that CRH may serve as a "placental clock" that controls the duration of pregnancy, and that measurement of plasma CRH levels in the late second trimester may predict the onset of labor.[688] However, recent studies have shown that such tests are not clinically useful.[433,435,716-718] In light of these data, the use of plasma CRH as a predictor of preterm labor—as well as other serum markers such as activin A—remains investigational.[717]

Box 28.16 Guidelines for the Prevention of Preterm Delivery

STRATEGIES THAT HAVE NO PROVEN EFFICACY

- Bed rest[719]
- Regular prenatal care[720]
- Treatment of asymptomatic lower genital tract infection[721]
- Treatment of gingival disease[814]

STRATEGIES THAT MAY HAVE SOME EFFICACY

- Prevention and early diagnosis of sexually transmitted diseases and genitourinary infections
- Treatment of symptomatic lower genital tract infection[722]
- Cessation of smoking and illicit substance use
- Prevention of multifetal pregnancies
- Cervical cerclage, if indicated
- Intramuscular progesterone, if indicated
- Vaginal progesterone, if indicated

Box 28.17 Guidelines for the Management of Preterm Delivery

- Confirm the diagnosis of preterm labor
- Exclude contraindications to expectant management and/or tocolysis
- Administer antenatal corticosteroids, if indicated
- Group B β-hemolytic streptococcus (GBS) chemoprophylaxis, if indicated
- Pharmacological tocolysis
- Consider transfer to tertiary care center

Maintenance tocolytic therapy beyond 48 hours has not been shown to confer any therapeutic benefit, but does pose a substantial risk of adverse effects.[518,729,730] As such, maintenance tocolytic therapy is not generally recommended. Similarly, the concurrent use of two or more tocolytic agents has not been shown to be more effective than a single agent alone, and the cumulative risk of adverse effects generally precludes this course of management.[731] In the setting of preterm premature rupture of the fetal membranes, tocolysis has not been shown to be effective and is best avoided.[732]

There is increasing evidence that prophylactic supplemental progesterone may reduce the rate of preterm birth in women at high risk. While the exact mechanism by which progestogens help prevent preterm birth is unknown, the best evidence appears to favor the following mechanisms: (1) Progesterone helps maintain uterine quiescence in the latter half of pregnancy through inhibition of the expression of contraction-associated protein genes within the myometrium, stimulation of transcription of genes that inhibit uterine contractile activity, and by decreasing synthesis of stimulatory prostaglandins and cytokines.[672,733-737] (2) Although the drop in circulating progesterone levels that

Table 28.10 Management of Acute Preterm Labor

Tocolytic Agent	Route of Administration (Dosage)	Efficacy*	Maternal Adverse Effects	Fetal Adverse Effects
Magnesium sulfate	IV (4-6 g bolus, then 2-3 g/hr infusion)	Effective	Nausea, ileus, headache, weakness	Decreased beat-to-beat variability
			Hypotension	Neonatal drowsiness, hypotonia
			Pulmonary edema	
			Cardiorespiratory arrest	? Ileus
			? Hypocalcemia	? Congenital ricketic syndrome (with treatment >3 weeks)
β-Adrenergic agonists				
-Terbutaline sulfate	IV (2 μg/min infusion to a maximum of 80 μg/min)	Effective	Jitteriness, anxiety, restlessness, nausea, vomiting, rash	Fetal tachycardia Hypotension Ileus
	SC (0.25 mg q20min)	Effective	Cardiac dysrhythmias, myocardial ischemia, palpitations, chest pain	Hyperinsulinemia, hypoglycemia (more common with isoxsuprine)
-Ritodrine hydrochloride†	IV (50 μg/min infusion to a maximum of 350 μg/min)	Effective	Hypotension, tachycardia (more common with isoxsuprine)	Hyperbilirubinemia hypocalcemia
	IM (5-10 mg q2-4hr)	Effective	Pulmonary edema Paralytic ileus Hypokalemia Hyperglycemia, acidosis	? Hydrops fetalis
Prostaglandin inhibitors				
-Indomethacin	Oral (25-50 mg q4-6hr)	Effective	Gastrointestinal effects (nausea, heartburn), headache, rash	Transient oliguria, oligohydramnios
	Rectal (100 mg q12hr)		Interstitial nephritis	Premature closure of the neonatal ductus arteriosus and persistent pulmonary hypertension
			Increased bleeding time	? Necrotizing enterocolitis, intraventricular hemorrhage
Calcium channel blockers				
-Nifedipine	Oral (20-30 mg q4-8hr)	Effective	Hypotension, reflex tachycardia (especially with verapamil) Headache, nausea, flushing Potentiates the cardiac depressive effect of magnesium sulfate Hepatotoxicity	
Oxytocin antagonists				
-Atos iban	IV (1 μM/min infusion to a maximum of 32 μM/min)	Effective	Nausea, vomiting, headache, chest pain, arthralgias	? Inhibit lactation
Phosphodiesterase inhibitor				
-Aminophylline	Oral (200 mg q6-8hr) IV (0.5-0.7 mg/kg/hr)	? Effective ? Effective	Tachycardia	Fetal tachycardia
Nitric oxide donor				
-Nitroglycerine	TD (10-50 mg q day) IV (100 μg bolus, then 1-10 μg/kg/min infusion)	Unproven Unproven	Hypotension, headache	Fetal tachycardia

*Efficacy is defined as proven benefit in delaying delivery by 24-48 hr compared with placebo or standard control.
†The only tocolytic agent approved by the Food and Drug Administration.
IM, intramuscular; IV, intravenous; SC, subcutaneous; TD, transdermal.

occurs at the onset of labor in rodents and ruminants does not occur in humans,[733] recent molecular data suggest that alterations in levels of human progesterone isoforms may result in a functional withdrawal of progesterone activity at the level of the uterus.[697,738] (3) Progesterone may help prevent preterm premature rupture of membranes (PPROM), a common cause of preterm birth, via prevention of apoptosis in fetal membrane explants.[739]

The efficacy of progesterone supplementation for prevention of preterm birth appears to depend primarily on appropriate patient selection. *In vitro* and animal research suggests that the type of progestin, formulation, dose, and delivery route may also have a significant impact on efficacy.[740,741] There are two settings in which progesterone supplementation has been shown to reduce the rate of spontaneous preterm birth: (1) Women with a history of spontaneous preterm birth, (2) women with a short cervix on ultrasound examination in the current pregnancy.

The seminal study demonstrating the benefit of intramuscular progesterone supplementation to prevent recurrent preterm birth was the Maternal Fetal Medicine Units Network trial, in which Meis and co-investigators randomized 459 women with a history of spontaneous preterm delivery to weekly intramuscular injections of

17 alpha-hydroxyprogesterone caproate (17-OHP) or placebo beginning at 16 to 20 weeks of gestation and continuing until 36 weeks.[742] Weekly progesterone supplementation was associated with a significant reduction in the rate of recurrent preterm delivery, with greatest benefit seen in women with a prior spontaneous preterm birth before 34 completed weeks of gestation. Subsequent randomized trials using vaginal progesterone preparations to prevent recurrent spontaneous preterm birth have had mixed results.[743-745] Meta-analyses of randomized trials have demonstrated that progesterone supplementation is protective against recurrent preterm birth.[746-750] The most recent meta-analysis of six randomized controlled trials demonstrated a significant reduction in preterm delivery less than 37 weeks (RR 0.77, 95% CI 0.67-0.87), less than 35 weeks (RR 0.77, 95% CI 0.63-0.96), and less than 32 weeks (RR 0.61, 95% CI 0.45-0.82), as well as reduced rates of perinatal and neonatal death, respiratory distress syndrome, and necrotizing enterocolitis in the newborn.[749] The balance of data suggests that intramuscular 17-OHP is more efficacious than vaginal progesterone for prevention of recurrent spontaneous preterm birth.[735] A randomized controlled trial including 657 nulliparous women with singleton gestations found that intramuscular 17-OHP was not efficacious in preventing preterm birth in women with a short cervix (cervical length less than 30 mm at 16 to 22 weeks).[751]

Fonseca and colleagues performed the seminal study demonstrating the benefit of vaginal progesterone supplementation to prevent preterm birth in women with sonographically short cervix.[752] These investigators randomized 413 women with cervical length of 15 mm or less to receive nightly vaginal progesterone suppositories or placebo from 24 to 34 weeks' gestation, finding that vaginal progesterone was associated with a significant decrease in spontaneous preterm delivery before 34 weeks' gestation (from 34.4% to 19.2%, RR 0.56, 95% CI 0.36-0.86). A recent meta-analysis of five randomized placebo-controlled trials, including data from 775 pregnancies, demonstrated the benefits of progesterone supplementation in women with asymptomatic short cervix on midtrimester ultrasound.[753] Treatment with vaginal progesterone in women with a singleton gestation and sonographic short cervix was associated with a significant reduction in the rate of preterm birth, and decreased neonatal morbidity and mortality. These benefits were similar at progesterone doses of 90, 100, and 200 mg daily.[753] The same meta-analysis demonstrated that in twin pregnancies with a short cervix, treatment with vaginal progesterone was associated with a nonsignificant reduction in preterm birth at less than 33 weeks' gestation, and a significant reduction in composite neonatal morbidity and mortality.

In the absence of short cervix, progesterone supplementation in twin pregnancies does not appear to be beneficial. A randomized, double-blind, placebo-controlled study found that routine administration of vaginal progesterone does not prevent early preterm birth (<34 weeks' gestation) in twin gestations.[754] This finding was confirmed in another double-blind, placebo-controlled randomized trial including 677 women.[755] Routine administration of intramuscular 17-OHP also failed to reduce the rate of preterm birth in women with twin gestations in randomized controlled trials.[756-758] Randomized controlled trials in triplet pregnancies have also failed to demonstrate efficacy of intramuscular 17-OHP in preventing preterm birth.[759,760] The mechanism leading to preterm birth in multiples may be different than that in singleton pregnancies. It has been proposed that excessive uterine stretch may precipitate preterm birth multiple gestations. If this is indeed the mechanism, a recent *in vitro* study demonstrating lack of progesterone inhibition of stretch-induced mitogen activated protein kinase (MAPK) activation or gene expression in myometrial cells may shed light on the failure of progesterone supplementation to prevent preterm birth in these cases.[761,762]

Enthusiasm for widespread use of progesterone supplementation to prevent preterm birth should be tempered by recognition that the long-term effects on both women and their offspring have not yet been fully elucidated.[763] While concerns about an increased risk of miscarriage and stillbirth in women exposed to progestins in pregnancy[742,754,756,764] have largely been laid to rest,[759,760,765] concern persists regarding a potential increased incidence of hypospadias in male fetuses exposed to exogenous progestins before 11 weeks' gestation.[766,767] Recent work has demonstrated that a negative-feedback loop involving inhibitory transcription factors zinc finger E-box binding homeobox proteins 1 and 2 (ZEB1 and ZEB2) and members of the microRNA (miRNA)-200 family may mediate the effect of progesterone on contraction-associated proteins in the uterus during pregnancy.[736] Caution should be used, however, when targeting the ZEB-miRNA-200 loop for therapeutic intervention, as it has also been implicated in cancer progression.[737,768]

Postterm Pregnancy

Postterm (prolonged) pregnancy refers to a pregnancy that has extended to or beyond 42 weeks (294 days) of gestation. Approximately 10% (range 3% to 14%) of all singleton pregnancies continue beyond 42 weeks of gestation and 4% (2% to 7%) continue beyond 43 completed weeks in the absence of obstetric intervention.[769] Accurate pregnancy dating is critical to the diagnosis. The lowest incidence of postterm pregnancy is reported in studies using routine sonography for confirmation of gestational age.[770]

Although the majority of postterm pregnancies have no known cause, an explanation may be found in a minority of cases. Primiparity and prior postterm pregnancy are the most common identifiable risk factors for prolongation of pregnancy.[769,771,772] Genetic predisposition may also play a role,[771,772] as concordance for postterm pregnancy is higher in monozygotic twins than dizygotic twins.[773] Women who themselves are a product of a prolonged pregnancy are at 1.3-fold increased risk of having a prolonged pregnancy, and recurrence for prolonged pregnancy is increased twofold to threefold in women who previously delivered after 42 weeks.[774,775] Rarely, postterm pregnancy may be associated with placental sulfatase deficiency or fetal anencephaly (in the absence of polyhydramnios) or CAH.[776]

Perinatal mortality after 42 weeks of gestation is twice that at term (4 to 7 versus 2 to 3 deaths per 1,000 deliveries), and is increased fourfold at 43 weeks and fivefold to sevenfold at 44 weeks compared with 40 weeks.[776-778] Uteroplacental insufficiency, asphyxia (with and without meconium), intrauterine infection, and "fetal dysmaturity (postmaturity) syndrome" (which refers to chronic IUGR

due to uteroplacental insufficiency) all contribute to the excess perinatal deaths. Postterm infants are larger than term infants, with a higher incidence of macrosomia (2.5% to 10% vs 0.8% to 1%).[779,780] Complications associated with fetal macrosomia include prolonged labor, cephalopelvic disproportion, and shoulder dystocia with resultant risks of orthopedic or neurological injury. Prolonged pregnancy does not appear to be associated with any long-term neurological or behavioral sequelae.[781]

Postterm pregnancy is also associated with risks to the mother, including an increase in labor dystocia (9% to 12% vs 2% to 7% at term), an increase in severe perineal injury related to macrosomia (3.3% vs 2.6% at term), and a doubling in the rate of cesarean delivery.[744,782,783] The latter is associated with higher risks of complications such as endometritis, hemorrhage, and thromboembolic disease.

The management of postterm pregnancy should include confirmation of gestational age, antepartum fetal surveillance, and induction of labor if spontaneous labor does not occur. Postterm pregnancy is a universally accepted indication for antenatal fetal monitoring.[769,770,784] However, the efficacy of this approach has not been validated by prospective randomized trials.[770] No single method of antepartum fetal testing has been shown to be superior.[770,785] ACOG has recommended that antepartum fetal surveillance be initiated between 41 and 42 weeks of gestation, without a specific recommendation regarding type of test or frequency.[769,784] Many investigators would advise twice-weekly testing with some evaluation of amniotic fluid volume.

Delivery is typically recommended when the risks to the fetus by continuing the pregnancy are greater than those faced by the neonate after birth. In high-risk pregnancies, the balance appears to shift in favor of delivery at around 38 to 39 weeks of gestation. Management of low risk pregnancies is more controversial. Factors that need to be considered include results of antepartum fetal assessment, favorability of the cervix, gestational age, and maternal preference after discussion of the risks, benefits, and alternatives to expectant management with antepartum monitoring versus labor induction. Delivery should be affected immediately if there is evidence of fetal compromise or oligohydramnios.[786,787]

In low-risk postterm gravida, both expectant management and labor induction are associated with low complication rates. However, the risk of unexplained intrauterine fetal demise—which, in one large series, was 1 in 926 at 40 weeks, 1 in 826 at 41 weeks, 1 in 769 at 42 weeks, and 1 in 633 at 43 weeks[788]—disappears after a fetus is delivered. Hannah and colleagues[789] randomly assigned 3407 low-risk women with uncomplicated singleton pregnancies at 41 weeks of gestation to induction of labor (with or without cervical ripening) within 4 days of randomization or expectant management until 44 weeks. Elective induction resulted in a lower cesarean delivery rate (21.2% vs 24.5%, respectively), primarily related to fewer surgeries performed for nonreassuring fetal testing. These findings have been confirmed by a subsequent large randomized clinical trial.[790] In addition, a meta-analysis of 26 trials of routine versus selective induction of labor in postterm patients found that routine induction after 41 weeks was associated with a lower rate of perinatal mortality (OR 0.20; 95% CI, 0.06- 0.70) and no increase in the cesarean delivery rate.[785,791] Taken together, these data suggest that there does appear to be an advantage to routine induction of labor at 41 weeks of gestation, using cervical ripening agents when indicated, regardless of parity or method of induction.

Stephen H. Culp

Breast Cancer

Etiology

The development of *de novo* cancer is a complex process involving several mutational and epigenetic events. Hanahan and Weinberg delineated six key requirements for cancer to develop: "sustaining proliferative signaling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, and activating invasion and metastasis."[1] These attributes allow "cancer cells to generate their own mitogenic signals, resist exogenous growth-inhibitory signals, evade apoptosis, proliferate without limits (i.e., to undergo immortalization), undergo angiogenesis and, in more advanced cancers, invade and metastasize."[1]

Genome wide analyses suggest that multiple mutations are present in breast cancer, some of which regulate the six key pathways and some that are merely bystanders.[2] Vogelstein and his colleagues have coined the term: *driver mutations* for those that regulate the six key processes and *passenger mutations* for the bystanders.[2,3] The Vogelstein group identified 167 mutated genes in the breast cancers examined, with 14 considered to be candidate "driver" genes and the other 153 "passenger" genes. These mutations probably alter no more than 20 key signaling pathways.[3] This dynamic of cancer development is consistent with the idea that a large number of mutations, each associated with a small growth or cell death advantage, drive tumor progression.[4] Based upon these concepts, the specific signaling pathways altered by mutations are considered more important for emphasis than identification of individual mutations.

A number of specific mutations have been associated with an increased incidence of breast cancer.[5] Whole genome and GWAS (gene wide association studies) have identified more than 20 mutations, each of which impart only a small increase in frequency of breast cancer in the populations studied.[6-11] The most common include *BrCa1* and *BrCa2*, *FGFR2*, *IKBKE*, *ATM*, *BRIP-1*, *BR1P1*, and *TP53* genes.[12-18] Mutations of the BrCa1 and BrCa2 genes are associated with approximately 5% of breast cancer cases.[19] Rarer genetic syndromes include mutations of the p53 gene in the Li-Fraumeni syndrome; impaired cell cycle check point surveillance in the ataxia-telangiectasia syndrome (ATM); mutations in the *PTEN* gene in the Cowden syndrome; the *MLH1/MSH2* genes in the Muir-Torre syndrome; a *STK 11* mutation the Peutz-Jeaghers syndrome and *Chek 2* mutations.[5] Studies in identical twins suggest that approximately 27% of breast cancers are associated with genetic factors but the specific genes are unknown in 22% of these.[20]

Risk Factors

Dietary, Environmental, and Lifestyle Factors

As key roles in breast cancer etiology, these factors contribute to the fourfold differences in incidence between Japan with a rate of 23 women per 100,000 per year and the United States at 90/100,000 per year.[21-25] Epidemiological observations suggest a role for high fat diet, alcohol, exercise, and obesity in the genesis of breast cancer.[13,26,27] In Japan, the rate of breast cancer peaks at the age of menopause but in the United States, incidence continues to increase until age 90. The difference in postmenopausal patterns may result from the increase in obesity and associated aromatase increments in women in the United States compared to Japan. This differential breast cancer rate does not appear genetic since Japanese women who move to the United States experience an increased rate of breast cancer that later approaches that of North American women.

Hormonal Factors

Hormonal factors and particularly estrogens contribute to the development of breast cancer. Administration of exogenous estrogens to various animal species results in breast neoplasms.[28] Spontaneous development of breast cancer in aging rats can be prevented by oophorectomy or administration of aromatase inhibitors to block estrogen production. As outlined in Figure 29.1, epidemiological studies implicate several hormonal factors which are associated with an increased incidence of breast cancer.

Intensity of Estrogen Exposure

The majority of risk factors for breast cancer relate to the duration or intensity of a woman's exposure to endogenous or exogenous estrogens (Fig. 29.1). Early menarche and/or late menopause increase breast cancer risk.[29] Elevations

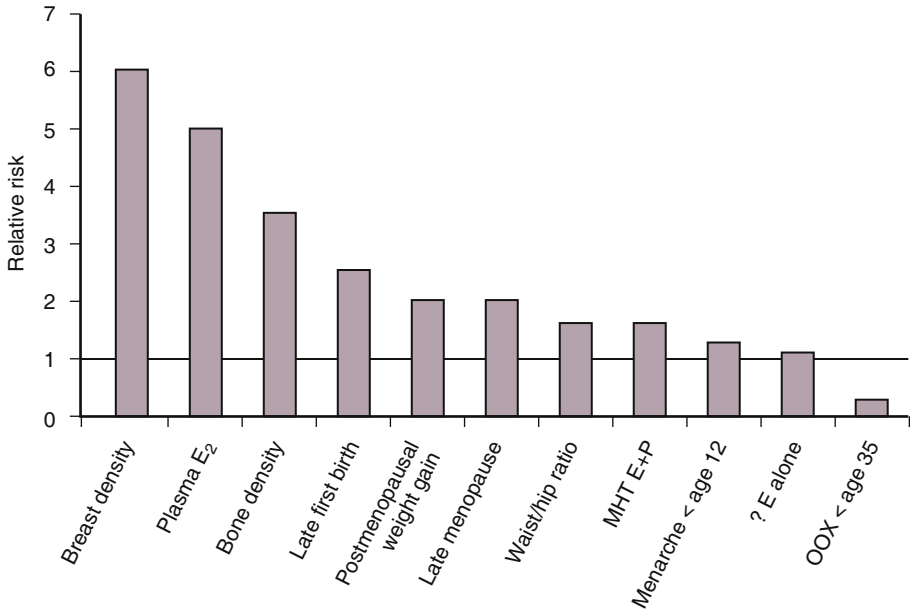

FIGURE 29.1 Relative risk of breast cancer as a function of several factors which relate to the long-term exposure to estradiol (E_2). The question mark indicates data are conflicting, but the bar represents the majority opinion. E, estrogen; MHT, menopausal hormone therapy; OOX, oophorectomy; P, progestine. *(From Santen R. Endocrine–responsive cancer. In Kronenberg HM, Melmed S. Polonski KS, Larsen PR [eds].* Williams Textbook of Endocrinology, *11th ed, Philadelphia, WB Saunders, 2008, Figure 42.2.)*

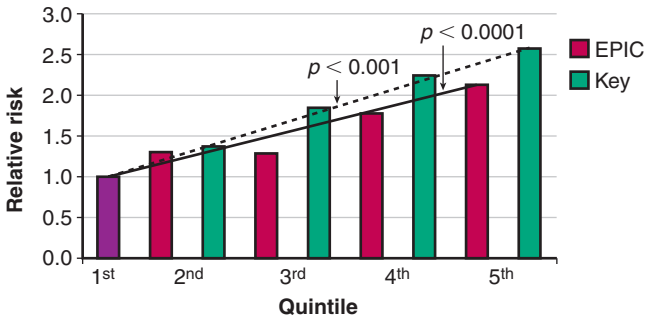

FIGURE 29.2 Risk of breast cancer related to levels of free plasma estradiol (i.e., non-sex-hormone bound estradiol) in postmenopausal women. The relative risk of breast cancer is related to the levels of free plasma estradiol divided into quintiles for the first to the fifth quintile. The solid and dotted lines indicate the trend analyses of increased relative risk versus the quintile of estradiol. *(Adapted from [30; 31.] Reprinted with the permission of the Endocrine Society from Yager JD and Santen RJ. Mechanisms relating estrogens to breast cancer,* Translational Endocrinology and Metabolism *3[1]:75–93, 2012.)*

in circulating estradiol levels predict the risk of developing breast cancer over the ensuing years in postmenopausal women (Fig. 29.2).[30-31] Estrogen levels provide information independent of other known risk factors.[32] An estradiol in the top quintile may increase the relative risk of breast cancer by threefold to fivefold (Fig. 29.2).[30,31,33] An index weighing several circulating estrogens (E1, E2, E3, E1-S, E2-S) provides a higher estimate of risk than estradiol alone.[34] Estrogen metabolites, which do not act through the estrogen receptor, are also associated with an increased risk of breast cancer. For example, weighted averages of several estradiol metabolites involving the 4-hydroxylation pathway predict a greater risk of breast cancer than levels of E2 alone.[35]

Putative markers of long-term estrogen exposure such as bone density are also predictive. Women in the top quartile of bone density have a threefold increased risk of breast cancer (Fig. 29.1); a history of fracture or height loss lowers the risk.[36-37] Late first birth increases the risk 2.8-fold and is believed to relate to the lack of the differentiating effect of pregnancy on type of breast lobule present.[38] Gain of at least 20 kg as an adult increases breast cancer risk twofold and weight loss reduces the risk.[21,39] Increased waist-hip ratio exerts a similar increase in risk.[22] Combined analyses of multiple studies indicate that alcohol intake can increase the risk of breast cancer, perhaps by decreasing the clearance of estradiol.[26] Increased exposure to estradiol *in utero*, as shown by twin studies, may increase risk of breast cancer by as much as twofold. Early pregnancy and prolonged duration of breastfeeding diminish the risk.[27] More dramatic is the 75% reduction in risk caused by bilateral oophorectomy before age 35 or use of anti-estrogens by premenopausal and postmenopausal women.[40-43]

Sources of Estrogen

The estradiol present in breast tissue is synthesized in three sites: the ovary, extra-glandular tissues, and the breast itself. Direct glandular secretion by the ovary results in delivery of estradiol to the breast through an endocrine mechanism in premenopausal women. After the menopause, extra-glandular production of estrogen from ovarian and adrenal androgens in fat and muscle provides the second source of estradiol. Thirdly, the breast itself can synthesize estradiol via aromatization of androgens to estrogens, cleavage of estrone-sulfate to free estrone via the enzyme sulfatase, and conversion of estrone to estradiol via 17βOH-HSD. Classic studies involving infusion of radiolabeled androgens and estrogens into women provide direct evidence of both *in situ* production in breast and uptake from plasma.[44] Recent studies relating plasma estrogen levels to expression of estrogen responsive genes in breast tumor tissue suggest that ER mediated uptake might predominate over *in situ* synthesis.[45] Several factors regulate *in situ* estradiol synthesis but the most important is the degree of obesity which increases the amount of aromatase in breast and consequently, estradiol production. The mechanism for obesity related induction of aromatase involves leptin, adiponectin, and AMP-kinase which allow CRTC2 to become detached

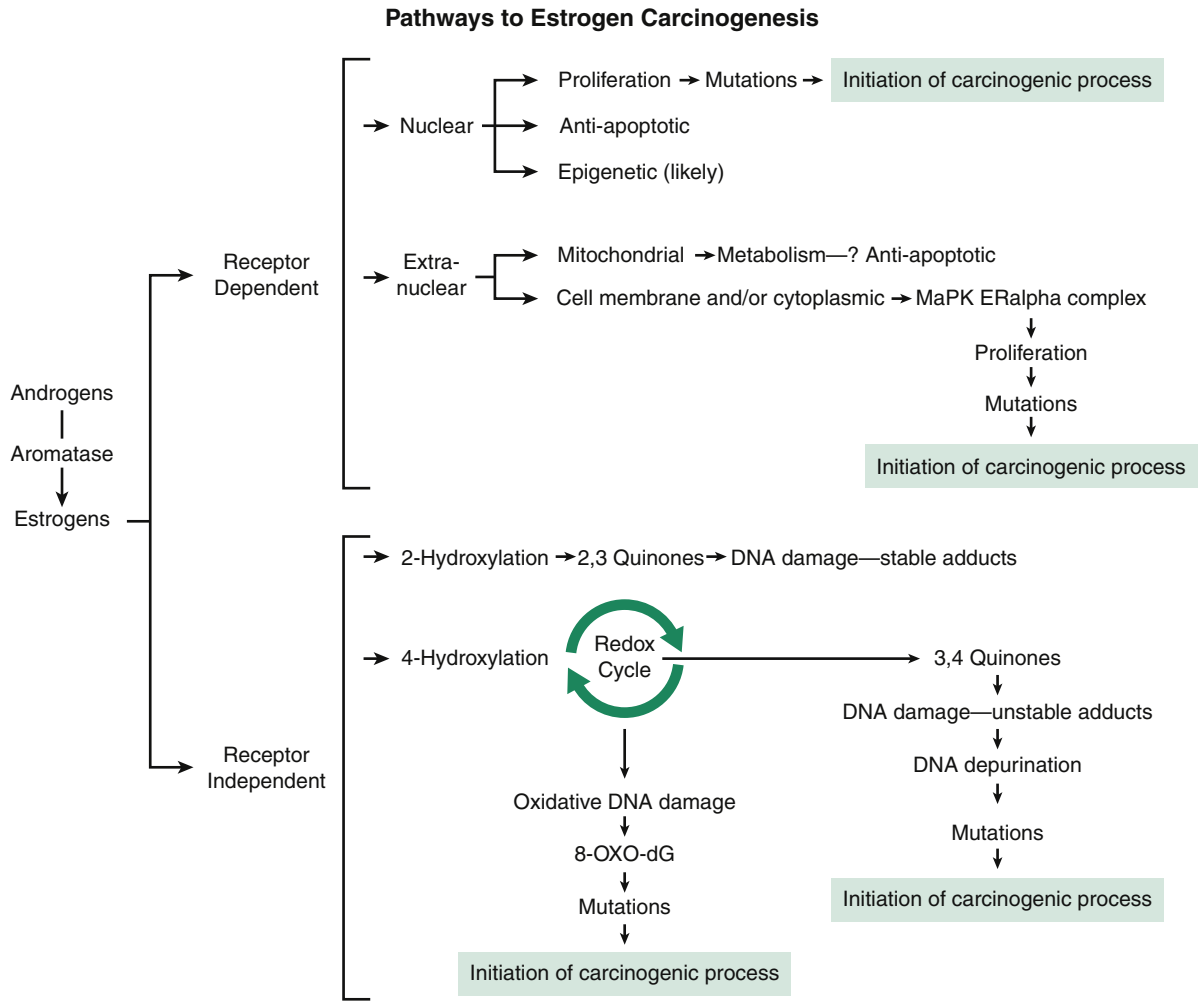

FIGURE 29.3 Diagrammatic pathway to illustrate the ER dependent and ER independent mechanisms whereby estrogens contribute to the development of breast cancer. ER, estrogen receptor. *(Reprinted with the permission of the Endocrine Society from Yager JD and Santen RJ. Mechanisms relating estrogens to breast cancer,* Translational Endocrinology and Metabolism *3[1]:75–93, 2012.)*

from a 14-3-3 protein, and enter the nucleus to increase aromatase transcription.[46]

Estrogen Induced Carcinogenesis

The precise mechanisms for estrogen induced carcinogenesis are becoming better understood. Current data suggest that both ERα dependent and independent mechanisms are involved in the initiation of *de novo* breast cancer (Fig. 29.3).[28,47] Via ERα, estradiol increases the rate of proliferation of breast cells through nuclear transcriptional mechanisms and through extranuclear effects resulting from activation of MAP kinase. After entering the nucleus, activated MAP kinase and ERα bind to estrogen response elements (ERE) on the DNA cistrome.*[48] ERα also binds to separate ERE sites both in the absence of MAP kinase or through tethering, to adaptor protein-1 (AP-1) and specificity protein-1 (SP-1) proteins to induce additional proliferation stimulatory genes.

As the number of cell divisions increase through accelerated proliferation, the frequency of mutations is enhanced pari passu.[47] As a contributory factor, less time is available for DNA repair when cells are dividing rapidly. Estrogens also enhance tumor promotion by increasing the rate of propagation of mutated cells. Enhanced cell proliferation is considered to be a key feature of the carcinogenic process, not just in the breast, but in several organs. These steps are generally considered the primary processes by which estrogens initiate mutations which ultimately lead to neoplastic transformation.[47]

Accumulating evidence implicates estrogen metabolism as an additional mutagenic process in breast but this mechanism is not fully proven and remains controversial. ERα independent mutational effects of estrogen involve metabolites of estradiol which may directly damage DNA through a pathway involving the CYP 1B1 cytochrome p450 enzyme (Fig. 29.3).[28] This p450 enzyme catalyzes conversion of estradiol to 4-0H-estradiol, a catechol-estrogen which is then further metabolized to 3, 4 estradiol-quinone. This highly reactive species binds covalently to guanine or adenine

*Cistrome is defined as the set of cistrons within the genome where a cistron is a type of gene which contains a cis-acting target (DNA binding site) of a trans-acting factor (e.g., transcription factor, pioneer factor, restriction enzyme, etc.) and promotes transcription of a unique series of genes involved in proliferation.

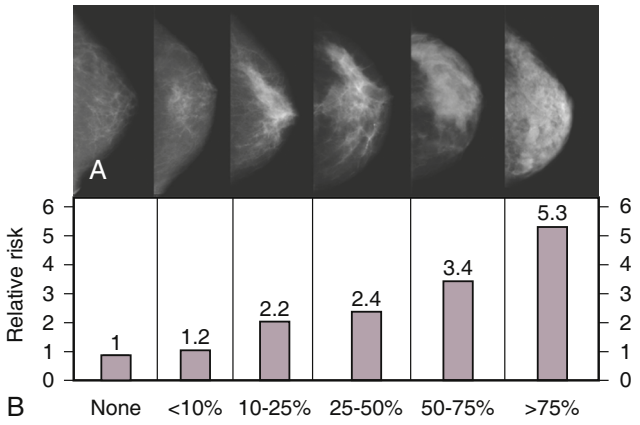

FIGURE 29.4 Relative risk of breast cancer as a function of the degree of mammographic density. **A,** Six categories of breast density as illustrated by mammograms. **B,** Relative risk of breast cancer for each category of density. *(From Boyd NF, Bying JW, Jong RA, et al. Quantitative classification of mammographic densities and breast cancer risk: results from the Canadian National Breast Screening Study,* J Natl Cancer Inst *87[9]:670–675, 1995.)*

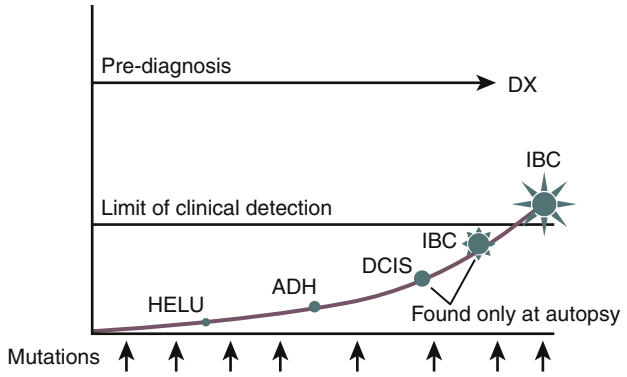

FIGURE 29.5 Diagram representing the sequential development of breast cancer. The first predisposing lesion is called a hyperplastic elongated lobule unfolded (HELU) which progresses to atypical ductal hyperplasia (ADH) and then ductal carcinoma *in situ* (DCIS) and finally to invasive breast cancer (IBC). It should be noted that the role of the HELU is not universally accepted. It has been recently estimated that 14 "driver" mutations on average are found in established breast cancers (see text). A lesion must reach 1 cm before it is detected clinically by mammogram. Accordingly, there is a large reservoir of undiagnosed tumors too small to be detected by palpation or imaging techniques (see text). DX, diagnosis.

molecules in the DNA helix and forms unstable complexes which result in depurination. Error prone or replicative repair of the depurinated sites leads to point mutations.[28] The 3, 4 estradrol-quinones can also be back converted to 4-OH–estradiol by quinone reductase (a process enhanced by tamoxifen) resulting in a redox cycle which generates reactive oxygen species.[49] Oxygen free radicals in turn may directly damage DNA through production of 8-OXO-D-guanine which also leads to depurination.

The receptor independent hypothesis involving estrogen metabolites is supported experimentally by studies demonstrating the mutagenic potential of estradiol on estrogen receptor negative Michigan Cancer Foundation-10 (MCF-10) breast cancer cells *in vitro* and the transformation of these cells to cancer *in vivo*.[50-51] Experiments in castrate estrogen receptor knock out animals bearing the Wnt-1 oncogene demonstrate a dose dependent acceleration of breast tumor onset and an increase in tumor incidence.[52] In women, menopausal hormone therapy as well as plasma estrogen levels are associated with an increased incidence of ER-breast cancer, as well as an enhanced rate of ER+ tumors.[53-55]

Mammograhic density

Among all other risk factors, breast density represents the most powerful for predicting breast cancer risk (Fig. 29.4).[56-57] Increase in breast cancer risk from lowest to highest breast density category is on the order of fivefold depending upon the age of the patient (Fig. 29.4) with greater relative risk in older women. Mammographic density, when added to the factors used in the Gail predictive model, increases the power of prediction (albeit only modestly) and thus is independent of several other risk factors.[58-59] The cause(s) of increased breast density are poorly understood but are partly related to genetic factors as shown by twin studies.[60] Recent data suggest that areas of increased breast density contain higher levels of aromatase than nondense areas suggesting a role for increased *in situ* estrogen production.[61] Exogenous estrogens increase and anti-estrogens reduce breast density. As evidence of the biological import of breast density, only those individuals with a reduction of greater than 10% with tamoxifen experienced prevention of breast cancer.[62] It should be noted that on a practical basis, menopausal hormonal therapy with estrogen plus a progestogen and its associated increase in breast density alters the sensitivity and specificity of breast cancer detection with mammography.[57]

Natural History of Breast Cancer

A variety of data suggest that *de novo* breast cancers take many years to grow to a size large enough to be clinically detectable by mammography or by palpation (Fig. 29.5). The doubling time of tumors approximates 200 days in postmenopausal and 160 days in premenopausal women.[63] Mammographic thresholds for clinical detection vary as a function of breast density and age but average 1.16 cm for 50- to 80-year-old women. Palpation thresholds are larger and are estimated to approximate 2.0 cm. *De n*ovo tumors must undergo 30 doubling times to reach the detection threshold and on average this would require 16.4 years (Fig. 29.6A). Only *de novo* tumors with a doubling time of 50 days or less would reach the detection threshold over a period of 5 to 7 years and only 15% of tumors have doubling times less than 50 days. Accordingly, most newly diagnosed breast tumors had been present for several years prior to detection.[63]

Based on these considerations, one would expect a large reservoir of occult, undiagnosed tumors in 50- to 80-year-old women. Eight autopsy studies have examined this possibility and reported that an average of 7% of women harbor occult, undiagnosed tumors, 6% of which were DCIS and 1% invasive (Table 29.1). Assuming an average doubling time of 200 days and detection threshold of 1.16 cm, the time to reach detection for tumors of each doubling category are shown in Figure 29.6B. Tumors having undergone 5 doublings would take 13 years to reach detection whereas

those having undergone 25 doublngs would take only 2.5 years (Fig. 29.6B). Using these statistics (i.e., 200 day doubling time, 7% prevalence of occult tumors, and mammographic detection threshold of 1.2 cm) a recently developed model was used to predict the population incidence of breast cancer (Fig. 29.7). Comparison of model-predicted with population-incidence data demonstrated excellent concordance and served to validate the model. The natural history of occult tumors becomes quite important when interpreting data regarding risks of breast cancer from exogenous hormone therapy.

Exogenous Hormones and Breast Cancer Risk

In premenopausal women, use of oral contraceptives for 10 or more years increases the relative risk of breast cancer by approximately 10% to 20%.[27,64-66] This increase affects very few women since the age-related absolute incidence of breast cancer is minimal in women taking oral contraceptives. The median age in the largest study of oral contraceptive use was 26 years old.[66] Based on Surveillance Epidemiology and End Results (SEER) population incidence data for 25- to 30-year-old women (approximate incidence 12/100,000 per year), use of an oral contraceptive would result in only 1.2 to 2.4 extra breast cancers per 100,000 women per year.

The concept that menopausal hormone therapy (MHT) increased the risk of breast cancer was initially controversial as it was based exclusively on conflicting observational studies.[55,67] However, the large CGHFBC study (Collaborative Group on Hormonal Factors in Breast Cancer Study) served to clarify the factors responsible for the differing conclusions among the various observational reports, as outlined below[68]:

1. The relative risk of breast cancer from MHT is small and large studies with a long duration of follow-up are required to minimize type I and type II statistical errors.
2. The risk of breast cancer increases linearly with duration of MHT use. Accordingly, comparisons of "ever users" with "never users" are invalid since duration of estrogen use is not considered.
3. The increased risk of breast cancer *imparted* by MHT dissipates within 4 years of cessation of therapy.

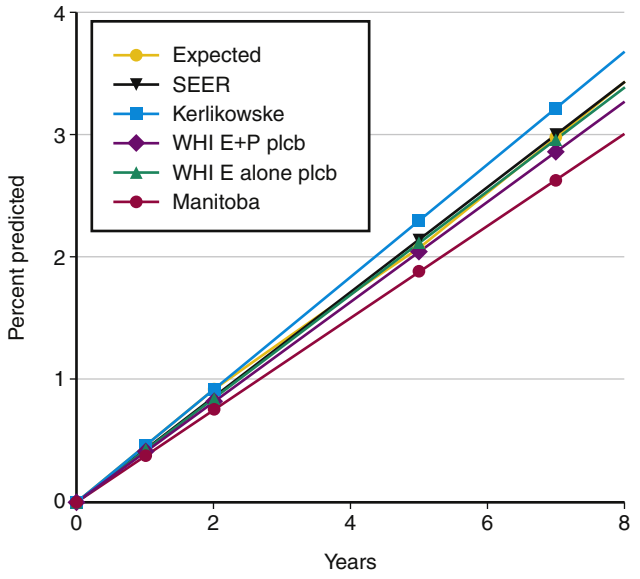

FIGURE 29.7 The observed percent incidence of breast cancer from the SEER, BCSC, Manitoba, WHI E+P placebo arm and WHI E alone placebo arms are compared with the predicted incidence based on the OTG model. SEER, surveillance epidemiology and end results; BCSC, Breast Cancer Surveillance Consortium; Manitoba, breast cancer mammographic screening data from Manitoba, Canada; WHI E+P, placebo arm of the Women's Health Initiative conjugated equine estrogen plus medroxyprogesterone acetate study; WHI E, same study but conjugated equine estrogen alone; OGT, occult tumor growth model. *(Reprinted with permission from Santen RJ, Yue W, Heitjan DF. Modeling of the growth kinetics of occult breast tumors: role in interpretation of studies of prevention and menopausal hormone therapy,* Cancer Epidemiol Biomarkers Prev *21[7]: 1038–1048, 2012.)*

Therefore, only women using MHT within 4 years of study might be found to be at increased risk.

4. Breast cancer risk also diminishes over a 4-year period following the menopause, presumably as a reflection of decreased estrogen and progesterone levels. As a result, analyses of observational studies need to match users vs. nonusers as to time following menopause.
5. The increased risk of breast cancer from MHT is higher in lean women. Inclusion of a large proportion of obese women in a single study might then obscure associations between MHT use and breast cancer risk.

When the CGHFBC took these confounding factors into account, the pooled observational data were relatively consistent and suggested an increased risk of breast cancer in women using estrogen plus a progestogen (P) over 5 years or taking estrogen alone long-term for 10 or more years.[68]

WHI ER+P study: The large, prospective, randomized, Women's Health Initiative (WHI) trial in postmenopausal women first published in 2002 strongly supported the observational data on E+P.[69] Nearly 16,000 postmenopausal women with an average age of 63 enrolled in the estrogen plus progestin arm of the WHI study and received either placebo or conjugated equine estrogens (0.625 mg) plus medroxyprogesterone acetate (2.5 mg) for 5 years. At study termination after 5.2 years, the relative risk was reported as 1.26 (RR 1.26, 95% CI 1.00 to 1.59). The absolute increase in risk (i.e., attributable risk) was small with 4 cases per 1000 women treated for 5 years.

In the original WHI report, it was noted that 74% of the participants were never users of MHT, 19.7% were past users, and 6.4% were current users. Among the never users, breast cancer risk was not increased (RR 1.09, CI 0.86 to 1.40), a statistic confirmed in a subsequent publication in 2006 (Fig. 29.8A and B). In another analysis, the risk of MHT was shown to be higher for women who initiated treatment within 5 years of menopause (deemed a short gap time) as opposed to those who initiated after a long interval (long gap time).

Effect of Specific Progestogens

The WHI E+P study utilized only one progestogen, medroxyprogesterone acetate (MPA), and did not address whether different progestogens might have lesser effects on breast cancer risk. Several observational studies examined the effects of various types of progestogen as well as differences between combined continuous and sequential regimens.[69,70] The Million Women Study suggested that all types of progestogen are associated with an increased risk of breast cancer and that a class effect of progestogens is responsible. An interesting but as yet unconfirmed finding, however, is that progesterone itself appears to be associated with a lower risk of breast cancer than synthetic progestogens. The French component of the European Prospective Investigation into Cancer and Nutrition (EPIC) study reported on 2354 cases of invasive breast cancer among 59,216 French postmenopausal women followed for an average of 8.1 years. This study reported a relative risk of 1.08 (CI 0.89 to 1.31) for estradiol in combination with micronized progesterone.[71] In contrast, the relative risk (RR) for estradiol combined with synthetic progestogens in that study was 1.69 (1.50 to 1.91), similar to risks reported in other epidemiological studies. This finding requires confirmation before general acceptance is warranted.

An understanding of the physiological basis for the association of progestogens with breast cancer rests on data indicating that progestogens are mitogenic on breast tissue in contrast to their anti-mitogenic effects on the uterus.[72] While data from cell cultures or animal studies are conflicting, the weight of evidence from patients suggests that progestogens are mitogenic in breast. Mammographic studies demonstrate that estrogen/progestogen combinations increase breast density to a greater extent than estrogen alone or placebo.[73] Histological examination demonstrates enhanced cell proliferation and percent of the breast containing glandular tissue as a function of duration of progestogen usage.[72] Increased proliferation would be expected to increase both initiation and promotion of breast cancer in a manner similar to that thought to occur with estrogens.[74]

Confounding Factors

Several commentators have pointed out factors confounding the interpretation of the WHI studies: (1) the frequency of dropouts (30%) and drop-ins (7%) (i.e., patients randomized to placebo and then deciding to take MHT during the study), (2) the exclusive use of MPA as the progestogen, (3) the average age of participants was 63 years old, (4) the fact that 26.5% of women had used prior hormone therapy and then underwent washout before starting MHT, (5) the

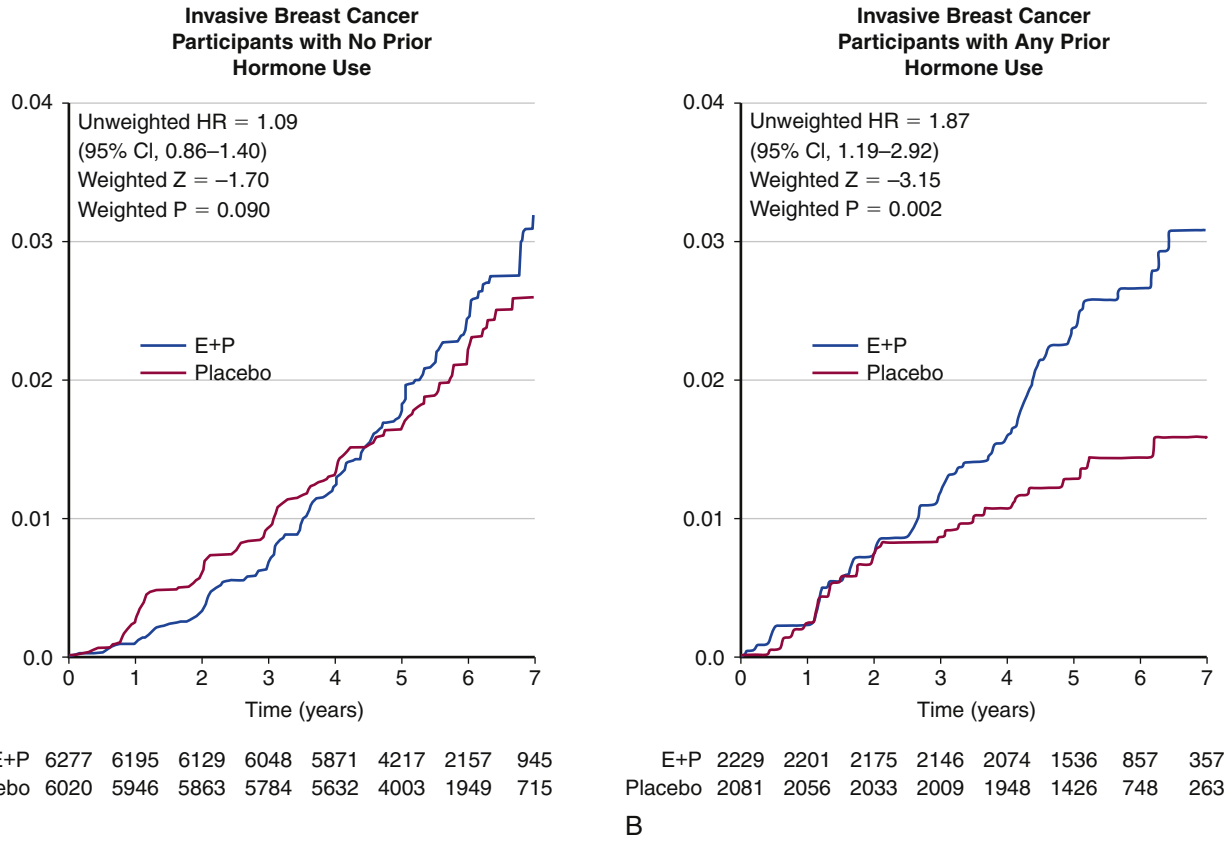

FIGURE 29.8 Data from the Women's Health Initiative trial comparing placebo to hormone therapy in a group of women who had never used hormone therapy previously **(A)** and in another group who did **(B).** HR, hazard ratio; CI, confidence intervals. *(Adapted from Anderson GL, Chlebowski RT, Rossouw JE, et al. Prior hormone therapy and breast cancer risk in the Women's Health Initiative randomized trial of estrogen plus progestin.* Maturitas *55[2]:103–115, 2006.)*

paucity of women with menopausal symptoms, (6) the fact that only 3.5% of the subjects were in the 50- to 54-year-old age group which represents women who usually consider initiation of MHT use and, (7) limitation of an increase in breast cancer to women who had previously used MHT and then stopped before randomization (Fig. 29.8A and B). Despite these issues, the WHI remains the only large randomized trial and the data on E+P and breast cancer risk appear valid. Further, the conclusions are congruent with the findings of the majority of properly conducted observational studies as reported in a recent meta-analysis.[45]

WHI E Alone Study

Another arm of the WHI compared placebo with conjugated equine estrogen alone in women who had previously undergone a total abdominal hysterectomy.[75] Three other, smaller randomized controlled trials (RCTs) of estrogen alone have also been reported in the past 10 years including the WEST (Women's Estrogen for Stroke Trial), ESPRIT (European/Australasian Stroke Prevention in Reversible Ischemia Trial), and EPAT (Estrogen in the Prevention of Atherosclerosis Trial) studies 1.[67] Data pooled from the four RCTs reported a paradoxical reduction in breast cancer risk (RR 0.79, CI 0.61 to 1.01) that approached but did not reach statistical significance. In the 11.8 year follow-up of the WHI E alone trial (i.e., 7 years of E alone and 4.8 years of subsequent observation), the reduction in breast cancer risk did reach statistical significance in the total group (RR 0.77, CI 0.62 to 0.95) and to an even greater extent in compliant patients (sensitivity analysis RR 0.69, CI 0.49 to 0.95) (Fig. 29.9).[76] The protective effect was confined to those without a family history of breast cancer or benign breast disease.[76]

The observational trials reporting an increased risk of breast cancer with long-term estrogen use and the WHI study reporting a reduced risk would seem paradoxical.[76-78] A plausible explanation for this discrepancy is the "Gap Time," the duration between onset of menopause and start of MHT. Women starting many years after onset of menopause (i.e., "long gap") experienced a significant reduction in breast cancer risk (RR 0.58, CI 0.36 to 0.93), whereas those starting immediately after menopause ("short gap") did not (RR 1.12, CI 0.39 to 3.21 reported initially and 0.89, CI 0.66 to 1.20 in a later analysis).[76,79] Data from the Nurses' Health Study suggest that the increased risk only occurs in women using estrogen alone for more than 10 years, particularly in lean women [i.e., body mass index (BMI) less than 25] (Fig. 29.10).[77,78] As discussed below, the reduction in risk in the "long gap" group may have resulted from a pro-apoptotic effect of estrogen.

An important issue is often overlooked in discussions of the WHI E alone trial. Forty-eight percent of women had received MHT previously but were eligible for study entry after a 3-month "wash out" period. Fifty-two percent had never taken menopausal hormone therapy and are termed "hormone naïve." Only the "hormone naïve group"

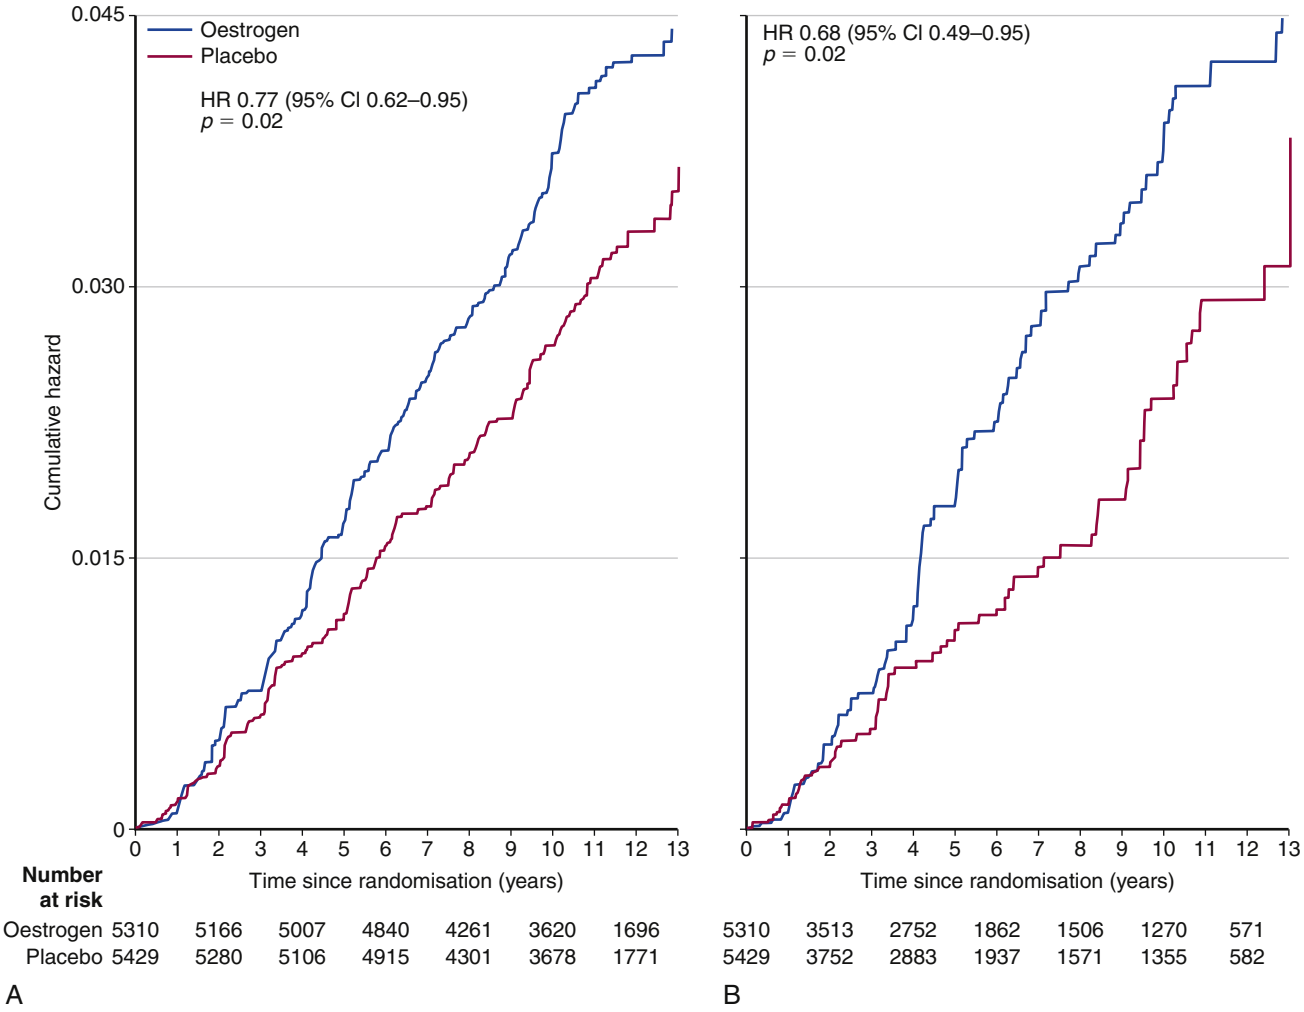

FIGURE 29.9 Kaplan–Meier estimates of cumulative hazards of invasive breast cancer in the WHI randomized trial of conjugated equine estrogen with the intention to treat principle **(A)** and with adjustments for adherence **(B).** WHI, Womens Health Initiative; HR, hazard ratio; CI, confidence intervals. *(Reproduced with permission from Anderson GL, Chlebowski RT, Aragaki AK, et al. Conjugated equine oestrogen and breast cancer incidence and mortality in postmenopausal women with hysterectomy: extended follow up of the Women's Health Initiative randomized placebo-controlled trial,* Lancet Oncology *13:476–486, 2012.)*

experienced a decrease in breast cancer risk (RR 0.65, CI 0.46 to 0.92). The 48% of women entering after cessation of MHT and a wash out period experienced no reduction (RR 1.02, CI 0.70 to 1.50), a response similar to that in the "short gap" patients.[69]

In the 11.8-year follow-up in the WHI, women receiving E alone experienced a lower overall mortality (30 deaths versus 50 deaths, RR 0.62 95%, CI 0.39 to 0.967) than those on the placebo arm.[76] Six deaths directly related to breast cancer were observed in the E alone group and 16 in the placebo arm (RR 0.37, CI 0.13 to 0.91). In contrast, the 11-year follow-up of the WHI E+P arm reported a slight increase in breast cancer death rate in the MHT arm (i.e., 0.63 extra deaths per 1000 women over 5 years). All-cause mortality was also slightly higher in the E+P group (1.07/1000/5 years), perhaps related to the average age of 63 in those entered.

Estrogen Paradox. Comparison of short-term estrogen use, which may decrease breast cancer risk by 30% (Fig. 29.9), with long-term administration for 10 to 20 years (Fig. 29.10), which appears to increase risk by 41% to 77%, suggests an "estrogen paradox."[77,78] One potential explanation for the "estrogen paradox" is that estradiol can exert two separate mechanistic effects based on timing: estradiol induced apoptosis *short-term* and the initiation-promotion of new cancers *long-term*. Recent studies demonstrate that estradiol can induce apoptosis in breast tumors that have been deprived of estradiol over a prolonged period.[80,81] In addition, high-dose estrogen administration to women with advanced breast cancer induces tumor regression in approximately 40% of ER positive patients.[82,83] At entry to the WHI estrogen alone study, the average age of the women was 63 years old, 12 years beyond the average age of menopause. Accordingly, women who had never previously taken hormone therapy were in a state of long-term estradiol deprivation, 12 years on average. If these patients had occult undiagnosed tumors (discussed later in the chapter), estrogen alone might have caused apoptotic cell death in them.

Occult Tumor Reservoir. Modeling studies examined the implications of the 7% of occult breast tumors found

at autopsy. A pro-apoptotic effect of estradiol would be expected to reduce the size of those tumors such that they would not be detected over the 5 years of follow-up (Fig. 29.11). This could explain the significant reductions of breast cancer in subgroups of women in the WHI and Nurses Health studies. This short-term estrogen effect might then be superseded by a procarcinogenic effect of estradiol if the patients received this hormone over a prolonged period of up to 25 years (Fig. 29.10).[77,78,84] The "estrogen paradox" hypothesis is speculative and will require prospective, randomized, controlled trials over a longer period of time for confirmation.

Decreasing Breast Cancer Incidence in the United States

Breast cancer incidence decreased by 6.7% after the first publication of the WHI studies as documented by SEER population data in the United States.[85] ER positive tumors decreased by 14.7% (95%, CI 11.6 to 17.40) and ER negative by 1.7% (95%, CI −4.6 to +8.0). This finding was surprising since breast cancer incidence had been gradually increasing until 1999 and then plateaued until 2003. Ravdin and colleagues suggested that this might reflect the substantial cessation of use of MHT in women noted in 2002 and 2003 after publication of the WHI study.[85] A county by county analysis from California indicated that the steepest decline in breast cancer incidence (22.6%) occurred in counties with the greatest drop in MHT use, whereas the smallest decrease (8.8%) was observed in those with the lowest fall-off in use.[86] Decreased screening mammography could not explain these results since a large mammography screening study demonstrated nearly identical results.[87] One mechanistic explanation for these findings is that a subset of the occult breast cancers might regress in response to cessation of estrogen plus progestogen use and therefore not grow to the threshold of diagnosis over the next 2 to 3 years (Fig. 29.11). A study modeling the growth of occult tumors attributed the changes in breast cancer rate to an increase in doubling time from 200 days to 150 days in the women using E + P and a reduction in incidence rate upon cessation as doubling times fell back to 200 days.[63] If this explanation proves correct, one might expect a rebound in breast cancer incidence over the ensuing years.

Relative, Absolute, and Attributable Risks from MHT

A full understanding of the magnitude of risk from MHT requires knowledge of the precise meaning of statistical terms. Epidemiologists use *relative risk analysis* as a tool which provides substantial power to determine statistical significance of differences between groups. However, the term "relative risk" is misleading to patients since absolute or actual risk may be quite small in magnitude when relative risk is high. The lay press, patients, and many physicians confuse the terms relative, absolute, or attributable risk. The specific methods used to describe the endpoints reported in published studies of MHT confound the process of benefit and risk assessment. Various publications have described relative, absolute, or excess risks and examined

time frames ranging from 1 to 20 years. The initial WHI study and observational studies primarily reported relative risks (RR), a statistic relating the percent increment in an event in one population to that in another.[67,69] Other studies report absolute risk which describes the number of events in a population of given size. Relative risk provides meaningful information only when absolute risk is high but not when low. Excess (or attributable) risk subtracts the absolute risk in an untreated control group from that in a treated population. For an individual woman, excess risk or benefit is a more meaningful statistic since it represents an estimate of what she can expect to experience as a result of taking MHT.

Benign Breast Disease and Risk of Breast Cancer

Benign breast lesions with an enhanced rate of proliferation predict an increased incidence of breast cancer over time (Fig. 29.12).[88] Hyperplastic ductal lesions are often multicentric suggesting that some type of underlying abnormality is present which predisposes to such lesions. This has been called a "field defect" or more recently, a "mutator phenotype."[89] The multifocal nature of the associated benign hyperplastic lesions is most apparent in breast tissue from women with cancer. Examination of tissue adjacent to an invasive breast cancer or in the contralateral breast reveals one or more additional hyperplastic lesions in approximately 40% of patients.[90] The nature of the *field defect* or mutator phenotype has not been specifically identified but hypothetically could represent a single mutation of a gene controlling local estrogen production, cellular proliferation, DNA repair, metabolism of procarcinogens to carcinogens or other cellular events.

Available data suggest that benign breast lesions are frequently adenomas which then progress to frank neoplasms upon acquisition of additional mutations—80% to 90% of hyperplastic lesions contain DNA mutations similar to those in the contiguous tumors. Extensive molecular-genetic studies have now described progression of abnormalities in the spectrum of breast lesions.[89]

A major consideration for women who present with breast problems is whether they have a higher than normal risk of developing breast cancer. Certain breast lesions such as fibrocystic changes are associated with no increased risk of subsequent breast cancer unless a strong family history is present. Other lesions, characterized by the presence of increased cellular proliferation such as usual ductal hyperplasia, hyperplastic elongated lobular units, and solitary or multiple papillomas impart a small (i.e., less than twofold) relative increase in risk (Fig. 29.12).[88,89,91] With atypical ductal hyperplasia (ADH), the relative risk (RR) is 3.88 overall and 10.35 in those with multifocal (i.e., 3 or more) lesions with calcifications. In younger women, ADH imparts a 6.75 RR (i.e., women younger than 45 years old).[91] The relative risk of development of invasive cancer is increased tenfold to twelvefold when ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS) are present.

Proliferative lesions can progress to invasive cancer as evidenced by the increase in ipsilateral breast cancer in women harboring these lesions. However, risk of contralateral breast cancer is also increased when the period of observation extends over more than 10 years, suggesting an underlying defect affecting both breasts. The Mayo Clinic study of nearly 15,000 women established that only lesions with increased proliferation impart an increased risk of breast cancer unless a strong family history is present.[88] This clarified a prior study which did not distinguish proliferative from non-proliferative lesions and concluded that low category breast disease, including fibrocystic changes conveys an increased risk.[92] The anti-estrogen, tamoxifen, reduces the number of ADH lesions in high risk women and the risk of breast cancer.[42]

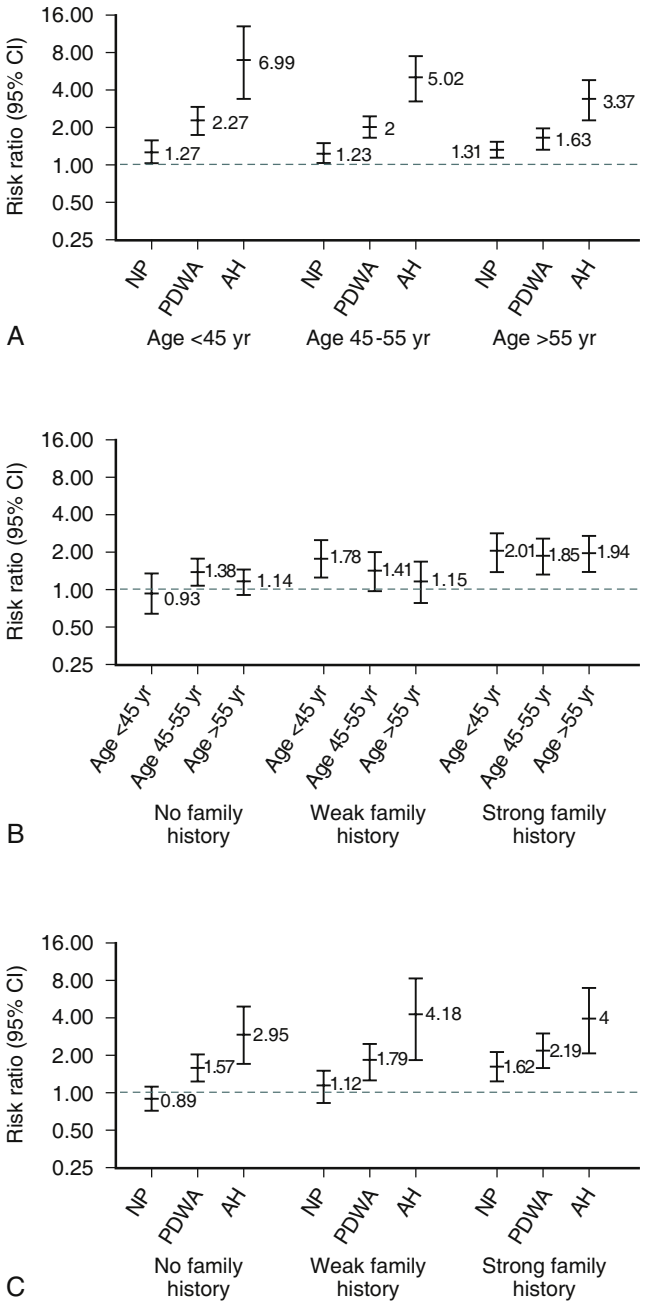

FIGURE 29.12 Risk of breast cancer related to various benign breast lesions and family history of breast cancer. Estimating Breast Cancer Risk

To aid in assessing breast cancer risk, a questionnaire developed by Gail, utilizes answers to seven questions to calculate the 5-year and lifetime risk of developing breast cancer.[93] This model has recognized deficiencies in that it does not consider breast density, plasma estradiol levels, bone density, body mass index, weight gain in adulthood, second degree relatives with breast cancer, proliferative lesions of breast other than ADH, alcohol intake, or birth control pill and MHT use.[13] Nonetheless, several prospective studies validated the Gail model in high risk (National Surgical Adjuvant Breast Project [NSABP] prevention study) and in average risk women (the Nurses Health Study). The ratio of observed to expected cancers using this tool was 1.03 (95% confidence limits of 0.88 to 1.21) in the high risk patients and 0.94 (95%, CI 0.89 to 0.99) in average risk women and both were highly statistically significant. This risk tool is available as the "RISK DISK" from the National Cancer Institute. When family history is the primary predictor of breast cancer, the Claus model has been validated and widely applied.[93]

Newer models are being developed to enhance the power of risk prediction. Although only validated in one prospective study, the Tyrer/Cuzick model appeared to out-perform the Gail model in a population with a high familial breast cancer component.[94,95] This new model combines the factors utilized in the Claus and Gail models as well as a history of MHT use and appears quite promising as a new risk prediction tool. As mentioned above, addition of mammographic density to the Gail model improves risk prediction but to only a minor extent.[58,59,96] However, precise quantitation of breast density is infrequently utilized and a practical method (such as the "Risk Disk") is not yet available to integrate breast density into the Gail model to make the necessary calculations. Critical reviews of all of the various risk detection models are available.[95] It should be noted that analysis of data regarding occult, undiagnosed tumors leads to the conclusion that the breast cancer risk models are actually identifying women harboring occult, undiagnosed tumors rather than those at high risk of *de novo* tumors.[63]

Breast Cancer Risk and Clinical Decisions

Knowledge about underlying breast cancer risk influences advice given by healthcare providers and choices made by patients. Women known to be at high risk of breast cancer will frequently choose a surrogate for MHT (discussed later in the chapter) to treat menopausal symptoms. Those at low risk will usually chose estrogen or an estrogen and progestogen combination to relieve symptoms. Those at intermediate risk of breast cancer have several options including use of a selective estrogen receptor modulator (SERM), other alternatives to estrogen, watchful waiting, or MHT. The Endocrine Society has constructed a Menopause Map using these considerations to aid in the decision making process (http://www.hormone.org/menopausMAP/).

As a working guide, categories are arbitrarily defined based upon use of risk prediction models: with high risk ≥3% chance of breast cancer in 5 years; intermediate risk = 1.5% to 3% , and low risk ≤1.5%. Those classified as high risk include patients with a family history of breast cancer (particularly if associated with ovarian cancer), prior history of atypical hyperplasia (AH) or lobular carcinoma *in situ*, and age over 60 years old when combined with early menarche, late menopause, or first live birth. Intermediate risk patients have some risk factors but not others. Low risk patients are under 60 years of age; have a late onset of menarche, early menopause, early age of first live birth, and no family history of breast cancer; and lack predisposing breast lesions. Since no formal risk tool incorporates breast density, bone density, nor plasma estradiol levels into its assessment, physicians must take these factors into account in advising patients.

Prevention of Breast Cancer

Depending upon risk category, women may wish to take tamoxifen or raloxifene to prevent breast cancer. Both raloxifene and tamoxifen are now approved for this use in the United States. Evidence supporting anti-estrogens for prevention is substantial. A meta-analysis of the five large prevention trials demonstrated 42% reduction in breast cancer risk with tamoxifen when compared to placebo.[97] The most definitive trial, NSABP P-1, involved 13,388 women randomized to receive either placebo or 20 mg of tamoxifen daily[42] (Fig. 29.13). Eligibility into the study required an intermediate or high risk of developing breast cancer, defined in the study as a 1.67% or greater chance of developing a new breast cancer over a 5-year period. The rate of breast cancers in the tamoxifen group was reduced by 50% compared to the placebo group (Fig. 29.13). Considered separately, the risk of invasive breast cancer was reduced by 49% and noninvasive

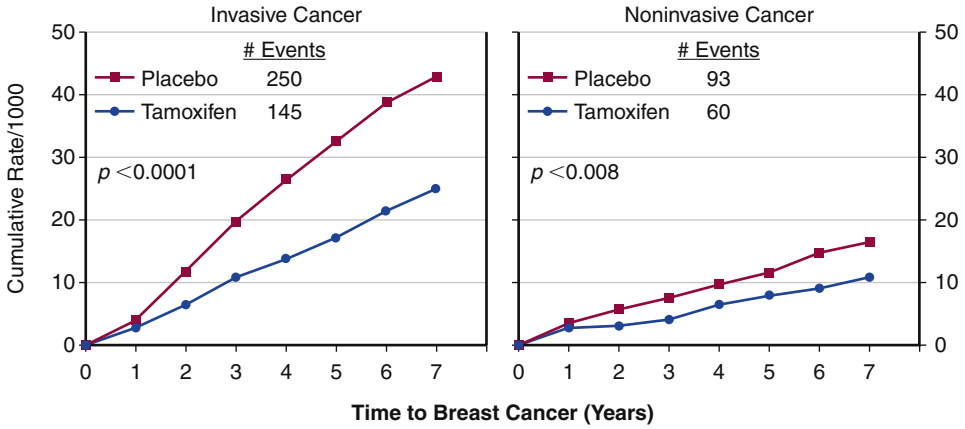

FIGURE 29.13 Results of the NSABP-P1 breast cancer prevention trial with tamoxifen versus placebo. *Left panel* is the effect of tamoxifen on invasive cancer and *right panel,* on noninvasive cancer. *(From Fisher B, Costantino JP, Wickerham DL, et al. Tamoxifen for the prevention of breast cancer: current status of the National Surgical Adjuvant Breast and Bowel Project P-1 study (per pub med),* J Natl Cancer Inst *97 [22]:1652–1662, 2005.)*

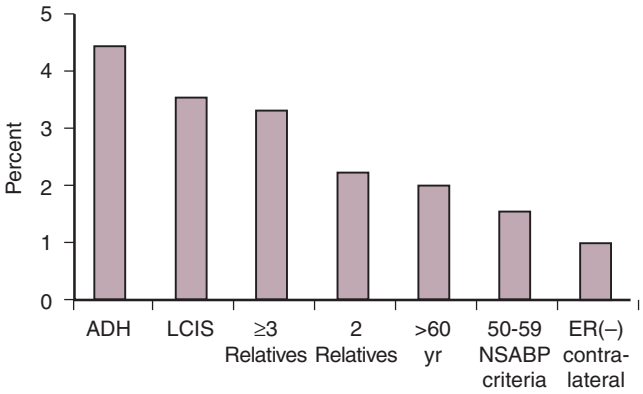

FIGURE 29.14 Absolute benefit from tamoxifen expressed as percentage of women whose breast cancer was prevented as a function of the underlying risk factor present. ADH, atypical ductal hyperplasia; ER, estrogen receptor; LCIS, lobular carcinoma *in situ;* NSABP, National Surgical Adjuvant Breast and Bowel Project. *(From Santen R. Endocrine-responsive cancer. In Kronenberg HM, Melmed S, Polonsky KS, Larsen PR [eds].* Williams Textbook of Endocrinology, *11th ed., Philadelphia, Saunders, 2008, Figure 42.88.)*

by 50%. This effect occurred in women of all ages studied (younger than 49 years old, 50 to 59 years old, 60 to 69 years old, and older than 70 years old) and in those with LCIS, ADH, and a family history of breast cancer. The benefits of tamoxifen related to the underlying risk of breast cancer and the specific risk factor present (Fig. 29.14).

Tamoxifen for treatment of breast cancer is considered well tolerated and safe. However, for use in otherwise normal women, infrequent side effects and toxicity become more important. Up to 40% of women starting on tamoxifen do not continue it because of perceived side effects including depression and mood changes.[98-102] A majority of eligible women choose not to start tamoxifen for breast cancer prevention.[103]

To compare risks and benefits in a meaningful way, the NSABP data are expressed as the number of women per 100 with a specific benefit or adverse event after 5 years of study. With respect to benefits, new invasive breast cancers were prevented in 1.7 of 100 women, noninvasive cancers in 0.67, and bone fractures in 0.50 for a total of 2.87 in 100 women benefitted after 5 years. Risks of tamoxifen are primarily related to its estrogenic effects on uterus, a prothrombotic effect, and adverse effects on the lens of the eye. To validly estimate actual risks to a patient, one must correct for the underlying risks in the population under study. For that reason, analysis of adverse events includes determination of *attributable risk* and involves subtracting the underlying rate from the total observed on tamoxifen. This indicates an excess of 1.5 of 100 women who developed cataracts, 0.69 with endometrial cancer (nearly exclusively in postmenopausal women), 0.27 with CVA, 0.25 with deep venous thrombosis, and 0.23 with pulmonary embolus or a total of 2.94 per 100.[104] The new endometrial cancers were predominantly Stage I and pulmonary emboli nonfatal. Neither risk nor benefit was observed regarding cardiovascular effects but the number of patients was not sufficient for statistical significance.

The increased incidence of uterine cancer in patients on tamoxifen presents a clinical management problem. Substantial study has examined how best to detect this cancer early.[105] Transvaginal ultrasound was initially proposed as a means of assessing both endometrial hyperplasia, as a precursor lesion, and early cancer. A prospective study demonstrated a mean increase in endometrial thickness from 3.5 ±1.1 to 9.2 ±5.1 mm in response to 5 years of tamoxifen. In 20% of women, endometrial thickness exceeded 10 mm or appeared suspicious for neoplasm. In this subset of women, biopsies revealed atrophy in 73%, polyps in 17%, hyperplasia in 7.7%, but endometrial cancer in only one patient.[106] This and other studies concluded that endometrial thickness does not usually indicate hyperplasia but rather, the presence of edema and dilated myometrial glands. It should be noted that nonprospective studies report a higher prevalence of benign polyps (5% to 55%) and hyperplasia (8% to 16%) but these are likely to be overestimates from selection bias.[107,108] Based upon these studies, recommendations for screening include yearly gynecological exam and endometrial sampling and ultrasound only for those with signs of abnormal vaginal bleeding.[105,106]

Another SERM, raloxifene, appears to prevent breast cancer in postmenopausal women without increasing the risk of endometrial cancer. After initial positive findings regarding raloxifene, the study of tamoxifen and raloxifen (STAR) trial compared raloxifene with tamoxifen in a "head to head" prevention trial in 18,000 postmenopausal women with a predicted risk greater than 1.67% at 5 years.[43,109] Both agents prevented invasive breast cancer by an estimated 50% but raloxifene exhibited a superior toxicity profile with 30% fewer thrombo-embolic events ($p = 0.01$); 38% fewer endometrial cancers ($p = 0.07$); 21% fewer cataracts ($p = 0.002$); an 84% reduction in uterine hyperplasia ($p < 0.01$), and 55% fewer unplanned hysterectomies. No differences between agents were observed in cardiovascular events, strokes, or fracture rates. A surprising finding was that raloxifene did not appear to prevent noninvasive breast cancer whereas tamoxifen has previously been shown to do so.[43] Longer term follow-up of the STAR trial demonstrated that tamoxifen was superior to raloxifene in preventing invasive breast cancer as well (Fig. 29.15).[110] This later study clearly demonstrates the superiority of tamoxifen over raloxifene for breast cancer prevention albeit with a higher risk of endometrial cancer with tamoxifen. Two other SERMs, arzoxifene and lasofoxifene, also prevent breast cancer but have not been approved for this indication.[111,112]

Trials of the aromatase inhibitors in the adjuvant setting uniformly demonstrate a greater reduction of contralateral cancers with the aromatase inhibitors (AIs) than with tamoxifen and suggest that AIs would be superior for prevention as well.[113,114] A recent study reported the prevention of breast cancer in postmenopausal women at high risk of breast cancer (i.e., Gail scores less than 1.66) with the steroidal AI, exemestane.[115] A total of 4560 women were randomized to the AI or placebo. At a median follow-up of 35 months, a 65% reduction in breast cancer was observed with the AI (HR 0.35 95%, CI 0.18 to 0.70). Minimal quality of life differences were observed. This agent is not currently approved for use in prevention.

Guidelines for Breast Cancer Prevention

Premenopausal women with a 5-year risk of breast cancer greater than 1.67% over 5 years are candidates for

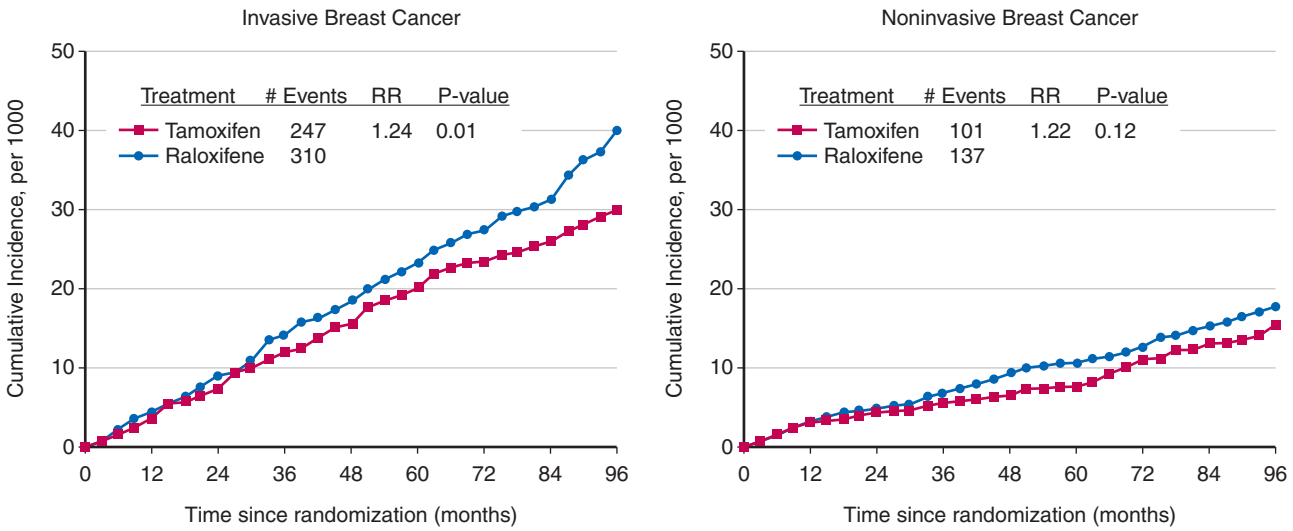

FIGURE 29.15 Comparison of tamoxifen with raloxifene for prevention of breast cancer as reported in the STAR trial update. *Left panel,* Invasive breast cancer. *Right panel,* Noninvasive breast cancer. *(From Vogel VG, Costantino JP, et al. Update of the National Surgical Adjuvant Breast and Bowel Project Study of Tamoxifen and Raloxifene (STAR) P-2 Trial,* Cancer Prevention Research *3(6):696–706, 2010.)*

tamoxifen unless they are at increased risk for DVT or pulmonary emboli. Post-menopausal women with similar breast cancer risk are candidates for tamoxifen if they no longer have a uterus and lack a predisposing risk for DVT or pulmonary emboli. Raloxifene may be preferred over tamoxifen in women with a uterus. Lesser efficacy must be balanced against improved uterine safety when raloxifene is being considered. The decision to take tamoxifen or raloxifene should be made by the patient in partnership with her healthcare provider and based upon a full discussion of individual risks and benefits expressed in absolute and not relative terms.[116,117] Prevention strategies for women carrying BrCA1 or BrCA2 mutations often involve more aggressive steps such as bilateral oophorectomy or mastectomy but tamoxifen may also be effective in these patients.[19,118]

Critical Assessment of Breast Cancer Prevention Strategies

Estimates indicate that between 20 and 100 women (depending upon underlying risk) need to be treated with tamoxifen to prevent one breast cancer. Available data demonstrate only a reduction in newly diagnosed breast cancers but effects on overall survival are not yet known. Recent modeling data suggest that the primary effect of tamoxifen is to reduce the growth of pre-existing, occult tumors and not to prevent *de novo* tumors.[63] Tumors whose growth was blocked by tamoxifen during 5 years of administration might re-grow later. For this reason, data on overall survival (to be available from the ongoing IBIS 1 trial) will be critically important.[97]

Future studies will need to utilize additional factors to select women at higher risk of developing breast cancer.[13] A study of raloxifene examined women with factors suggesting high exposure to estrogen long-term (i.e., increased bone mineral density, high BMI and high plasma estradiol levels). Results indicated that raloxifene was more effective in preventing breast cancer in women with high than with low long-term estrogen exposure.[119] A critical need at present is to develop a more powerful breast cancer risk model that incorporates genetic factors, breast density, levels of estrogen and its metabolites, history of fracture, waist hip ratio, and obesity as well as the factors utilized in the Gail and Claus risks prediction models.[13]

Hormonal Treatment of Breast Cancer: Background

Biological Subtypes of Breast Cancer

A major advance in the field of breast cancer research utilizes cDNA array analysis to assess the molecular and biological properties of individual tumors.[120,121] This methodology enabled a new biological classification of breast cancer based upon the degree of expression of key discriminant genes. Five common subtypes of breast cancer are generally agreed upon including luminal A, luminal B , basal, ERB-B2+, and tumors with normal breast gene expression. As shown in Figure 29.16, each subtype has a different prognosis. Data from separate molecular signature methods are largely concordant.[122-126] Additional subtypes such as Claudin low are being identified.

Methods such as Blue Print are being developed to limit the number of genes to be measured to classify subsets of tumors.[127] The differential biological properties, responses to therapy, and survival rates which characterize each of these subtypes justify the conclusion that individual breast cancers represent at least five and probably more disease entities. On a practical basis, cDNA array data are not always available clinically and testing is expensive. For these reasons, recent emphasis has focused on approximating the biological subtypes by immuno-histochemical methodology. Table 29.2 provides criteria for determining subtypes based on ER, PgR, HER-2, and Ki67 measurements.[128]

Stem Cell Composition

Emerging data suggest that tumor stem cells represent an important component of the cellular composition of mammary tumors.[129] With continuing potential for replication,

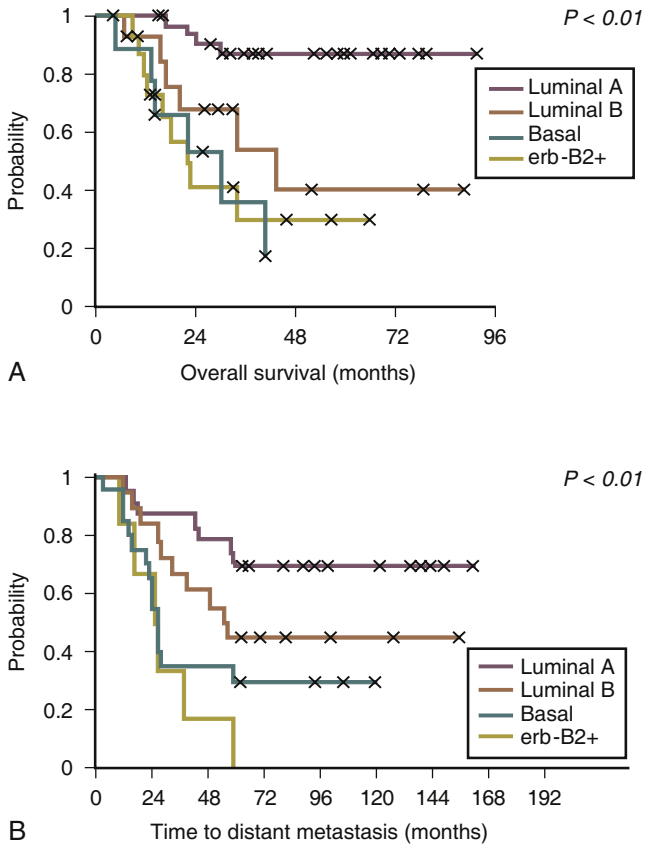

FIGURE 29.16 cDNA analysis of breast cancer tissues with categorization into Luminal A, Luminal B, Basal, and ERBB2 and the probability of overall survival and time to distant metastasis. The normal subtype is not shown. Luminal A, Luminal B, Basal, ERBB2, subtypes of breast cancer based on molecular signatures. *(Data reproduced from Sotiriou C, Ney SY, McShane LM, et al. Breast cancer classification and prognosis based on gene expression profiles from a population-based study,* Proc Natl Acad Sci USA *100(18):10393–10398, 2003.)*

stem cells may repopulate tumors after the more differentiated cells are destroyed by endocrine or chemotherapy. Tumor stem cells appear to have enhanced migratory and invasive potential and could play a major role in metastasis and colonization of tumors at distant sites.[1] Major effort is currently being directed toward stem cell targeted therapies to eliminate the ability to self-propagate.[130,131]

Prognostic Factors

Approach to the patient with breast cancer requires knowledge of the degree of aggressiveness and natural history of the type of tumor present. Figure 29.17 illustrates the prognostic power of various biological factors by comparing the effects of individual parameters on 5-year survival. The most powerful clinical and pathologically based prognostic parameters include nodal status, tumor grade and size, proliferative indices, and ERα content. This information can be integrated and used to determine prognosis during follow-up. A web based tool called adjuvant online (adjuvantonline.com) has been developed to calculate prognosis in individual women and to guide patients and their physicians in the choice of various therapeutic options.[132,133]

Other prognostic factors include HER2/neu content, degree of aneuploidy, and expression of certain oncogenes

Table 29.2 Surrogate Definitions of Intrinsic Subtypes of Breast Cancer

Intrinsic subtype	Clinico-pathological definition
Luminal A	Luminal A ER and/or PgR positive HER2 negative Ki-67 low (<14%)
Luminal B	Luminal B (HER2 negative) ER and/or PgR positive HER2 negative Ki-67 high Luminal B (HER2 positive) ER and/or PgR positive Any Ki-67 HER2 over-expressed or amplified
Erb-B2 over-expression	HER2 positive (nonluminal) HER2 over-expressed or amplified ER and PgR absent
Basal-like	Triple negative (ductal) ER and PgR absent HER2 negative

ER, estrogen receptor; PgR, progesterone receptor; HER2, human epidermal growth factor receptor-2; Ki-67, name of monoclonal antibody to detect proliferation. Named after the city of Kiel, Germany.

or coactivators such as cyclin-D1, A1B1, MAP kinase, Ras, human epidermal growth factor receptor (HER) III, and IV, heregulin, c-Src, 3-hydroxy-3methyl-glutaryl-CoA (HMG-CoA) reductase and ornithine decarboxylase (ODC) levels.[42,134] ERβ may also serve as a prognostic marker but interpretation is confounded by the presence of five ERβ isoforms and only ERβ 1 and 2 have been extensively studied.[135-139]

A risk score incorporating many of the above factors provides a more powerful means of assessing aggressiveness than use of single components. For example, a commercially available method, OncotypeDx^{R}, assigns a relative weight to the expression of each of 21 genes quantitated by polymerase chain reaction (PCR).[123,140-142] Women with node negative, ER + breast cancers are categorized into groups with low, intermediate, or high risk of recurrence. As evidence of its biological significance, the low-risk group experienced a 6.8% recurrence rate at 10 years versus 30.5% in the high-risk group. When patient age and tumor size are added to the model, only the cDNA score remains statistically significant upon multivariate analysis. The Mammoprint method is similar and involves the expression of 70 genes.[143,144] Both the Oncogene Dx^{R} and Mammoprint^{R} methods have been FDA approved in the United States and employed clinically. Other methodologies are being actively studied but are as yet not ready for clinical use. One involves measurement of circulating tumor cells in the blood of patients with breast cancer and the other assesses micrometastases in lymph nodes and bone marrow.[134,145]

Treatment of Established Breast Cancers

In the United States in 2011, 229,060 new cases of breast cancer were diagnosed and 39,920 died of this disease.[146] One approach to improve patient outcome is earlier diagnosis. Mammographic screening and digital mammography have increased the sensitivity of detecting early disease.[147]

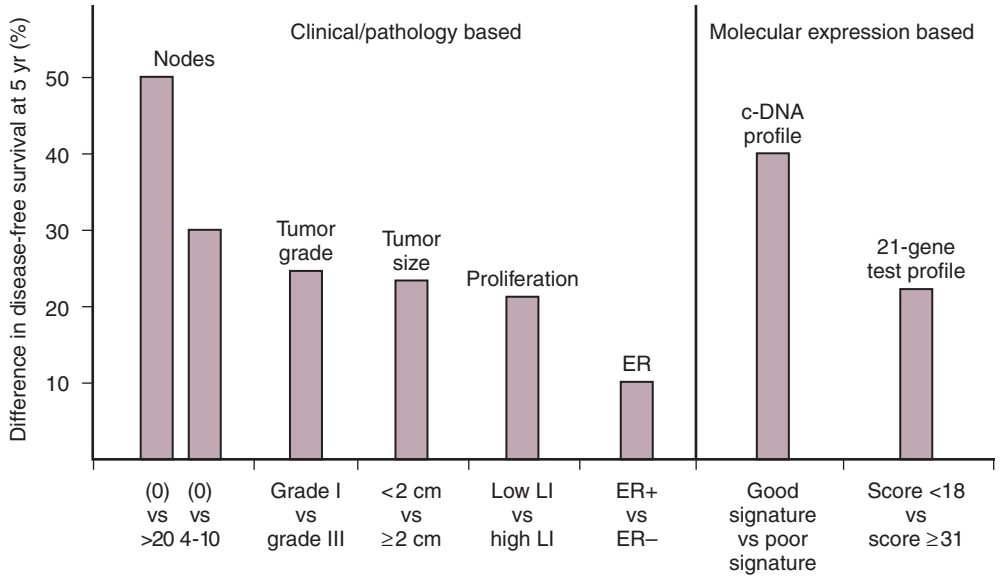

FIGURE 29.17 The prognostic value of several parameters related to patients with an initial diagnosis of breast cancer. All values are presented as the percent difference in disease free survival at the 5-year interval. The method of presentation allows one to determine the increased numbers of women per 100 who would be alive without recurrence at 5 years if they have a favorable prognostic factor compared with those with an unfavorable factor. ER, estrogen receptor; LI, labeling index. *(From Santen R. Endocrine responsive cancer. In Kronenberg HM, Melmed S, Polonsky KS, Larsen PR [eds]. Wiliams Textbook of Endocrinology, 11th ed, Philadelphia, WB Saunders, 2008.)*

Tumors generally must exceed 2 cm to be detected by palpation versus 1.1 cm by mammography and less than 1 cm for MRI. Earlier detection and use of adjuvant therapy likely explain the 12% decline in breast cancer death rate in the United States and Western Europe over the past 10 years. Adjuvant hormonal therapy is effective and associated with minimal side effects and toxicity compared to chemotherapy.

Hormones and Tumor Growth

The mechanisms whereby estradiol stimulates breast cancer growth are complex and involve direct regulation of genes involved in stimulation of proliferation and blockade of apoptosis. In addition, induction of growth factors through secondary actions and cross talk between growth factor and estrogen pathways at both upstream and downstream levels contribute to tumor growth.[148,149] Membrane initiated, extra-nuclear effects of estradiol on growth factor mediated mitogenic pathways transduce these signals through nuclear actions.[48] Hormonal treatment strategies utilize agents that abrogate the effects of estrogen on these extra-nuclear and nuclear pathways and thus inhibit growth and induce apoptosis.

Hormonal Therapies

Anti-estrogens, blockade of estrogen synthesis with aromatase inhibitors, suppression of ovarian function with GnRH analogues or use of additive androgens, progestins, and estrogens all represent proven hormonal therapy.[150] Patients who initially respond to hormonal therapy eventually relapse but frequently respond subsequently to second or third line therapies. The responses to sequential hormonal therapies suggest an adaptive process whereby tumors do not become totally resistant to hormonal therapy but develop a transitional state during which alternative means of blocking hormonal pathways causes tumor regression. As an example, patients relapsing following oophorectomy or tamoxifen treatment commonly respond secondarily to inhibitors of estrogen production (aromatase inhibitors).[150]

Predictive Factors

Hormone Receptors

Measurement of ERα and PR receptors provides the most robust means of predicting who will respond initially to hormonal therapy. Approximately 70% of breast tumors in postmenopausal women are ERα positive and 50% in premenopausal. Fifty to 75% of patients with ER+ and PR+ tumors respond to hormonal therapy versus 30% to 50% with ER+ and PR− tumors. Absence of ERα in the tumor predicts that fewer than 5% to 10% of women will experience benefit and, if both ERα and PR are negative, an even lower percent.[150]

With prior use of quantitative tissue binding assays for ER, the percentage of patients responding increased as a function of ER concentration.[150] As an example, responses to tamoxifen increased as a function of ER level with a statistically significant ($p = 0.002$) positive trend.[151] Data from the Oncotype DX assay provide confirmation regarding the role of ER quantitation. The absolute level of ER mRNA, which varies over more than a 300-fold range, correlates linearly with improved responses to hormone therapy. These data suggest that the concentration of receptor provides more useful information than using the standard dichotomized, negative or positive designation.[152] Quantitative receptor measurements also provide additional information about chemotherapy responsiveness as initially

suggested by Lippmann and colleagues. Low ERα levels, in addition to predicting nonresponsiveness to hormonal therapy, also predict a high likelihood of responding to chemotherapy.[153,154]

Standard clinical determinations of receptor content involve immuno-histochemical (IHC) analysis which has largely replaced ligand binding assays. Current criteria require that only 1% of cells be ERα positive to score the tumor ER+.[155] An alternative approach is to semi-quantitate the level of ER in tumors using the Allred scoring system which classifies tumors on the basis of proportion of cells positive and intensity of staining using a scale of 0 to 8.[156] As opposed to the ligand binding assays, IHC techniques detect only ERα but not ERβ. While ERβ may confer prognostic and predictive information, data are not yet sufficient to recommend its routine clinical assessment.[136,157]

An initial problem with ERβ measurements was the variable reliability of specific antibodies and differences in methodology but these problems have been largely solved.[138] However, the presence of five isoforms with differing biological import provide additional difficulties in the interpretation of ERβ data.[135,136] In addition, certain tumors make ERβ variant proteins which can hetero-dimerize with full length ERα or ERβ and exert dominant negative effects.[158] Additional studies are needed before ERβ measurements will be considered clinically useful.

Biological Parameters

Studies over the past several decades provide strong evidence that biological parameters also predict the potential effectiveness of hormonal therapies. Older age, long disease free survival, high degree of tumor differentiation, metastases to bone and skin and prior response to endocrine therapy predict a higher likelihood of responses to hormonal therapy.[150]

Signaling Pathway Signatures

Factors suggested as being predictive of responses to hormonal therapy but not fully validated for clinical use include ER coactivators and corepressors, members of the EFG-R family, and protein profiling signatures.[159,160] Gene array signatures have also been suggested as possible predictive tools but are not fully validated. The OncotypeDx^{R} risk score showed a nonsignificant ($p = 0.06$) trend as a predictive marker with low-risk score patients deriving substantial benefit from tamoxifen and those with high-risk scores minimal responses.[159]

Hormone Resistance

***De Novo* Resistance.** Approximately 40% of women with ER+ tumors fail to respond to initial hormonal therapy. Several new techniques have been employed to identify women with *de novo* resistance and to understand the mechanisms involved. DNA expression signatures have provided a degree of insight but these are not deemed sufficiently established at present to apply clinically[128,161-164] (NCCN Breast Cancer Panel, 2006 http://www.nccn.org/).

Acquired Resistance. Women who initially respond to hormonal therapy nearly uniformly relapse after an average of 12 to 18 months due to acquired resistance.[150] Recent concepts hold that breast cancer cells are inherently plastic and capable of adapting to any given hormonal therapy with utilization of one of several alternative signaling pathways. Sequential second and third line hormonal therapies can then block these alternative pathways and induce additional responses.[165-171]

Multiple individual factors and integrative pathways may be involved in resistance in individual tumors as outlined in Table 29.3 and described in detail in several reviews.[148,149,172,173] Most information has been gained from study of breast cancer cells grown *in vitro* or as xenografts and exposed long term to tamoxifen or estrogen deprivation. Grouped according to the general mechanistic categories involved in acquired resistance, these include (1) loss of ERα or its functionality, (2) conversion of tamoxifen from an estrogen antagonist to agonist, (3) enhanced extra-nuclear effects of ERα, (4) up-regulation of non-ERα-mediated cell proliferation pathways, (5) signaling pathway modifications resulting in reduced apoptosis, (6) changes in the breast tumor microenvironment, (7) development of hypersensitivity to estrogen, and (8) miscellaneous metabolical and cellular changes. As these individual components frequently work in concert through pathway cross-talk, research emphasis currently focuses on integrative signatures to assess these interactions and to determine which pathways predominate.

A few specific examples from recent data highlight the complexity of changes resulting in acquired resistance. Truncation of the estrogen receptor into a 36 Kd isoform results in an anti-estrogenic ER.[174] Enhanced expression of the ER coactivator AIB1 results in tamoxifen resistance.[148] Up-regulation of signaling pathways involving MAP kinase, PI-3 kinase (also named protein kinase B), AKT, mammalian target of rapamycin (mTOR), vascular endothelial growth factor (VEGF), HER-2, and fibroblast growth factor (FGF) result in proliferative and angiogenesis signals independent of ER alpha. Scaffold proteins such as 14-3-3-ξ, when up-regulated, result in coordinated overexpression of the MAP-kinase, EGF-R, AKT, and HER-2 pathways.[175] Alterations of BCL Xl, caspase 9, BIK, BCL-2, and Bcl-2 homologous killer (BAK) can dampen apoptosis and thus add to increased tumor cell survival. Tumors adapting to estrogen deprivation therapy become hypersensitive to lower amounts of circulating estrogen which then "drive" cell proliferation.[176-178] Alterations of the microenvironment mediated by the integrins, Crk-associated substrate (CAS), adhesions molecule, and immune cell function can contribute to hormone resistance.[148]

Concepts regarding resistance developed from experiments in breast cancer cell cultures and xenografts frequently translate into clinically important concepts. As examples, HER-2 and AIB1 over-expressing tumors exhibit resistance to tamoxifen in patients.[148] The estrogen hypersensitivity concept likely explains secondary responses to aromatase inhibitors in patients relapsing after oophorectomy since the third generation aromatase inhibitors lower estradiol levels substantially below these achieved by oophorectomy.[179] Addition of growth pathway inhibitors to hormonal therapies, as a means to counteract resistance, provide a degree of additional clinical benefit as reviewed below.

Table 29.3 Acquired Hormone Resistance

General Category	Specific Alteration
Loss of ERα or loss of ERα function	• DNA methylation • ↑ Receptor degradation • Alternative splicing with ERα 36 receptor with antagonistic properties • ↑ Micro RNA regulation ERα • Corepressor and coactivator modulations • Antagonism of ERα by ERβ variants • Altered FoxA1 pioneer factor function
Enhanced estrogen agonistic activity of tamoxifen	• ↑ AIB1 co-activator function • ↓ NCOR corepressor function • ↑ PELP • ↑ HER-2 • ↑ IGF-1/IGF-1 R • ↑ EGF-R • ↓ miR 342 • ↑ 14-3-3
Enhanced non-genomic actions of ERα; enhanced cell proliferation through non-ERα mediated mechanisms	• ↑ Growth factor mediated pathways (EGF, IGF-1/insulin, PAK-1, IKK, SRC, c-myc, AP-1, NFκβ, PTEN mutations, HER-2, MAP-K, PI-3K/AKT, mTOR, VEGf, FGF) • ↑ Cell cycle mediators (cyclin D1, cyclin E), NKκβ • ↓ Cell cycle repressors (p21, p27, RB, micro RNA 221, 222)
Reduced apoptosis	• ↓ BCLXL, ↓ caspase 9, ↓ BIK, ↓ BAK, ↓ BCL-2
Hypersensitivity to estradiol	• ↑ ERα concentration • ↑ MAP-K • ↑ PI-3-K • ↑ mTOR • ↑ HER-2
Change in micro environment	• Altered integrin function • Altered stromal, immune cell function • Altered cellular matrix adhesion molecules • CAS activation
Alteration of metabolical pathways	• ↓ HMG-CoA reductase

ER, estrogen receptor; NCOR, nuclear receptor corepressor; PELP, proline, glutamic acid, leucine rich protein; HER-2, human epidermal growth factor receptor-2; IGF-1, insulin like growth factor-1; IGF-1R, insulin like growth factor-1 receptor; EGF-R, epidermal growth factor receptor; MIR 342, micro RNA numner 342; 14-3-33, name of scaffold protein; PAK-1, P21 activated kinase 1; IKK, inhibitor of nuclear factor K_β kinase; SRC, short for sarcoma, proto-oncogene encoding a tyrosine kinase; C-MYC, a regulator gene that codes for a transcription factor; AP-1, adaptor protein 1; NFKB, nuclear factor kappa light chain enhancer of activated B cells; PTEN, phosphatase and tensin homolog; HER-2, human epidermal growth factor receptor-2; MAP-K, mitogen activated protein kinase; PI-3K, phosphoinositol-3-kinase; AKT, also known as protein kinase β; mTOR, mammalian target of rapamycin; VEGF, vascular endothelial growth factor; FGF, fibroblast growth factor; RB, retinoblastoma protein; P21,27, cell cycle inhibitors named for molecular weight; Cyclin E, cell cycle stimulating protein variety E; BCL-XL, BAK, BCL-2, BIK, family of evolutionary proteins; HMG-CoA reductase, 3-hyroxy-3 methyl-glutaryl-CoA reductase.

Hormonal Therapies for Breast Cancer

Background

Decisions regarding hormonal therapy must take into account age and menopausal status; tumor size, invasiveness, biological aggressiveness, receptor content, and metastatic sites; and prior responses to hormone therapy. *In situ* cancer is viewed differently than invasive. The treatment of ductal carcinoma *in situ* involves local excision with preservation of wide tumor free margins and radiotherapy for selected lesions. Hormonal therapy, used for ER+ lesions, reduces local recurrences and prevents new ipsilateral and contralateral tumors.

Patients with invasive breast cancer undergo lumpectomy or mastectomy and, if warranted, radiotherapy. Most patients then receive adjuvant therapy to destroy occult cancer cells at loco-regional and distant metastatic sites. Adjuvant therapy refers to the treatment used after breast surgery and before signs of recurrent disease in an attempt to eradicate micro-metastases or occult, non-resected local tumor cells. Upon tumor recurrence, the disease is called advanced and first, second, and third line hormonal or chemotherapies are then utilized in sequence. A recently introduced approach, neo-adjuvant hormonal therapy, involves use of hormonal therapy for 3 to 4 months prior to surgery for patients with large tumors. The goal is to reduce the size of the lesion so as to make lumpectomy a feasible alternative to mastectomy.

Mechanisms and Efficacy

The molecular mechanisms underlying the use of hormonal therapy and the efficacy of specific approaches will be reviewed in the next section. Practical recommendations about specific sequences based on current guidelines are then covered in a later section of this chapter.

Tamoxifen

Mechanisms of Action

In premenopausal women, tamoxifen exerts anti-estrogenic effects on breast which are similar to those induced by surgical removal of the ovaries with resultant estrogen deprivation. The estrogen agonistic properties of tamoxifen in premenopaual women are minimal. In postmenopausal women, tamoxifen acts an anti-estrogen on breast tissue but exerts estrogen agonistic effects on uterus, vagina, bone, pituitary, and liver.[150,180-182] For this reason, tamoxifen is classified as a selective estrogen receptor modulator or SERM as is its close relative, toremifene. Attempts to determine the

mechanistic reasons for the divergent actions of tamoxifen on various tissues in premenopausal and postmenopausal women have led to a better understanding of the complexity of ER mediated transcriptional regulation. (Reviewed briefly here and covered in more detail in Chapter 11.)

Tamoxifen binds to ERα in its ligand binding domain (AF 2) which then facilitates the binding of the anti-estrogen-ER complex to specific estrogen response elements on DNA (EREs).[183] Conformational changes in the ER binding pocket at helix 12 induced by anti-estrogens hinder binding of coactivators to the ER and facilitate binding of corepressors. The continued presence of corepressor in the complex is thought to explain the anti-estrogenic properties of tamoxifen. The relative amounts of corepressor and coactivator in certain tissues and the presence of other factors regulate whether tamoxifen acts as an agonist or antagonist. As examples, up-regulation of HER and AIB1 appear to enhance the estrogen agonistic properties of tamoxifen.[171] Additional estrogenic effects are mediated by membrane initiated (extra-nuclear) actions at the cell membrane as well as by tethering of the ER to binding sites on c-Jun, SP-1, IGF-R, PI-3 kinase, HER-2-Neu, c-Src.[184-187]

Metabolism of Tamoxifen

The metabolical conversion of tamoxifen to 4-OH tamoxifen and then to endoxifene is thought to be critical for the efficacy of tamoxifen since these two metabolites are much more active than the parent compound.[188] Based on the fivefold to tenfold higher blood levels of endoxifen than 4-OH tamoxifen in women taking this medication, it has been proposed that endoxifen is the major active metabolite. Conversion to endoxifen is mediated by the cytochrome p450 enzyme, CYP 2D6. Initial reports suggested a poorer prognosis in tamoxifen treated patients with low levels of CYP2D6 activity. More recent reports have not confirmed this finding and definitive conclusions await further studies.[188-192] In the meantime, clinical guidelines NCCN Breast Cancer Panel, 2006, (http://www.nccn.org/) suggest avoiding certain SSRIs such as fluoxetine and paroxetine that can block cyp2D6 and thus endoxifene formation in women being treated with tamoxifen. Based on the conflicting clinical evidence, routine measurement of CYP2D6 is not recommended (NCCN Breast Cancer Panel, 2 http://www.nccn.org/006).

Overall Efficacy

Until recently, the overall benefit of tamoxifen was usually reported as the relative improvement in frequency of defined events such as tumor recurrence or survival. In the neo-adjuvant, adjuvant, and advanced disease settings, tamoxifen results in a relative benefit of approximately 50%. Absolute benefit rate has now been widely accepted as a more relevant statistic. This is defined as the absolute number of women per hundred treated who benefit from taking tamoxifen. The absolute benefit increases as a function of the event rate even though the relative 50% benefit does not change. The most important response parameter is disease recurrence which is reduced by tamoxifen (Fig. 29.18).

Efficacy in Ductal Carcinoma in situ *(DCIS)*

Randomized trials demonstrate the benefit of tamoxifen in women with DCIS.[193] In a large NSABP clinical trial, 13% of women treated with lumpectomy, irradiation, and placebo experienced a new tumor event over 5 years.[193] One third of these new events involved appearance of a contralateral breast cancer; one third a new ipsi-lateral tumor and one-third, local recurrence of the original tumor. Tamoxifen reduced these events in absolute terms by 5% with equal benefit in preventing new contra-lateral and ipsi-lateral tumors and recurrence of the original tumor. A later post-hoc analysis reported that only women with ER+ tumors benefitted from this approach.[194] A 13.6-year follow-up confirmed the durability of the responses to tamoxifen.[180] The beneficial effects of tamoxifen appear to be limited to those who had not received radiotherapy after excision.[195]

Adjuvant Therapy for Invasive Cancer

Tamoxifen is active only in women whose tumors are ER+ and/or PR+. A recent overview analysis provided a synopsis of our knowledge regarding adjuvant therapy with tamoxifen.[151] Use of tamoxifen for 5 years resulted in a reduction of cancer recurrence of 50% for the first 5 years and 39% for years 5 to 9. Breast cancer mortality at year 15 was reduced relatively by 30% which represented an absolute improvement of 9%. Premenopausal or postmenopausal women with positive lymph nodes at the time of diagnosis experienced a 10.9% absolute prolongation of recurrence free survival at 5 years in response to tamoxifen. A lesser effect (5.6%) was observed in those with negative nodes[196] (Fig. 29.18A). Tamoxifen also caused an absolute 1% to 5% reduction of contralateral breast cancers at 5 years depending upon underlying risk. More importantly, tamoxifen causes an increase in overall survival, suggesting that this drug may cure a fraction of patients. Longer follow-up, however, will be needed to verify this possibility (Fig. 29.18B and C).

Direct comparative studies indicate superiority of 10 years versus 5 years of tamoxifen therapy.[197] Previously, the optimal duration of use was generally agreed to be 5 years. Although usually only administered for 5 years, benefit carries over long-term ("carry-over effect"). The most recent update reported that the relative risk (RR) of disease specific mortality with tamoxifen versus placebo was 0.66 for years 0 to 4, 0.68 for years 5 to 9, and 0.68 for years 10 to 14 ($p < 0.001$) (Fig. 29.18B and C).[151]

Advanced Invasive Disease

Nearly half of women with ER+ advanced disease benefit from tamoxifen. Responses last 12 to 18 months on average before relapse.[150] Efficacy is limited to those with ER+ and/or PR+ tumors.[196] Selected studies indicate that the presence of HER 2 is associated with a decreased response to tamoxifen,[198,199] but not all data support this conclusion.[200] One large study [anastrozole, tamoxifen, alone and in combination (ATAC)] also suggested that ER+ and PR− tumors also respond less well to tamoxifen but a similar trial (Breast intergroup-BIG-1-98) did not confirm this observation.[113,114,201] Women with disease in soft tissue and bone experience the highest percentage response to tamoxifen whereas those with extensive liver metastases, brain metastases, or lymphangitic spread to lung appear to be relatively tamoxifen resistant even when the tumors are ER+.[150]

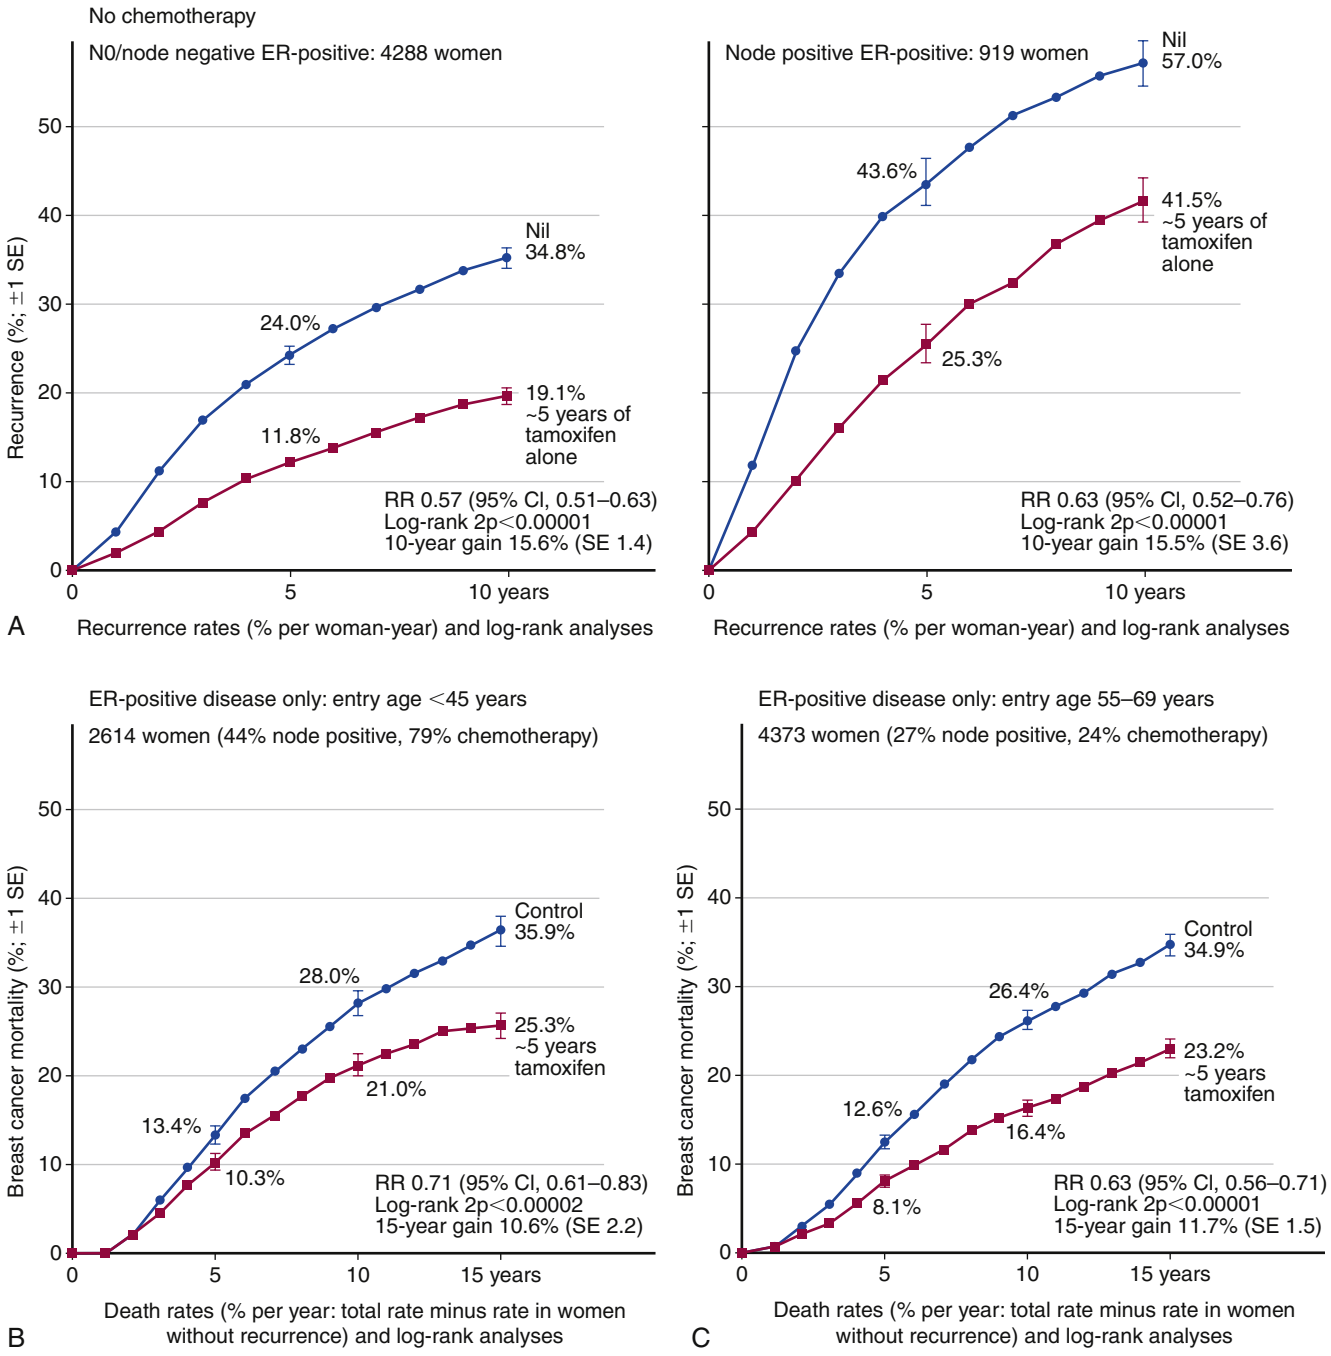

FIGURE 29.18 Effect of tamoxifen as adjuvant therapy of breast cancer on recurrence. Women receiving no adjuvant hormonal therapy (nil) are compared to those taking tamoxifen for 5 years. Women are then followed for up to 15 years. **A,** *Left panel,* Node negative ER+ disease. *Right panel,* Node positive ER+ disease. **B,** Effect of tamoxifen in node positive ER+ women less than 45 years of age on breast cancer specific mortality. **C,** Effect of tamoxifen in women ages 55 to 69 years old with ER+ tumors regardless of lymph node status. ER+, estrogen receptor positive; RR, relative risk. *(From Early Breast Cancer Trialist's Collaborative Group Relevance of breast cancer hormone receptors and other factors to the efficacy of adjuvant tamoxifen; patient–level meta-analysis of randomized trials,* Lancet *378:771–784, 2011.)*

Inhibitors of Estradiol Synthesis

Mechanisms

The aromatase enzyme catalyzes the rate limiting step in the conversion of androgens to estrogens.[202] One steroidal aromatase inhibitor, exemestane, and two nonsteroidal, anastrozole and letrozole, are highly potent and specific and approved in the United States and Europe. Both subclasses of inhibitor reduce aromatase to 1% to 2.5% of baseline activity in postmenopausal women,[203] substantially reduce plasma estradiol levels, suppress tissue concentrations of this steroid in breast tumors and are devoid of estrogen agonistic properties. Only postmenopausal patients benefit from aromatase inhibitors since interruption of estradiol negative feedback with a reflex increase in luteinizing hormone (LH) and follicle stimulating hormone (FSH) results in override of aromatase blockade in premenopausal women.[204]

Efficacy

Adjuvant Therapy. The efficacy of these agents in the adjuvant setting has been examined by trials comparing AIs with tamoxifen. Two similar large trials, the ATAC (Anastrazole and Tamoxifen Alone and in Combination—ATAC trial), and the Breast International Group (BIG) 98 trials compared the effects of nonsteroidal AIs (letrozole or anastrozole) versus tamoxifen with endpoints of time to progression of disease, time to treatment failure, and overall survival.[113,114,205] A third trial utilized the steroidal AI, exemestane.[206] At 5 years of follow-up, all three trials demonstrated an absolute superiority of the AI of approximately 3%. The BIG-98 study reported an 18% (HR 0.82 95%, CI 0.70 to 0.95) significant increase in overall survival with letrozole but only after correcting for selective crossover of tamoxifen patients.[207] Improved overall survival was not seen in the ATAC trial. On the basis of these data, the AIs have now been approved in the United States for use in the adjuvant setting. The third generation aromatase inhibitors (AIs) anastrozole, letrozole, and examestane have now been proven superior to tamoxifen in direct head to head trials.[110-114,208,209]

Sequential Use. Several studies are currently comparing the sequential use of AIs or tamoxifen during adjuvant therapy.[188,210-214] The IES study (International Exemestane Study) compared the effect of 5 years of tamoxifen with 2 to 3 years of tamoxifen with crossover to exemestane at 2 to 3 years.[215] This study showed a reduction in new cancer events in the AI compared to the tamoxifen group. The ABCSG-ARNO trial was similar but used anastrozole rather than exemestane. Switch to the AI resulted in a 3% improvement in event free survival and in overall survival.[213] However, with extended follow-up (median 71 months), the BIG-98 trial reported similar disease free survivals for the tamoxifen to lerozole sequence and the letrozole to tamoxifen sequence.[216] This finding was supported by the TEAM trial.[217] A meta-analysis of these studies reported benefit of the sequential use of an AI after tamoxifen.[218]

A four-arm study reported the comparison of 5 years of tamoxifen, 5 years of letrozole, and the switching from one to the other at 2 to 3 years. The estimated disease free percentages for the letrozole monotherapy, letrozole followed by tamoxifen, and tamoxifen followed by letrozole arms was respectively 87.9%, 87.6%, and 86.2%. These data suggest that either sequence is relatively equivalent (Fig. 29.19). However, nonsignificant trends favor the initial use of an AI in the patients with positive nodes.

Extended Use. Extended therapy with 5 years of letrozole after an initial 5 years of tamoxifen increased disease free survival and overall survival in women with lymph node +, ER+, and PR+ tumors.[219] In a separate subgroup analysis of this study, the group with positive nodes also reported improved overall survival.[188,220,221] The NSABP B-33 and ABCSG-6a trials reported similar findings.[188]

Advanced Invasive Disease. Five large, multicenter, multinational, randomized trials directly compared the AIs with tamoxifen.[222-228] All followed similar trial designs and included postmenopausal patients with locally advanced or metastatic breast cancer. No women had received adjuvant tamoxifen within 12 months and none were known to be ER negative. All trials demonstrated the superiority of the AIs in clinical efficacy with incremental responses ranging from 2% to 13%. The differences were statistically significant in all but one trial in which the receptor status was unknown in 55% of patients.[222] A recent meta-analysis of these data reported the superiority of AIs over tamoxifen with odds ratios (OR) for overall response of 1.56 (95% CI 1.17-2.07) and for clinical benefit with an odds ratio of 1.70 (95% CI 1.24 to 2.33).[208] In this analysis, the trend toward improved overall survival did not reach statistical significance (OR 1.95 95%, CI 0.88 to 4.30) but a Cochrane review did report significant survival benefit.[229] These data allow the conclusion that the AIs are superior to tamoxifen for objective response rate and clinical benefit.

Comparison Among AIs. A comprehensive, direct head to head comparisons of the three approved AIs: letrozole anastrozole, and exemestane in the neoadjuvant setting have shown that each of these agents have similar efficacy even though letrozole is more potent in suppressing estrogen levels.[230,231]

Side Effects and Toxicity of AIs versus Tamoxifen. AIs are associated with unique side effect and toxicity profiles compared to tamoxifen (Table 29.4). When analyzing these data, it should be kept in mind that adherence to the various therapies has not been complete and the side effect profile can contribute to lack of compliance.[188] Pooled data indicate that the AIs are associated with deep venous thromboses (DVT) and endometrial carcinoma (EC) less commonly than with tamoxifen.[232] On the other hand, the AIs are associated with an increased odds of developing bone fractures (OR 1.47 95%, CI 0.34 to 1.61) and cardiovascular disease (OR 1.26, 95% CI 1.10 to 1.43), particularly in more advanced stage 3 and 4 disease.[232-234]

Combining observations from all trials, it appears that nausea, hot flashes, and GI distress were comparable with tamoxifen or an AI. Comparisons of aromatase inhibitors with placebo (or with tamoxifen) reveal an increase in hot flashes, osteoporosis, and myalgia with aromatase inhibitors. Surprisingly, women receiving placebo or tamoxifen also experience these same side effects quite commonly. For example in the placebo arm of the extended letrozole trial,[235] arthralgias occurred in 16.6%, hot flashes in 40.5%, and myalgias in 9.5%.[235] Cholesterol levels are slightly higher in patients taking aromatase inhibitors as opposed to tamoxifen but this may reflect the lipid lowering properties of tamoxifen. If cholesterol levels do rise in response to the AIs, the increase is minor.[236] Generally considered to be unique to the AIs is a form of arthritis-arthralgia shown recently in GWAS studies to be associated with the inflammatory cytokine, interleukin (IL) 17 receptor.[237]

Fulvestrant

Clinical and experimental data suggest that long-term exposure to tamoxifen might induce tumors to undergo adaptive mechanisms and cause the agonistic properties of this SERM to predominate.[171] Based upon these observations, anti-estrogens were developed that were relatively devoid of agonist properties and were originally called "pure

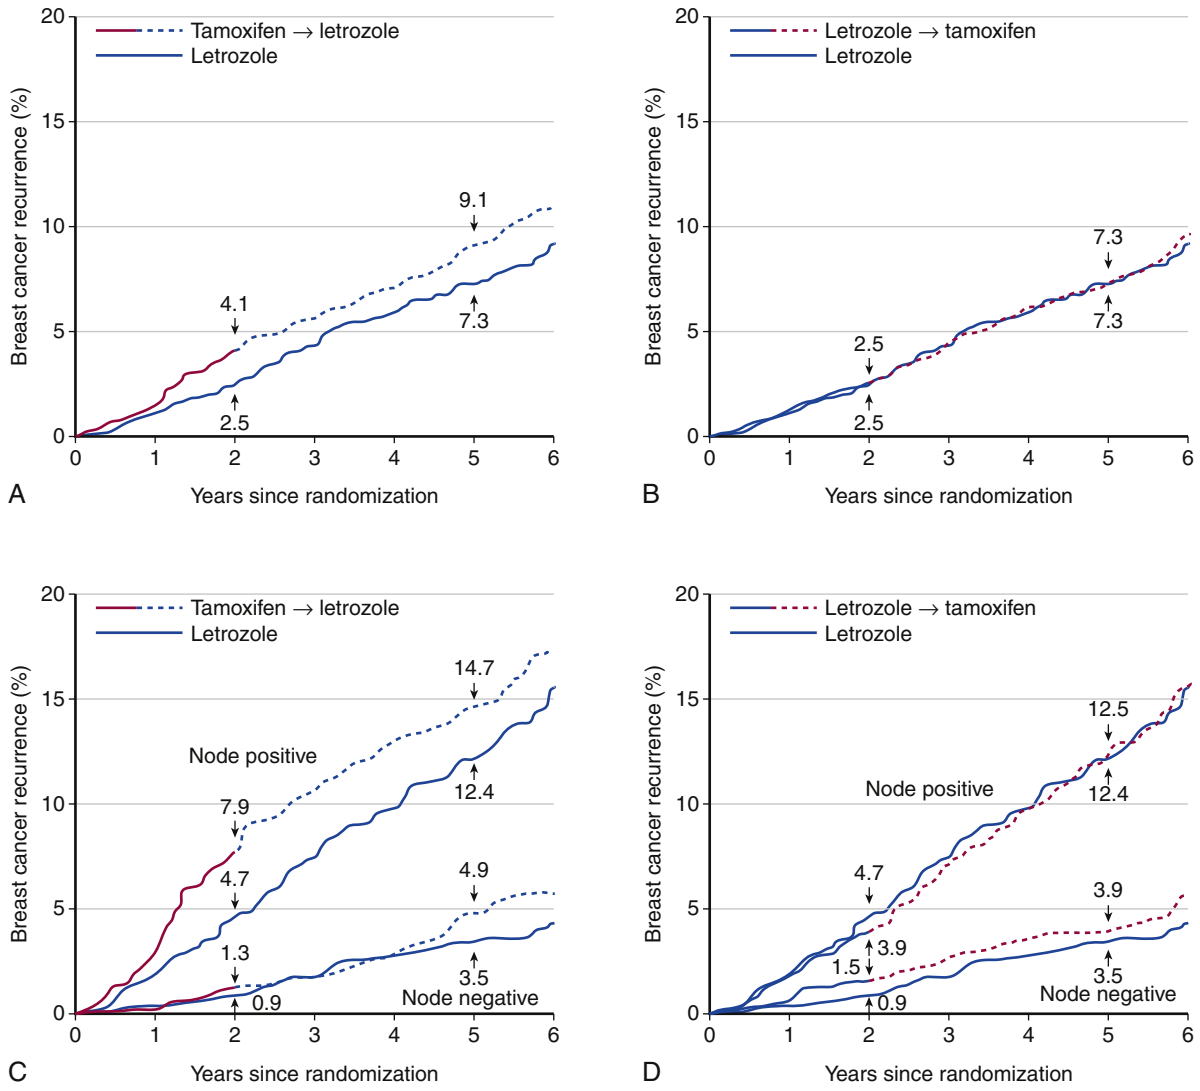

FIGURE 29.19 Results of the Breast International Group 98 (BIG 98) trial with four arms; tamoxifen for 5 years, letrozole for 5 years, tamoxifen for 2 years with switching to letrozole and letrozole for 2 years with switching to tamoxifen. Panels **A-D** illustrate the results. *(From The BIG-98 Colaborative Group Letrozole therapy alone or in sequence with tamoxifen in women with breast cancer,* N Engl J Med *361:766–776, 2009.)*

anti-estrogens." Fulvestrant, the FDA approved drug in this class, largely lacks estrogen agonist effects. It has two separate mechanisms of action: (1) it inhibits E2 mediated transcription by favoring binding of corepressors to the ER complex and (2) increases the rate of degradation of the ER.[238] Because of its effect to reduce the concentration of the ER, fulvestrant has now been termed an "Estrogen Receptor Down-Regulator or SERD."

A comparative study in 458 women with advanced disease demonstrated similar efficacy in patients treated with fulvestrant or the aromatase inhibitor anastrozole in patients progressing after prior endocrine treatment. Clinical benefit

(i.e., complete objective response, partial objective response, and stable disease for 6 months) occurred in 44.5% receiving fulvestrant versus 45% receiving the AI, anastrozole. Another study compared tamoxifen with fulvestrant as first line therapy of advanced breast cancer and found similar efficacy with respect to all parameters examined.[239] Finally, patients initially treated with fulvestrant and relapsing continue to maintain responsiveness to aromatase inhibitors or to tamoxifen.

After the introduction of fulvestrant, the concept arose that higher doses were needed to achieve maximum efficacy. Initial trials comparing standard to loading dose regimens to high dose therapy reported similar results with each approach.[240,241] Later studies of high dose fulvestrant reported a longer time to progression with this SERD versus anastrozole (23.4 months for fulvestrant versus 13.1 months for anastrozole, $P = 0.0496$).[242] Another study in metastatic disease also showed that high dose fulvestrant was superior to lower dose (HR 0.80, 95% CI 0.68 to 0.94).[243] Two studies examined the combination of fulvestant with an AI with one reporting positive results and the other not.[244,245] Based upon these data, the appropriate role of fulvestrant in the clinical armamentarium remains to be fully defined.

Surgical Oophorectomy. Prophylactic oophorectomy in premenopausal women represented the first adjuvant endocrine therapy for breast cancer. While initially thought to be ineffective, meta-analyses demonstrate clear benefit with a 6% absolute survival advantage at 15 years for patients less than 50 years of age who are lymph node negative and a 12.5% survival advantage for node positive patients (Fig. 29.20). Since receptor status was unknown in patients in these early trials, a large fraction of receptor negative patients were likely included and the results probably underestimated results for patients with receptor positive tumors. In the advanced disease setting, surgical oophorectomy induces clinical benefit in approximately 50% of ER+ and/or PR+ patients.[150]

Medical Oophorectomy. Medical ovarian suppression with GnRH analogues effectively replicates the hormonal effects of surgical oophorectomy (see chapter 31 for description of GnRH analogues and mechanism of action). Two studies indicate that the GnRH analogues also produce clinical effects similar to those induced by surgical oophorectomy in the advanced disease setting.[246,247] With respect to adjuvant therapy, studies have examined the effects of chemotherapy vs. Med OOX rather than comparing Med OOX to no treatment. The Zoladex Early Breast Cancer Research Association Study (ZEBRA) demonstrated equivalence of the GnRH agonist, goserelin, to standard CMF (cytoxan, methotrexate, 5-fluoro-uracil) chemotherapy on overall survival in ER+ patients.[248]

Ongoing studies are addressing two questions. The first is whether chemotherapy followed by complete ovarian deprivation is superior to chemotherapy followed by partial ovarian deprivation. Davidson and colleagues showed the superiority of CAF (cytoxan, doxorubicin, fluorouracil) followed by Med OOX plus tamoxifen versus CAF alone or CAF plus Med OOX.[249] The complete estrogen blockade strategy (Med OOX plus tamoxifen) improved time to

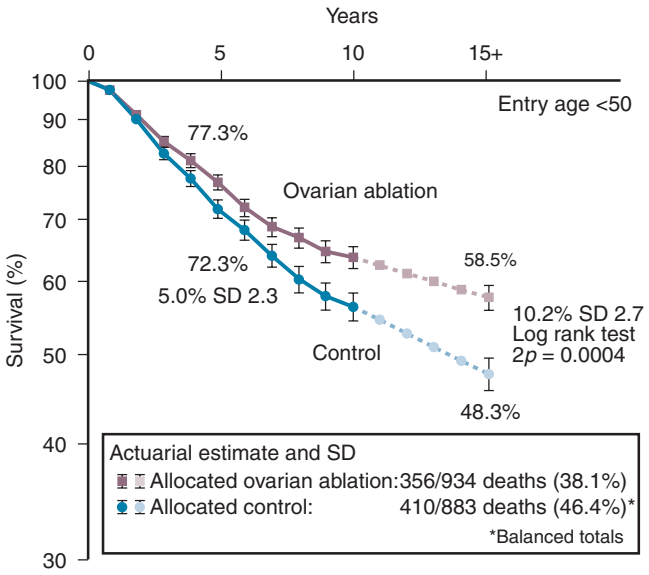

FIGURE 29.20 Survival data in patients undergoing a prophylactic oophorectomy in comparison with a group of women not receiving this therapy. *(From Santen R. Endocrine-response cancer. In Kronenberg HM, Melmed S, Polonsky KS, Larsen PR [eds].* Williams Textbook of Endocrinology, *11th ed, Philadelphia, WB Saunders, 2008, Figure 42.18.)*

treatment failure and disease free survival but not overall survival when compared to Med OOX without tamoxfen. One component of the SOFT trial is also addressing this point by comparing tamoxifen alone versus medical oophorectomy plus tamoxifen, versus medical oophorectomy plus an AI in patients who had received standard chemotherapy.[250] A recent study indicated that the AI plus medical oophorectomy (Med OOX) was not as effective as Med OOX plus tamoxifen.[251]

The second question addresses whether AIs are superior to tamoxifen for complete ovarian deprivation when given following chemotherapy and Med OOX. The TEXT Trial is addressing this issue by comparing Med OOX plus tamoxifen with Med OOX plus exemestane. Finally, to determine if chemotherapy is required at all when using complete estrogen deprivation, the PERCHE study will compare a chemotherapy/complete estrogen deprivation arm with one using only complete estrogen deprivation. Other studies will evaluate treatment effects in young patients with cancer since they are known to have a worse prognosis than older premenopausal women. The ongoing trials (SOFT, TEXT, PERCHE) which examine the individual roles of Med OOX, an AI, chemotherapy, and the combination of these agents should provide information regarding this subset of patients.

Chemical Castration. Chemotherapeutic agents destroy granulosa cells in the ovary and may result in transient or permanent amenorrhea and menopausal symptoms in premenopausal women (Fig. 29.21).[252] Complete ovarian destruction, as evidenced by the onset of amenorrhea, is more common in women over age 40.[252] Of interest is the return of menses in up to 20% of women over 40 when an aromatase inhibitor is started.[253] The effect of chemical castration was not initially felt to be clinically important. However, recent data suggest that adjuvant chemotherapy in premenopausal women exerts its anti-tumor effects on

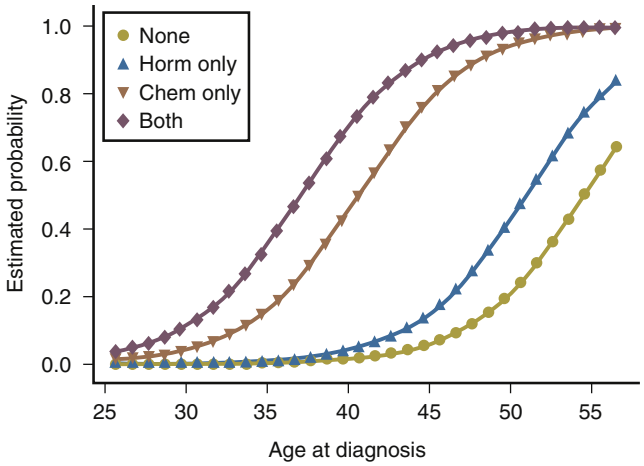

FIGURE 29.21 Cumulative frequency analysis of development of amenorrhea as a function of age in women with breast cancer in comparison with no treatment. The effect of chemotherapy on ovarian function reduces the age of menopause by an average of nearly 20 years. *(Taken from the data of Goodwin PJ, Ennis M., Pritchard KI, et al. Risk of menopause during the first year after breast cancer diagnosis,* J Clin Oncol *17[8]:2365–2370, 1999.)*

neoplasms with high ER levels through an ovarian ablative effect to a substantial degree.[254]

As a test of the contribution of chemical castration to efficacy, several trials have compared adjuvant chemotherapy to Med OOX with and without tamoxifen in premenopausal women.[250,255,256] The chemotherapy and hormonal therapies appear to produce comparable antitumor effects in women with moderate or high levels of estrogen receptor (ZEBRA trial).[250] The International Breast Cancer Study Group (IBCSG) trial VII compared CMF with goserelin as adjuvant therapy in premenopausal women. In those with ER+ tumors, disease free survival was 81% in both groups at 5 years.[257] These results suggest that at least part of the benefit of chemotherapy in premenopausal women results from "chemical castration."

Further support of the chemotherapy castration hypothesis comes from studies showing that chemotherapy is less effective in patients without complete cessation of menses and that addition of Med OOX in this setting provides improved responses.[258,259] It would appear then, that in women younger than age 40, addition of medical oophorectomy to chemotherapy would be beneficial. On the other hand, addition of Med OOX to chemotherapy in women older than 40 years old with ER positive tumors might not since chemical castration will be complete. In younger women at high risk of recurrence, chemotherapy followed by hormonal therapy is more efficacious than chemotherapy alone. These and other observations suggest that effects of chemotherapy are partially due to a reduction of hormone secretion and partially to cytotoxic effects.

Hormone Additive Therapy. Androgens or estrogens are generally considered inferior to use of tamoxifen and aromatase inhibitors as hormonal treatment.[150] Until recently, high dose estrogen had been used sparingly because of the increased side effect profile versus tamoxifen. However, a 20-year follow-up of a randomized comparison of tamoxifen with diethylstilbestrol (DES) reported a significant survival advantage in patients receiving the estrogen and lack of cross resistance between these two therapeutic approaches.[83] This surprising study suggests reconsideration of use of high dose estrogen in selected patients.[82] A series of preclinical studies demonstrated the likely mechanism for the beneficial effects of estradiol, namely the stimulation of apoptotic tumor cell death by estrogens.[80,81,260] A recent review reports a 30% response to use of high-dose estrogen in women refractory to multiple hormonal agents.[82]

Emerging Therapies. Neo-adjuvant therapy represents the use of an antitumor agent prior to surgery in an attempt to shrink the tumor sufficiently to allow lumpectomy rather than mastectomy.[181] The concept of neo-adjuvant chemotherapy has been adopted into clinical practice whereas neo-adjuvant hormonal therapy is now undergoing clinical trial. A nonrandomized trial demonstrated an 81% reduction on tumor volume with letrozole versus 75% with anastrozole and 48% with tamoxifen.[261] More recently, a randomized trial involving 324 patients compared letrozole 2.5 mg daily with tamoxifen 20 mg daily in women with ER+ tumors of greater than 2 cm in size.[262] Letrozole caused a 55% rate of objective response (CR and PR) versus 36% for tamoxifen ($p < 0.001$). Breast conserving surgery was chosen in 45% of patients receiving letrozole and 35% receiving tamoxifen ($p < 0.001$). Approximately 50% of women had a sufficient reduction in size of tumor to allow lumpectomy. Of interest is the fact that Her 2 positive tumors responded better to the AI (i.e., 88% response) than to tamoxifen (i.e., 21%).[199]

A similar trial [Immediate Preoperative Arimidex, Tamoxifen, or Combined with Tamoxifen (IMPACT)] confirmed the greater ability to perform lumpectomy in women receiving the AI (46% versus 22%, $p = 0.03$), but objective tumor responses in the AI and tamoxifen arms were similar.[263] Current guidelines consider neo-adjuvant endocrine therapy still to be experimental but this approach is becoming more widely used with emergence of these two studies. Nonetheless, comparison of groups of patients treated conventionally and with neo-adjuvant endocrine therapy with analysis of survival will be required to confirm the major utility of this approach.

Responses to neoadjuvant therapy might provide predictive information regarding long-term hormonal responsiveness or even overall survival. Emerging evidence suggests that a reduction of the Ki67 proliferation index might provide the best parameter to predict long-term outcome whereas apoptotic indices appear not to be informative.[264] cDNA array changes might also provide useful predictive information but verification of this possibility requires additional study.[265]

Anti-Growth Factor Therapy. Preclinical data suggest that tumors exposed to tamoxifen or to aromatase inhibitors adapt by up-regulating growth factor pathways. An attractive hypothesis is to administer growth factor pathway inhibitors concomitantly with endocrine therapies to inhibit the development of resistance. Several studies in xenograft models have proven the principle that this strategy can work and several clinical trials of this concept are underway. Limited studies suggest a progression free survival benefit of adding either trastuzamab or lapatinib to an AI in postmenopausal women with HER-2 and hormone receptor

positive metastatic breast cancer.[266,267] Two studies examined the effects of mTOR inhibitors in combination with AIs with one reporting positive results and the other negative.[268,269] The most recent study, breast cancer trials of oral everolimus-2 (Bolero-2), examined the mTOR inhibitor everolimus in women relapsing on an aromatase inhibitor and found an extended progression free survival.[269a] Results from addition of the EFG-R inhibitor gefitanib to hormonal therapy have been mixed with no consistent benefit.[270-272]

Recommended Approaches to Hormonal Treatment of Breast Cancer

Specific guidelines regarding hormonal therapy are based on several factors: subtype of breast cancer (i.e., Luminal A and Luminal B, Table 29.2) endocrine response category, menopausal status, and age of the patient. General principles regarding hormone therapy provided in this section attempt to consolidate two independent sets of recommendations: those of the 2011 St. Gallen expert panel and the NCCN guidelines.[128,273] It should be noted that the St. Gallen guidelines recently adapted an approach based on subtypes of breast cancer. Because of the simplicity of the approach, the St.Gallen guidelines are described here but these generally conform to the NCCN guidelines.

Adjuvant Treatment of Localized Breast Cancer (DCIS)

Consideration should be given to use of tamoxifen for 5 years for prevention of recurrence and contralateral breast cancer in both premenopausal and postmenopausal women with ER+ ductal carcinoma *in situ*.

Invasive Breast Cancer

Neoadjuvant Endocrine Therapy

This represents an option to be considered for postmenopausal patients with ER or PR positive disease. AIs are to be preferred based on trial data demonstrating greater efficacy than with tamoxifen. Treatment should be continued for 4 to 8 months with the primary goal to enable breastsparing excision with elimination of the need for mastectomy.

Adjuvant Therapy

Luminal A Tumors. The majority of patients can be treated with hormonal therapy alone. Unfavorable nodal status or other factors may suggest inclusion of chemotherapy (Table 29.5). Small tumors up to 0.5 cm with negative lymph nodes are so favorable that endocrine treatment may not be warranted.

In premenopausal women, evidence supports the use of tamoxifen, ovarian suppression with a GnRH analogue, tamoxifen plus ovarian suppression with a GnRH analogue, or surgical oophorectomy as adjuvant therapy. The St. Gallen panel recommends either tamoxifen alone or combined with ovarian suppression with consideration of surgical oophorectomy under selected circumstances.[274]

In postmenopausal women, current recommendations suggest the use of either AIs or tamoxifen as preferred initial adjuvant therapies for postmenopausal women with ER and/or PR+ tumors larger than 1 cm unless there are contraindications. If the lymph nodes are positive, the tumors are ER+ PR−, or the patient has a propensity for thromboembolism, an AI would generally be considered preferable.[275]

Table 29.5 Selection of Endocrine ± Chemotherapy

Clinico-Pathological Subtype	Type of Therapy
Luminal A	Endocrine therapy alone unless high nodal status or other indicator of high risk (e.g., Oncotype Dx score)
Luminal B (HER-2 negative)	Endocrine therapy with or without cytotoxic chemotherapy depending on level of endocrine receptor expression, high risk (e.g., Oncotype Dx score, nodal status), perceived risk, and patient preference
Luminal B (HER-2 positive)	Cytotoxics + anti-HER-2 agents + endocrine therapy (preference for aromatase inhibitors supported by selected data); no data are available to support omission of cytotoxics in this group

HER-2, human epidermal growth factor receptor-2, Oncotype Dx, 21 gene molecular diagnostic score to predict prognosis.

Luminal B/HER2− Tumors

In premenopausal women, endocrine therapy is the same as in the Lumina A patients. The inclusion and type of cytotoxics depends on level of endocrine receptor expression, perceived risk, and patient preference. Use of the OncotypeDx or Mammoprint signatures might be considered as a means to decide about chemotherapy.

In postmenopausal women, endocrine therapy is the same as in the Luminal A patients. The inclusion and type of cytotoxics may depend on level of endocrine receptor expression, perceived risk, patient preference, or molecular signature as above.

Luminal B/HER2+ Invasive Tumors

In premenopausal women, endocrine therapy is the same as in the HER2− patients. Adjuvant therapy with trastuzamab should be added in those with a tumor greater than 1 cm or positive lymph nodes and considered in those with smaller tumors. No evidence is available that supports the omission of cytotoxics in this group.

In postmenopausal women, the same endocrine therapy is chosen as in the luminal B and HER2− patients. The same considerations with respect to tumor size are applicable with respect to adding adjuvant trastuzamab as in premenopausal women. No evidence is available that support the omission of cytotoxics in this group.

Duration of Adjuvant Hormonal Therapy in Women with Luminal A and B Tumors

Premenopausal at diagnosis: Hormone therapy is recommended for 5 years. In selected patients, an aromatase inhibitor may be considered for an additional 5 years if the patient has become postmenopausal and no further endocrine therapy if the patient is still premenopausal.

Postmenopausal at diagnosis: The NCCN lists five possible approaches and does not specifically prefer one over another. These include (1) an AI for 5 years, (2) tamoxifen for 2 to 3 years and then switch to an AI for 2 to 3 years to complete the 5 years or to extend the AI to a total of 5 years, (3) an AI for 2 to 3 years with switch to tamoxifen to complete the 5 years, (4) tamoxifen for 4.5 to 6 years with an AI for an additional 5 years, and (5) tamoxifen for 5 years for those with a contra-indication to an AI, who decline its use, or are intolerant. When trastuzumab is used in HER2+ patients, the minimum duration should be 1 year.

Treatment of Advanced Disease

Prior Endocrine Therapy Less Than One Year Ago

Both Luminal A and B tumors are considered for hormone therapy with attention to menopausal status. Premenopausal women with intact ovarian function who had received tamoxifen previously should receive ovarian ablation or suppression therapy plus endocrine therapy as for postmenopausal women. The postmenopausal women relapsing after less than 1 year of therapy are considered to be hormone refractory and chemotherapy would usually be the preferred the next step.

Prior Endocrine Therapy More Than One Year Ago

Both Luminal A and B tumors are considered for hormone therapy. In premenopausal women, the tumor is considered possibly hormone responsive and ovarian ablation or suppression plus endocrine therapy with an AI if tamoxifen was previously used as for postmenopausal women is preferred. In postmenopausal women relapsing after more than 1 year of endocrine therapy, the preferred choices are either an AI, tamoxifen (or toremifene), or a selective estrogen receptor down regulator such as fulvestrant. If visceral disease is present in any of these categories, initial chemotherapy should be considered.

Sequential Endocrine Therapies

An individual responding to one hormone therapy can be considered to possibly benefit from a second, third, or even fourth line endocrine therapy. These include steroidal aromatase inhibitors, nonsteroidal inhibitors, fulvestrant, tamoxifen or toremifene, megestrol acetate, fluoxymesterone, and ethinyl estradiol or estradiol (estrace). After the use of second line endocrine therapy, no data are available to know which third and fourth line therapies are preferable.

Use of Chemotherapy

After the patient fails to respond to a sequential hormone therapy, the next choice is chemotherapy. Discussion of the current choices of chemotherapy is beyond the scope of this chapter. The interested reader is referred to the NCCN guidelines.[273]

Strategies Undergoing Evaluation

In premenopausal women, conclusive data regarding the superior efficacy of complete estrogen deprivation with Med OOX plus tamoxifen or an AI are lacking and the subject of ongoing study. Nonetheless, the St. Gallen Panel accepted the concept of complete estrogen suppression as reasonable for very young patients, especially in the intermediate and high-risk groups. This approach was also considered appropriate alternative therapy for premenopausal women at any age at high-risk, especially if chemotherapy did not induce complete ovarian failure. The Panel did not recommend GnRH analogues plus aromatase inhibitors outside of clinical trials.

Long-Term Quality of Life in Breast Cancer Survivors

With earlier diagnosis of breast cancer, an increasing percentage of women survive breast cancer long term. Two thirds of these women are menopausal at the time of diagnosis and half of the premenopausal women undergo permanent ovarian failure as a result of chemotherapy. Menopausal hormone therapy (MHT) is generally thought to be contraindicated in these women since estrogens may cause re-growth of residual tumor tissue after surgery or cause a second primary.[67] Data from *observational* studies, however, do not provide evidence of a deleterious effect. *Prospective* studies of the safety of MHT in this setting are conflicting as the Habits trial reports an increase in risk of recurrent breast cancer with MHT,[276] whereas the Stockholm trial does not.[277] The differences in results may relate to the increased use of tamoxifen (51%) in the Stockholm trial versus the Habits trial (22%) but this conclusion requires experimental confirmation. Until this issue is more definitively resolved, it is prudent to avoid estrogens in breast cancer survivors if alternatives to estrogen are effective.[67]

Several agents are available to substitute for estrogen. These include bisphosphonates to prevent or treat osteoporosis, statins to prevent heart disease, venlafaxine and gabapentin to diminish the number and severity of hot flashes,[278-280] vaginal moisturizes and lubricants without estrogen for symptoms of urogenital atrophy, and SSRIs for depression thought to be associated with estrogen deficiency. This approach does not protect against Alzheimer disease or improve cognitive function but the recent WHI study demonstrated that MHT increased rather than decreased the risk of dementia.[281] Use of low dose vaginal estrogens should only be used with caution and informed consent of the patient because of systemic absorption.[282] In general, these alternative approaches are not as effective as exogenous systemic estrogen. If alternatives to estrogen are not satisfactory, women might choose to receive MHT after a full discussion of the risks and benefits and with informed consent.

Breast Cancer in Men

The incidence of breast cancer in men is 100-fold lower than in women with 2140 new cases diagnosed in 2011 and 450 deaths.[146] The incidence of male breast cancer has increased over the past 8 years from 1450 cases per year in 2004 to 2140 in 2011. Median age at diagnosis is 65 to 67 years old and 35% occur in men 70 years old and older.[283] Approximately 90% are invasive ductal carcinomas but DCIS (ductal carcinoma *in situ*) is not uncommon.

Known risk factors include family history; clinical disorders associated with reduced testosterone production

or estrogen excess such as orchitis, orchiectomy, undescended testes, testicular injury, obesity, exogenous estrogen administration, and Klinefelter syndrome; radiation exposure; Jewish ancestry; BrCa1 and BrCa2 carriers, low levels of physical activity; prior chest wall irradiation, and benign breast disease.[284] Suggestive risk factors include the Cowden, Lynch, and Li-Fraumeni syndromes; mutations in PTEN, T53, and PALB2; and cirrhosis. Inconclusive factors reported in the literature to be possibly associated include mutations of the androgen receptor gene, the Chek 2 gene, prostate cancer, gynecomastia, occupational exposures, electromagnetic frequency exposure, high temperatures, diet, and alcohol.[285]

Male breast cancer typically presents as a painless, firm mass often associated with nipple retraction or ulceration, fixation of skin to underlying muscle, and palpable axillary nodes.[286] Diagnosis is then made by mammography and biopsy of the lesion. At presentation of breast cancer, 37.5% of men have regional lymph node involvement versus only 29.2% of women with this disease. Tumors are larger at diagnosis in men than in women and 41.7% of men have tumors localized to their breast versus 50.5% of women. The percent ER and PR positive is higher in men (90.6% and 81.2%) than in women (76% and 66.7% respectively). Two percent to 15% express HER2, a figure lower than in women. The 5-year survival rate is 63% and 10-year, 41%.[283]

Modified radical mastectomy is the usual surgical approach. Surgical assessment of the axillary nodes is an essential component of primary therapy. Sentinal node biopsy, as in women, can be considered but available data in support of this approach in men is limited due to the infrequency of male breast cancer. Adjuvant radiotherapy, particularly in men with positive nodes, is usually recommended but survival benefit is unknown. As 90% of men have ER + tumors, tamoxifen is chosen as the initial adjuvant therapy. Upon recurrence, if sufficient time has elapsed since adjuvant use, tamoxifen induces an 80% response rate and is the preferred first line therapy. Second line and later therapies can involve megestrol acetate, GnRH agonist analogues, and androgen. Aromatase inhibitors have been effective in a few patients but orchiectomy or GnRH suppression is required to prevent reflex rises in testosterone which can abrogate the estrogen suppressive effects. HER2 targeted therapy and chemotherapy have been effective in inducing remissions in selected patients. No randomized, controlled trials are available to accurately assess relative efficacies of various therapies for male breast cancer.[287]

Prostate Cancer

Incidence

Carcinoma of the prostate is the most common solid tumor and second leading cause of death from cancer in American men. Approximately 241,740 will be diagnosed with prostate cancer and 28,170 men will die from this disease in the United States in 2012.[146] The incidence of detected prostate cancer has increased exponentially over the past 2 decades but with a more gradual increase in the number of disease related deaths. Increased detection reflects not only an aging population but also the use of more sensitive screening techniques such as the measurement of serum prostate specific antigen (PSA),[288] first introduced in the mid-1980s. With the utilization of PSA, the incidence of newly diagnosed cancer of the prostate increased 18% per year from 1989-1992, compared to a 6% per year increase during the years 1985 to 1989. This increase subsequently leveled off to 14% per year between the years 1992 to 1995.[289] With its widespread use, PSA has increased the detection rate of clinically localized prostate cancer almost twofold compared to the use of digital rectal exam (DRE) alone.[290]As a result of PSA screening at diagnosis, the percentage of patients with low-risk disease, defined as clinical stage T1/T2a, biopsy Gleason score of 6 or less, and a serum PSA less than 10 ng/mL has increased.[291] In 1989, 31% of men at diagnosis met the criteria for low-risk disease versus 47% in 2002. Controversy has arisen as to whether or not these patients should undergo definitive treatment.

The global incidence of prostate cancer varies substantially. In Europe, the overall incidence rate was 93.4 per 100,000 in 2008 and tended to be lowest in the southern and eastern regions and highest in northern and Western Europe.[292] For example, the lowest and highest recorded incidence rates in 2008 were in Ukraine (27.7 per 100,000) and Ireland (183.1 per 100,000), respectively. Although the incidence of premalignant prostate lesions and latent prostate cancer is approximately the same in Japan and China as in the United States, the rates of invasive cancer differ markedly.[293,294] Additional mutations and promotional factors necessary to convert latent to invasive cancer apparently occur less commonly in the Japanese and Chinese living in Asia. In contrast, the initial mutations leading to latent cancer occur at the same rate. These observations suggest that environmental or dietary factors may influence later steps in the mutational process or factors that promote tumor growth. In support of these concepts, prostate cancer incidence increases when men migrate to a more western environment. Japanese men living in Hawaii have an incidence rate higher than those in Japan but lower than Caucasians living in the United States.[295]

Endocrinology of Prostate Cancer Growth

DHT, the 5 alpha-reduced product of testosterone (T), binds to the AR with a 2.5-fold higher affinity than T itself and serves as the major regulator of prostatic tumor growth. Direct effects of androgen itself, indirect effects induced by stimulation of growth factors, or a combination of these two mechanisms may mediate androgen induced proliferation.[296] Approximately 7000 μg of testosterone are secreted daily by the testes of which 500 μg are converted into DHT in various peripheral tissues (Fig. 29.22). The adrenal gland provides an additional 5% of the androgen produced in adult men. Testosterone as well as pre-androgens such as androstenedione, dehydroepiandrosterone (DHEA), and DHEA-sulfate originate in the adrenal and are also converted in peripheral tissues into DHT. In addition to peripheral conversion, a large fraction of the DHT present in benign and malignant prostatic tissue is produced locally in the prostate gland from circulating precursors. Therefore, approximately 40% of intraprostatic DHT originates from steroids of adrenal origin.

Prostate cancer cells contain ARs that bind DHT and transmit proliferative signals in androgen dependent prostate cancer. As opposed to the use of receptor assays in breast cancer, measurement of the AR does not provide

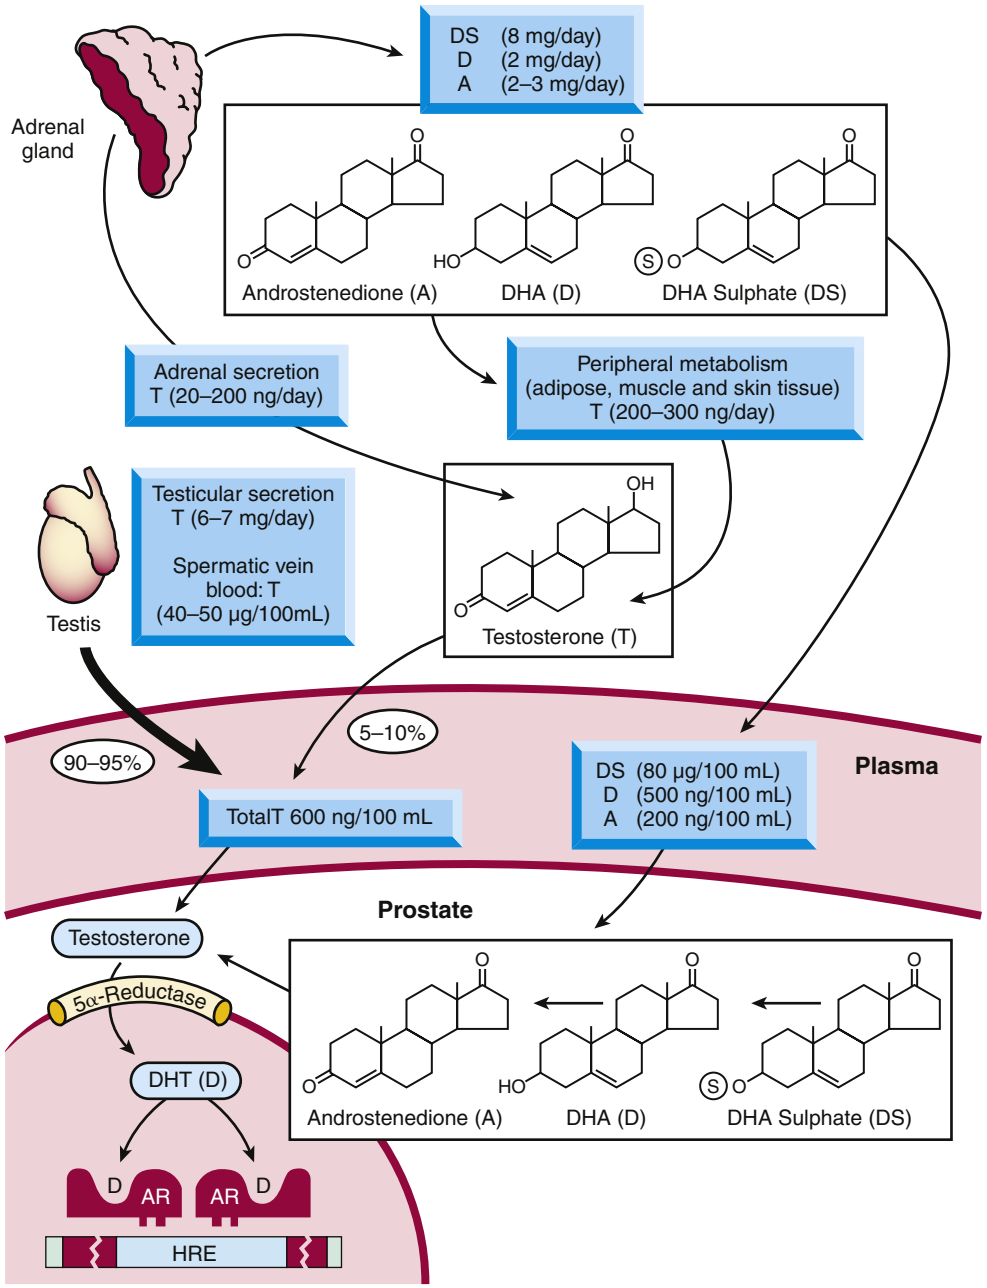

FIGURE 29.22 Diamgrammatic representation of the sources of hormones available to prostate tissue. *(From Santen R. Endocirne responsive cancer. In Kronenberg HM, Melmed S, Polonsky KS, Larsen PR [eds].* Wiliams Textbook of Endocrinology, *11th ed, Philadelphia, WB Saunders, 2008.)*

predictive information regarding hormone responsiveness. Mutations of the AR occur but the frequency in early stage prostate cancer is quite low.[297,298] However, in metastatic and androgen-independent tumors, the incidence of mutations is much higher (up to 40%).[299] The frequency and type of mutation appears to be influenced by selective pressure, namely that exerted by anti-androgens. For example, men treated with flutamide exhibit higher levels of mutations compared to men not receiving this anti-androgen.[300] The majority of these mutations occur at AA 877, the same site mutated in LnCAP cells which allows flutamide to become an androgen agonist. This finding helps explain the occurrence of flutamide withdrawal responses observed in men with prostatic cancer (discussed later in the chapter).[301-303]

Men with prostate cancer respond to androgen deprivation for varying time periods. Typically, after an initial response to androgen blockade therapy, tumors will progress and this will usually be in concert with an increase in serum PSA. Secondary responses to blockade of adrenal androgens occur as evidenced by a 50% or greater decrease in PSA levels and often by pain reduction and improvement of fatigue but rarely by objective regression of tumor mass or healing of bone lesions.

Several theories might explain secondary hormonal responses and evolution into completely androgen independent growth, but none are definitively proven. Nonmutually exclusive mechanistic theories include development of hypersensitivity to residual androgens, enhancement of androgen receptor action by phosphorylation of key sites in the receptor, and ligand independent activation of the receptor via growth factors or mutations. A concept that underlies all of the proposed theories is that growth factor

pathways can become up-regulated and/or activate the AR independently of ligand in tumors leading to androgen resistance.[304] For example, the phosphatidylinositol 3-kinase (PI3K)/AKT signaling pathway regulates activity of the AR through phosphorylation of the receptor itself as well as downstream targets resulting in resistance to apoptosis and increased cell survival.[305,306] Altered downstream targets of PI3K/AKT include mTOR, p70S6 kinase, and 4E-BP1.[307,308] In addition, mutations or inactivation of PTEN are found commonly in advanced prostate cancer. PTEN is a phosphatase that dephosphorylates and inactivates PI3K. With mutational inactivation of PTEN, an associated up-regulation of phosphorylated, activated AKT occurs as well as downstream activation of mTOR. Antibody-based approaches demonstrate that loss of PTEN is highly correlated with activation of AKT and phosphorylation and activation of S6, a substrate of p70S6 kinase. For this reason, use of agents to block mTOR, such as temsirolimus and everolimus, are currently being examined in prostate cancer.[309-312] MMP-9 is also up-regulated in the process of development of resistance and could serve as an additional target for therapy.[313]

Etiology

Primary nonmodifiable risk factors for prostate cancer development include age, race, and family history.[314] The Surveillance Epidemiology and End Results (SEER) Registry reports that the incidence of prostate cancer increases with age from 9.2/100,000 between ages 40 to 44 years old to 984.8/100,000 at ages 70 to 74 years old.[315] Incidence is increased in African-American males with an age adjusted relative risk of 1.73 (95% CI 1.23 to 2.45). The mortality rate is nearly double compared to Caucasian males. Genetic factors are also important as the relative risk for a man with one first-degree relative with prostate cancer increases over twofold with even higher risk with multiple first-degree relatives.[316,317] Overall, men with prostate cancer report a positive family history 3.1 to 4.3 times more commonly than men without and twin studies have shown a genetic component in 42% (95% CI: 29, 50%).[20]

Specific genetic lesions resulting in prostate cancer development are uncommon and evidence is lacking regarding causality in potential loci. However, recent genome-wide association studies have identified 46 susceptibility loci which are currently being studied in order to better create risk prediction models.[318] Candidate genes based on linkage analysis include *BRCA2*,[319] *RNASEL* (an endoribo-nuclease), macrophage scavenger receptor 1 gene *(MSR1)*, AR (androgen receptor), CYP17 (cytochrome p450 enzyme responsible for the 17 hydroxylation of steroids), and SRD5A2 (the predominant form of 5-alpha reductase in the prostate).[320] Several epidemiological studies have reported a correlation between the number of polyglutamine repeats (CAG) on the *AR* and incidence of prostate cancer but others have not confirmed this finding.[320] Data from the Utah pedigrees identified another high-risk gene on chromosome 17p called prostate cancer susceptibility gene encoding a metal dependent hydrolase (ELAC/HPC2) in exon 1 of the *AR* gene.[321,322] BRCA2 but not *BRCA1* was associated with prostate cancer in Ashkenazi Jews whereas most series in unselected populations do not show this association.[323]

A recent preliminary finding suggested that fusions between two genes could activate carcinogenic pathways, a concept analogous to the fusion of the bcr-abl genes in leukemia. Based upon outlier cDNA studies, fusions between the TMPRSS2 and the ETS genes EGR and ETV1 were commonly found in prostate cancer (i.e., in more than 90% of the 57% of tumors that over express *EGR* or fusion between TMPRSS2 and ETS gene [ETV1]) and may play an etiological role.[324]

Modifiable risk factors that have been proposed include diet, body mass index, smoking, and physical activity. The significant differences in age standardized global incidence rates provide highly suggestive evidence that dietary and environmental factors play major roles in risk. Differential ingestion of high fat diets, red meat, green tea, or soy products provide potential explanations for the divergent rates of prostate cancer among different populations.[325-327] Several case-control studies examining western diets have shown a positive association with prostate cancer risk but these studies are confounded by potential recall bias and do not prove causality.[328-330] Others suggest that components of vegetables such as lycopene or antioxidants such as vitamin E and selenium may reduce the risk of prostate cancer. However, results examining dietary supplements have been mixed, possibly due in part to the difficulty in accurately recording the true intake of vitamins and minerals. Surprisingly, studies including the *Cancer Prevention Study* and the *National Institutes of Health-American Association of Retired Persons Diet and Health Study* both demonstrated that multivitamin users were at higher risk for fatal prostate cancer compared to those men who did not consume multivitamins.[331,332] One study, the *Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study* which supplemented alpha-tocopherol (50 mg/day) to elderly Finnish smokers, did demonstrate a decreased risk of prostate cancer.[333] However, the Selenium and Vitamin E Cancer Prevention Trial enrolling over 35,000 men, did not find an association between prostate cancer risk and either Vitamin E or Selenium.[334] In summary, prospective studies of dietary factors and supplements have not confirmed beneficial effects of any of these components.[335,336]

Chronic or recurrent inflammation may play a role in the development of prostate cancer. Prostatitis, diagnosed by symptoms, occurs in 9% of men between 40 and 79 years old.[320] Inflammatory cells release oxidants that could result in DNA damage and act as initiators of prostate cancer. A lesion called "proliferative inflammatory atrophy" has been proposed as a precursor to prostatic intraepithelial neoplasia (PIN) and prostate cancer.[337] Chronic inflammation is associated with proliferative inflammatory atrophy and signs of molecular stress such as high levels of glutathione-S-transferase A1 and cyclooxygenase-2 (COX-2). These observations suggest that inflammation increases oxidative stress which in turn causes DNA adducts which could then contribute to prostate cancer development.[320]

Hormonal factors and particularly circulating androgens likely play a role in the initiation and promotion of prostatic cancer. Men surgically orchiectomized early in life, historically Chinese Emperor-serving eunuchs or Italian Castrati singers,[338] end up with nonpalpable or rudimentary prostates and in theory would rarely develop prostate cancer, although the latter has been difficult to document in the published literature.[339]

Ross and colleagues suggested that the lower frequency of prostate cancer in Japanese and Chinese populations may relate to a lower level of 5-alpha reductase activity than in their Caucasian counterparts, perhaps on a genetic basis.[340] This could lead to lower levels of dihydrotestosterone (DHT) in prostatic tissue and less androgen induced proliferation. However, direct isotopic kinetic measurements of 5-alpha reductase activity in Chinese versus Caucasian men demonstrated no differences in the levels of this enzyme, at least in peripheral tissues.[341]

Clearly, the most important advancement of our understanding of the relationship between androgens and the prostate came from the work of Charles Huggins, eventually leading to his award of the Nobel Prize in 1966. The novelty of Huggins' findings was that hormones stimulated prostate tumors to grow and also enhanced tumor cell survival.[342] Huggins demonstrated that orchiectomy controlled tumor growth, at least temporarily in men with advanced metastatic prostate and prolonged their survival. Subsequent studies on Dominican Republic pseudo-hermaphrodites and other males who congenitally lack the type II 5-alpha reductase enzyme helped confirm the importance of DHT in prostate growth and development.[343,344]

Prevention

A large randomized, controlled trial, the *Prostate Cancer Prevention Trial (PCPT)* tested the hypothesis that reduction of DHT formation with finasteride,[345] an inhibitor of type II 5-alpha reductase, would reduce prostate cancer incidence. The trial, initiated in 1993 and enrolling 18,882 men aged 55 or older with a normal digital rectal exam (DRE) and initial PSA of 3.0 or lower, included 9060 men in the final analysis. A biopsy was performed at the end of the study (7 years) or for clinical indications (e.g., abnormal DRE or adjusted PSA of 4.0 or higher). At the end of 7 years of therapy, 4368 men receiving finasteride and 4692 receiving placebo were available for analysis. The finasteride group experienced a 24.8% reduction in prostate cancer diagnosis (95% CI: 18.6 to 30.6%; $P < 0.001$). However, tumors of Gleason grade 7 to 10 occurred in 15% more men receiving finasteride (280 of 757 tumors or 37%) than in those taking placebo (237 of 1068 tumors or 22%; $P < 0.001$). High-grade disease occurred in 6.4% of the finasteride group and 5.1% of the placebo group. Five deaths due to prostate cancer occurred in each study arm. Side effects in the finasteride group included reduced volume of ejaculate, erectile dysfunction, loss of libido, and gynecomastia ($P < 0.001$ versus placebo) but attributable risks of these side effects ranged only from 1% to 13%.

These results stimulated multiple follow-up studies to identify possible reasons for the finding of an increase in higher grade lesions. Possible explanations included pathological artifact, volume-grade artifact, or detection bias. One of the effects of finasteride is shrinkage of normal prostate volume to 50% of the original size. Therefore, it is theoretically possible that biopsy of larger prostates (i.e., men on placebo) would result in fewer high-grade cancers detected and that the true incidence would be similar between the two groups. Notably, this detection bias was demonstrated in retrospective reviews.[346,347]

If the increase in high-grade lesions were real and not artifactual, several mechanisms have been postulated. The results could be due to selection of androgen-independent clones induced by lower intra-prostatic DHT as has been observed in hypogonadal men with prostate cancer.[345,348] Polymorphisms of genes involved in estrogen metabolism that are associated with increased risk of prostate cancer could have been involved.[349] Since the Gleason grading system was created based on prostate tumors that were hormonally-naïve,[350] finasteride may have altered the diagnosis of high-grade cancer by modulating the influence of the epithelium.[351,352]

Despite the evidence that finasteride did decrease the incidence of low-grade prostate cancers, debate continues as to whether or not it should be used in prostate cancer prevention. Analysis of the lifetime implications, side effects (e.g., erectile dysfunction, loss of libido, and gynecomastia), and cost effectiveness of using finasteride for prostate cancer prevention does not appear to support its routine use.[353]

The reduction by dutasteride of prostate cancer events (REDUCE) trial[354] examined the possibility that blocking both type I and type II 5-alpha reductase might be superior to blocking only type II. Dutasteride, approved in 2002, blocks both type I and type II 5 alpha reductase subtypes and putatively might be superior for prevention of prostate cancer. Dutasteride in comparison with finasteride, induces a greater reduction in both serum[355] (94.7% versus 70.8%) and intra-prostatic[356] (greater than 90% versus 68% to 86%) DHT levels.[355,356] The REDUCE trial enrolled a total of 6729 men with the following characteristics: ages 50 to 75 years old, initial PSA of 2.5 to 10 ng/mL, and negative biopsies at the time of enrollment. Among the men randomized to 0.5 mg/day of dutasteride (n = 3305) or placebo (n = 3424), 659 and 858 developed prostate cancer within the 4-year study period demonstrating a 22.8% (95% CI: 15.2, 29.8) reduction in relative risk of prostate cancer in the treated group. Unlike the PCPT trial, however, no increased risk of high-grade cancers was noted with dutasteride.[357] Although the lack of an increase in high-grade cancer in the REDUCE trial would support that this finding was an artifact in the PCPT, these studies were designed differently. Most importantly, subjects in the REDUCE trial underwent a biopsy at the beginning of the study and were enrolled only if this was negative. Therefore, in the PCPT, some subjects may have harbored occult prostate cancer that went undetected until well into the study.

Epidemiological and secondary endpoint data suggested the possibility that other approaches such as supplementation of selenium, vitamin E, and lycopene might prevent prostate cancer but available data are not supportive. The *Selenium and Vitamin E Cancer Prevention Trial* (SELECT) randomized 34,887 men,[358] aged 55 years old or older (50 years old if African-American) with normal DRE and PSA of 4.0 ng/mL or less, to receive selenium, vitamin E, both agents, or placebo. No significant differences in prostate cancer incidence were observed and the study was stopped in 2008. Notably, extended follow-up through 2011 demonstrated an actual increased risk in prostate cancer development with vitamin E.[359]

Early Case Detection

DRE provided the only prostate cancer screening modality available prior to the PSA era and cancers then were

detected at more advanced stages. The introduction of serum PSA allowed detection of earlier stage disease. PSA is secreted into prostatic ducts under androgen influence and activation of PSA occurs upon cleavage of seven amino-terminal amino acids by the protease human kallikrein 2.[360] Although investigators have localized PSA to the periurethral glands of males and females as well as the apocrine sweat glands in males,[361] the vast majority of PSA is produced by prostatic acinar and ductal epithelium which secrete the protein into surrounding lumina. PSA circulates in the blood either free or complexed with the serum proteins, α2-macroglobulin or α1-antichymotrypsin.[362] A change in the serum concentration of PSA in an individual can signify an abnormal process such as cancer of the prostate. Alternatively, other benign entities can cause an increase in serum PSA such as benign prostatic hyperplasia (BPH), infection, inflammation (e.g., chronic prostatitis), ejaculation, urinary obstruction, and recent manipulation or "trauma" to the genitourinary tract (e.g., catheterization, prostate needle biopsy, or cystoscopy). A simple screening DRE, however, should not cause a significant elevation of serum PSA.

Although BPH results in a tenfold increase in prostatic tissue concentration of PSA, the presence of cancer leads to a tenfold increase in serum PSA secondary to epithelial membrane disruption.[363] The histological hallmark of prostate cancer formation is the disappearance of the basal cell layer and disruption of the luminal epithelial cell layer. This disruption allows PSA, normally secluded from the surrounding prostatic stroma, to "leak" into the serum through both lymphatic vessels and capillaries.

A serum total PSA value of 4 ng/mL or greater or an abnormal DRE are the accepted thresholds before proceeding to prostate needle biopsy, most commonly using transrectal ultrasound. Common practice involves obtaining biopsies of ultrasound detected-hypoechoic lesions as well as 12 cores from different areas of the prostate. As for sensitivity and specificity, the positive and negative predictive values of PSA will depend on the chosen threshold. Based on multiple investigations in patients with a normal DRE and a PSA value between 4 and 10 ng/mL, the positive predictive value (PPV) approximates 30%.[364-369] However, the PPV increases to approximately 60% when total serum PSA is greater than 10 ng/mL.[364,367,370]

Because lower stage prostate cancers can be indolent and of no clinical significance, screening with PSA has undergone considerable scrutiny. As shown in Figure 29.23 causes of death other than prostate cancer predominate as men age. This is particularly striking in tumors with low Gleason scores. For some clinicians, the decision to use a threshold of 4 ng/mL seems quite arbitrary. In order to improve its sensitivity, specificity, and overall performance as a biomarker in prostate cancer screening, multiple variations of PSA use have been introduced over time. These include PSA Density, the ratio of free to bound PSA in the bloodstream, PSA velocity, age-adjusted PSA, and PSA doubling time.

PSA Density

Due to concern that an elevated PSA may be the result of BPH and not prostate cancer (both diseases of "older" men), investigators advocated the use of PSA density to help distinguish between the two conditions.[371-374] PSA density is obtained by dividing the total serum PSA by total prostate gland volume (measured using transrectal ultrasound).[371,372] Although the optimal cutoff is unknown, men with BPH have a significantly lower PSA density compared to those with cancer. Benson and colleagues demonstrated that the mean PSA density was 0.04 in men with BPH and 0.58 in those with prostate cancer, respectively. No PSA density greater than 0.12 was seen in patients with BPH.[371,372] In addition, in patients with a PSA density greater than 0.10, 97% of subjects had prostate cancer.

Although, PSA density did seem initially promising and improved PSA screening specificity, subsequent studies have shown its use to miss an unacceptable amount of prostate cancer cases. A large multicenter trial demonstrated that, in men with PSA values between 4 and 10 ng/mL, 47% of those with prostate cancer would not be identified if the PSA density cutoff were 0.15.[290] This lack of sensitivity in PSA density may be secondary to additional sources of error including variability among ultrasound technicians as well as variability in sample analysis.[366] In addition to PSA density, one can measure Transition Zone PSA Density.[375] In patients with BPH, the primary site for prostate enlargement is the transition zone (TZ). Theoretically, by measuring the PSA density based on the TZ, the accuracy of using PSA density would increase. However, because measurement of TZ PSA density again requires the use of trans-rectal ultrasound and is even more subject to inter-technician variability, it has not gained widespread use.

Protein-Bound PSA

Serum PSA exists as either unbound (free) or bound to the protease inhibitors α1-chymotrypsin or α2-macroglobulin. Patients with prostate cancer have a higher proportion of α1-chymotrypsin bound PSA compared with men without prostate cancer.[376] To exploit this difference, assays were developed to detect the ratio of free to protein-bound PSA. Currently, a ratio of free PSA to total PSA less than or equal to 10% is indicative of cancer while a ratio greater than 20% is likely due to a benign cause such as BPH. The assay is most useful in patients with total PSA values between 4 and 10 ng/mL.[377] Unfortunately, many men exhibit free to total ratios between 10% and 20% thereby hampering the full utility of this assay.

PSA Velocity

The rate of serum PSA increase (PSA velocity or PSAV) can be used to detect prostate cancer. Although questions exist concerning its predictive value,[378,379] PSAV has been shown to be significantly different between men with and without cancer. Current recommendations are to proceed to biopsy if there is an increase in total PSA of 0.75 ng/mL or greater per year with at least three different measurements over an 18- to 24-month period.[378,380-383] Using the cutoff point of 0.75 ng/mL leads to a sensitivity of 72% and a specificity of 90% in men with occult prostate cancer and a PSA less than 10 ng/mL. Unfortunately, the utility of using PSA velocity as a screening tool may be limited because of potentially large intra-individual variability, specifically in the context of shorter time intervals and lower total PSA.[381,384,385] A number of men with occult prostate cancer, especially those with a total PSA less than 4 ng/mL, do not have a PSA increase of 0.75 or greater in 1 year.[386]

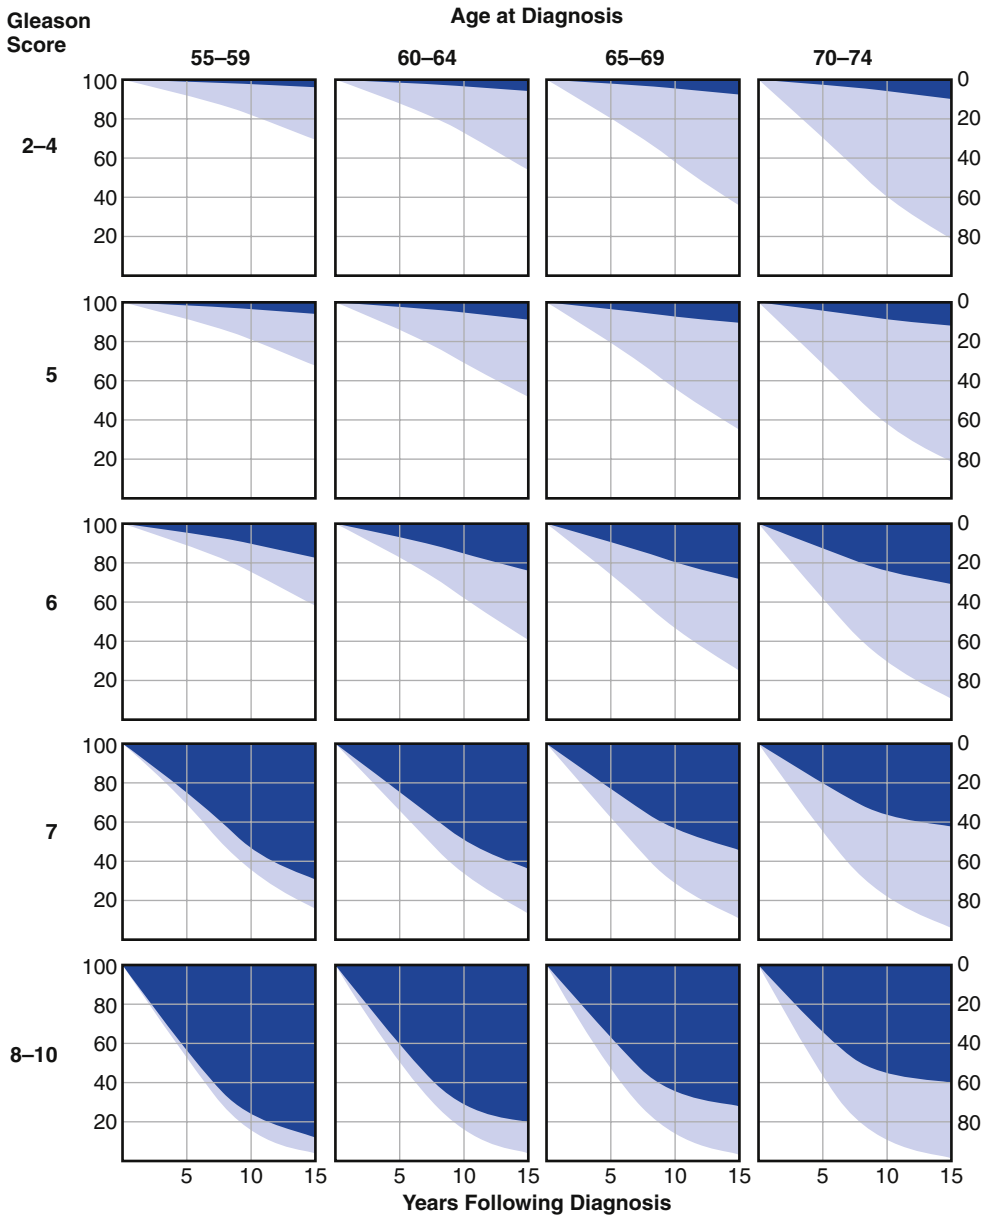

FIGURE 29.23 Total mortality *(shaded areas)* versus prostate cancer specific mortality *(solid areas)* in men of ages 55 to 74 years old at time of diagnosis and as a function of Gleason score. *(From Santen R. Endocrine responsive cancer. In Kronenberg HM, Melmed S, Polonsky KS, Larsen PR [eds].* Williams Textbook of Endocrinology, *11th ed, Philadelphia, WB Saunders, 2008.)*

Age Adjusted PSA

Normal serum PSA values increase with age. Therefore, an increase in serum PSA in a younger man due to prostate cancer may not reach the biopsy threshold of 4 ng/mL. Studies have shown that 22% of men with PSA values between 2.6 and 4 ng/mL have cancer of the prostate.[387] Therefore, one recommendation is to use age-specific PSA values to better capture younger men who have occult prostate cancer but a PSA value less than 4 ng/mL.[388,389] Theoretically, by creating age-specific thresholds, more younger men (age less than 60 years) with prostate cancer would be identified while more older men (age greater than 60 years) without prostate cancer would be spared a biopsy.[390,391]

Multiple studies examining this issue have demonstrated that while sensitivity would indeed be increased in younger men through the use of age-specific thresholds, the sensitivity would be significantly decreased in older men. Osterling and colleagues, comparing the use of age-specific PSA against the standard PSA greater than 4 ng/mL in men 50 years old or older, found that the positive predictive value increases from 37% to 42% with age-specific PSA. However, the detection rate of cancer decreased to 3.8% from 5.7%.[391,392] In another study examining 6600 men 50 years old or older, investigators found that by increasing the age-specific threshold, 47% of localized prostate cancer was missed, although there was a decrease of 44% in the number of unnecessary biopsies. Overall, while age-specific PSA does offer the advantage of decreasing the number of biopsies in older men without prostate cancer, the number of cancer cases missed significantly limits its value in prostate cancer screening.

PSA Guidelines

Various professional societies have provided guidelines for PSA screening, both for and against, but no general agreement exists.[393,394] Additionally, randomized trials have demonstrated conflicting results. The *European Randomized Study of Screening for Prostate Cancer* involved

Table 29.6 AJCC Prostate Cancer Stage Groupings

	Stage 1		Stage IIa					Stage IIb			Stage III	Stage IV		
Jewett-Whitmore stage	A1		A2, B0-2								C1-3	D1		D2

PSA level (ng/mL)	<10	<10	<20	10-19.9	10-19.9	<20	<20	Any	≥20	Any	Any	Any	Any	Any

over 182,000 men from eight European countries and ages 50 to 74 years old at the time of study entry.[395] At a median follow-up time of 11 years, the authors demonstrated a significant reduction in cause-specific mortality (relative reduction of 21% in PSA-screened group) but no significant reduction in overall mortality. The *Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial*, with an updated follow-up 13 years after enrollment of 76,685 men between 55 and 75 years old, demonstrated no significant difference in mortality based on PSA screening.[396]

A common-sense approach suggests screening only when test results would dictate diagnostic and therapeutic decisions. The patient needs to understand the consequences of a positive test and be willing to proceed with further diagnostic and therapeutic measures if the PSA were positive. Accordingly, patients selected for screening should be those in whom definitive treatment or hormonal manipulations and not surveillance would be the likely choice if cancer were detected. Based upon this reasoning, informed consent of the patient is required before embarking on screening with PSA.

Repeat Biopsy

Men with borderline PSA values (2.6 to 4.0 ng/mL) often undergo prostate biopsy under ultrasound and, in 75% of those men biopsied, no evidence of prostate cancer is found. When to re-biopsy if no cancer is found remains an unresolved but important clinical question. A recent study analyzed the records of 24,893 men being followed as part of a community based screening study and identified 1011 with subsequent prostate cancer. Based upon these data, the authors recommended repeat biopsy in men with a PSA of 2.6 to 4.0 ng/mL if they had high-grade PIN, initial PSA of 3.6 to 4.0 ng/mL, abnormal DRE, a family history of prostate cancer or a PSA velocity of 0.1 ng/mL or greater.[397] The complication rate of ultrasound-guided biopsy is reasonably low but does increase slightly when 10 or 15 cores are taken rather than 6.

Clinical Staging

Clinical staging of prostate cancer provides a means of determining prognosis and is used for making treatment decisions. Two analogous systems have been used in the past but the TNM classification is now preferred (Table 29.6). Newer modalities, including Tesla and Endorectal MRI are now being used to better define tumor size and assess for extra-prostatic extension.[398,399]

Decisions Regarding Definitive Treatment

Risk Stratification

Logical choices among various therapeutic options require assessment of the likelihood that complications and death from prostate cancer will ensue. Several algorithms provide a means to assess risk; the most widely used is the Partin nomogram developed at Johns Hopkins Hospital and based on patients undergoing radical prostatectomy.[400] The Partin nomogram predicts the risk of extraprostatic extension, lymph node involvement, and seminal vesicle involvement based on pre-operative PSA, Gleason score at biopsy, and clinical T stage. The National Comprehensive Cancer Network (NCCN) has devised another practical risk stratification system (Fig. 29.24) which initially divides patients into clinically localized, locally advanced and metastatic disease; then into low, intermediate and high risk subgroups; and finally according to expected survival of less than or greater than 10 to 20 years. The purpose of the NCCN guidelines is to better enable the physician to guide appropriate therapies.[401] One underlying but nonetheless important principle in assessing patient risk is the hallmark spectrum of biological aggressiveness exhibited by prostate cancer. At one end of the spectrum are "latent" prostate cancers, defined as small tumors less than 0.5 g that will not progress or result in cause-specific death. On the other end of the spectrum are large bulky tumors with high Gleason grade which most always rapidly progress. A key consideration is that older men frequently die of other existing medical conditions and not prostate cancer itself (Fig. 29.23). In men with a limited life expectancy as a result of other medical conditions, the risks of definitive therapy for prostate cancer most likely outweigh any foreseen benefits. As a practical guide, the NCCN has established guidelines for initial assessment, staging, and recurrence risk for prostate cancer (Fig. 29.25).

Definitive Treatment Strategies in Localized Disease

Three competing strategies are recommended for management of localized prostate cancer: active surveillance, radical prostatectomy, and radiotherapy. A key question is whether radical prostatectomy prolongs disease-free (DFS) and overall survival (OS) when compared to surveillance. This issue has recently been examined in a randomized, controlled, clinical trial comparing radical prostatectomy to surveillance in men with clinically localized disease.[402] Six hundred and ninety-five men with localized prostate cancer, a life expectancy of greater than 10 years, and a mean age of 64.7 years

Recurrence Risk	Recurrence Risk	Recurrence Risk
Clinically Localized:	Clinically Localized:	Clinically Localized:
Very Low: • T1c • Gleason score ≤6 • PSA <10 ng/mL • Fewer than 3 prostate biopsy cores positive, ≤50% cancer in any core • PSA density <0.15 ng/mL/g		High: • T3a or • Gleason score 8–10 or • PSA >20 ng/mL
Low: • T1-T2a • Gleason score ≤6 • PSA <10 ng/mL	Intermediate: • T2b-T2c or • Gleason score 7 or • PSA 10-20 ng/mL	Locally Advanced: Very High: T3b-T4
		Metastatic: Any T, N1 Any T, Any N, M1

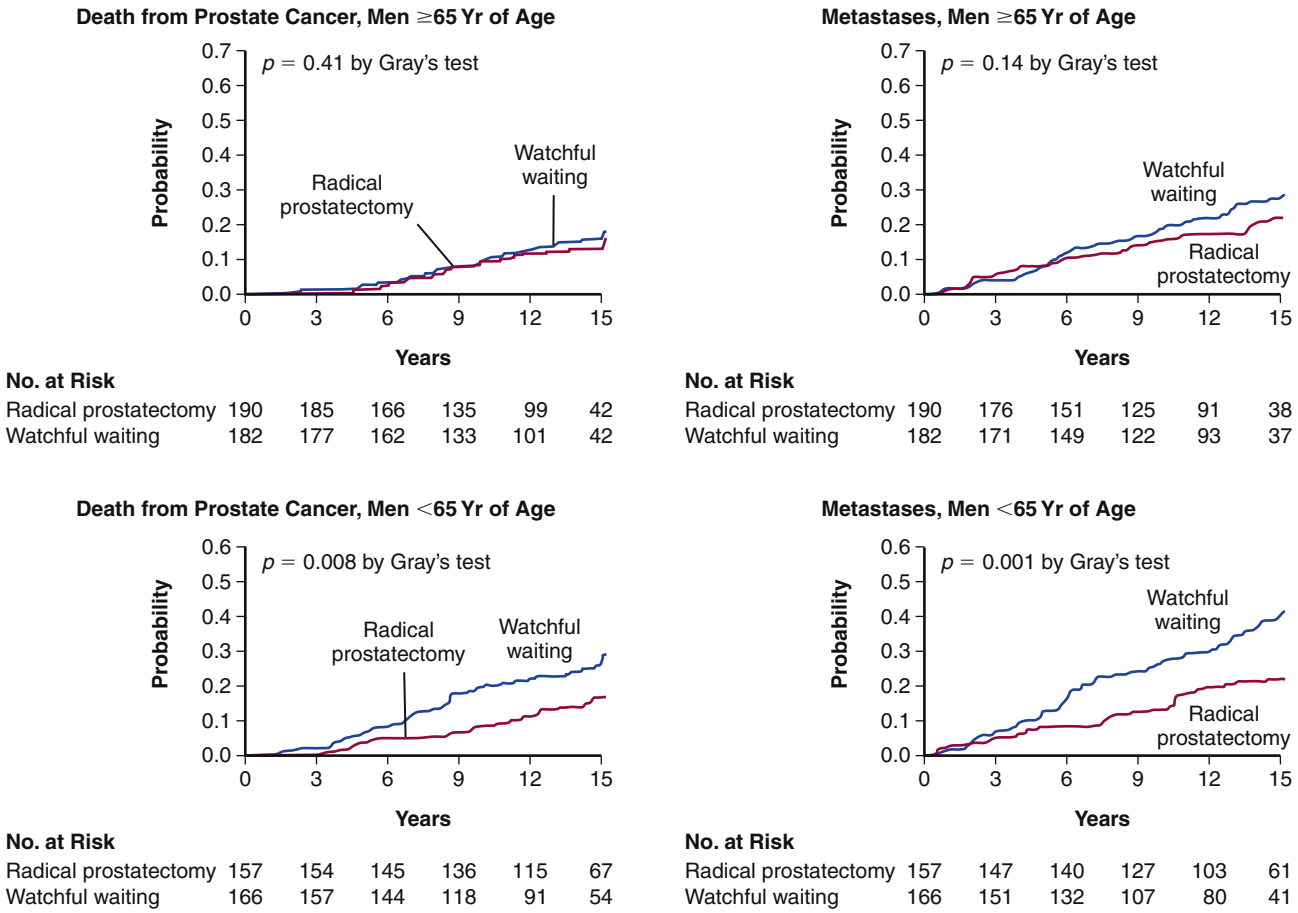

FIGURE 29.26 Death from prostate cancer in men treated with watchful waiting versus radical prostatectomy. Panels labeled as to specific subgroups examined. *(From Bill-Axelsen A, et al. Radical prostatectomy versus watchful waiting in early prostate cancer,* N Engl J Med *364[18]: 1708–1717, 2011.)*

were randomized and followed for a median of 8.2 years (Fig. 29.26). At the time of the initial study, 83 men in the surgery group and 106 in the surveillance group died of all causes ($p = 0.04$). Death was due to prostate cancer in 8.6% of the surgical group and 14.5% of the surveillance group. The difference in death rates became greater at the 10-year time period (5.3 percentage points) than at the 5-year time frame (2.0 percentage points). The risk of distant metastases was reduced to 1.7% from 10.2% by surgery and the rate of local progression from 25.1% to 19.1%. Further follow-up in 2008 and 2011 confirmed the reduction in death from prostate cancer in patients undergoing surgery.[403,404] Although this study does demonstrate improvement in both OS and DFS with surgery, the effect is rather small. Nonetheless, the decrease in incidence of metastases and local tumor progression can be considered clinically significant.[402,404]

Observational studies over several decades demonstrated the efficacy of radiotherapy (both delivered in the conventional external beam format and as brachytherapy) as definitive therapy in men with prostate cancer and as an alternative to surgical prostatectomy. Recent studies addressed whether neo-adjuvant or adjuvant androgen deprivation therapy enhances the overall efficacy of therapy in men with aggressive disease. Radiation Therapy Oncology Group (RTOG) trial 86-10 examined the role of neo-adjuvant endocrine therapy prior to radiation. The incidence of local progression at 5 years was 46% for patients with T2-4 tumors receiving adjuvant hormonal therapy and 71% for those receiving radiation alone ($p = 0.001$) but no difference in overall survival (OS) was noted. Studies examining neoadjuvant hormonal therapy prior to prostatectomy demonstrate no change in cause-specific survival but do show lower risk of positive margins at the time of surgery. Current clinical trials examining neoadjuvant abiraterone, an irreversible inhibitor of 17 α-hydroxylase/C17, 20 lyase (CYP17A1) that is currently approved for management of castration-resistant prostate cancer, are currently underway.

Radiotherapy with concomitant (adjuvant) androgen deprivation therapy has been the subject of two randomized trials.[405,406] A RTOG study involved patients with T3 and T4 disease given radiation therapy followed by medical castration with goserelin starting at the last week of irradiation.[407] Disease-free survival (DFS) at 5 years was 60% for the goserelin arm and 44% for radiation alone ($p < 0.0001$). Only the subset of men with Gleason grade 8 to 10 tumors experienced a survival benefit from 66% to 55% ($p = 0.03$). However, the 10-year follow-up demonstrated a survival benefit for all patients treated with adjuvant hormonal therapy on multivariate analysis (HR 1.3; $p < 0.001$). DFS was also improved (HR 2.2; $p = 0.0003$).[407] In a similar EORTC trial, the 5-year DFS was 85% in the adjuvant hormone treated group (goserelin) versus 48% in the radiation alone group ($p = 0.001$). Importantly, OS was significantly increased in the adjuvant hormonal group (79% versus 62%; $p = 0.001$).

The majority of data favor the use of adjuvant hormonal therapy in patients undergoing radiation therapy as definitive treatment for prostate cancer but only for high risk localized or locally advanced disease.[408,409] Analysis of pooled data from the RTOG neo-adjuvant and adjuvant trials concluded that the key consideration may be the necessity for long-term rather than short-term hormonal therapy in either neo-adjuvant or adjuvant therapy approaches.[409] In those men receiving short-term hormonal therapy (goserelin and flutamide for 2 months before and 2 months after radiotherapy), statistically significant improvements were observed for the endpoints of distant metastasis-free and no evaluable disease (NED)-free intervals but not for OS. Only long-term adjuvant therapy improved OS and only in the subset of men with Gleason Grade 7 to 10 tumors. These conclusions on long-term versus short-term adjuvant hormonal therapy were further supported by a nonrandomized Canadian trial.[410]

Brachytherapy, conformal radiation therapy and intensity modulated radiation therapy (IMRT) provide approaches that minimize side effects and allow for higher radiation doses to the cancer tissue itself.[411-413] Current guidelines suggest the use of conformal or IMRT in preference to standard dosimetry methods. IMRT allows dose intensification that may or may not eliminate the need for adjuvant hormonal therapy. Brachytherapy with implanted seeds provides another useful alternative.

Use of anti-androgen therapy is not indicated for clinically localized disease. The *Early Prostate Cancer (EPC)* program examined the use of 150 mg of bicalutamide in addition to standard treatment (e.g., radiation, prostatectomy, or surveillance) for clinically localized disease (71% of 2285 patients) or locally advanced but nonmetastatic disease (29%).[414] At a median follow-up time of 9.7 years, PFS was significantly improved in the bicalutamide group (HR 0.85; $p = 0.001$) although there was no significant improvement in OS. Patients with locally advanced disease treated with radiotherapy derived the greatest benefit in terms in OS. However, patients with localized disease did not benefit in terms of either PFS or OS.[414]

Locally Advanced or Metastatic Disease

Androgen deprivation represents the earliest form of systemic therapy for locally advanced and metastatic prostate cancer and observational studies have demonstrated its efficacy. Three methods have been historically used: surgical castration, high-dose estrogen, and GnRH agonist analogues. Surgical castration as well as high-dose estrogen in the form of DES has been used as treatment of prostatic cancer since the 1940s. In the VACURG studies, 5 mg of DES decreased the rate of recurrence of prostate cancer but increased the cardiovascular death rate. Following this observation, careful dose response studies indicated that 3 mg of DES daily minimizes the risk of cardiovascular disease acceleration and maximizes the beneficial effects on prostate cancer. Gynecomastia and impotence are the major side effects. However, DES is no longer available in the United States.

GnRH superagonist or antagonist analogues are now available which suppress testosterone to castrate levels and cause tumor responses equivalent to those induced by castration. Comparison of the various monotherapies was the subject of a meta-analysis involving 10 separate trials which concluded that orchiectomy,[415] GnRH agonist analogues, and DES produced equivalent survival in men and that no differences existed among the various GnRH analogues currently available. The decision between surgical castration and GnRH analogues (GnRH-A) represents a major question. While surgical orchiectomy produces a rapid decrease in serum androgen levels, it does not require patient compliance long-term, and is effective in inducing tumor regression in nearly 90% of patients, more than half of men in the United States prefer medical castration as a means to avoid surgery, most likely due to the psychological impact of castration.

Highly potent agonist analogs of GnRH have been approved for use in prostate cancer and effectively produce a "medical orchiectomy." These compounds paradoxically inhibit LH secretion by the pituitary suppressing testicular testosterone production. Initially, GnRH-A administration increases LH threefold to fourfold and testosterone twofold for 1 to 2 weeks. Thereafter, LH is profoundly suppressed and plasma testosterone levels fall from approximately 500 ng/dL to castrate levels of 15 ng/dL. Hormonal inhibition continues for up to 2 years of continuous therapy. The initial rise in testosterone causes a transient disease flare in 5% to 10% of patients, producing an objective increase in tumor size in approximately 3% of patients and a subjective increase in bone pain from metastases in the remainder. Although tumor flare is usually transient, severe reactions with spinal cord compression or death have been observed in the occasional patient. Based on this, it is necessary to administer an anti-androgen such as bicalutamide during the initial few weeks of GnRH-A therapy.

Newer GnRH receptor antagonists have been developed to block the interaction of GnRH with its receptor on the pituitary gland resulting in an immediate and substantial reduction in LH and testosterone levels without causing the flare phenomenon. In a phase III, randomized clinical trial,[416] degarelix, approved by the FDA in 2008 for patients with advanced prostate cancer, demonstrated equal effectiveness compared to leuprolide at suppressing testosterone to castrate levels. Notably, degarelix suppressed levels of both testosterone and PSA significantly faster and no patient experienced a testosterone surge compared to 81% of leuprolide-treated patients.

The major rationale for using a GnRH-A is to induce castrate testosterone levels without requiring surgical removal of the testes. Both testosterone and DHT levels in patients treated with either a GnRH-A or orchiectomy fall to a similar extent. Objective regressions occur as frequently as with orchiectomy and a meta-analysis study including 10 randomized controlled trials with 1908 patients,[415] provided evidence that medical and surgical castration exert equal clinical effects. Initially, a major problem with GnRH-A therapy was the requirement for daily subcutaneous administration with the possibility of noncompliance with daily injections and incomplete androgen suppression. Third-generation formulations are now available which allow injections at 3- to 6-month intervals or implants yearly. These biodegradable preparations appear highly effective, well tolerated, and acceptable to patients. Because some androgen responsive cells remain in prostate tumors after relapse on the GnRH agonists, continued GnRH-A treatment is advocated upon disease relapse and preferably for life.

Immediate versus Delayed Hormonal Therapy for Locally Advanced or Metastatic Disease

Historically, approximately 25% of men presented with either metastatic or lymph node positive disease. However, currently less than 5% of men present with synchronous metastatic disease.[417] Whether to initiate hormonal treatment immediately in these patients or to defer until symptomatic is a major question, especially in light of recent evidence demonstrating increased cardiovascular disease and mortality with use of androgen deprivation therapy.[418-421] Because cure with hormones is not possible, the two goals of treatment are to increase life expectancy and to relieve symptoms. If treatment were to be advocated in asymptomatic patients, the therapy should improve the length of patient survival. Rigorously controlled series from the Veterans Administration Cooperative Urological Research Group (VACURG) trials during the 1960s indicated no clear survival benefit from endocrine therapy in patients with stage C or D disease (i.e., advanced) at the time of diagnosis.

Based upon these findings, standard practice usually involved withholding hormonal therapy until symptomatic metastatic disease developed. However, two studies provide evidence favoring therapy immediately upon detection of metastatic disease. Messing and colleagues studied men with prostate cancer found to have positive pelvic lymph nodes at the time of radical prostatectomy.[422] The study randomized men into either an immediate therapy group (medical or surgical orchiectomy) or into a group observed until an indication for hormonal treatment occurred. Death due to prostate cancer occurred in 3/47 men in the immediate treatment group and 16/51 in the deferred group ($p < 0.01$). At a median follow-up of 11.9 years in 2006,[422] there was continued benefit of early androgen deprivation in OS, DFS, and CSS. In another study, 934 men with locally advanced prostate cancer or with asymptomatic metastatic disease were randomized to immediate vs. deferred hormonal therapy. An initial report concluded that there was an OS benefit from immediate therapy. Overall, 203 men died from prostate cancer in the immediate therapy arm and 257 in the deferred group ($p = 0.02$). However, on extended follow-up, the OS benefit was no longer statistically significant. Regardless, deaths due to prostate cancer were reduced to 241 in the immediate therapy arm versus 287 in the deferred arm ($p = 0.0019$).[423] In this group of elderly men, deaths from other causes occurred commonly and were not influenced by immediate hormonal therapy. Nonetheless, there were fewer cases of cord compression (10 versus 24); pathological fracture (14 versus 22), extraskeletal metastases (47 versus 62), and ureteral obstruction (49 versus 64) in the immediate treatment group.[423]

Another study,[424] randomized men not accepting radical prostatectomy to immediate or deferred androgen therapy and found no differences in overall pain free time and performance status. CFS tended to be longer in the immediate group ($P = 0.09$) but OS was identical ($P = 0.96$). Other evidence of efficacy of early therapy comes from nonrandomized studies from the Mayo clinic which demonstrated a statistically significant survival advantage for early endocrine therapy (castration) in men with stage D1 (T0-3, N1-2, M0) disease.[425] Seventy-three patients underwent either radical prostatectomy or radical prostatectomy combined with orchiectomy. An advantage for immediate adjuvant therapy was demonstrated as 5-year survival rates were 93% in the immediate orchiectomy group and 80% in the deferred orchiectomy group. In another study,[426] benefit was seen only in patients with diploid and not in those with tetraploid or aneuploid tumors. Finally, a subset analysis of men in the radiation therapy oncology group trial number 85-31 (RTOG 85-31) study examined a group of 139 men with capsular penetration or seminal vesicle involvement; 71 men received RT plus LH-RH agonist therapy and 68 RT alone.[427] Statistically significant improvement in PFS and freedom from biochemical relapse (i.e., PSA), was observed in the LH-RH group. However, there was no statistically significant difference in OS in this relatively small subset of men followed for a median of 5 years only.

A systematic review in 2002 concluded that early androgen deprivation therapy resulted in significant reductions in both disease free progression and complications due to progression.[428] PFS was significantly higher at years 1, 2, 5, and 10 (OR 3.99, 4.79, 3.15, and 3.49, respectively) in men treated with early androgen deprivation and OS at 10 years was also improved (OR 1.5; 95% CI 1.04, 2.16). Taken together, these data suggest that immediate hormonal therapy may be efficacious for asymptomatic men presenting with lymph node spread. Nonetheless, in elderly men with increased risk of dying of non-prostate cancer causes, deferred therapy appears to be a reasonable choice.

The American Society of Clinical Oncology (ASCO) critically analyzed these data and commented that all of the trials cited above were conducted before the routine use of PSA testing. The ASCO review was considered to be limited by the variability in the interventions as well as in the stages of the cancers of the patients enrolled. From this analysis, the guidelines concluded that data at the present time do not provide definitive evidence that early endocrine therapy is beneficial regarding improved survival of patients presenting with metastatic disease. Longer follow-up and additional studies sufficiently powered to detect an increase in overall survival are needed before definitive conclusions are warranted.[429,430]

Men who experience a rise in PSA after an initial fall to undetectable levels after radical prostatectomy might also benefit from hormonal therapy. Data indicate that a rapid rise in PSA suggests the presence of metastatic disease whereas a slow rise suggests local recurrence. In a single small study, 68% of men progressed to detectable clinical disease upon observation for a median of 19 months. With adjuvant hormonal therapy or radiotherapy, the rate of progression to clinically detectable disease decreased to 21%.[431]

Adverse Effects of Androgen Deprivation Therapy

Medical or surgical castration causes an abrupt reduction of androgen levels resulting in hot flashes in up to 80% of patients, 27% of whom report this to be the most troublesome adverse event. Bone density falls in men in response to declines in androgens and their aromatized estrogen metabolites and the risk of fracture increases starting 1 year after initiation of therapy. Either pamidronate or zoledronic acid, both potent intravenous bisphosphonates, can

Table 29.7 Secondary Hormonal Therapies for Recurrent Disease

Modality	Responders	Total Patients	Percent Responding	Clinical Setting
Flutamide	23	100	23%	First relapse after medical or surgical orchiectomy
Prednisone	21	101	21%	First relapse after medical or surgical orchiectomy
Flutamide withdrawal	29	138	21%	Relapse after combined androgen blockade or flutamide
Aminoglutethimide + hydrocortisone	14	29	49%	After anti-androgen withdrawal
Hydrocortisone	16	82	20%	After anti-androgen withdrawal
Ketoconazole Hydrocortisone	43	72	60%	After anti-androgen withdrawal
Megestrol l acetate	17	119	14%	After anti-androgen withdrawal
DES	71	243	29%	After anti-androgen withdrawal
Abiraterone	797	231	29% (PSA response); improved survival 14.8 months vs placebo 10.9 months ($P < 0.001$)	After anti-androgen withdrawal and docetaxel

The full version of this table, including references, can be found on the companion Expert Consult web site at www.expertconsultbook.com.

completely abrogate the effects of androgen deprivation on bone. Significant erectile dysfunction occurred in 78.6% and 73.3% of men after orchiectomy and GnRH-A therapy, respectively.[432] Other metabolical effects that occur as a result of androgen deprivation therapy include a decrease in hemoglobin and lean body mass, increase in total body fat mass and rises in total cholesterol and triglyceride levels. Fatigue and psychological distress tend to be more common in men receiving active therapy compared to those choosing to defer treatment. Finally, gynecomastia occurs in 1% to 16% of men treated with androgen deprivation therapy.

Secondary Hormonal Therapies for Recurrent Disease

Disease that recurs following medical or surgical castration can be treated with secondary hormonal therapies. Prior to the PSA era, the clinician had to rely on bone x-rays and soft tissue changes to document responses and these were rarely observed. Consequently, the efficacy of secondary hormonal therapies was controversial. More recently, clinicians have accepted a 50% decline in PSA as reflecting an objective response to therapy. Studies demonstrate that this PSA endpoint predicts a significantly prolonged median overall survival, objective progression free survival and time to pain progression.[433] Using PSA measurements, it has now been possible to show efficacy of a number of secondary hormonal therapies. Responses to anti-androgens, ketoconazole, abiraterone, flutamide, bicalutamide, aminoglutethimide, DES, and glucocorticoids alone range from 14% to 60%. Head to head comparisons are unavailable for these agents and relative efficacy cannot be compared[434] (Table 29.7).

Anti-Androgen Withdrawal

Experimental studies with LnCAP cells *in vitro* detected a mutation in the androgen receptor in this cell line that caused it to paradoxically respond to flutamide with increased proliferation. As a result of this observation, clinical studies examined whether tumors in some patients might adapt to flutamide by developing mutations allowing flutamide to behave as an androgen agonist. In support of this possibility, approximately 40% of men on flutamide experienced tumor regression after withdrawal (so called withdrawal responses). These data suggest that a first step in patients receiving flutamide, either as part of a complete androgen blockade regimen (discussed later in the text) or as secondary hormonal therapy, is to stop flutamide. These withdrawal responses occur with bicalutamide as well but are less common.[435]

Other Secondary Hormonal Therapies

Prior to the PSA era, objective regression, stabilization and/or symptomatic relief were reported with several agents (Table 29.7). These included a high dose formulation of DES (stilphostrol) and tamoxifen. A study using high dose tamoxifen (160 mg/m2/day) observed only a 3.3% rate of objective response based upon PSA in heavily pretreated men with prostate cancer.[436] Each of these agents could be considered for patients relapsing slowly after castration. Recent emphasis has focused on blockade of adrenal androgens that contribute to intra-prostatic DHT. Ketoconazole, an agent which blocks the 17α-hydroxylase/C17, 20 lyase complex was initially in combination with glucocorticoid replacement used for this purpose. A more recent development has been the drug abiraterone which irreversibly blocks the 17α-hydroxylase/C17, 20 lyase complex. Clinical trials have shown abiraterone to increase survival,[437,438] with minimal side-effects, in post-chemotherapy, hormonal refractory patients. In a phase II study by Morris and colleagues, 58 patients with progressive metastatic prostate cancer despite docetaxel therapy were treated with abiraterone (1000 mg daily) plus prednisone (5 mg twice daily). A greater than 50% decline in PSA levels was noted in 36% of patients, partial responses were seen in 18% of patients, and improved performance status was observed in 28% of patients. Based on initial data, phase III trials are underway but at present, abiraterone is now clinically approved for use in castrate men who have failed chemotherapy.

Other Nonhormonal Treatment Measures

Potent bisphosphonates effectively reduce the incidence of skeletal related events in men with hormone refractory

prostate cancer. A large, randomized phase III trial demonstrated that zoledronic acid significantly reduced the incidence of pathological fractures, spinal cord compression, the need to treat with radiotherapy for bone, and bone pain in men with prostate cancer. The dose used was 4 mg every 3 weeks for 24 months. The number with an SRE (skeletal related event) decreased from 49% for placebo to 38% with zoledronic acid ($P = 0.28$).[439] Based on these data, it is recommended that zoledronic acid be routinely used in patients with hormone refractory prostate cancer who have at least one bone metastasis. In patients with no lesions, routine bone scans should be used to detect new lesions and zoledronic acid started when the initial lesion is found.

Treatment of Hormone Refractory Recurrent Disease

At a certain point, the tumor becomes invariably refractory to all hormonally based therapies. Unfortunately, diagnostic tests are nonexistent to distinguish between hormone dependence and independence. Men with a rapid downhill course with widespread systemic metastases should probably receive chemotherapy. Others will have already been treated with all available options of endocrine therapy. Chemotherapy, combination chemo-hormonal therapy, or experimental targeted therapy is chosen at that point. The choice of chemotherapeutic agents is beyond the scope of this chapter and the interested reader is referred to the National Comprehensive Cancer guidelines.[401]

Alternative Approaches to Prostate Cancer Therapy

Monotherapy with anti-androgens, either steroidal or non-steroidal, provides an alternative to surgical or medical castration. Non-steroidal agents, flutamide and bicalutamide, bind to androgen receptors and block the cellular effects of circulating T and DHT on cell proliferation. Interruption of the androgen negative-feedback system results in reflex increments in serum LH, T, and DHT levels. Prior studies with anti-androgens suggested that these agents partially preserve erectile function. However, data suggest that only 20% of all treated men maintain morning erections and sexual activity with anti-androgen therapy. When only men capable of sexual function before treatment are considered, 18% reported a reduction in sexual function score on bicalutamide and 37% after castration.[440] Side effects occur in 4% to 10% of patients and include hot flashes, gynecomastia, hepatotoxicity, nonspecific ophthalmological changes, and diarrhea (particularly for flutamide).[429] Bone density improves in men receiving bicalutamide, most likely secondary to the 146% increase in estradiol and the fact that estradiol is the major mediator of bone density in men.[441]

Randomized trials have compared anti-androgens as monotherapy with medical or surgical castration. Initial studies showed that 50 mg of bicalutamide is not as effective as orchiectomy.[442] Later studies utilized 150 mg of bicalutamide and compared medical or surgical castration with 150 mg of bicalutamide in patients with locally advanced (T1-4, N+, MO) and metastatic disease.[443] Bicalutamide was equivalent to medical or surgical castration for locally advanced but not metastatic disease.[440] Pooled mature data from these studies suggest no survival difference between bicalutamide 150 mg daily and surgical castration. Other available data suggest that bicalutamide is not as effective as castration.[442] Meta-analyses of studies involving 2717 patients comparing monotherapy with various anti-androgens suggested that the hazard ratio for recurrence was greater with anti-androgen monotherapy than with medical or surgical castration but statistical significance was approached but not reached (HR 1.22, 95% CI 0.99, 1.50).[444] Even though anti-androgen monotherapy appears not as effective as castration, some men may choose this therapy in preference to surveillance.[443] The ASCO guidelines include an option for discussion of monotherapy with a nonsteroidal anti-androgen as an alternative to surgical castration or GnRH-A. This recommendation was based upon the data indicating less toxicity with respect to libido and physical capacity but inferior time to progression of disease compared to the LH-RH agonists.[429]

Neo-Adjuvant Hormonal Therapy Prior to Radical Prostatectomy

This approach involves either medical castration with GnRH analogues, steroidal or non-steroidal anti-androgens, or a combination of these agents prior to prostatectomy. Neoadjuvant strategies used for 3 to 6 months prior to radical prostatectomy result in an increase in organ confined cancers and decrease in positive surgical margins.[445] However, no differences in PSA detectable relapse rates have yet been observed in several trials. PFS and OS with neoadjuvant strategies are comparable to other modalities.[446,447] The recent NCCN guidelines strongly discourage this approach.[401]

Complete Androgen Blockade

A more comprehensive strategy for the endocrine treatment of prostate cancer, called complete or maximum androgen blockade (MAB), has been proposed. The rationale rests upon three considerations:

1. The adrenal glands contribute 5% of the total androgen pool.
2. The concentrations of DHT in prostate cancer tissue of patients fall by only 50% to 80% after surgical orchiectomy and DHT levels in that tissue after castration still are higher than in nonandrogen-target tissues.
3. *In vitro* systems demonstrate that some tumor cell clones are hypersensitive to the proliferative effects of androgen.

Based upon these considerations, it was thought that combined inhibition of both testicular and adrenal androgens via MAB might be more effective than inhibition of testicular androgen secretion (TAS) alone. Thirty-six studies have examined the concept of MAB as initial endocrine therapy for advanced disease in randomized trials but the results and conclusions drawn from them conflict. However, three systematic reviews (two with meta-analysis of the literature), one meta-analysis of individualized patient data, one large randomized trial, and one Markov model critically examined this issue.[444,448,449] These studies, involving nearly 90% of men treated worldwide, provided several definitive conclusions regarding this strategy. The benefits of MAB are minimal and range from 1% to 5% improvement in overall survival. The additional cost of MAB as opposed to TAS alone approximates $1,110,000 per quality adjusted life year and the number needed to treat to benefit one patient is estimated to be between 20 and 100.

These meta-analyses provide reasons for discrepancies among prior results. First, MAB regimens using nonsteroidal anti-androgens provide only a 1% to 5% improvement in overall survival. An example of data from one of the meta-analyses is presented in Figure 29.27. This difference is statistically significant $p = 0.005$ but of marginal significance clinically. Second, MAB regimens using the steroidal anti-androgen, cyproterone acetate, produce adverse survival effects compared to TAS. Third, analysis of studies of MAB which pool patients treated either with cyproterone acetate or nonsteroidal anti-androgens demonstrate no survival benefit produced by MAB over TAS. Fourth, men with disease limited to the axial skeleton did not gain more benefit from MAB than those with metastases to the appendicular skeleton. A large prior study had reported this to be the case. Fifth, results were similar when subsets of men treated with surgical or medical castration or with flutamide or nilutamide were examined.

Past controversies about MAB can be explained by fact that some trials used cyproterone acetate, an anti-androgen that shortens survival in these patients. Other trials did not use short-term anti-androgen in the medical castration group and the disease flare may have compromised overall efficacy. Finally, early trials used daily GnRH injections that may not have induced effective medical castration because of the need for compliance with daily injections for 5 years. It should be noted that no properly designed study has compared MAB to sequential androgen blockade (SAB—defined as initial castration followed by anti-androgen upon relapse). In the largest study to date of MAB, use of anti-androgen upon relapse in the placebo group was left to the investigator's discretion and only 50% of men on the placebo arm later took an anti-androgen.[448] For this reason, no information is available whether anti-androgen therapy given at the time of relapse after medical or surgical orchiectomy (i.e., SAB) is as effective as MAB. This is an important issue since flutamide given upon relapse after castration (SAB) causes objective benefit in 23% of patients.

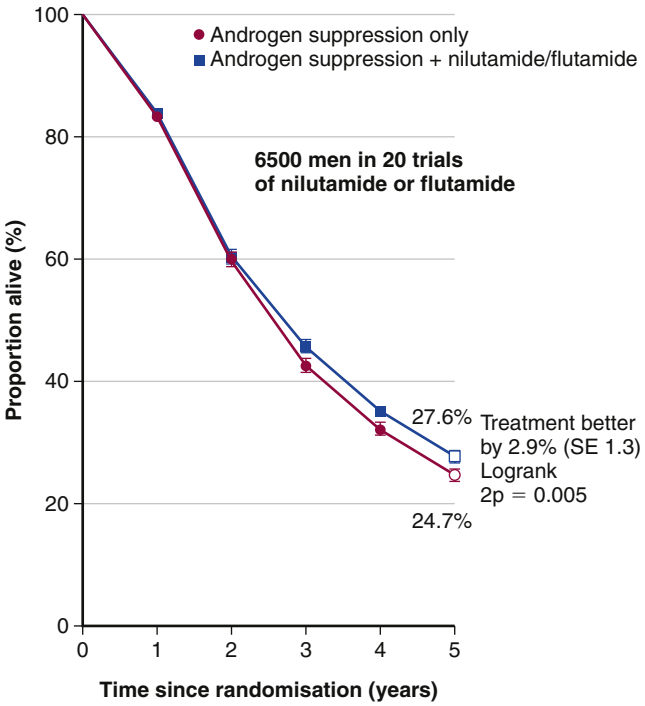

FIGURE 29.27 Meta-analysis of effects of complete androgen blockade versus antiandrogen therapy alone. *(From Santen R. Endocrine responsive cancer. In Kronenberg HM, Melmed S, Polonsky KS, Larsen PR [eds].* Wiliams Textbook of Endocrinology, *11th ed, Philadelphia, WB Saunders, 2008. Copyright National Comprehensive Cancer Network, 2012.)*

Based upon the data presented and additional considerations discussed, ASCO and NCCN guidelines favor the sequential androgen blockade and the use of anti-androgens only after relapse from medical or surgical orchiectomy.[429] However, if GnRH agonists are used to produce a medical orchiectomy, short-term use of an anti-androgen to prevent disease flare is necessary. In patients with metastatic disease, GnRH-A should not be used in men at risk of neurological compromise due to metastasis, ureteral or bladder outlet obstruction due to local encroachment or severe bone pain persisting with narcotic analgesic use.

Intermittent Androgen Deprivation Therapy

Multiple trials are examining the use intermittent ADT in an attempt to reduce the side effects of therapy without altering efficacy.[450,451] The basic tenet of intermittent ADT is to continue ADT until the serum PSA falls to a low level and then stop treatment. No side effects or toxicity are likely to occur during this treatment holiday period. ADT is then started again only when the serum PSA rises to a predetermined level. This cycle is repeated until there is clear evidence of disease progression, either clinically or through continued elevated PSA. Recent data published in abstract form suggest that intermittent androgen deprivation therapy is not as effects as continuous treatment.[452]

Algorithm for Treatment of Prostate Cancer

No standard approach to the treatment of prostate cancer has been universally agreed upon. Specific accepted options for each risk group are included in the NCCN guidelines and detailed as follows:

Initial Treatment of Localized disease

Low Risk

Less than 10-year life expectancy: Active surveillance or radiation therapy.

Greater than 10-year life expectancy: Active surveillance or RT or radical prostatectomy.

Intermediate Risk

Less than 10-year life expectancy: Active surveillance or RT or radical prostatectomy.

Greater than 10-year life expectancy: radical prostatectomy or RT.

High Risk

Androgen ablation (2 to 3 years) plus RT or RT and short term androgen ablation, or radical prostatectomy (if low volume and resectable).

Initial Treatment of Locally Advanced Disease

Androgen ablation for 2 to 3 years or RT and short term androgen ablation.

Initial Treatment of Metastatic Disease

Any T,N1: androgen ablation or RT and androgen ablation.
Any T, Any N, M1: androgen ablation.

Considerations Regarding Initial Treatment of Clinically Localized Prostate Cancer

No consensus exists regarding selection of radical prostatectomy, radiation therapy, or active surveillance. Individual considerations, including age, risk factors for recurrence, overall health of the patient and life expectancy, influence these decisions that are often based on personal choices. In general, the younger and healthier the patient, the more likely is a choice of radical prostatectomy. The older and more debilitated, the more likely is the choice of active surveillance or doing nothing. In men with clinical T3 disease, radiation therapy plus hormonal therapy is generally preferred over radical prostatectomy except in a few T3 cases with low volume disease. Radiotherapy is often selected for patients falling at neither extreme. Adjuvant hormonal therapy used with radiotherapy should be limited to patients with higher risk disease. The likelihood of recurrence with low or intermediate risk disease may be too small to warrant the associated symptoms, bone loss, anemia and other problems associated with androgen deprivation.

Considerations Regarding Initial Therapy in Men with Metastatic Disease at Time of Diagnosis

Men with node positive or metastatic disease at presentation are not treated definitively with radical prostatectomy or irradiation but frequently are offered hormonal therapy prior to development of symptomatic disease.[401] This decision is based upon incomplete data suggesting superior efficacy of early rather than late hormonal therapy in locally advanced disease. Randomized trials with a large number of patients will be required before definitive advice can be given regarding management of patients with PSA relapses.

Which hormonal therapy to use is essentially a matter of choice. Meta-analyses of several trials suggests that medical castration and surgical castration have equal efficacy but individual trials indicate that anti-androgens are less effective.[415,429] In the opinion of the authors, surgical orchiectomy appears preferable for the initial treatment of these patients. The operation is relatively minor; can be performed under local anesthesia if desired, and is cost effective. Rapid and complete cessation of testicular androgen secretion ensues, and patient compliance after surgery is not a factor. Unwarranted cardiovascular or other toxic side effects are unknown. The incidence of impotence and loss of libido is the same as with other available therapies with the exception of the anti-androgens.

In actual practice, nearly half of patients in the United States prefer a form of medical castration for psychological or other reasons. The greater safety of the GnRH-A favor their use over DES and for this reason, DES is no longer available in the U.S. To prevent tumor flare, anti-androgens should be used for at least 2 weeks prior and 2 weeks after initiation of GnRH therapy. Alternatively, the Gn-RH antagonists are not associated with a transient rise in testosterone and can be used without a concomitant anti-androgen. Maximum androgen blockade long term is not recommended based upon the individual studies and meta-analysis reviewed above but should be discussed with the patient.[429] Some patients may choose to continue the anti-androgens long term to gain the slight, 1% to 5% maximal benefit from maximum androgen blockade. An anti-androgen alone could be chosen as an alternative but is not preferred.

At the present time, medical castration with GnRH agonists can be achieved with 3 to 6 monthly injections or yearly implants which are well tolerated and should not be associated with cardiovascular complications. Cost is the limiting factor. When concern regarding erectile dysfunction is a major issue, the persistence of libido and erectile function in a subset of patients treated with anti-androgens as primary therapy may be a decisive factor. Under these circumstances, some men may choose monotherapy with anti-androgens, even though this approach is not as effective as medical or surgical castration. This decision represents a quality of life issue that is an increasingly important consideration in prostate cancer therapy.

Considerations Regarding Disease Recurrence

Upon first recurrence, men treated with radiotherapy or radical prostatectomy are then treated with either medical or surgical orchiectomy. Anti-androgen monotherapy can be offered but is not preferred. Anti-androgen therapy provides a reasonable next option after medical or surgical castration unless previously given as part of a MAB regimen. Those receiving an anti-androgen as part of a MAB regimen are observed for an anti-androgen withdrawal response. Regarding choice of anti-androgen, bicalutamide is preferred to flutamide because of its better side effect profile and potentially superior efficacy. Upon relapse, men are observed for anti-androgen withdrawal response and only treated further when progressive disease is documented.

A variety of therapies are available for men relapsing after anti-androgen withdrawal. One group prefers ketoconazole and hydrocortisone because of its lack of toxicity and observed efficacy (i.e., 60% PSA response rate),[302] but this has now been superseded by abiraterone.[437,438] Each of the other agents listed on Table 29.7 could be used as alternatives or as third line therapies. Further choices of chemotherapy alone or chemotherapy in combination with hormonal agents are a matter of individual preference.

Endometrial Carcinoma

Endometrial cancer is the most common of the gynecological malignancies with 47,130 estimated cases and 8010 deaths from the disease in 2012 in the U.S.[146] The majority occur in postmenopausal women with a small percentage in premenopausal women and up to 14% in women under the age of 45.[453] Endometrial cancer is highly associated with obesity, a condition that is significantly increasing in incidence in the U.S.[454] Endometrial cancer can be categorized into types 1 and 2.[455] Associated with unopposed estrogen excess, type 1 endometrial cancer often has a good prognosis. When well differentiated (grade 1), type 1 cancers commonly expresses the progesterone receptor (PR). In

contrast, type 2 cancers are not associated with estrogen excess, are high grade, and may exhibit aggressive histological subtypes. Treatment considerations require distinction between type 1 and 2 tumors.

The standard of care for endometrial cancer is surgical with total hysterectomy and removal of both fallopian tubes and ovaries via laparotomy, a vaginal approach, laparoscopy, or robotically assisted laparoscopy. In the U.S., the hysterectomy is often associated with staging surgery, including removal of the pelvic and para-aortic lymph nodes (Boxes 29.1 and 29.2, Table 29.8). Lesions are often heterogeneous (Fig. 29.28). With surgical staging and radiation where appropriate, the cure rate for endometrial cancer confined to the corpus (stage I) is ≥80% depending on stage, grade, and histological subtype. Type 1 cancers in general are more likely to present in early stage and to be cured with surgery.

Type 1 endometrial cancer is most often confined to the corpus at the time of diagnosis. Data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program report that 83% of patients had disease confined to the uterus and cervix at the time of diagnosis.[456] Despite the association of this cancer with a good prognosis, 10% to 15% of patients will present with advanced disease. In addition, the rate of recurrence in patients with "good prognosis" early stage disease may be as high as 9%.[457] Adjuvant systemic therapy is often required for those patients with advanced or recurrent disease. Hormonal therapy will likely be instituted at some point in the course of management of recurrent or persistent disease. With respect to type 2 disease, hormonal therapy is less likely to be effective.

Box 29.1 Staging of Endometrial Carcinoma

CORPUS CANCER SURGICAL STAGING, FIGO 2010

Stage 1	Tumor confined to the corpus uteri
Stage 1A	No or less than half myometrial invasion
Stage 1B	Invasion equal to or more than half of the myometrium
Stage 2	Tumor invades the cervical stroma, but does not extend beyond the uterus
Stage 3	Local and/or regional spread of the tumor
Stage 3A	Tumor invades the serosa of the corpus uteri and/or adenxae
Stage 3B	Vaginal and/or parametrial involvement
Stage 3C	Metastases to pelvic and/or para-aortic lymph nodes
Stage 4	Tumor invades bladder and/or bowel mucosa and/or distant metastases
Stage 4A	Tumor invasion of bladder and/or bowel mucosa
Stage 4B	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

PTEN, phosphatase and tensin homolog.

This chapter will initially review endometrial cancer with an emphasis on hormone related components and discuss epidemiology, prognosis, and treatment. The features of type 1 and 2 endometrial cancer will be compared and contrasted, and the important implications of this classification highlighted. We will then discuss several key specific issues. The first is primary hormonal therapy with the preservation of the uterus to allow future fertility in premenopausal women. This discussion will also apply to the treatment of complex atypical hyperplasia (CAH), the precursor lesion to type 1 endometrial cancers (also called endometrial epithelial neoplasia). Second, the chapter will address the use of adjuvant hormonal therapy in postmenopausal women presenting with recurrent or persistent advanced endometrial cancer.

Epidemiology

Endometrial cancer is the most common of the gynecological malignancies, the seventh most common cancer in women worldwide, and the fourth most frequent cancer diagnosed in American women. The disease occurs after menopause in over 70% of cases.[458] Endometrial cancer is highly associated with obesity and, in the industrialized world, likely due to lifestyle and dietary habits.

Based on epidemiological, histological, and molecular pathological analyses, two types of endometrial tumors can be distinguished: type 1 and type 2[459] (Table 29-8). Type 1 endometrial cancers are histologically endometrioid, represent up to 80% of endometrial cancers, and are generally associated with CAH, also called Endometrial Intraepithelial Neoplasia (EIN).[460-462] Type 1 tumors are low grade (grade 1 or grade 2), often present in early stage (stage I, confined to the corpus), and are usually curable with surgery alone or surgery plus radiotherapy. Type 1 carcinomas are associated with mutations in the *ras* proto-oncogene and in the *PTEN* tumor suppressor gene, and may show microsatellite instability. Mutations in the *p53* tumor suppressor gene are not usually present. Evidence links endocrine and nutritional lifestyle factors, including obesity, to the risk of type 1 but not type 2 tumors.[463]

Type 2 tumors include three separate histological types: high grade endometrioid (grade 3), serous papillary, or clear cell carcinomas. The suggested precursor lesion for type 2 tumors has been termed endometrial glandular dysplasia.[464] Type 2 tumors may develop from atrophic endometrial tissue in older women.[455,461,465] In contrast to type 1 tumors, these tumors are not generally believed to be hormonally driven and most do not express estrogen (ER) or progesterone receptors (PR). A majority of type 2 tumors have *p53* mutations, but almost never microsatellite instability or *PTEN* mutations.

Risk Factors for Endometrial Carcinoma

Unopposed Estrogen

Risk factors for type 1 endometrial cancer include any clinical scenario which may result in prolonged estrogen exposure without sufficient progesterone. This "estrogen excess" effect was noted in the U.S. in the late 1970s when it was recognized that the use of unopposed estrogen replacement therapy was associated with a twofold to twelvefold increased risk of uterine cancer.[466-469] The increased risk does not manifest itself for 2 to 3 years and longer use is associated with higher risk. Exogenous estrogen effects are strongest among women who are thin, normotensive, nonsmokers, and nondiabetics.[466,470] Adding a progestogen to the exogenous estrogen as part of so-called "combination" menopausal hormone therapy reduces or eliminates the risk of uterine cancer. Endometrial risk is also increased with the use of tamoxifen as a result of its estrogen agonistic properties in postmenopausal women with breast cancer and an intact uterus.[471,472] Anovulatory menstrual cycles are characterized by lack of luteal phase progesterone secretion resulting in unopposed estrogen effects on the endometrium with an associated increased risk of endometrial neoplasia. A common anovulatory condition associated with endometrial carcinoma is the polycystic ovarian syndrome (usually with associated metabolic syndrome). Insulin resistance may also lead to the development of endometrial cancer via the insulin growth factor receptor.[463]

Obesity

Production of estrogen in extraglandular tissues is catalyzed by the enzyme aromatase which increases linearly as a function of obesity (Table 29.9).[204] Accordingly, plasma estrogen levels increase proportionately with body weight or body mass index. Obesity is thought to increase the risk of endometrial cancer due to the enhancement of stimulation of endometrial tissue by estrogens.[474-476] Increased production of estrogen leads to excess stored estrone in adipose tissue and a reservoir of estrogen available for continuous tissue delivery.[473,477] Excess body weight is also associated with the prevalence of anovulation.

Obesity has been associated with a twofold to fivefold increase in endometrial cancer risk in both pre- and postmenopausal women and has been estimated to account for 40% or more of type 1 endometrial cancer incidence

in affluent societies.[478] While in many studies, risk rose approximately linearly with increasing Body Mass Index (BMI), a few studies showed a threshold effect, with an increase only among obese women with a BMI of 30 kg/m^2 or higher.[478] Epidemiological evidence also suggests a possible protective effect of regular physical activity perhaps by reducing obesity or through other means.[473]

Prolonged Estrogen Exposure

Early age at menarche and late age at menopause are risk factors that may reflect prolonged exposure to estrogen in the presence of anovluatory cycles.[479-481] Other risk factors for endometrial cancer that are associated with increased endogenous estrogen levels include high serum levels of androstenedione, the substrate for aromatase, and lower levels of serum sex-hormone binding globulin (SHBG) which allows increased delivery of estrogen to tissue.[482] Reduction in risk results from alcohol consumption, perhaps due to attenuation of endogenous estrogen, and cigarette smoking. Nulliparity increases the risk of endometrial cancer but the precise mechanisms are unknown.[479,480]

Genetic Factors

While most cases of endometrial cancer are sporadic, genetic factors, such as Lynch syndrome or hereditary nonpolyposis colorectal cancer *(HNPCC)* significantly increase the risk of endometrial cancer.

Environmental and Life-Style Factors

Incidence rates of endometrial cancer are up to 10 times higher in Western, industrialized countries than in Asia or rural Africa. Increases in incidence rates over time after industrial development or migration from low-risk to high-risk areas suggest that endometrial cancer has strong environmental risk factors which are related to the westernization of lifestyle.[463] Life-style factors likely include level of physical activity and obesity.[483,484]

Epidemiological Data Specific to Young Women with Endometrial Cancer

Retrospective reports suggest that between 2% to 14% of women presenting with endometrial cancer will be less than 40 years old.[453,485-493] The majority of young women with endometrial cancer present with menstrual irregularity. In a series from Massachusetts General Hospital (MGH), 29 of 91 women (32%) with endometrial cancer presented with menorrhagia or increasing menorrhagia and 39 of 91 (43%) presented with irregular menses or menometrorrhagia.[453] Similarly, 26 of 32 women in the Crissman series presented with irregular vaginal bleeding.[487]Other studies of young women with endometrial cancer have also reported high rates of irregular bleeding as the presenting complaint.[486,489,492]

Obesity is also a risk factor for endometrial cancer in younger women. The three largest studies regarding BMI are shown in Table 29.9. Data from these studies indicate that obesity rates in younger women range from as low as 38% to as high as 62%.[453] Interestingly, these obesity rates in young women seem to be higher than those of older women with endometrial cancer. In the series from Gallup and Stock, an obesity rate of 43.8% in women younger than 40 years old with endometrial cancer contrasted with 18% in a group of patients treated at the same institution who were older than 40 years old.[488]

All young women with endometrial cancer, however, are not obese. In the series from MGH, 52% of women younger than 40 years old with endometrial cancer were of normal weight (BMI less than 30), and 43% had a BMI of 25 or less.[453] That study reported a trend toward higher stage disease and high-risk histology in the normal weight women, though the differences did not reach statistical significance. Schmeler and colleagues presented a series of women younger than 50 years old and of normal weight seen at the MD Anderson Cancer Center.[494] They suggested that hormonal factors, and in particular polycystic ovarian syndrome (PCOS), may be a risk factor for developing endometrial cancer in those women with normal weight. Retrospective data suggest that normal weight younger women are not at higher risk for poor survival, though the numbers are too small in all studies to reach any conclusion.

Infertility is also associated with endometrial cancer in women under 40 years old, in contrast to their postmenopausal counterparts who are often"fertile" during their premenopausal years. In the series from MGH, 11 patients were diagnosed with endometrial cancer incidentally during infertility evaluation.[453] In Gallup and Stock's study, 44% of women younger than 40 years old with endometrial cancer were classified as "infertile."[488] Schmeler and colleagues reported a 17% prevalence of infertility in women under age 50 with endometrial cancer.[494] The finding of infertility makes sense if we assume that the infertility is a result of anovulation from disorders such as PCOS, which is associated with high levels of circulating unopposed estrogen.

Genetic disorders, particularly Lynch syndrome, are associated with endometrial cancer, usually at a young age. In fact, endometrial cancer is the most common cancer of Lynch syndrome in women and may be the presenting cancer in some patients.[495] Finally, endometrial cancer in a young woman may result from an estrogen producing ovarian tumor such as a granulosa cell tumor.

Complex atypical hyperplasia (CAH) is the precursor lesion for type 1 endometrioid adenocarcinoma. When this diagnosis is made on an endometrial biopsy, there is a high likelihood that a grade I endometrioid adenocarcinoma will coexist and be found on the hysterectomy specimen. Kurman and Norris established retrospectively that a preoperative diagnosis of CAH resulted in a postoperative diagnosis of grade 1 adenocarcinoma on the hysterectomy specimen in 29% of cases.[496] This study has since been confirmed prospectively by the Gynecology Oncology Group (GOG).[497,498] In the GOG's study, all women with a preoperative community diagnosis of CAH underwent hysterectomy within 12 weeks of diagnosis. The rate of carcinoma in the examined uterus was 43%. From the data presented above, it is clear that a diagnosis of CAH on an endometrial biopsy should be treated as if a grade 1 adenocarcinoma were present.

Receptor Mediated Effects

Role of the PR: Evolving data over the past decade have emphasized the complexity of the role of the progesterone receptor (PR) in mediating endometrial cancer in the

corpus. We now have a better understanding of the interactions between the two isoforms of the progesterone receptor: PRA and PRB. The two isoforms can have divergent responses and the ratio between the isoforms are likely to be important.[499-503] Several cofactors and co-repressors can influence PR-mediated action.[504-509]

The presence of a PR in an endometrial tumor does not predict response to progestogens. The study of Arnett-Mansfield and colleagues illustrates the difficulty of utilizing immunohistochemistry and the presence or absence of receptor to predict response.[510] The authors studied PR isoforms in archived endometrial cancer tissue. Ninety-six percent of tumors expressed PR. Only 30% of tumors expressed PRA alone, 42% expressed both isoforms, and 28% expressed PRB alone. PRB-only tumors had low levels of PR and those tumors that expressed both isoforms tended to express predominantly PRA. Based on their data, the authors hypothesized that loss of PRB resulted in the development of endometrial cancer. Other authors support these findings.[502]

Utility of PR Measurements

Most endometrioid adenocarcinomas express PR.[511] The lower grade tumors express PR more frequently, with a decrease in PR expression with increasing tumor grade.[512-514] Tumor heterogeneity (Box 29.2) is an important factor to consider as progesterone therapy may exert responses in some areas of the uterus and not in others. Tumors can have both PR+ and PR− areas.[515-518] Therefore, the presence of PR by immunohistochemistry does not reliably predict response to progesterone therapy. Accordingly, molecular markers of progesterone response that are measurable in paraffin-fixed tissue will be needed in the future to predict response of an individual tumor to progesterone therapy. The significance of PR levels in CAH lesions has not been clarified but it is assumed that they are responsive to progesterone. Retrospective data presented below demonstrate that CAH has a higher response rate to progesterone than well differentiated adenocarcinoma, with resolution rates of 70% to 90% or higher.

Treatment

Primary Treatment of Women Younger Than 40 Years Old for Fertility Preservation

The majority of data supporting primary hormonal therapy of endometrial cancer for the purposes of preserving fertility are derived from small, nonrandomized, retrospective observations of women treated with nonstandardized regimens and are subject to reporting bias. Data from several reviews and individual studies summarize available information.

Ramirez and colleagues published a retrospective literature review of patients treated with progestins[519] and identified 27 studies describing 81 patients treated with hormones for endometrial cancer. Overall, the response to progestin therapy was 76%, with a median time of response of 12 weeks. Documentation regarding pregnancy was available for 20 patients, all of whom were able to conceive at least once following treatment. Gotlieb and colleagues performed a similar and more comprehensive literature review and identified 101 women with a mean age of 29 years treated with hormones for endometrial cancer, with a 71% initial response rate, minimal time to response of 3.6 months, and 56 live births.[520]

Few prospective studies exist for progestin treatment in premenopausal women for the purposes of preserving fertility. A Japanese group reported a multi-center prospective study of patients with EC and CAH younger than 40 years old who were treated with 600 mg of medroxyprogesterone acetate (MPA) for 26 weeks.[521] Forty-five patients were treated, with a complete response (CR) rate of 55% in EC patients and 82% in CAH patients. During the 3-year follow-up period there were 12 pregnancies and 7 live births. Notably, there were also 14 recurrences in 30 patients, demonstrating the high-risk of recurrent disease following treatment cessation.

A recent literature review and meta-analysis of all prospective and retrospective published studies considering young women suggests an overall response rate to progestin therapy of 48% for endometrial cancer and 66% for complex atypical hyperplasia.[522] After complete response, recurrence rates were 23% in patients with CAH and 35% in patients with EC. Forty-one percent of patients with CAH and 35% of patients with EC were able to achieve pregnancy.

These and other studies provide the data to support that the majority of younger women will respond to hormonal therapy with an overall response rate of approximately 70% when EC and CAH are combined. The response rates for EC are lower than for CAH. The presence of ER and PR does not necessarily imply response to hormonal therapy and the recurrence risk is not insignificant, with a range of 8% to 66%.[523]

These studies provide the basis for agreement among most experts that only those women with grade 1 tumors lacking myometrial invasion (as assessed radiologically) may be considered for hormonal treatment for the purposes of fertility preservation (Box 29.3 gives an example of a treatment algorithm for this clinical scenario). Higher grade tumors or invasive tumors should be treated with curative surgery, as progression of disease and death from disease is a real phenomenon that has been reported in the literature.[524]

There is no standardized drug, delivery system, or dosing schedule for treating women with primary endometrial cancer for the purpose of preserving fertility with hormones. Most gynecological oncologists choose megestrol acetate (MA) as a first choice, but doses and schedules are not standardized. Doses as low as 40 mg daily and as high as 160 mg four times daily have been reported. Oral medroxyprogesterone acetate (MPA), depo-medroxyprogesterone acetate, and combinations of tamoxifen and progesterone have also been suggested. While some authors suggest using cyclic therapy to induce a monthly withdrawal bleed, most advocate continuous treatment which ultimately results in an atrophic endometrium. Since progestin may be poorly tolerated by many women, with breast tenderness and weight gain being frequent complaints, it is probably best to use the lowest dose that will also be successful in reversing the neoplastic endometrium. Notably this lowest dose probably varies from woman to woman and likely its success is dependent on patient's BMI and individual tumor.

Many women with endometrial cancer treated with progestins will require ART to achieve pregnancy. Since ART generates very high serum estradiol levels (which thereby put the patient at risk for recurrence if pregnancy is not achieved), many community *in vitro* fertility (IVF) programs may feel uncomfortable managing these patients.

Box 29.3 Treatment Algorithm for Primary Hormonal Treatment of Premenopausal Women with Endometrial Carcinoma Who Wish to Preserve Fertility

- Confirm that the tumor is endometrioid and grade 1 by pathological review. If diagnosis was made by endometrial biopsy, perform dilatation and curettage (D&C) to ensure complete sampling of the endometrial cavity.
- Obtain a careful medical history and perform physical examination with particular attention to family history. A family history that suggests Lynch syndrome should result in genetic counseling and possible testing as patient is at increased risk for colon and ovarian cancer. Attention should also be paid to medical history that might complicate future pregnancies (obesity, diabetes, hypertension).
- MRI and/or ultrasound should be performed to rule out adnexal metastases and evaluate for myometrial invasion.

If the tumor is well sampled and grade 1 with no evidence of extrauterine disease or myometrial invasion, the patient should undergo:

- Informed counseling, preferably with a gynecological oncologist.
- Treatment with progesterone, either continuous or cyclic.
- Resampling in 3 months to assess response.
- If resolution of disease: patient should be encouraged to achieve pregnancy quickly. Many of these patients will require artificial reproductive technology (ART).
- If incomplete resolution of disease: patient may be retreated with another medication regimen or a higher dose of the same formulation and resample in 3 months.

Once childbearing is complete or if treatment fails, the patient should be counseled for definitive surgical therapy consisting of TAH–BSO with lymphadenectomy.

Moreover, many of these women are in the older range of reproductive age and therefore have lower success rates for IVF, perhaps requiring multiple attempts at ovulation induction to achieve pregnancy. These risks must be considered in the overall counseling of patients when they are contemplating hormonal management for preservation of fertility.

Pathological Assessment of Progestin Therapy

The GOG is trying to understand the molecular basis of progestin response in several prospective ongoing studies. In GOG study 211, postmenopausal women undergoing hysterectomy for a known diagnosis of endometrioid adenocarcinoma were treated with a single intramuscular (IM) dose of depo-medroxyprogesterone acetate 400 mg 21 to 24 days prior to hysterectomy. As described in a preliminary abstract,[525] 60 patients had initial biopsies and hysterectomy specimens available for study. Only one complete response was seen, but 37 tumors had partial response, more frequently in tumors of lower grade. While 90% of tumors were initially ER and PR positive, it was noted that both ER and PR were significantly down-regulated following progesterone treatment.

Alternative Methods of Treatment

Several authors have suggested the use of a progesterone intrauterine device (IUD) as a means of treating endometrial cancer with high doses of progesterone without systemic side effects. In the study from Montz and colleagues, women with clinical stage I, grade 1 endometrial cancer underwent hysteroscopy and curettage followed by placement of a progesterone IUD and resampling every 3 months.[526] Seven of 11 patients demonstrated complete response at 6 months and 6 of 8 at 12 months. Dhar and colleagues performed a similar study using a levonorgestrel containing IUD.[527] Four women with grade 1 adenocarcinoma that expressed PR were treated with IUD; only one patient had a complete response within 6 months. However, this study did not exclude myometrial invasion prior to the treatment with the IUD. In both studies, the majority of patients were postmenopausal and underwent hormonal treatment because it was felt that they were poor surgical candidates; thus, it is impossible to know whether a similar treatment regimen in premenopausal women would have similar outcome. Moreover, two women were reported to possibly have developed adenocarcinoma in the uterine isthmus while using a levonorgestrel IUD, suggesting that either the uterine cavity does not receive a uniform dose of progestin, or that the cancer is not uniformly receptive to progesterone treatment.

Follow-Up of Therapy

Appropriate follow-up has not been not standardized with respect to frequency of endometrial resampling, duration needed before a complete response may occur, or duration of required follow-up to rule out recurrence. It is clear, however, that responses may not be seen at the first 3-month resampling, and that the recurrence risk is high. The authors' opinion is that patients be resampled 3 months after beginning hormonal therapy. If an incomplete response is documented, a further 3-month trial of treatment, perhaps with increased dose or different medication, may be appropriate. If pregnancy is not desired in premenopausal women, a "maintenance" hormonal treatment must be utilized to prevent recurrence once regression of the lesion has been documented histologically. This maintenance therapy might consist of the birth control pill, monthly withdrawal bleeds with progesterone, or continuous progestin therapy, either by mouth, intramuscular, or by intrauterine device. The subgroup of premenopausal women desiring pregnancy require a modified approach. Once complete remission is established, pregnancy should be aggressively pursued, with artificial reproductive technology (ART) if required.

Management of Recurrent or Persistent Endometrial Cancer

Data Upon Which to Base Conclusions

In most clinical trials of hormonal therapy, the histological type and grade of endometrial cancer have not been specified and interpretation is confounded by these factors. Because type 2 cancers are more likely to present in late stages, and to persist or recur, there may be a majority of this type in any clinical trial of this nature. (Sub-types of endometrial cancer are listed in Table 29.8.)

Progestational Agents

Use of these agents to successfully treat patients with advanced or recurrent cancer has a long history. The activity of progestins in this setting was reported in the 1950s by Kelley and Baker.[528] They and others demonstrated that

30% to 40% of patients responded to progestin therapy, with response durations ranging from 23 to 29 months.[529] More recent studies, using standard response criteria as well as new imaging procedures, have indicated that response rates are more likely to be in the 10% to 15% range.[530,531] Nevertheless there has been enthusiasm for progestin (hormonal) therapy in this disease setting for years, especially given the historically low response to standard chemotherapy agents and the relatively low rate of side effects of hormonal therapy. Early reports regarding progestin treatment of advanced or recurrent endometrial cancer considered intravenous progesterone delivery.[532] Subsequently, after it was demonstrated that serum concentrations of medroxyprogesterone acetate (MPA) are similar whether given by parenteral or oral routes, studies began to focus on oral progestins.[533]

The Gynecology Oncology Group (GOG) has completed multiple studies of hormonal treatment of advanced or recurrent endometrial cancer (Tables 29.10 and 29.11). While different forms of progestin have been used most

frequently, the GOG has also studied combination therapy with tamoxifen, the aromatase inhibitor anastrozole, gonadotropin releasing hormone analogues, among others. Unfortunately many of these studies have demonstrated these drugs to have activity that does not merit further study.

Tables 29.10 and 29.11 outline selected GOG studies that have been published using hormonal therapy in advanced or recurrent endometrial cancer. Table 29.10 shows those studies that were felt to be positive studies that merited further study. The details of select studies will be discussed below.

GOG protocol 48 was one of the first large studies of progestin in the modern clinical era.[534] In this study, with 331 women with measurable disease, the response rate to 150 mg MPA daily was 18%, and the duration of response was short. Subsequently, GOG protocol 81 was undertaken to determine if higher doses of progestin would result in higher response rates. This prospective trial accrued 324 women between 1985 and 1989[535] and randomized subjects to either 200 or 1000 mg per day of MPA orally. Determination of the presence of estrogen or progesterone receptor was not required for study entry, but the data were collected when available. Interestingly, the overall response rates (complete plus partial; 25% and 16% for low-dose and high-dose regimens, respectively) favored the low-dose regimen. The crude relative odds of responding to the high-dose regimen was 0.56. When the data were controlled for pretreatment prognostic factors, including tumor grade and stage, age of patient, and performance status, the response rate still favored the low-dose regimen.

Not surprisingly, the response to progestin treatment was highly associated with tumor grade. Patients with grade 1 cancers experienced tumor regression more frequently in response to treatment than patients with high grade tumors with response rates of 37% (22 of 59 patients), 23% (26 of 113), and 9% (12 of 127) for those with grade 1, 2, or 3, respectively. A statistically significant trend demonstrated greater response rates with increased differentiation of the tumor. Similarly, tumors with a positive hormone receptor status responded more frequently than negative tumors with response rates of 37% (17 of 46) for patients who were progesterone receptor-positive and 8% (7 of 86 patients) for those negative. On average, the overall survival and progression-free survival were longer for those assigned to the low-dose regimen than for those assigned to the high-dose regimen. After the initial performance status, progesterone-receptor level, tumor grade, and age were adjusted for, the risk of death, was 31% greater for those on the high-dose regimen than for those on the low-dose regimen. Similarly, the risk of first progression or death was 35% greater for those on the high-dose regimen. The oral progestin therapy was well tolerated, with thrombophlebitis, the most frequent adverse effect, occurring in only 5% of patients.

GOG 121 expanded on the results of GOG 81, utilizing a different formulation of progestin.[536] In this phase II study, patients were treated with megestrol acetate (MA) at a dose of 800 mg daily in divided doses. While the ORR was only 24%, it is notable that the clinical trial population was heterogeneous: 47% of the patients had high grade histology (grade 3) and only 50% of patients had endometrioid histology. Thus less than half of the patients had endometrial cancers that would be considered to be type 1 and likely to respond to hormonal therapy. When only the patients with grades 1 to 2 disease were considered (which eliminates all of the high risk histologies), the response rate was 37%. Toxicities of MA were minimal, with weight gain being the most common side effect.

A potential consequence of progestin treatment is the decrease in PR concentration, resulting in a relatively short treatment response.[537] Tamoxifen citrate has been shown to increase PR in animal models.[538] The aim of GOG protocols 119 and 153 was to utilize alternating treatment with tamoxifen and MA to see if the tamoxifen would counterbalance the MA down-regulation of PR.[539,540] In GOG 153, patients were treated with MA 80 mg BID for 3 weeks followed by tamoxifen citrate 20 mg BID for 3 weeks. This alternating sequence was continued at 3-week intervals until disease progression or adverse events. There were 21.4% CRs and 5.4% PRs for an ORR of 27%. The response rate was highest at 38% for those tumors that were grade 1. Weight gain was the most common adverse event and thromboembolic events the most serious. These data, while not directly comparing results with megestrol–acetate or MPA, would not appear superior to use of progestogens alone.

The GOG also evaluated the combination of daily tamoxifen and intermittent weekly MPA in GOG 119. Thirty-three percent of patients responded (6 CR and 13 PR). A scientific corollary study was performed as part of GOG 119 to determine the relationship of ER and PR to clinical outcome.[541] Pretreatment tumor tissue from metastatic or recurrent endometrial cancer lesions was obtained from all patients on study. Immunohistochemistry was performed for ER and PR on paraffin fixed tissue as well as the PR isoforms PRA and PRB on fresh frozen tissue. As expected, ER and PR significantly decreased with increasing tumor grade. ER prior to hormonal therapy was significantly related to clinical response to daily tamoxifen and intermittent MPA. ER expression was highly correlated with the expression of PRA, but not PRB. Except for ER, there was no correlation between receptor expression and clinical response.

Other cooperative groups have performed hormonal studies in the advanced or recurrent population with similar results.[542,543] Combinations of hormones as well as hormones plus chemotherapy have been considered.[544]

Hormonal Treatment with New Biological Agents

Low response rates to hormonal agents in patients with advanced or recurrent endometrial cancer have prompted investigators to consider novel targeted agents in this population. One example is the drug LY353381 (arzoxifene), a third generation selective estrogen modulator (SERM). While first generation SERMs such as tamoxifen have mixed estrogen agonist and antagonist activity, second and third generation SERMs have more selective estrogen antagonism. As a third generation SERM, arzoxifene is a potent estrogen antagonist. A recent phase II study of arzoxifene in 34 patients revealed a 31% response rate; all responses occurred in patients whose tumors expressed PR.[545] Toxicity was minimal, with hot flashes the most common side effect. Further study of this drug and others like it are ongoing.

Conclusions

A subgroup of endometrial cancers are hormonally driven and will respond to hormone based therapy, but our current

understanding of the molecular aspects of response are limited. There is a significant need for incorporation of translational studies in clinical trials in this disease in order to obtain a better understanding of the mechanism of action of hormones and to identify markers for response. Since hormonal treatment has fewer side effects than chemotherapy, identifying those patients who will respond to hormonal treatment in the setting of advanced or recurrent disease may significantly impact quality of life.

Finally, obesity remains a significant and increasing clinical problem in the U.S. and other developed countries, and we expect to see rising rates of endometrial cancer across all age groups in this setting. Education about avoiding obesity and increasing physical activity is expected to significantly impact the rate of endometrial cancer development, particularly in young women for whom fertility preservation may be paramount.

Table S29.7 Secondary Hormonal Therapies for Recurrent Disease

Modality	Responders	Total Patients	Percent Responding	Clinical Setting	Reference
Flutamide	23	100	23%	First relapse after medical or surgical orchiectomy	(1)
Prednisone	21	101	21%	First relapse after medical or surgical orchiectomy	(2)
Flutamide withdrawal	29	138	21%	Relapse after combined androgen blockade or flutamide	(3; 4)
Aminoglutethimide + hydrocortisone	14	29	49%	After anti-androgen withdrawal	(5)
Hydrocortisone	16	82	20%	After anti-androgen withdrawal	(6)
Ketoconazole Hydrocortisone	43	72	60%	After anti-androgen withdrawal	(7)
Megestrol l acetate	17	119	14%	After anti-androgen withdrawal	(8)
DES	71	243	29%	After anti-androgen withdrawal	(9)
Abiraterone	797	231	29% (PSA response); improved survival 14.8 months vs placebo 10.9 months ($P < 0.001$)	After anti-androgen withdrawal and docetaxel	(8)

CHAPTER 30

Medical Approaches to Ovarian Stimulation for Infertility

Bart C.J.M. Fauser

Concepts of Ovarian Stimulation

Ovarian stimulation is a central component of many infertility therapies. At the outset of this chapter, it is important to emphasize that two different concepts of ovarian stimulation exist. These approaches differ in both the starting point (i.e., the type of patients) and end points (i.e., the aim of the medical intervention).

Ovulation Induction

In the strict sense of the term, ovulation induction refers to the triggering of ovulation, that is, the rupture of the preovulatory follicle and release of the oocyte. In the clinical context however, this term refers to the type of ovarian stimulation for anovulatory women aimed at restoring normal fertility by generating normo-ovulatory cycles (i.e., to mimic physiology and induce single dominant follicle selection and ovulation). Ovulation induction represents one of the most common interventions for the treatment of infertility.[1] Anovulation represents one of the few states of absolute infertility, but excellent cumulative pregnancy rates can be achieved if normal menstrual cyclicity is restored.

After the exclusion of intrinsic ovarian abnormalities (e.g., premature ovarian failure), follicle development can be stimulated by various pharmacological compounds, and normo-ovulatory cycles can usually be obtained. This can be achieved with appropriate monitoring of ovarian response and in the hands of skillful clinicians. Because of various more subtle inherent ovarian abnormalities in most of these women, especially in patients suffering from polycystic ovary syndrome (PCOS), the risks of multiple pregnancy and ovarian hyperstimulation syndrome (OHSS) are considerable. However, the occurrence of these complications can be reduced to an acceptable level, especially with low-dose gonadotropin protocols.[2] The therapeutic window for an acceptable ovarian response is small, with a major individual (and to some extent cycle-to-cycle) variability in response. Approaches for gonadotropin ovulation induction include slowly and prudently surpassing the individual follicle-stimulating hormone (FSH) threshold for ongoing follicle development, as will be discussed later in this chapter.

Many other approaches for ovulation induction are available. These approaches include interfering with negative estrogen feedback anti-estrogens or aromatase inhibitors, the use of insulin-sensitizing agents, and laparoscopic surgical methods.

Ovarian Hyperstimulation

This treatment modality has become an integral part of assisted reproductive technologies (ART). The aim of ART is to bring more male and female gametes closer together and thereby increase the chances of pregnancy. The goal of ovarian hyperstimulation per se is to induce ongoing development of multiple dominant follicles and to mature many oocytes in order to improve chances for conception either *in vivo* (empirical ovarian hyperstimulation with or without intrauterine insemination, IUI) or *in vitro* with *in vitro* fertilization (IVF). This approach of interfering with physiological mechanisms underlying single dominant follicle selection is usually applied in normo-ovulatory women. Although ovarian hyperstimulation can also be performed in anovulatory women, this approach should be clearly differentiated from ovulation induction. The physiological concepts that underlie current approaches to ovulation induction and ovarian hyperstimulation are described later in this chapter.

Concepts of Follicle Development Regulation Relevant to Ovarian Stimulation

Initiation of growth of primordial follicles, also referred to as primary recruitment, occurs continuously and in a random fashion and development from the primordial up to the preovulatory stage takes several months.[3,4] The great majority of primordial follicles which enter this development phase undergo atresia prior to reaching the antral follicle stage. The regulation of early follicle development and atresia and the degree to which early stages of follicle development are influenced by FSH remain unclear, but evidence suggests that the transforming growth factor β superfamily and factors regulating apoptosis (i.e., programmed cell death) are involved.[5,6] Only at more advanced stages of development do follicles become responsive to FSH and obtain the capacity to convert the theca cell–derived substrate androstenedione (AD) to estradiol (E_2) by the induction of the aromatase enzyme.

Owing to demise of the corpus luteum during the late luteal phase of the menstrual cycle, E_2, inhibin A,

and progesterone levels fall. This results in an increased frequency of pulsatile gonadotropin-releasing hormone (GnRH) secretion inducing rising FSH levels at the end of the luteal phase.[7,8] Although each growing follicle may initially have an equal potential to reach full maturation, only those follicles that happen to be at a more advanced stage of maturation during this intercycle rise in FSH (levels surpassing the so-called *threshold* for ovarian stimulation) gain gonadotropin dependence and continue to grow[2] (Fig. 30.1). This process is referred to as cyclic, gonadotropin-dependent recruitment as opposed to the recently mentioned initial, gonadotropin-independent recruitment of primordial follicles.[4] Based on indirect observations it is believed that the cohort size of healthy early antral follicles recruited during the luteofollicular transition is around 10 per ovary.[9,10] During the subsequent follicular phase, FSH levels plateau during initial days[11,12] and are gradually suppressed thereafter by ovarian inhibin B[13] and E_2[14] negative feedback. A rise in inhibin B occurs just after the intercycle rise in FSH. It may therefore be proposed that inhibin B limits the duration of the FSH rise. Decremental follicular phase FSH levels (effectively restricting the time when FSH levels remain above the threshold, referred to as the FSH *window*) (Fig. 30.1) appear to be crucial for selection of a single dominant follicle from the recruited cohort.[11] Only one follicle escapes from atresia by increased sensitivity for stimulation by FSH and luteinizing hormone (LH).[2] The important concept of increased sensitivity of the dominant follicle for FSH has been confirmed by human studies showing developing follicles to exhibit a variable tolerance for GnRH antagonists-induced gonadotropin withdrawal.[15,16] On the other hand, early stages of follicle development being independent from gonadotropins is confirmed in hypophysectomized women presenting with preovulatory graafian follicles within 2 weeks after the initiation of ovarian stimulation with exogenous gonadotropins.[17]

A central role has also been demonstrated for LH in monofollicular selection and dominance in the normal ovulatory cycle.[18-20] Although granulosa cells from early antral follicles respond only to FSH, those from mature follicles also contain LH receptors and therefore become responsive to both FSH and LH. The maturing dominant follicle may become less dependent on FSH because of the ability to respond to LH. It is suggested that the leading follicle continues its development owing to LH responsiveness, whereas smaller follicles enter atresia because of insufficient support by decreasing FSH concentrations during the late follicle phase. The dominant follicle can be distinguished by ultrasound from other cohort follicles by a size greater than 10 mm diameter.[10] The concept of both endocrine and autocrine up-regulation is supported by several other observations that characterize the dominant follicle, including the *in vitro* induction of aromatase enzyme activity,[21] ovarian morphology,[22] and endocrine changes in follicle fluid[23] and serum. These observations all show that enhanced E_2 biosynthesis is closely linked to preovulatory follicle development.

These concepts of follicular development and selection have come to underlie contemporary approaches to therapeutic ovulation induction in women suffering from anovulatory infertility. Moreover, our increasing understanding of the processes underlying monofollicular selection has enabled the development of new approaches to ovarian hyperstimulation for assisted reproduction treatments.

Preparations Used for Ovarian Stimulation

Evidence of the endocrine pituitary-gonadal axis arose early in the 20th century, when it was observed that lesions of the anterior pituitary resulted in atrophy of the genitals. The first convincing evidence supporting the existence of two separate gonadotropins (initially referred to as Prolan A and Prolan B) was provided by Fevold and Hisaw in 1931, and both LH and FSH were subsequently isolated and purified. In 1928, Aschheim and Zondek described the capacity of urine from pregnant women to stimulate gonadal function. The concept of stimulating ovarian function by the exogenous administration of gonadotropin preparations has

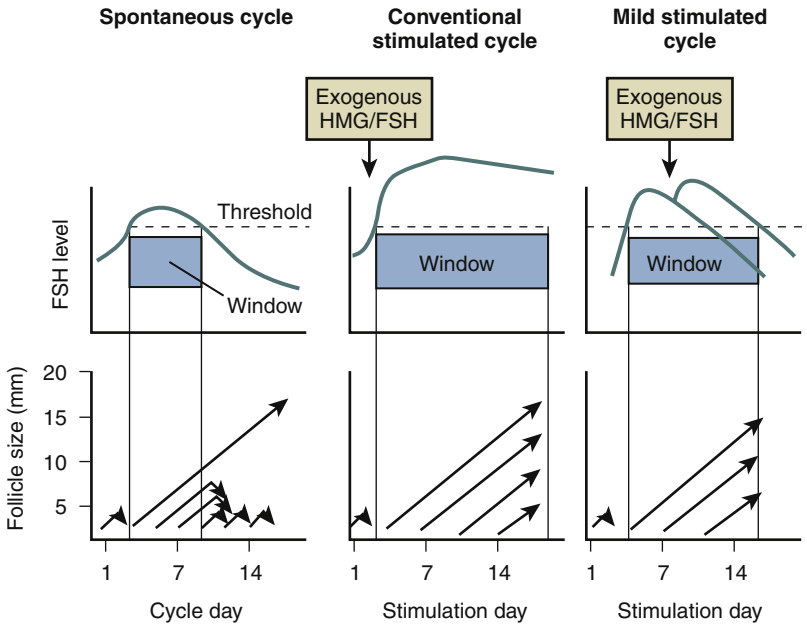

FIGURE 30.1 The follicle-stimulating hormone (FSH) threshold and window concept for monofollicular selection *(left panel)*, as conventionally applied to achieve multifollicular development *(middle panel)*. Each *arrow* represents a developing follicle. The *right panel* represents the concept of extending the FSH window by administering exogenous FSH in the midfollicular phase to maintain FSH levels above the threshold allowing multifollicular development. HMG, human menopausal gonadotropin. *(Adapted from Macklon NS, Stouffer RL, Giudice LC, Fauser BC. The science behind 25 years of ovarian stimulation for in vitro fertilization.* Endocr Rev *27[2]:170–207, 2006.)*

intrigued investigators for many decades. As early as 1938, Davis and Koff had already described the ability of purified pregnant mare serum to induce ovulation in humans by intravenous administration. However, these initial attempts had to be stopped due to species differences and resulting antibody formation impacting on efficacy and safety. Not until 1958 did Gemzell describe the first successful use for ovulation induction of gonadotropin preparations derived from human pituitaries. Shortly thereafter, Lunenfeld reported the clinical use of gonadotropin extracts from urine of postmenopausal women (for an historical overview, see Gruhn and Kazer[24] and Lunenfeld[25]).

A second important development allowing for ovarian stimulation on a large scale was a fine example of medical serendipity. The first estrogen antagonist tested in cancer patients was found to induce ovulation.

Clomiphene Citrate

In the late 1950s the first nonsteroidal estrogen antagonist (MER-25) was tested in patients to assess the efficacy of the compound in women with cystic mastitis, breast cancer, endometrial hyperplasia, or endometriosis. Some of these women with endometrial hyperplasia were of reproductive age and suffering from long-standing amenorrhea due to the Stein-Leventhal syndrome. To the great surprise of the investigators, the initiation of the medication in these women was followed by the recommencement of menstrual cycles.[26] Shortly thereafter, the ovulation-inducing capacity of the next generation of closely related anti-estrogens (MRL/41; clomiphene citrate, CC) (Fig. 30.2) was recognized.[27] More than half a century later, CC is still the most applied drug for infertility therapies worldwide, accounting for around two thirds of all prescriptions.

Clomiphene citrate is a racemic mixture of two stereoisomers. The enclomiphene isomer has a relatively short half-life, whereas the zuclomiphene isomer has an extended clearance. The two isomers demonstrate different patterns of agonistic and antagonistic activity *in vitro*.[28] Stimulation of ovarian function is elicited by raised pituitary FSH secretion due to blockage of E_2 steroid feedback by CC. Overall a 50% to 60% increase of serum FSH levels above baseline has been described.[29] The exact nature of the mechanism of action of CC is still uncertain.[30,31] Induced changes in other systems, like insulin-like growth factor (IGF) may partly explain the capacity of CC to stimulate the ovary.[30] However, anti-estrogenic effects at the uterine level (cervical mucus production and endometrial receptivity) are believed to underlie the observed discrepancy between achieved ovulation and pregnancy rates. The impact of a concomitant rise in LH on ovarian response to CC is also uncertain. CC for ovulation induction is considered to be relatively safe because steroid negative feedback remains intact. The oral route of administration and low costs represent additional advantages of this preparation. CC was originally developed for clinical use by the Merrel company in 1956, and it is still considered to represent the first-line treatment strategy in most anovulatory infertility. In addition, this compound was a central component in the early days of IVF[32,33] and is still often applied for the empirical treatment of unexplained infertility, alone or in combination with IVF.

Gonadotropin Preparations

Clinical experiments in the late 1950s demonstrated that extracts derived from the human pituitary could be used to stimulate gonadal function.[34] Subsequently, experiments involving the extraction of both the gonadotropic hormones LH and FSH from urine of postmenopausal women led to the development of human menopausal gonadotropin (hMG) preparations. From the early 1960s these preparations were used for the stimulation of gonadal function in the human.[35] It soon became clear that hMG was a very potent compound. Its ability to directly stimulate the ovaries was accompanied by the inherent risks of ovarian hyperstimulation. Initial use in the treatment of anovulation was associated with high rates of multiple pregnancy and OHSS. The potential for dangerous complications induced the need for monitoring of ovarian response and dose adjustment. More recently introduced low-dose protocols applied in conjunction with intense ovarian response monitoring have substantially contributed to improved treatment outcomes.

Initial attempts in the 1970s by Edwards and Steptoe to enable the conception of a baby through IVF also involved hMG stimulation protocols. Because of a lack of pregnancies (presumed due to abnormal luteal function) it was decided to switch to natural cycle IVF. It was an unstimulated cycle that led to the conception of the first IVF baby, Louise Brown, who was born on July 25, 1978.[36] Subsequent IVF pregnancies were reported from Australia to occur after ovarian stimulation with CC.[32] The more widespread use of hMG for successful IVF was developed thereafter in the United States.[37] For over 2 decades, gonadotropin preparations have also been extensively applied for ovarian stimulation in ovulatory women for empirical treatment of unexplained subfertility. Here the aim is to increase monthly fecundity rates by increasing the number of oocytes available for fertilization *in vivo* (with or without the additional use of IUI). These trends, and the rapid expansion in the use of IVF treatment, underlie the enormous increase in worldwide demand and sales for gonadotropin preparations.

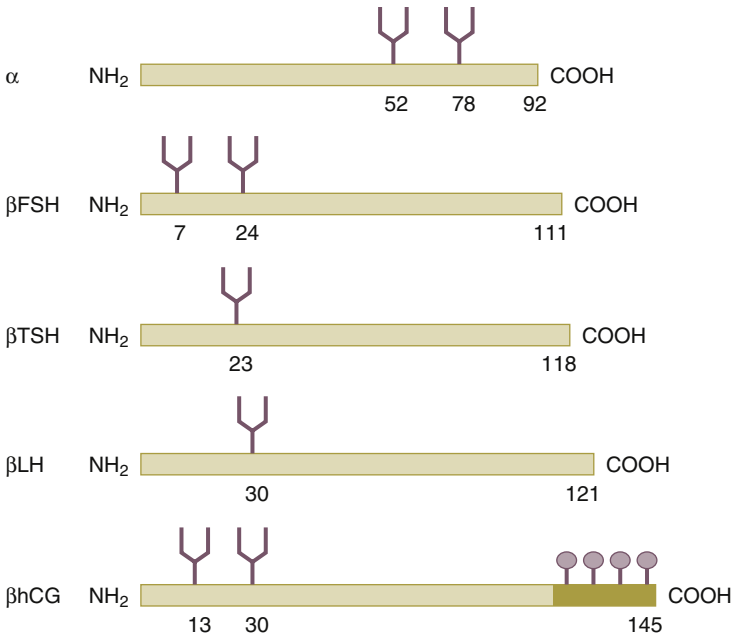

FIGURE 30.3 Structure of the common α subunit and hormone-specific β subunit of the human glycoprotein hormones: follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and human chorionic gonadotropin (hCG).

The early extraction techniques were very crude, requiring around 30 L of urine to manufacture enough hMG needed for a single treatment cycle. The FSH to LH bioactivity ratio of these early preparations was 1:1. As purity improved, it was necessary to add human chorionic gonadotropin (hCG) in order to maintain this ratio of bioactivity.[38] These initial preparations were very impure with many contaminating proteins; only less than 5% of the proteins present were bioactive. Bioactivity of gonadotropin preparations continues to be assessed by the crude *in vivo* rat ovarian weight gain Steehlman and Pohley assay. This rather anachronistic technique has the disadvantage of allowing considerable batch-to-batch inconsistency in bioactivity. However, improved protein purification technology allowed for the production of hMG with reduced amounts of contaminating nonactive proteins and eventually the development of purified urinary FSH (uFSH) preparations by using monoclonal antibodies since the late 1980s.[39] The currently available pure products allow for less hypersensitivity reactions, and less painful subcutaneous administration. Because of the worldwide increased need for gonadotropin preparations, demands for postmenopausal urine increased tremendously and adequate supplies could no longer be guaranteed. In addition, concern regarding the limited batch-to-batch consistency along with possibilities of urine contaminants emerged.[39]

Through recombinant DNA technology and the transfection of human genes encoding for the common α subunit and hormone-specific β subunit of the glycoprotein hormone (Fig. 30.3) into Chinese hamster ovary cell lines,[40] the large-scale *in vitro* production of human recombinant FSH (recFSH) has been realized.[41] The first pregnancies using this novel preparation in ovulation induction[42] and in IVF[43] were reported in 1992. Since then, numerous large-scale, multicenter studies have been undertaken, demonstrating their efficacy and safety. The recombinant products offer improved purity, consistency, and large-scale availability. Because of its purity, recFSH can now be administered by protein weight rather than bioactivity, and so-called "filled-by-mass" preparations[44] are now available for clinical use. During recent years, recLH and rechCG have also been introduced for clinical application.[29] Finally, a long-acting recFSH agonist (a man-made chimeric hormone generated by the fusion of the carboxy-terminal peptide of hCG to the FSH β chain) has recently been introduced into the clinic after efficacy and safety had been established in large sample size trials where IVF clinics from all over the world participated.[45-47]

GnRH Analogs

In 1971, the small decapeptide gonadotropin-releasing hormone (GnRH) was isolated and its structure elucidated by Schally and Guillemin (Fig. 30.4). Some years later, both investigators jointly received the Nobel prize for this discovery. Amino acid substitutions have revealed the significance of specific regions for its stability, receptor binding, and activation of the gonadotrope cells. This decapeptide is secreted by the hypothalamus into the portal circulation in an intermittent fashion, stimulating the pituitary gonadotropes to synthesize and secrete LH and FSH. Early studies demonstrated that pituitary down-regulation could be induced by the continued administration of GnRH.[48] Clinically safe GnRH agonists were developed relatively easily by replacing one or two amino acids. An increased potency could be achieved by replacing glycine for D-amino acids at position 6 and by replacing Gly-NH_2 at position 10 by ethylamide.[49] Such simple structural changes render these compounds more hydrophobic and more resistant to enzymatic degradation. The administration of GnRH agonists induces an initial stimulation of gonadotropin release for 2 to 3 weeks (the so-called "flare effect") followed by a down-regulation (or desensitization) due to the clustering and internalization of pituitary GnRH receptors.

GnRH agonists have been used clinically since 1981 to induce a "chemical castration" for steroid-dependent disease states such as fibroids and endometriosis in females and prostate cancer in males. The first paper concerning its use in IVF for the prevention of a premature LH rise also

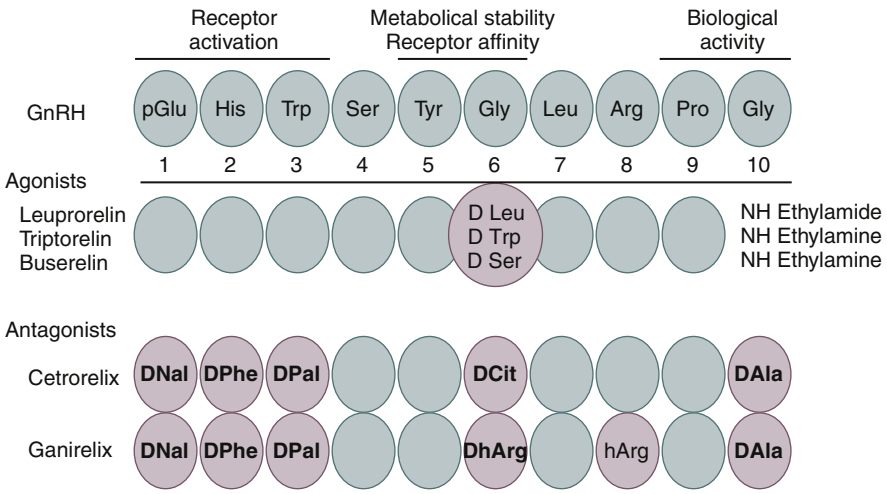

FIGURE 30.4 Structure of the native decapeptide gonadotropin-releasing hormone (GnRH), as well as the modified, commercially available GnRH agonists and antagonists. appeared in the early 1980s.[50] Shortly thereafter, the use of GnRH agonists such as buserelin, triptorelin, or leuprorelin to down-regulate the pituitary prior to administration of gonadotropins (a strategy that became known as the "long protocol") became the standard of care. The recent clinical introduction of GnRH antagonists may ultimately lead to a new standard of care in IVF practice.

It has taken almost 3 decades to develop GnRH antagonists with acceptable safety and pharmacokinetic characteristics. The first-generation antagonists were developed by replacing amino acids histidine at position 2 and tryptophan at position 3, but these compounds suffered from low potency. In second-generation compounds, the activity was increased by incorporating a D-amino acid at position 6. However, the widespread clinical application of these compounds was hampered by frequent anaphylactic responses due to histamine release. By introducing further replacements at position 10, third-generation compounds were developed.[51,52] Subsequently both the compounds ganirelix and cetrotide were shown to be safe and efficacious in IVF. These third-generation GnRH antagonists were registered in 2001 for use in IVF. The immediate suppression and recovery of pituitary function renders these compounds appropriate for short-term use in IVF. Clinical uptake of GnRH antagonists in IVF has been rather slow. Recent meta-analysis has confirmed the use of antagonist cotreatment to be effective and safe[53,54] It is estimated that at present around the world almost 50% of all IVF is with GnRH antagonist co-treatment. Further extended use of GnRH antagonist in steroid-dependent disease states such as endometriosis or myomas will depend on the development of depot or slow release formulations.

Outcomes of Ovarian Stimulation

Ovulation Induction

Amenorrheic women with anovulation exhibit virtually no chance of spontaneous conception and ovulation induction may restore normal fertility. However, the aim of mimicking normo-ovulatory cycles cannot always be achieved, and therefore, the chances of complications such as multiple pregnancy or OHSS should be taken seriously, especially in PCOS patients. Oligomenorrheic women may or may not have incidental spontaneous ovulations, and therefore, spontaneous pregnancies may occur. For obvious reasons, fertility specialists see only oligomenorrheic women who have failed to conceive, and these patients will usually respond well to ovulation induction. The balance between success and complications resulting from ovulation induction is dependent on many factors, including patient characteristics, gonadotropin preparations and dose regimens used, the intensity of monitoring ovarian response to stimulation, and willingness to cancel the cycle in case of hyper-response. An alternative option under those circumstances would be to convert ovulation induction to IVF. Cumulative live birth rates of ovulation induction have been reported to be around 75% to 80%,[55,56] with a coinciding incidence of multiple pregnancies of more than 10% and of OHSS of less than 2%.

OHSS is a potentially life-threatening complication characterized by ovarian enlargement, high serum sex steroids, and extravascular fluid accumulation, primarily in the peritoneal cavity. In severe cases, hypotension, increased coagulability, reduced renal perfusion, and oliguria may occur. Deranged liver function tests, venous and arterial thrombosis, renal failure, and adult respiratory distress syndrome can ensue, and fatalities have been reported.[57] Moderate to critical OHSS is very rare with CC but constitutes an important complication of gonadotropin use.[58] The incidences of mild, moderate, and severe OHSS following gonadotropin ovulation induction have been reported to be 20%, 6% to 7%, and 1% to 2%, respectively.[29] In addition to PCOS, risk factors for the development of OHSS include young age and low body weight.[58] The risk is further increased when adjuvant GnRH agonist treatment is employed.[59]

The contribution of ovulation induction treatment to the number of triplet and higher order pregnancies is considerable.[59,60] It has been calculated that 40% of higher order multiple births in the United States could be attributed to the use of ovulation-inducing drugs without assisted reproduction.[61]

Ovarian Stimulation

As previously outlined, the aim of ovarian hyperstimulation alone or in combination with assisted reproductive techniques is to bring an increased number of gametes (oocytes and sperm) together in order to augment pregnancy

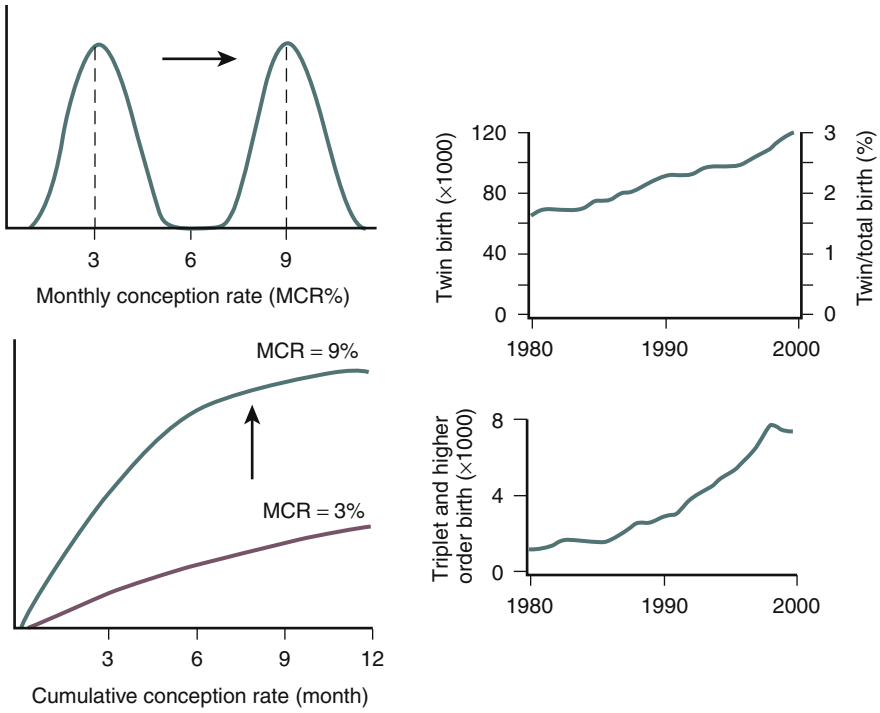

FIGURE 30.5 Monthly conception rate in unexplained infertility increasing from 3% to 9% per cycle due to ovarian stimulation and resulting increase in cumulative conception rates over a 12-month period *(left)*; increased occurrence of multiple pregnancies (twin, triplet, and higher order) between 1980 and 2000 associated with ovarian stimulation *(right)*. *(Left from Stovall DW, Guzick DS. chances. Ovarian hyperstimulation alone may give rise to a two- to fourfold increase in pregnancy rates. The associated risk of OHSS and the occurrence of twin and higher order multiple births is dependent on the magnitude of ovarian stimulation, the intensity of ovarian response monitoring, and the criteria applied for cycle cancellation should too many follicles develop. The overall incidence of severe ovarian OHSS associated with ovarian hyperstimulation is less than 5%.[62]

Initial studies suggested that a threefold increase in monthly probability of pregnancy can be achieved with empirical ovarian hyperstimulation in the treatment of unexplained infertility[63] (Fig. 30.5). Subsequently, a large multicenter study showed that ovarian hyperstimulation with gonadotropins and IUI both exhibit an independent additive effect on pregnancy chances. Moreover, overall cumulative pregnancy rates with this combined therapy were reported to be 33% within three cycles, but at the price of an unacceptably high multiple pregnancy rate of 20% for twins and 10% for higher-order multiple pregnancy.[64] It has been proposed that a similar cumulative pregnancy rate could be achieved by expectant management over a 6-month period, obviously with much lower chances of multiple pregnancy. [65] In an analysis from one large European fertility center of 1878, pregnancies obtained from IUI cycles stimulated with gonadotropins, 16% were twins and 6% were triplets or higher order.[66] Less intense ovarian stimulation may reduce the incidence of higher order multiple pregnancies, but probably at the expense of a reduction in overall conception rate. On the basis of a 2-year experience in a large U.S. infertility clinic involving 3347 consecutive ovarian stimulation cycles (ovulation induction and ovarian hyperstimulation combined) in approximately 1500 women, a 30% pregnancy rate was described. Twenty percent of these pregnancies were twins, along with 5% triplets and 5% quadruplets or higher order.[67] The most worrying conclusion of this analysis was that the number of large antral follicles or serum E_2 levels during the late follicular phase had only limited value in predicting higher order multiple gestations. The true rate of multiple pregnancies arising from ovarian stimulation with or without IUI remains uncertain, however,[68] as few national registers record the outcome of ovarian stimulation. The most recent summary of the European IVF monitoring consortium involving 33 countries, over 1000 clinics and almost 500,000 IVF/ICSI cycles reported for the year 2007 a multiple delivery rate of 22.3% (including 1% triplets). For approximately 170,000 IUI cycles performed in Europe, twin deliveries were reported in 11.7% of cycles whereas the triplet rate was 0.5%.[69]

Some years ago it was estimated that ovarian stimulation with or without IUI is responsible for around 30% of multiple births (Fig. 30.6). It is easier to influence chances for multiple gestations after IVF, because the occurrence is primarily dependent on the number of embryos transferred. Therefore, ovarian hyperstimulation for IVF is merely the factor allowing for the generation of multiples, but not the sole determining factor like in IUI. Unsurprisingly, the incidence of twin pregnancies following IVF without stimulation[70] or with hyperstimulation combined with single embryo transfer is close to normal.[71,72] Over the years, the number of embryos transferred in IVF has decreased, but larger numbers continue to be transferred in the United States compared to Europe. On the basis of a large nationwide data set from the United Kingdom, it was reported quite some years ago that the number of embryos transferred could be reduced from three to two without a concomitant drop in overall pregnancy chances.[73] The policy of two embryo transfer was adopted by many major European IVF centers during the 1990s. Subsequently it was demonstrated that in young women in whom two high-quality embryos are transferred, the chances of a twin pregnancy are actually higher than for a singleton pregnancy.[74,75] An increasing number of centers, especially

in Northern in Europe, have adopted a single embryo transfer policy in selected women. Overall good clinical results have been reported, escpecially in the context of improved results of cryopreserved surplus embryos. Provided that the embryology lab performance is good, single embryo transfer policy can be introduced in the clinic without any decrease in overall pregnancy chances per oocyte harvest (hence the cumulative fresh plus cryo embryo transfer).[76-79]

The number of embryos transferred in the United States is substantially higher, with current American Society for Reproductive Medicine (ASRM) practice committee guidelines proposing more focus on wider society benefits of single embryo transfer.[80,81] In general, overall IVF results in Europe are slightly lower compared to the United States, but with an overall reduced incidence of multiple and premature birth (Fig. 30.7).

Given the risks associated with ovarian stimulation, couples should be well counseled regarding their spontaneous chances for pregnancy prior to commencing therapy (Table 30.1). These chances are often underestimated,[82] both by the doctor and by the patient and the price to be paid for interventions (the increased incidence of multiple pregnancies) may frequently be underemphasized. How should the increased chances for pregnancy on the one hand be balanced with the high complication rates inevitably associated with ovarian hyperstimulation? Until recently, fertility specialists tended to lean heavily in the direction of increasing pregnancy rates at all costs. In doing so, an iatrogenic epidemic of multigestation came about, with major health, psychosocial, and financial consequences.

Higher order multiple pregnancies have a major adverse impact on perinatal morbidity and mortality rates. Mortality rate is increased fourfold to sevenfold in twins and up to twentyfold in triplets.[60] Children born from multiple pregnancies have more chances for perinatal complications and subsequent health problems, chiefly associated with prematurity and low birth weight.[61] Chances for cerebral palsy are increased almost fiftyfold in children from triplet pregnancies.[83] Even the second child from a twin pregnancy delivered at term presents with a significant increased risk for death due to complications of vaginal delivery.[84] Besides the medical and emotional burden, the financial costs associated with multiple pregnancies should be taken into account by policy makers. Obstetric and neonatal costs are increased

Table 30.1 Hypothetical Model of Cumulative Spontaneous Pregnancy Rates in Five Categories, According to Duration of Subfertility

Category	MFR (%)	Cumulative Pregnancy Rate After (%)			
		6 Mo	12 Mo	24 Mo	60 Mo
Superfertile	60	100	—	—	—
Normally fertile	20	74	93	100	—
Moderately subfertile	5	26	46	71	95
Severly subfertile	1	6	11	21	45
Infertile	0	0	0	0	0

five- to sevenfold in higher order multiples, and by the age of 8 costs for low-birth-weight children are increased eightfold.[61] Finally, possibilities of more subtle health risks which may be revealed only later in life should also be taken seriously.

Perhaps one strategy that may help improve the situation would be to agree to a new way of defining success from infertility therapy. The appropriate outcome measure should be shifted from pregnancy rate per treatment cycle toward live birth or preferably, healthy singleton child per started course of treatment.[85]

Ultimately, however, the risk to benefit ratio of ovulation induction and ovarian hyperstimulation is determined by the practice of the clinician. In the following sections we provide an overview of the medical approaches applied in contemporary practice.

Induction of Ovulation in Anovulatory Women

Principles of Ovulation Induction

The aim of induction of ovulation in anovulatory women is to stimulate a single follicle to develop up to the preovulatory stage and subsequently ovulate. As stated before, this therapeutic goal should be clearly distinguished from two other forms of ovarian stimulation. First, ovulatory women with unexplained infertility may undergo a mild form of ovarian hyperstimulation aimed at producing two or three follicles and an increased chance of fertilization in a given cycle. This treatment, which is frequently combined with IUI, is discussed later in the chapter. Second, ovarian hyperstimulation may be applied in ovulatory women undergoing IVF treatment, where multifollicular development is required to produce multiple oocytes. In contrast to these two therapeutic approaches, which produce a superphysiological situation, ovulation induction aims to mimic the normal physiological monofollicular ovulatory cycle. Ovulation induction is characterized therefore by tighter therapeutic margins and a need for careful monitoring and skilled management if success without complications is to be achieved. Ovarian surgical techniques such as laparoscopic drilling offer an alternative to medical therapies in this context. Again, the aim of this treatment paradigm is to institute monofollicular ovulatory cycles.

Anovulatory disorders account for around 25% of causes of infertility.[86] This proportion may increase with the rising prevalence of obesity. Anovulation is usually manifested as the absence (amenorrhea) or infrequent occurrence (oligomenorrhoea) of menstrual periods. Although oligomenorrhoea may be associated with occasional ovulation, the chance of a woman conceiving within a year of unprotected intercourse is clearly diminished unless therapeutic steps are taken. Many medical approaches have been developed to achieve the goal of inducing the monthly development of a single dominant follicle and subsequent ovulation. In recent years, increased understanding of the pathophysiology of ovarian dysfunction has enabled the development of clinical strategies which aim to mimic the endocrine control of normo-ovulatory cycles. Achieving this within the narrow therapeutic margins of stimulating single rather than multiple follicular developments remains a challenge to clinicians.

The second European Society of Human Reproduction and Embryology (ESHRE) and ASRM sponsored PCOS consensus workshop acknowledged that much attention should be paid to the condition of the woman (in terms of food intake, lifestyle, smoking habits, etc.) before embarking on any form of ovulation induction.[87]

Classification of Anovulation

Ovarian dysfunction can be readily classified in everyday clinical practice on the basis of the assessment of serum gonadotropin and estrogen levels in peripheral blood. This concise approach, currently known as the World Health Organization (WHO) classification of anovulation, was developed by Insler and colleagues.[88] Amenorrhea may coincide with either low or normal E_2, whereas oligomenorrhea is associated with normal estrogens only. Low estrogens combined with low gonadotropin levels suggest a central origin of the disease at the hypothalamic-pituitary level.[89] This cause of anovulation occurs in less than 10% of infertile women and is termed WHO class 1. Low estrogens in combination with high gonadotropins suggest defective ovarian function per se, usually on the basis of premature ovarian failure (POF) (currently referred to as primary ovarian insufficiency [POI]) or ovarian dysgenesis. This cause of anovulation, termed WHO class 3, occurs in around 5% of infertile women and around 1% to 2% of the general female population. Anti-müllerian hormone (AMH) may help to identify women with POI with some residual ovarian activity.[90]

The majority (80% to 90%) of anovulatory women present with estrogen and FSH levels within normal limits. LH levels may be increased in these women. Polycystic ovary syndrome (PCOS), exhibiting FSH and E_2 concentrations within the normal range, represents the great majority of these women. Recently, new criteria for the diagnosis of PCOS have been supported by the ASRM and ESHRE. The so-called Rotterdam consensus criteria are broader than the NIH (National Institutes of Health) criteria primarily because polycystic ovaries are now included. The incidence of PCOS as defined by the Rotterdam criteria is therefore higher.[91]

An additional cause of anovulation with an endocrine etiology is hyperprolactinemia which may present with normal or reduced gonadotropin and E_2 concentrations. This

may be considered as a variant of WHO class 1 anovulation because high serum prolactin levels suppress GnRH release by the hypothalamus by altering opioid receptor stimulation. Hyperprolactinemia may also present with normal gonadotropin and E_2 concentrations, and may then be considered as a variant of WHO class 2. The pathophysiology and treatment of hyperprolactinemia are discussed in detail in Chapter 3.

Preparations for Treating Anovulation

Anti-Estrogens

Background

The most widely used anti-estrogen for treating anovulation is CC, the development and pharmacology of which are addressed in the introduction to this chapter. In terms of its relative efficacy, safety, cost, and ease of use, it remains some 40 years after its introduction into clinical practice the most important therapeutic agent in use. The principal indication for CC is the treatment of anovulatory infertility in women with an intact hypophyseal-pituitary-ovarian axis. In this role it remains the first-line therapy. Given orally in the early to midfollicular phase, it causes a 50% rise in the endogenous serum FSH level,[92] thus stimulating follicle growth. This rise in FSH is accompanied by a similar rise in serum LH levels. Limitation of the duration of administration to 5 days is aimed at allowing FSH levels to fall in the late follicular phase and the mechanisms for monofollicular development and ovulation to operate. However, elevated gonadotropin levels may persist into the late follicular phase in some women.[93] The long half-life zuclomiphene isomer (which exhibits predominant estrogen agonist activity) has been shown to persist and accumulate across consecutive cycles of treatment.[94] However, the resulting concentrations are well below those demonstrated to have any effects *in vitro* and are unlikely to be of clinical significance.

Preparations and Regimens

The conventional starting dose of CC is 50 mg/day, starting from day 2 until day 5 of the menstrual cycle, for 5 consecutive days. In normogonadotropic amenorrheic women, treatment can be initiated following a progesterone-induced withdrawal bleeding. Whether CC is commenced on cycle day 1 or 5 does not appear to affect outcomes.[95] Should 50 mg/day fail to elicit follicle growth, the dose should be increased to 100 mg/day in the subsequent cycle, followed by 150 mg/day, which is usually considered to be the maximum dose beyond which alternative treatments are indicated. The LH surge occurs between 5 and 12 days following the last day of CC administration. Intercourse is therefore advised for a week from the fifth day after the last day of CC administration. Some advocate hCG administration as a surrogate for the LH surge to trigger ovulation and to time intercourse. However, recent studies showed no improvement in outcomes, despite the increased monitoring required to time hCG administration.[96,97]

Clinical Outcome

Between 60% and 85% of anovulatory women will become ovulatory with CC, and 30% to 40% will become pregnant.[87] In a meta-analysis based on four placebo-controlled studies in oligomenorrheic patients, the odds ratio with CC was 6.8 for ovulation and 4.2 for pregnancy.[98]

Why some women with WHO class 2 anovulation do not respond to CC is not fully understood. Altered individual requirements for FSH at the ovarian level, the local intraovarian effect of autocrine or paracrine factors, and variations in FSH receptor expression or FSH receptor polymorphisms may contribute. A number of studies have pointed to being overweight as a factor.[99] In a multivariate analysis of factors found to predict outcome of CC ovulation indication, the free androgen index (FAI), body mass index (BMI), presence of amenorrhea (as opposed to oligomenorrhea), and ovarian volume were found to be independent predictors of ovulation.[99] The possibility of using clinical data to individualize treatment and optimize outcomes is discussed later in this chapter.

The occurrence of ovulation can be identified by the use of temperature charts and midluteal urinary pregnanediol or serum progesterone measurements.[87] Although results of large trials indicate that monitoring by ultrasound is not mandatory to ensure good outcomes,[87] the practice in many centers is to monitor the first cycle to allow adjustment of dose where necessary. The cumulative pregnancy rate in ovulatory women with CC in 6 to 12 months of treatment is around 70%,[99] with conception rates per cycle around 22%.[87]

Why do some women who become ovulatory with CC not conceive? Reasons include patient selection, the regimen used, and the presence of other causes of subfertility. The anti-estrogenic effects of CC on the reproductive tract have been particularly implicated. Negative effects on tubal transport, quantity and quality of cervical mucus,[29] and the endometrium[100] have all been reported.

Miscarriage rates of 13% to 25% are reported. Although these numbers appear high, they are similar to the spontaneous miscarriage rate[101] and those observed in infertile women undergoing IVF. In general, it does not appear that the miscarriage rate is significantly increased in anovulatory women treated with CC.

Side Effects and Complications

Apart from hot flushes, which may occur in up to 10% of women taking CC, side effects are rare. Nausea, vomiting, mild skin reactions, breast tenderness, dizziness, and reversible hair loss have been reported, but less than 2% of women are affected. The mydriatic action of CC may cause reversible blurred vision in a similar number.[26]

The multiple pregnancy rate is less than 10%, and OHSS is rare.[87] The putative increased risk of ovarian cancer reported to be associated with the use of CC for more than 12 months[102] has led CC to be licensed for just 6 months of use in some countries.

Tamoxifen is, like CC, a nonsteroidal selective estrogen receptor modulator (SERM). In contrast to CC, tamoxifen contains only the zu-isomer and appears to be less anti-estrogenic at the uterine level. The possible advantages of tamoxifen over CC include an agonistic effect at the endometrium. Many uncontrolled studies in the area of ovulation induction have suggested that tamoxifen may be a safe and efficacious alternative to CC. A meta-analysis of four randomized controlled studies revealed tamoxifen to be as effective as CC in inducing ovulation. However, despite the

theoretical benefits, no significant improvement in pregnancy rates was observed compared with CC.[103] Clinicians should therefore base their choice of treatment on familiarity with the given regimen.

Insulin-Sensitizing Agents

Background

The role of insulin-resistance in the pathogenesis of ovarian dysfunction in many PCOS patients has led to the introduction of insulin-sensitizing agents as adjuvant or sole treatment regimens for the induction of ovulation. The most extensively studied insulin-sensitizing drug in the treatment of anovulation is metformin. Metformin (dimethylbiguanide) is an orally administered drug used to lower blood glucose concentrations in patients with non-insulin-dependent diabetes mellitus (NIDDM).[104] It is antihyperglycemic in action, and increases sensitivity to insulin by inhibiting hepatic glucose production and by increasing glucose uptake and utilization in muscle. These actions result in reduced insulin resistance, lower insulin secretion, and reduced serum insulin levels.

Many papers have been published in recent years advocating the clinical usefulness of this compound for ovulation induction. The absence of well-designed and properly powered studies did not dampen enthusiasm for metformin in this context, and it has been widely introduced into clinical practice. Recently, however, two large, placebo-controlled randomized studies comparing metformin to CC and metformin as adjunctive therapy to CC have shown no benefit of metformin.[105,106]

Preparations and Regimens

The first studies reporting the use of metformin as an ovulation induction agent suggested that metformin improved insulin sensitivity; lowered LH and total and free testosterone concentrations; and increased FSH and sex hormone–binding globulin levels.[107,108] This, and subsequent uncontrolled studies, indicated that correction of hyperinsulinemia has a beneficial effect in anovulatory women, by increasing menstrual cyclicity, improving spontaneous ovulation, and thus promoting fertility.[109,110] It is recommended that metformin be commenced at 500 mg/day orally, rising to 500 mg three times a day over 7 to 10 days.[109] Depending on response, this may be increased to 1000 mg twice a day. The optimal duration of treatment remains unclear. However, most studies reporting a beneficial effect from metformin have shown this within 2 to 4 months.[111,112]

Clinical Outcome

The majority of studies on the outcome following metformin therapy are small and uncontrolled or simply case series.[113] Most of the available data on restoration of menses following metformin therapy are on predominantly obese hyperinsulinemic women with PCOS. Similarly, studies of the ability of metformin to induce ovulation have been primarily carried out in obese women. In a meta-analysis of 15 studies involving 543 participants with PCOS, metformin was found to be effective in achieving ovulation with odds ratios of 3.88 (CI 2.25 to 6.69) for metformin versus placebo and 4.41 (CI 2.37 to 8.22) for metformin and clomiphene versus clomiphene alone.[114] However, a recent large multicenter

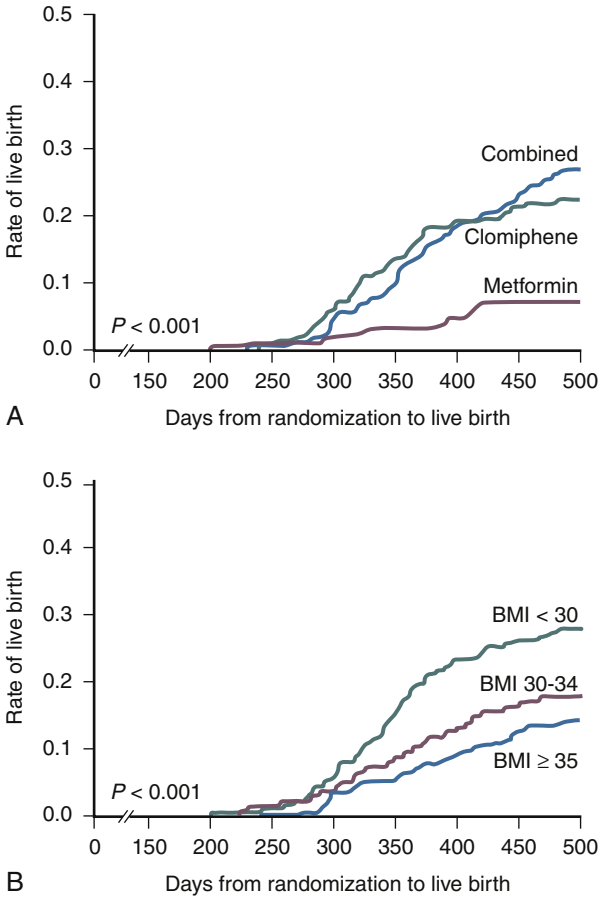

FIGURE 30.8 Kaplan-Meier curves for live births following ovulation induction with clomiphene, metformin, or both treatments combined **(A)** and body mass index (BMI) **(B)**. *(Adapted from Legro RS, Barnhart HX, Schlaff WD, et al. Clomiphene, metformin, or both for infertility in the polycystic ovary syndrome.* N Engl J Med *356:551–566, 2007.)*

study has clarified the role of metformin as an alternative first-line ovulation induction agent in women with PCOS.[106] In this study, 626 women with PCOS were randomized to receive 50 to 150 mg CC plus placebo from cycle day 3 to 7500 to 2000 mg daily doses of extended release metformin plus placebo, or a combination of metformin and CC. Treatment was continued for up to 6 months. Obesity was not an exclusion criterion. The results of this study are summarized in Figure 30.8. The primary end point of live birth rate was 22.5% after treatment with CC, compared with a significantly lower rate of just 7.2% following metformin treatment. Combination therapy with both metformin and CC yielded a live birth rate of 26.8%, which did not differ significantly from that achieved with CC treatment alone. The relatively poor performance of metformin in terms of live birth rates was partly explained by a low conception rate, which was just 21.7% following metformin, compared with 39.5% in the CC group. In terms of ovulation rates alone, the combination of metformin and CC was superior to either individual therapy. However, in a study of 228 women randomized to receive CC plus metformin or CC plus placebo, no significant difference in ovulation rates was observed (64% versus 72%, respectively).[105] A significantly larger proportion of women in the metformin group discontinued treatment because of side effects (16% versus 5%).

Box 30.1 Maternal and Perinatal Risks Associated with Polycystic Ovary Sydrome

MATERNAL
- Gestational diabetes*
- Pregnancy-induced hypertension*
- Preeclampsia
- Delivery by cesarean section

NEONATAL
- Admission to a neonatal intensive care unit
- Perinatal mortality
- Premature deliveries

*Outcome confirmed by subgroup analysis of higher validity studies.

It has been suggested that metformin may reduce the rate of miscarriage compared with CC-derived pregnancies. However, in the study of Legro and colleagues, the rate of first trimester loss did not differ significantly between the treatment groups, although the study was not powered to detect this.[106]

Metformin therapy has also been proposed to aid weight loss in obese women with PCOS. Many studies have now examined the effect of metformin on BMI, and the evidence is conflicting. However, the majority of observational studies addressing weight loss with metformin have revealed a reduction in the BMI of 1% to 4.3%.[111] More recently, a double-blinded randomized trial compared metformin 850 mg twice daily treatment with placebo in 143 PCOS women with a BMI greater than 30. After 6 months' treatment no significant difference in weight loss or menstrual frequency was observed. In contrast, lifestyle modification was to improve cycle regularity by improving weight loss.

Attention has turned in recent years to the possible benefits and safety of metformin administration during pregnancy. PCOS pregnancies demonstrate a greater incidence of perinatal and maternal complications such as gestational diabetes, preeclampsia, and premature delivery[115] (Box 30.1). A number of studies have appeared suggesting a role for metformin to ameliorate these complications. However, most of these studies are not randomized or suffer from small numbers and surrogate outcomes. Although metformin crosses the placenta, there is no clear evidence of toxicity when taken during pregnancy. Larger well-designed studies are still required to address the possible therapeutic benefits of metformin during pregnancy in women with PCOS.

In summary, although some individual studies continue to suggest a benefit of metformin pretreatment[116] a recent Cochrane analysis involving 40 trials failed to establish improved live birth rates of metformin cotreatment.[117]

Side Effects and Complications

Metformin has been used for many years for the treatment of diabetic patients and appears to be safe for long-term use, with few side effects reported. Rarely, lactic acidosis may occur[114] if hepatic or renal disease is present, and these patients should be excluded before commencing therapy. The main side effects of metformin are nausea and diarrhea, which may occur in 10% to 25% of patients and contribute to the weight loss effects observed with metformin. If these symptoms persist despite lowering the dose, alternative therapy should be given. For this reason, metformin should be started at a low dose that gradually rises (see earlier discussion).

Gonadotropins

Background

Women with WHO class 2 anovulation who fail to ovulate or conceive following ovulation induction with antiestrogens can be successfully treated with exogenous gonadotropins. Exogenous gonadotropins have been widely used for the treatment of anovulatory infertile women since 1958.[2,25] Improvements in purification techniques led to increasing relative amounts of the active ingredients and the first urine-derived preparation containing only FSH (uFSH) became available in 1983. The development and application of production techniques based on immunoaffinity chromatography with monoclonal antibodies enabled the production of highly purified uFSH. In the 1980s, recombinant DNA technology led to the development and, later, the clinical introduction of human recombinant FSH (recFSH). This advance promised not only unlimited availability, but improved purity and batch-to-batch consistency compared to urinary derived products.

The development of recombinant gonadotropins also provided the opportunity to elucidate more clearly the physiology of ovarian E_2 synthesis. During further follicular development, LH has a synergistic action with FSH. Theca cells are stimulated by LH to convert cholesterol into androstenedione (AD) and testosterone (T) by cytochrome P450 side chain cleavage oxidases and 3β-hydroxysteroid dehydrogenase. Aromatase activity in the granulosa cells is induced by FSH and converts AD and T into estrone and E_2. The involvement of two cell types (granulosa and theca cells) and two hormones (LH and FSH) to produce estrogens from cholesterol has led to the "two cell, two gonadotropin" concept. In addition to stimulating aromatase activity, FSH also induces LH receptors and further increases FSH receptor formation on granulosa cells while stimulating DNA and protein synthesis by the cell.[118] Clinical observations in the treatment of anovulatory women have supported this concept.

In the treatment of WHO class 1 (hypogonadotropic hypogonadal) anovulation, women with intact pituitary function can be treated with pulsatile GnRH therapy to restore the periodic release of FSH and LH. The treatment of hypogonadotropic women with FSH alone leads to follicular development but not pregnancy.[17] Exogenous LH is therefore required to treat this form of anovulatory infertility. Until recently, hMG was the only source of exogenous LH for this group of patients. Now recLH or rechCG offers the possibility for a more sophisticated approach to treatment.

Recent studies have demonstrated the safety and appropriate dose required to affect follicle development and subsequent pregnancy. It has been established that baseline levels of at least 0.5 to 1 IU LH should be sufficient to provide maximal stimulation to thecal cells.[119] In a study of hypogonadotropic women undergoing treatment with

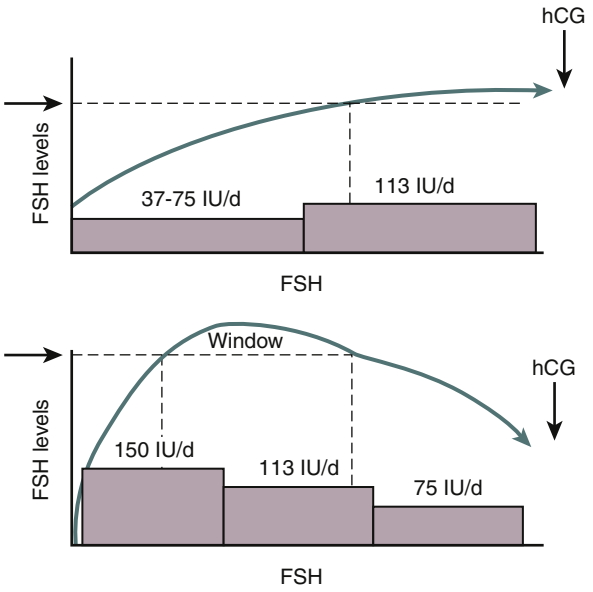

FIGURE 30.9 Schematic representation of serum follicle-stimulating hormone (FSH) levels and daily dose of exogenous FSH during low-dose step-up or step-down regimens for ovulation induction.

recFSH and recLH, a dose of 75 IU per day of recLH was observed to result in follicular development and pregnancy. However, further increases in LH levels above the threshold level needed to gain a response did not appear to induce a greater degree of ovarian stimulation.[120]

Preparations and Regimens

In addition to urinary derived FSH products, recFSH has been clinically available since 1996 in the form of follitropin alpha and follitropin beta. More recently, a long-acting recFSH (corifollitropin alpha), a recLH, and a rechCG have been added to the clinical arsenal for ovarian stimulation.

In order to achieve development of a single dominant follicle with exogenous gonadotropins, specific treatment and monitoring protocols are needed. The two most frequently encountered in the literature and in clinical practice are the low-dose step-up and, more recently, step-down protocols (Fig. 30.9). The initially described standard step-up protocol had a starting dose of FSH 150 IU/day.[121] However, this regimen was associated with a high complication rate. Multiple pregnancy rates of up to 36% were reported, and ovarian hyperstimulation occurred in up to 14% of treatment cycles.[2] As a result, this protocol has been largely abandoned.

The concept of the FSH threshold proposed by Brown[122] postulated that FSH concentrations must exceed a certain level before follicular development will proceed (Fig. 30.1). Once this level is reached, normal follicular growth requires only a minor further increase above this threshold. Exposure to excessive FSH serum concentrations may lead to excessive follicular development. This concept formed the theoretical basis for low-dose step-up regimens for ovulation induction. A low-dose, step-up protocol designed to allow the FSH threshold to be reached gradually has now become the most widely used regimen, reducing the risk of excessive stimulation and development of multiple preovulatory follicles. The recommended initial starting dose of FSH is 37.5 to 50 IU/day.[87] The dose is increased by 50% if after 14 days, no response is observed on ultrasonography (and serum estradiol monitoring). The detection of an ovarian response is an indication to continue the current dose until hCG can be given to trigger ovulation. If equal daily doses of FSH are given from the beginning of the follicular phase, steady-state serum FSH concentrations are reached after 5 to 7 days.[123] During step-up regimens, elevated FSH serum concentrations may occur during the late follicular phase, which may, in a similar manner, interfere with selection of a single dominant follicle. Previous suppositions that steroid negative feedback remained intact during low-dose step-up regimens have not been substantiated by scientific data.

In contrast to the concept of the FSH threshold on which the low-dose step-up protocol is based, the concept of the FSH "window" stresses the significance of the duration of FSH elevation above the threshold level, rather than the magnitude of elevation of FSH for single dominant selection.[124] This concept was substantiated by the demonstration that elevating FSH levels high above the threshold level for a short period of time in the early follicular phase does not increase the number of dominant follicles.[125] Conversely, when the physiological decrease of FSH in a normal cycle is prevented by administration of FSH in the late follicular phase, the augmented sensitivity for FSH allows several follicles to gain dominance[126] (Fig. 30.10). As demonstrated previously in the monkey model, when the negative feedback effect of estradiol on gonadotropin production is suppressed by administration of anti-estrogens, selection of the preovulatory follicle is overridden.[127] Further studies regarding the process of selection of the dominant follicle in the normal cycle have indicated that throughout the cycle up to 10 nondominant follicles (measuring between 2 and 10 mm in diameter) can be visualized by transvaginal ultrasound. The dominant follicle itself can be identified once it has reached a diameter beyond 9 mm.[10] Endocrine studies have confirmed that E_2 levels in the serum[11] and follicle fluid[23] begin to rise only after a dominant follicle is present. The above-mentioned initial research findings provided the theoretical basis for developing and monitoring a step-down regimen of ovulation induction.

It was subsequently demonstrated that the late follicular phase FSH profile during a step-down regimen closely resembled serum FSH levels in the spontaneous cycle.[128] Moreover, a median daily fall of 5% to 10% in serum FSH levels was observed in women treated with the step-down regimen, and in those treated with a low-dose step-up regimen a reduction was observed in just 39% of treated women.[129] In the majority of women, the FSH levels remained stable in the late follicular phase.

With the aim of rapidly achieving the FSH threshold for stimulating follicle development, step-down regimens normally begin therapy with 150 IU/day, started shortly after a spontaneous or progesterone-induced bleed. This dose is continued until a dominant follicle (≥10 mm) is observed. The dose is then decreased to 112.5 IU/day followed by a further decrease to 75 IU/day 3 days later, which is continued until hCG is administered to induce ovulation.[130] Should no ovarian response be observed after 3 to 5 days, the FSH starting dose should be continued.

For some patients an initial dose of 150 IU/day is too high, reflecting major individual differences in the FSH

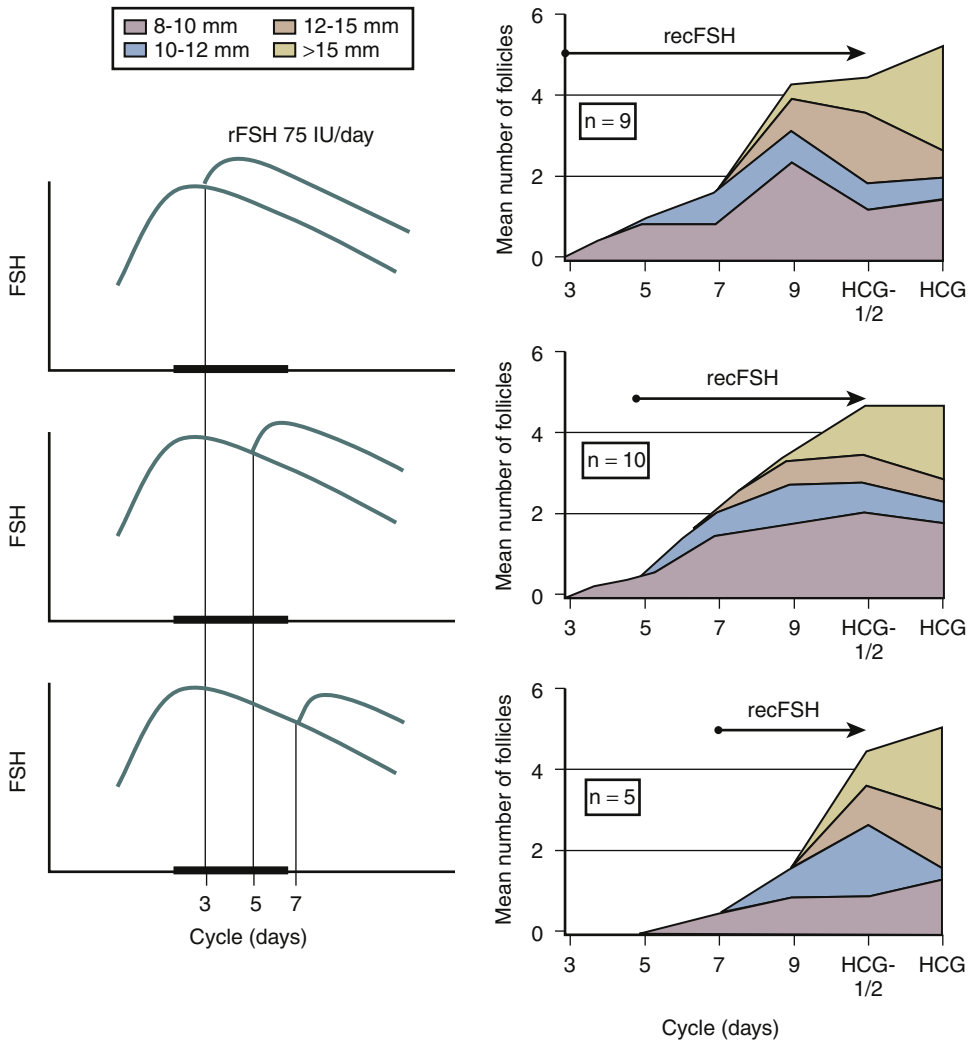

FIGURE 30.10 Observations substantiating the follicle-stimulating hormone (FSH) window concept in the human. Multiple dominant follicle growth can be observed in normo-ovulatory women receiving daily low doses of exogenous FSH, starting on cycle day 3, 5, or 7. *(From Hohmann FP, Laven JS, de Jong FH, et al. Low dose exogenous FSH initiated during the early, mid or late follicular phase can induce multiple dominant follicle development.* Hum Reprod *16:846–854, 2001.)*

threshold. The appropriate starting dose may be determined by using the low-dose step-up regimen for the first treatment cycle in order to assess the individual FSH response dose.[131] Patients who demonstrate good follicular growth with a fixed regimen of 75 IU/day, (the "good responders" who might have been at risk of OHSS with the normal starting dose of the step-down regimen) can thus be identified. Conversely, those who do not respond with ongoing follicle growth to the initial dose should have the daily dosage increased. The second cycle may then be initiated as a step-down regimen with a starting dose 37.5 IU above the effective dose in the preceding low-dose step-up cycle.

Experience to date has indicated that the major drawback of the step-down regimen is the risk that the initial starting dose is too high for some patients. In an effort to overcome this problem, sequential low-dose step-up and step-down regimens have been proposed.[132] Starting with a step-up regimen, the FSH dose is reduced when the leading follicle has reached 14 mm diameter. Comparisons with a group treated with a low-dose step-up regimen showed the incidence of monofollicular cycles to be similar. This approach requires further evaluation and the problem of the large individual variability in the dose of exogenous FSH required for monofollicular development remains to be properly addressed.

Clinical Outcomes

In what remains one of the largest series describing outcomes using the low-dose step-up regimen, 225 women with PCOS, with ovulation and pregnancy rates of 72% and 45%, respectively, were reported.[133] Studies focusing on further reducing the starting dose have reported the feasibility of commencing with 50 IU or 37.5 IU.

In a randomized trial comparing outcomes following the low-dose step-up versus step-down protocol, the clinical benefits of a more physiological means of stimulating follicle development were reflected in an incidence of monofollicular cycles of 88% compared to 56% observed in women treated with the step-up regimen, presumably reducing the risk of multiple pregnancy and hyperstimulation[129] (Table 30.2). Potential health and economic benefits were also apparent because those treated with the step-down regimen required a mean duration of treatment of just 9 days, as opposed to 18 days in women treated with the low-dose step-up regimen.

A multicenter randomized study comparing the step-up versus step-down protocol using recFSH reported a shorter duration of stimulation when the step-down protocol was used.[134] The cumulative rate of clinical gestations did not differ between the two groups, but in contrast to the findings

Table 30.2 Comparison of Ovarian Response and Clinical Outcome Following the Low-Dose Step-Up and the Step-Down Regimens for Gonadotropin Induction of Ovulation

	Low-Dose Step-Up			Step-Down

NR, not recorded.

of an earlier single-center study, the step-up protocol was associated with a higher rate of monofollicular development and a lower rate of ovarian hyperstimulation (Table 30.2). These differences may reflect the necessity for increased skill and care in monitoring step-down stimulation cycles, which is easier to ensure in a single-center setting. Largely for this reason, low-dose step-up protocols remain the most widely used approach.

The degree to which the type of FSH compound employed may influence outcomes in ovulation induction continues to be subject of some controversy. Two meta-analyses comparing the effectiveness of daily uFSH to daily hMG for inducing ovulation in women with PCOS who had not responded to CC demonstrated no difference in pregnancy rate per treatment cycle. However, the women given FSH were less likely to have moderately severe or severe ovarian hyperstimulation syndrome.[59] The total dose of recFSH needed and duration of treatment was less, and the complication rates were similar. In a later meta-analysis of randomized controlled trials comparing recFSH with uFSH for ovulation induction in women with CC-resistant PCOS, no significant differences were demonstrated for the ovulation rate (OR 1.19, 95% CI 0.78 to 1.8). Furthermore, the odds ratios for pregnancy rate (0.95, 95% CI 0.64 to 1.41), miscarriage rate (1.26, 95% CI 0.59 to 2.7), multiple pregnancy rate (0.44, 95% CI 0.16 to 1.21), and ovarian hyperstimulation syndrome (1.55, 95% CI 0.5 to 4.84) showed no significant difference between recFSH and uFSH.[135] In terms of cost-effectiveness, a recent randomized study showed that a lower total dose of recFSH than highly purified urinary FSH was required to achieve the same outcomes. This translated into a 9.4% cost reduction in favor of recFSH.[136]

The success in early clinical studies of pure FSH preparations, increasingly devoid of LH, has served to enhance the impression that excess LH is detrimental to oocyte development and chances of pregnancy following therapeutic intervention. However, a number of recent clinical studies, together with an increasing understanding of the function played by LH in oocyte maturation, have begun to redefine the role of LH as a therapeutic agent in anovulatory fertility. In normogonadotropic anovulation, endogenous LH does not normally require supplementation. Indeed, the focus on LH in this group of patients has been primarily directed at reducing the potential detrimental effects associated with excessive LH.[137] More recently, however, the demonstration of the importance of late follicular LH in optimizing dominant follicle development oocyte quality has reopened the debate as to the role of LH in ovulation induction.[19] Supplementation of LH activity may offer advantages in some patients by hastening large follicle development and therefore shortening the duration of treatment.[138] Moreover, the work of Zeleznik and co-workers[18] referred to a potential therapeutic role for LH in effecting monofollicular stimulation as part of a sequential ovarian stimulation protocol following initiation with recFSH. This concept has been supported in a study in which anovulatory women with a hyper-response to recFSH were randomized to continue treatment with the addition of either placebo or recLH.[139] In those in whom LH was administered, a trend toward fewer preovulatory follicles was observed. As the availability of recombinant gonadotropins leads to increasing knowledge of the processes of follicular development and selection, further refinements in the efficacy and safety of ovulation induction are likely.

Adverse Effects and Complications

The complications of ovulation induction with gonadotropins are primarily related to excessive ovarian stimulation. Although the aim of therapy is monofollicular growth, multiple follicular developments may occur, causing symptoms of OHSS. Moreover, the development of multiple follicles raises the real risk of multiple pregnancies. In order to increase the chance of therapeutic success and reduce the risks of complications, careful monitoring of treatment is required. Ovarian response to gonadotropin therapy is monitored using ultrasound to measure follicular diameter. The scans, usually performed every 2 or 4 days, should be focused on identifying follicles of intermediate size; hCG (5000 to 10,000 IU subcutaneously or intramuscularly) is

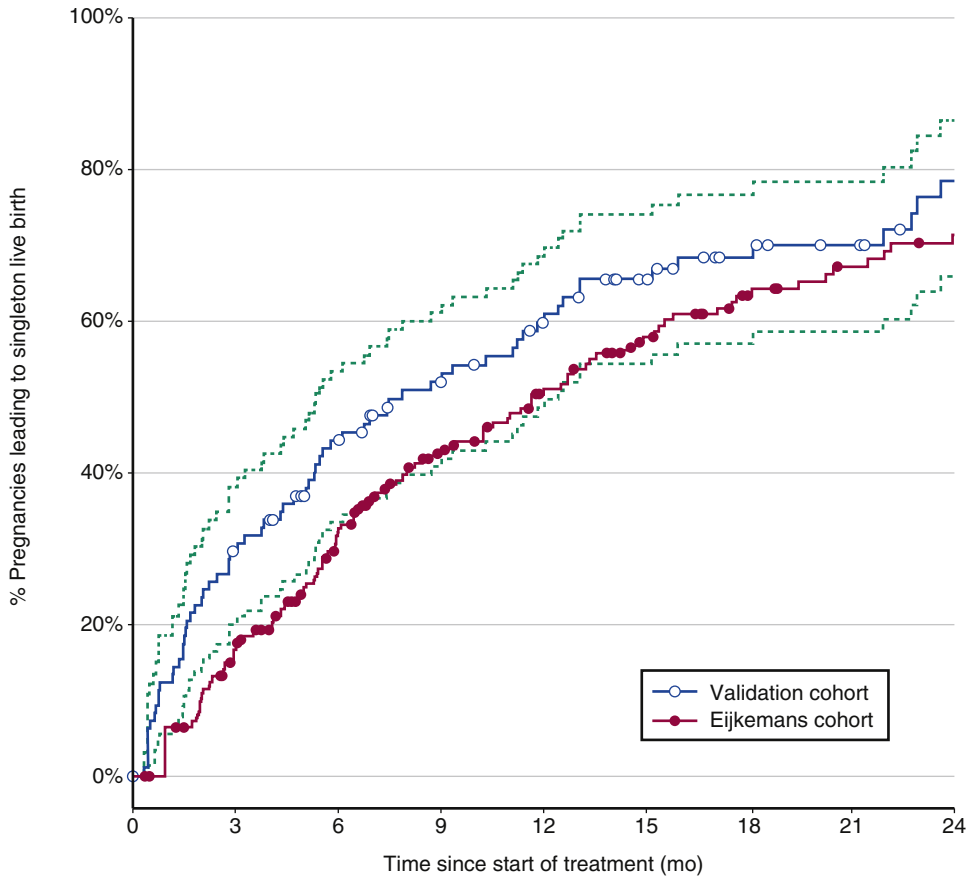

FIGURE 30.11 Cumulative pregnancy rates leading to single live-birth following ovulation induction in PCOS. *(Adapted from Veltman-Verhulst SM, Fauser BC, Eijkemans MJ: High singelton live birth rate confirmed after ovulation induction in women with anovulatory polycystic ovary syndrome: validation of a prediction model for clinical practice,* Fertil Steril *98, 761–768, 2012.)*

given on the day that at least one follicle measures more than 18 mm. If more than three follicles larger than 15 mm are present, stimulation should be stopped, hCG withheld, and use of a barrier contraceptive advised in order to prevent multiple pregnancies and OHSS. Measurements of serum E_2 may also be useful.[130] Ovarian stimulation with gonadotropins has not been shown to be associated with long-term risks. Urinary derived FSH is associated with a theoretical risk of transmission of prion proteins. However, the risk of infection is considered to be minimal and not in itself a reason to prescribe recFSH over uFSH.[140]

As confirmed recently, high cumulative singleton live birth rates of almost 80% can be achieved using CC as first line and low dose FSH as second line ovulation induction treatment in PCOS, with 14% multiple pregnancy rates[55,56] (Fig 30.11). PCOS women with a poor prognosis for ovulation induction, in whom alternative treatment strategies such as IVF may be considered, can best be identified by age, duration of infertility, and body weight.

Pulsatile GnRH

In the normo-ovulatory woman, the pattern of GnRH pulse stimulation alters with the phase of the menstrual cycle, effecting differential gonadotropin synthesis and secretion.[141] During the luteal-follicular transition, pulses occur every 90 to 120 minutes. This slow pulse frequency, in the presence of low E_2 and inhibin A levels, favors FSH production. In the midfollicular or late follicular phase, GnRH frequency increases, favoring LH secretion.[142] In the luteal phase, the production of progesterone increases hypothalamic opioid activity, thus slowing GnRH pulse secretion. This again favors FSH secretion in the luteofollicular transition.

The application of pulsatile GnRH therapy has been demonstrated to be an effective, reliable, and safe alternative to gonadotropin therapy for treating this form of anovulation.[143] Due to the intact ovarian-pituitary feedback system during pulsatile GnRH treatment, the resulting serum FSH and LH concentrations remain within the normal range and the chances of multifollicular development and ovarian hyperstimulation are therefore low. Little ovarian response monitoring is therefore needed during treatment.

The intravenous route appears superior to the subcutaneous route.[144] In order to mimic the normal pulsatile release of GnRH, a pulse interval of 60 to 90 minutes is used with a dose of 2.5 to 10 μg per pulse. The lower dose should be used initially in order to minimize the likelihood of multiple pregnancies.[145] The dose should then be increased to the minimum dose required to induce ovulation. Pulsatile GnRH administration may be continued throughout the luteal phase until menses or a positive pregnancy test. Alternatively, it may be discontinued after ovulation, and the corpus luteum supported by hCG.[49]

Clinical Outcomes

Pulsatile GnRH administration is primarily indicated for women with hypogonadotropic hypogonadal anovulation (WHO type 1) who have normal pituitary function.[146] In these patients, cumulative pregnancy rates of 83% to 95% after six cycles have been reported, with multiple

pregnancies accounting for 3% to 8% of pregnancies.[145,147] Lower ovulation and pregnancy rates have been observed in women with WHO type 2 anovulation, including PCOS.[148] This may be because anovulation in PCOS in part reflects the effects of a persistant, rapid frequency of GnRH stimulation of the pituitary, causing increased LH and T levels.[142] In a recent meta-analysis of four trials comparing pulsatile GnRH with gonadotropins for ovulation induction in women with PCOS, the small size and short follow-up of the studies meant that the authors were unable to draw conclusions on their relative effectiveness.[149]

Regular menstruation occurring approximately every 4 weeks indicates that the woman is having ovulatory cycles. Ultrasonography and measurements of serum progesterone are not usually needed for monitoring therapy. Local complications such as phlebitis may occasionally be encountered when intravenous administration is used. To avoid this, pulsatile GnRH can be administered subcutaneously. This route is certainly simpler than the intravenous approach. However, pharmakinetic studies comparing the two routes have shown that the plasma GnRH profiles are damped after subcutaneous administration, and that bioavailability is reduced.[150] However, the increased convenience offered by the subcutaneous route has led to this approach being favored by many. Smaller devices and more patient friendly delivery systems continue to be developed.

Aromatase Inhibitors

In recent years the use of aromatase inhibitors to mimic the actions of CC has been proposed.[151] Rather than antagonizing estrogen feedback activity at the hypothalamic-pituitary axis, this approach aims at reducing the amount of estogens being synthesized. Aromatase inhibitors block the conversion of AD and T to estriol (E_3) and estradiol (E_2), respectively.[152] This increases gonadotropin secretion, resulting in stimulation of ovarian follicles.[151] Aromatase inhibitors have been in clinical use for more than 20 years, primarily in the treatment of postmenopausal patients with advanced breast cancer. The more recently developed third generation of aromatase inhibitors are characterized by their potency in inhibiting the aromatase enzyme without significantly inhibiting inhibition of other steroidogenesis enzymes. One of the third generation compounds, letrozole, has been the focus of study as a potential therapeutic agent for inducing ovulation.

Clinical Outcomes

When given in the early follicular phase, letrozole reduces estrogenic feedback at the pituitary-hypothalamic axis, causing a subsequent increase in gonadotropin secretion. This was shown in monkeys to stimulate follicle development.[153] Subsequent small clinical studies employing a dose of 2.5 mg/day from day 3 to day 7 of the menstrual cycle have suggested that it may be an effective ovulatory agent in CC-resistant women.[151] A local effect at the ovary to increase sensitivity to FSH by blocking the conversions of androgens to estrogens has also been proposed, because accumulating intraovarian androgens may increase FSH receptor gene expression.[154]

Although the concept of applying aromatase inhibitors as an alternative to CC or as adjuvant therapy to CC or gonadotropins seems attractive and preliminary data on pregnancy outcome were encouraging[155,156] (adequately powered comparative controlled randomized studies are limited), a recent systematic review and meta analysis, involving 13 randomzed controlled trials, concluded that aromatase inhibitors should not be recommended as first line ovulation induction treatment in the absence of good quality evidence of efficacy.[157]

Adverse Effects and Complications

Although letrozole has a half-life that allows rapid disappearance following cessation of treatment in the midfollicular phase, the possible effects of this drug on ensuing pregnancy remain to be clarified. The performance of further clinical studies has been inhibited because an association was reported between letrozole and fetal toxicity. However, a recent analysis of outcomes in 911 newborns following conceived by CC or letrozole showed no difference in the overall rates of major and minor congenital malformations.[158] In the absence of sufficiently powered, randomized controlled trials establishing efficacy and safety, the routine clinical use of aromatase inhibitors is not advocated.[87]

Opioid Antagonists

Background

Endogenous opioid peptides have been shown to play an important role in regulating the pulsatile secretion of gonadotropins by inhibiting the hypothalamic pulse generator that directs GnRH secretion.[159] Infusion of the opiate receptor antagonist naloxone was shown to increase serum LH levels when administered during the late follicular and luteal phase of the cycle.[160]

Clinical Outcomes

Several groups have used naltrexone, an orally active opioid receptor antagonist, to treat ovulatory disorders, with varying degrees of success. The earlier observation that gonadal steroids enhance opioid modulation of gonadotropin secretion was postulated to explain the inability of two groups to demonstrate an increase in gonadotropin secretion or resumption of ovulation in women with WHO class 1 anovulation.[161] However, others have observed restoration of the menstrual cycle.[162] In an uncontrolled study, 19 of 22 women with CC-resistant anovulation were observed to become ovulatory under naltrexone treatment (sometimes in combination with CC), with 12 conceiving.[163] Treatment with 25 mg twice daily was commenced on the first day of a spontaneous or progesterone-induced cycle and continued until a positive pregnancy test occurred or, if no response was observed, for 21 days of treatment. Others have employed doses of up to 100 mg/day.[164] Conclusions as to the efficacy, optimal regimen, and safety of opiate antagonists for inducing ovulation cannot yet be made, however. No randomized controlled studies demonstrating their value for this condition have yet been published, and opiate anatagonists remain at best second-line, alternative therapy.

Dopamine Agonists

These agents are primarily used in the treatment of anovulation secondary to hyperprolactinemia. The treatment of hyperprolactinemia and the agents available for treatment is covered in detail elsewhere (see Chapter 3).

Adjunctive Therapies

Dexamethasone

Glucocorticoids have been proposed as a useful adjuvant to both CC and gonadotropin ovulation induction in women with PCOS with a therapeutic rationale based on reducing ovarian androgen levels, improving ovulatory function, and reducing resistance to ovulation induction agents.[166] Although the source of high androgen secretion in anovulatory women with PCOS is primarily ovarian, 50% to 70% also demonstrate excessive adrenal androgen levels.

In order to normalize (without suppressing) adrenal steroid production, daily oral doses of dexamethasone (0.25 to 0.5 mg) or prednisone (5 to 10 mg) have been employed in a continuous regimen. Although widely used, the value of adjuvant corticosteroid administration with CC or gonadotropins for ovulation induction remains questionable. In a study of women with PCOS, the chance of ovulation after glucocorticoid suppression of adrenal androgens was not predicted by either basal DHEAS (dehydroepiandrosterone sulfate) levels or suppressed levels, and limited effects on ovulation were observed.[165] A randomized controlled study in 80 women with CC resistance and normal serum DHEAS levels showed significantly higher ovulation and pregnancy rates when 2 mg/day dexamethasone was added from cycle day 2 to 12 to CC 100 mg.[166]

While major complications from the adjuvant use of low-dose glucocorticoids are rare, weight gain is a common problem. Other reported side effects include glucose intolerance and osteoporosis. Given possible side effects, their use should remain as a second-line therapy subject to further research.

Gonadotropin-Releasing Hormone Agonists

Adjuvant GnRH agonist treatment has also been proposed to improve outcomes and reduce complications of ovulation induction. Early uncontrolled studies indicated that the concomitant use of GnRH agonist with ovarian stimulation regimens in women with PCOS was safe and improved treatment outcome.[167] Further studies indicated that premature luteinization could be prevented by employing GnRH agonists, but no clear difference in pregnancy rates was demonstrated.[168] Although, a meta-analysis of five prospective studies[169] suggested that improved pregnancy rates could be achieved at similar ovulation rates when GnRH agonists were also employed, a later systematic review concluded that GnRH agonist as an adjunct to FSH and hMG does not improve pregnancy and OHSS rates, and should therefore not be recommended as a standard treatment for this patient group.[170]

Conflicting data on the effects on ovulation and pregnancy rates, combined with reports of severe OHSS with adjuvent GnRH agonist therapy and the additional burden for the patient of prolonged treatment cycles, mean that adjuvant GnRH agonists remain a second-line therapy in conjunction with FSH stimulation.

The availability of GnRH antagonists provides new opportunities to modify ovulation induction regimens. Particular attributes of GnRH antagonists that might be of value in this context include their competitive binding properties, immediate suppression of the pituitary without a flare-up effect, and rapid resumption of gonadal function on discontinuation. However, few studies have appeared which further explore its role in this clinical context.

Additional Treatable Factors Influencing the Balance of Efficacy and Risks

Obesity

Among women with WHO class 2 anovulation, obesity may be present in up to 50%. In addition to enhancing the features of insulin resistance mentioned earlier, overweight (BMI greater than 32) is also associated with reproductive dysfunction, despite regular menstrual cycles.[171] In recent years, considerable attention has been given to the role of lifestyle factors and management in improving outcomes in obese anovulatory women. Even a small (2% to 5%) reduction in weight has been shown to improve metabolical indices including insulin resistance.[172] In addition, weight loss can lead to a rise in sex hormone–binding globulin (SHBG) concentrations, a decrease in FAI and T levels, and improvement in cyclicity.[173-175] A relatively modest reduction in weight has been shown to increase the frequency of ovulation in obese anovulatory women to more than 70%.[176] Energy restriction acting to temporarily improve insulin senstivity may be important,[175] because improvements in endocrine and clinical parameters occurred maximally during the period of energy restriction. During subsequent weight maintenance, many benefits were reversed.[175]

The evidence for the benefits of weight loss, combined with recent data confirming BMI to be a major factor influencing outcome of ovulation induction,[87] make the treatment of obesity an important adjuvant treatment that should precede ovulation induction.[87] Given the baseline risks of ovulation induction, and the possible risks of obesity for subsequent pregnancy and general health, weight loss in cases of obesity should be considered as a prerequisite to medical ovulation induction treatment.[177-180]

Tobacco Smoking

Epidemiological data provide strong evidence for a causal association between cigarette smoking and other lifestyle factors and decreased fertility. For a recent review of the impact of smoking and other lifestyle factors on fertility treatment outcomes, see Homan and colleagues.[181] Dose-dependent effects of smoking have been reported in relation to the duration to conception.[182] Moreover, there is evidence of increased risk of early pregnancy loss in smokers[183] and a reduced mean age at menopause.[184] Although properly designed studies of the effect of smoking on outcomes of ovulation induction are scarce, data from studies in assisted conception point to detrimental effects on ovarian function and oocyte quality, which are likely to be applicable to the situation concerning ovulation induction.[185] In any discussion of infertility therapy, the clinician should emphasize the risks of smoking for outcome of treatment. Indeed, preconceptional care and lifestyle advice should be an integral part of the modern fertility clinic.

Ovarian Stimulation in the Empirical Treatment of Unexplained Infertility

Principles of Ovarian Stimulation

The aim of ovarian stimulation is to intervene in the mechanisms regulating single dominant follicle selection in order to mature multiple follicles and obtain multiple oocytes for

fertilization *in vivo* (either after timed intercourse or IUI) or *in vitro* (IVF). Ovarian stimulation is usually performed in normo-ovulatory infertile women in order to increase chances for pregnancy. However, the development of multiple follicles inherently also increases the undesired risk of (higher order) multiple pregnancies and OHSS. In IVF, OHSS risks are reduced because of the puncture of all visible large follicles to retrieve the oocytes, and incidences of multiple pregnancies can be controlled by limiting the number of embryos transferred.

Obviously, oligovulatory and anovulatory women may also qualify for either IUI or IVF after failed ovulation induction. Hyperstimulation may also be performed in these women, aiming at multiple follicle development. It should again be emphasized that this condition of hyperstimulation in these patients is distinctly different from ovulation induction in which the aim is to mimic physiology and stimulate ongoing growth and ovulation of a single dominant follicle. However, these patients are usually difficult to manage because of an unpredictable major individual variability in response and a tendency to hyper-respond to stimulation protocols.[186]

Although daily administration of ovary stimulating agents allows for dose adjustments based on individual ovarian response monitoring, the clinical evidence for the efficacy of such an approach is scant. A hyper-response may be counteracted by a dose decrease or the complete cessation of exogenous gonadotropins for some days (the latter strategy is referred to as "coasting").[187] An excessive number of follicles for ovulation induction or hyperstimulation for IUI may be reduced by follicle puncture[188] or cycle cancellation. When, in contrast, low ovarian response to standard stimulation is observed, recent evidence indicates that a gonadotropin dose increase does not result in improved outcome.[189,190] This is not surprising if the pathophysiological background of low response is taken into consideration. Low response to ovarian hyperstimulation may be the first sign of advanced ovarian aging.[191] Women with a previous low response to hyperstimulation have been shown to enter menopause at an earlier age.[192]

During the normal menstrual cycle the midcycle LH surge represents the trigger for inducing final oocyte maturation, the rupture of the follicle and release of the oocyte, and finally luteinization of granulosa and theca cells allowing for the formation of the corpus luteum. As mentioned before, the synchrony of endocrine events inducing the LH surge is disrupted in ovarian hyperstimulation. Therefore, the endogenous LH surge is replaced by an exogenous hCG bolus injection, timed by the visualization of large graafian follicles upon ultrasound. Finally, these follicular phase interventions result in luteal phase abnormalities[193] requiring luteal phase supplementation by either hCG or exogenous progestins.

Therapeutic Approaches

Unexplained infertility is usually diagnosed by exclusion, when standard infertility investigation shows no abnormalities. However, no agreement exists with regard to the preferred extent of standard investigation as well as the interpretation and prognostic value of many of these tests. Usually, ovulation is assessed by a midluteal phase serum progesterone assay, tubal patency is established by hysterosalpingogram, and male factor infertility excluded by semen analysis. Again, the interpretation of any of these tests is not without difficulty and many clinicians perform additional tests to further explore possible causes of infertility.[62] Hence, the term *unexplained infertility* is notoriously ambiguous and may mean anything in between undiagnosed infertility and normal fertility in which a pregnancy did not occur merely by chance. This may especially be the case in young women who have been attempting to conceive for a relatively short time.[65]

It should be realized that many biologically relevant processes important for obtaining a pregnancy—such as oocyte chromosomal constitution, subtle sperm abnormalities, *in vivo* conception, embryo transport and nidation, and finally endometrial receptivity—cannot be studied accurately as yet. It is to be expected that with the advancement of our understanding of these processes, the percentage of couples diagnosed with unexplained infertility, and therefore potential need for empirical ovarian hyperstimulation, will decrease.

When a couple presents with unexplained infertility, it is extremely important to assess chances of spontaneous pregnancy before commencing on any kind of empirical therapy. As mentioned before, ovarian hyperstimulation (with or without additional interventions such as IUI) may enhance pregnancy chances per cycle, but at the cost of patient stress and discomfort, chances for side effects such as multiple gestation and OHSS, and high costs[194,195] (Fig. 30.5). Similar cumulative pregnancy rates may be achieved with expectant management for 6 to 12 months.[65] Expectant management may represent the most favorable approach in many young women with a short duration of infertility.

Results are frequently reported from combined interventions such as ovarian hyperstimulation and IUI. These studies are often uncontrolled, and few are sufficiently powered to differentiate between the independent effects of hyperstimulation and IUI and the potential additive effects of combining both interventions. In recent years, the picture has become clearer. Although the absolute treatment effect appears relatively limited, given the low cost and ease of administration, CC can be recommended as first choice medication for the treatment of unexplained infertility. In terms of pure efficacy, however, a meta-analysis of five trials indicated that gonadotropins may be superior to CC as ovarian stimulation agents for the treatment of unexplained infertility.[196] Treatment with CC was associated with significantly reduced odds ratios of pregnancy per woman compared to gonadotropins (OR 0.41; 95% CI 0.17 to 0.8). As far as complications are concerned, no significant differences could be found for miscarriage (OR 0.61; 95% CI 0.09 to 4) or multiple birth (OR 1.1; 95% CI 0.2 to 7). The incidence of OHSS or cycle cancellation rates could not be assessed.

For unexplained infertility, the combination of IUI with ovarian hyperstimulation potentially bypasses several possible barriers to fertility, including minor sperm abnormalities, sperm-cervical mucus interactions, timing of sperm delivery problems, and a possible beneficial effect of ovarian stimulation on endometrial receptivity. The most important benefit is likely to be the stimulation of multiple follicles. Although a meta-analysis by Hughes[197] has addressed questions relating to the benefits of FSH and IUI alone compared with combined therapy, less than a third of the studies included in the analysis make use of treated control subjects.

Moreover, the conclusions that both FSH and IUI improve fecundity are derived from regression analysis and are open to discussion.[198] Other studies have indicated that ovarian hyperstimulation with both CC and gonadotropins improve the fecundity rate compared to IUI alone.[68] However, a study comparing intracervical insemination alone with FSH in combination with IUI showed a statistically higher pregnancy rate with the latter treatment combination.[64] The number needed to treat was 31 cycles. This implies that it would take 31 cycles of treatment before there would be one more singleton live birth with FSH and IUI than with intracervical insemination alone.[199] The number needed to treat of FSH in combination with IUI in order to obtain an extra pregnancy above that obtained with IUI alone is even greater.[199] When the costs of multiple pregnancies arising from multiple follicle development are taken into account, the cost effectiveness of FSH and IUI combined therapy for this indication may be limited. Cost-effectiveness analyses have led to the conclusion that IUI with or without hyperstimulation should precede IVF.[200] In clinical practice the benefits of ovarian hyperstimulation in combination with IUI need to be weighed against the additional discomfort and costs of monitoring applied, often unsuccessfully,[67] to avoid multiple pregnancy.[201] Clearly, more studies are needed to elucidate the optimal approach to treating unexplained infertility, and the role ovarian hyperstimulation should play. Although it is increasingly recognized that treatment success should be defined in terms of cumulative multiple cycles, at present cumulative live birth rates remain poorly reported, and comparisons with expectant management after multiple cycles have not been made.

Preparations for Ovarian Stimulation

Clomiphene Citrate

Preparations and Regimens

Daily doses of 50 to 100 mg are given usually from days 5 until 9[28] and ovulation is triggered by exogenous hCG. Little ovarian response monitoring is required, and luteal support is probably not necessary.

Clinical Outcome

A retrospective analysis of 45 published reports conclude that the adjusted pregnancy rate per initiated cycle is 5.6% for CC alone, versus 8.3% for CC plus IUI compared to an estimated pregnancy rate from expectant management of 1.3%.[201] A meta-analysis on the basis of six randomized trials[202] concluded that CC administration was superior to no treatment, with an odds ratio for clinical pregnancies of 2.4 (95% CI 1.2 to 4.6) per patient and 2.5 (1.4 to 4.6) per cycle. As stated before, an earlier meta-analysis[197] indicated an independent significant improvement in pregnancy rates for clomiphene, exogenous FSH, and IUI. Most recent analysis suggests no benefit of CC in unexplained infertility.[202]

Adverse Effects and Complications

Adverse effects include hot flushes, mood swings, headache, and visual disturbances. The principal complication remains multiple pregnancy, which occurs in around 10% of pregnancies, and a slightly increased chance for OHSS. Long-term use of CC (more than 12 months) may be associated with a slight increase in the risk of ovarian epithelial cancer.[102]

Gonadotropins

Preparations and Regimens

Usually exogenous gonadotropin administration is started around cycle day 3 to 5 at daily doses of 75 to 225 IU for several days in fixed dose regimens. Thereafter, doses may be adjusted on the basis of ovarian response monitoring by ultrasound and/or E_2 assays. The therapeutic window for gonadotropins achieving the desired goal (two to three preovulatory follicles) is rather small, and a considerable proportion of treatment cycles are canceled because of hyper-response (and the related increased chance of higher order multiple pregnancy) or because they fail to achieve multiple dominant follicle development. The need for cancellation is highly dependent on the stimulation protocol applied and the rigidity of cancellation criteria applied. This in turn depends on whether higher order multiple pregnancies are considered an acceptable side effect of treatment, or whether this should be seen as a failure of treatment to be prevented at any price. Moreover, premature luteinization during ovarian hyperstimulation for IUI may occur more frequently than generally assumed. This may have a detrimental impact on treatment outcome. Recent studies of GnRH antagonist cotreatment during gonadotropin hyperstimulation have demonstrated a reduced incidence of a premature LH rise but no significant improvement in pregnancy rates.[203] However, this approach renders ovarian stimulation protocols more complicated and expensive, increasing the frequency of hospital visits required for monitoring.

Clinical Outcome

A meta-analysis based on 5214 cycles reported in 22 trials concluded an odds ratio for pregnancies associated with FSH compared to expectant management of 2.35 (95% CI 1.9 to 2.9).[197] A retrospective analysis based on 45 previous papers concluded a significantly increased pregnancy rate occurred after either hMG alone (7.7%) or hMG plus IUI (17.1%).[201] A subsequent large multicenter study[64] confirmed that ovarian hyperstimulation with gonadotropins and IUI both exhibit an independent additive effect on pregnancy chances. The applied treatment regimen for ovarian hyperstimulation (150 IU/day FSH from cycle day 3 to 7) resulted in high frequency of conception. Overall cumulative pregnancy rates when this was combined with IUI therapy were reported to be 33% within three cycles, but at the price of an unacceptable high multiple pregnancy rate of 20% twins and 10% higher-order multiple pregnancy.[64] Women undergoing combined hyperstimulation and IUI were 1.7 times more likely to achieve a pregnancy in a given cycle compared to those receiving IUI alone. However, only 53% of these pregnancies resulted in a live birth with a substantial number of triplet and quadruplet births, despite the fact that fetal reduction has been applied in some of these women. Indeed, 30% of occurring pregnancies were multiples, including 9% triplets and quadruplets. No information was provided regarding perinatal mortality and morbidity rates.

Introduction of ovulation for assisted reproduction programmes.* Baillieres Clin Obstet Gynecol *4:451–573, 1990.)*

Adverse Effects and Complications

Those effects relating to gonadotropins in general are discussed earlier. In the context of ovarian stimulation for the treatment of unexplained infertility, we again stress the risk of multiple pregnancy associated with the use of these drugs. The ability of careful monitoring to allow prevention of this complication is limited even in highly skilled hands,[67] and the decision to employ gonadotropins in the context of treating ovulatory women for unexplained infertility should be preceded by an open and informed discussion with the couple over the risks of treatment and the limitations of monitoring. It is clear that an individual approach is required when addressing these issues, and that there is a need to individualize treatment in order to ensure optimal outcomes.

Ovarian Stimulation for in Vitro *Fertilization*

Therapeutic Approaches

The general aim of ovarian stimulation in this clinical context is to induce the development of multiple dominant follicles in order to be able to retrieve many oocytes to allow for inefficiencies in subsequent fertilization *in vitro*, embryo culture, and embryo selection for transfer and implantation (Fig. 30.12).[29] Hence, multiple embryos can be transferred in the great majority of patients and often spare embryos can be cryopreserved to allow for subsequent chances of pregnancy without the need for repeated ovarian stimulation and oocyte retrieval.[28] The paradigm of so-called "controlled" ovarian stimulation by high doses of exogenous gonadotropins and GnRH agonist long protocol cotreatment for IVF has constituted the gold standard for clinicians throughout the world since the early 1990s. It appears that large numbers of developing follicles is still considered a useful surrogate marker of successful IVF, whereas its significance in relation to the chance of achieving a pregnancy resulting in a healthy baby born is in doubt.[72,203] The ovarian stimulation protocols required to produce a large number of follicles have become extremely complex and costly over the years,[28,52] creating considerable side effects, risks of complications, and the need for intense monitoring of ovarian response.[204] The total number of retrieved oocytes required to achieve a single live birth is somewhere around 25, suggesting a very substantially oocyte wastage.[205] Physicians appear to be in control of ovarian stimulation, owing to their ability to adjust the gonadotropin doses or the type of preparation on the basis of ovarian response monitoring. However, the major individual variability in response is out of the doctor's control and is an extremely important determining factor for both success and complications of IVF treatment.[206] A good ovarian response to standard stimulation indicates normal ovarian function and a good prognosis for successful IVF. A low ovarian response suggests ovarian aging and is therefore associated with poor IVF outcome. A low response can to some extent be predicted by chronological age and endocrine and ultrasound aging parameters assessed before the initiation of treatment, as

will be discussed later.[192,207] However, the widely applied approach to increase gonadotropin doses administered in case of insufficient ovarian response has very little scientific foundation. The occurrence of a severe hyper-response comes as a surprise in most cases.[58,197] However, recent research indicates that the initial AMH level may represent a useful tool to identify women and risk for an exaggerated response to ovarian stimulation.[208] Severe OHSS is induced by hCG and is therefore often associated with pregnancy. This can be prevented from happening by refraining from embryo transfer in the cycle at risk and cryopreserving all available embryos for transfer in another cycle. Current approaches also include the triggering of an endogenous LH surge inducing final oocyte maturation by a bolus dose of GnRH agonist.[209] For obvious reasons, such an approach can only be used in stimulation protocols employing GnRH antagonist cotreatment.

Slowly, ovarian stimulation protocols have shifted from the use of hMG to uFSH to recFSH.[210] In recent years, several groups have focused on the potential significance of late follicular phase LH levels for clinical IVF outcome. Indeed, it has been shown that dominant follicle development can be stimulated exclusively by LH rather than FSH, opening new possibilities for therapeutic interventions,[19] as discussed in more detail later.

Despite the fact that the first child born after IVF was conceived in a spontaneous menstrual cycle, natural cycle IVF received little attention. The major focus has been the improvement of complex ovarian stimulation regimens. Natural cycle IVF offers major advantages such as negligible complications (arising from multiple pregnancy or OHSS), reduced patient discomfort, and a low cost. The efficacy of natural cycle IVF is hampered, however, by high cancellation rates due to premature ovulation or luteinization. A systematic review of 20 selected studies involving a total of 1800 cycles showed a 7.2% overall pregnancy rate per started cycle, and 16% per embryo transfer.[70] Cumulative pregnancy and live birth rates over four cycles of 42% and 32%, respectively, have been reported.[211] Despite the relatively high failure rate, the approach of natural cycle may still be cost effective. In one study, it was calculated that natural cycle IVF could be offered at 23% of the cost of a stimulated cycle.[212]

More recently a modified natural cycle[213] has been proposed, in which GnRH antagonists are instituted to prevent premature ovulation, and low-dose exogenous gonadotropin co-treatment is given as add-back to prevent a GnRH antagonist induced involution of follicle development. Using this approach, which (like natural cycle IVF) aims to achieve monofollicular development, cumulative pregnancy rates of 44% have been reported over nine cycles of treatment.[213]

Preparations

Clomiphene Citrate

Background

After the first baby born following IVF in a natural cycle,[39] four normal IVF pregnancies were reported following ovarian stimulation with CC.[35] In subsequent years, many groups reported IVF results following CC, with or without gonadotropin cotreatment.[214] Combined CC and hMG regimens were considered the standard of care before GnRH agonist cotreatment to induce pituitary down-regulation came into use. (For a comprehensive historical overview, see reference 198.) The advantages of these combined regimens included reduced requirements for hMG and higher luteal phase progesterone levels alleviating the need for luteal phase supplementation.[32] Recent studies have reported clinical outcomes of combined regimens applying CC, gonadotropins, and GnRH antagonist.[32]

CC usually induces the development of at least two follicles, which may sometimes elicit a premature LH rise. By virtue of the fact that CC is therapeutically active through interference with estrogen feedback, this compound cannot be combined with GnRH agonist cotreatment for prevention of a premature LH surge. Moreover, undesired antiestrogenic effects of CC at the level of the endometrium have been implicated by some in the observed discrepancy between relatively low embryo implantation rates coinciding with successful ovarian hyperstimulation.

Preparations and Regimens

Clomiphene citrate administration is usually initiated on cycle day 2, 3, or 5, and given daily for 5 subsequent days with doses varying between 100 and 150 mg/day. In most applied regimens, exogenous gonadotropin medication (150 IU/day) is initiated after cessation of CC. It seems that CC alone induces a limited but dose-dependent increase in the number of developing follicles. However, the addition of gonadotropins elicits a more intense ovarian response. Sufficiently powered randomized comparative trials to support one approach over the other are lacking.

Clinical Outcome

Reported outcome is variable in the literature, but in general pregnancy rates appear higher compared to natural cycle IVF, but lower compared to conventional gonadotropin and GnRH agonist protocols. Again, most studies are uncontrolled but an extensive summary of almost 40,000 cycles reported in the literature suggests an overall pregnancy rate per embryo transfer of 20.5%.[215]

Adverse Effects and Complications

Because of the relatively mild stimulation, the incidence of side effects or complications of CC treatment for IVF is low, as discussed earlier. Overall side effects are CC dose related and are completely reversible once medication is stopped.

Gonadotropins

Background

Gonadotropin preparations have been used for ovarian stimulation since the early days of IVF and were originally developed in the United States.[214] The daily administration of these preparations is usually efficacious in the induction and maintenance of growth of multiple dominant follicles, allowing for the retrieval of many oocytes for IVF. Preparations initially used were hMG (containing both LH and FSH bioactivity), followed by purified uFSH and more recently recFSH. No general consensus exists with regard to starting day and doses of gonadotropins. In conclusion, based on seven randomized controlled trials (RCTs) involving a

total of 2563 cycles, although higher gonadotropin doses may result in the retrieval of 1 or 2 more oocytes, improved clinical outcomes in terms of pregnancy rates could not be demonstrated.[216]

A chimeric FSH agonist (so-called recFSH-CTP), generated by the fusion of the carboxy-terminal peptide (CTP) of hCG (responsible for its prolonged metabolical clearance compared to LH) with the FSH-β chain has recently been introduced in the IVF clinic.[45] Corifollitropin alpha can be administered with a 7 day injection free interval and has been shown to be safe with high efficacy.[217]

The type, duration, and dosing of GnRH analog cotreatment to suppress endogenous pituitary gonadotropin release (as will be discussed later in the chapter) may also affect the preferred gonadotropin preparation. Classical principles teach us that both LH and FSH are required for adequate ovarian estrogen biosynthesis and follicle development. Theca cell–derived androgen production (which is under LH control) is mandatory as a substrate for the conversion to estrogens by FSH-induced aromatase activity of granulosa cells.[29] A number of studies have indicated that excessively suppressed late follicular phase LH concentrations may be detrimental for clinical IVF outcome.[218,219] Under these circumstances the use of urinary preparations containing both LH and FSH activity or the addition of recLH or rechCG next to exogenous FSH may be useful.[29] It is uncertain as yet, however, for which patients this approach may be beneficial. Recent meta-analyses failed to show clinically relevant differences in relation to late follicular phase LH concentrations,[220] or when cycles with or without the addition of exogenous LH are compared.[221]

Recently the concept that exogenous LH is capable of selectively stimulating the development of the more mature dominant follicles has been developed. A shift from FSH to LH preparations during stimulation may therefore be useful in order to stimulate a more homogeneous cohort of follicles for IVF.[18,19,222]

Preparations and Regimens

To allow for the clinical introduction of recombinant FSH, large-scale, multicenter, comparative trials in IVF were published from 1995 onward.[223] It should be noted, however, that these studies, including several hundreds of women, were sponsored by pharmaceutical companies. The results should therefore be interpreted with an appropriate degree of caution. For instance, it was arbitrarily chosen for all initial studies that recFSH would only be compared with uFSH and not hMG, although the latter preparation was still considered to be the gold standard by the majority of clinicians. Several independent comparative trials have been published since then, but sample size of these single-center studies was usually insufficient to allow for the detection of relatively small differences. An early meta-analysis[224] as well as health economics studies[225,226] indicate a slightly improved outcome for recFSH compared to uFSH. However, recently published multicenter, company-sponsored trials reported similar clinical outcomes comparing uFSH versus recFSH, or hMG versus recFSH[227,228] which was confirmed in the most recent meta-analysis.[229]

Many different regimens are applied with little if any proof of their efficacy and safety. Different starting days and doses are applied worldwide along with incremental or decremental doses. In case of imminent OHSS resulting from the development of too many follicles, the possibility of complete cessation of gonadotropin administration (coasting) has been advocated by several investigators.[187] Studies of the efficacy of this approach thus far undertaken have been limited and inconclusive. Adequate doses for gonadotropin preparations may also vary, depending on whether GnRH agonist or antagonist co-treatment is used.[230] Major individual differences in body weight may also determine response.[231] Because endogenous gonadotropins are suppressed by GnRH antagonists for a limited period of time (as will be discussed later), less exogenous FSH is required. The ideal day of initiation of gonadotropin therapy is another variable that has been poorly characterized so far, and may also vary dependent on GnRH agonist or antagonist co-treatment. It is surprising to conclude that very few of the previously mentioned questions with regard to applied dose regimens can be answered on the basis of scientific evidence by properly designed studies.

Usually starting doses vary between 100 and 300 IU/day and doses are often altered depending on the observed individual ovarian response. A typical daily starting dose would currently be 150 to 225 IU in Europe and 225 to 300 IU in the United States. Only few randomized studies regarding dose regimens can be found in the literature. A single-center RCT from Rotterdam showed that a doubling of the hMG dose in low responders after a 225 IU/day dose for 5 days is not efficacious compared to continued similar doses.[232] Moreover, an RCT in which higher versus standard dose of FSH was administered to expected poor responders showed no difference in pregnancy rates.[233] All together a meta analysis[216] encompassing all RCTs comparing different FSH doses failed to show a difference in favor of high-dose regimens where pregnancy chances are concerned (Fig 30.13), indicating that the widely applied practice of a gonadotropin dose increase in case of low response is not efficacious.

The approach of starting exogenous FSH early during the luteal phase of the preceding cycle recognizes the physiological principle of early recruitment of a cohort of follicles for the next cycle.[2] However, this protocol did not result in improved ovarian response in women with a low oocyte yield during previous IVF attempts.[234]

The perceived need to allow programming of oocyte retrieval led to a number of studies addressing the role of oral contraceptives (OCs) for this indication. Fixed schedule protocols were developed by a number of groups in which OCs were administered in advance of ovarian stimulation and planned follicle aspiration. Despite their apparent efficacy, ease of administration, and fewer side effects, subsequent randomized studies comparing OCs to GnRH agonists as a means of preventing premature luteinization showed the superiority of the latter and because of this, OCs are no longer widely used for this indication. To facilitate the planning of the initiation of exogenous gonadotropins in a GnRH antagonist cycle, independent of the menstrual period, OC pretreatment has been evaluated in a number of small studies and a recent meta-analysis.[235] Although there is evidence that OC pretreatment may aid in the scheduling of IVF cycles when GnRH anatagonists are used, at present there is no evidence that they improve live birth rates.

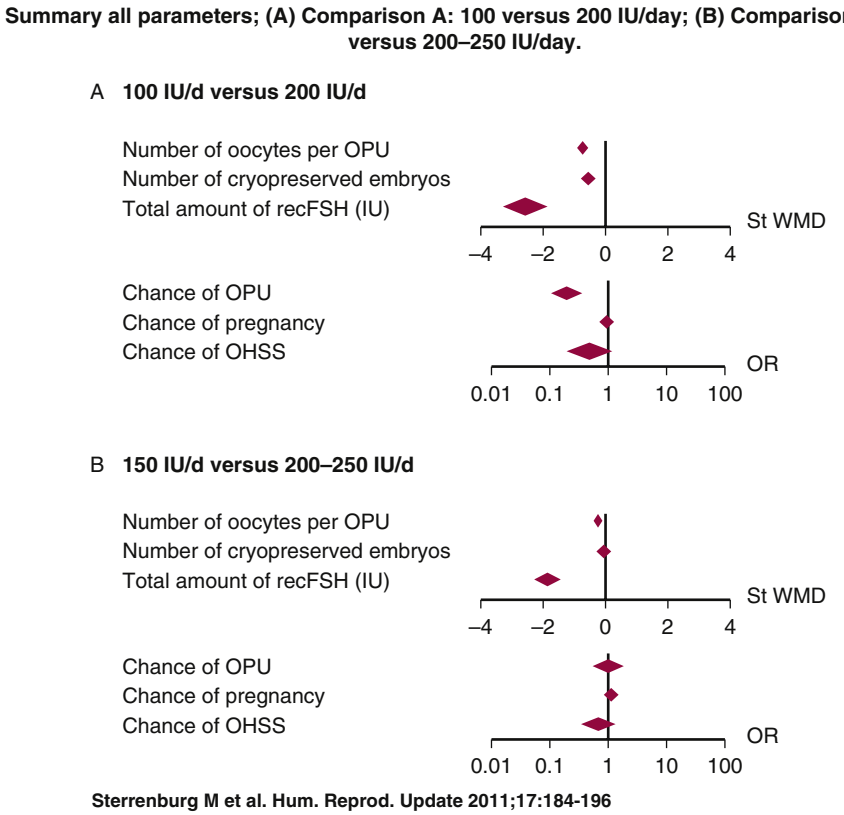

FIGURE 30.13 Summary of clinical outcomes from a meta-analysis comparing different FSH doses for ovarian stimulation for IVF. *(Graph from Sterrenburg et al. Clinical outcomes in relation to the daily dose of recombinant follicle-stimulating hormone for ovarian stimulation in* in vitro *fertilization in presumed normal responders younger than 39 years: a meta-analysis.* Human Reprod Update *17:184, 2011.)*

Gonadotropin-Releasing Hormone Agonist Cotreatment

During initial studies with hMG stimulation of multiple follicle development for IVF it became apparent that a premature LH peak occurred in around 20% to 25% of cycles, due to positive feedback activity by high serum E_2 levels during the midfollicular phase of the stimulation cycle.[32] This advanced exposure to high LH resulted in premature luteinization of follicles and either cycle cancellation due to follicle maturation arrest or severely compromised IVF outcome. The clinical development of GnRH agonists in the early 1980s[60] allowed for the complete suppression of pituitary gonadotropin release during ovarian stimulation protocols for IVF.[32] Induced pituitary down-regulation indeed resulted in significantly reduced cancellation rates and improved overall IVF outcome.[236,237] Moreover, the approach of GnRH agonist cotreatment did facilitate scheduling of IVF and timing of oocyte retrieval. Frequently used preparations include buserelin, triptorelin, nafarelin, and leuprorelin. To some degree, the extent and duration of pituitary suppression are dose related, but surprisingly few dose finding studies have been performed. In addition, randomized studies comparing different GnRH agonists are scarce.

Due to the intrinsic agonist activity of the compound, pituitary down-regulation is preceded by an initial stimulatory phase (referred to as the "flare" effect) which lasts for around 2 weeks. In this long protocol, GnRH agonist treatment therefore usually commences in the luteal phase in the preceding cycle and is continued until hCG administration. Stimulation with gonadotropins is started when pituitary and ovarian quiesence has been achieved. Moreover, it is uncertain whether ovarian response to exogenous stimulation is affected by GnRH agonist cotreatment.[238] Some women suffer from serious hypoestrogenic side effects, such as mood changes, sweating, and flushes. Alternative approaches include the short (and sometimes ultrashort) protocols in which the initial flare effect of GnRH agonist treatment is used to stimulate the ovaries. Attempts to discontinue GnRH agonist administration during the ovarian stimulation phase[239,240] have not shown beneficial effects. Reported clinical results of these alternative clinical protocols remain variable, and the GnRH agonist long protocol has remained the standard of care for over a decade.[32]

Gonadotropin-Releasing Hormone Antagonist Cotreatment

Two third-generation GnRH antagonists (cetrorelix and ganirelix) became available for large-scale clinical studies around 1995. Previous generations of the antagonist suffered from problems with pharmaceutical formulation and related bioavailability along with the local or systemic induction of histamine release. The potential advantage of a GnRH antagonist is that pituitary gonadotropin secretion is suppressed immediately after initiation of therapy. Therefore the co-treatment with GnRH antagonist can be restricted to the time in the cycle at risk for a premature rise in LH (i.e., the midfollicular to late follicular phase of the cycle).[32]

Both single, high-dose and multiple, low-dose GnRH antagonist regimens have been described. Multiple, daily dose regimens are most widely used at present. Initial dose finding studies suggested that a daily injection of 0.25 mg represents the minimal effective dose to suppress a

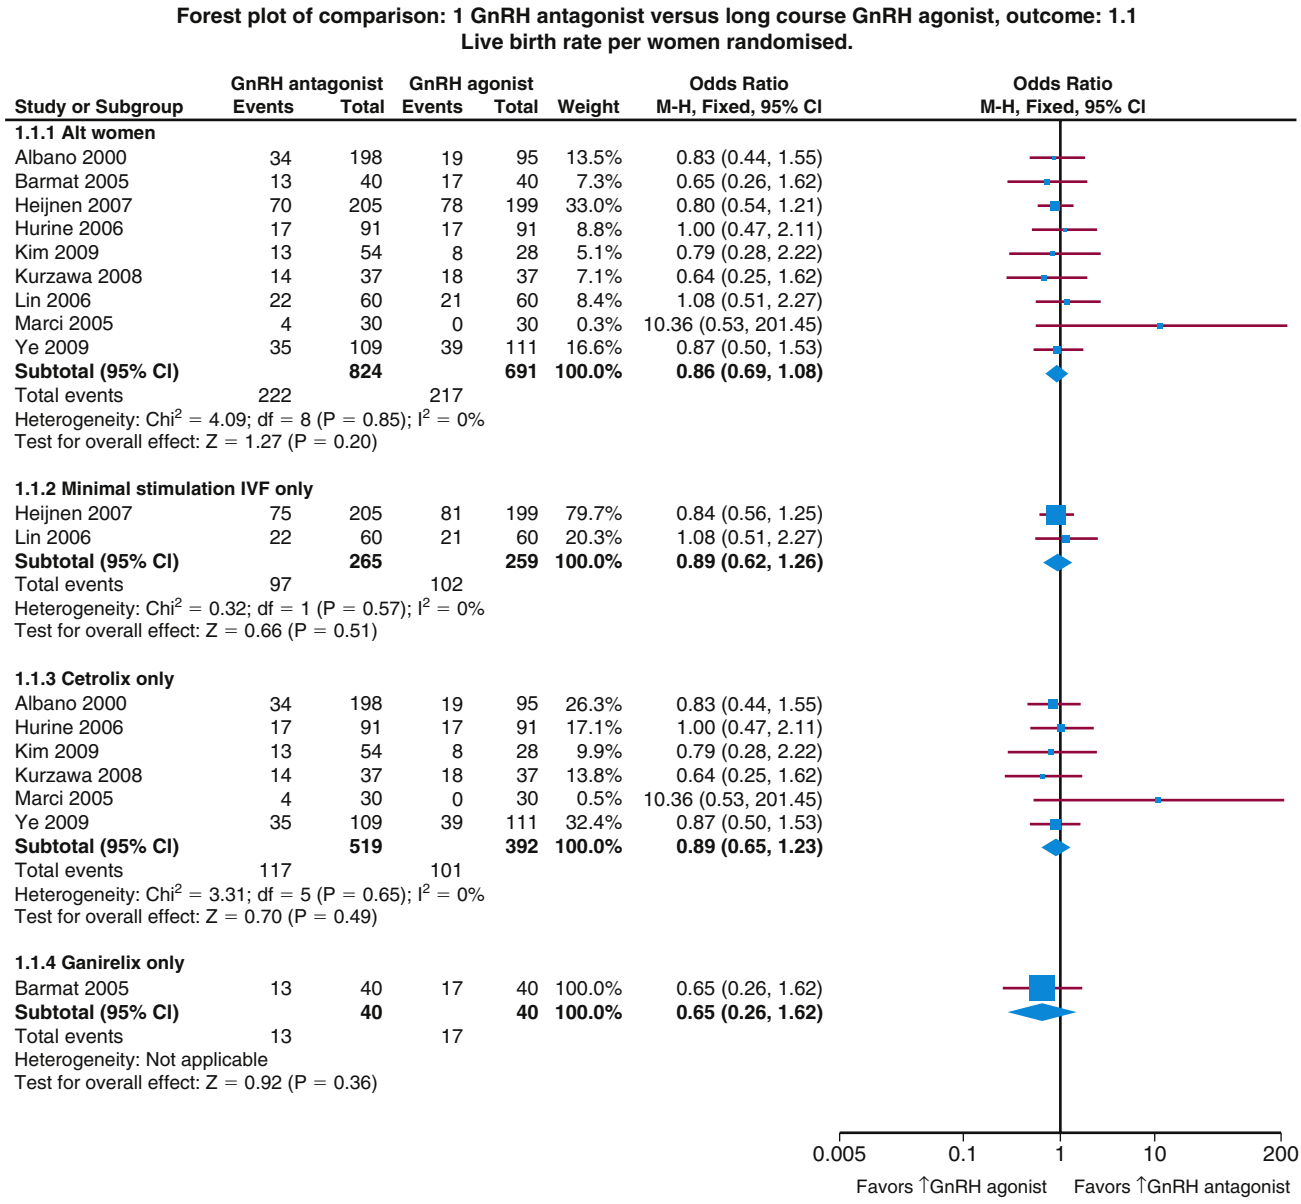

FIGURE 30.14 Forest plot of live-birth rate per women randomized comparing GnRH antagonist versus GnRH agonist long protocol cotreatment for IVF. *(Adapted from Al Inani, Gonadotrophin-releasing hormone antagonists for assisted reproductive technology.* Cochrane database *11; [5]:2011, CD001750.)*

premature LH rise in most patients. In all phase 3 comparative trials of the daily GnRH antagonist co-treatment regimen, it was initiated on cycle day 6. However, in principle, GnRH antagonists need only be given when there is follicular development and rising E_2 levels which might give rise to a premature elevation in pituitary LH release due to positive feedback mechanisms. However, a meta-analysis of four studies comparing fixed with flexible regimens showed a trend toward lower pregnancy rates following the flexible protocol (OR 0.7, 95% CI 0.47 to 1.05).[241] The first meta-analysis published comparing outcomes following cotreatment with GnRH antagonist versus GnRH agonist[230] based on five multicenter RCTs concluded that the GnRH antagonist is as efficient as GnRH agonist in preventing a premature LH surge in IVF (OR 1.76, 95% CI 0.75 to 4.16). However, a small but significant reduction in pregnancies was observed per started cycle (OR 0.79, 95% CI 0.63 to 0.99). Since then, protocols have been refined, and a recent meta-analysis of later studies has shown no difference in live birth rates[242] (Fig. 30.14).

Concerns have been raised regarding the possibility of direct effects of GnRH antagonists on the embryo. However, no adverse effects were observed on the freeze–thaw embryos of GnRH antagonist cycles.[243] Possible detrimental effects of GnRH antagonists at the endometrial level or on follicle development could not be confirmed.[32] Moreover, recent studies have indicated that gonadotropin regimens do not need to be adjusted when GnRH antagonists are commenced.[244,245] Furthermore, exogenous LH is probably not required next to FSH.[221,246]

Despite improving outcomes, the debate regarding the advantages and disadvantages compared with GnRH agonists continues (Box 30.2).[247] The most recent meta-analysis comparing GnRH agonist versus antagonist cotreatment,

Box 30.2 Advantages and Disadvantages for the Use of GnRH Antagonists in IVF

ADVANTAGES

- Prevention of premature LH increase is easier and takes less time.
- GnRH antagonists are not associated with an acute stimulation of gonadotropins and steroid hormones.
- The initial stimulation by GnRH agonists can induce cyst formation, which is avoided with GnRH antagonists.
- No hot flushes are observed with GnRH antagonists.
- Inadvertent administration of the GnRH analog in early pregnancy can be avoided as GnRH antagonist is administered in the midfollicular phase.
- Requirements for exogenous gonadotropins are reduced, rendering ovarian stimulation less costly.
- Duration of ovarian stimulation protocols is shortened, improving patient discomfort.

DISADVANTAGES

- GnRH antagonist cotreatment represents a novel approach and more knowledge is necessary for its optimization.
- GnRH antagonists offer less flexibility regarding cycle programming as compared with the long GnRH agonist protocol.
- Reduced ability to gain an orderly daily volume of oocyte retrievals compared with GnRH agonist, although this can be improved by using the oral contraceptive pill.

GnRH, gonadotropin-releasing hormone; IVF, *in vitro* fertilization; LH, luteinizing hormone.

demonstrated comparable live birth rates and reduced OHSS rates.[248] In light of a reduced duration of treatment, less injections needed, similar success rates and reduced complications, GnRH antagonist should be considered first line treatment.

Approaches for Induction of Final Oocyte Maturation

In the natural normo-ovulatory cycle, rupture of the dominant follicle and release of the oocyte are triggered by the midcycle surge of LH. This sudden enhancement of pituitary synthesis and release of LH (and FSH) is elicited by high late-follicular phase E_2 levels in combination with slightly elevated progesterone levels.[249] In stimulated cycles for IVF, estrogen levels are prematurely elevated, which may induce unpredictable but advanced LH rises. As mentioned before, GnRH agonist cotreatment is required in order to prevent this from happening. Consequently, exogenous hCG should be used during the late follicular phase under these circumstances to replace the endogenous LH surge. This approach has been considered the standard of care for the induction of final stages of oocyte maturation before oocyte retrieval along with corpus luteum formation in IVF.[32] Exogenous hCG is also implicated in sustained luteotropic activity[239] due to its prolonged circulating half-life.[249] Unfortunately, hCG is therefore also believed to contribute to chances of developing OHSS.[187]

Initial studies during ovarian hyperstimulation for IVF (before the widespread use of GnRH agonist cotreatment) showed that an endogenous LH surge could be induced reliably by the administration of GnRH or a bolus injection of GnRH agonist.[250] The induction of an endogenous LH (and FSH) surge is more physiological compared to exogenous hCG because of the much shorter half-life.[251,252] Moreover, luteal phase steroid concentrations seem closer to the physiological range,[253] which may improve endometrial receptivity.[254] As the follicular phase cotreatment with GnRH agonist has been the standard of care for over a decade, alternative approaches for the induction of oocyte maturation has received little attention. However, the suppressive effect of follicular phase GnRH antagonist administration can be reversed immediately by administering native GnRH or GnRH agonist.[255] Indeed, a randomized trial confirmed that the triggering of final stages of oocyte maturation can be induced effectively by a single bolus injection of GnRH agonist even after the follicular phase co-treatment with a GnRH antagonist. This was demonstrated by the observed gonadotropin surge and quality and fertilization rate of recovered oocytes. The concept of GnRH agonist triggering as a valid alternative to hCG is appealing due to the virtual elimination of OHSS.[255] However, the preferred luteal phase supplementation under those circumstances is not yet well defined.

Recombinant LH and recombinant hCG have recently become available for clinical use. An early large randomized trial comparing 250 μg rechCG versus 5000 IU uhCG for the induction of oocyte maturation in a total of 190 women undergoing IVF showed that the number of mature oocytes retrieved and luteal phase serum concentrations of progesterone and hCG concentrations were significantly higher.[256] Considering the short half-life of recLH two injections with a 1- to 3-day interval may be considered.

The introduction of GnRH antagonists into clinical practice now makes it possible to employ a bolus injection of GnRH agonist to induce an endogenous LH surge. Although previously shown to be effective in achieving this,[253] randomized studies comparing this approach to hCG administration showed lower implantation and ongoing pregnancy rates.[257] Recent data indicate that standard luteal support regimens may be insufficient in this setting, and improved results may be achieved when this is addressed.[258,259]

Luteal Phase Supplementation

Since the early days of IVF it has been described that the luteal phase of stimulated IVF cycles is abnormal. In fact, it was already stated in the first extended report on IVF by Edwards and Steptoe[39] that "the luteal phase of virtually all patients was shortened considerably after treatment with gonadotropins" and it was suggested that high follicular phase estrogen levels due to ovarian hyperstimulation might be involved. Initial studies in the United States in 1983 concerning hMG-stimulated IVF cycles also confirmed the occurrence of an abnormal luteal phase in IVF cycles with characteristic features of elevated progesterone levels along with a significantly reduced luteal phase length[260] (Fig. 30.15).

As mentioned earlier, GnRH agonist cotreatment became the standard of care for the prevention of a premature rise in LH. Typically, GnRH agonist treatment is initiated in the luteal phase of the preceding cycle and continued until the late follicular phase. It became apparent, however, that

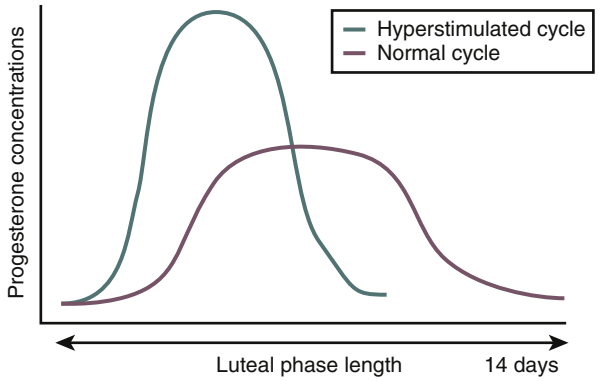

FIGURE 30.15 Schematic representation of changes in luteal phase length and endocrine profile induced by ovarian hyperstimulation for *in vitro* fertilization. *(From Jones HW]. What happened? Where are we?* Hum Reprod *11[Suppl 1]:7–21, 1996.)*

prolonged pituitary recovery from down-regulation during the luteal phase[261] resulted in lack of support of the corpus luteum by endogenous LH and advanced luteolysis.[262] It was observed shortly thereafter that the corpus luteum can be rescued by the administration of hCG,[32] and this treatment modality became the standard of care for luteal support during the late 1980s. Outcome was better compared to progesterone supplementation, but 5% of hCG-supplemented patients developed OHSS. Because of this association between hCG and OHSS,[187] luteal phase hCG support has been largely replaced over the years by luteal phase progesterone supplementation.[263] A recent meta-analysis of luteal support in stimulated IVF cycles involving a total of 69 studies and 16,327 women concluded supplementation by synthetic progesterone represents the current method of choice, with no improved outcomes using either estrogen or hCG supplementation.[264,265]

Attempts to secure pituitary recovery during the luteal phase by the early follicular phase cessation of GnRH agonist cotreatment all failed, because it takes at least 2 to 3 weeks for LH secretion to recover.[32] Because of the rapid recovery of pituitary gonadotropin release after discontinuation of GnRH antagonist it has been speculated that luteal phase supplementation may not be required following the late follicular phase administration of antagonist.[266] Preliminary observations related to ovarian stimulation and GnRH antagonist cotreatment for IUI seem to favor this contention.[267] However, various studies in IVF applying GnRH antagonist cotreatment have now clearly shown that luteolysis is also initiated prematurely resulting in a significant reduction in the length of the luteal phase along with greatly compromised chances for pregnancy.[268-270] More detailed studies could confirm that early luteal and midluteal phase LH levels remained suppressed following the follicular phase administration of GnRH antagonist.[270,271]

Moreover, luteolysis is advanced in the nonsupplemented luteal phase after either hCG or GnRH agonist triggering of oocyte maturation.[270] Collectively, this indicates that high early luteal phase steroid production is primarily responsible for advanced luteolysis, due to massive negative feedback resulting in greatly suppressed LH secretion.[203] Mild stimulation regimens resulting in lower serum steroid levels have therefore been advocated as a means of benefiting the luteal phase.[264]

Clinical Outcome of IVF

The most recent report concerning IVF in Europe performed in the year 2008 involves 532,000 cycles (from over a thousand clinics in 36 countries) with a clinical pregnancy rate per aspiration of 28.5% (including 21% twins and 1% triplets).[272] The most recent U.S. data involve almost 150,000 cycles in 2009 with live birth rates per fresh embryo transfer using nondonor oocytes of around 30% with a total multiple pregnancy rate of 31%.[273]

Adverse Effects and Complications

Complications related to invasive IVF procedures such as oocyte retrieval and embryo transfer, predominantly involve infection and bleeding along with anesthesia problems.[274] The drawbacks associated with profound ovarian stimulation for IVF include considerable patient discomfort such as weight gain, headache, mood swings, breast tenderness, abdominal pain, and sometimes diarrhea and nausea. In this respect it is important to comprehend that after a first unsuccessful IVF attempt around 25% of patients refrain from a second cycle, even in countries where costs are covered by health insurance companies. The most common reason for treatment discontinuation is burden of treatment.[275]

OHSS is a potentially life-threatening complication characterized by ovarian enlargement, high serum sex steroids, and extravascular fluid accumulation, primarily in the peritoneal cavity. Mild forms of OHSS constitute around 20% to 35% of IVF cycles, moderate forms 3% to 6% of cycles, along with 0.1% to 0.2% severe forms.[66,225] To some extent, patients at risk of developing OHSS may be recognized by the following features: young age, PCOS, profound hyperstimulation protocols with GnRH agonist long protocol cotreatment, large numbers of preovulatory graafian follicles, high serum E_2 levels, high (greater than 5000 IU) bolus doses of hCG to induce final oocyte maturation, the use of hCG for luteal phase supplementation, and finally the occurrence of pregnancy. In fact, the incidence of OHSS is directly related to hCG concentrations with a twofold to fivefold increased incidence in case of multiple pregnancy.

Preventive strategies in case of imminent OHSS include cessation of exogenous gonadotropins for several days (coasting), follicular aspiration, prevention of pregnancy during the stimulation cycle by cryopreserving all embryos, or the prophylactic infusion of glucocorticoids or albumin. The risk of OHSS may also be lowered by using alternative strategies to induce oocyte maturation, such as inducing an endogenous LH surge by administration of a single bolus dose of GnRH agonist or the short half-life preparation of recLH instead of hCG. Finally, current efforts focus on individualized dosing of ovarian stimulation based on initial screening characterstics, such as female age, body weight, AMH concentrations, and antral follicle count.[276-278] The most important complication related to IVF treatment is multiple pregnancy. The magnitude of the problem has been discussed previously in this chapter (Fig. 30.5). (For recent reviews see Fauser and colleagues[69] and Verberg and colleagues[70]) Between the years of 1980 and 2000, twin birth

rates in the United States increased by 75%, and currently represent around 3% of total births.[69] Similar trends have been reported in European countries.[70] Although an association between increased female age and multiple gestation is clearly established, the delay in childbearing accounts for no more than 30% of the observed overall increase in multiple pregnancies.[69] Although the available data indicate that the majority of twin births are still unrelated to infertility therapies[69] up to 80% of higher order multiple births are considered to be due to ovarian stimulation and ART. Births resulting from infertility therapies account for around 1% to 3% of all singleton live births, 30% to 50% of twin births, and more than 75% of higher order multiples.

Pregnancy complications include increased risk of miscarriage, preeclampsia, growth retardation, and preterm delivery. Perinatal mortality rates are at least fourfold higher in twin, and at least sixfold higher in triplet, births compared with singleton births. Moreover, the risks of prematurity in twin and higher order multiple birth are increased sevenfold to fortyfold, and for low-birth-weight infants tenfold to seventyfivefold, respectively. Adverse outcomes among children conceived through IVF are largely associated with multiple gestation.

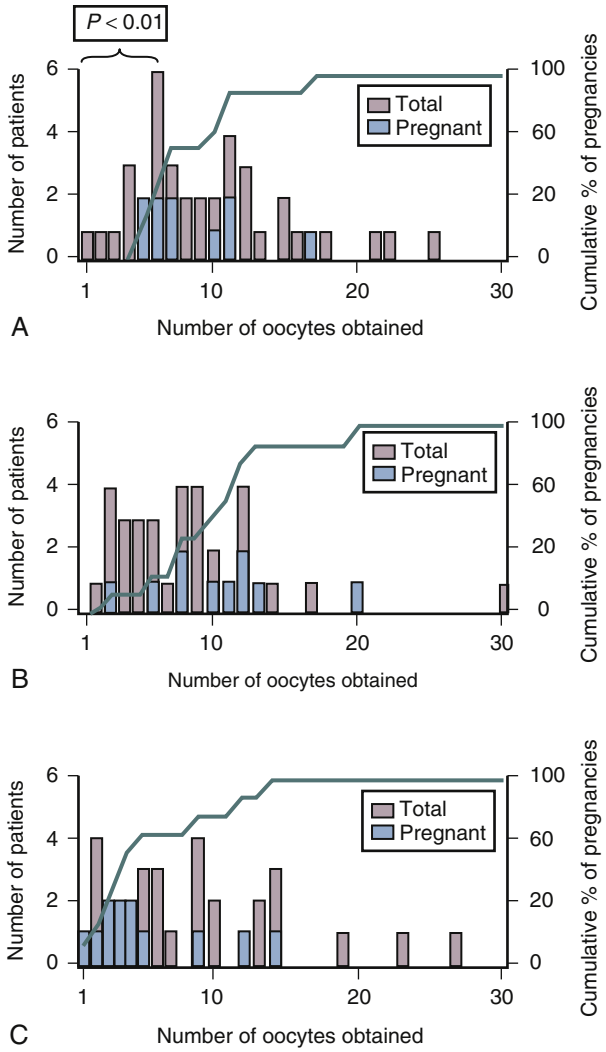
Recent data are reassuring with respect to possible long-term health consequences such as ovarian cancer, breast cancer, and advanced menopausal age.[279]

New Approaches to Mild Ovarian Stimulation for IVF

After the initial years of IVF, profound ovarian stimulation became the rule for more than 2 decades. The stimulation of growth of large numbers of follicles and the retrieval of many oocytes has been viewed as an acceptable marker of successful IVF treatment. Medication regimens to achieve profound ovarian stimulation are extremely complex and expensive, take many weeks of frequent injections, and require intense monitoring. Moreover, patient discomfort and chances for serious side effects and complications are considerable. In addition, this profound stimulation gives rise to greatly abnormal luteal phase endocrinology, and its impact on endometrial receptivity and therefore IVF success is mostly unknown.

Attitudes toward profound ovarian stimulation are changing,[204,280] particularly given the growing tendency to transfer a reduced number of embryos. It has previously been demonstrated on the basis of the U.K. national database that reducing the number of embryos tranferred from three to two does not diminish chances of birth despite a reduction in risk of multiple birth.[87] In Europe, an increasing number of centers are carrying out single transfer in younger women. Emphasis may therefore now be directed toward the development of more simple and milder stimulation protocols[29,216,224,281] or the improvement of natural cycle IVF outcomes.[83,211,213] The increasing quality of embryo cryopreservation programs will serve to encourage the transfer of one embryo at a time.[282]

Previous studies in normo-ovulatory female volunteers[125,126] confirmed that the development of multiple dominant follicles can be induced by interfering with decremental FSH concentrations during the midfollicular to late follicular phase. As shown previously, this decrease is required for the selection of a single dominant follicle.[11,12] These



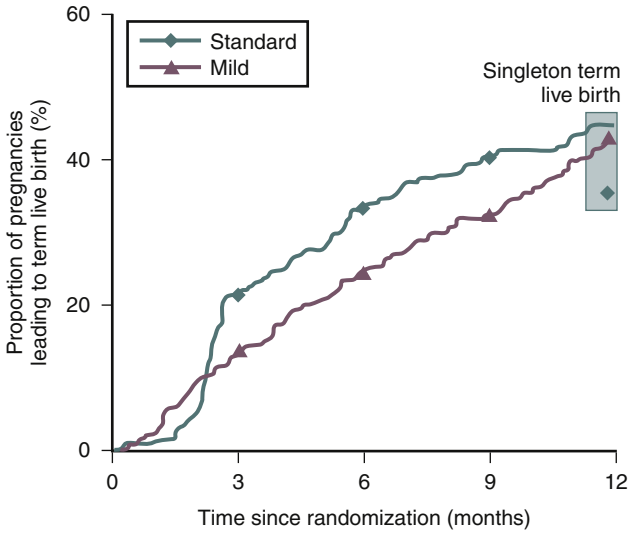


FIGURE 30.16 Number of women undergoing *in vitro* fertilization who did or did not achieve a pregnancy in relation to the amount of oocytes retrieved, comparing conventional hyperstimulation with gonadotropin-releasing hormone (GnRH) agonist long protocol **(A)** with two mild stimulation protocols employing GnRH antagonist cotreatment (**B** and **C**). *(Adapted from Hohmann FP, Macklon NS, Fauser BC. A randomized comparison of two ovarian stimulation protocols with gonadotropin-releasing hormone [GnRH] antagonist cotreatment for in vitro fertilization commencing recombinant follicle-stimulating hormone on cycle day 2 or 5 with the standard long GnRH agonist protocol.* J Clin Endocrinol Metab *88:166–117, 2003.)*

observations are in agreement with previous findings in the monkey model.[127,283] We were subsequently able to demonstrate that the initiation of exogenous FSH (fixed dose, 150 IU/day, GnRH antagonist cotreatment) as late as cycle day 5 results in a comparable clinical IVF outcome, despite a reduced duration of stimulation (number of ampules used) and increased cancellation rates[284] (Fig. 30.16).

To test the efficacy of this mild stimulation protocol in standard practice, a large randomized effectiveness study has been performed to analyze whether a strategy including the mild stimulation protocol in combination with single embryo transfer (SET) would lead to a similar outcome assessed over a 1-year interval after initiation of treatment, while reducing patients' discomfort, multiple

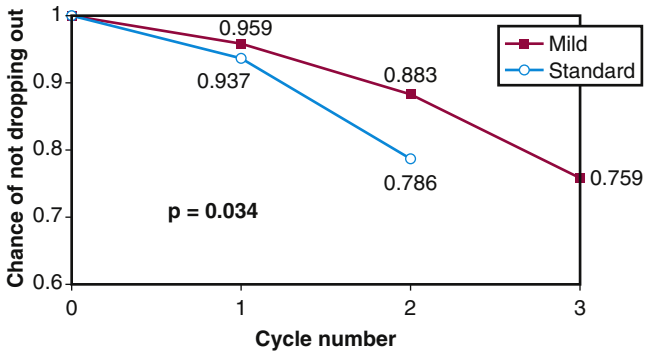

FIGURE 30.18 Chances of not dropping cut from successive IVF treatment cycles applying either mild IVF or standard IVF. *(Adapted from Verberg et al. Why do couples drop-out from IVF treatment? A prospective cohort study.* Hum Reprod *23[9]: 2050–2055, 2008.)*

pregnancies, and costs compared with standard treatment.[72] The study included a total of 404 patients and observed that because of the shorter duration of treatment per cycle, less medication needed, and a reduction in twin pregnancies, the mild approach led to an equal chance of live birth after a year of treatment while reducing the total costs (Fig. 30.17).

Apart from clinical efficiacy and costs (see later in the chapter), emotional stress should be considered an important negative side effect associated with IVF treatment. Following mild stimulation, patients reported fewer side effects and stress related to hormone treatment compared with conventional stimulation.[285] Consequently drop out rates have been reported to be significantly reduced during mild stimulation (Fig 30.18). Treatment-related stress has been found to be the most important reason patients drop out of IVF treatment.[286] The early drop-out of treatment deprives the couple of an optimal cumulative chance of achieving pregnancy, and therefore also impacts on the success of the respective IVF program. Mild stimulation might therefore have a positive impact on cumulative treatment success rates as it positively affects the chance that patients are willing to continue treatment following a failed attempt.[288]

Other novel protocols under investigation include the replacement of FSH by LH, an approach based on the acquired LH responsiveness of granulosa cells of dominant follicles. Besides the expected reduction of gonadotropin usage, this ovarian stimulation approach might also reduce the number of small, less mature follicles, possibly reducing the chance of OHSS, because smaller ovarian follicles are unlikely to be responsive to LH.[169] Several randomized controlled trials [222,289,290] have shown that this approach can result in a significant reduction in FSH needed and in the number of small follicles at final oocyte maturation. Pregnancy rates do not appear to be compromised. More extensive studies are required to determine the critical threshold for FSH replacement by LH stimulation and the most appropriate dosage of LH or hCG.

There are indications that the degree of ovarian stimulation affects both the morphological embryo quality and the chromosomal constitution of the developed embryos.[291-294] This phenomenon could be the result of interference with the natural selection of good quality oocytes or the exposure of growing follicles to the potentially negative effects of ovarian stimulation. A randomized trial concerning the chromosomal analysis of human embryos following mild ovarian stimulation for IVF showed a significantly higher proportion of euploid embryos compared to conventional ovarian stimulation, suggesting that through maximal stimulation the surplus of obtained oocytes results in chromosomally abnormal embryos.[295]

Toward Individualized Treatment Algorithms

As previously highlighted, the chance of achieving a spontaneous pregnancy is frequently underestimated by couples and their physicians.[99] An increasingly assertive patient population, who continue to delay childbearing for career, social, or other reasons is putting physicians under greater pressure to intervene in order to aid the couple in achieving their goal quickly and with minimal disruption to busy lives.[296] Time is increasingly an issue for couples seeking to conceive, and the commercial pressures and competition between IVF centers can lead to couples being accepted into IVF programs without a sound indication. Yet the virtue of patience can pay dividends for many who are now subject to premature and unnecessary intervention. Most couples seeking help will present with subfertility rather than absolute infertility. On the basis of a modest range of investigations and certain individual characteristics, the chances of an individual couple conceiving spontaneously over a given period of time can be calculated. It is known for instance that the spontaneous monthly fecundity rate declines with increasing duration of subfertility. After 3 years the residual

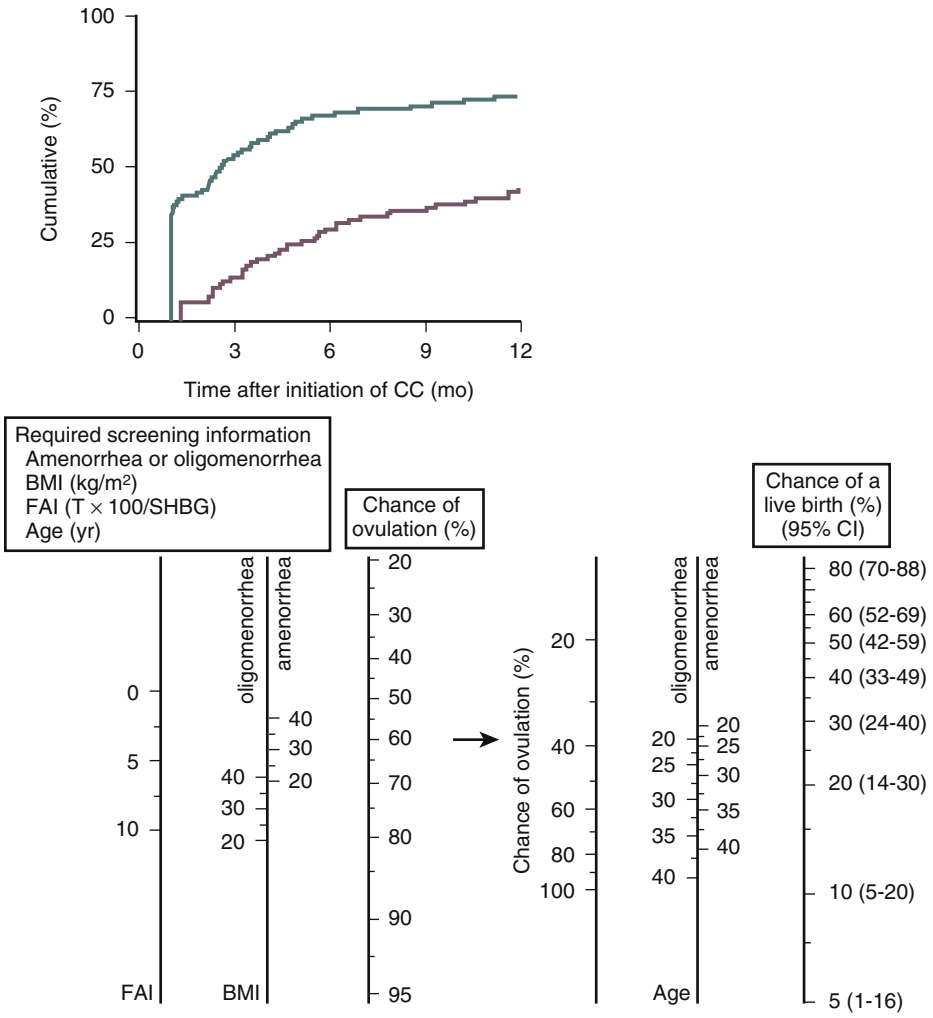

FIGURE 30.19 Cumulative percentage of patients who ovulate or conceive following the initiation of clomiphene citrate, CC *(top)*, and a two-step nomogram predicting chances of live birth following clomiphene citrate on the basis of initial screening characteristics *(bottom)*. BMI, body mass index; FAI, free androgen index. *(From Imani B, Eijkemans MJ, te Velde ER, et al. A nomogram to predict the probability of live birth after clomiphene citrate induction of ovulation in normogonadotropic oligoamenorrheic infertility.* Fertil Steril *77:91–97, 2002.)*

likelihood of spontaneous pregnancy in untreated couples with unexplained infertility falls to 40% and after 5 years to 20%.[99]

In recent years a number of prediction models for calculating individual chances of spontaneous conception in subfertile couples have been published.[297-299] The chance of conception over a given time frame can be calculated from the results of a number of fertility investigations and patient parameters such as age and duration of infertility. Caution is, however, required when applying a prediction model developed elsewhere to one's own patient population. Before a prediction model can be introduced into everyday clinical practice, prospective external validation is required. Furthermore, knowledge of the development cohort is important when selecting a model for application in one's own setting. The mean duration and degree of subfertility in a primary care population is less than in a tertiary population. As a result, the conclusions derived from models developed in academic centers may have limited relevance for primary subfertility management and vice versa.[99]

The majority of women undergoing ovulation induction have WHO class 2 anovulation. Although this is a highly heterogeneous group, the treatment for these women is the same.[300] The identification of patient characteristics predictive of ovulation induction outcome would allow the design of individual treatment regimens, and would provide useful information regarding the factors that determine the extent of ovarian dysfunction. In recent years a number of studies addressing these issues have been published. In one study the criteria that could predict the response of women with WHO class 2 anovulation to treatment with CC were identified.[122] Following multivariate analysis, the free androgen index (FAI), body mass index (BMI), presence of amenorrhea (as opposed to oligomenorrhea), and ovarian volume were found to be independent predictors of ovulation.[301] The area under the receiver operating curve in a prediction model using these factors was 0.82. By adding additional endocrine factors, the area under the curve increased to 0.86.[299] In a subsequent study, those factors which could predict conception following ovulation were studied. Multivariate analysis of a number of clinical, endocrine, and ultrasound characteristics revealed lower age and the presence of amenorrhea to be the only significant parameters for predicting conception. Initial LH levels were not found to be important. From these data, a nomogram was constructed[177] (Fig. 30.19) which may assist in the selection of patients for clomiphene therapy, and those for whom this first-line treatment will be of little value. In this latter group, early recourse to gonadotropin therapy is indicated [302]

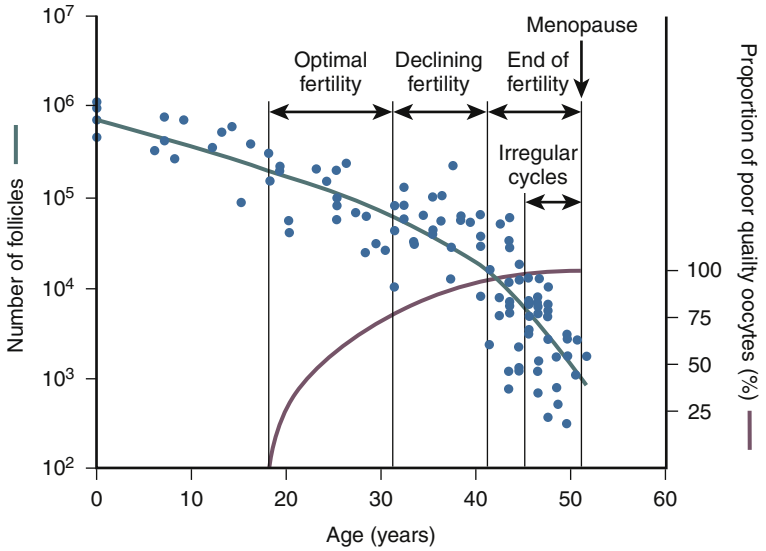

FIGURE 30.20 The decline in follicle number and the increase in poor-quality oocytes in relation to reproductive events with increasing female age. *(From Broekmans FJ, Knauff EA, te Velde ER, et al. Female reproductive ageing: current knowledge and future trends.* Trends Endocrinol Metab *18[2]:58–65, 2007.)*

When gonadotropin therapy for ovulation induction is selected, the duration of treatment, the amount of gonadotropins administered, the associated risks of cycle-to-cycle variability, multifollicular development, OHSS, and multiple pregnancy might all be reduced if the starting dose were individualized. This would require the means to reliably predict the dose of FSH at which a given individual will respond by way of monofollicular selection to dominance—in other words, their individual FSH threshold for stimulation. A prediction model has recently been developed which may be used to determine the individual FSH response dose (which is presumably closely related to the FSH threshold).[131] Women about to undergo low-dose step-up ovulation induction with recFSH, were subject to a standard clinical, sonographic, and endocrine screening. The measured parameters were analyzed for predictors of the FSH dose on the day of ovarian response. In multivariate analysis, BMI, ovarian response to preceding CC medication (CC-resistant anovulation [CRA], or failure to conceive despite ovulatory cycles), initial free insulin-like growth factor-I (free IGF-I), and serum FSH levels were included in the final model.[131] In a subsequent analysis of women with PCOS who had undergone ovulation induction with the step-down regimen, a correlation was observed between the predicted individual FSH response dose and the number of treatment days before dominance was observed.[302] Application of this model may enable the administration of the lowest possible daily dose of exogenous gonadotropins to surpass the individual FSH threshold of a given patient and achieve follicular development and subsequent ovulation. Refining ovulation induction therapy in this way offers the prospect of improving safety, reducing the risk of multiple pregnancies, and improving the efficiency of gonadotropin ovulation induction.

The ability to predict clinical outcome from ovulation induction with gonadotropins would also be of value in the individualization of treatment regimens. In a prediction model for outcome after FSH ovulation induction,[186] simple patient characteristics combined with endocrine factors were again shown to enable (limited) prediction of outcome following FSH ovulation induction.[303] The most important end point for ovulation induction is overall singleton live birth. Data are now available to allow the prediction of a given couple achieving this from conventional ovulation induction strategies over an extended period of time (Fig. 30.12).[55] This observation has been confirmed 10 years later.[302] Regarding IVF treatment, it appears that the most prominent factor determining outcome is the individual variability in ovarian response to stimulation. Rather than exhibiting the desired response, women can present with either a hyporesponse or a hyper-response to stimulation. Studies undertaken so far have been unable to demonstrate a beneficial effect of gonadotropin dose increase in patients who exhibit a poor response to standard dose regimens.[189,232] This may help in counseling the patient, because the chances of successful IVF in these women will be extremely low.

Poor ovarian response appears to be related to ovarian aging[191] and early menopause (Fig. 30.20).[192] In IVF, the association between poor ovarian response due to diminished ovarian reserve with cycle cancellation and poor success rates is well established.[304] Age is an important predictor of IVF outcome.[306] However, chronological age is poorly correlated with ovarian aging. A major individual variability exists in follicle pool depletion within the normal range of menopausal age, as complete follicle pool exhaustion may occur between 40 and 60 years of age. The quantity and quality of the primordial follicle pool diminishes with age, reducing ovarian reserve.[307] This results in a decline in both therapy-induced and spontaneous pregnancies.[308] However, some women older than 40 years of age will show a good response to ovarian stimulation and subsequently conceive with IVF, yet other women under 40 may fail to respond as a result of accelerated ovarian aging. In recent years, attention has been given to the identification of sensitive and specific markers for ovarian aging which may enable prediction of poor or good response. This would open the way to improved counseling and patient selection for IVF.

The first endocrine marker for ovarian reserve is the early follicular phase FSH level,[309] which has been shown to be an independent predictor to age of IVF outcome.[310] More recent studies have indicated that while FSH level

is a stronger predictor of cycle cancellation due to poor response and the number of oocytes collected at pick-up, age is more closely related to the chance of pregnancy.[310] In current practice, women with raised baseline FSH levels are usually advised against IVF treatment due to the anticipated poor outcome. However, although young women with high FSH levels demonstrate lower numbers of growing follicles and a high probability of cycle cancellation, normal ongoing pregnancy rates may be observed if oocytes and embryos are obtained.[310] Older women (older than 40 years old) with normal baseline FSH levels may demonstrate lower cancellation rates, but the implantation rate per embryo and the ongoing pregnancy rates are lower than those observed in young women with elevated FSH.[310] FSH has been suggested to be of greater value in predicting ovarian reserve than other ovarian markers such as inhibin B. However, in a meta-analysis, baseline FSH levels showed only a moderate predictive performance for poor response and a low predictive performance for nonpregnancy was observed.[311] Other markers may therefore have an adjunctive value when diagnosing diminished ovarian reserve. The ultrasound measurement of the number of antral follicles present on cycle day 3 has been shown in a number of studies to predict poor ovarian reponse. Addition of basal FSH and inhibin B levels to a logistic model with the antral follicle count appears to further improve the performance of this marker.[312] At present no single reliable marker for ovarian reserve has been identified.[310] Anti-müllerian hormone (AMH), a member of the transforming growth factor-β superfamily, has been proposed as another candidate in this context. It is produced by granulosa cells of growing preantral and small antral follicles and is directly involved in primordial follicle pool depletion in the rat. Serum levels decline with age[313] and recent studies have shown that poor reponse to IVF can be predicted by reduced baseline serum AMH concentrations.[310] Additional research firmly established AMH as the most useful marker for ovarian response prediction and individualized gonadotropin dosing.[313,314]

To some extent, women likely to present with a reduced response to ovarian stimulation can be predicted, but hyper-response (and the threat of OHSS) comes as a surprise in the great majority of cases. It is uncertain, as yet, which patients are likely to present with hyper-response (at risk for OHSS).[206] Early recognition of women at risk may give rise to effective, altered stimulation protocols and improved safety.[187]

The use of nomograms for individualising FSH dose for ovarian stimulation in IVF may optimize the risk to benefit dose of FSH in IVF. In recent years, several models have been developed based on multiple regression analysis.[315,316] Factors consistently observed to be predictive of the number of oocytes obtained were age, the total number of antral follicles, and smoking status.[317] Others have suggested that ovarian volume and and blood flow as measured by Doppler ultrasound are predictive factors.[312] A model combining all these factors has been developed to prescribe the optimal dose of rFSH that will yield 5 to 14 oocytes.[315] In a prospective randomized study, the application of this model increased the proportion of "appropriate ovarian responses" and decreased the need for dose adjustments during ovarian stimulation.[316]

In those who do respond to ovarian hyperstimulation for IVF and for whom embryos are available for transfer, individualizing treatment in order to optimize outcomes should involve consideration of the number of embryos to be transferred. As stated earlier, although a trend toward the transfer of fewer embryos is now clear, fear of a lower chance of pregnancy may discourage couples and their physicians from transferring two embryos or less. This applies particularly when single embryo transfer is being considered. The ability to identify those treatment cycles in which single embryo transfer would avoid the risk of twin pregnancy without reducing the chance of achieving a singleton pregnancy would certainly encourage the adoption of single embryo transfer into clinical practice. In recent years, a number of authors have tried to identify those factors that may predict the chance of birth and of multiple birth on the basis of key characteristics of the patient, the cycle, and the embryos available for transfer.[75, 318] Important determining factors thus far identified include the age of the woman, the duration of infertility, and the number of oocytes obtained following ovarian hyperstimulation. We have previously developed a prediction model to allow the chance of pregnancy and twin pregnancy to be assessed in a given transfer cycle should one or two embryos be transferred.[88] Application of this model allows a subgroup of young patients with good quality embryos to be identified for whom applying single embryo transfer could drastically diminish the twin rate without compromising singleton pregnancy rates.

As with models designed to predict spontaneous pregnancy, untested models for predicting IVF outcome can show a disappointing performance when used on patients from a different but plausibly similar population.[319] Therefore, before such a model can be applied in clinical practice, its reliability in predicting the selected outcomes should be validated on a different population to that on which it was developed. External validation of our model has demonstrated that it may be applied in different populations following a simple calibration process to adjust for local success rates.[89]

Health Economics of Ovarian Stimulation

Although a tendency to increased IVF consumption can be observed every year, IVF or IUI should not be routinely applied for all kinds of infertility problems. Assisted reproduction should not replace a proper infertility workup. A recent meta analysis involving six RCTs concluded that the effectiveness of IVF for unexplained infertility remains questionable.[320] Moreover, the economic implications of a more widespread use of assisted reproduction should be considered seriously when making decisions regarding treatment.[321,322]

The diagnosis by exclusion of unexplained infertility and subfertility is made in around 30% of couples in whom conventional diagnostic tests are normal. The prognosis for conception significantly decreases when the duration of infertility is at least 3 years along with an advanced female age beyond 35.[298] Again, chances of spontaneous conception are usually underestimated both by the doctor and the patient.[99] On the other hand, it appears that high costs prevent many couples with an indication for this treatment modality from undergoing IVF (i.e., undertreatment due to insufficient access to ART services). Data from the United States suggest that in states where IVF is not covered, only

one third of couples with a valid indication for IVF actually undergo treatment.[291] Moreover, IVF is available in only 25% of the countries worldwide.[322] In contrast, in a commercial environment couples may be exposed to risks associated with assisted reproduction too early (i.e., overtreatment under conditions in which expectant management might have been more appropriate). Indeed, in various European countries such as France, The Netherlands, and Sweden where IVF is covered by health insurance, a threefold higher use of IVF per capita compared to the United States can be observed.[323]

Cost-effective health care involves the achievement of a desired treatment goal at the lowest possible expenditure. IVF cost effectiveness should assess costs per live birth. So far, calculations of costs per live birth have only included direct costs related to neonatal care. The inclusion of indirect costs (i.e., including midterm and long-term health sequelae such as mental retardation, cerebral palsy, and learning disabilities) would presumably double the overall costs.

The financial consequences of multiple pregnancies are substantial for both parents and healthcare providers. However, the economic impact of a multiple pregnancy is not limited to increased costs of maternal hospitalization and obstetric and neonatal (intensive) care. Lifetime costs for chronic medical care, rehabilitation, and special education related to extreme prematurity must also be taken into account. For a low-birth-weight child, the average cost of heathcare and education up to the age of 8 years is seventeenfold higher than the costs for a normal birth weight child.[324] It has also been shown that multiple births contribute disproportionately to hospital inpatient costs, especially during the child's first year of life.[325]

Because of the limited use of ovarian stimulating medication, the per cycle costs of mild stimulation IVF cycles will be lower than conventional stimulation approaches. However, to analyze the cost effectiveness of mild stimulation, the total cost per live birth should be analyzed. Besides the costs for medication, medical consultations and visits, laboratory charges (general, hormone, and embryology), ultrasound procedures, IVF procedures (oocyte retrieval and embryo transfer), hospital charges, nurse coordinator costs, administrative charges, fees for anesthesia, costs for complications, travel expenses, and lost wages should be taken into account.[322]

Those who advocate milder strategies in IVF point to recent studies that show that the costs for IVF per year of treatment are comparable with conventional stimulation approaches, and the costs for the pregnancy and neonatal period are significantly lower following mild stimulation and single embryo transfer.[326]

Conclusions and Future Perspective

Any form of ovarian stimulation increases chances of pregnancy per cycle but at the expense of increased complication rates, most importantly multiple pregnancies (Fig. 30.8) and OHSS. This holds especially true for ovarian hyperstimulation aiming at maturing multiple dominant follicles for fertilization either *in vivo* (following intercourse or IUI) or *in vitro* by IVF. With IVF, the incidence of occurring multiple pregnancies can be controlled by the number of embryos transferred. Moreover, various strategies may significantly reduce chances for OHSS. In skillful hands and with proper ovarian response monitoring, chances for complications are lowest for ovulation induction. The aim of this intervention is to mimic physiological circumstances in anovulatory women, hence, single dominant follicle development and ovulation.

Special care should also be taken to carry out a proper infertility workup in order to diagnose other treatable infertility factors. This will also allow a proper assessment to be made of pregnancy chances for a given couple, either spontaneously or after infertility therapies. Along these lines, only patients with a proper indication will be exposed to the discomfort, risks, and costs associated with assisted reproduction and ovarian hyperstimulation.

Milder forms of ovarian hyperstimulation (or indeed none at all) may be considered for empirical treatment of unknown infertility (with or without IUI) due to the inherent risk of higher order multiple pregnancies. In general, however, the price to pay is a slightly lower pregnancy rate per cycle. Overall, assessment of cumulative pregnancy rates over a given period of time (which may involve multiple cycles) may be similar.

A trend can be observed toward hyperstimulation and assisted reproduction as first-line treatment in anovulatory infertility, especially PCOS. This shift in clinical practice is not based on sound scientific evidence. In fact, healthy live birth rates from conventional ovulation induction strategies are good, with acceptable rate of multiple pregnancies and OHSS.[64] Newly introduced compounds to the field of ovulation induction such as insulin sensitizers and aromatase inhibitors may further improve outcomes.

With regard to IVF, many new treatment modalities have been introduced over the years without proper preceding evaluation for efficacy and safety. The current most profound clinical challenge is to find the right balance between improving chances for success coinciding with an acceptable complication rate. The paradigm of so-called "controlled" ovarian hyperstimulation using maximum stimulation by exogenous gonadotropins together with the GnRH agonist long protocol has been taken for granted for more than a decade. Potential detrimental effects of this approach with regard to patient discomfort and safety, oocyte quality, corpus luteum function, and endometrial receptivity have been largely ignored. Large numbers of preovulatory follicles and oocytes subsequently retrieved have been applied as useful surrogate outcome parameters for successul IVF.[280] Maximum ovarian stimulation along with the transfer of large numbers of embryos in an attempt to maximize pregnancy rates per IVF cycle may by itself have a major impact on patient dropout rates, costs, and overall IVF outcome and should therefore be considered seriously. The introduction of GnRH antagonists allows for a careful reevaluation of current IVF strategies. We can now render stimulation protocols simpler, starting with a spontaneous menstrual cycle, allowing for more subtle interference with dominant follicle selection. Final stages of oocyte maturation can now also be stimulated, applying different drugs and strategies for the induction of an endogenous LH surge. Finally, effects of these altered follicular phase interventions on corpus luteum function and endometrial development (important for embryo implantation) should be assessed.

Especially in the light of a continued trend worldwide to reduce the number of embryos transferred, novel approaches of mild ovarian stimulation or even natural cycle IVF deserve reevaluation. It does not seem logical to stimulate the ovary profoundly in order to generate numerous embryos in case the aim is to transfer only one or two of them. Moreover, the possible relationship between quantity of oocytes stimulated and quality (i.e., genetic competence) of embryos obtained[295] should be studied in greater detail. Finally, in the light of a reduced number of fresh embryos being transferred, the continuing improvement of techniques to cryopreserve supernumerary embryos such as vitrification (allowing couples additional pregnancy chances without having to go through ovarian stimulation and oocyte retrieval) seems of pivotal significance.

Individualizing ovarian stimulation in order to optimize outcomes between risks and desired outcomes is likely to improve in the future with the development of pharmacogenetics. Clinical studies have shown that FSH receptor gene polymorphisms influence the ovarian response to stimulation in women undergoing IVF,[327] raising the possibility that genotyping could aid in tailoring FSH dosing based on individual ovarian sensitivity.[278]

Choosing the "best" embryo for transfer is still problematic, because the assessment of embryo morphology is still crude and inaccurate. More information is urgently needed regarding randomized controlled trials replacing a single embryo with or without preimplantation genetic aneuploidy screening. The paradigm of measuring success in terms of positive pregnancy test per IVF retrieval or transfer treatment should shift in future studies to take into account the balance between the chance of a healthy live (singleton) birth per started IVF treatment, which may involve multiple cycles in relation to risks and complications, patient discomfort, and costs.[101] Fortunately, large IVF centers now begin to report their cumulative IVF outcomes, independent from the number of cycles performed.[328-330] The health economics evaluation of IVF should be no different from other complex medical interventions. In this context, the impact of ovarian stimulation on embryo quality, corpus luteum function, and endometrial receptivity should be studied in greater detail.

CHAPTER 31

Assisted Reproduction

Elizabeth S. Ginsburg
Catherine Racowsky

The essence of mammalian reproduction is the fusion of a sperm and an egg resulting in a conceptus, which can grow and differentiate into a new organism. Mammalian reproduction is an efficient process that typically occurs entirely within the bodies of the male and female partners and requires no intervention or assistance from a third party. The essence of *assisted reproduction* is that a third party, the reproductive biologist, directly handles the oocyte and sperm to enhance the probability of achieving a pregnancy. In general, at least part of the manipulation of the sperm and oocyte occurs outside the body of the male and female partners.

Many techniques are currently utilized that involve manipulation of oocytes, sperm, and embryos to improve the probability of a successful outcome. *In vitro* fertilization and embryo transfer (IVF-ET) is the most commonly performed assisted reproductive technology (ART) procedure, involving the culture of aspirated oocytes and spermatozoa *in vitro*, followed by the transcervical replacement of the resulting embryo(s) into the uterine cavity. One variation of IVF-ET is intracytoplasmic sperm injection (ICSI), in which fertilization is achieved by injection of a sperm into the oocyte. In contrast, gamete intrafallopian tube transfer (GIFT) is the direct placement of aspirated oocytes and prepared spermatozoa into the fallopian tube, and zygote intrafallopian tube transfer (ZIFT) entails the laboratory culture of aspirated oocytes with spermatozoa followed by the direct placement of zygotes into the fallopian tubes. GIFT and ZIFT are rarely performed any more because live birth rates are higher with IVF. Therefore, this chapter focuses on IVF-ET, use of donor gametes, gestational carriers, and cryopreservation of embryos, and their indications, implementation. These techniques, along with intracytoplasmic sperm injection (ICSI) and other manipulation of gametes and embryos discussed in Chapter 32, are collectively referred to as the ARTs.

Assisted reproduction is more than 110 years old, with the first successful transfer of embryos from a donor to a recipient rabbit being achieved by Heape in 1890.[1] In 1959, Chang[2] successfully fertilized a rabbit oocyte *in vitro*. In the human, successful capacitation of sperm *in vitro* and the fertilization of human oocytes matured *in vitro*[3] were followed by the insight that preovulatory oocytes were optimal for *in vitro* fertilization.[4] These exploratory steps culminated in 1978 with a term birth resulting from the *in vitro* fertilization of a single preovulatory human oocyte obtained from a natural menstrual cycle, transferred to the uterus at the eight-cell stage.[5] Assisted reproduction is the jewel in the crown of reproductive medicine. It is one of the best examples in reproductive medicine of the transfer of knowledge obtained by laboratory scientists to an application that treats human disease. Assisted reproduction is a vast field encompassing both the sublime secrets of how two haploid cells combine to create a diploid zygote that contains all the information necessary to grow and develop into a complex mammal, and the pragmatically empirical application of the technology to treat infertility. As assisted reproduction becomes the standard treatment for infertility, the pace of knowledge transfer from bench to bedside is increasing, challenging our concepts of self, family, and society.

In sexual reproduction, unique haploid cells fuse at fertilization to form a diploid cell that divides to form daughter cells that undergo multiple subsequent divisions, and subsequent differentiation to develop into an entire organism. In turn, some diploid progenitor cells divide by the process of meiosis to produce unique haploid cells that can fuse to yield a new, totally unique diploid organism.

Sexual reproduction has two processes that maximize diversity in a species. One crucial process is that diploid cells give rise to unique haploid cells through genetic recombination between homologous chromosomes during meiosis. Exchange of genetic material between maternally and paternally derived chromosomes markedly increases the genetic diversity of the resultant haploid cells (Figs. 31.1 and 31.2). One theoretical advantage of sexual reproduction is that the process of meiosis permits the random recombination of genetic material, thereby increasing the range of traits displayed by members of the species. This diversity increases the chances of success of the species in adapting to an ever-changing environment. A second process of sexual reproduction is that the haploid cells fuse during fertilization to form a new and unique diploid cell. The single-cell diploid zygote has all the genetic information necessary to grow and develop into an adult organism.

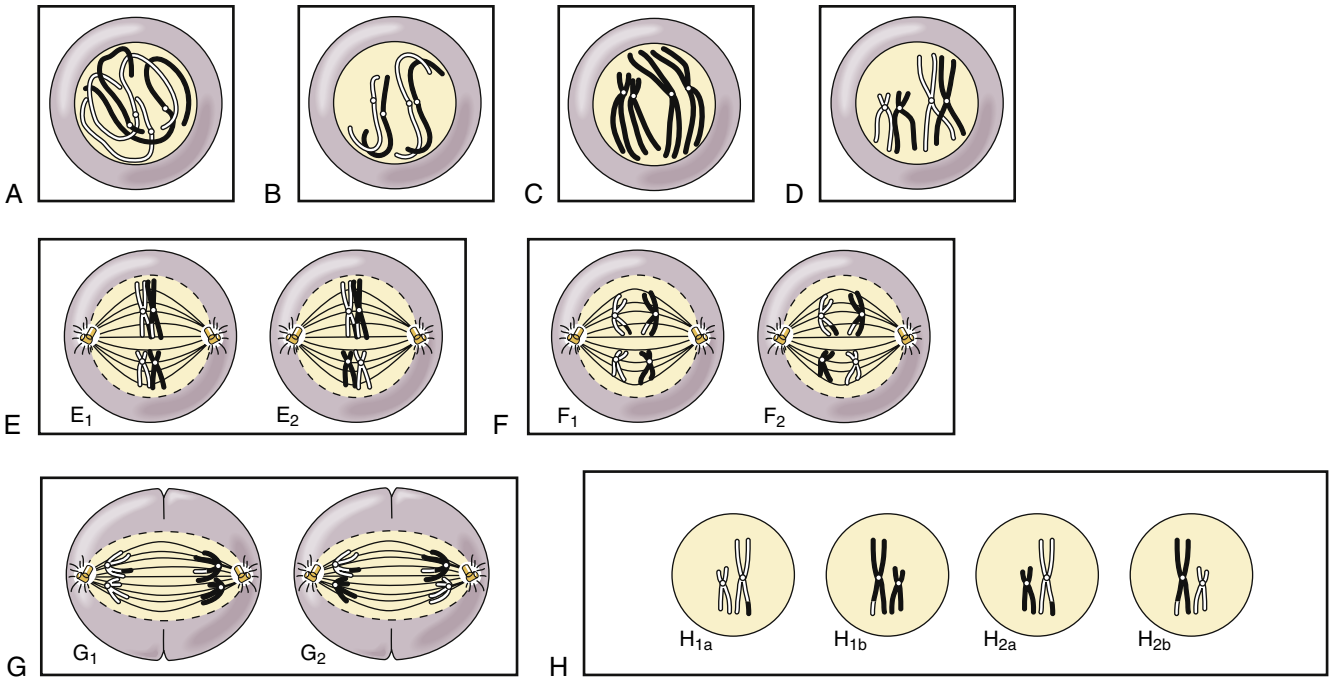

FIGURE 31.1 The first meiotic division. Two of the 23 chromosome pairs are shown to simplify the presentation. Chromosomes from the maternal source are shown in outline, chromosomes from the paternal source are shown in solid color. **A,** Leptotene. **B,** Zygotene. **C,** Pachytene. **D,** Diplotene. **E,** Metaphase (E_1, and E_2). **F,** Early anaphase (F_1, and F_2). **G,** Late anaphase (G_1 and G_2). **H,** Telophase (H_1 and H_2). One set of distributions of chromosome pairs is delineated in E_1 through H_1, an alternative combination in E_2 through H_2. Homologous recombination and random segregation increase the diversity of genetic material passed to the gametes. *(From Thompson JS, Thompson MW.* Genetics in Medicine. *Philadelphia, WB Saunders, 1986, p 19.)*

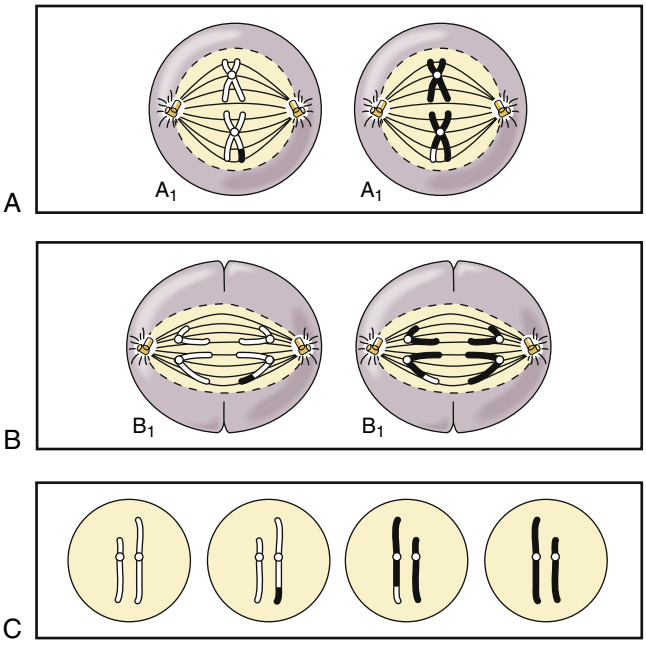

FIGURE 31.2 The second meiotic division. **A,** Metaphase. **B,** Anaphase. **C,** Telophase. A_1 and A_2 represent H_{1a} and H_{1b} from *Figure 31.1*. *(From Thompson JS, Thompson MW.* Genetics in Medicine. *Philadelphia, WB Saunders, 1986, p 20.)*

The Gametes

In most species that reproduce by sexual reproduction, two types of gametes are produced. The egg, or ovum, is large and nonmotile. The sperm or spermatozoa are small and motile. The developing egg is referred to as an *oocyte* and is one of the largest cells in the body. A mature human oocyte measures approximately 110 μm in diameter.[6] By contrast, the diameter of a human sperm head is 2 to 3 μm.[7] In some species, the oocyte is totipotent; once stimulated by artificial means, it can give rise to an entire adult organism. Such an artifical stimulus can occur by mechanical activation or chemical stimulation[8] and is called parthenogenesis.

The generation of the germ cells is achieved through meiosis (Figs. 31.1 and 31.2). During meiosis, duplication of diploid deoxyribonucleic acid (DNA) in the progenitor cell is followed by two successive cell divisions, which result in derivative packets of haploid DNA. As the progenitor cell enters prophase I, each duplicated chromosome consists of two joined sister chromatids; homologous chromosomes align in bivalents and genetic recombination occurs. In the first meiotic division, one homologue (consisting of linked sister chromatids) of each chromosome pair is distributed to each daughter cell (Fig. 31.1). No DNA replication occurs in the second meiotic division, and the strands of the sister chromatids are separated to the derivative haploid cells (Fig. 31.2).

The Oocyte

The process of formation of oocytes, known as *oogenesis*, begins when the primordial germ cells migrate into the

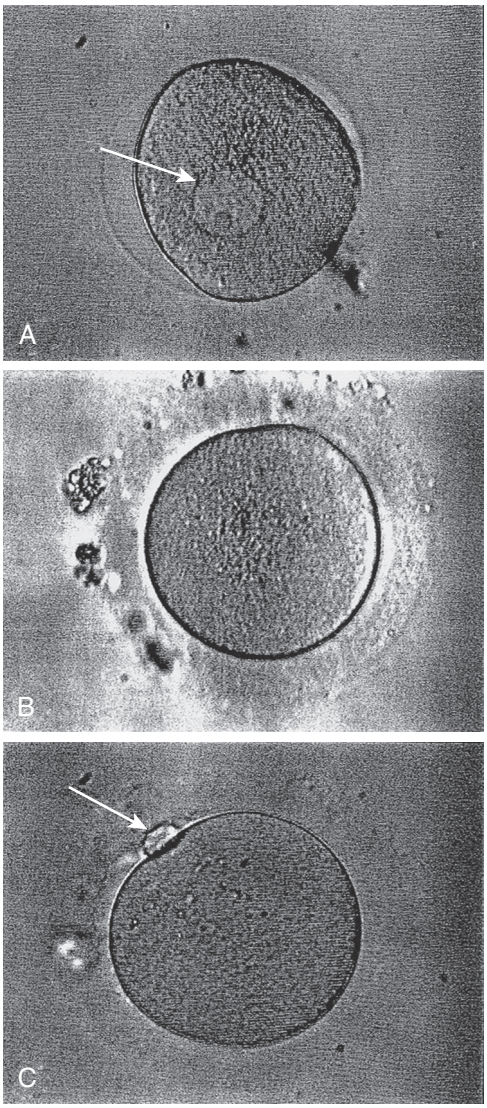

FIGURE 31.3 Oocytes at the three most commonly observed stages of meiotic maturation. **A,** Oocyte at the germinal vesicle (GV) stage; note the nucleus with its characteristic single nucleolus *(arrow)* and granular cytoplasm. **B,** Oocyte at metaphase I; note the absence of both a nucleus and a polar body and less granular cytoplasm compared with the GV-stage oocyte. **C,** Oocyte at metaphase II; note the presence of the first polar body *(arrow)* and the smooth cytoplasm. *(All photos courtesy of Dr. Gena Ratiu, Brigham and Women's Hospital ART Laboratory, Boston, MA.)*

embryonic gonad and become *oogonia* (see Chapter 8). The oogonia proliferate by mitotic division, become invested with a single layer of granulosa cells, and differentiate into primary oocytes. The primary oocyte duplicates its complement of DNA, enters the meiotic process, reaches diplotene of prophase I of meiosis, and then enters a state of prolonged meiotic arrest or "hibernation." Such an arrested so-called germinal vesicle (GV) stage oocyte (Fig. 31.3A), synthesizes a coat of glycoproteins, the *zona pellucida*, and remains arrested until the follicle in which it is enclosed either degenerates (atresia) or is recruited into the pool of growing follicles and ultimately is selected to become the dominant follicle. Under the influence of the luteinizing hormone (LH) surge, the fully grown GV-stage oocyte in the dominant follicle resumes meiosis to progress through metaphase I (Fig. 31.3B) and anaphase I, to reach telophase I. Upon extrusion of the first polar body at telophase I, the oocyte completes meiosis I to become a secondary oocyte. The secondary oocyte then rapidly proceeds to metaphase II of meiosis (Fig. 31.3C) to complete the so-called process of "meiotic maturation." Completion of meiotic maturation takes approximately 36 hours. The oocyte is ovulated at metaphase II, the stage at which it awaits subsequent fertilization. The progression through meiotic maturation from prophase I to metaphase II, and then to telophase II following fertilization, is shown diagrammatically in Figure 31.4.

A normal mature haploid human oocyte has a complement of 23 chromosomes. However, meiotic errors occur resulting in a high incidence of aneuploid oocytes. Such errors typically occur during the first meiotic division and involve a variety of mis-segregations including nondysjunction of homologous chromosomes and predivision of sister chromatids.[9] Resulting oocytes either possess too few chromosome copies and are referred to as hypohaploid, or have too many copies and are termed hyperhaploid. Maternal age is the main factor associated with the occurrence of aneuploidy[10,11] which, in turn, accounts for the majority of failed conceptions (reviewed by Hassold and colleagues[12]). The root cause of such age-related aneuploidy appears to relate to abnormalities in morphology of the meiotic spindle,[13] as well as a decrease in chromosome cohesion caused by an increase in inter-kinetochore distance between sister chromatids.[14]

Regardless of chromosome number, an oocyte that has reached metaphase II (i.e., completed nuclear maturation) has not necessarily achieved cytoplasmic maturation. Although the molecular processes underlying acquisition of cytoplasmic maturity remain poorly understood, it is clear that cytoplasmic maturation is critical for the oocyte to

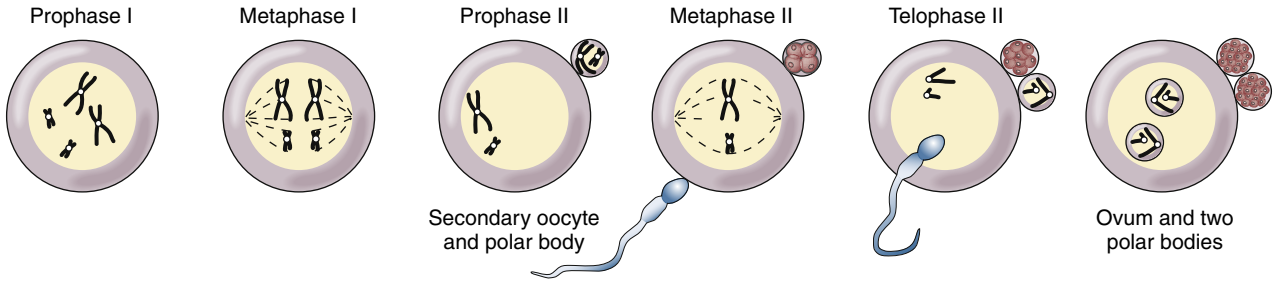

FIGURE 31.4 Stages of meiotic maturation and completion of the second meiotic division after fertilization. *(From Thompson JS, Thompson MW.* Genetics in Medicine. *Philadelphia, WB Saunders, 1986, p 23.)*

undergo "activation" at fertilization. Inadequate or absent oocyte activation leads to fertilization failure and/or abnormal syngamy and early developmental programming.[15]

The Sperm

In contrast to the egg, sperm are among the smallest cells in mammals. Sperm are highly specialized for the sole purpose of transporting DNA to an oocyte. Sperm consist of four key functional components:

1. The acrosome which contains enzymes that aid in digesting and penetrating the cumulus oophorus.
2. The nucleus which contains highly compacted DNA.
3. The midpiece, which includes the centrosome that is key in human embryogenesis, as well as mitochondria which provide the energy source for sperm.
4. The tail, which contains the axoneme and the dynein motor proteins.

To maximize transport efficiency, the sperm has no ribosomes, endoplasmic reticulum, or Golgi apparatus. However, small ribonucleic acids (RNAs) are transported within the sperm and may have a role in embryogenesis.[16]

Spermatogenesis differs significantly from oogenesis (Fig. 31.5) (see Chapter 13). In the embryo, primordial germ cells migrate to the testis and enter a state of arrest until puberty. Under the influence of testosterone and other hormones, the spermatogonia divide mitotically and generate two pools of derivative cells. The cells of one pool continue to divide mitotically and serve as the spermatogonial stem cells. The second pool of cells will enter meiosis and become primary spermatocytes (46 duplicated chromosomes in human). The primary spermatocytes proceed through the first meiotic division and then become secondary spermatocytes (22 duplicated autosomal chromosomes, plus a duplicated X chromosome or a duplicated Y chromosome). After the second meiotic division, the secondary spermatocytes become spermatids (haploid number of single chromosomes), which then differentiate into mature sperm. The process of meiotic reduction of the spermatogonia, as well as maturation of the spermatids (spermiogenesis), occurs inside the seminiferous tubule, with the precursor cells located at the outer border of the tubule and the mature sperm in the lumen of the tubule. The developing sperm cells undergo nuclear division but do not complete cytoplasmic division until near the end of sperm differentiation (see Fig. 31.5). Consequently, the developing germ cells are connected by cytoplasmic bridges in a syncytium, which allows the diploid spermatogonium to produce proteins and cellular materials for the haploid sperm.

Upon entry into the epididymis, the sperm undergo sequential steps of differentiation, largely related to the acquisition of motility, and the ability to bind to and penetrate the oocyte. Recent proteomic studies have revealed specific epididymal proteins thought to be directly related to these sperm maturation processes, and differences in the epididymal proteome have been reported in infertile men.[17,18] Thus, sperm from the caput epididymis are generally unable to undergo natural fertilization, but gain the ability to fertilize by the time they reach the cauda epididymis.

During ejaculation, the sperm are exposed to stabilizing factors from the seminal fluid that preclude the ability of the sperm to undergo the acrosome reaction. The sperm undergo a process of "capacitation" as they progress through the female reproductive tract that includes removal of cholesterol from the membranes and an influx of calcium, ultimately resulting in hyperactive motility, the ability to undergo the acrosome reaction in response to the zona pellucida proteins of the oocyte plasma membrane.[19] Sperm capacitation can be facilitated in the laboratory prior to ART or artificial insemination by sperm processing methods that remove the sperm from seminal plasma.[20] Defects of capacitation have been associated with male infertility.[21]

Sperm penetrate the cumulus cell layers surrounding the egg through their hyperactivated motility which is induced by cumulus cell progesterone secretion.[22] The sperm motility and hyaluronidase secretion allow the sperm to move through the cumulus extracellular matrix to reach the zona pellucida. On reaching the zona pellucida, the capacitated sperm then undergo the *acrosome reaction*, a process that is essential for fertilization. The acrosome is a large secretory cap on the sperm head that contains proteases and hyaluronidases. In the acrosome reaction, the outer acrosome membrane fuses with the plasma membrane of the sperm and the contents of the acrosome are emptied. In many

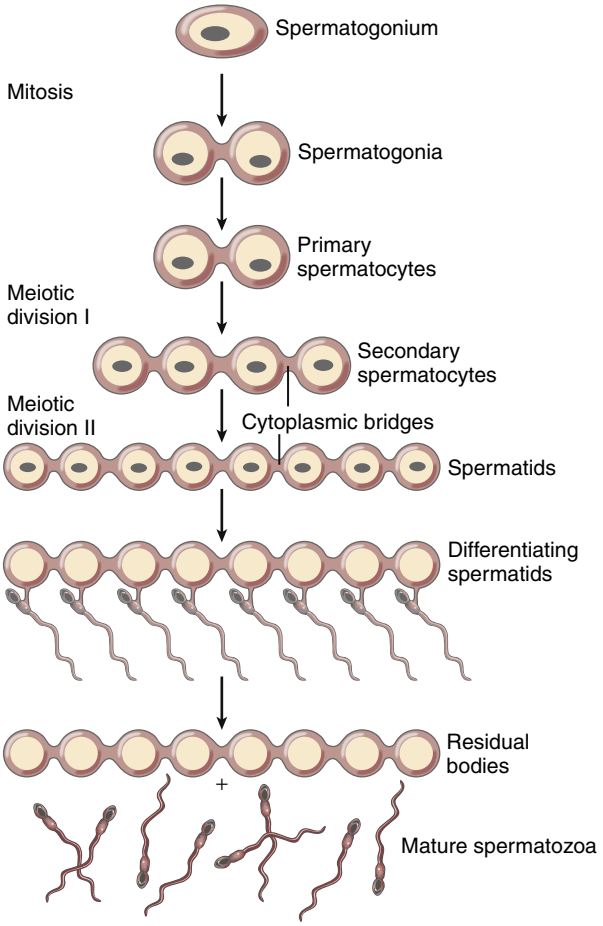

FIGURE 31.5 The progeny of a single maturing spermatogonium remain connected to each other by cytoplasmic bridges. The cytoplasmic bridges allow the spermatids to receive proteins from the parent cell apparatus without bearing the burden of protein machinery (e.g., endoplasmic reticulum). *(Redrawn from Alberts B, Bray D, Lewis J, et al.* Molecular Biology of the Cell. *New York, Garland Publishing, 1994, p W31.)*

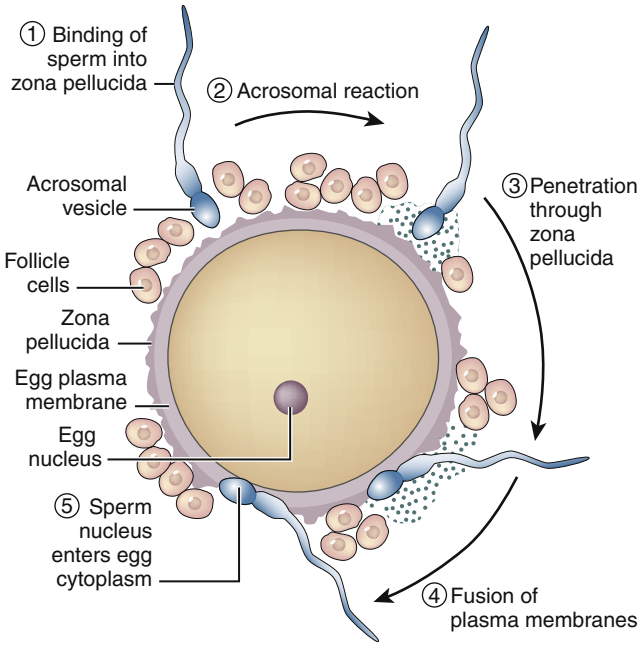

FIGURE 31.6 Key steps in the process of fertilization. *Step 1,* binding of sperm to zona pellucida involves zona protein ZP3 and a sperm protein, probably a carbohydrate-binding protein such as 1,4-galactosidase. *Step 2,* acrosome reaction. *Step 3,* penetration of sperm through zona pellucida. *Step 4,* fusion of plasma membranes of sperm and oocyte. Depolarization of oocyte membrane and secretion of cortical granules—the primary and secondary blocks to polyspermy. *Step 5,* sperm nucleus enters egg cytoplasm. *(Redrawn from Alberts B, Bray D, Lewis J, et al.* Molecular Biology of the Cell. *New York, Garland Publishing, 1994, p 1031.)*

species, the acrosome reaction is initiated by the glycoproteins of the zona pellucida[23,24] and can be accelerated by progesterone.[25-27]

Fertilization

The process of fertilization involves at least two key initial steps: interaction and penetration of the zona pellucida by the sperm, followed by fusion of the sperm and oocyte membranes (Fig. 31.6). Although the mechanisms that allow the human sperm and zona pellucida of the oocyte to interact are not fully characterized, use of antibodies and antagonists to candidate molecules has greatly advanced understanding in this area.[28] Prevailing data suggest that a dynamic array of zona pellucida receptor-sperm ligand interactions regulate sperm-zona binding.[28] In mouse, the zona pellucida contains three glycoproteins (ZP1, ZP2, and ZP3)[29] but the human zona has a fourth glycoprotein, ZP4.[30] ZP2 and ZP3 have a filament structure, and ZP1 appears to link ZP2 and ZP3 in a complex three-dimensional array, for the absence of either ZP2 or ZP3 prevents assembly of the zona matrix.[31] In the human, capacitated sperm can be induced to undergo the acrosome reaction by ZP1, ZP2, and ZP4, although downstream signaling events may be different with ZP3 compared to ZP1 or ZP4.[32] In an early study, purified ZP3 blocked the ability of sperm to bind to the oocyte zona pellucida in a dose-dependent manner, implying that ZP3 is the zona pellucida sperm receptor,[33] and data from several other studies have implied that O-linked carbohydrate moieties underly the interaction of ZP3 and the sperm receptor.[34] Recently, the nature of this carbohydrate ligand has been further identified as the sialyl-Lewis sequence, a member of the selectin family.[35] Nevertheless, the biological complexity of the sperm-egg recognition process appears to reflect participation by a series of sperm proteins,[28] and involve sperm binding to both ZP1, ZP3, and ZP4, but not ZP2, which appears to only bind previously acrosome-reacted sperm.[32]

The search for the sperm receptor to the ZPs has been difficult, and it appears that since knock-out studies of putative receptors have generally not precluded binding, there is likely a small number of proteins on the sperm surface that appear to be responsible for interaction with ZP3.[28] These proteins include fertilin,[36] galactosyltransferase, and cyritestin. βl,4-Galactosyltransferase on the sperm surface appears to be important for the ZP3-induced acrosome reaction.[37] Fertilin and cyritestin are members of the ADAM (*a d*isintegrin *a*nd *m*etalloprotease) family of proteins, which can bind to integrins but also have proteolytic activity. The sperm of mice lacking cyritestin (ADAM3) have defective binding to the zona pellucida.[38] Fertilin, a heterodimeric sperm surface protein composed of α and β subunits, was originally thought to be involved in fusion of sperm with the egg plasma membrane (the oolemma). However, mice lacking fertilin β (ADAM2) show defects in zona binding.[39] More recent studies have implicated involvement of a new candidate enzyme, mouse sperm lysozyme-like protein (mSLLP1), in sperm-oolemmal binding.[40] This protein is located in the equatorial segment of acrosome-reacted sperm in both mouse and human, and appears to bind to the entire oolemma except in that region where sperm normally do not bind, overlying the meiotic spindle.[40]

The roles of ZP3 and the galactosyltransferase and ADAM proteins in fertilization in the human are not fully characterized. Studies suggest that some metaphase II oocytes that fail to be fertilized have reduced ZP3 levels as determined by immunohistochemistry.[41] Another egg protein that is essential for successful fertilization is CD9, a member of the tetraspanin family. In mouse eggs lacking this oolemma protein, sperm-egg fusion fails to occur, resulting in infertility.[42]

After completion of the acrosome reaction, the sperm lose their affinity for ZP3,[43] and the continued attachment of the sperm to the oocyte appears to be dependent on ZP2.[44] The sperm penetrates the zona pellucida, in part, by the forward mechanical thrust provided by the flagellum, but likely is also dependent on the release of hydrolytic enzymes secreted by the acrosome, including the acrosomal 26S proteasome, that causes disruption of the continuity of the zona pellucida.[45,46]

Sperm binding and fusion to the oolemma is believed to be a complex process, possibly involving more than one receptor to sperm acrosomal proteins.[47,48] Once the sperm fuses with the oolemma, a depolarization of the oolemma occurs that acts as the primary block to polyspermy. Shortly thereafter, the inositol phospholipid cell-signaling pathway is activated and submembrane cortical granules release their contents.[49] The contents of the cortical granules change the glycoprotein coat of the zona pellucida, preventing sperm binding by hydrolyzing the oligosaccharides of ZP3 and by the proteolytic cleavage of ZP2. In the mouse at least, this proteolytic cleavage is achieved by exocytosis of the cortical

granule metalloendoprotease, ovastacin.[50] This process creates a secondary block to polyspermy.

After fusion of the sperm with the oolemma, the sperm phospholipase C (PLC) isoform PLC-zeta mobilizes the Ca^{2+} signal that induces egg activation and embryo development, with a tight association reported between the type of calcium oscillations and embryo development.[51,52] Accordingly, abnormalities in PLC-zeta negatively affect fertilization rates and possibly embryo development, confirming the key role of this factor in triggering oocyte activation. This finding suggests that certain types of infertility could be caused by failure of the sperm cell to properly activate the oocyte due to a defective PLC-zeta factor.[53-55]

Recent studies have begun to demonstrate the important role that sperm may play in post-fertilization events. Once in the oocyte, sperm chromatin and DNA integrity are necessary to ensure normal embryo development.[56,57] It is now clear that DNA damage in spermatozoa, in the form of single and double-stranded DNA breaks, has a negative influence on blastocyst development and ICSI outcome.[58] However, there is a strong need to standardize the specific tests used to quantify the extent of DNA damage.[56] Similarly, centrosome integrity is critical for successful fertilization and embryo development, and data indicate that the replacement of defective centrosomes, which are responsible for specific forms of male infertility, with functional donor sperm centrosomes can restore normal functionality.[59,60]

A great deal of research has recently emerged providing insight regarding the sperm epigenome and its potential role in early embryonic developmental programming.[61] Varying epigenetic modifications of the sperm genome occur, including histone retention and modification, DNA methylation and protamine incorporation into the chromatin.[57] Sperm from some infertile patients show different patterns of epigenetic marking compared with fertile men, particularly at certain imprinted and developmental loci.[62-64]

The sperm cell also contains various forms of RNA, (e.g., mRNA, miRNA, siRNA)[57,65,66] as well as more than 2000 proteins with unknown roles. Data are emerging which indicate that sperm-derived micro RNAs may be involved in normal embryogenesis.[16]

The Early Conceptus and Implantation

Sperm penetration into the oocyte triggers the oocyte to complete meiosis by rapid progression from metaphase II to telophase II. Telophase II is characterized by elimination of one of the sister chromatids of each chromosome through extrusion of the second polar body. The retained set of oocyte chromatids undergoes decondensation, followed by decondensation of the set of sperm chromatids, each to form a pronucleus. The zygote is therefore characterized by the presence of two pronuclei and two polar bodies (Fig. 31.7A). Following migration to the center of the oocyte, and then apposition of the two pronuclei, pronuclear membrane breakdown occurs, the maternal and paternal chromosomes intermingle at syngamy, and the diploid zygote is formed. Shortly thereafter, the chromosomes undergo condensation and the paired homologues (one maternal and one paternal) align on the metaphase plate of the first mitotic spindle, in preparation for the first cleavage division. The embryo then progresses through several cleavage divisions (Fig. 31.7B through D), giving rise to an embryo comprising multiple cells or blastomeres.

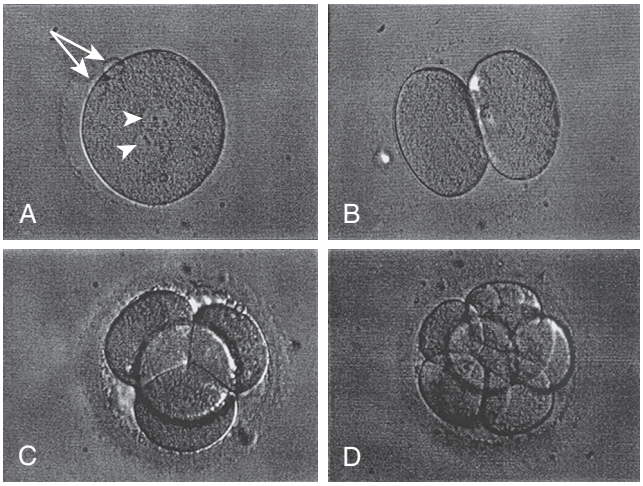

FIGURE 31.7 Development of human embryos during the first 72 hours after insemination. **A,** A zygote at 18 hours, showing two polar bodies *(arrows)* and two pronuclei in apposition *(arrowheads)* with several distinct nucleoli polarized toward the juxtaposed nuclear membranes. **B,** A two-cell embryo at 28 hours. **C,** A four-cell embryo at 44 hours. **D,** An eight-cell embryo at 68 hours.

In human embryos, the blastomeres are thought to be totipotent up to around the eight-cell stage[67] and removal of one, or even two, blastomeres from eight-cell embryos does not necessarily disrupt embryo development. However, a recent elegant study in which one of a pair of transferred embryos was biopsied and then DNA finger-printed showed that the implantation rate of the biopsied embryos was significantly lower than that of the non-biopsied embryo[68] (see Chapter 32). Beyond the eight-cell stage, the cells clearly begin to undergo differentiation. Compaction ensues to form the morula stage as blastomeres adhere because of secretion of cell adhesion molecules such as E-cadherin.[69] Tight junctions form between blastomere membranes, and pockets of fluid begin to accumulate among the blastomeres (Fig. 31.8A). Concomitant with onset of coalescence of these small fluid collections to form a fluid-filled cavity (the blastocoele), the first signs of overt cellular differentiation occur; the surface cells begin to undergo a change in shape from spherical to squamous epithelial-like to form trophectoderm cells, while a small cluster of inner cells retain their spherical appearance, ultimately to form the inner cell mass (Fig. 31.8B). The trophectoderm cells form the trophoblast, which gives rise to the extra-embryonic structures, such as the placenta, and the inner cell mass gives rise to the embryo. Following enlargement of the blastocoelic cavity, which causes expansion of the blastocyst (Fig. 31.8C and D), the blastocyst ultimately escapes from the zona pellucida in preparation for implantation (Fig. 31.8E and F).

Strictly speaking, the embryonic stage consists of the period from the development of the primitive streak through the initial steps in the development of all the major organs. As defined, in the human, the embryonic stage begins approximately 14 days after fertilization. In assisted reproduction, however, most authorities use the term "embryo" to describe the conceptus from the first cleavage through

the initial stages of organ development. This convention will be followed in the remainder of this chapter.

The molecular events underlying the process of implantation in humans are not completely understood (see Chapter 10). The human embryo enters the uterus approximately 4 days after fertilization, at the *morula stage*. Within 5 to 6 days of fertilization, the embryo reaches the *blastocyst stage* and begins the hatching process, thereby allowing the outer covering of syncytial trophoblast cells to interact with the endometrial surface. The trophectoderm nearest the inner cell mass, the polar trophoblast, plays an important role in the interaction of the blastocyst and the endometrium.[70] The interaction of the blastocyst with the endometrium involves phases of apposition, stable adhesion, and invasion. The blastocyst can attach to the endometrium only during a critical window of implantation corresponding to menstrual cycle days 19 to 24.[71] This "implantation window" is characterized by the formation of pinopodes which are fully developed for only 1 or 2 days. Although the molecules that control the attachment of the blastocyst to the uterine epithelium are not well characterized, recent transcriptomic analyses[72] have shown that several growth factors, cytokines, integrins and adhesion molecules are expressed in the trophectoderm and endometrium at the time of implantation. Differential secretion of some chemokines and growth factors attract the blastocyst to the pinopodes, while the repellent activity of the glycoprotein, MUC-1, appears to play an important role in repulsion of the blastocyst away from less desirable implantation areas.[73] Moreover, gene and protein expression studies have revealed that endometrial glands and stroma have distinct mRNA signatures that depend on the day of the cycle.[74] Interestingly, COS in general leads to disruptions in the transcriptional activity of genes involved in endometrial receptivity[75,76] and these distributions may be altered by different COS protocols.[76] These alterations in endometrial receptivity may partly explain the reduced birth weight in neonates conceived following fresh embryo transfer (i.e., under the influence of COS) versus that of neonates conceived following transfer of thawed embryos (i.e., into a "prepped" uterus).[77]

After attachment of the blastocyst to the uterine epithelium, the syncytiotrophoblast invades the endometrium and, by 12 days after fertilization, the conceptus is completely embedded in the endometrial stroma. Once this contact is established, human chorionic gonadotropin (hCG), secreted by the syncytiotrophoblast, can be detected in the maternal circulation.[78] Invasion of the syncytiotrophoblast then proceeds, ultimately to form the chorionic villi and establishment of a hemochorial placentation.

In Vitro *Fertilization: Clinical and Laboratory Aspects*

Pre-IVF Evaluation

As detailed in Chapters 23 and 24, testing to determine the etiology of infertility will help predict the likelihood of healthy pregnancy and delivery with various treatments, including IVF. Prior to IVF, the basic evaluation must include appropriate genetic testing, ovarian reserve testing, a uterine cavity evaluation, and semen analysis. As detailed below, the etiology of infertility has implications as to the prognosis for pregnancy and live birth with IVF.

Indications for IVF

In current clinical practice, the standard indications for IVF are tubal factor infertility, endometriosis, mild to moderate cases of male factor infertility, and idiopathic or unexplained infertility. Decreased ovarian reserve (i.e., depletion of the ovarian follicular pool), however, is seen with increasing frequency as women delay childbearing, and as women exposed to chemotherapy and other cancer treatments survive their disease and attempt to conceive. The most recent Center for Disease Control (CDC) detailed national report for the United States from 2009[79] shows that among couples who underwent ART using autologous oocytes, only 7.7% had tubal factor, with 4.2% having endometriosis, 18.8% having male factor, 13.5% unexplained infertility, 11.5% decreased ovarian reserve, 6.8% ovulatory dysfunction, 1.4% uterine factor, 7.7% other causes, and multiple female factors were diagnosed in 10.6%. Indeed, as the technology has improved, the application of IVF has broadened. IVF is now recommended for essentially all infertility conditions that

have not been successfully treated by other modalities, as first line treatment if this is the patient preference, or if clinical presentation indicates that it is the most appropriate therapy. For example, IVF has been advocated as a potential first line treatment of polycystic ovary syndrome (PCOS) in order to avoid ovarian hyperstimulation and multiple gestation. However, IVF is less successful if the female partner has diminished ovarian reserve. In this situation, donor egg has been demonstrated to be highly effective. Likewise, IVF is not likely to be successful in cases of severe male factor infertility; in this situation, ICSI is very effective (see Chapters 24 and 32). A good prognosis patient who would have a high risk pregnancy should she conceive a multiple pregnancy may be best treated with IVF and transfer of a single embryo, rather than with other modalities in which the multiple pregnancy rate is higher, and generally poorly predictable.

Tubal Factor Infertility

Surgical treatment and IVF are both possible therapeutic options for distal tubal occlusion, although no prospective trials have been reported comparing their relative efficacies. It is clear that IVF provides superior delivery rates to surgery. However, surgery is reasonable in women younger than 35 years old, with no other causes of infertility and mild tubal disease, as pregnancy rates in other patient populations are poor.[80] It is clear that the presence of hydrosalpinges (defined as fluid filled tubes on ultrasound, not merely occluded fallopian tubes) is detrimental to IVF outcomes. There are several meta-analyses of IVF outcomes in the setting of hydrosalpinges. A 2010 Cochrane review indicates that unilateral or bilateral removal of hydrosalpinges, or separation of the hydrosalpinges from the uterus result in higher delivery rates in IVF.[81] There is concern, however, that salpingectomy rather than division of the fallopian tubes and separating them from the uterus can result in elevated follicle stimulating hormone (FSH) levels, and reduced ovarian response during ovarian stimulation for IVF. [82] The Essure birth control device which occludes fallopian tubes proximally via hysteroscopy has been employed in a few small reports, with births reported. One study treated 20 women with the Essure device bilaterally or unilaterally (based on hydrosalpinx location).[83] There were 12 live births, with one complicated by premature rupture of membranes (PROM) and the other by placenta previa. In practice, Essure devices have beeen seen protruding into the endometrial cavity. Data are insufficient to recommend the Essure rather than laparoscopic salpingectomy or separation as first line treatment for hydrosalpinges. Given this, women who have documented tubal patency following tubal surgery, and who are younger than 35 years old and fail to conceive after 12 months, should undergo IVF, whereas those who are ≥35 years old and who fail to conceive after 6 months should proceed to IVF.

Endometriosis

For women presenting with infertility and early-stage endometriosis, IVF has not been definitively documented by a randomized clinical trial to be superior to other available treatments, such as expectant management, human menopausal gonadotropin (hMG) with intrauterine insemination (IUI), or surgical treatment (see Chapter 26).[84] However,

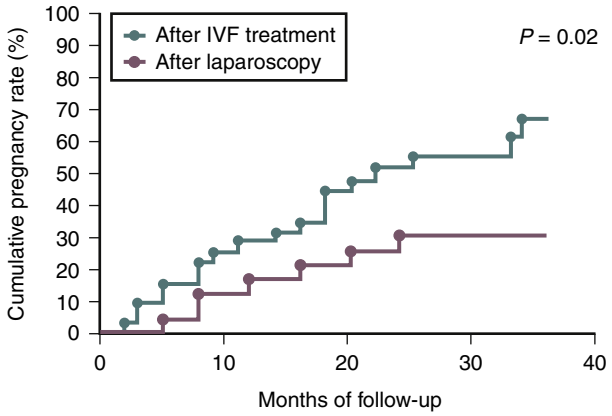

FIGURE 31.9 Cumulative conception rate curves during 36 months for women 32 years of age or older with infertility and endometriosis. *Top curve*, Cumulative conception rate after *in vitro* fertilization (IVF) treatment. *Bottom curve*, Cumulative conception rate with expectant management after laparoscopy. *(From Kodama H, Fukuda J. Karube H, et al. Benefit of in vitro fertilization treatment for endometriosis-associated infertility.* Fertil Steril *66:974-979, 1996, with permission of the American Society for Reproductive Medicine.)*

nonrandomized studies suggest that IVF treatment results in a higher pregnancy rate per cycle than conception attempts after surgical treatment, hMG with IUI, clomiphene treatment with IUI, or expectant management. For example, in one retrospective study of infertile women with advanced endometriosis, surgical treatment was associated with a cumulative pregnancy rate of 24% at 9 months after surgery. In a similar group of infertile women with advanced endometriosis, two cycles of IVF treatment were associated with a 70% pregnancy rate.[85] Another study of 313 women with endometriosis and infertility looked at crude pregnancy rates and estimated cumulative fecundity. The fecundity after one cycle of IVF was higher than that of 6 cycles of controlled ovarian hyperstimulation and IUI. After stratification for stage of disease, the benefit of IVF was more pronounced, and women with stage IV endometriosis and older than age 38 were much more likely to conceive from IVF than from COH and IUI treatment. Prior failure to conceive did not impact the likelihood of pregnancy from IVF.[86] It is controversial as to whether endometriosis is associated with lower IVF pregnancy rates than other infertility diagnoses. A recent cohort study from the Society of Assisted Reproductive Technologies database found that it is not.[87]

For infertile couples, the older the female partner, the more important is timely treatment with IVF. For example, Kodama and associates[88] demonstrated that in women 32 years of age or older with endometriosis, treatment with IVF resulted in a significantly higher pregnancy rate than that observed in the control group (Fig. 31.9). In women 32 years of age or older, the cumulative pregnancy rate was 59% in those women treated with IVF and 29% in women treated with expectant management. In contrast, in women under the age of 32, the cumulative pregnancy rate during the 3 years of the study was 64% in the women treated with IVF and 53% in the control group. Because IVF is often more expensive per cycle than other treatments (such as hMG and IUI), it is often reserved for couples who have failed to conceive after these other forms of treatment (see Chapter 30).

Retrospective analyses from many IVF centers indicate that IVF treatment of infertility associated with endometriosis is associated with a pregnancy rate similar to that observed with IVF treatment of tubal factor infertility. Olivennes and colleagues[89] reported that IVF treatment resulted in a live birth rate per cycle of 31% for women with endometriosis and 32% for women with tubal factor infertility. When the results were analyzed by surgical stage of the endometriosis (revised American Society for Reproductive Medicine classification),[90] the live birth rate per cycle was stage I, 27%; stage II, 31%; stage III, 36%; and stage IV, 33%. Another study of 31 women with stage I and II endometriosis compared to 67 women with stage III and IV endometriosis or 87 women with tubal disease were compared. The cumulative live birth rates after up to 4 cycles of IVF and ICSI were 40.3% for stage III and IV, 55.8% for stage I and II and 43.7% in tubal factor controls.[91] All stages combined, CDC data from 2009 indicate that the per cycle live birth rate for women with endometriosis as the primary infertility diagnosis was 35.3% compared to 33.7% for unexplained infertility and 32.2% for tubal factor.[92] However, some women with advanced endometriosis (stage III and IV) have undergone oophorectomy plus a contralateral ovarian cystectomy or bilateral ovarian cystectomies (for endometriomas); these women appear to have markedly reduced success with IVF due to decreased ovarian reserve from premature depletion of the oocyte pool.[93-97]

Patients often ask whether surgical treatment of active endometriosis prior to IVF improves the likelihood of pregnancy. There are no randomized trials on this issue. Retrospective studies are not adequately controlled, although there are retrospective data. One study of women with stage I or II endometriosis found that the implantation and live birth rates per oocyte retrieval were higher in 399 women who underwent laparoscopic treatment of visible endometriotic lesions compared with 262 women who underwent diagnostic laparoscopy (30.9% versus 23.9% [$P = 0.02$] and 27.7% versus 20.6% [$P = 0.004$] respectively).[98]

Male Factor

Male factor infertility is a broad category that ranges from minimally abnormal semen parameters to total sperm counts of less than 5 million per ejaculate. In general, men with severe semen abnormalities are probably best treated with ICSI (see Chapters 24 and 32). Very severe decreases in the number of motile sperm per ejaculate (less than 1.5 million) and decreases in the number of sperm with normal morphology are associated with poor pregnancy rates in standard IVF.[99,100] Typically, ICSI is indicated as front line treatment for men with fewer than 10 million sperm per mL in the whole ejaculate or less than 5 million/mL after processing. Prior to undergoing ICSI, men with severe male factor infertility (less then 5 million sperm per mL in unwashed ejaculate) should have a karyotype and Y chromosome microdeletion assessment because the incidence of karyotypic and genetic abnormalities is high in this group.[101] In a study of 1935 men with severe male factor infertility, 1214 with nonobstructive azospermia and 721 with severe oligoasthenospermia, the incidence of karyotypic abnormalities was 16.4% and 5.8%, respectively. The incidence of Y chromosome microdeletions was 9.5% and 1.9% respectively.[102] The incidence of chromosomal abnormalities increases with decreasing sperm count.[103] Nevertheless, such men are good candidates for IVF. ICSI in cases of severe male factor infertility provides fertilization and pregnancy rates comparable to those seen in standard IVF (see Chapter 32).

Idiopathic Infertility

For 10% to 17% of infertile couples, thorough evaluation reveals no identifiable cause of infertility. Data reported to the Society for Assisted Reproductive Technology (SART) in 2010 show that 13% of IVF and ICSI cycles initiated were for a primary infertility diagnosis of "unknown factor" infertility.[104] "Unexplained," or idiopathic, infertility is a term applied to those couples who have completed an infertility evaluation that includes laparoscopy. For the purposes of this chapter, however, idiopathic infertility refers to couples who have completed the basic steps of the infertility evaluation (semen analysis, documentation of ovulation, and tubal patency), but who may not have had laparoscopy, as laparoscopy is no longer part of the standard initial infertility evaluation in the United States.

Many couples with idiopathic infertility achieve successful pregnancies after a stepwise treatment approach (see Chapter 30), which may include empirical clomiphene treatment followed by empirical gonadotropin ovarian stimulation with IUI treatment.[105] One randomized trial has been performed seeking to answer the question of the most cost-effective path towards IVF treatment. In this trial, 247 couples with the female partner ages 21 to 39 year old and having unexplained infertility were randomized to undergo 3 cycles of clomiphene citrate and IUI therapy, and if not pregnant either 3 cycles of gonadotropin IUI followed by up to 6 cycles of IVF, or IVF directly following clomiphene IUI treatment.[106] Delivery rates per cycle of treatment were 7.6% for cc IUI, 9.8% for gonadotropin IUI, and 30.7% for IVF. Couples who underwent IVF after clomiphene IUI were pregnant on average 3 months earlier (8 versus 11 months). In addition, the cost per delivery was $9800 lower for the fast treatment arm.[106] It is important to note that if other treatments are attempted and fail prior to IVF, women are older by the time they undergo IVF, resulting in a higher likelihood that their ovarian reserve has diminished. This, in turn, may result in lower chances of conception with IVF due to older age at the time that IVF is initiated.

Polycystic Ovary Syndrome and Anovulation

Until recently, infertile women with polycystic ovary syndrome (PCOS) in whom both clomiphene and gonadotropin ovulation induction failed had few remaining treatment options except surgical procedures to reduce thecal and stromal androgen production. However, evidence has accumulated that IVF is often effective for such patients. A meta-analysis comparing IVF outcomes in PCO patients, diagnosed by Rotterdam criteria, to non-PCO patients found higher oocyte retrieval cancellation rates (presumably due to risk of ovarian hyperstimulation, higher oocyte numbers, lower fertilization rates), but equivalent pregnancy rates per embryo transfer. As the incidence of oocyte immaturity is high in PCO patients, this is not a suprising finding, and is reassuring in that pregnancy rates are acceptable, despite the ovarian mileu of PCO.[107]

Polycystic ovarian syndrome patients are at high risk of ovarian hyperstimulation syndrome. This risk may be mitigated by use of GnRH antagonists rather than agonists, and avoidance of hCG ovulatory triggering, with substitution of a GnRH agonist (see later in chapter). A prospective, randomized placebo-controlled trial of 120 PCO patients treated with metformin 500 mg three times per day during IVF treatment with a long GnRH agonist protocol until menses or a positive pregnancy test revealed that the relative risk of ovarian hyperstimulation was 0.28 (95% CI 0.11 to 0.67) with metformin use. The metformin arm also used somewhat more gonadotropins (1350 IU [range, 950 to 1800] versus 1275 IU [range 900 to 1750], $P = 0.018$), fewer nonperiovulatory follicles on the day of hCG administration (4.3 [range, 0 to 6] versus 5.5 [range, 2 to 9], $P = .034$) and lower estradiol levels at hCG (1951 pg/mL [range, 342 to 4021], versus 2346 [range, 709 to 4123], $P = 0.29$). Implantation rates (41% versus 31%) and live birth rates per cycle (29% versus 27%) were not different.[108,109]

For women with hypothalamic amenorrhea, as with PCO, treatment with IVF avoids a high risk of multiple gestation that is in turn associated with multiple follicular development with gonadotropins (see Chapter 30).

Uterine Factor

Fibroids

The uterus may be considered as abnormal and a contributor to infertility due to many factors including aquired defects such as fibroids, polyps, intrauterine adhesions, or congenital anomalies. Many investigators have reported that submucosal leiomyomas are associated with decreased pregnancy rates with IVF (see Chapter 27). In addition, a number of studies suggest that hysteroscopic myomectomy of submucosal myomas improves pregnancy rate with IVF.[110-112]

The effect of intramural myomas on IVF outcome is less certain. Some investigators have found that intramural myomas are associated with decreased pregnancy rates in IVF. In one report, 112 women with intramural myomas (the largest of which had a mean diameter of 2.3 cm) and 322 women without myomas undergoing IVF were prospectively studied.[113] The ongoing pregnancy rate was 15.1% in the women with myomas and 28.3% in the women without myomas ($P < 0.003$). Logistic regression demonstrated that intramural myomas were associated with a reduced OR for pregnancy (OR 0.46, 95% CI 0.24-0.88, $P < 0.02$) after controlling for age of the female partner and number of embryos available for transfer. Other investigators have reported that intramural myomas up to 7 cm in diameter that do not distort the uterine cavity do not substantially influence IVF outcome. The impact of myomas on IVF was studied in 141 patients with myomas and 406 women without myomas. The OR for pregnancy was 0.73 in the myoma group (95% CI 0.49-1.19, $P = 0.21$) after controlling for the age of the female partner.[114] Surrey and colleagues examined consecutive IVF cycles in 399 women undergoing IVF with and without leiomyomas. They found that the live birth rate was not affected by the presence of intramural leiomyomas provided that the endometrial cavity was hysteroscopically normal. They did not recommend prophylactic surgical intervention for intramural fibroids.[115] In contrast, a meta-analysis of 19 observational studies in 6087 IVF cycles supports the contention that intramural fibroids which do not distort the cavity are associated with decreased live birth rates (RR 0.79, CI 0.70 to 0.88, $P < 0.0001$).[116] If there is, indeed, an impact of intramural fibroids on IVF live birth rates, the question remains as to whether myomectomy returns the pregnancy rate to expected levels, or whether the biology of the uterus is different and somehow more hostile in women who develop intramural fibroids. Additional large-scale studies are needed to determine if intramural myomas reduce IVF success rates, and if so, whether myomectomy is of benefit.

Adenomyosis

Adenomyosis is typically diagnosed pathologically, at the time of hysterectomy. However, a study of first gonadotropin releasing hormone (GnRH) antagonist IVF cycles in women younger than age 39 with good embryo quality comparing 38 women with ultrasound diagnosed adenomyosis to 175 without, found that the clinical pregnancy rate was 23.6% compared to 44.6% in controls ($P = 0.017$). After adjustment for maternal age and duration of infertility the difference was significant, OR 0.417, CI 0.175 to 0.989, $P = 0.047$.[117] Another small study of 19 women with adenomyosis and 256 controls, also found lower ongoing pregnancy and higher miscarriage rates.[118]

Other Factors

Endometrial polyps may also decrease live birth rates with IVF.[119] However, studies are inconsistent. If polyps do play a role in miscarriage or lowering pregnancy rates it appears to be in large polyps 2 cm or more in size.[120] This may be due to the fact that polyps less than 1 cm have been found to regress.[121] Cervical stenosis can impair effective embryo transfer and thus lower pregnancy rates with IVF.[122] Placing a Malecot catheter after hysteroscopic evaluation in preparation for IVF appears to improve the efficacy of embryo transfer in women with cervical stenosis.[123] Other methods including cervical dilation and resection to improve ease of transfer have also been reported.[124]

Congenital Defects

Müllerian anomalies appear to be associated with a reduced pregnancy rate in IVF. In a study of 37 women with müllerian anomalies undergoing IVF, the live birth rate per initiated cycle was 8%, compared with 25% in a control group without müllerian anomalies. Following IVF, women with *in utero* exposure to diethylstilbestrol and uterine anomalies have very low pregnancy rates compared with those without anomalies.[125]

Decreased Ovarian Reserve

Decreased ovarian reserve is increasingly acknowledged as a significant infertility factor, and is likely second only to age as a predictor of IVF delivery rates. It has become increasingly clear that IVF is most successful for infertile couples when the female partner has an adequate ovarian follicular pool. As a woman ages, there is a decline in her ovarian follicular pool.[126] Some reports suggest that the decline in the oocyte pool accelerates after age 37. In addition to the chronological age of the female partner, the biological age of the ovary (a measure of the remaining ovarian

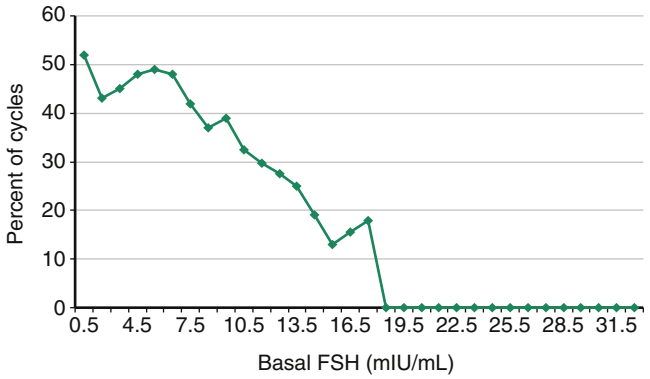

FIGURE 31.10 Delivery rates per initiated cycle after *in vitro* fertilization (IVF) treatment as a function of the basal follicle-stimulating hormone (FSH) concentration of the female partner. Data based on 18,018 couples. *(From Scott RT, Elkind-Hirsch KE, Styne-Gross A, Miller KA, Fratarelli JL. The predictive value for in vitro fertility delivery rates is greatly impacted by the method used to select the threshold between normal and elevated basal follicle stimulating hormone.* Fertil Steril *89:868-878, 2008, with permission of the American Society for Reproductive Medicine.)*

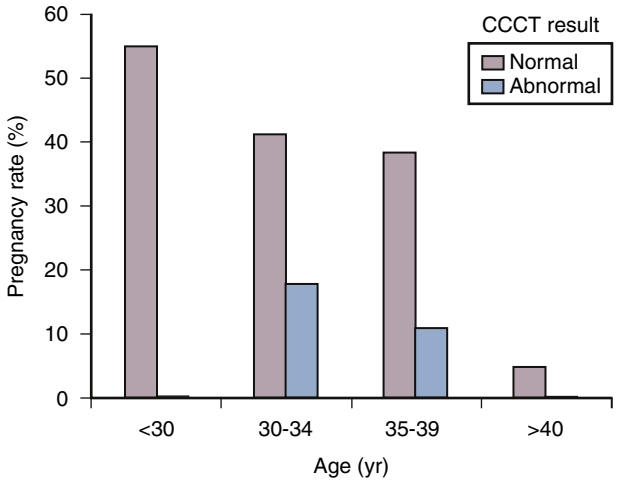

FIGURE 31.11 Clinical pregnancy rates as a function of both age and the response to a clomiphene citrate challenge test (CCCT) in a general infertility population observed prospectively. The illustration is based on data from 236 couples. In women with an abnormal CCCT result (suggestive of a depleted oocyte pool), pregnancy rates are low regardless of the age of the female partner. In women older than 40 years of age, pregnancy rates are low with *in vitro* fertilization even if the CCCT result is normal. *(From Scott RT, Hofmann CE. Prognostic assessment of ovarian reserve.* Fertil Steril *63:1-11, 1995, with permission of the American Society for Reproductive Medicine.)*

follicular pool) as determined by follicular phase cycle day 3 follicle-stimulating hormone (FSH) concentration[127] is also a strong predictor of IVF pregnancy rates. However, the method used to establish the threshold to separate "normal" from "abnormal" FSH levels has great impact on the use of day 3 FSH as a screening criterion.[128]

A large study of 18,019 IVF cycles of older patients (36.2 ± 4.8, mean ± SD) investigated the relationship between cycle day 3 FSH concentration and IVF delivery rates. FSH levels measured in a multitude of FSH assays were included, as this reflects actual clinical practice. A threshold between normal and abnormal FSH levels was then assessed. The study showed that no live births occurred in this older population with basal FSH levels of greater than 18.0 mIU/mL and that between 1 to 7 mIU/mL live birth rates were relatively constant, but underwent a decline between 8 to 11 mIU/mL which was more precipitious beyond 12 mIU/mL (Fig. 31.10).[128] Similar trends were observed for each age group. When the interaction of age and the results of a clomiphene challenge test were examined, in women with a normal clomiphene citrate challenge test response (suggesting an adequate follicular pool), the age of the female partner remained an important prognostic variable.[129] Similar results have been observed in a general infertility population (Fig. 31.11).

The ovarian antral follicle count (the number of ovarian antral follicles between 2 and 10 mm in maximal diameter measured on ultrasound) appears to be a better predictor of ovarian reserve than is FSH. Women with fewer than 7 total antral follicles have diminished ovarian reserve and have generally poorer outcomes in IVF.[130] In addition, ovarian volume, which reflects antral follicle count, also appears to correlate with IVF success, but is not useful in the setting of ovarian cysts. Women with small ovarian volumes also suffer lower pregnancy rates with ART.[131,132]

Müllerian inhibiting substance (MIS), also known as anti-müllerian hormone (AMH), is a glycoprotein growth factor synthesized in granulosa cells. A number of studies have demonstrated that AMH is reduced with increasing age and, as such, is a useful marker of ovarian reserve. Seifer and colleagues were the first to demonstrate that AMH is significantly reduced in women who responded poorly to ovarian stimulation in IVF cycles.[133] Pregnancy and delivery rates are also lower in ART in women with low serum levels of AMH.[134] AMH has the advantages of minimal cycle-to-cycle variation,[135] its levels do not change significantly across the menstrual cycle, and it is accurate in women on oral contraceptives.[136]

Inhibin B, a hormone secreted by the granulosa cells, has also been studied as a marker of ovarian reserve. Inhibin B directly inhibits pituitary secretion of FSH in a manner similar to that of estradiol, and thus was thought to be a marker of ovarian health.[137,138] However, the utility of inhibin B as a marker of ovarian reserve is limited by the lack of a uniform commercial assay.

Meta-analyses confirm that although ovarian reserve tests are helpful in predicting response to ovulation induction, and selecting ovarian stimulation protocols, they are not accurate independent predictors of live birth rates.[139,140] Age remains a major factor. Young women with decreased ovarian reserve have pregnancy and delivery rates substantially higher than older women with equally low ovarian reserve.[141] Yanushpolsky and colleagues found that women under age 40 undergoing clomiphene citrate challenge testing who had FSH levels greater than 10 mIU/mL on either day 3 or day 10, had approximately half the pregnancy and live birth rates of women with FSH levels less than 10 mIU/mL.

As shown in Figure 31.12, in assisted reproduction cycles the proportion of pregnancies that end in spontaneous abortion increases with age of the female partner due to increases in oocyte aneuploidy. Many authorities advise that women, particularly over age 40, with a depleted oocyte

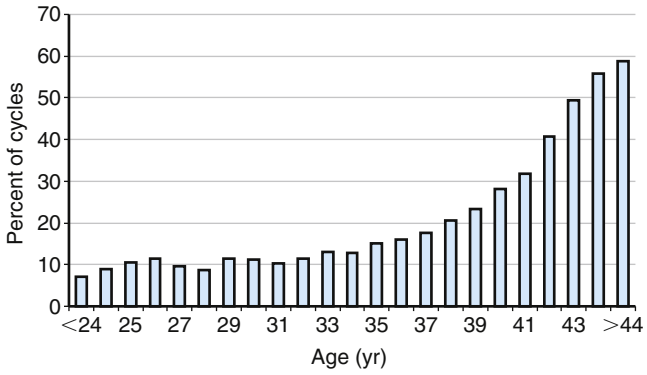

FIGURE 31.12 Percentage of ART (assisted reproductive technology) cycles using fresh nondonor eggs or embryos that resulted in spontaneous abortion, by age of woman in 2009. *(From CDC Assisted Reproductive Technology [ART] Report 2009. Available at www.cdc.gov/art/ART2005. Accessed Sept. 30, 2012.)*

pool and who have a poor response to gonadotropin stimulation should consider either treatment with donor oocytes or adoption.

Multiple Infertility Factors

Many couples have multiple factors contributing to their low fecundability. In general, the greater the number of infertility factors, the lower the success with IVF treatment. For example, in one study of the efficacy of IVF on couples for whom the only identifiable infertility factor was endometriosis, the live birth rate per cycle was 31%. In women with endometriosis and a male partner with an abnormal semen analysis, the live birth rate per cycle was 16%. For women with both endometriosis and tubal disease, the live birth rate per cycle was 8%.[89] Similarly, in a study of the effectiveness of IVF on women presenting with tubal disease with or without other infertility diagnoses, the live birth rate per transfer was 30% in women with tubal disease alone, 25% in women when tubal factor occurred in combination with male factor, and 20% and 19%, respectively, in cases of previous diethylstilbestrol exposure or immunological infertility.[142] In 2009, U.S. data reported to the CDC revealed that 10.6% of cycles involved more than one female infertility diagnosis, and 17.8% involved both male and female infertility factors[92]; delivery rates per stimulated cycle were 23.4% and 28.6%, respectively. In comparison, the delivery rate for cycles with unexplained infertility, endometriosis and male factor were 33.7%, 35.3%, and 37.6%, respectively, whereas those for poorer prognosis categories such as decreased ovarian reserve (14.5%) and uterine factor (25.4%) were more similar to cycles with multiple infertility diagnoses.

A recent study of data reported to SART found that per stimulation attempt delivery rates in women undergoing IVF/ICSI for uterine factor or decreased ovarian reserve were lower than all other causes of infertility.[87]

Preimplantation Genetic Testing (PGT)

Couples without infertility, but who are carriers of single gene defects or chromosomal translocations, are candidates for IVF with PGT so as to reduce the likelihood of transmission of disease or to avoid recurrent pregnancy loss. Good ovarian reserve and creation of fairly large numbers of good quality embryos are critical for optimizing the likelihood of pregnancy and delivery with PGT, as at least 25% of embryos are likely to be unsuitable for transfer (e.g., in cases of recessive gene defects). Chromosomal screening in order to avoid aneuploid pregnancy loss or miscarriage is currently under development; it is unclear if such screening will increase the likelihood of delivery per IVF stimulation initiated. PGT is detailed in Chapter 32.

Overview of IVF Statistics

As IVF has evolved as a scientific field, the reporting of treatment has continued to change and improve. Currently, most studies report the live delivery rate per IVF cycle initiated (i.e., per cycle in which gonadotropin therapy was begun). This statistic is helpful for patients deciding if the risk/benefit ratio is appropriate for them to undertake IVF. However, a more accurate representation may be the cumulative live birth rate per stimulation, which would include the number of deliveries for transfers of fresh and frozen embryos resulting from a single cycle of controlled ovarian stimulation.[143] This is a more difficult outcome to track reliably as it requires tracking the embryos used during cryopreserved embryo transfers back to the cycles in which they were created.

For the calculation of the delivery rate, multiple gestations are counted as one delivery, not two deliveries in the case of twins or three deliveries in the case of triplets. Unfortunately, many investigators use other numerators (clinical pregnancy, ongoing pregnancy) and denominators (pregnancy rate per oocyte retrieval or embryo transfer) when calculating IVF success rates. Many critics believe that these rates are overly optimistic and are not a realistic estimate of the success of IVF, as they do not include women who began stimulation but whose cycles were cancelled due to low response, failed fertilization or other causes.

One of the most remarkable features of IVF is the continuous improvement in its efficacy. From 1986 to 2009, there has been a significant increase in the deliveries per IVF cycle initiated, from less than 9% to 30% (Table 31.1).[104,144]

IVF is a highly effective treatment for most infertility diagnoses, with the exception of uterine factor, multiple concurrent female infertility factors, and decreased ovarian reserve (Fig. 31.13). Not surprisingly, advancing female age correlates inversely with successful IVF outcome regardless of infertility diagnosis (Table 31.2). As previously discussed, as a woman ages, follicles are depleted, as measured by decreased ovarian reserve[145] and her chances to achieve a pregnancy with IVF diminish. As seen in Figure 31.14, live birth rates in IVF are relatively stable between the ages of 25 and 31 years, at which point the birth rates gradually decline up to age 35. The decline in birth rates becomes steeper after age 35, and in women older than 44 years old, the live birth rate approaches 0%.

Patient Counseling

Counseling is critical for patients interested in proceeding directly to IVF. In virtually all outcome studies, age is the most critical predictor of live birth with IVF treatment,

followed by ovarian reserve.[146,147] Unfortunately, normal ovarian reserve test results do not trump age; the unusual 44-year-old woman with normal ovarian reserve testing is likely to respond to gonadotropins but still has a delivery rate with IVF of less than 1% (Fig. 31.14)[92] due to the high incidence of aneuploidy in oocytes with increasing age.[148,149] Prior history of pregnancy and delivery, particularly with IVF, does increase the likelihood of success with IVF; however, again, age and ovarian reserve are still of critical importance.

Ovarian Stimulation

Natural cycle IVF and "mild stimulation" IVF are covered in detail in Chapter 30.

Natural Cycle IVF

Natural cycle IVF is possible through careful monitoring of the menstrual cycle with serum estradiol and transvaginal sonography, in order to identify the time when the dominant follicle can be aspirated to yield a fertilizable oocyte. Although conceptually appealing, natural cycle IVF is associated with low pregnancy rates. In one study of 74 such cycles, oocytes were harvested in approximately 50% of the cycles, and the pregnancy rate per cycle initiated was 3%.[150] In another study of 114 natural IVF cycles, the pregnancy rate per cycle initiated was 4%.[151] In true natural cycle IVF the spontaneous ovulation rate is high, the rate of obtaining no oocytes and embryos is high, and pregnancy and delivery rates are low.[150] IVF is a resource-intensive treatment, and pregnancy rates in the range of 3% to 4% per natural IVF cycle initiated are not cost effective.

Mild Ovarian Stimulation

"Mild" stimulation regimens, although poorly defined in the literature, have been gaining popularity. Such regimens may include the use of clomiphene or aromatase inhibitors with 75 to 150 IU of gondadotropins, but in some publications gonadotropin dosing is actually quite high. This treatment may be appropriate in selected young women with low expected rates of oocyte aneuploidy, and high

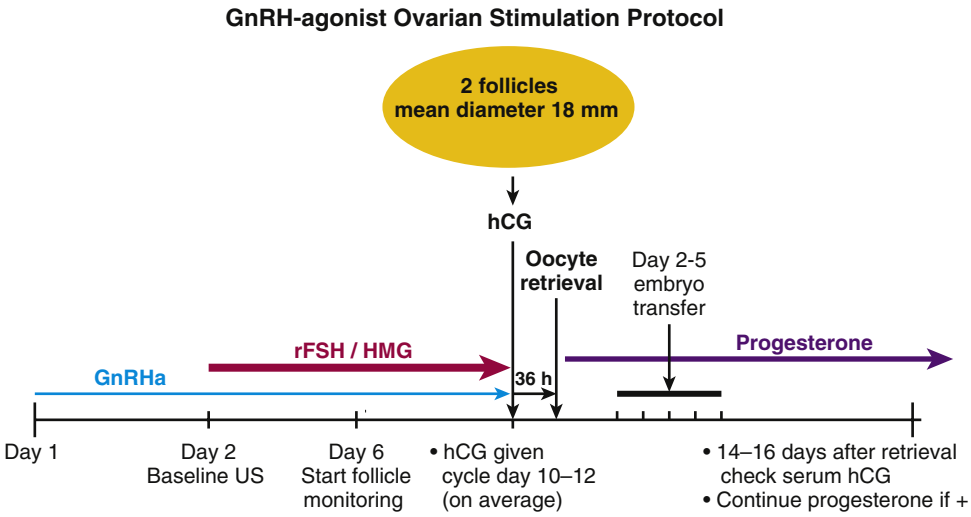

FIGURE 31.15 Schematic representation of the GnRH-agonist protocol for ovarian stimulation for *in vitro* fertilization (IVF). Protocols for ovarian stimulation. In Ginsburg ES, Racowsky C. New York,* Springer Science+Business Media, *In Press.)*

embryo implantation rates. In Europe, such treatment has been more widely adopted, perhaps in part due to the fact that many countries have legislation restricting the number of embryos that may be cultured and/or transferred, as well as lower maximal maternal ages that are considered acceptable.

The approach in the United States is largely based on data showing that higher numbers of oocytes and the ability to select the best embryos from a cohort have been shown to optimize pregnancy rates at all ages. Consequently, success is critically dependent on generating an adequate number of mature follicles that contain developmentally competent oocytes, while avoiding ovarian hyperstimulation syndrome. Large retrospective cohort studies suggest that obtaining enough embryos to allow for embryo selection is important in order to maximize pregnancy rates. One study of 7422 women treated with the long GnRH-agonist protocol found that pregnancy rates per cycle initiated were highest when 13 oocytes were obtained (28%).[152] Another study of 400,135 IVF cycles performed between 1991 and 2008 also found that the pregnancy rate per cycle correlated with the number of oocytes retrieved. The median number of oocytes retrieved was nine, with a live birth rate per initiated cycle of 21%. Live birth rates correlated with number of oocytes retrieved across all age groups, and were maximal when 15 oocytes were obtained, plateaued between 15 and 20 oocytes, and were lower if over 40 oocytes were retrieved.[153] Therefore, the predominant approach to ovarian stimulation for IVF in the United States is to aim for the development of multiple follicles in order to allow for embryo selection, particularly in women at advanced ages (i.e., older than age 38) when aneuploidy rates increase and embryo implantation rates decrease.

Medications used for ovarian stimulation include clomiphene, clomiphene-hMG; clomiphene-rhFSH (recombinant human FSH); hMG alone; immunopurified (highly purified) urinary human FSH (hpFSH) alone; rhFSH alone, and various combinations of the above. Compared to clomiphene alone, the combination of clomiphene plus low dose human gonadotropins (FSH or hMG) increases the number of follicles stimulated, but the number of oocytes retrieved, and the pregnancy rates are lower than expected with standard stimulation in normal responders.[154] Though such regimens do allow for lower cost stimulations,[155] the live birth rate per embryo transfer is low (19%). Therefore, in terms of the expected live birth rate per initiated stimulation and the cumulative live birth rate (which would include transfer of cryopreserved embryos), these regimens are likely inferior to standard dosing of gonadotropins alone[156] and may not ultimately be cost-effective.

Standard Ovarian Stimulation

Below we focus on controlled ovarian stimulation protocols as used for IVF in the U.S. In addition, we consider decision making in protocol selection.

GnRH-Agonist Down-Regulation Regimens

In ovarian stimulation for IVF, the main purpose of a GnRH-agonist analog or antagonist is to prevent a premature LH surge (triggered by the high concentrations of estradiol) while follicles are still immature. GnRH-agonist analogs differ from the native decapeptide GnRH in amino acid positions 6 and 10. They are resistant to degradation, giving them long half-lives and prolonged receptor occupancy. The initial administration of a GnRH-agonist analog is associated with an increase in LH and FSH secretion (agonist phase). Long-term administration causes down-regulation and partial desensitization of the pituitary GnRH receptor, resulting in the suppression of pituitary secretion of LH and FSH. The addition of a GnRH-agonist analog to regimens of ovarian stimulation for IVF-ET appears to be associated with an increase in the number of oocytes retrieved, the number of embryos transferred, and the clinical pregnancy rate.[157,158] In the standard down-regulation protocol, the GnRHa is begun in the midluteal phase of the prior menstrual cycle, and ovarian stimulation begins with or after the onset of the subsequent menstrual period (Fig. 31.15).

For example, one study demonstrated that treatment with a GnRH agonist (buserelin) plus hMG resulted in more oocytes retrieved (9.3 versus 6.2), more embryos (4.3 versus 2.8), and a higher clinical pregnancy rate (20% versus 14%) than did stimulation with clomiphene plus hMG.[159]

In another study, comparison of a stimulation regimen using the same medications also demonstrated that buserelin-hMG stimulation resulted in a higher pregnancy rate than that observed with clomiphene-hMG (36% versus 18%).[160] The type of GnRH-agonist analog used does not appear to be crucial to obtaining the improved outcomes. Studies with D-Trp6 GnRH-agonist analog also demonstrate improved pregnancy rates (21% versus 12%) compared with ovarian stimulation regimens that do not use GnRH agonists for IVF-ET. [161] The addition of a GnRH-agonist analog to a gonadotropin-stimulation regimen appears to suppress premature LH surges, reduces the chance of premature luteinization of granulosa cells, and reduces cycle cancellation due to premature luteinization or ovulation.

Among a smaller number of women, GnRH-agonist down-regulation protocols may excessively suppress endogenous pituitary LH secretion. If rhFSH is the only exogenous gonadotropin used, low serum levels of estradiol may result.[162] When follicular dynamics were compared between GnRHa and GnRH-antagonist cycles, it was found that the modulation of the FSH-induced protein kinase A pathway by protein kinase C was different in agonist versus antagonist cycles.[163] The changed modulation of this pathway results in lower levels of serum and follicular estradiol via lower levels of aromatase activity. It does not appear, however, that low levels of estradiol are, in fact, detrimental to pregnancy rates in these IVF cycles.[164] When LH levels are too high, premature ovarian luteinization may occur. It is unclear whether LH is required for optimal ovarian stimulation as studies do not uniformly indicate that the addition of LH to ovarian stimulation improves pregnancy rates, though estradiol levels are higher.[165-167]

It is important to note that women with normal ovarian reserve typically will produce optimal numbers of oocytes (discussed later in the chapter) from down-regulation regimens. However, women with decreased ovarian reserve may not respond even to high-dose gonadoptropin treatment after down-regulation. In some cases, employing lower doses of GnRH agonists will allow down-regulation without excessive suppression of response.[168,169] A randomized trial of a half dose of triptorelin (1.87 mg) adequately suppressed the pituitary, but required a lower dose of FSH ampules (42 ± 2 versus 59 ± 3) and there were more mature oocytes (10.1 ± 0.54 versus 7.4 ± 0.55), fertilized oocytes (8.24 ± 0.35 versus 6.34 ± 0.37) and embryos (7.8 ± 0.36 versus 5.9 ± 0.37) than when the standard 3.75 mg dose was given. There were no significant differences in pregnancy (38.8% versus 25.3%), implantation (22.6% versus 13.8%) or miscarriage (6.1% versus 5.0%) rates. However the cumulative pregnancy (fresh plus frozen embryo transfers) rate was significantly higher in the diluted agonist group (56.8% versus 35.4%).[170]

GnRH-Agonist Flare or Short-Course Regimen

In the down-regulation protocol, GnRH-agonist analogs are usually started in the luteal phase of the cycle preceding the IVF-ET cycle (long protocol). In the GnRH-agonist flare regimen, the GnRH agonist is begun in the early follicular phase of the IVF-ET cycle, typically between cycle days 1 and 3. Basically, the flare regimens take advantage of both the agonist and down-regulation properties of GnRH-agonist analogs. In the first few days of treatment, during the early follicular phase, the GnRH agonist stimulates endogenous LH (and FSH) secretion from the pituitary. The increased LH secretion stimulates more ovarian androstenedione production, which increases the substrate available for aromatization. However, the increased secretion of both LH and ovarian androstenedione may not be optimal, as some studies suggest that elevated circulating LH and intrafollicular androgen levels are not associated with optimal oocyte function.[171] In one study of women treated with a GnRH-agonist down-regulation or a GnRH flare regimen, follicular fluid androstenedione concentrations were 27 ng/mL versus 57.3 ng/mL ($P < 0.05$), respectively.[172] In any case, the elevated androstenedione results in higher estradiol levels, and the increased FSH secretion may increase follicular recruitment. With continuing administration of the GnRH-agonist analog, the down-regulation effects of the analog begin and premature LH surges are prevented.

In one study, women with a previous poor response to standard long-protocol GnRH-agonist down-regulation plus gonadotropin stimulation were treated with a flare regimen using microdose leuprolide acetate (20 μg every 12 hours), initiated in the early follicular phase of the treatment cycle, plus gonadotropin. Compared with a previous cycle of down-regulation, microdose GnRH agonist plus gonadotropin resulted in greater ovarian stimulation, higher serum estradiol concentration, and increased numbers of follicles and oocytes retrieved.[173] It should be noted, however, that women with normal ovarian reserve have higher cycle cancellation rates[174] and may have lower pregnancy rates with a flare as compared to down-reglulation protocol. In one large cohort study of women under 40 with normal baseline FSH levels, the GnRH flare regimen was associated with a lower delivery rate per cycle compared with the GnRH-agonist down-regulation regimen (15.1% versus 21.3%, $P < 0.05$).[175] Other investigators have reported similar trends.[176] The GnRH flare probably should not be the first choice ovarian stimulation regimen in women undergoing their first cycle of IVF or those who have a good prognosis. Flare protocols however are beneficial in poor responders who are unlikely to respond well to long or down-regulation protocols (discussed later in the chapter).

GnRH-Antagonist Regimens

A theoretical problem with the GnRH-agonist analogs is that LH secretion is stimulated at the initiation of treatment, which is not consistent with the physiology of the normal early menstrual cycle. The GnRH antagonists offer the possibility of acutely suppressing LH secretion without an initial increase in LH release.[177,178] Thus, pituitary LH secretion can be controlled within the stimulation cycle itself; such control is not possible with the GnRH agonists, which must be begun during the previous menstrual cycle to achieve full down-regulation by the time stimulation begins. GnRH antagonists are typically administered as a small daily dose (cetrorelix or ganirelix, 0.25 mg daily by subcutaneous injection), usually starting on cycle day 6 to 8 or when the lead follicle reaches 14 mm in diameter[179] or as a single large dose (cetrorelix, 3 mg subcutaneously, which has a 4 day duration of action) on approximately cycle day 8[180] (Fig. 31.16). Both protocols block a spontaneous LH surge.

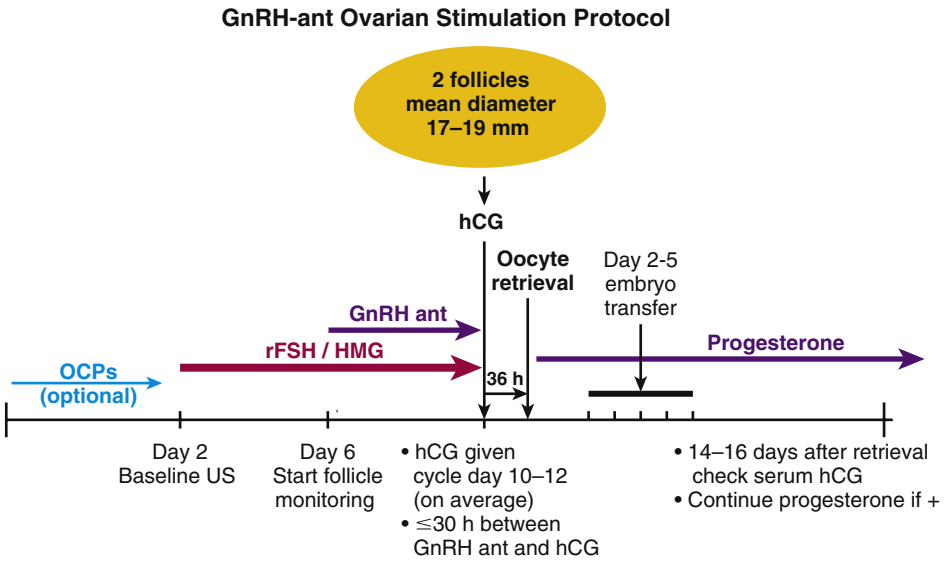

FIGURE 31-16 Schematic representation of the GnRH-antagonist protocol for ovarian stimulation for *in vitro* fertilization (IVF). FSH, follicle stimulating hormone; GnRH-ant, gonadotropin-releasing hormone antagonist; hCG, human chorionic gonadotropin; hMG, human menopausal gonadotropin; US, ultrasound. *(From Cheong Y, Ginsburg ES, Macklon N. Protocols for ovarian stimulation. In Ginsburg ES, Racowsky C. New York,* Springer Science+Business Media, *In Press).*

The impact of a GnRH antagonist on ovarian stimulation for IVF is heavily dependent on the dose of GnRH antagonist administered. At small doses, the suppression of LH is minimal. With large doses, near complete suppression of LH is achieved. In one study, the impact of six doses of the GnRH antagonist ganirelix on LH secretion and IVF outcomes was studied.[181] A fixed daily dose of recombinant FSH was administered. Ganirelix produced a dose-dependent suppression not only of LH (Table 31.3) but also of serum androstenedione and estradiol. The use of oral contraceptives prior to GnRH antagonist cycles is common in order to have some control over the start of cycles. Initial studies that lead to FDA approval used oral contraceptives for approximately 3 weeks prior to stimulation. In oligo-anovulatory patients it is preferable to ensure that the patient is not pregnant prior to starting stimulation; a course of contraceptive pills after an anovulatory progesterone level accomplishes this, and allows the patient and clinician to start the stimulation in a scheduled way. A three-arm randomized IVF trial comparing OCP pretreatment in GnRH antagonist (n =110) versus agonist (n =111) versus GnRH antagonist without OCP treatment (n =111) showed that the OC-scheduled antagonist regimen appeared more similar to the agonist regimen rather than the no-OCP GnRH antagonist regimen. Suppression was more profound at the start of stimulation ($P \leqq 0.001$), as manifested by slower follicular growth ($P \leqq 0.001$), longer stimulation (11.7 and 10.3 days respectively versus 9.4; $P \leqq 0.001$), and more rFSH utilized (2667 and 2222 IU versus 1966 IU; $P \leqq 0.001$). In the three groups, the number of oocytes was similar (13.1, 12.9, and 11.5, respectively); and the number of good quality embryos (5.1, 5.7 and 5.0) were similar.[182] One meta-analysis evaluated 4 RCTs in 847 patients and found no difference in ongoing pregnancy rates[183] though duration of stimulation and gonadotropin requirements were higher after OCP pretreatment. However, in a follow-up study the authors found that ongoing pregnancy rates were lower in OCP pre-treated GnRH-antagonist cycles (relative risk: 0.80, 95% CI 0.66-0.97), and again that duration of stimulation and gonadotropin requirements were higher.[184] Another meta-analysis including estradiol and progesterone pretreatment had similar findings, including slightly lower ongoing pregnancy rates, however concluded that no changes in clinical practice were indicated as numbers in trials were small.[185] A recent randomized trial showed longer stimulation and gonadotropin requirements but no difference in clinical pregnancy rates when 4 mg oral estradiol (comparable to 20 mcg ethinyl estradiol) versus no treatment was begun prior to stimulation. In our program we use 10 to 21 days of oral contraceptives. Not all patients have a withdrawal bleed after oral

Table 31.3 Efficacy of GnRH in Preventing Premature Luteinizing Hormone Surges in Women Undergoing Ovarian Stimulation

Dose of Ganirelix	0.0625 mg	0.125 mg	0.25 mg	0.50 mg	1.0 mg	2.0 mg
Number of women	30	65	68	69	64	26
FSH (IU/L)	9.1	9.0	9.1	10.2	9.8	8.8
LH (IU/L)	3.6	2.5	1.7	1.0	0.6	0.4
Androstenedione (ng/mL)	2.6	2.6	2.4	2.2	2.0	1.5
Estradiol (pg/mL)	1475	1130	160	823	703	430
Pregnancy rate per cycle	23.3%	23.1%	33.8%	10.1%	14.1%	0%

Women undergoing IVF received recombinant FSH (Puregon) starting on cycle day 2 and continuing daily until three follicles with a mean diameter greater than 17 mm (as determined) were achieved when hCG was given to initiate the ovulatory process. The women were randomized to receive the GnRH antagonist, ganirelix, on a daily basis starting on cycle day 7 at one of six doses (0.0625 mg, 0.125 mg, 0.25 mg, 0.5 mg, 1.0 mg, 2.0 mg). Serum FSH, LH, androstendione, and estradiol concentration were measured on the day of hCG administration. Large doses of ganirelix markedly suppressed serum LH, androstenedione, and estradiol concentrations. Pregnancy rate per cycle was maximal with a dose of ganirelix of 0.25 mg.

The Ganirelix Dose Finding Study Group: A double-blind randomized dose-finding study to assess the efficacy of the gonadotropin-releasing hormone antagonist ganirelix [org 37462] to prevent premature luteinizing hormone surges in women undergoing ovarian stimulation with recombinant follicle stimulating hormone [Puregon]. *Hum Reprod* 13:3023-3031, 1998.

contraceptives, so a baseline ultrasound is performed on day 2 of the menstrual period following pill cessation, or 4 days after the last pill, as the vast majority of women will have had a withdrawal bleed by that point.

GnRH Agonist vs GnRH-Antagonist Protocols in "Normal" Responders

Most studies of IVF have demonstrated that both GnRH agonists in a down-regulation protocol and GnRH antagonists are associated with similar rates of cycle cancellation due to a premature LH surge, as well as similar rates of ovarian hyperstimulation syndrome (OHSS). An older Cochrane review of five randomized controlled trials comparing GnRH antagonist (n = 1211) to GnRH agonists in a down-regulation protocol (n = 585) for IVF, revealed that the odds ratio (OR) for becoming pregnant in the GnRH antagonist group was 0.79 (95% confidence interval [CI], 0.63 to 0.99) compared with the GnRH agonist group.[186] However, a recent Cochrane review by the same first author found, in forty-five RCTs (n = 7511) comparing the antagonist to the long agonist protocols in women with normal ovarian reserve, that there was no evidence of a statistically significant difference in rates of live-birth (9 RCTs; odds ratio [OR] 0.86, 95% CI 0.69 to 1.08) or ongoing pregnancy (28 RCTs; OR 0.87, 95% CI 0.77 to 1.00). There was a statistically significant lower incidence of OHSS in the GnRH antagonist group (29 RCTs; OR 0.43, 95% CI 0.33 to 0.57). Therefore, it appears reasonable to use clinical judgement in choosing which type of protocol to use in patients with normal ovarian reserve.[187]

"Poor Responder" Protocols

"Estradiol Priming" GnRH-Antagonist Protocols

A variation of GnRH antagonist use in IVF utilizes a luteal estradiol patch or oral estradiol (e.g., 0.3 mg patches changed qod or 4 mg oral estradiol daily) followed by GnRH-antagonist suppression (Fig. 31.17). Following a menstrual period, gonadotropin stimulation with GnRH antagonist support is utilized. The hypothetical advantage of this approach is to improve the synchrony of the developing follicles by reducing antral follicle sizes and follicular phase heterogeneity[188] making it best suited for use in poor responders. In one report, patients using the "patch" protocol had a lower cycle cancellation rate, more oocytes retrieved and more embryos transferred than in a prior cycle.[189] A meta-analysis looking at GnRH antagonist cycles with and without pretreatment did find that more oocytes were retrieved after estradiol pretreatment compared to no pretreatment.[185]

Microflare Protocol

The "microdose" flare protocol employs diluted or low dose GnRH agonist typically starting day 1 or 2 of the menstrual cycle (Fig. 31.18). The goal is to provide stimulation with enough suppression so as to avoid a spontaneous LH surge, but not enough to suppress endogenous pituitary LH and FSH release so that ovarian stimulation is augmented by endogenous gonadotropins. The protocol is often used with oral contraceptive pretreatment starting day 1 to 2 of menses. The microdose leuprolide acetate protocol has been compared to the estrogen priming protocol in prospective randomized trials in poor responders, with no difference in clinical or live birth rates reported. However, numbers are quite small and likely not powered adequately to show any significant differences in outcomes.[190] In one larger trial of 116 cycles, the estrogen priming protocol used higher doses of gonadotropins, (3247.8 ± 634.6 versus 2994.8 ± 611 IU), yet similar numbers of oocytes were retrieved and fertilized. There was no significant difference between the two groups in terms of the implantation rates (9.8% versus 7.9%) and the clinical pregnancy rates per transfer (16.3% versus 15.6%).[191]

Another study randomized 270 poor responders to a standard flare protocol (0.05 mg/day of triptorelin) versus antagonist, with no hormonal lead-in for either treatment. Triptorelin was started at the time of stimulation on cycle day 2, and cetrorelix was started at a follicular diameter of ≥14 mm. A fixed dose of 400 IU r FSH was used. As expected, estradiol at hCG was lower in the antagonist group, but oocyte yield, fertilization, and implantation rates were not different. However, the ongoing pregnancy rate, was higher in the antagonist group (12.2 versus 4.4%,

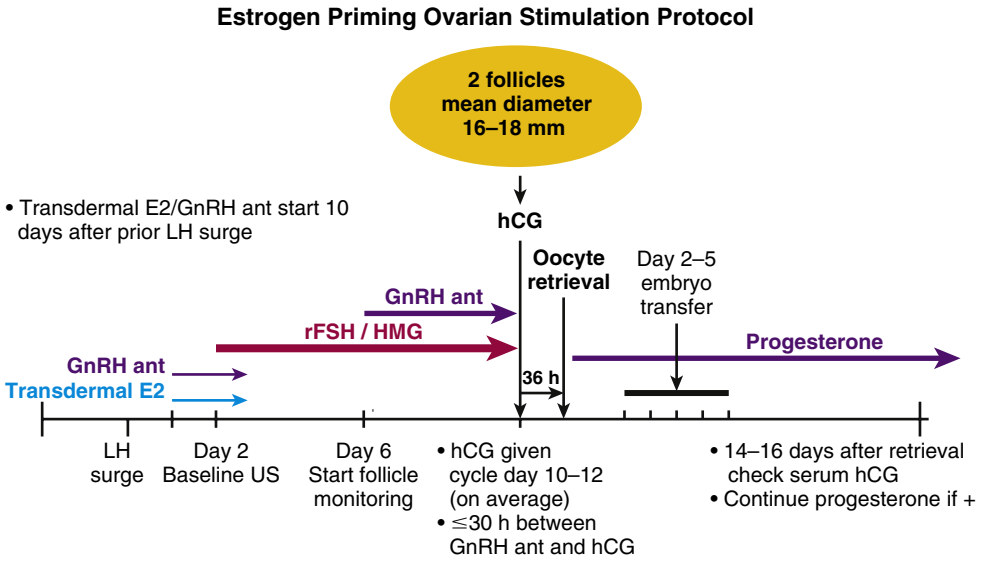

FIGURE 31.17 Schematic representation of the "patch" or "estrogen priming" protocol for ovarian stimulation for *in vitro* fertilization (IVF). FSH, follicle stimulating hormone; GnRH-ant, gonadotropin-releasing hormone antagonist; hCG, human chorionic gonadotropin; hMG, human menopausal gonadotropin; US, ultrasound. *(From Cheong Y, Ginsburg ES, Macklon N. Protocols for ovarian stimulation. In Ginsburg ES, Racowsky C. New York,* Springer Science+Business Media, *In Press.)*

$P < 0.048$; difference 7.8%; 95% CI: 0.2 to 14.0); however, the confidence interval does slightly overlap 1.0.[192] Another trial of 55 poor responders found equivalent pregnancy rates between the flare and antagonist groups. However, there were more mature eggs retrieved, and more high quality embryos transferred, as well as a higher fertilization rate in the flare group (84% versus 63%).[193]

Cycle Monitoring in IVF

In GnRH-agonist cycles, documentation of pituitary downregulation is performed by assessing serum estradiol and progesterone levels after menses has begun; levels should be suppressed, and depending on the assays used, estradiol levels are typically less than 50 pg/mL and progesterone less than 1.0 ng/mL. A baseline estradiol is also performed to rule out any large ovarian cysts which could grow in response to treatment, and to rule out potential malignancy. Simple ovarian cysts need not necessarily prevent the start of stimulation but persistent complex cysts greater than 3 cm warrant surgical treatment prior to ovarian stimulation, unless the patient is known to have endometriosis and the cyst has a typical endometriotic cyst appearance.

As the pituitary is not suppressed at the start of GnRH-antagonist cycles, only a baseline ultrasound is needed. After the first 4 or so days of stimulation, serum estradiol and ultrasound examinations are typically performed to assess for the development of mature sized follicles; programs typically use at least 1 to 2 follicles with a mean diameter of 18 mm as an indication for administration of a trigger hCG injection. Mature oocytes, however, are generally obtained from smaller sized follicles as well.

Final Follicle Maturation

Final follicle and oocyte maturation prior to retrieval requires stimulation by high concentrations of LH. Prior to the availability of recombinant hormones, the most accessible source of LH-like material was urinary human chorionic gonadotropin (hCG). Recently, recombinant hCG (rhCG) has become available.[194] Typically hCG is administered as 5000 or 10,000 units (250 μg of rhCG is approximately equivalent to 10,000 units of hCG) to stimulate final follicle maturation. In a clinical trial, hCG was compared with recombinant human LH (rhLH) for final follicle maturation. The investigators reported that hCG and rhLH had similar efficacy for maturing follicles and oocytes and performed similarly in terms of pregnancy rates. However, the rhLH was associated with slightly lower rates of OHSS, probably due to its shorter half-life.[195] It should be noted that the rate of OHSS is in part dependent on the dose of FSH administered during follicle stimulation.[196] rhCG is formulated for subcutaneous use whereas urinary hCG preparations are FDA approved for intramuscular use.

When ovarian stimulation is performed using a combination of GnRH antagonist plus rhFSH, it is possible to use a single dose of a GnRH agonist to stimulate the pituitary to release a surge of LH that will initiate final follicle maturation. For example, in one small clinical trial, women undergoing IVF were stimulated with rhFSH and the GnRH antagonist ganirelix, and then randomized to receive either hCG (10,000 IU), triptorelin (0.2 mg), or leuprolide (0.5 mg) to initiate final follicle maturation. In the GnRH agonist groups (triptorelin and leuprolide), the endogenous secretion of LH peaked at 4 hours after the injection and LH levels returned to baseline by 24 hours. After the hCG injection, circulating hCG peaked at 24 hours and remained elevated for 5 days. Estradiol and progesterone levels were similar up until the day of oocyte retrieval in all three groups. In the luteal phase, estradiol and progesterone levels were greater in the hCG group than in the triptorelin or leuprolide groups. Similar numbers of oocytes and mature oocytes were retrieved in all three groups, and fertilization rates were also similar.[197] Stimulation of an endogenous LH surge with a GnRH agonist is associated with a lower rate of early OHSS.

Oocyte Retrieval

Oocyte retrieval is typically performed 35 to 36 hours after hCG administration by a transvaginal sonography-guided technique using a 16 to 17G needle, and generally under

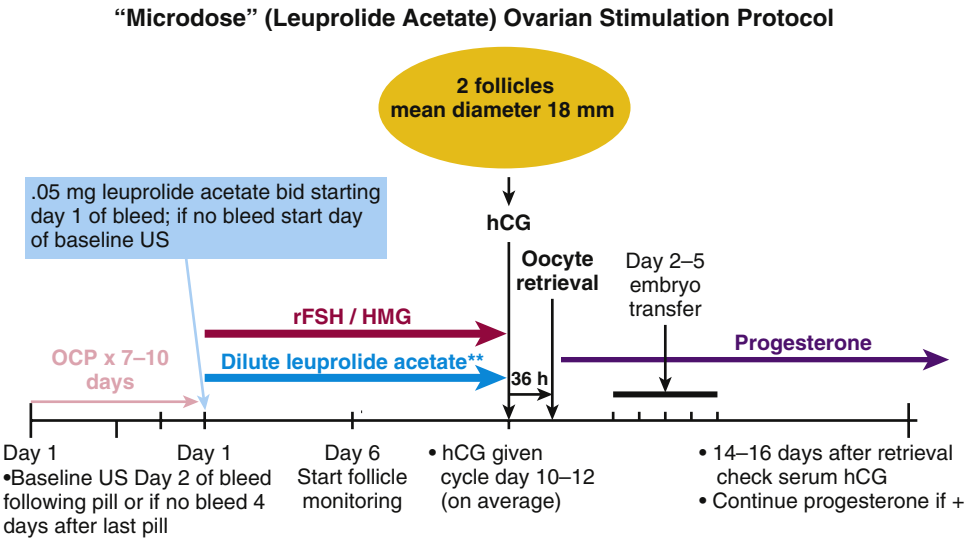

FIGURE 31.18 Schematic representation of the "microflare" protocol for ovarian stimulation for *in vitro* fertilization (IVF). FSH, follicle stimulating hormone; GnRHa, gonadotropin-releasing–hormone agonist; hCG, human chorionic gonadotropin; hMG, human menopausal gonadotropin; US, ultrasound. *(From Cheong Y, Ginsburg ES, Macklon N. Protocols for ovarian stimulation. In Ginsburg ES, Racowsky C. New York,* Springer Science+Business Media, *In Press.)*

intravenous anesthesia. Reports of oocytes in the human fallopian tube after hCG administration suggest that a time interval between hCG administration and oocyte retrieval of about 36 hours maximizes oocyte maturation and minimizes the chance of spontaneous ovulation (Fig. 31.19). Before 30 hours, oocytes in the lead follicles may not be mature. After 38 hours following hCG administration, ovulation begins and oocytes are lost into the peritoneal cavity. The number of oocytes retrieved is largely dependent on the number of large follicles present at the time of retrieval. In general, oocytes can be harvested with a high rate of success from follicles with a mean diameter greater than 12 mm (Fig. 31.20).[198]

Preparation of the vagina with saline, or antibacterial agents[199] followed by copius saline irrigation is typically performed prior to retrieval, and intravenous antibiotics often administered, though there are no randomized trials proving benefit.[200,201] In cases of abnormal anatomy when ovaries are not accessible transvaginally,[202] retrieval can be performed with transabdominal ultrasound guidance, or as in the early years of IVF, via a laparoscopic approach. Regardless of the route of oocyte retrieval, traps containing follicular fluid are passed off to the embryology laboratory which should be directly adjacent to the operating room.

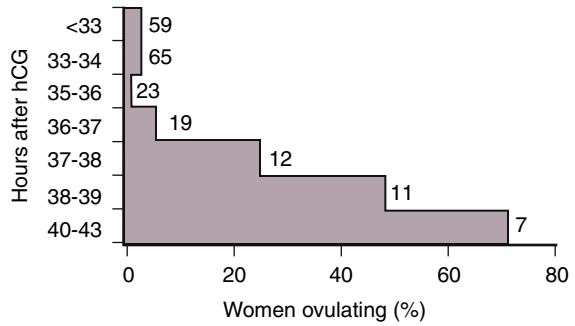

FIGURE 31.19 Interval between an injection of human chorionic gonadotropin (hCG) and the percentage of women in whom follicular rupture has occurred. The number of women studied is indicated to the right of the bar. *(From Edwards RG. Physiological aspects of human ovulation.* J Reprod Fertil *18[suppl]:87-101, 1973.)*

The embryologist immediately picks up and then assesses the oocytes for maturity.

Assessing Oocyte Quality

Ideally, both nuclear and cytoplasmic maturation should be assessed because both processes are required for an oocyte to fertilize successfully and support early embryonic development. Typically, only 70% to 80% of retrieved oocytes have achieved nuclear maturation (i.e., have emitted the first polar body and are in metaphase II); the remaining 20% to 30% are at either prophase I or metaphase I. As no overt morphological changes in the oocyte have yet to be associated with cytoplasmic maturation, the proportion of retrieved oocytes that are cytoplasmically mature remains unknown. However, this proportion is likely quite small since, even after consideration of the multiple factors involved in formation of a viable healthy embryo, the overall efficiency of oocyte to liveborn in ART is only about 5%.[203]

Current techniques for assessing oocyte quality fall into the two major categories, invasive and non-invasive. The invasive approach involves polar body biopsy and preimplantation genetic screening (PGS) which enables, by extrapolation, determination of the oocyte chromosomal complement,[204] as well as insight into the oocyte transcriptome[205] (see Chapter 30). Noninvasive assessment continues to rely on visual inspection of the morphological appearance of the surrounding cumulus oophorus with a light microscope. During the periovulatory period in response to the midcycle surge of LH or exogenous hCG, the cumulus cells secrete glycosaminoglycans,[206,207] resulting in expansion of the cumulus oophorus, and a radiating appearance of the inner corona radiata cells. Although the overall disposition of the surrounding cumulus-corona cells may thus provide some guide to quality of the enclosed oocyte,[208] this association is not perfect. Nuclear maturity and emission of the first polar body is most accurately determined by visualization of the oocyte itself (Fig. 31.2).

The imperfect prediction of oocyte maturity by morphological assessment of the cumulus-corona radiata cells has

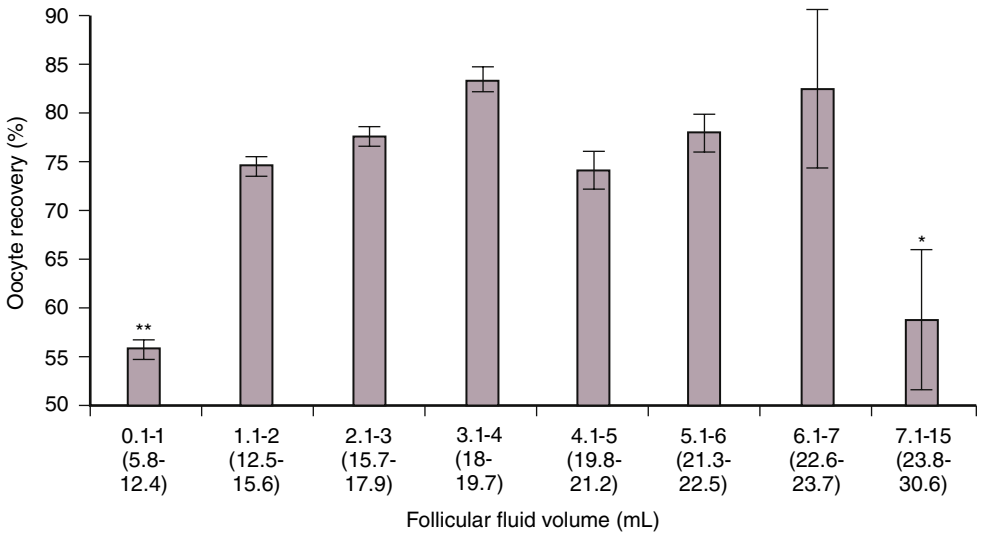

FIGURE 31.20 Percentage of follicles from which an oocyte was obtained at the time of retrieval as a function of follicle size. Mean, SEM; *$P < 0.01$; **$P < 0.001$. Numbers in parentheses represent corresponding follicular diameter in millimeters as determined by sonography. *(From Wittmaack FM, Kreger DO, Blasco L, et al. Effect of follicular size on oocyte retrieval, fertilization, cleavage, and embryo quality in in vitro fertilization cycles: a 6-year data collection.* Fertil Steril *62:1205-1210, 1994, with permission of the American Society for Reproductive Medicine.)*

led to development of alternative non-invasive approaches to assess oocyte quality. Use of polarized light to visualize the size and shape of the meiotic spindle,[209] and the thickness of the inner zona pellucida layer[210] have been correlated with outcome.[211] However, because of the cost of the polarizing system and the sensitivity of the results to oocyte positioning it is unlikely that this approach will be routinely adopted in the IVF laboratory. Alternatively, genomic approaches are being aggressively pursued. Expression of genes specifically associated with cumulus expansion such as *PTGS2*, *HAS2*, and *GREM.1VCAN* and *RPS6KA2*,[212-215] as well as those involved in the calcium signaling pathway[216] have all been found to have some predictive value. Other genes have been associated with oocyte meiotic stages and specific maturation conditions,[217,218] and cumulus cell gene expression has been used in multivariable models to predict embryo quality and implantation.[219] Furthermore, membrana granulosa cell genes involved in the luteinization process have been associated with oocyte quality,[220] and a recent study has revealed a correlation between mature (as opposed to propeptide) forms of *GDF9* in follicular fluid and oocyte nuclear maturation and embryo quality.[221]

Although such molecular studies provide insight into the differential expression of biomarkers associated with developmentally competent versus incompetent oocytes, much work remains to be done to identify a gene network algorithm that can be applied clinically for identification of oocytes that have acquired both nuclear and cytoplasmic competence.[216] Moreover, if ever established clinically, the laboratory protocols will need to be streamlined to ensure that each oocyte is individually tracked with fidelity of its association with corresponding cumulus and/or granulosa cells ensured.

Collection, Assessment and Preparation of Sperm

Semen is typically collected by masturbation or occasionally by sexual intercourse using a condom lacking spermicide. In cases of male factor infertility, retrograde ejaculation, electroejaculation, testicular biopsy or epididymal aspiration may be employed (see Chapter 24). Moreover, for men with markedly abnormal semen parameters, ICSI is recommended (see Chapters 24 and 32).

Assessment of ejaculated semen begins with determination of the time it takes for the specimen to liquefy. A normal specimen has liquefied within 60 minutes at room temperature, although usually this occurs within 15 minutes. The liquefied specimen is then examined for color, volume, viscosity, and pH. Initial assessment of the raw, unprocessed, specimen is then undertaken by phase-contrast microscopy to determine the concentration, motility, and agglutination of sperm, and presence of any cellular elements other than the sperm. Sperm morphology may be assessed from smears stained, for example, with Papanicolaou stain. Classification of sperm morphology typically involves assessment of the shape of the head, and defects in the neck, midpiece, and tail (World Health Organization [WHO] Manual), and is generally performed using Kruger's strict criteria.[99]

Further tests may be performed on a case-by-case basis [for example, sperm antibody assessment or viability assessment using the hypo-osmotic (HOS) test].[222] The WHO reference values of semen variables are shown in Table 31.4. If the semen parameters are abnormal, the number of sperm isolated from the specimen is related to both fertilization and pregnancy rate following routine IVF.[223] As the number of sperm in the unwashed specimen decreases below 10 to 20 × 10^6/mL, the incidence of chromosomal abnormalities increases.[224,225] Therefore, nonobstructive azoospermia and severe oligospermia (less than 5 million/mL) are indications for karyotype evaluation (see Chapter 24).[226] Interestingly, the incidence of aneuploidy in sperm appears to increase with increased incidence of sperm DNA fragmentation,[227] although as mentioned previously, there is a strong need to standardize the specific tests used to quantify the extent of DNA damage.[56]

Table 31.4 WHO Reference Limits for Semen Characteristics (2010)

Parameter	Lower Reference Limits
Semen volume (mL)	1.5 (1.4-1.7)
pH	≥7.2
Total sperm number (10^6 per ejaculate)	39 (33-46)
Sperm concentration (10^6/mL)	15 (12-16)
% Total motility (progressive and non-progressive)	40 (38-42)
% Progressive motility	32 (31-34)
Sperm morphology (normal forms %)	4 (3.0-4.0)
Vitality (live sperm, %)	58 (55-63)
Immunobead test (motile sperm with bound beads, %)	<50

Values are lower reference limits (5th centiles and their 95% confidence intervals).
WHO laboratory manual for the examination and processing of human semen, 5th edition, Cambridge University Press, 2010.

The liquefied semen specimen is processed for isolation of the sperm by a variety of techniques, including swim-up, and centrifugation techniques using a density gradient comprising a polymer (e.g., Isolate). For normal semen specimens, both techniques generate high-motility sperm for oocyte insemination.[228] For semen with abnormal sperm characteristics (e.g., low sperm concentration), however, most studies demonstrate that sperm prepared by the gradient centrifugation technique are superior to sperm prepared by the swim-up technique. For example, in one study on abnormal semen (defined by WHO criteria), density gradient centrifugation resulted in selection of sperm with higher scores for the acrosome reaction, the HOS test and nuclear maturity, than those selected with a swim-up procedure.[229]

In preparation for incubation with the oocytes, sperm prepared by either the swim-up or gradient centrifugation technique are incubated in a protein-supplemented medium for up to 4 hours to initiate the process of capacitation.

Incubation of Sperm with Oocytes and the Fertilization Check

For standard IVF, the number of sperm used for insemination will vary depending upon whether the oocytes are inseminated in microdrops of 100 to 200 μL medium or

in a larger volume (usually 1 mL). Typical numbers used for microdrop insemination range from 25,000 to 50,000 sperm, while those for insemination in a 1 mL volume, typically holding 3 to 5 oocytes, usually range from 100,000 to 300,000. For men with normal semen parameters, higher concentrations of sperm do not significantly improve the fertilization rate.

Approximately 16 to 18 hours later, the oocytes are examined for fertilization. The cumulus-corona radiata cells are gently removed from the oocyte which is then examined under an inverted microscope with Hoffman illumination at around 100× magnification. A zygote with two pronuclei (PNs) and two polar bodies is morphological evidence of normal fertilization. All oocytes with either less than or more than 2PNs are discarded. The 2PN zygotes are then set up in culture either separately or in groups.

Embryo Culture Media

Substantial improvements in culture systems for clinical IVF have occurred since the culture of the first viable human embryo in the 1970s. In contrast to the use of Ham's F10 medium or Earle's balanced salt solution supplemented with maternal serum for use in these early days of clinical IVF, a multitude of commercial culture media are now available for growing human embryos in culture.[230,230a]

Early attempts to culture human embryos to the blastocyst stage required the use of feeder cells to support embryo development.[231] However, significant improvements in human IVF culture media were made in the 1990s using two different approaches: the so-called "back to nature" approach and the "let the embryo choose" approach.[230] These approaches resulted in successful culture of human embryos to the blastocyst stage without feeder cell support.

The "back to nature" approach drew upon assessment of the energy substrate profiles in fallopian tube and uterine fluids. The results indicated that, in contrast to the fallopian tube, the glucose concentration in uterine fluid was relatively high, but the lactate and pyruvate concentrations were relatively low.[232] These observations led to development of a pair of media, reflecting these differences in energy substrate concentration, that are used in sequence for support of human blastocyst formation: the first medium, relatively high in lactate and pyruvate, is used from days 1 to 3 of culture, and the second medium, relatively high in glucose, is used from days 3 to 5.[233] The resultant paired media comprise the sequential media system.

The "let the embryo choose" approach is based on determination of blastocyst formation rates following systematic adjustments in medium composition in numerous experiments using the simplex optimization approach.[234] This approach has resulted in development of a single medium for the culture human embryos from day 1 to day 5 or 6. This system is referred to as the single-step system.

Numerous studies support efficacy of both sequential and single-step systems for growing human embryos to the blastocyst stage.[235,236] Although the overall weight of the evidence indicates that neither system is likely superior to the other,[237] the single-step system offers advantages to lab management including increased simplicity and requirement of less quality control testing, and therefore may be more economical.

Embryo Culture Systems

Standard systems used for culturing human embryos are not physiological. Typical systems comprise a culture dish containing: (1) 25-50 μL volumes of medium placed either onto the surface of the dish in microdrops or into wells sunk into the dish surface; or (2) a larger volume of medium that covers the entire surface area of the dish. Regardless of which system is used, all provide fluid, macro, relatively stagnant and chemically static environments on an inert substrate. In contrast, the embryo *in vivo* not only is exposed to a moist 3-D micro environment that is chemically dynamic, but also is in contact with epithelial surfaces rich in glycoprotein.[238] Due to the nonphysiological nature of current IVF systems, new systems and culture platforms are under development that are designed specifically to address physical and chemical requirements of the embryo. These include the Well of the Well or WOW system,[239,240] and a micro-fluidic, micro-channel approach which has the potential to perform almost all steps of the IVF process with minimal embryologist intervention.[241,242] However, none of these innovations have yet to be integrated into routine IVF, and it is unclear whether there is any increase embryo viability and thus implantation rates, over the traditional 2-D systems currently in use.

The one fact that is becoming accepted regarding human embryo culture is the beneficial use of low oxygen tension (5%), rather than atmospheric oxygen (20%). The detrimental effect of 20% oxygen on *in vitro* development of bovine embryos was shown 20 years ago,[243] and recent experiments in mice have revealed that this effect is irreversible.[244] Consistent with these observations, a prospective randomized trial showed that following culture of embryos in low versus high oxygen tension, there was a significant increase in both the conversion rate of human zygotes to blastocysts (47.8% versus 42.1%; $P = 0.02$), as well as the live birth rate (42.1% versus 32.2%; $P = 0.04$).[245] Of note, a recent meta-analysis of studies involving cleavage stage transfers showed no improvement in implantation ($P = 0.63$) rate for embryos cultured in 5% versus 20% oxygen, but a significant increase in implantation rate for the low oxygen tension group after days 5 to 6 transfer ($P = 0.006$).[246] Therefore, the beneficial effect of low oxygen tension may manifest only after activation of the embryo genome on day 3, although further studies are required to investigate this interpretation of available data.

Evaluating Embryo Quality

The goal of evaluating embryo quality is identification of an embryo marker that predicts pregnancy rate more accurately than the age of the female partner and the number of embryos transferred.[247] Such a marker should lead to the development of highly successful single embryo transfer protocols and reduce the risk of multiple gestations.[248]

As with approaches for assessing oocyte quality, those for evaluating embryo quality fall into the two broad categories of invasive and non-invasive. Invasive approaches entail PGS of one, or occasionally two, biopsied blastomeres

Table 31.5 The Timeline for the Development of the Conceptus from Pre-Zygote (Fertilized Egg) to Implanting Blastocyst and the Location of the Conceptus in the Reproductive Tract

Conceptus	Fertilization	Location of Stage of the Days after Conceptus in the Reproductive Tract
Pre-zygote—fertilized	0	Fallopian tube (oocyte)
2-cell embryo	1	Fallopian tube
4-cell	2	Fallopian tube
8-cell	3	Fallopian tube
Morula	4-5	Utero-tubal junction
Blastocyst	5	Intrauterine
Implanting, hatched blastocyst	5-6	Intrauterine

from a cleavage stage embryo, or several trophectoderm cells excised from the trophoblast (see Chapter 32). Non-invasive methods include morphological assessment paradigms, and screening of spent culture media for constituent changes that may relate to embryo viability.

Despite limitations of determining embryo quality using the light microscope, such morphological evaluation remains the first-line approach for assessing viability. Human embryos follow a specific developmental timeline,[249] during which milestones are reached in a coordinated sequence that are typified by characteristic morphological features (Table 31.5) Therefore, utilization of the Darwinian concept of "survival of the fittest" has proved useful. Historically, evaluation has been performed only once, within a few hours of transferring cleavage stage embryos on either day 2 or day 3. In this setting, evaluations have included assessment of cell number, degree of fragmentation (typically assessed as percentage of the volume of the embryo fragmented), cytoplasmic pitting, compaction, symmetry of blastomeres with respect to size and shape, and absence of vacuoles and multinucleation. Although each of these parameters has been shown to have some value in predicting quality and pregnancy rate,[250-252] cell number, fragmentation, and symmetry remain the most commonly assessed characteristics for day 3 embryos. Compared with eight-cell embryos lacking fragments and having perfect to near-perfect symmetry (i.e., blastomeres of uniform size and shape; Fig. 31.21A), those exhibiting low cell number and fragmentation, but with severe asymmetry (Fig. 31.21B), have significantly lower implantation rates,[252] which are further compromised when fragmentation is very high (Fig. 31.21C).

In addition to evaluations performed on day 3, assessments on day 1 have revealed a relationship between implantation potential and prezygote morphology at 16 to 18 hours after insemination (pronuclear size, size and number of nucleolar precursor bodies, and cytoplasmic appearance),[253-255] as well as the ability of embryos to complete the first mitotic division by 27 hours after insemination.[256,257] Moreover, embryos are typically considered of high quality if they are able to reach the blastocyst stage by 120 hours after insemination, exhibit a complete trophectoderm surrounding an expanded fluid-filled cavity, and have a tightly packed cluster of inner cell mass cells.[258]

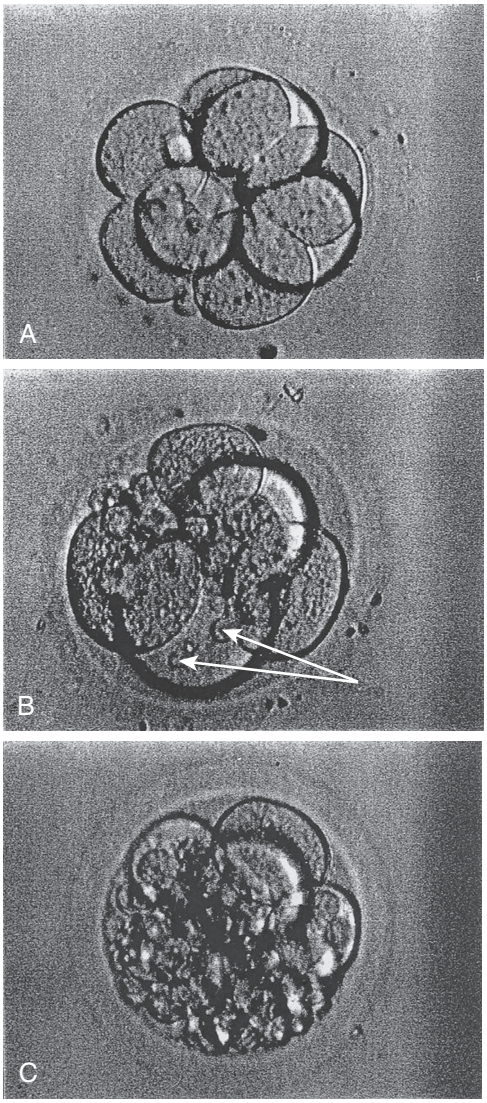

FIGURE 31.21 Day 3 embryos showing various degrees of asymmetry and fragmentation. **A,** An eight-cell embryo with minimal fragmentation but having blastomeres somewhat discordant for size and shape (i.e., exhibiting moderate asymmetry). **B,** A six-cell embryo with severely asymmetrical blastomeres but exhibiting slight fragmentation, with a few fragments interspersed among the blastomeres *(arrows)*. **C,** A five-cell embryo showing moderately asymmetrical blastomeres and a high degree of fragmentation, with more than half the volume of the embryo fragmented, likely resulting from the fragmentation of several blastomeres.

In view of the reported benefit of independent morphological evaluations on specific days of culture, numerous studies have investigated the possible additional value of undertaking morphological evaluations on sequential days in culture. This approach enables a developmental library of morphological information to be built on each embryo that might improve embryo selection. Although several studies do not show benefit in scoring embryos on days other than on day 3 immediately before transfer,[259] other studies indicate that multiscoring systems may enable improved embryo assessment.[260] Indeed kinetic parameters acquired from time-lapse imaging of embryos during very early development hold promise for improving embryo assessment.[261,262]

Early concerns that embryo development might be perturbed by the constant, albeit low level, light exposure required during such imaging have not been borne out by data that show comparable development of sibling zygotes cultured in a standard incubator versus a time-lapse imaging system.[263,264] Retrospective analysis of imaged embryos has shown that three parameters predicted development to the blastocyst stage with greater than 93% accuracy: duration of the first cytokinesis, time interval between the end of the first cleavage and initiation of the second cleavage (from 1 to 2 cells embryo) and synchronicity of the blastomeres in the second cleavage division, from the 2 to 4 cell stage.[265] A further retrospective study has corroborated the apparent significance of duration of the second cell cycle and synchrony of the second and third cell divisions with implantation potential.[266] Another recent study has also documented a relationship between times required to complete the second and third mitotic divisions and the potential to develop to high scoring blastocysts.[267] Of note, however, as all the above analyses were retrospective, it is currently unknown what utility these developmental kinetic markers have for prospective embryo evaluation and selection, and whether evaluation based exclusively on these time-sensitive markers would result in superior implantation rates compared with those obtained following evaluation by conventional morphological evaluation alone. Further research is required in this area, and the ultimate combination of morphological features required for optimum evaluation of developmental competence remains to be identified.

Several studies have investigated possible marker candidates in the medium used to culture the embryos. These markers include soluble human leukocyte antigen (sHLA-G),[268] markers for amino acid metabolism,[269,270] and specific protein peaks associated either with implantation failure or success using proteomic profiling.[271] Each of these approaches hold some promise for identifying a marker(s) for embryonic developmental competency, but their standard application in the IVF laboratory awaits further research and confirmation of efficacy.

Cleavage Stage versus Blastocyst Transfer

Early attempts of clinical IVF in the late 1960s and 1970s began with transfer of cleavage stage embryos on day 2. At that time, *in vitro* systems were rudimentary and so it seemed prudent to remove the embryos from culture and place them in the maternal environment as soon as possible.[5] In addition, because only a handful of oocytes were retrieved and few embryos were created, there was no need for embryo selection, which is the main objective of extending the culture interval in current IVF approaches. Today, with more embryos typically created than will be transferred, the decision regarding whether to transfer at the cleavage (days 2 and 3) or blastocyst (days 5 and 6) stage remains a central challenge in most IVF programs. This challenge is complicated by our continuing inability to predict with certainty which cleavage stage embryos will develop into viable blastocysts.

Transferring human embryos at the blastocyst stage offers several theoretical advantages: (a) improved temporal synchronization between embryo and uterus at the time of transfer; cleavage-stage embryos typically undergo development in the fallopian tube with traversal of the uterotubal junction being at the morula stage, 4 to 5 days after fertilization (Table 31.5); (b) the possibility of selecting developmentally more competent embryos, because blastocyst stage embryos have proved their ability to progress through normal developmental milestones *in vitro* although, of note, selection against aneuploid embryos progressing to blastulation appears to be weak[272]; and (c) the rationale to transfer fewer embryos with higher implantation potential, thereby reducing the risk of multiple gestations.[233,273]

Despite these theoretical advantages to blastocyst transfer, there are several potential disadvantages. Extending culture to the blastocyst stage appears to result in attrition of some embryos that otherwise would support viable pregnancies following cleavage-stage transfer. In one study of blastocyst transfer, when there were no eight-cell embryos present on day 3, the pregnancy rate was higher when transfer occurred on day 3 as compared with day 5 (33% versus 0%).[274] Moreover, for some patients with healthy-appearing day 3 embryos, all of the embryos underwent developmental arrest or degeneration before day 5, leaving no embryos for transfer.[274] The inability to predict which cleavage-stage embryos will develop into blastocysts *in vitro* has led to a significantly higher incidence of canceled embryo transfers in patients randomized to day 3 versus day 5 culture.[275] Blastocyst transfer has also been associated with an increased risk of monozygotic twinning[276,277] and the obstetrically more serious condition of monochorionic twinning.[278] Moreover, a high rate of dizygotic twinning can be expected in good prognosis patients even following transfer of only two blastocysts.[279,280] Finally, concerns have been raised regarding possible adverse effects of longer durations of culture on the risks of epigenetic mutations in offspring,[281,282] particularly as animal data indicate that developmental programming is modifiable by *in vitro* manipulations,[283,284] and children born from blastocyst transfer may be at a slightly increased risk for preterm birth[285] and adverse neonatal outcomes compared with those conceived following cleavage stage transfer.[286]

Randomized controlled trials comparing the efficacy of blastocyst transfer with cleavage-stage transfer have revealed the importance of patient selection (based on patient age, number and quality of embryos, etc.) and the time during treatment for selecting patients to proceed with blastocyst transfer. In a recent Cochrane review of 12 randomized controlled trials involving 759 day 2 and 3 transfers and 751 day 5 and 6 transfers, clinical pregnancy rates were similar for the two groups (OR, 1.14; 95% CI, 0.99 to 1.32), but live birth rates were significantly higher in the day 5/6 group (OR, 1.40; 95% CI, 1.13 to 1.74).[275] However, these results were corroborated only when restricting the analysis to those trials involving women with good prognosis for success (6 RCTs: OR, 1.43; 95% CI, 0.99 to 2.07), and not for those with poor prognosis or who were unselected for trial participation.[275] Moreover, the time point during treatment for selection of patients to blastocyst transfer is important: live birth rates were only significantly increased when randomization occurred on days 2 and 3 (OR, 2.17; 95% CI, 1.42 to 3.33), rather than at cycle start (OR, 1.25; 95% CI, 0.90 to 1.73) or on the day of or after egg retrieval (OR, 0.97; 95% CI, 0.37 to 2.58).[275] This observation

highlights that the overall quality of the cleavage stage embryo cohort directly correlates with the likelihood of successful development of at least one viable blastocyst.

Regardless of prognostic group, fewer surplus embryos are frozen in blastocyst versus cleavage stage cycles, and available data show significantly increased cumulative pregnancy rates in the group of patients having day 2 and 3 transfers (4 RCTS: OR, 1.58; 95% CI, 1.11 to 2.25).[275] This observation is likely due not only to the decreased number of embryos frozen on day 5/6, but also to the historically poor survival of frozen blastocysts experienced by many programs. With the recent establishment of highly successful vitrification methods for blastocyst cryopreservation,[287] it may be that cumulative pregnancy rates with blastocyst transfer will meet, or even exceed, those of cleavage stage transfer.

Collectively, available data indicate that the best candidates for blastocyst transfer are those women with good prognosis (based on age, number and quality of embryos). Serious consideration should be given to single blastocyst transfer in this group because of the risk of dizygotic twinning after transfer of two blastocysts.[288] Indeed, the first IVF human pregnancy occurred after the transfer of a single blastocyst-stage embryo to the uterus, although it resulted in an ectopic implantation.[289] It is possible that for patients with good prognosis, the IVF technique will eventually go full circle, returning to the transfer of a single, blastocyst-stage embryo.

Embryo Transfer

The embryo transfer is conceptually a simple procedure, involving loading the embryo or embryos to be transferred into a catheter and transferring them into the midfundal portion of the uterus. However, it is a critical part of the ART cycle; there may be significant differences in pregnancy rates between clinicians, even when only those transfers that had high quality embryos are included.[290] One study found a range of pregnancy rates from 17% to 54.3% in the same program.[291] The mechanical aspects of embryo transfer appear to influence implantation and pregnancy rates. For example, traumatic embryo transfers resulting in blood on the embryo transfer catheter are associated with a decreased rate of embryo implantation and clinical pregnancy.[292] In addition, transfers made in the presence of high-frequency uterine contractions (as detected by ultrasound) appear to be associated with lower pregnancy rates.[293] Embryo transfers performed with soft, flexible catheters lead to higher pregnancy rates than do rigid catheters.[294,295] This was confirmed in a meta-analysis of published randomized trials.[296]

Performance of transabdominal ultrasound guidance during transfer, if feasible based on patient body habitus, confirms depth of transfer and may reduce trauma to the endometrium, however it does require the patient to have a full bladder, which is uncomfortable for her. Several investigators have reported that ultrasound guidance of the catheter during embryo transfer slightly improves implantation rate and may improve pregnancy rates.[297-299] Although randomized trials have not consistently found that US guidance improves implantation or live birth rates, meta-analyses suggest a benefit. The most recent meta-analysis found that published trials are of poor quality, with 42 of 59 trials excluded from analysis.[299a] Nevertheless the authors concluded that, overall, the ongoing pregnancies per woman randomised to ultrasound guided ET (441/1254 or 35.2%) was significantly higher than for clinical touch (350/1218 or 28.7%); (OR 1.38, 95% CI 1.16 to 1.64, $P < 0.0003$). The majority of studies show that the optimal depth of transfer from the fundus is approximately 15 mm, and pregnancy rates were lower at 1.5 to 2.0 cm as compared to 1.0 cm or greater than 2 cm.[300] Therefore US guidance for ET is appropriate when feasible.

Table 31.6 ASRM/SART Recommended Limits on Number of Embryos to Transfer

Cleavage-Stage Embryos				
Prognosis	**<35y**	**35-37y**	**38-40y**	**>40y**
Favorable*	1-2	2	3	5
All others	2	3	4	5
Blastocysts				
Prognosis	**<35y**	**35-37y**	**38-40y**	**>40y**
Favorable[a]	1	2	2	3
All others	2	2	3	3

*Favorable means first cycle of IVF, good embryo quality, excess embryos available for cryopreservation, or previous successful IVF cycle.
In frozen embryo transfer cycles, the number of good-quality thawed embryos transferred should not exceed the recommended limit on the number of fresh embryos transferred for each age group.
ASRM Practice Committee. Guidelines on number of embryos transferred. *Fertil Steril* 92:1518-1519, 2009.

Number of Embryos to Transfer

The issue of multiple gestations, particularly high-order multiple gestations (triplets and above), is a significant problem in assisted reproduction, associated with poorer obstetric outcomes and the neonatal complications of prematurity and low birth weight. The social and economic impact of such gestations on the families involved and on society in general cannot be underestimated. As a result, numerous approaches have been tried to reduce the rate of multiple gestations. In some Western European countries a legislative approach has severely restricted the number of embryos transferred in IVF cycles. Several countries have included significant disincentives for physicians who exceed the mandated number of transferred embryos. For example, such physicians face loss of license in Sweden and the United Kingdom and potential imprisonment in Germany and Switzerland. The United States has taken a largely voluntary approach, with a series of guidelines on the number of embryos transferred published by SART and the ASRM (Table 31.6). These guidelines, based on age and prognosis, have gradually reduced the acceptable number of transferred embryos, particularly in women age 37 and younger.[301] The result has been a decline in the percentage of triplet births from ART from 11.4% to 7.4%, a 35% decline between 1995 and 2001, with the largest decrease (20.8%) from 1998 and 1999, the year following the publication of the first SART guidelines.[302] The triplet live birth

rate has dropped to 1.5% or less in all age categories in the 2010 national SART data report.[104]

Elective Single Embryo Transfer

Since the 1950s, the incidence of twin gestations has doubled and the number of triplet gestations has tripled. Currently, approximately 40% of twin gestations and 80% of triplet gestations are the result of infertility therapy; however, only 8% of twins and 14% of triplets result from ART.[303] Moreover, since 1998, the percentage of triplets resulting from IVF has progressively decreased.[302,304] Nevertheless, an important question remains: How many embryos should be transferred to maximize the live birth rate and minimize the number of high-order multiple gestations? Overall, there are correlations among the number of embryos transferred and both the pregnancy rate and the high-order multiple gestation rate,[305] with the quality of the embryos transferred an important determinant in both. As discussed earlier, most centers take advantage of this relationship by stringent morphological grading to assess embryo quality. However, in general, scoring of cleavage-stage embryos is not a foolproof predictor of implantation rate. The pregnancy and multiple gestation rates are also dependent on the age of the female partner. For women older than 36 years, more embryos must be transferred to produce the pregnancy rates achieved in younger women,[306] a trend that is even more pronounced in women over the age of 39.[307]

To date the most significant impact on reducing multiple gestations, not only high-order multiples but also twins, has come from the use of elective single embryo transfer (SET). This practice has been more widely accepted in Europe; single embryo transfer represented only 6.7% of U.S. cycles versus 13.7% of European cycles in 2002,[308] and only 9.6% of cycles in women less than 34 years old in the United States in 2009.

Several groups have investigated the use of SET in women undergoing IVF. In the first randomized clinical trial, Gerris and colleagues randomized patients younger than 34 years old undergoing their first IVF cycle with at least two "top-quality" embryos to either SET or double embryo transfer (DET). Within this group with excellent prognosis, those women with a DET achieved a higher ongoing pregnancy rate than those with a SET (74.0% versus 38.5%, $P = 0.013$); however, the multiple gestation rate of 30% was higher in the DET group than in the SET group (30% versus 4%).[309]

A large Scandinavian multicenter study randomized 661 women under 36 years old undergoing IVF treatment to either a single cycle of DET or a cycle with SET, followed by cryoembryo transfer for those patients who failed to conceive in their SET cycle. The live birth rate was 38.8% in the SET group versus 42.9% in the DET group ($P > 0.05$).[310] The authors concluded that the live birth rate was not substantially lower in the SET group. That conclusion, however, was based on the fact that to achieve such a pregnancy rate, two cycles (one fresh and one frozen) were necessary in 158 patients (48%), and the live birth rate for SET-only patients was 27.6%, substantially lower than that in the DET group (42.9%, $P < 0.001$). It is not clear how acceptable to patients two cycles of ART would be to achieve similar results to those in a single DET cycle.

The challenge in balancing the risks of multiple gestations and the lower pregnancy rate with elective SET may lie in defining an appropriate patient population for SET. The studies to date show that SET is a viable option for women younger than 36, undergoing their first or second IVF cycle who have at least two excellent-quality embryos which have high implantation potentials, as blastocyst stage transfer of embryos on day 5 results in higher implantation rates than does cleavage stage transfer and may optimize delivery rates with eSET. Morphologically top quality blastocysts (those expanding by day 5 after oocyte retrieval with a high quality inner cell mass and trophectoderm) may implant at rates of 70% or greater[258,311] with high quality cleavage stage embryos implanting at rates of 50% or more.[312] However, triplets may occur in 2% of double blastocyst transfers,[279] indicating the risk of high order multiple pregnancy after monochorionic twinning. Of note, the SART and ASRM guidelines recommend that strong consideration be given to SET for patients younger than 35 years old having the most favorable prognosis, defined as the first IVF attempt with good-quality embryos and excess embryos for cryopreservation (Table 31.6).

A major contributor to the high-order multiple pregnancy rate may be patients' pressure on physicians to transfer more than two embryos to increase the probability of a successful cycle.[313] This pressure is especially strong when patients pay for their IVF treatment; where patients pay for their IVF therapy, the triplet pregnancy rate is higher than in areas where insurance pays for IVF therapy.[314,315] Shared risk programs, in which young, good prognosis patients pay a fairly high fixed up-front cost, but have a money-back guarantee if they do not take home a baby, may increase acceptance of eSET. [315]

Luteal Phase Support in Fresh Embryo Transfers

In IVF cycles, the ovary and endometrium are buffeted by numerous countervailing forces that are not controlled by normal feedback mechanisms. The endometrium, for example, is exposed to extremely high levels of estradiol and abnormally high levels of androgens. These high hormone levels may result in abnormal epithelial and stromal maturation, especially if luteal progesterone does not adequately balance the estrogen effect. Because oocyte retrieval is associated with the removal of a large number of granulosa cells, the adequacy of ovarian progesterone production after oocyte retrieval has been a major concern since the inception of IVF. Two major methods of luteal-phase support have been used in IVF cycles: progesterone supplementation, usually by intramuscular injection at doses of 25 or 50 mg daily,[316,317] and intramuscular hCG at doses ranging from 1500 to 10,000 IU administered once or more during the luteal phase.[318] Both hCG and progesterone appear to be associated with an increased pregnancy rate compared with no luteal support.[319] In general, hCG is associated with a higher rate of OHSS.[320]

The timing of the initiation of luteal phase support with progesterone affects the pregnancy rate. In a well-designed clinical trial, women undergoing IVF were randomized to receive progesterone supplementation starting either after oocyte retrieval or 12 hours before oocyte retrieval.

The pregnancy rate with progesterone supplementation after oocyte retrieval was significantly better than with progesterone 12 hours before oocyte retrieval (24.6% versus 12.9%, $P < 0.011$).[321] In another well-designed study, women were randomized to start luteal phase support with vaginal progesterone either 3 or 6 days after oocyte retrieval. The clinical pregnancy rate per transfer was significantly better in the group that started luteal phase support at 3 days rather than 6 days.[322] These studies demonstrate that the optimal window for initiating luteal phase support begins after oocyte retrieval but ends by the third day after oocyte retrieval.

The length of time necessary for luteal phase support has not been clearly delineated. Most centers continue support until it is clear whether the patient is pregnant. In one study, discontinuing progesterone support after a positive hCG resulted in pregnancy outcomes similar to continuing progesterone for an additional 3 weeks after a positive hCG.[323] A recent randomized trial in 220 women using micronized progesterone vaginally found no difference in miscarriage or ongoing pregnancy rates when progesterone was discontinued at 5 versus 8 weeks of gestation. However, there was substantially more bleeding in the group discontinuing treatment at 5 weeks.[324] Given the anxiety first trimester bleeding causes patients, treatment beyond 5 weeks seems reasonable.

A major problem with the use of progesterone for luteal phase support is the pain and sterile abscesses associated with numerous daily intramuscular injections. Alternative routes have been explored, although oral administration does not appear to be as effective as intramuscular injection.[325] Randomized trials using vaginal progesterone administered in a polycarbophil gel preparation suggest equivalent pregnancy rates to intramuscular progesterone[317] with one study showing superiority of vaginal gel in young patients.[326] Meta-analyses have not found any difference in delivery rates between different vaginal progesterone preparations including vaginal micronized progesterone suppositories,[327] or between vaginal preparations and intramuscular progesterone.[328]

Another controversy regarding luteal phase support concerns estrogen. Though the importance of the effect of luteal progesterone on the endometrium in implantation and early pregnancy maintenance is well established, the role of supplemental estrogen is less clear. In cycles utilizing GnRH agonists or GnRH antagonists, the profound suppression of gonadotropins in the follicular phase may carry over to the luteal phase. Several groups have investigated the benefit of the addition of estrogen in the luteal phase in IVF. A prospective randomized study involving 166 women undergoing 231 IVF cycles with long-protocol GnRH-agonist suppression examined the effect of luteal phase estrogen support. Participants were given 0 mg, 2 mg, or 6 mg estradiol over the entire luteal phase. Pregnancy rates were improved by estrogen supplementation in a dose-related manner, with the highest rates in the 6 mg group (23.1% versus 32.8% versus 51.3%, $P < 0.001$).[329] A recent randomized trial found that in patients on long GnRHa protocols the addition of 4 mg oral estradiol to vaginal progesterone was associated with lower miscarriage rates than progesterone alone. Other studies have found no benefit, including a randomized trial in poor responders.[330,331] A recent meta-analysis could not confirm a benefit in clinical pregnancy rates with luteal estradiol supplementation.[320]

Adjuncts to Standard IVF Medications

Baby Aspirin

Another area of controversy concerns the utilization of low-dose (baby) aspirin as an adjunct to IVF-ICSI treatment. Aspirin inhibits cyclooxygenase in platelets as well as thromboxane A2 (a potent vasoconstrictor) and prostacyclin (a vasodilator). However, in low doses the vasoconstrictor inhibition predominates. Therefore, use of low-dose aspirin has been proposed to increase ovarian blood flow, improving folliculogenesis and promoting implantation. Some practitioners begin aspirin during ovarian stimulation, while others utilize it only in the luteal phase, believing that it may contribute to excessive bleeding during oocyte retrieval. A meta-analysis of seven trials included 1241 women undergoing ovarian stimulation for IVF or ICSI.[332] There was no significant improvement in IVF and ICSI outcome for women taking aspirin in terms of clinical pregnancy (relative risk [RR] 1.11, 95% CI 0.95 to 1.31) or live birth (RR 0.96, 95% CI 0.64 to 1.39). There were no differences between the groups with respect to miscarriage or ectopic pregnancies. The authors concluded that the currently available data do not support the use of aspirin in IVF cycles.

Acupuncture

Acupuncture has been used as part of traditional Chinese medicine for thousands of years. It is based on the premise that energy (Qi) flows through the body in particular pathways, which are abnormal in disease states, and which can be manipulated through acupuncture. Acupoints, particularly auricular points, are targeted in infertile women to change energy flow in the uterus and ovaries. Electroacupuncture involves attachment of electric cables to the acupuncture needles, whereas manual acupuncture involves inserting and rotating the needles. Studies have used acupuncture before and during stimulation, before and after embryo transfer, and during the luteal phase of the cycle.

In general, studies employing acupuncture before and after embryo transfer have tended to find positive effects on pregnancy rates. A number of studies have been performed. An early study randomized 160 patients with good embryo quality to acupuncture 25 minutes before and 25 minutes after embryo transfer versus no acupuncture.[333] No differences in uterine artery pulsatility were found, and the clinical pregnancy rate was higher in the acupuncture group (42.5% versus 26.3%; $P = 0.03$). Another study employed a similar design, but controls lay quietly for a period of time equal to that of acupuncture.[334] Pregnancy rates in patients with good embryos were equivalent.

In a single blind randomized trial of 228 IVF patients, acupuncture was performed using acupoints determined by the acupuncturist, based on eastern medicine tenets, for each individual patient on day 9 of stimulation and before and after embryo transfer.[335] Control subjects had acupuncture needles placed near but not at true acupoints. The two groups were equivalent for ovarian stimulation and baseline parameters. Ongoing pregnancy rates were significantly higher in the acupuncture group (30.9% versus 22%; $P = 0.08$). A large, well-designed double blind randomized trial

of 370 patients employed acupuncture 25 minutes before and after embryo transfer.[336] The placebo group was treated with retractable needles (sham acupuncture) at the same acupoints. Pregnancy rates were higher in the sham group (55.1 versus 43.8%, $P = .038$) though the difference in ongoing pregnancy rates did not reach significance. It is possible that sham acupuncture had an effect, or that acupuncture has no effect. Another even larger sham-controlled randomized trial of 635 patients[337] found no differences in implantation, clinical pregnancy or live birth rates. A recent study of electoacupuncture in 309 women undergoing fresh or cryopreserved embryo transfer were randomized to "mock" treatment which included weak electrical stimulation and two other groups with higher doses of electrical stimulation once or twice after embryo transfer.[338] Pregnancy rates were lower in the "mock" group; though the groups were equivalent, the study population was poorly defined overall.

Four large meta-analyses have been performed.[339-342] Manheimer and colleagues evaluated 7 trials in which 1366 women were randomized to acupuncture within 1 day of embryo transfer, and controls either underwent no treatment or sham acupuncture.[339] Of those trials reporting clinical outcomes, ongoing pregnancy rates were higher (5 trials, RR 1.87; 95% CI: 1.40 to 2.49) as were live birth rates (4 trials, RR 1.91; 95% CI: 1.39 to 2.64). El-Toukhy and colleagues analyzed five trials, including 877 patients, with acupuncture performed around the time of oocyte retrieval, and found no difference in clinical pregnancy rates (RR = 1.06; 95% CI: 0.82 to 1.37, $P = 0.65$).[340] When they analyzed trials including 1623 patients with acupuncture performed around the time of embryo transfer there was also no difference in pregnancy rates (RR = 1.23; 95% CI: 0.97 to 1.58; $P = 0.1$). Cheong and colleagues analyzed 14 randomized trials involving 2670 subjects.[342] Analyses were performed based on the timing of acupuncture: near the time of ooctye retrieval, on the day of embryo transfer, and repeat acupuncture performed on and after the day of embryo transfer. Six trials included live birth data. Acupuncture around the time of oocyte retrieval had no impact on IVF pregnancy rates, and acupuncture on the day of embryo transfer was only potentially beneficial when therapy was repeated subsequently. The most recent meta-analysis included 24 trials with 5807 total participants.[341] This analysis pooled clinical pregnancy rates from 23 studies and found that they were higher in acupuncture versus control groups. Only six studies included live birth rates, and these did not differ between treatment and control groups.

In summary, the weight of the evidence indicates that acupuncture at the time of oocyte retrieval appears not to be beneficial, but when performed at embryo transfer, the procedure may marginally improve clinical pregnancy rates. However, as discussed by Cheong and colleagues,[342] studies with highly disparate designs are difficult to pool for analysis, and results may be confounded by the fact that sham acupuncture is not necessarily inert.

DHEA Supplementation

Dihydroepiandrosterone, an androgen secreted by both ovaries and the adrenal glands, has been studied as an adjunct to gonadotropins to improve ovarian stimulation in poor responders. Pregnancy rates have been reported to be higher in patients with basal testosterone levels greater than 20 ng/dL.[343] DHEA, via conversion from DHEAS, is responsible for 48% of follicular fluid testosterone synthesis during gonadotropin stimulation.[344] DHEA may also increase ovarian IGF-1 expression and induce FSH receptor up-regulation, amplifying gonadotropin action.[345,346] There are multiple small non-randomized trials of DHEA use before and during IVF in poor responders, some showing increased mature oocyte numbers,[347] and some showing increases in pregnancy rates.[348,349] However, the patient populations and ovarian stimulation regimens differ widely and there is no consistency of dose or duration of DHEA utilized. There is thus far only one small prospective randomized trial. In this, 33 women with diminished ovarian reserve and a prior failed IVF cycle were randomized to receive DHEA 75 mg or placebo daily before and during a similar protocol as used in the prior failed cycle.[350] Day 3 embryo quality was significantly improved and live birth rates were significantly increased (23.1% versus. 4.0%; $P = 0.006$) after DHEA administration compared to placebo.

The mechanism underlying a potential beneficial effect is unclear. It has been postulated that because levels of hypoxic inducible factor 1 levels were significantly lower in poor responders treated with 75 mg DHEA during ovarian stimulation, that improvements in the follicular microenvironment may be induced.[347] One study supplemented women who had decreased ovarian reserve with DHEA 25 mg orally three times per day for 30 to 90 days, and found that serum AMH levels improved by approximately 60% during treatment, particularly in women younger than 38 years old; women who conceived with IVF also showed greater AMH improvements.[351] Therefore there is some biological evidence supporting a potential role of DHEA supplementation in improving IVF outcomes for poor responders, however it is clear that large, controlled trials in well defined patient populations are needed to confirm a benefit, and to define proper dose and duration of treatment.

GH Supplementation

Growth hormone (GH) has been studied for many years as an adjunct to gonadotropins in an effort to improve ovarian response. Evidence indicates that GH directly stimulates the development of small antral follicles to gonadotrophin-dependent stages, as well as maturation of oocytes. GH stimulates insulin like growth factor I. Though IGF-I has no apparent effect on primordial follicle development, both IGF-I and IGF-II stimulate growth of secondary follicles, and stimulate granulosa cell proliferation and steroidogenesis.[352]

The co-administration of GH with gonadotropins to anovulatory hypogonadotropic women reduces the gonadotropin dose required to achieve ovulation.[353]

The literature regarding the use of GH in poor responders suggests an improvement in response and live birth rates, however the definition of poor response and ovulation induction protocols as well as GH dosing vary widely. For example, one study of prior poor responders used a long GnRHa protocol with GH used from the start of agonist at a dose of 4 IU per day and reported a higher number of fertilized oocytes and a trend toward a higher clinical pregnancy rate.[354] In a larger study of 100 women older than 40 years old, not defined as poor responders, GH 8 IU was used daily starting stimulation day 7 through

the day of hCG administration.[355] Peak estradiol levels (1523 ± 203 pg/mL versus 912 ± 129 pg/mL, $P < 0.05$), implantation rates (6.2% versus 1.7%; $P < 0.05$), and live birth rates (22% versus 4%; $P < 0.05$) were higher after GH co-administration. A Cochrane review in 2010 included 10 studies of 440 subfertile couples. A meta-analysis demonstrated a statistically significant difference in both live birth rates (OR 5.39, 95% CI 1.89 to 15.35) and pregnancy rates (OR 3.28, 95% CI 1.74 to 6.20) supporting the use of adjuvant growth hormone in *in vitro* fertilization protocols in women who are considered poor responders.[356] However, the authors caution that the included studies are small, and vary greatly, so it is still unclear which dose of GH should be used, and which subgroups of poor responders will in fact benefit from co-treatment.

Embryo Cryopreservation

Protocols for Embryo Cryopreservation

IVF often generates substantial numbers of excess embryos that cannot be safely transferred fresh in the oocyte retrieval cycle because of the risk of high-order multiple gestation. The development of successful embryo cryopreservation techniques allows multiple transfer cycles after just one ovarian stimulation and oocyte retrieval, as first reported by Zeilmaker and colleagues in 1984.[357] An important issue in embryo cryopreservation is the use of an optimal cryoprotectant and freezing protocol. Although slow cooling methods using cryoprotectants such as dimethyl sulfoxide (DMSO) or 1,2-propanediol have been successfully used for years for cryopreserving both 2PN zygotes and cleavage stage human embryos, vitrification protocols are now commonly used instead. Comparable results for slow-freezing versus vitrification have generally been reported, although prospective randomized trials are limited.[358]

The challenges associated with freezing blastocysts are different from those associated with freezing pronuclear or cleavage stage embryos due to the large fluid-filled blastocoel cavity that presents an increased risk of intracellular ice crystal formation. Early attempts at successful blastocyst cryopreservation using slow-freezing methods varied widely.[359] Although the recent introduction of blastocyst vitrification has provided promising results[287] with some programs achieving implantation rates comparable to those of fresh transfers,[358] more research is needed to evaluate the need and optimum methods for collapsing blastocysts before vitrification,[360] as well as safety issues such as storage, transport and the use of the very high cryoprotectant levels involved.

Protocols for Uterine Preparation

The endometrium appears to be more receptive when endometrial preparation is achieved with a controlled estradiol and progesterone regimen, as compared to that which occurs in an ovarian stimulation cycle. One randomized trial found an 84.0% versus a 54.7% clinical pregnancy rate per transfer after cryopreserved versus fresh cycle transfer.[361] Cryopreserved embryos may be replaced during a natural menstrual cycle, however some studies indicate that uterine preparation using a controlled sequential estradiol and progesterone regimen results in superior pregnancy and live birth rates. Nevertheless a recent Cochrane review did not find a difference in clinical outcomes among different methods of endometrial preparation, or after transfer in a natural cycle.[362] The critical factor may be to ensure synchronization of embryo development with the start of progesterone (i.e., with luteal endometrial development).

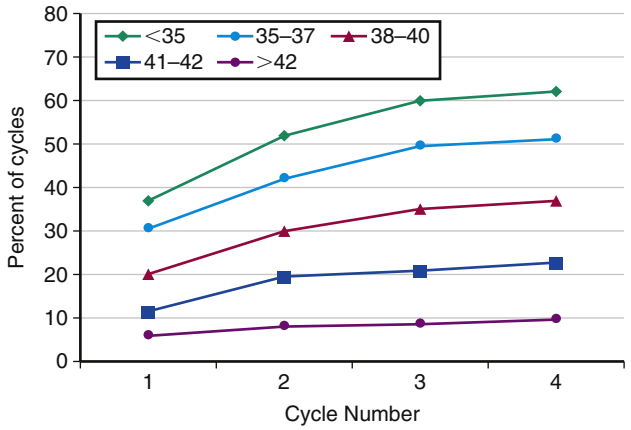

FIGURE 31.22 Plots of the cumulative delivery rates per woman (n = 14,265) for up to four *in vitro* fertilization–embryo transfer cycles according to the age of woman at first cycle using autologous oocytes. *(From Stern JE, Brown MB, Luke B, Wantman E, Lederman A, Missmer SA, Hornstein MD. Calculating cumulative live-birth rates from linked cycles of assisted reproductive technology (ART): data from the Massachusetts SART CORS.* Fertil Steril *94:1334-1340, 2010, with permission of the American Society for Reproductive Medicine.)*

Repeat *In Vitro* Fertilization Cycles

Because the majority of patients completing a single IVF cycle do not become pregnant, many will request a repeat IVF cycle. A specific cause of the IVF cycle failure may be identified (e.g., poor oocyte and embryo yield related to elevated cycle day 3 FSH concentrations, or poor oocyte/embryo quality). In most cases, however, a specific cause cannot be identified. Pregnancy rates appear to drop with repeated IVF attempts, however pregnancies still occur out to eight attempts or more. In one center, pregnancy rates were equivalent in cycles 1 and 2, 3 and 4, and 5 through 8.[363] At some centers, repeated IVF cycles after cycle 3 are associated with lower per-cycle pregnancy rates.[364]

A large study of 14,265 women of various ages from the SART database of Massachusetts residents who underwent up to four ART cycles demonstrated that the cumulative pregnancy rate per woman increased for all five age groups (Fig. 31.22).[365] Another investigation from a single center estimated cumulative pregnancy rates for women up to six cycles. Conservative estimates show a plateauing of pregnancy rates after the fourth attempt. For example, even in young women younger than 34 years old, the cumulative live birth rates after the first, second, third, fourth, fifth, and sixth cycles were 33%, 49%, 59%, 63%, 65%, and 65% respectively.[366] However, data concerning the pregnancy rate in repeat IVF cycles are confounded by decisions made by clinicians and patients. For example, when a patient has had a poor response to ovarian stimulation, the clinician may suggest discontinuation of IVF treatments. This would select patients with a "better prognosis" to repeat IVF. In fact, according to 2009 data from the CDC, 61.2% of U.S. ART cycles were in women undergoing their first cycle,

20.3% in women undergoing their second cycle, 11.3% in women undergoing their third cycle, and 6.1% in women in their fourth and 7.2% who had four or more previous treatments. These data suggest a selection bias in who receives prolonged ART treatment.[367] In every age bracket, women with prior ART cycles but no live births have a lower pregnancy rate than women undergoing their first ART cycle.[368]

IVF Risks and Their Management

Risk of Oocyte Retrieval

Oocyte retrieval can be associated with pelvic bleeding that requires transfusion or surgical exploration, or pelvic infection. Both complications are rare, occurring in fewer than 1 in 500 cases. A large prospective study of 2670 oocyte retrievals reported vaginal hemorrhage in 8.6% of cases, with a significant loss (estimated at greater than 100 mL) in 22 (0.8%). There were two cases of post procedure bleeding from an ovary causing hemoperitoneum. One case required emergency laparotomy. There was one case of pelvic hematoma formation which did not require intervention. Postoperative pelvic infection occurred in 18 (0.6%) of the cases and included 9 with pelvic abscess formation. Examination of the pus from these cases suggested inoculation of vaginal organisms into the peritoneal cavity by the oocyte retrieval needle.[369] Another prospective study of over 1058 cases assessing complications related to ultrasound-guided transvaginal retrieval reported vaginal bleeding requiring tamponade (2.8%) but no suturing was needed. There were no infections. There were no complications related to anesthesia (95% had general anesthesia and 5% had sedation with midazolam), 0.7% of patients had severe postprocedural pain requiring hospital admission, and it is possible that these patients did have postoperative bleeding as hemoperitoneum after retrieval causes significant pain. There was one ureteral injury.[370] A survey questionnaire study of over 10,000 IVF cycles in several centers reported a 0.5% complication rate after oocyte retrieval.

Risk of Fertilization Failure

Total fertilization failure (TFF) after standard IVF is an infrequent and unpredictable phenomenom, with the reported incidence ranging from 5% to 20%,[370a-c] in couples with otherwise unexplained infertility. Some studies in which idiopathic infertility couples had their oocytes split between ICSI and IVF suggest that such couples may have improved fertilization with ICSI.[371,372] However, since transfers involved embryos from both IVF and ICSI, it is difficult to determine the efficacy of one treatment over the other. Of note, at least two randomized trials of ICSI versus IVF for couples with unexplained infertility have shown no benefit of ICSI in terms of fertilization, implantation, clinical pregnancy, or live birth rates.[373,374]

Following TFF with standard IVF insemination, ICSI in the next cycle overcomes TFF in more than 95% of cases,[375,376] thus implicating failure of normal sperm and oocyte interactions including the abnormal release of sperm proteasomes resulting in inhibition of sperm binding to the zona pellucida.[377] In those rare cases that fail to fertilize following ICSI, studies with heterologous gametes have been undertaken to help determine the contributing factor.[378] Although an instance of spontaneous activation has been reported,[379] post-ICSI failure to fertilize is most likely due to the inability of the oocyte to activate.[15] Artificial oocyte activation (AOA) protocols using calcium ionophores,[380,381] strontium chloride,[382] or electrical impulses[383,384] have therefore been used. However, despite reassuring reports on obstetric, neonatal, and 1-year-old children, the routine use of AOA warrants caution, as alterations in calcium oscillations are associated with alterations in gene expression and embryonic development in a mouse model.[385,386]

Ovarian Hyperstimulation Syndrome (OHSS)

Current regimens of ovarian stimulation for IVF typically produce major increases in follicle numbers as well as circulating estradiol, with estradiol concentrations routinely reaching in the range of 1200 pg/mL or higher. The severity of OHSS is correlated most closely with the number of small to medium sized follicles at the time of hCG administration.[387] The intensive stimulation of ovarian follicle growth increases the risk of OHSS (see Chapter 30). Circulating androgen levels also increase substantially in women undergoing ovarian stimulation for IVF (Fig. 31.23)[388] though the impact on the ovary and endometrium remains to be fully characterized. However, in many model systems, excessive follicular androgen secretion is associated with suboptimal follicle and oocyte function. Although GnRH-agonist analogs have few adverse effects in ovarian stimulation protocols for IVF-ET, cases of OHSS caused by the administration of the GnRH agonist alone have been reported.[389]

Ovarian stimulation with gonadotropins for IVF is associated with up to a 5% risk of severe OHSS. Risk factors seem to be peak estradiol concentrations greater than 2000 pg/mL, the presence of more than 15 follicles greater than 12 mm in diameter, and the establishment of a successful pregnancy.[390] OHSS that develops during IVF cycles typically resolves with conservative management (see Chapter 30).

A number of strategies have been proposed to prevent OHSS. Withholding hCG and cancellation of the cycle is effective but fails to achieve a pregnancy. Continuing the cycle and freezing all embryos created is largely effective but requires a second cycle (albeit a simpler, cryoembryo transfer) to achieve a pregnancy. As previously noted, early OHSS incidence is reduced in GnRH antagonist cycles where an ovulatory dose of a GnRH-agonist is administed, even with very elevated estradiol levels. However, if a patient at high risk of OHSS conceives, placental hCG generally causes the syndrome to worsen and be more prolonged.

Another strategy involves "coasting," in which the doses of gonadotropins are withheld (sometimes for days) until estradiol levels decline to safer levels along with less follicular stimulation, likely decreasing the cohort of growing follicles.[391] The number of oocytes obtained, not suprisingly, is generally lower than the number of follicles measured on the day of hCG administration. A randomized trial comparing coasting to GnRH antagonist treatment in women at high risk of OHSS found fewer eggs and fewer high quality embryos in the coasting arm, but pregnancy rates were not different; no OHSS occurred in either arm.[392] A Cochrane review identified 16 studies related to coasting and OHSS, however only 4 met study criteria, and the authors concluded that a benefit of coasting for OHSS prevention could not be documented.[393] Intravenous administration of albumin has not been shown to reduce the incidence of OHSS

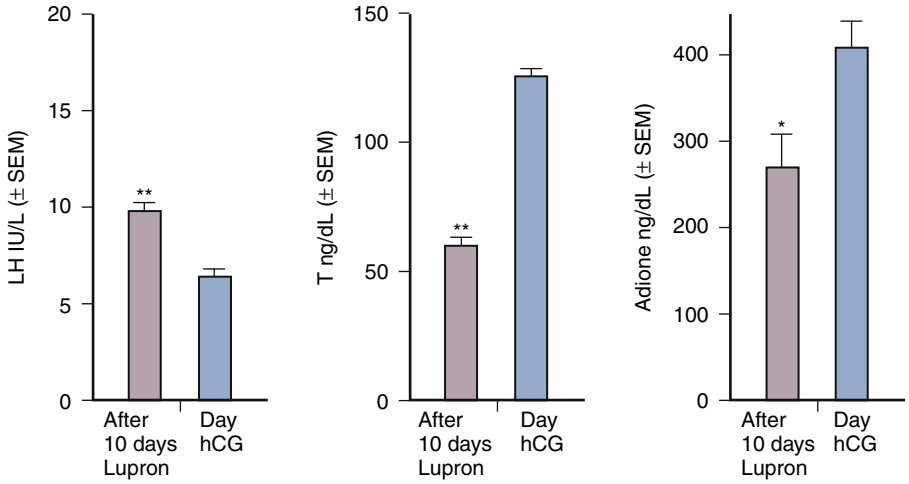

FIGURE 31.23 Androgen levels in normal ovulatory infertile women undergoing *in vitro* fertilization and receiving leuprolide (Lupron) and hMG (human menopausal gonadotropin) for ovarian stimulation in preparation for oocyte retrieval. Luteinizing hormone (LH), testosterone (T), and androstenedione (Adione) were measured after 10 days of leuprolide acetate treatment, 1 mg daily by subcutaneous injection, and then again after leuprolide plus hMG stimulation, just before the administration of human chorionic gonadotropin (hCG). After 10 days of leuprolide treatment, LH concentrations were in the normal follicular phase range. Testosterone and androstenedione concentrations increase significantly with ovarian stimulation. Mean, SEM; *$P < 0.05$; **$P < 0.001$. *(From Martin KA, Hornstein MD, Taylor AE, et al. Exogenous gonadotropin stimulation is associated with increases in serum androgens in IVF-ET cycles.* Fertil Steril *68:1011-1016, 1997, with permission of the American Society for Reproductive Medicine.)*

in randomized trials; a meta-analysis including 1999 subjects found the OR for OHSS to be 0.8 (CI 0.52 to 1.22) and pregnancy rates were unaffected.[394]

OHSS does appear to be at least partially preventable by the administration of the dopamine agonist cabergoline to at-risk patients.[395] The enzyme tyrosine hydroxylase, critical in the production of dopamine, is down-regulated eightfold in OHSS.[396] By adding the dopamine agonist cabergoline, Alvarez and colleagues hoped to restore dopamine and at the same time reduce vascular permeability through the vascular endothelial growth factor (VEGF) pathway. They randomized 82 oocyte donors at risk of developing OHSS to 0.5 mg daily cabergoline for 8 days or placebo. The incidence of moderate OHSS was reduced to 20% in the cabergoline group compared with 44% in the placebo group ($P = 0.04$). Hematocrit, hemoglobin, and ascites were all significantly lower in the group treated with cabergoline compared to placebo.[395]

There are no randomized trials of cabergoline for prevention of OHSS in women undergoing embryo transfer that are powered to evaluate ongoing pregnancy rates, and in one randomized trial of women undergoing embryo transfer, only early OHSS was reduced.[397] Therefore, at this time we suggest limiting use of cabergoline to cycles in which no embryo transfer is planned. To date, one randomized trial compares cabergoline to GnRH antagonist for treatment of early onset OHSS, with improved resolution on antagonist.[398] Another method to reduce the severity of OHSS is the use of GnRH agonists after hCG administration.[399,400]

For patients with established severe OHSS including tense ascites, paracentesis may both ameliorate symptoms and lessen duration and severity.[401] Paracentesis should be performed with sterile technique using either a transvaginal or transabdominal approach, based on the location of the largest pockets of ascitic fluid. It is safe to drain liters of ascitic fluid in one procedure. This is also a more cost effective approach than is hospitalization.[402]

Ectopic Pregnancy

IVF is known to carry the risk of ectopic pregnancy, with the incidence in some reports double to triple that in the general population. The Bourne Hall Clinic, site of the first successful human IVF treatment, reported an ectopic pregnancy rate in 1995 of 4.5% (135 of 3,000 clinical pregnancies in IVF patients).[403] However, a more recent report of SART clinic data found an ectopic pregnancy rate of 1.8% of cycles initiated, and 2.2% of clinical pregnancies.[404] The high prevalence of tubal disease and endometriosis in women undergoing IVF is associated with ectopic risk. It has also been suggested that factors intrinsic to the IVF process such as high volumes of culture medium used for embryo transfer may contribute.[403,405] There does not seem to be a difference in the incidence of ectopic pregnancies between women undergoing a day 3 or day 5 embryo transfer.[406]

Heterotopic pregnancies, involving a concomitant intrauterine and extrauterine gestation, occur in as many as 1 in 100 pregnancies after IVF. This is due to both the transfer of multiple embryos and the underlying fertility problems of the IVF population, including tubal disease. In the general population, the rate of heterotopic pregnancies is approximately 1 in 3500 conceptions.[407,408] The ectopic pregnancy can be treated either by surgical removal or by the selective injection of potassium chloride or hyperosmolar glucose.[409,410] If the ectopic pregnancy is to be treated surgically, salpingectomy rather than salpingostomy is appropriate; in a heterotopic pregnancy, it is not possible to determine whether the salpingostomy has been successful, because the intrauterine pregnancy maintains elevated hCG levels, so that documentation of complete resolution by following hCG levels down is not possible. If the ectopic pregnancy is removed surgically, vasopressin should be avoided, and sutures or the harmonic scalpel may be preferable to electrocautery

to minimize the chance of diminished blood flow to the intrauterine pregnancy.[411,412]

Cancer Risk in Women Undergoing IVF

Although some studies have suggested that drugs used to induce ovulation may be associated with an increased risk of ovarian cancer, the data are weak. Infertility and nulliparity are risk factors for ovarian cancer.[413] Most recent studies have reported no relationship between cancer and ovarian stimulation in women who have had IVF. A Swedish registry study reported that of 1,394,061 women, 95,775 had cancer. Of 24,058 women who had been treated with IVF, 1279 appeared in the cancer register. Cancer risk was elevated prior to IVF treatment (OR 1.37, 95% CI 1.27 to 1.48) and was especially high for ovarian cancer (3.93). The risk for cancer after IVF was significantly lower (OR 0.74, 95% CI 0.67 to 0.82), mainly due to a lower than expected risk for breast and cervical cancer. The risk of ovarian cancer was increased, but lower than the risk before IVF, with an OR of 2.13. The authors hypothesized that there may be a joint etiology for both infertility and ovarian cancer risk.[414] A recent meta-analysis of infertile patients concluded that the risk of ovarian cancer does not appear to be increased by treatment with ART compared to nontreatment.[415] A cohort of 9175 women who purchased medications for IVF performed between 1996 to 1998 in Finland were compared to age and residence-matched controls and further adjusted for socio-economic position and marital status. A linkage to the Finnish Cancer Registry for 1996 to 2004 was perfomed. The overall cancer incidence and combined incidence of hormonal-related breast, uterine and invasive ovarian cancers were similar among IVF women and controls. IVF women had less cervical cancer (OR 0.51, 95% CI 0.30 to 0.85), but more skin cancers other than melanoma (OR: 3.11, 95% CI: 1.02 to 9.6). IVF women had more invasive ovarian cancers and fewer breast than controls, but the numbers of cases were small and not significantly different. Larger studies are needed.[416]

There are conflicting data concerning an increased risk of breast cancer and IVF treatment. Late maternal age at first pregnancy is a well described risk factor for breast cancer, or in the offspring derived from IVF pregnancies.[417] In a recent cohort study of 21,025 Australian women, 7123 of whom underwent IVF, there were 384 breast cancers (55 were *in situ*). IVF utilization in the cohort was fairly low, with 50% of those who underwent IVF having only 1 to 2 cycles. There was no overall increase in the rate of breast cancer in women who had IVF (HR 1.10, 95% confidence interval [CI] 0.88 to 1.36). However, there was an increased rate in women who began IVF treatment when younger than 24 years old compared with those of the same age who did not undergo IVF, even after adjusting for late age at first delivery and multiple gestation (HR 1.56, 95% CI 1.01 to 2.40).[418] Of note, however, other covariates such as socioeconomic status and age at menarche were not taken into consideration in this analysis.

Management of High Order Multiple Gestations

Couples with a multiple gestation have the choice of expectant management or elective reduction of one or more fetuses. The most widely used method of elective reduction is transvaginal or transabdominal injection of potassium chloride into the fetal heart. The transabdominal approach is usually performed at 10 to 13 weeks of gestation; the transvaginal approach is typically used earlier.

For those couples who choose expectant management, approximately 15% will spontaneously lose one fetus, resulting in a twin pregnancy.[419] The risk of spontaneous miscarriage of the entire triplet pregnancy was 25% in one study of 12 expectantly managed triplets compared to 6% in 143 triplet pregnancies that underwent reduction to twins.[420] The risk of significant prematurity was 25% in the nonreduced triplets and 4.9% in those reduced to twins. In a retrospective series of 185 triplet pregnancies that underwent reduction to twins and 70 that were expectantly managed, median birth weight was 500 g higher and gestation was about 3 weeks longer in the reduced pregnancies. The rates of preterm delivery were significantly lower in the reduced group (11.17 versus 36.76% for delivery at ≤32 weeks and 40.58 versus 83.82% for delivery at ≤35 weeks, reduced versus nonreduced group).[421] Likewise the expectantly managed triplets were more likely to have very low birth weights (10.98% versus 28.44% for birth weight ≤1500 g and 68.55 versus 92.89% for birth weight ≤2500 g, reduced versus nonreduced group). Total fetal loss was significantly higher in the reduced group than in the nonreduced group (15.41% and 4.76%, respectively), mainly due to the higher miscarriage rate in the reduced group (8.11% versus 2.86% in the nonreduced group). The authors extrapolated the results to predict that severe handicaps would be expected in 0.63% of children due to extreme prematurity in the reduced group and 1.64% in the nonreduced group. A review of data pooled from 6 studies had 482 expectantly managed triplets and 411 that were reduced to twins. The rate of miscarriage was higher (8.1% versus 4.4%; relative risk [RR] =1.83, 95% confidence interval [CI] = 1.08 to 3.16, $P = 0.036$) and the rate of early preterm delivery was lower (10.4% versus 26.7%, RR= 0.37, 95% CI = 0.27 to 0.51, $P < 0.0001$) in the reduced group. Reduction of a triplet pregnancy to a singleton rather than a twin increases the likelihood of term live birth without increasing fetal loss rates.[422]

Some researchers maintain that it is "fairly well established" that multifetal reduction for quadruplet pregnancy improves pregnancy outcomes. Although no randomized studies have been reported, some series observe an increase in the length of gestation from 31 weeks to 35 weeks, in quadruplet pregnancies that had been successfully reduced to twins.[423] Nevertheless, reduction in the number of quadruplet pregnancies after IVF treatment is undoubtedly best achieved by transferring no more than two high-quality embryos in those women at highest risk for multifetal pregnancy.

Birth Outcomes in IVF Pregnancies (Multiple and Singleton Gestations)

The majority of twin births are naturally conceived, however the incidence of multiple birth delivery is 20 times higher with IVF treatment.[424] Transfer of multiple embryos is the primary reason for the high incidence of multiple gestation in IVF pregnancies,[302] though the incidence of

monochorionic twinning has been reported to be increased by procedures such as ICSI, assisted hatching, and blastocyst transfer.[278] The outcome of pregnancies produced by IVF is directly related to the number of fetuses established. Of the live births resulting from IVF in the U.S. in 2009, 29% were twins, and 3% were triplets or higher-order gestations.[425]

Pregnancies complicated by multiple gestations are associated with increased prematurity, low birth weight, gestational hypertension, diabetes, a higher incidence of birth defects, and increased perinatal mortality rate. Early studies proposing an association between IVF and poor obstetric and perinatal outcomes often did not adequately control for the increased rate of multiple gestations associated with IVF treatment. Several recent large studies and meta-analyses have reviewed the obstetric outcomes associated with ART. The FASTER (First and Second Trimester Evolution of Risk) Research Consortium, sponsored by the National Institute of Child Health and Human Development (NICHHD) prospectively investigated singleton pregnancies from an unselected obstetric population between 1999 and 2002.[426] A total of 36,062 pregnancies, including 1222 that used ovulation induction and 554 that used ART, were evaluated. Ovulation induction was associated with a greater risk of placental abruption, total loss after 24 weeks, and gestational diabetes, and IVF was associated with an increase in preeclampsia, gestational hypertension, placental abruption, placenta previa, and risk of cesarean delivery compared with naturally established pregnancies. There was no association between IVF and total growth restriction or aneuploidy for fetal anomalies. Significantly, this study adjusted for age, race, marital status, years of education, prior preterm delivery, prior total anomaly, body mass index, and bleeding with the recent pregnancy. A meta-analysis of 15 studies comprising 12,283 IVF and 1.9 million spontaneously conceived singletons concluded that IVF singleton pregnancies were associated with increased rates of perinatal mortality (OR 2.2, 95% CI 1.6 to 3), preterm delivery (OR 2, 95% CI 1.4 to 2.2), low birth weight (OR 1.8, 95% CI 1.4 to 2.2), very low birth weight (OR 2.7, 95% CI 2.3 to 3.1), and small size for gestational age (OR 1.6, 95% CI 1.3 to 2.0).[427] In a more recent large cohort study in 242,715 women with singleton pregnancies of whom 4111 used ovulation induction, 2351 used IUI and 4570 underwent IVF, all the ART procedures were associated with increases in preterm delivery, abnormal placentation and small for gestational age babies, suggesting that the causes of infertility rather than the type of fertility treatment underly the findings.[428] A systematic review of controlled studies concluded that IVF singleton pregnancies were at elevated risk for very preterm and preterm births as well as very low birth weight, low birth weight, and small-for-gestational-age infants. The IVF pregnancies were associated with more neonatal intensive care unit (NICU) admissions, a higher incidence of cesarean delivery, and an increased perinatal mortality rate.[429] A large meta-analysis examining 27 studies resulting in singleton births concluded that the risk of preterm births in singleton pregnancies resulting from IVF-ET and GIFT was twice that of naturally conceived pregnancies.[430]

An NICHD workshop on infertility, assisted reproductive technology, and adverse pregnancy outcome summarized the areas of increased risk as follows: Increased perinatal risks included preterm birth, low birth weight (less than 2500 g), very low birth weight (less than 1500 g), small size for gestational age, NICU admissions, stillbirths, neonatal mortality, and cerebral palsy. Maternal risks identified were preeclampsia, placenta previa, placental abruption, gestational diabetes, and cesarean delivery.[431] An American College of Obstetricians and Gynecologists Committee opinion concluded that "a growing body of evidence suggests an association between pregnancies resulting from ART and perinatal morbidity (possibly independent of multiple births), although the absolute risk to children conceived through ART is low."[432] Some have argued, however, that it is not possible to separate the ART-associated perinatal risks from those due to the underlying reproductive disease.[431] Infertile couples may also be at risk for a wide range of adverse reproductive outcomes not necessarily related to their treatment. A large cohort study from Belgium examined the perinatal outcome of 12,011 singleton and 3108 twin births from non-IVF assisted reproduction treatments compared with outcomes from natural conceptions.[433] The treatments consisted of controlled ovarian stimulation with and without intrauterine insemination. Among singletons resulting from infertility treatment, there was a higher incidence of prematurity, low and very low birth weight, and transfer to the NICU; among twin pregnancies resulting from infertility treatment they found an increased rate of neonatal mortality, assisted ventilation, and respiratory distress syndrome. The study demonstrated that both singletons and twins resulting from non-IVF fertility treatment have worse perinatal outcomes than naturally conceived children.

Another clue as to why IVF pregnancy outcomes may be worse than naturally conceived pregnancies comes from two Scandinavian studies examining the effect of vanishing twins on pregnancy outcomes from IVF.[434,435] The Danish study included 642 survivors of a vanished co-twin, 5237 primary singletons, and 3678 primary twins. The rate of small-for-gestational-age (SGA) infants was significantly higher in survivors than in singletons (OR 1.5, 95% CI 1.03 to 2.2), as was the risk of low birth weight (OR 1.71, 95% CI 1.06 to 2.74). The Swedish study included 8941 IVF singletons, and also found a significantly higher rate of SGA in those singletons associated with a vanishing twin.

Because ART cycles produce more multiple gestations than naturally conceived pregnancies, it is likely that they also produce more vanishing twins. The data suggest that the survivor of a vanishing co-twin has a worse obstetric prognosis than a fetus conceived as a singleton. Whether or not the vanishing twin phenomenon accounts for all or some of the increased perinatal risk seen in IVF singleton, but not IVF twin gestations, requires future investigation. A study evaluating 12,021 singleton and 3108 twin births compared those naturally conceived to those conceived through ovulation induction with or without IUI (OI and IUI). Cases were matched for maternal age, parity, fetal sex, and year of birth. There was a significantly higher incidence of prematurity (less than 32 and less than 37 weeks), low and very low birth weight, transfer to the neonatal intensive care unit and most neonatal morbidity parameters for the OI and IUI singletons, and twin pregnancies resulting from OI and IUI showed an increased rate of neonatal mortality, assisted ventilation and respiratory distress syndrome.

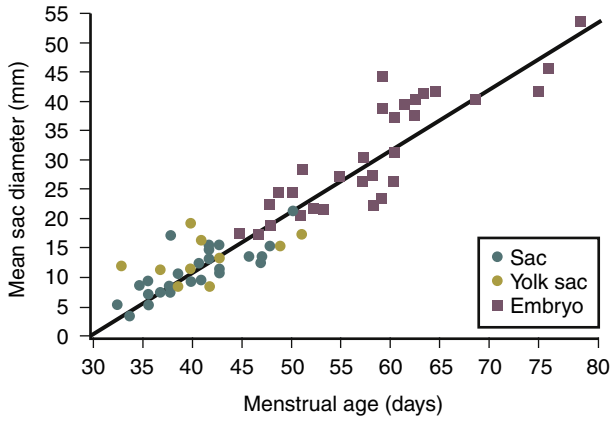

FIGURE 31.24 Relationship between pregnancy dating as determined by menstrual age and gestational sac size as measured by the mean sac diameter. *(From Nyberg DA, Mack LA, Liang FC, Patten RM. Distinguishing normal from abnormal gestational sac growth in early pregnancy* J Ultrasound Med *6:23-27, 1987.)*

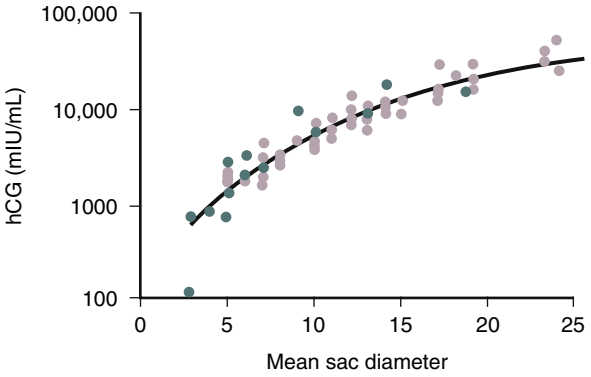

FIGURE 31.25 Relationship between mean gestational sac diameter as measured by the mean sac diameter and the serum human chorionic gonadotropin (hCG) concentration. *Green dots represent present series; gray dots represent previously published data. (From Nyberg DA, Mack LA, Liang FC, Jeffrey RB. Early pregnancy complications: Endovaginal sonographic findings correlated with human chorionic gonadotropin levels.* Radiology *167:619-622, 1988.)*

These data suggest that subfertility rather than procedures used to treat it underlie the poorer neonatal outcomes seen in IVF pregnancies.[433]

Pregnancy Outcome

Among women who achieve pregnancy after IVF, approximately 20% will experience a spontaneous abortion, and as previously reviewed 2% to 4.5% will have an ectopic pregnancy. Clearly, the incidence of miscarriage is highly associated with maternal age (Fig. 31.12) due to increasing aneuploidy as women age. Studies have not shown that paternal age contributes significantly to miscarriage or birth defects.[436] Early pregnancy should be monitored both by transvaginal sonography and by serial hCG levels to ensure that an abnormal pregnancy is diagnosed as early as possible (Figs. 31.24 and 31.25).

Birth Defects

The issue of IVF and the risk of birth defects is complex and the analysis of this subject has been limited by several factors including additional testing performed on ICSI offspring, underreporting of malformations in national birth registries, the effect of maternal age, the effect of multiple gestations, and the inclusion of severe male factor patients, whose children may be subject to an increased rate of chromosomal anomalies due to paternal transmission.[437,438]

The picture is further complicated by the fact that congenital malformations are more common in offspring from multiple pregnancies than from singleton pregnancies and are more common in children of women of advanced reproductive age. Because multiple gestations in older women are more common in IVF pregnancies, a potential bias may be introduced. Therefore, analyses restricted exclusively to singleton births in age-matched women make most sense. One of the difficulties in designing such studies is that pregnancies resulting from IVF are often scrutinized more carefully than other pregnancies. For example, the frequency and intensity of ultrasound testing might be higher in such pregnancies. In one of the larger and better-controlled matched cohort studies, Hansen and colleagues reported a twofold increase in major malformations from IVF (8.6%) compared to normal control subjects (4.2%) from a birth registry in Western Australia.[439] A strength of this particular study was that a single-blinded pediatrician determined which anomalies would have been detected independent of the surveillance method used. However, even this approach has been criticized on the presumption that a pediatrician could hypothesize which malformation might be ICSI-induced.[440]

A study from the Danish national birth cohort compared the incidence of congenital malformations in children born from three groups of couples: fertile couples, infertile couples who conceived without treatment, and infertile couples who required treatment to conceive.[441] Compared to children conceived by fertile couples, singletons conceived by infertile couples without treatment had a higher rate of malformations, hazard ratio (HR 1.70, 95% CI 1.07 to 1.35); and for those conceiving with treatment, the (HR 1.39, 95% CI 1.23 to1.57). Although this study did not specifically examine the types of infertility treatment used, and thus did not address the effect of IVF on birth defects, it did demonstrate that infertility in and of itself confers a higher risk of birth defects, even without treatment.

In the largest U.S. study to examine congenital malformations associated with infertility treatments, Olson and colleagues compared offspring from naturally conceived pregnancies, IVF, and intrauterine inseminations (IUI).[442] The malformation rate among the IVF children (6.2%; OR 1.44, 95% CI 1.12 to 1.85) was higher than among control subjects (4.4%), though the rate among IUI children was not statistically higher than the control group (5.0%; OR 1.14, 95% CI 0.7 to 1.87). The authors speculated that they were not able to show an increase in malformations among the IUI-conceived children because the number of infants was so small ($n = 343$) compared to that in the IVF group ($n = 1462$) or the control group ($n = 8422$).

A study of 15, 045 babies born after ART from 7 centers in China found a much lower incidence of birth defects than in other studies, with one or more malformations in 1.25% of all ART babies combined, compared to 1.35% in the general population. The malformation rate was higher in ICSI than in

IVF babies, but failed to reach statistical significance (1.58% versus 1.11%; OR, 1.42; 95% CI,0.99 to 2.03; $P = 0.52$).[443]

A recent cohort study of 308,974 births, of which 6163 were from assisted reproduction, was unique in that it included couples with infertility who conceived without treatment, couples who underwent IVF, and couples who underwent IVF and ICSI for male factor and nonmale factor infertility. The incidence of malformations was 8.3% in the ART group and 5.8% in babies not involving ART (unadjusted OR 1.47; 95% CI 1.33 to 1.62). After multivariate adjustment, the OR was 1.28 (1.16 to 1.41). When IVF and ICSI were analyzed separately after multivariate adjustment, the OR was no longer significant for IVF (7.2% birth defect rate; OR 1.07, 0.90 to 1.26) but was for ICSI (9.9% birth defect rate; OR 1.57, 1.30 to 1.90).[444] Of note, couples with a history of infertility, with or without ART treatment, were also at increased risk of having children with malformations.

Several meta-analyses have been performed to investigate any association between ART and malformation rate in offspring. One reviewed 25 studies comparing birth defects in ART and non-ART offspring.[445] The overall OR of malformations was 1.29 (95% CI 1.21 to 1.37) and reached statistical significance. The statistical significance remained in subgroup analysis of singleton births and major malformations. The authors concluded that there is an overall 30% to 40% increased risk of birth defects associated with ART. A more recent meta-analysis identified studies published into 2011 and included 56 studies, 46 of which compared IVF/ICSI babies to those spontaneously conceived and found a pooled OR of 1.37 (CI 1.26 to 1.48). Twenty four studies compared IVF and ICSI babies and found no difference in malformation rates 1.05 (0.91 to 1.20).[446] However, many of the included studies had crude, rather than adjusted risks. Tests for heterogeneity found that studies differed widely, with some assessing birth defects only at birth, some up to age 2, some were population based and some clinic based. In addition, the absence of infertile control groups conceiving without ART was a major deficiency, as discussed by the authors.

Another way to consider birth defect data is to analyze specific malformations. Although cardiovascular, musculoskeletal, and urogenital malformations seem more common in IVF offspring than non-IVF offspring, no single defect seems to predominate.[447]

Taken together, the literature suggests that infertile couples are at higher risk of having children with congenital malformations, and that this may be increased further by the use of ICSI.

Risks of Cancer in IVF Children

A Swedish cancer registry study of the years 1982 to 2005 was compared to a registry including data on IVF. An increased risk of Langerhans cell histiocytosis (LCH) was found in children born from IVF prior to 2002. The OR for LCH children born after IVF was 3.2 (CI 1.4 to 7.3), with a higher incidence prior to 2002 (OR 5.2, CI 2.3 to 11.9). The reason for the association was unknown.[448] A recent case control study performed in Greece and Sweden found an association between early childhood acute lymphoblastic leukemia (ALL) (age under 3.8 years) and ART.[449] Another Swedish study followed a cohort of 26,692 children born after IVF 1982 to 2005 and compared cancer incidence in them and children not conceived with ART. Factors including premature delivery, respiratory diagnoses, and low Apgar scores were risk factors for cancer in children and young adults. There were 53 cases of cancer in IVF children compared to 38 expected; 18 were leukemias and of them 15 were ALL. There were six cases of Langerhans histiocytosis (1.0 expected). The risk estimate for cancer was 1.42 (CI 1.09 to 1.87). The authors concluded that the risk factors could be preterm birth and neonatal hypoxia rather than ART procedures themselves.[450]

Overall, recent evidence raises questions about an increase in childhood cancers in children conceived through IVF. However, further research is needed to investigate this possibility.

Epigenetic Abnormalities

It has recently been postulated that reproductive technologies may be associated with epigenetic changes in one of the two inherited alleles for a particular imprinted gene. Such modifications, which may result from changes in differential DNA methylation or modifications in the histones, lead to either activation or suppression of a gene.[451] Attention has particularly focused on the possibility that ART is associated with an increase in imprinting defects resulting in rare congenital disorders such as Beckwith-Wiedemann and Angelman syndromes. In 2003, DeBaun and colleagues were the first to report an association between an imprinting disorder and ART.[452] Among ART offspring, they found a 4.6% prevalence of Beckwith-Wiedemann syndrome, a congenital disorder involving growth and neoplasia, compared with a background rate of 0.8% in the U.S. population. An increased incidence of several other imprinting syndromes has been reported in children conceived through assisted reproductive technologies.[281]

Although one study from the Netherlands reported five cases of retinoblastoma in children from IVF, a much higher prevalence than seen in the general Dutch population,[453] the Boston Collaborative Drug Surveillance Program identified no children born from IVF with retinoblastoma compared with 6.7 cases per 100,000 births in the general population.[454] A very large study from the Swedish national health registry involving more than 16,000 children born after ART failed to find an increase in childhood cancers or infant tumors in either IVF or ICSI offspring.[455] A study from the Netherlands National Retinoblastoma Center identified retinoblastomas in seven children conceived by IVF or ICSI but no hypermethylation of the RB1 promoter was seen; this study reached the conclusion that an association between IVF and ICSI and retinoblastoma was unlikely to be due to an epigenetic mechanism.[456]

Aside from specific imprinting diseases as discussed above, attention has recently been focused on subtle genome-wide epigenetic alterations in phenotypically normal children conceived from ART.[457] Widespread changes in DNA methylation have been identified, including genes linked to adipocyte development, insulin signaling, and obesity. These observations may link to reports that metabolical parameters and body composition may differ between children conceived via IVF and spontaneous conception. From 8 to 18 years of age, IVF children appear to have altered body fat composition, though they also appear to have a

more favorable lipid profile and higher IGF-I and IGF-II levels than non-IVF children.[458,459]

Although the etiology of these alterations is unknown, it appears that the infertility of the couple per se may be responsible. Nevertheless, further research is required to determine whether there is any association between the ART procedures themselves and an increased risk of imprinting disorders. As the overall absolute incidence of these diseases is, thankfully, extremely small, routine screening for imprinting diseases in ART children is not recommended.

Psychological and Cognitive Development in IVF Offspring

Another concern regarding pregnancies resulting from ART is the neurological development of children conceived through IVF. Although the majority of such studies are reassuring, several studies have demonstrated an increased incidence of cerebral palsy in children born through ART. One study found an increased risk for cerebral palsy in IVF children (OR 3.7, 95% CI 2 to 6.6); some of the increased risk was associated with multiple gestations, but the higher risk persisted when singletons alone were analyzed (OR 2.8, 95% CI 1.3 to 5.8). No difference in neurological development was seen between IVF twins and control twins.[460]

A second study also showed an increased risk of cerebral palsy among IVF offspring even after accounting for maternal age, educational level, parity, gender of offspring, and small size for gestational age. Importantly, however, the differences disappeared with adjustment for multiple gestations and prematurity.[461]

Long-term developmental, psychological, and cognitive studies on offspring of ART pregnancies are now available and generally show normal cognitive and motor development, as well as appropriate neurological function up to age 8.[462-465] Psychological development has also been demonstrated to be normal in children conceived via ART up to age 5.[466,467] However, IVF offspring appear to be at elevated risk of hospitalization in childhood, perhaps reflecting their higher rate of medical problems in the neonatal period.[468]

Paternal Age and IVF Outcome

In men undergoing ART treatment, increasing age is associated with lower ejaculate volume, worse semen parameters and a higher incidence of DNA fragmentation.[469] There is a significant body of literature indicating a paternal age-related association with infertility,[470] which appears to be more pronounced in men ≥40 years or older.[470,471] The impact of paternal age on IVF outcomes has also been analyzed, particularly using the oocyte donor model, in which oocyte-related factors (e.g., female age, female infertility diagnosis, etc.) and endometrial receptivity issues are more easily controlled. However, conflicting results exist even when using this model. Some studies have found either no association,[472] or a very limited association,[473] between paternal age and live births, while other studies have found significant age-related declines in live birth rate or other outcome parameters.[474,475]

One retrospective study evaluated the impact of paternal age in 672 IVF cycles with ovum donors who were ≤35 years old.[474] Not suprisingly, as men aged, semen parameters worsened, and the utilization of ICSI increased. Fertilization rates were lower with conventional insemination in men older than 60 years old. The number of cryopreserved embryos was significantly lower as men aged ($P < 0.05$), as also was the number of embryos with more than seven cells on day 3, as well as the proportion of embryos developing to the blastocyst stage ($P < 0.05$). As blastocyst formation is dependent upon successful paternal genome activation (which occurs around the four to eight-cell stage),[67] any inverse association between paternal age and blastocyst formation likely reflects perturbation of this fundamental developmental event. In this same retrospective study of 672 cycles,[474] implantation rates were significantly lower in cycles where the man was older than 60 years old, compared to those with men 50 to 59 years old (22% versus 43%, $P = 0.022$), and there was a trend toward lower clinical pregnancy rates (50% versus 72%, $P = 0.14$). Of note, the age of the recipients increased as paternal age increased and no multivariate analysis was performed to control for this potential confounder. As there is some evidence that recipient age may be inversely related to implantation rates,[476] it is unclear as to whether the observations in this study should be exclusively attributed to paternal age.[474]

Another study of 484 ovum donation recipient couples was analysed. The mean paternal age in cycles achieving clinical pregnancy was lower than in cycles that did not result in pregnancy (43.2 ± 8.1 years versus 46.8 ± 7.8 years; $P = 0003$). Semen parameters were found to be notably lower in men 40 to 50 years old compared to those younger than 40 years old, particularly for teratospermia ($P = .0001$), and ICSI was performed in all cycles.[477] However, again multivariate analysis was not performed, and donor and recipient ages were not taken into account. In another study of 1392 donor cycles in 1083 recipient pairs, male age was again associated with lower semen volume and sperm motility; however, there was no association with male age and live birth rate even after adjustment for female recipient age.[473]

Taken together, it is clear that further research with very substantial datasets and appropriate statistical analyses is required to resolve whether there is a paternal age-related association with incidence of live birth in IVF.

Most studies of natural conceptions have not found that paternal age is related to chromosomal abnormalities in offspring;[478] however, some believe that there is a paternal contribution.[479] The American College of Medical Genetics does not suggest additional prenatal screening on the basis of paternal age alone.[479] In general, however, advanced paternal age (older than 40 years old) is associated with higher rates of miscarriage,[470,476] some autosomal dominant conditions, autism spectrum disorders, and schizophrenia.[470,480] There is a lack of data investigating whether IVF offspring have an increased risk for any of these paternal age-related disorders compared with that of naturally conceived children. However, as IVF registeries continue to expand, sufficiently robust datasets should eventually be available to enable this gap in our knowledge to be filled.

Oocyte Donation

Early studies of IVF with oocyte donation clearly established the feasibility of the technique, with pregnancy rates being reported in the range of 25% per cycle.[481,482] The technique is now very well established with its utilization

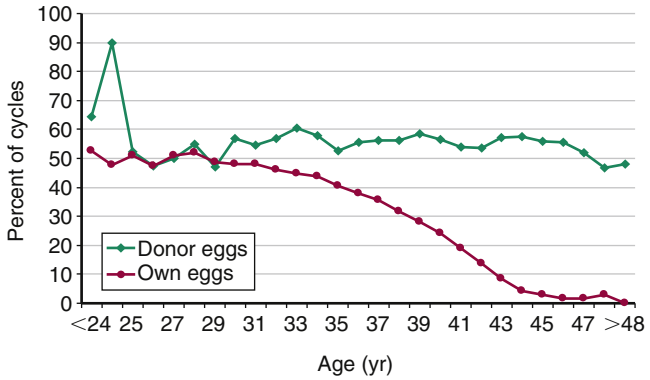

FIGURE 31.26 Percentages of transfers that resulted in live births for 2009 assisted reproductive technology (ART) cycles using fresh embryos from own or donor eggs, by patient's age. *(From CDC Assisted Reproductive Technology [ART] Report 2009. Available at www.cdc.gov/art/ART2009. Accessed Sept. 30, 2012.)*

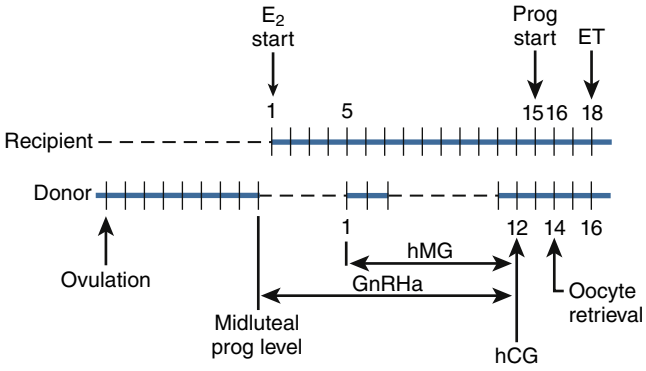

FIGURE 31.27 Schematic of the synchronization of oocyte donor and embryo recipient on a gonadotropin-releasing hormone-agonist analog (GnRHa) with exogenous estrogen (E_2) and progesterone (Prog) protocol. hMG, human menopausal gonadotropin; hCG, human chorionic gonadotropin; ET, embryo transfer. *(From Schmidt-Sarosi CL. In vitro fertilization with donor oocytes. In Keye WR, Chang RJ, Rebar RW, Soules MR [eds]. Infertility: Evaluation and Treatment. Philadelphia, WB Saunders, 1995, p 781.)*

being particularly related to maternal age, although women with premature ovarian failure also benefit from the procedure. In the U.S. in 2009, less than 5% of ART cycles used oocyte donation in women younger than 35 years old, there was a gentle increase in utilization to 12.9% in women at 40 years, but a dramatic age-related upswing to 91.8% in patients older than 48 years old.

An important question in reproduction is, "Which factor has the greater impact on fertility, oocyte age or uterine age?" On the basis of results from IVF with oocyte donation, both factors affect the likelihood of pregnancy and its outcome, but oocyte age appears to have a far greater impact on fecundability than uterine age.[483] As seen in Figure 31.26, while there is a dramatic and unrelenting decline in pregnancy rates with increasing age in women using their own oocytes, this decline is not seen in women using donor (and presumably younger) eggs. However, there is evidence that uterine aging may be related to lower implantation and ongoing pregnancy rates. One study analysed 143 cycles of oocyte donors younger than 30 years old. The implantation rate was higher ($P = 0.042$) and the abortion rate was apparently lower in women younger than 34 years old than in recipients ≥40 years or older.[484] In another study of IVF with oocyte donation, pregnancy losses were substantially higher in women older than 40 years old compared with women younger than 40 years old.[485] Some conflicting data nevertheless exist: In 222 cycles of shared egg donation to 444 recipient pairs, recipient age was not found to be associated with pregnancy rates.[486] Furthermore, a recent analysis showed no difference in pregnancy rates in young recipients compared with those in their late 40s.[487]

IVF with oocyte donation requires the coordination of the reproductive tracts of the donor and recipient (Fig. 31.27). An important insight provided by this technique is that for women with ovarian failure, steroid replacement with estradiol and progesterone is adequate to prepare the endometrium for successful pregnancy. No other ovarian hormone is required to achieve a successful pregnancy. Most oocyte donation programs use "fresh" oocytes, and the theoretical problem of possible transmission of infection from oocyte donor to recipient has never been documented, but in the United States is highly regulated under FDA oversight.

An important ethical issue is the age at which women should be advised not to pursue IVF with oocyte donation. Some centers have treated women over 60 years of age; other centers restrict the application of this technique to women younger than 50. In addition, oocyte donation may be associated with some health risks, and so it is recommended that donors do not donate for more than six cycles.[488]

Gestational Carrier Cycles

Another form of third-party reproduction involves the use of a gestational carrier in which a woman other than the infertile woman conceives a pregnancy for her. In this scenario, the infertile woman undergoes controlled ovarian stimulation and egg retrieval and her oocytes are fertilized *in vitro*, but the resulting embryo(s) is implanted into the uterus of a gestational carrier. The carrier's endometrium is prepared and the synchronization of the cycles of the two women is similar to that of the egg donor and recipient.

Indications for the use of a gestational carrier include congenital absence of the uterus, congenital müllerian malformations, hysterectomy, or surgically uncorrectable anatomical abnormalities such as intrauterine adhesions. Another indication involves women who have a serious medical illness that precludes a safe pregnancy.

Although the mechanics of a gestational carrier cycle are relatively straightforward and routine, this type of third-party reproduction involves complex legal, psychological, and sometimes ethical issues. Potential carriers should have undergone prior uncomplicated pregnancies and completed psychological as well as medical screening. A signed contract between the parties is necessary and laws pertaining to the legal status of the baby vary according to state. Pregnancy rates are dependent on the reproductive prognosis of the oocyte source. Despite its many medical and social complexities, gestational carriers offer some infertile women the opportunity to reproduce using their own and their

partner's gametes when they would otherwise not be able to have a genetic child.

In Vitro Oocyte Maturation

An alternate approach to the retrieval of mature oocytes following ovarian stimulation is the aspiration of immature oocytes and their subsequent maturation *in vitro*. In the setting of *in vitro* maturation (IVM), GV-stage oocytes are retrieved when the follicles reach a diameter of 6 to 12 mm, either with or without hCG priming.[489] Although priming with hCG may improve maturation rates following culture, compared with no priming,[489] such an approach should not strictly be referred to as IVM because the oocytes may have begun the maturation process *in vivo* under the influence of the hCG. Retrieved oocytes are typically cultured for 28 to 36 hours to allow time for progression to metaphase II,[490] thereby simulating the timing from the LH surge *in vivo*.[491] A specialized, smaller needle (19 or 20 gauge, rather than the 16 to 17G needle) is generally used to remove the more adherent immature oocyte-cumulus complex from the membrana granulosa cells lining the follicle, and a lower pressure on the aspiration pump is desirable to obtain a higher yield of oocytes.[492]

The efficiency of IVM varies depending upon whether the oocytes arise from polycystic ovaries, naturally cycling ovaries, or ovaries primed with low doses of gonadotropins. There is also considerable heterogeneity in success rates among clinics even when similar procedures are used in comparable patient populations.[489] The majority of studies indicate that while more than 60% of IVM oocytes achieve nuclear maturation by progressing to metaphase II,[489] a low percentage successfully acquire cytoplasmic maturation and exhibit the ability to support pronuclear formation and early embryonic development. Only 40% to 80% of fertilized IVM oocytes progress through early cleavage, and of those that do cleave and that are transferred, implantation rates of less than 15% are seen in the majority of studies.[489] This low efficiency is further diminished for oocytes matured without their cumulus-corona cells.[493] Therefore, attempts to salvage immature oocytes for clinical use after cumulus-corona cell removal in preparation for ICSI is not recommended with the IVM protocols currently available.[494]

Several challenges remain before IVM can be reliably applied in ART. The IVM system requires optimization; the culture medium requires further refinement beyond the reported benefits of supplementation with Activin A,[495] or the epidermal growth factor family members amphiregulin (Areg) and epiregulin (Ereg) EGF-like growth factors.[496] Use of a three-dimensional culture system to support the structural integrity of the oocyte-cumulus complex either in a prematuration phase[497] or during maturation[498,499] requires further investigation. Moreover, the optimal duration of IVM remains to be determined, and the optimal protocols for preparation of a receptive endometrium need to be identified. Research targeting these gaps in our knowledge is worthwhile. IVM is associated with lower costs due to use of less gonadotropin, and the technique eliminates the possibility of OHSS, thereby having particular application in women at increased risk for this syndrome such as those with PCOS. Furthermore, available data, albeit with still relatively small numbers of children born, indicate that obstetric, perinatal, and neonatal outcomes after IVM are comparable to those resulting from IVF and ICSI.[500] Finally, an efficacious IVM protocol is required when oocytes are cryopreserved at the GV stage for subsequent attempts to achieve pregnancy.

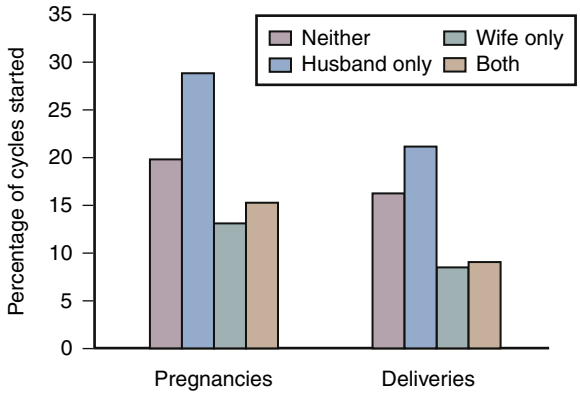

FIGURE 31.28 The pregnancy and delivery rates per cycle intiated after *in vitro* fertilization, stratified by the smoking habits of the male and female partners. Smoking by the female partner substantially decreased the delivery rate per cycle initiated. Smoking by the male partner did not decrease the pregnancy rate. *(From Pattinson HA, Taylor PJ, Pattinson MH. The effect of cigarette smoking on ovarian function and early pregnancy outcome of in vitro fertilization treatment.* Fertil Steril *55:780-784, 1991, with permission of the American Society for Reproductive Medicine.)*

Environmental Exposures and Lifestyle Factors in Assisted Reproductive Techniques

Cigarette Smoking

The effect of cigarette smoking on clinical outcomes has been studied both for IVF and GIFT cycles. In IVF cycles, cigarette smoking is associated with no major change in peak estradiol concentration or number of oocytes retrieved. However, cigarette smoking appears to decrease the pregnancy and live birth rates in IVF if the female partner smokes, but not if the male partner smokes (Fig. 31.28). The effect of smoking on IVF outcome may be dose-dependent. Smoking produces the greatest effects on IVF delivery rates when the female partner smokes more than 20 cigarettes daily (Fig. 31.29).[501]

A clue to the link between cigarette smoking and reduced pregnancy rates in IVF is the observation that smoking accelerates the rate of oocyte loss. Smoking appears to increase prematurely a woman's cycle day 3 FSH concentrations[502,503]; women who smoke have a depleted oocyte pool and may have prematurely aged follicles. However, the antral follicle count may not be affected.[504] Women over 35 years old who smoke during IVF, with or without ICSI have fewer oocytes retrieved and smoking may also affect uterine receptivity. An egg donation model assessing smoking in the recipient found a dose-dependent effect. Recipients smoking more than 10 cigarettes a day had a lower pregnancy rate (52.2% versus 34.1%) than recipients smoking 0 to 10 cigarettes per day.[505] Smoking does not appear to impact fertilization or embryo quality scores in most studies, although the majority of studies are limited by the lack of adjustment for potential confounders.[506]

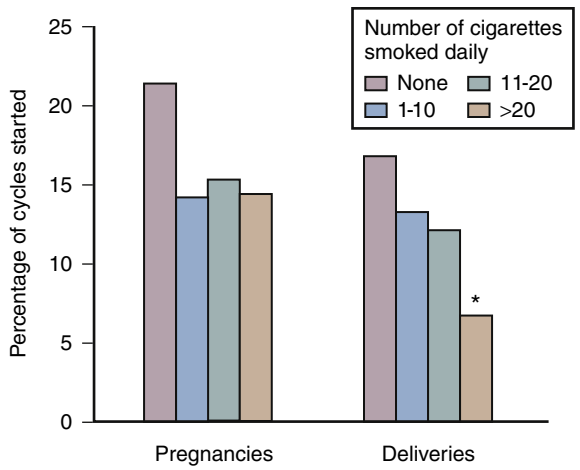

FIGURE 31.29 The *in vitro* fertilization pregnancy and delivery rates per cycle initiated, stratified by the magnitude of the exposure of the female partner to cigarette smoke. When the female partner smoked more than 20 cigarettes per day, there was a substantial decrease in the delivery rate per cycle initiated. *(From Pattinson HA, Taylor PJ, Pattinson MH. The effect of cigarette smoking on ovarian function and early pregnancy outcome of in vitro fertilization treatment.* Fertil Steril *55:780-784, 1991, with permission of the American Society for Reproductive Medicine.)*

However, in a retrospective analysis of a prospective cohort study, cotinine (a nicotine metabolite) was measured in the follicular fluid collected during 3270 IVF treatment cycles from 1909 nonsmoking women between 1994 and 2003. Multivariate analyses found a significant increase in the risk of failed implantation among women exposed to second hand smoke compared with those unexposed (OR 1.52; 95% CI 1.20 to 1.92; risk ratio [RR] 1.17; 95% CI 1.10 to 1.25). There was also a significant decrease in the odds for a live birth among second hand smoke exposed women (OR 0.75; 95% CI, 0.57 to 0.99; RR 0.81; 95% CI 0.66 to 0.99).[507]

Although the effects of smoking on ovarian function may be irreversible, women should discontinue smoking before undergoing an IVF cycle, and should avoid exposure to second hand smoke.

Caffeine Consumption

A prospective study of 221 couples undergoing ART in Southern California reported a reduced pregnancy rate for women consuming 2 to 50 mg caffeine/day (50 mg is roughly the amount of caffeine in half a cup of coffee), compared with women consuming 0 to 2 mg per day during the week of their initial visit (OR 3.1, 95% CI, 1.1 to 9.7). Caffeine intake the week before the procedure or the week after the procedure was not associated with a reduction in IVF success.[508] However, in another study of 618 women undergoing IVF, the average caffeine consumption was 456 mg per day, primarily from coffee, and after multivariate adjustment was associated with a higher risk of miscarriage ($P = 0.007$).[509] Less than 200 mg caffeine intake has not been associated with increases in miscarriage in a prospective cohort study.[510] Although the data are limited, available evidence suggests that it would seem prudent to counsel couples undergoing IVF to limit their caffeine intake to no more than 2 cups per day.

Alcohol Consumption

In one prospective study of 221 women with female factor infertility, one drink per day increased a woman's risk of not becoming pregnant and significantly increased her risk of miscarriage (OR 2.21, 95% CI 1.09 to 4.99).[511] In a large prospective cohort study, 2545 couples contributed 4729 cycles. Drinking was common: 41% of women and 58% of men drank one to six drinks per week. Women drinking ≥4 drinks or more per week were 16% less likely to have a live birth compared with those who drank less than four drinks per week (OR 0.84, CI 0.71 to 0.99). For couples in which both partners drank at least four drinks per week, the odds of live birth were 21% lower compared with couples in which both drank fewer than four drinks per week (OR 0.79; CI 0.66 to 0.96).[512] Based on these collective data, couples undergoing IVF should be counseled that alcohol consumption reduces live birth rates and should be avoided.

Marijuana Use

There are minimal data on marijuana use and IVF, but a single study reported that women who used marijuana more than 90 times in their lifetime had fewer eggs retrieved and one fewer embryo transferred than non-users. Moreover, women smoking marijuana more than 10 times in their lives also had smaller infants at birth compared to nonusers.[513] Clearly, more research is required to investigate the association between marijuana use and IVF success rate.

Obesity

The relationship between body mass index and IVF success rates has recently been reported. In a study of United States IVF clinic data reported to SART, increasing obesity was associated with a significantly lower chance of clinical pregnancy with the use of autologous oocytes ($P < 0.0001$), but no difference with the use of donor oocytes. The live birth rates declined in proportion to the extent of obesity, notably so in young women (younger than 35 years) who generally have higher pregnancy rates.[514,515] In a study from a single center of 1721 women undergoing their first IVF attempt, an inverse U-shaped association between BMI and live birth was observed (Fig. 31.30). These results indicate that women with below normal BMI also have a reduced likelihood of success with IVF success. Although the underlying reason for these observations remains to be clarified, a recent study has suggested that oocyte abnormalites may be partly responsible, at least in morbidly obese women, as reflected by abnormalities in the number of spindles and alignment of chromosomes in those oocytes that failed to fertilize in this population.[516]

Exercise

There has been only one study examining the effect of exercise on IVF outcome. Three large IVF programs in the Boston area prospectively enrolled 2232 patients undergoing their first IVF cycle in a study of outcome predictors. All patients filled out a questionnaire that included the amount, type, and frequency of exercise. Women who reported exercising ≥4 or more hours per week for 1 to 9 years were almost three times more likely to experience cycle cancellation (OR 2.8, 95% CI, 1.5 to 5.3), twice as likely to experience pregnancy loss (OR 2.0, 95% CI, 1.2 to 3.4), and 40% less likely to have a live birth (OR 0.6, 95% CI, 0.4 to 0.8)

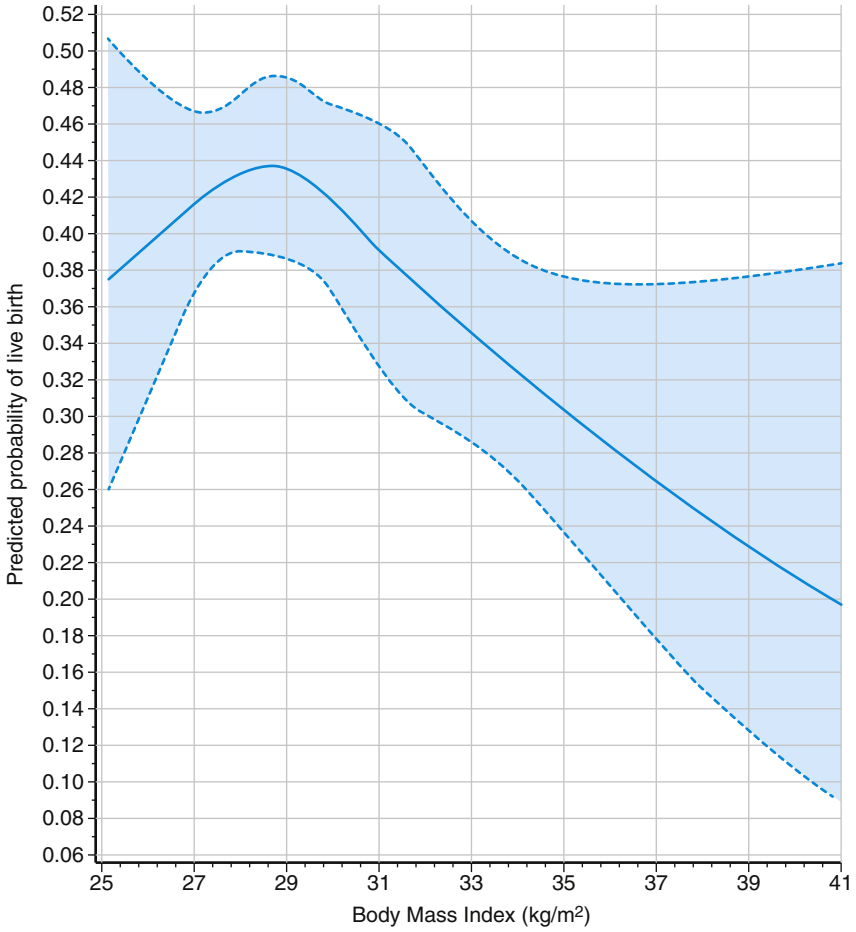

FIGURE 31.30 Cubic regression spline of the predicted probability of live birth by body mass index, adjusted for age, among 1721 women undergoing their first fresh *in vitro* fertilization (IVF) cycle. *Dashed lines* represent 95% confidence intervals. *(Shah DK, Missmer SA, Berry KF, Racowsky C, Ginsburg ES: Effect of obesity on oocyte and embryo quality in women undergoing* in vitro *fertilization,* Obstetrics and Gynecology *118:63–70, 2011.)*

than women who reported not exercising.[517] In this same study, women reporting cardiovascular exercise had a 30% lower chance of a successful live birth than those reporting no cardiovascular exercise. However, when women performed either walking or cardiovascular exercise for more than 9 years, there was no effect on live birth rates compared with those who did not exercise.

Although one should be cautious about drawing conclusions based on single studies, several modifiable life style behaviors seem to influence successful outcomes in assisted reproduction. As with other questions in this field, well-designed studies are sorely needed.

Concluding Remarks

Since the birth of the first IVF baby in 1978, there have been many advances in the field of ART. These advances, both clinical and in the laboratory, have resulted in consistent improvements in success rates over time. However, a deficiency in the field of assisted reproduction is that there are few randomized studies demonstrating the superiority of assisted reproductive techniques over other forms of fertility treatment, such as pelvic reconstructive surgery or empirical ovarian stimulation with gonadotropins, which may be optimal treatments in specific patient populations. Furthermore, many new assisted reproductive technologies are introduced into clinical practice without adequate clinical trials to demonstrate their utility in relation to "standard" IVF treatment procedures. A multitude of factors contribute to the likelihood that a single attempt at IVF will result in live birth. It is critical that rigorous research investigates new technologies prior to their being adopted into routine clinical practice, and that clinicians continually educate themselves about the advances in this rapidly evolving field.
